DISCLAIMER

Care has been taken to confirm the accuracy of the information present and to describe generally accepted practices. However, the authors, editors, and publisher are not responsible for errors or omissions or for any consequences from application of the information in this book and make no warranty, expressed or implied, with respect to the currency, completeness, or accuracy of the contents of the publication. Application of this information in a particular situation remains the professional responsibility of the practitioner; the clinical treatments described and recommended may not be considered absolute and universal recommendations.

The authors, editors, and publisher have exerted every effort to ensure that drug selection and dosage set forth in this text are in accordance with the current recommendations and practice at the time of publication. However, in view of ongoing research, changes in government regulations, and the constant flow of information relating to drug therapy and drug reactions, the reader is urged to check the package insert for each drug for any change in indications and dosage and for added warnings and precautions. This is particularly important when the recommended agent is a new or infrequently employed drug.

Some drugs and medical devices presented in this publication have Food and Drug Administration (FDA) clearance for limited use in restricted research settings. It is the responsibility of the health care provider to ascertain the FDA status of each drug or device planned for use in their clinical practice.

To purchase additional copies of this book, call our customer service department at **(800) 638-3030** or fax orders to **(301) 223-2320**. International customers should call **(301) 223-2300**.

PREFACE TO THE NINTH EDITION

It has been nearly 35 years since the first edition of *Applied Therapeutics: The Clinical Use of Drugs* was published. The use of case studies served as a founding principle for this innovative text and remains integral to the current edition. Our authors present patient cases that stimulate the reader to integrate and apply therapeutic principles in the context of specific clinical situations. We also strive to provide students and practitioners with a glimpse into the minds of clinicians who are assessing and solving therapeutic problems so that they too can develop and refine their own problem-solving skills. All chapters in this edition have been revised and updated to reflect our changing knowledge of drugs and the application of this knowledge to the therapy of patients.

Today, it is more critical than ever that health care providers make informed decisions regarding the clinical use of drugs. As our population ages, more people carry the burden of multiple chronic diseases. New knowledge about pathophysiology and drug targets has expanded our approaches to drug therapy and, in many cases, polypharmacy has become the standard of care. This, in turn, increases patient exposure to adverse medication events. Meanwhile, we observe a health care system under considerable stress. Shortages of nurses, pharmacists, physicians, and other health care providers interface with remarkable new technologies, increased costs, and decreased access to care. Ironically, the number of disadvantaged and underserved populations continue to increase at a time of remarkable economic growth. This underscores the importance of finding better

approaches to managing escalating costs while enhancing the quality of care provided. Systems and approaches to care that guarantee freedom from medical errors (including medication errors) are urgently needed.

The authors have drawn much information from the literature, current standards, and their clinical experiences to share how one might think about making sound and thoughtful therapeutic decisions. *However, it remains the responsibility of every practitioner to evaluate the appropriateness of a particular opinion in the context of the actual clinical situation, keeping in mind any new developments in the field. We strongly urge students and practitioners to consult several appropriate information sources when working with new and unfamiliar drugs.*

JULY 2008

PREFACE TO THE FIRST EDITION

In the past decade, new roles for the pharmacist have emerged. More and more frequently the pharmacist is placed in increasingly responsible positions within the health care delivery system. In this capacity (s)he is able to have a significant influence on the quality of health care delivered to the patient. M. Silverman and P. Lee have skillfully assessed the current and future role of the pharmacist in *Pills, Profits and Politics*.¹

“... It is the pharmacist who can play a vital role in assisting physicians to prescribe rationally, who can help see to it that the right drug is ordered for the right patient at the right time, in the right amounts and with due consideration of costs and that the patient knows how, when and why to use both prescription and non-prescription products.

“It is the pharmacist who has been most highly trained as an expert in drug products, who has the best opportunity to keep up-date on developments in this field and who can serve both physician and patient as a knowledgeable advisor. It is the pharmacist who can take a key part in preventing drug misuse, drug abuse and irrational prescribing.”

Many schools of pharmacy have made substantial curriculum changes to prepare their graduates for these responsibilities. Although traditional pharmacy courses have imparted factual information about drugs, they have not enabled the students to apply these facts to the drug therapy of patients. Similarly, traditional pharmacology and medical textbooks do not provide the professional with sufficient information to make a judgment regarding the selection and dosing of a particular product for a specific patient. To arrive at this decision, the clinician must consider a number of patient factors, including age, renal and hepatic function, concurrent disease states and medications and allergies. (S)he must also consider drug product factors, including bioavailability, pharmacokinetics, efficacy, toxicity, risk to benefit ratio, and cost.

We have found that students have most difficulty in *integrating* and *applying* the multiple components of their education

to formulate the safest, most rational drug regimen for a given patient. We have also observed that although the student is able to enumerate the adverse effects on a drug, (s)he is unable to recognize or monitor for these effects should they occur in his/her patient.

This text is an outgrowth of the clinical pharmacy courses taught at the University of California and at Washington State University. The major objective of these courses is to enable the student to practice effectively in the clinical setting. Lectures on the pathophysiology and medical management of disease states are supplemented with conferences where students are challenged with drug therapy questions frequently asked by physicians and by case histories, which require drug therapy assessment and the selection of appropriate alternatives. The objective of these conferences and this text is to enable the student to identify relevant factors in drug treatment, such as the probability of whether or not a specific drug is responsible for a patient's symptoms; the clinical significance of a drug interaction; why a specific drug is not achieving therapeutic blood levels; the dose for a patient with multiple disease states.

The success of the conference portion of our courses was a major determinant of the format used for this text; case histories that simulate the actual practice situations and frequently asked therapeutic questions are followed by well-referenced responses.

The authors have drawn much information from their clinical experiences. *It remains the responsibility of every practitioner to evaluate the appropriateness of a particular opinion in the context of the actual clinical situation and with due considerations of any new developments in the field.* Although the authors have been careful to recommend dosages that are in agreement with current standards and responsible literature, we suggest the student or practitioner consult several appropriate information sources when dealing with new and unfamiliar drugs.

ADDITIONAL RESOURCES FOR THE NINTH EDITION

The Ninth Edition of *Applied Therapeutics: The Clinical Use of Drugs* includes additional resources for both instructors and students, available on the book's companion website at <http://thePoint.lww.com/KodaKimble9e>.

Instructors

Approved adopting instructors will be given access to the following additional resources:

- Image Bank
- PowerPoint Presentations

Students

Resources for students include:

- New Interactive Quiz Bank
- Supplemental Cases
- Answers to Supplemental Cases
- Physiology, Pathophysiology, and Pharmacology Animations

In addition, purchasers of the text can access the searchable Full Text On-line by going to the *Applied Therapeutics:*

The Clinical Use of Drugs, Ninth Edition website at <http://thePoint.lww.com/KodaKimble9e>. See the inside front cover for more details, including the passcode you will need to gain access to the website.

Acknowledgment

Review questions for the Quiz Bank were written by Valerie B. Clinard, Larry N. Swanson, J. Andrew Bowman, Steven M. Davis, Steve Fuller, Dustin Wilson, Sarah McBane, Cynthia J. Johnston, Michelle L. Sharpe, Rebekah R. Arthur Grube, Charles Herring, James Groce, Tracy A. Dewald, Connie Lee Barnes, Nancy Allen-LaPointe, Roy Pleasants, II, Jennifer Schuh, Mary L. Townsend, Matthew T. Harris, Mara Watson, John Murray, Kimberly Lewis, Tina H. Thornhill, Jennifer Smith, Amber Peoples, Kimberly Tamura, Kathey B. Fulton, Melanie W. Pound, D. Byron May, Lydia Mis, Melissa D. Johnson, Andrew J. Muzyk, LeAnne Kennedy, Tara L. Bell, and Laura Bowers.

ACKNOWLEDGMENTS FOR THE NINTH EDITION

We are deeply indebted to the many dedicated people who have given of themselves to complete the ninth edition of this book. As always, we are most grateful to our contributing authors who have been attentive to meeting our stringent time deadlines and unique writing format. We especially thank the following section editors for their truly remarkable support as they edited chapters, assisted authors, and worked with our publishers at Lippincott Williams & Wilkins (LWW): Kathleen Hill-Besinque (Women's Health), Marcus Ferrone (Solid Organ Transplantation, Nutrition Issues), Patrick R. Finley and Kelly C. Lee (Psychiatric Disorders), Pamala Jacobson (Neoplastic Disorders), and Myrna Y. Munar (Renal Disorders).

The work of our editorial assistant and colleague, Loftin (Paul) Montgomery, Jr., is noteworthy. Paul's exceptional patience, attention to detail, and firm guidance helped us all stay on task. This edition would not have come to completion without his partnership. Above all, we are especially grateful for the understanding and support of our spouses (Kimberly, Tom,

Deter, Don, Carolyn, Linda, and Marilyn, respectively) during those nights and weekends we spent writing or editing, our children (both young and old), and now our grandchildren.

Finally, we dedicate our work to our students who inspire us and to the many patients we have cared for. Our patients have taught us over and over again how critical it is to tailor our knowledge to their specific circumstances, to listen well, and to welcome them as true partners in their care.

Clinical Pharmacist The Westerly Hospital
Westerly Rhode Island

Jiwon W. Kim, PharmD, BCPS

Assistant Professor of Clinical Pharmacy
Titus Family Department of Clinical Pharmacy and
Pharmaceutical Economics and Policy, School of Pharmacy,
University of Southern California
Clinical Pharmacist, Department of Pharmacy,
University of Southern California University Hospital
Los Angeles, California

Mark N. Kirstein, PharmD

Assistant Professor
Department of Experimental and Clinical Pharmacology
College of Pharmacy
University of Minnesota
Minneapolis, Minnesota

Kathryn Kiser, PharmD

Clinical Instructor
Pharmach Practice and Experiential Education
School of Pharmacy
Univesity of North Carolina
Chapel Hill, North Carolina

Dusko Klipa, PharmD

Pharmacy Practitioner, Liver Transplant
Instructor in Pharmacy, College of Medicine
Mayo Clinic in Jacksonville
Jacksonville, Florida

Daren L. Knoell, PharmD, FCCP

Associate Professor of Pharmacy and Internal Medicine
Davis Heart and Lung Research Institute
The Ohio State University Medical Center
The Ohio State University
Columbus, Ohio

Mary Anne Koda-Kimble, PharmD

Professor of Clinical Pharmacy and Dean
TJ Long Chair in Community Pharmacy Practice
School of Pharmacy
University of California, San Francisco
San Francisco, California

Wayne A. Kradjan, PharmD

Dean and Professor
College of Pharmacy
Oregon State University
Oregon Health & Science University
Corvallis, Oregon

Donna M. Kraus, PharmD

Pediatric Clinical Pharmacist
Associate Professor of Pharmacy Practice
Departments of Pharmacy Practice and Pediatrics
Colleges of Pharmacy and Medicine
University of Illinois at Chicago
Chicago, Illinois

Lisa A. Kroon, PharmD, CDE

Professor of Clinical Pharmacy
Department of Clinical Pharmacy
School of Pharmacy
University of California, San Francisco
San Francisco, California

Deborah Sako Kubota, PharmD

Formulary Pharmacist
Drug Information Services
Kaiser Permanente Medical Care Program
Downey, California

Samuel Kuperman, MD

Professor
Department of Psychiatry, Carver College of Medicine
Director Division of Child and Adolescent Psychiatry
University of Iowa Hospitals and Clinics
Iowa City, Iowa

Jonathan Lacro, PharmD, BCPS, BCPP

Associate Clinical Professor of Pharmacy
Department of Psychiatry, University of California, San Diego
Clinical Pharmacy Specialist in Psychiatry, Pharmacy Service
University of California San Diego
VA San Diego Healthcare System
San Diego, California

Alan H. Lau, PharmD

Professor
Department of Pharmacy Practice
College of Pharmacy
University of Illinois at Chicago
Chicago, Illinois

Kelly C. Lee, PharmD, BCPP

Assistant Professor of Clinical Pharmacy
Skaggs School of Pharmacy and Pharmaceutical Sciences
University of California San Diego
La Jolla, California

Susan H. Lee, PharmD

Associate Professor, School of Pharmacy
University of Washington
Surgery/Trauma Clinical Pharmacist, Department of
Pharmacy Services
Harborview Medical Center
Seattle, Washington

Lisa K. Lohr, PharmD, BCPS, BCOP

Clinical Assistant Professor
College of Pharmacy, University of Minnesota
Clinical Leader, Oncology/BMT, Department of
Pharmacy Services
University of Minnesota Medical Center, Fairview
Minneapolis, Minnesota

Rex S. Lott, PharmD

Associate Professor of Pharmacy Practice
Department of Pharmacy Practice & Administrative Science,
College of Pharmacy, Idaho State University
Mental Health Clinical Pharmacist, Department of Mental
Health & Pharmacy
Boise Veterans Affairs Medical Center
Boise, Idaho

Sherry Luedtke, PharmD

Associate Dean, Professional Affairs
Associate Professor, Pharmacy Practice
School of Pharmacy
Texas Tech University Health Science Center
Amarillo, Texas

May C. Mak, PharmD, CGP

Assistant Professor
Titus Family Department of Clinical Pharmacy and Pharmaceutical
Economics and Policy, School of Pharmacy, University of
Southern California
Manager, Anticoagulation Management Service, Department of
Medicine, University of Southern California
Clinical Pharmacist, HIV Adult Service, Los Angeles County
Hospital
Los Angeles, California

Joel Marrs, PharmD

Clinical Assistant Professor
Department of Pharmacy Practice, College of Pharmacy, Oregon
State University
Clinical Pharmacy Specialist, Pharmacy Department
Oregon Health & Science University Hospital
Portland, Oregon

James W. McAuley, PhD

Associate Professor
Division of Pharmacy Practice and Administration
College of Pharmacy
The Ohio State University
Columbus, Ohio

James P. McCormack, PharmD

Associate Professor
Faculty of Pharmaceutical Sciences
University of British Columbia
Vancouver, British Columbia, Canada

Jeannine S. McCune, PharmD, BCPS, BCOP

Associate Professor, Pharmacy Department
Affiliate Investigator, Clinical Research Division, Fred Hutchinson
Cancer Research Center
Clinical Director, Pharmacokinetics Laboratory, Seattle Cancer
Care Alliance
University of Washington
Seattle, Washington

Jennifer McNulty, MD

Staff Perinatologist
Long Beach Memorial Medical Center for Women
Associate Clinical Professor, School of Medicine
University of California, Irvine
Long Beach, California

Robert J. Michocki, PharmD, BCPS

Professor
Pharmacy Practice and Science
School of Pharmacy
University of Maryland
Baltimore, Maryland

Robert Keith Middleton, PharmD

Clinical Coordinator
Department of Pharmacy
Saint Clare's Hospital
Weston, Wisconsin

Melissa Mitchell, PharmD

Psychiatry Pharmacy Resident
Pharmacy Department
VA San Diego Healthcare System
San Diego, California

Myrna Y. Munar, PharmD, BCPS

Associate Professor
College of Pharmacy
Oregon State University
Portland, Oregon

Milap C. Nahata, PharmD

Professor and Chair
Pharmacy Practice and Administration, College of Pharmacy
Associate Director, Pharmacy, Ohio State University
Medical Center
The Ohio State University
Columbus, Ohio

Jean M. Nappi, PharmD, FCCP, BCPS

Professor of Pharmacy and Clinical Sciences
South Carolina College of Pharmacy
Professor of Medicine, Medical University of South Carolina
Charleston, South Carolina

Paul G. Nolan Jr., PharmD, FCCP, FASHP

Professor
Department of Pharmacy Practice and Science
College of Pharmacy
University of Arizona
Tucson, Arizona

Edith A. Nutescu, PharmD

Clinical Associate Professor
Department of Pharmacy Practice
College of Pharmacy
University of Illinois at Chicago
Chicago, Illinois

Cindy Lea O'Bryant, PharmD, BCOP

Assistant Professor
Department of Clinical Pharmacy, School of Pharmacy,
University of Colorado
Clinical Oncology Pharmacist
University of Colorado Health Sciences Center
Denver, Colorado

Judith A. O'Donnell, MD

Associate Professor of Clinical Medicine,
Division of Infectious Diseases, School of Medicine,
University of Pennsylvania
Hospital Epidemiologist and Director of Infection Control
Penn Presbyterian Medical Center
University of Pennsylvania Health Care System
Philadelphia, Pennsylvania

Neeta Bahal O'Mara, PharmD

Clinical Pharmacist
Dialysis Clinics, Inc.
North Brunswick, New Jersey

Robert Lee Page II, PharmD, FASCP, BCPS, CGP

Associate Professor
Departments of Clinical Pharmacy and Medicine, UCHSC
Schools of Pharmacy and Medicine
Clinical Specialist, Division of Cardiology,
University of Colorado Hospital
Denver, Colorado

Amy Barton Pai, PharmD

Associate Professor (Clinical Pharmacy)
Department of Pharmacy Practice; College of Pharmacy
University of New Mexico
Albuquerque, New Mexico

Louise Parent-Stevens, PharmD, BCPS

Clinical Assistant Professor
Department of Pharmacy Practice
College of Pharmacy
Clinical Pharmacist, Family Medicine Center,
University of Illinois at Chicago
Chicago, Illinois

Patricia L. Parker, PharmD, BCPS

Health Sciences, Assistant Clinical Professor
School of Pharmacy, University of California San Francisco
Clinical Coordinator
Department of Pharmacy, UC Davis Medical Center
San Francisco and Sacramento, California

Margaret M. Pearson, PharmD, MS

Division of Epidemiology, Mississippi State Department
of Health
Jackson, Mississippi

Paul P. Perry, PhD

Professor of Pharmacy
Pharmacy Practice Department,
College of Pharmacy, Touro University
Emeritus Professor of Psychiatry
Department of Psychiatry
Carver College of Medicine
University of Iowa
Vallejo, California and, Iowa City, Iowa

Jennifer Tran Pham, PharmD, BCPS

Clinical Assistant Professor
Department of Pharmacy Practice, College of Pharmacy
Neonatal Clinical Pharmacist, Pharmacy Department, University of
Illinois Medical Center at Chicago
University of Illinois at Chicago
Chicago, Illinois

David J. Quan, PharmD, BCPS

Health Sciences Associate Clinical Professor
Department of Clinical Pharmacy, School of Pharmacy
Clinical Pharmacist, Pharmaceutical Services, UCSF Medical
Center
University of California San Francisco
San Francisco, California

Ralph H. Raasch, PharmD

Associate Professor
Division: Pharmacotherapy and Experimental Therapeutics,
School of Pharmacy
Clinical Specialist, Pharmacy Department, University of
North Carolina Hospitals
University of North Carolina at Chapel Hill
Chapel Hill, North Carolina

Ellen Rhinard, PharmD, BCPS

Clinical Assistant Professor
Department of Pharmacy
School of Pharmacy, University of Washington
Seattle, Washington

Carol J. Rollins, MS, PharmD

Clinical Associate Professor
Department of Pharmacy Practice and Science, College of
Pharmacy
University Medical Center
Clinical Coordinator, Pharmacy Department, University Medical
Center
University of Arizona
Tucson, Arizona

Rebecca A. Rottman, PharmD, BCPS, CGP

Clinical Assistant Professor
College of Pharmacy, University of Texas at Austin, University of
Texas Health Sciences Center at San Antonio
Geriatrics Clinical Pharmacy Specialist, Department of
Pharmacy
South Texas Veterans Health Care System, Audie L. Murphy
Division
San Antonio, Texas

Jamila C. Russeau, PharmD, BCPS

Coordinator, Education and Staff Development
Coordinator, PGY-1 Pharmacy Residency
Department of Pharmacy
Mayo Clinic in Jacksonville
Jacksonville, Florida

Tricia M. Russell, PharmD, BCPS, CDE

Assistant Professor
Department of Pharmacy Practice,
Nesbitt School of Pharmacy, Wilkes University
Clinical Specialist, Ambulatory Care, Clinical Pharmacy
Geisinger Medical Group - Lake Scranton
Wilkes-Barre and Scranton, Pennsylvania

Joseph J. Saseen, PharmD, BCPS

Associate Professor
 Departments of Clinical Pharmacy and Family Medicine
 University of Colorado Health Sciences Center
 Schools of Pharmacy and Medicine
 University of Colorado at Denver and Health Sciences Center
 Aurora, Colorado

Larry D. Sasich, PharmD, MPH, FASHP

Acting Chair
 Department of Pharmacy Practice
 School of Pharmacy
 Lake Erie College of Osteopathic Medicine
 Erie, Pennsylvania

Katrina Schwartz, PharmD

Clinical Assistant Professor
 Department of Pharmacotherapy
 College of Pharmacy
 Washington State University
 Spokane, Washington

Timothy H. Self, PharmD

Professor of Clinical Pharmacy
 Department of Clinical Pharmacy, College of Pharmacy
 University of Tennessee
 Director, Internal Medicine Specialty Residency,
 Methodist University Hospital
 Memphis, Tennessee

Amy Hatfield Seung, PharmD, BCOP

Clinical Specialist, Hematological Malignancies
 Department of Pharmacy
 Director, Oncology Specialty Residency
 Sidney Kimmel Comprehensive Cancer Center at the
 Johns Hopkins Hospital
 Baltimore, Maryland

Carrie A. Sincak, PharmD, BCPS

Associate Professor
 Department of Pharmacy Practice, Chicago College of Pharmacy,
 Northwestern University
 Clinical Pharmacist, Internal Medicine, Pharmacy Department,
 Loyola University Medical Center
 Downers Grove and Maywood, Illinois

Hareleen Singh, PharmD

Clinical Assistant Professor
 Department of Pharmacy Practice, College of Pharmacy,
 Oregon State University, Oregon Health & Science University
 Clinical Pharmacist, Pharmacy Department
 VA Medical Center
 Portland, Oregon

Jessica Song, M.A., PharmD

Associate Professor, Pharmacy Practice
 Thomas J. Long School of Pharmacy and Health Sciences,
 University of the Pacific
 Pharmacy Residency Coordinator, Department of Pharmacy
 Services
 Santa Clara Valley Medical Center
 San Jose and Stockton, California

Suellyn J. Sorensen, PharmD, BCPS

Clinical Pharmacy Manager
 Clinical Pharmacist, Infectious Diseases
 Indiana University Hospital of Clarian Health Partners
 Indianapolis, Indiana

Anne P. Spencer, PharmD, BCPS

Associate Professor, Department of Pharmacy and Clinical Sciences
 South Carolina College of Pharmacy,
 Clinical Specialist, Department of Pharmacy Services,
 Medical University of South Carolina
 Charleston, South Carolina

Marilyn R. Stebbins, PharmD

Health Sciences Clinical Professor
 Department of Clinical Pharmacy, School of Pharmacy,
 University of California San Francisco
 Pharmacy Utilization Director,
 Mercy Medical Group, CHW Medical Foundation
 San Francisco and Sacramento, California

Irving Steinberg, PharmD

Associate Professor, Clinical Pharmacy & Pediatrics,
 Titus Family Department of Clinical Pharmacy and
 Pharmaceutical Economics & Policy; Director, Division of
 Pediatric Pharmacotherapy, Department of Pediatrics
 Women's and Children's Hospital, Los Angeles County &
 University of Southern California Medical Center
 University of Southern California School of Pharmacy & Keck
 School of Medicine
 Los Angeles, California

Glen L. Stimmel, PharmD

Professor of Clinical Pharmacy and Psychiatry
 Titus Family Department of Clinical Pharmacy and
 Pharmaceutical Economics & Policy
 Schools of Pharmacy and Medicine
 University of Southern California
 Los Angeles, California

Sana Sukkari, B Sc Phm, M. Phil

Assistant Professor
 Department of Pharmacy Practice
 School of Pharmacy
 Lake Erie College of Osteopathic Medicine
 Erie, Pennsylvania

Kelly M. Summers, PharmD

Assistant Professor of Pharmacotherapy
 Department of Pharmacy Practice and Science
 School of Pharmacy
 University of Maryland at Baltimore
 Baltimore, Maryland

David Taber, PharmD

Assistant Professor
 Departments of Clinical Pharmacy and Outcomes Science
 Clinical Pharmacy Specialist
 South Carolina College of Pharmacy, Medical University of
 South Carolina
 Charleston, South Carolina

Yasar Tasnif, PharmD

Assistant Professor
 Cooperative Pharmacy Program
 The University of Texas—Pan American
 University of Texas at Austin, College of Pharmacy
 Edinburg, Texas

Daniel J.G. Thirion, M.Sc, PharmD, BCPS

Clinical Assistant Professor
 Faculte de Pharmacie, Universite de Montreal
 Pharmacist, Internal Medicine Teaching Unit, Pharmacy
 Department, Hospital Sacre-Coeur de Montreal
 Montreal, Quebec, Canada

Toby C. Trujillo, PharmD, BCPS

Associate Professor of Clinical Pharmacy
School of Pharmacy, University of Colorado at Denver Health
Sciences Center
Clinical Coordinator
University of Colorado Hospital
Denver, Colorado

Candy Tsourounis, PharmD

Professor of Clinical Pharmacy
Department of Clinical Pharmacy
School of Pharmacy
University of California, San Francisco
San Francisco, California

Kimey Ung, PharmD

Clinical Pharmacist Specialist
Women's Pavilion at Miller Children's Hospital and Long Beach
Memorial Hospital
Long Beach, California

Kenneth John Utz, PharmD

Clinical Instructor
Department of Clinical Pharmacy
School of Pharmacy, University of Colorado
Denver, Colorado

John Valgus, PharmD, BCOP

Clinical Assistant Professor
Division of Pharmacotherapy, UNC School of Pharmacy
Clinical Hematology/Oncology Specialist, Department of Pharmacy
University of North Carolina Hospitals and Clinics
Chapel Hill, North Carolina

Geoffrey Wall, PharmD, BCPS, CGP

Associate Professor of Pharmacy Practice
Department of Pharmacy Practice, College of Pharmacy,
Drake University
Internal Medicine Clinical Pharmacist, Department of Pharmacy
Iowa Methodist Medical Center
Des Moines, Iowa

Kristin Watson, PharmD, BCPS

Assistant Professor of Pharmacotherapy
Pharmacy Practice and Science Department
School of Pharmacy
University of Maryland
Baltimore, Maryland

Charles Wayne Weart, PharmD, BCPS, FASHP

Professor, Pharmacy and Family Medicine
South Carolina College of Pharmacy
Medical University of South Carolina
Charleston, South Carolina

Timothy Edward Welty, PharmD, FCCP, BCPS

Professor
Department of Pharmacy Practice, McWhorter School of Pharmacy,
Samford University
Adjunct Associate Research Professor
Department of Neurology
University of Alabama, Birmingham
Birmingham, Alabama

C. Michael White, PharmD, FCP, PCCP

Associate Professor, Department of Pharmacy Practice
School of Pharmacy, University of Connecticut
Director, Cardiac Pharmacology Service
Hartford Hospital
Hartford, Connecticut

Bradley R. Williams, PharmD, FASCP, CGP

Professor, Clinical Pharmacy & Clinical Gerontology
Titus Family Department of Clinical Pharmacy and
Pharmaceutical Economics & Policy
School of Pharmacy, Andrus Gerontology Center
University of Southern California
Los Angeles, California

Dennis M. Williams, PharmD

Associate Professor
Division of Pharmacotherapy & Experimental Therapeutics, School
of Pharmacy
Clinical Specialist, Pharmacy Department, UNC Hospitals
University of North Carolina
Chapel Hill, North Carolina

Ann K. Wittkowsky, PharmD, CACP, FASHP, FCCP

Clinical Professor
Department of Pharmacy, School of Pharmacy, University of
Washington
Director of Anticoagulation Services, Department of
Pharmacy
University of Washington Medical Center
Seattle, Washington

Annie Wong-Beringer, PharmD

Associate Professor, Titus Family Department of Clinical Pharmacy
and Pharmaceutical Economics & Policy
School of Pharmacy, University of Southern California
Infectious Diseases Pharmacist
Department of Pharmacy, Huntington Hospital
Los Angeles and Pasadena, California

Lloyd Y. Young, PharmD

Professor Emeritus
Department of Clinical Pharmacy
School of Pharmacy
University of California, San Francisco
San Francisco, California

Wendy Zizzo, PharmD

Adjunct Professor of Behavioral Sciences
Alcohol and Other Drug Studies, San Diego City College
Assistant Clinical Professor of Pharmacy, Department of Clinical
Pharmacy, School of Pharmacy
University of California, San Francisco
San Diego and San Francisco, California

Paolo V. Zizzo, D.O.

Assistant Clinical Professor
Department of Medicine, School of Medicine, University of
California, San Diego
Clinical Internist, Private Practice
San Diego and Carlsbad, California

TABLE OF CONTENTS

| | | | | | |
|------------------|--|-------------|--|--|--|
| Section 1 | General Principles | 1-1 | | | |
| 1 | Assessment of Therapy and Medication Therapy Management <i>Marilyn R. Stebbins, Timothy W. Cutler, and Patricia L. Parker</i> | 1-1 | | | |
| 2 | Interpretation of Clinical Laboratory Tests <i>Catrina R. Schwartz and Mark W. Garrison</i> | 2-1 | | | |
| 3 | Herbs and Nutritional Supplements <i>Cathi Dennehy and Candy Tsourounis</i> | 3-1 | | | |
| 4 | Anaphylaxis and Drug Allergies <i>Robert K. Middleton and Paul M. Beringer</i> | 4-1 | | | |
| 5 | Managing Acute Drug Toxicity <i>Judith A. Alsop</i> | 5-1 | | | |
| Section 2 | General Care | 6-1 | | | |
| 6 | End-of-Life Care <i>Victoria F. Ferraresi and Thomas C. Bookwalter</i> | 6-1 | | | |
| 7 | Nausea and Vomiting <i>Lisa Lohr</i> | 7-1 | | | |
| 8 | Pain and Its Management <i>Dusko Klipa and Jamila C. Russeau</i> | 8-1 | | | |
| 9 | Perioperative Care <i>Andrew J. Donnelly and Julie A. Golembiewski</i> | 9-1 | | | |
| 10 | Acid-Base Disorders <i>Luis S. Gonzalez and Raymond W. Hammond</i> | 10-1 | | | |
| 11 | Fluid and Electrolyte Disorders <i>Alan H. Lau and Priscilla P. How</i> | 11-1 | | | |
| Section 3 | Cardiac and Vascular Disorders | 12-1 | | | |
| 12 | Dyslipidemias, Atherosclerosis, and Coronary Heart Disease <i>Matthew K. Ito</i> | 12-1 | | | |
| 13 | Essential Hypertension <i>Joseph J. Saseen</i> | 13-1 | | | |
| 14 | Peripheral Vascular Disorders <i>Anne P. Spencer and C. Wayne Weart</i> | 14-1 | | | |
| 15 | Thrombosis <i>Ann K. Wittkowsky and Edith A. Nutescu</i> | 15-1 | | | |
| 16 | Ischemic Heart Disease: Anginal Syndromes <i>Toby C. Trujillo and Paul E. Nolan</i> | 16-1 | | | |
| 17 | Myocardial Infarction <i>Robert Lee Page II, Jean M Nappi</i> | 17-1 | | | |
| 18 | Heart Failure <i>Harleen Singh and Joel C. Marrs</i> | 18-1 | | | |
| 19 | Cardiac Arrhythmias <i>C. Michael White, Jessica C. Song, James S. Kalus</i> | 19-1 | | | |
| 20 | Hypertensive Crises <i>Kelly Summers, Kristin Watson, Robert Michocki</i> | 20-1 | | | |
| 21 | Shock <i>Andrew D. Barnes and Susan H. Lee</i> | 21-1 | | | |
| Section 4 | Pulmonary Disorders | 22-1 | | | |
| 22 | Asthma <i>Timothy H. Self, Cary R. Chrisman, and Christopher K. Finch</i> | 22-1 | | | |
| 23 | Chronic Obstructive Pulmonary Disease <i>Philip T. Diaz and Daren L. Knoell</i> | 23-1 | | | |
| 24 | Acute and Chronic Rhinitis <i>Tina Penick Brock and Dennis M. Williams</i> | 24-1 | | | |
| 25 | Drug-Induced Pulmonary Disorders <i>Deborah Sako Kubota and James Chan</i> | 25-1 | | | |
| Section 5 | Gastrointestinal | 26-1 | | | |
| 26 | Upper Gastrointestinal Disorders <i>Randolph V. Fugit and Rosemary R. Berardi</i> | 26-1 | | | |
| 27 | Lower Gastrointestinal Disorders <i>Geoffrey C. Wall</i> | 27-1 | | | |
| 28 | Complications of End-Stage Liver Disease <i>Yasar O. Tasnif and Mary F. Hebert</i> | 28-1 | | | |
| 29 | Adverse Effects of Drugs on the Liver <i>Curtis D. Holt</i> | 29-1 | | | |
| Section 6 | Renal Disorders | 30-1 | | | |
| 30 | Acute Renal Failure <i>Donald F. Brophy</i> | 30-1 | | | |
| 31 | Chronic Kidney Disease <i>Amy Barton Pai and Todd A. Conner</i> | 31-1 | | | |
| 32 | Renal Dialysis <i>Myrna Y. Munar</i> | 32-1 | | | |
| 33 | Dosing of Drugs in Renal Failure <i>David J. Quan and Francesca T. Aweeka</i> | 33-1 | | | |
| Section 7 | Solid Organ Transplantation | 34-1 | | | |
| 34 | Kidney and Liver Transplantation <i>David J. Taber and Robert E. Dupuis</i> | 34-1 | | | |
| 35 | Heart and Lung Transplantation <i>Tamara Claridge and Gilbert J. Burckart</i> | 35-1 | | | |
| Section 8 | Nutrition Issues | 36-1 | | | |
| 36 | Adult Enteral Nutrition <i>Carol J. Rollins and Yvonne Huckleberry</i> | 36-1 | | | |
| 37 | Adult Parenteral Nutrition <i>Jane M. Gervasio and Jennifer L. Ash</i> | 37-1 | | | |
| Section 9 | Dermatologic Disorders | 38-1 | | | |
| 38 | Dermatotherapy and Drug-Induced Skin Disorders <i>Richard N. Herrier</i> | 38-1 | | | |
| 39 | Acne <i>Ellen E. Rhinard</i> | 39-1 | | | |

| | | | | | |
|-------------------|---|-------------|-------------------|---|-------------|
| 40 | Psoriasis <i>Timothy J. Ives and Kathryn L. Kiser</i> | 40-1 | 61 | Tuberculosis <i>Michael B. Kays</i> | 61-1 |
| 41 | Photosensitivity, Photoaging, and Burns <i>Timothy J. Ives</i> | 41-1 | 62 | Infectious Diarrhea <i>Gail S. Itokazu, David T. Bearden, and Larry H. Danziger</i> | 62-1 |
| Section 10 | Arthritic Disorders | 42-1 | 63 | Intra-Abdominal Infections <i>Kendra M. Damer and Carrie A. Sincak</i> | 63-1 |
| 42 | Gout and Hyperuricemia <i>KarenBeth H. Bohan and Tricia M. Russell</i> | 42-1 | 64 | Urinary Tract Infections <i>Douglas N. Fish</i> | 64-1 |
| 43 | Rheumatic Disorders <i>Steven W. Chen</i> | 43-1 | 65 | Sexually Transmitted Diseases <i>Jeffery A. Goad and Karl M. Hess</i> | 65-1 |
| 44 | Connective Tissue Disorders: The Clinical Use of Corticosteroids <i>William C. Gong</i> | 44-1 | 66 | Osteomyelitis and Septic Arthritis <i>Ralph H. Raasch</i> | 66-1 |
| Section 11 | Women's Health | 45-1 | 67 | Traumatic Skin and Soft Tissue Infections <i>James P. McCormack and Glen Brown</i> | 67-1 |
| 45 | Contraception <i>Jennifer L. Hardman</i> | 1 | 68 | Prevention and Treatment of Infections in Neutropenic Cancer Patients <i>Richard H. Drew</i> | 68-1 |
| 46 | Obstetric Drug Therapy <i>Kimey D. Ung and Jennifer McNulty</i> | 46-1 | 69 | Pharmacotherapy of Human Immunodeficiency Virus Infection <i>Julie B Dumond and Angela D.M. Kashuba</i> | 69-1 |
| 47 | Disorders Related to the Menstrual Cycle <i>Laura B. Hansen and Karen Gunning</i> | 47-1 | 70 | Opportunistic Infections in HIV-Infected Patients <i>Amanda H. Corbett</i> | 70-1 |
| 48 | The Transition Through Menopause <i>Louise Parent-Stevens</i> | 48-1 | 71 | Fungal Infections <i>John D. Cleary, Stanley W. Chapman, and Margaret Pearson</i> | 71-1 |
| Section 12 | Endocrine Disorders | 49-1 | 72 | Viral Infections <i>Milap C. Nahata, Neeta Bahal O'Mara and Sandra Benavides</i> | 72-1 |
| 49 | Thyroid Disorders <i>Betty J. Dong</i> | 49-1 | 73 | Viral Hepatitis <i>Curtis D. Holt</i> | 73-1 |
| 50 | Diabetes Mellitus <i>Lisa A. Kroon, Mitra Assemi, and Betsy A. Carlisle</i> | 50-1 | 74 | Parasitic Infections <i>J.V. Anandan</i> | 74-1 |

GENERAL PRINCIPLES

CHAPTER

1

Assessment of Therapy and Medication Therapy Management

Marilyn R. Stebbins, Timothy W. Cutler, and Patricia L. Parker

SOURCES OF PATIENT INFORMATION 1-2

- Data-Rich Environment 1-2
 - Paper Charts 1-2
 - Electronic Medical Record 1-2
- Data-Poor Environment 1-3
 - Pharmacy Information Systems 1-3

EFFECTIVE COMMUNICATION AND THE PATIENT INTERVIEW 1-4

- Communication 1-4

OBTAINING A PATIENT HISTORY 1-8

- Medical History 1-8

- Medication History 1-9

- Social History 1-10

APPROACH TO AND ASSESSMENT OF PATIENT THERAPY 1-11

- Problem List 1-11
- Subjective and Objective Data 1-11
- Assessment 1-13
 - Drug Therapy Assessment 1-13
- Plan 1-13
- Patient Education 1-13

MEDICATION THERAPY MANAGEMENT SERVICES IN THE COMMUNITY PHARMACY/AMBULATORY SETTING 1-13

- Medication Therapy Review (MTR) 1-14
- Medication Action Plan (MAP) 1-14
- Documentation of Services 1-15
- Billing for Medication Therapy Management Services 1-15

MEDICATION THERAPY MANAGEMENT IN THE ACUTE CARE SETTING 1-18

CONCLUSION 1-19

This chapter presents several approaches to assessing drug therapy and provides the framework for medication therapy management services (MTMS) across the continuum of care. The illustrations in this chapter primarily focus on the pharmacist; however, the principles used to assess patient response to drug therapy are of value to all health care providers.

MTMS was first described in the Medicare Modernization Act of 2003 (MMA 2003), which also established the first outpatient prescription drug benefit (also known as Part D) for those eligible for Medicare.¹ MTMS was defined in MMA 2003 as a *program of drug therapy management that may be furnished by a pharmacist and that is designed to assure, with respect to targeted beneficiaries described in clause (ii), that covered Part D drugs under the prescription drug plan are appropriately used to optimize therapeutic outcomes through improved medication use, and to reduce the risk of adverse events, including adverse drug interactions. Such a program may distinguish between services in ambulatory and institutional settings.*

According to MMA 2003, individuals can qualify to receive MTMS if they meet the following three criteria:

1. Take multiple Medicare Part D–covered drugs
2. Have multiple chronic diseases
3. Are likely to incur annual costs of at least \$4,000 for all covered Part D drugs

Although MTMS is the term used in MMA 2003 to describe medication management for those eligible under the Medicare Part D benefit, the same approach may be used for any patient. To respond to the need for further clarification of the term MTMS, 11 professional pharmacy associations more formally defined MTMS in a consensus document published in 2004.² According to this definition, MTMS could be applied to any patient in a variety of settings. Furthermore, this definition clarifies the type of activities involved in a medication therapy management (MTM) program.

MTMS has a direct relationship to pharmaceutical care. Pharmaceutical care has been described as *the responsible provision of drug therapy to achieve definite outcomes that are intended to improve a patient's quality of life.*^{3,4} In fact, MTMS has been described as a service provided in the practice of pharmaceutical care.⁵ However, unlike pharmaceutical

care, MTMS is recognized by payers, has current procedural technology (CPT) codes specifically for pharmacists, and has several clearly defined interventions. Therefore, MTMS will be the term used to describe the activity of MTM in various patient populations.

Both patient self-care and medication reconciliation are critical aspects of any MTMS encounter regardless of the setting (i.e., inpatient, community, ambulatory, or institutional). Patient self-care is defined by the World Health Organization as those *activities [that] individuals, families, and communities undertake with the intention of enhancing health, preventing disease, limiting illness, and restoring health. These activities are derived from knowledge and skills from the pool of both professional and lay experience. They are undertaken by lay people on their own behalf, either separately or in participative collaboration with professionals.*⁶ Patient self-care requires the patient to take responsibility for the illness; however, the help of a professional to structure healthy self-care is important. For example, patients with diabetes who monitor their blood glucose levels regularly and adjust their diet according to the guidelines published from the American Diabetes Association (ADA) would be practicing self-care. Self-care is often the work that the patient performs between visits with the provider. The patient should be involved in his own care to ensure the best outcomes.

Medication reconciliation is the process by which medication prescribing accuracy is ensured from one care setting to another or from one practitioner to another. Although not a new concept to the profession of pharmacy, there has been heightened awareness and intensified effort in this area of practice as a result of the Joint Commission. The Joint Commission is the national accrediting body for hospitals and other health care delivery organizations that has committed to improving patient care through an inspection and evaluation process. Through this process, the Joint Commission holds institutions to national consensus-based standards. In 2005, the Joint Commission announced its National Patient Safety Goal (NPS goal 8A and 8B) to *accurately and completely reconcile medications across the continuum of care*. This NPS goal required institutions to develop and test processes for medication reconciliation and to implement them by January 2006.⁷

The general approach to an MTMS patient encounter in various clinical settings will be discussed in the next sections. Figure 1-1 provides an overview of a patient encounter that includes patient information gathering from various data sources; interviewing the patient while utilizing effective communication skills; assessing the medical illness(es); developing a plan to manage the illness(es); documenting the service (including billing); and monitoring, follow-up, or referral for any additional issues that cannot be resolved during the encounter.

SOURCES OF PATIENT INFORMATION

Successful patient assessment and monitoring requires the gathering and organization of all relevant information.^{4,8} The patient (or family member or other representative) is always the primary source of information. The provider asks the patient a series of questions to obtain subjective information that is helpful in making a diagnosis or evaluating ongoing therapy. Likewise, pharmacists, home care nurses, and other providers without direct access to patient data also must obtain subjective

data or measure objective physical data to guide recommendations for therapy and to monitor previously prescribed therapy.

Data-Rich Environment

In a “data-rich environment,” such as a hospital, long-term care facility, or outpatient medical clinic, a wealth of information is available to practitioners from the medical record, pharmacy profile, and nursing medication administration record (MAR). In these settings, physicians, nurses, and patients are readily available. This facilitates timely, effective communication among those involved in the drug therapy decision-making process. Objective data (e.g., diagnosis, physical examination, laboratory and other test results, vital signs, weight, medications, medication allergies, intravenous flow rates, and fluid balance) are readily available. Likewise, the cases presented throughout this text usually provide considerable data on which to make more thorough assessments and therapeutic decisions. The patient record provides readily available information that is needed to identify and assess medical problems. It is necessary in order to design patient specific care plans and document MTMS. In some settings, patient insurance information is important to help understand the formulary choices and coverage of medications. When billing for MTMS, this insurance information is very important and would be available in a data-rich environment.

Paper Charts

A paper chart may be a source of valuable patient information. Paper charts may exist in a variety of settings, including the hospital, outpatient clinic, or institutional setting. This source of information is considered data rich but does have limitations. Paper charts are organized differently by site and by setting. The information contained in a hospital chart will be different from that contained in an outpatient clinic. Furthermore, it may be difficult to obtain a paper chart, or access may be delayed if another professional is using the chart. Significant data delays may occur in paper charts, as information such as laboratory results, test results, and chart notes may not be placed in the chart for several days after the test or documentation is complete. As a result, it is important to realize the limitations of this data-rich environment and that the information obtained during the patient interview is still extremely important.

Electronic Medical Record

An electronic medical record (EMR) is an electronic version of the paper chart. Once again, these records are available in hospitals, clinics, and institutional settings, but the type of EMR and the organization of information will vary among the different settings and software applications. The EMR provides a wealth of information and is one of the most complete sources of reliable information. Unlike a paper chart, the EMR may be interfaced with the laboratory, pharmacy, and radiology systems so that data is available real time with minimal delays. Unfortunately, clinicians may rely on the EMR too much for the patient information, which could lead to assumptions. For example, a patient who has metformin 500 mg twice daily listed in the EMR may actually be taking the medication once daily. Therefore, the data in the EMR is extremely useful, but it is still important to obtain information directly from the patient.

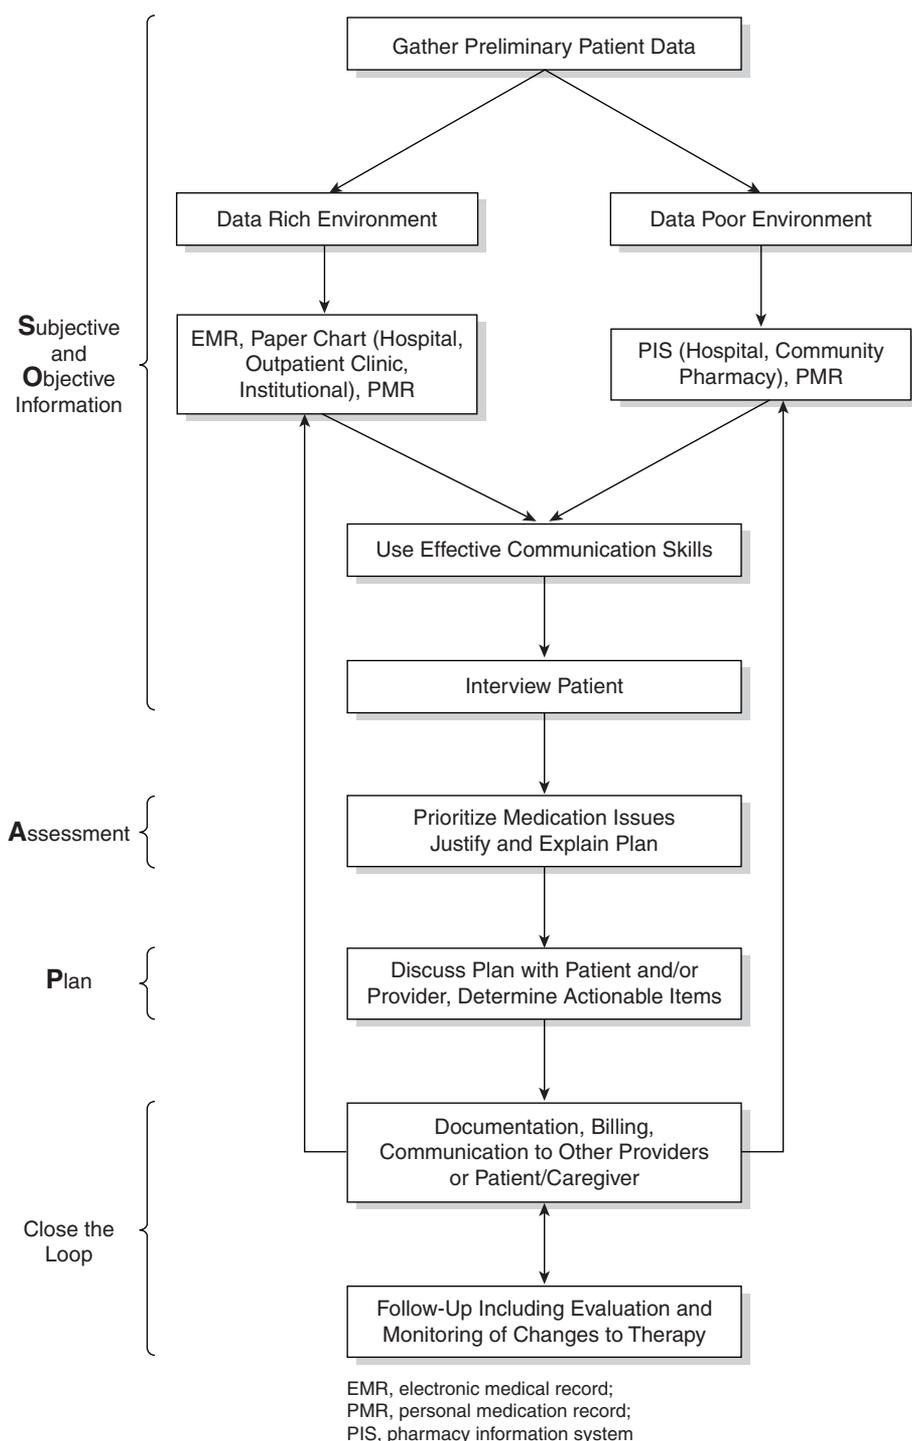

FIGURE 1-1 General approach to a patient encounter.

Data-Poor Environment

In reality, clinicians are often required to make assessments with limited information. Even in a relatively data-poor environment, such as a community pharmacy, valuable sources of information are still available, including (a) the medication profile, (b) patient data, and (c) the patient's insurance coverage information. In addition, it is often possible to consult with the prescriber (or the prescriber's office staff); however, contact may be delayed, and requests for information may be

met with resistance due to time constraints or other factors. As illustrated later in this chapter, the successful practitioner can make assessments and intervene on the patient's behalf even in the absence of all the available information.

Pharmacy Information Systems

Pharmacy information systems (PIS) are generally considered data poor. When discussing PIS, it is important to look at both inpatient and outpatient PIS. Pharmacy billing and inventory

management were the motivation behind the establishment of the early PIS. These initial systems provided fill lists, generated patient profiles, and produced medication labels, which were valuable to institutional pharmacies as the profession moved toward a unit dose medication distribution system. More modern functionalities allow for some limited documentation of clinical pharmacy activities, but still, this system is data poor. Current work flow for institutions functioning off of PIS consists of medication processing via a physician-generated hard copy medication order, which is provided to the pharmacy via delivery, facsimile, or scanner. After pharmacist review of the medication order for clinical appropriateness, the nurse is provided access to the medication either by direct pharmacy delivery or by means of an automated dispensing system. The nurse ensures that the patient receives the medication at the appropriate time and documents the administration on the medication administration record (MAR). Increased emphasis on patient safety has highlighted the importance of integrating PIS with other computerized systems utilized throughout the inpatient setting. This involves a transition from PIS to a data-rich clinical information system (CIS), which includes direct computerized physician order entry, clinical decision support, EMR, an electronic medication administration record (eMAR), and integration of various ancillary information systems such as pharmacy and laboratory services. Additional functionality incorporates the use of bar code technology, which allows the ability to track and promote quality assurance during the medication administration process. Information generated by the CIS is electronically transmitted to the pharmacy in real time, eliminating lost, illegible, or incomplete medication orders. Improved communication between various health care providers, decreased medication turnaround time, enhanced compliance with medication use policies and formularies, and reductions in medication errors may be benefits seen from this system. Although increasing numbers of institutions are incorporating this technology into their practice settings, implementation of CIS in hospitals has not occurred for numerous reasons, including expense and system complexity.

A variety of outpatient PIS exist. Some of these systems contain only basic data such as the medication profile, refill history, allergies, and insurance information. Other PIS allow the pharmacist to enter information such as progress notes, vital signs (blood pressure [BP], pulse, respirations), and lab results (blood glucose, cholesterol levels), but these systems are rarely linked to an EMR. Therefore, the information contained in the outpatient PIS is dependent on the ability of the pharmacist to obtain the information. As pharmacists perform more advanced services in the community pharmacy (such as immunizations, tobacco cessation, MTMS, etc.) that require documentation of services, the PIS will need to become a more robust source of data.

Especially in a data-poor environment, it is important that the clinician be a proactive interviewer where the interviewer often becomes an investigator. The investigative approach is direct and requires strong problem-solving abilities as well as requires the interviewer to actively listen to the patient. Questions should be formulated to obtain information such as the medication history, actual medication use, patient perception of care, use of over-the-counter (OTC) and natural or herbal products, and health beliefs (cultural or otherwise). This approach with the patient can help to verify and ensure the accuracy of other data sources. Not all patients are reliable historians, and

some are poor sources of information. Even when the patient is a poor historian, the interview is a critical source of information that cannot be obtained from other data sources. Patient interview techniques will be discussed in the next section.

EFFECTIVE COMMUNICATION AND THE PATIENT INTERVIEW

The ability to use effective communication principles and history-taking skills is crucial to a successful patient interaction.^{4,8} The importance of interviewing the patient, how to set the stage for the interview, general interview rules, and the essential information to be obtained from the interview are outlined in Table 1-1.

Ideally, the initial patient interaction should occur by appointment in a private, professional, and unhurried environment; however, the ideal often is not an option. The setting

Table 1-1 Interviewing the Patient

Importance of Interviewing the Patient

Establishes professional relationship with the patient to:

- Obtain subjective data on medical problems
- Obtain patient-specific information on drug efficacy and toxicity
- Assess the patient's knowledge about, attitudes toward, and pattern of medication use
- Formulate a problem list
- Formulate plans for medication teaching and pharmaceutical care

How to Set the Stage for the Interview

- Have the patient complete a written health and medication questionnaire, if available
- Introduce yourself
- Make the setting as private as possible
- Do not allow friends or relatives without permission of the patient
- Do not appear rushed
- Be polite
- Be attentive
- Maintain eye contact
- Listen more than you talk
- Be nonjudgmental
- Encourage the patient to be descriptive
- Clarify by restatement or patient demonstration (e.g., of a technique)

General Interview Rules

- Read the chart or patient profile first
- Ask for the patient's permission to conduct an interview or make an appointment to do so.
- Begin with open-ended questions
- Move to close-ended questions
- Document interaction

Information to Be Obtained

- History of allergies
- History of adverse drug reactions
- Weight and height
- Drugs: dose, route, frequency, and reason for use
- Perceived efficacy of each drug
- Perceived side effects
- Adherence to prescribed drug regimen
- Nonprescription medication use (including complementary and alternative medications)
- Possibility of pregnancy in women of childbearing age
- Family or other support systems

Adapted from work by Teresa O'Sullivan, PharmD, University of Washington.

may be the pharmacy, a clinic, or the bedside. Regardless of the setting, the process may be expedited by asking or helping the patient to complete a written self-assessment history form (current medical conditions and medications, height, weight, allergies, adverse drug reactions, immunizations, tobacco and alcohol use, pregnancy status, etc.) before obtaining a verbal history. Figure 1-2 presents a sample form.⁴

Communication

Once the self-assessment form is completed and reviewed, the pharmacist can focus on the patient interview. Setting the stage for the interview and getting off to a good start can be accomplished by greeting the patient with a smile, providing formal introductions, and explaining the purpose of the encounter. Asking the patient what expectations she may have will help to ensure that concerns are addressed. At this point, several other key issues may surface. During the interview, language barriers or cultural issues may be identified that need to be addressed. This will also provide an opportunity to look for clues that can help to determine the patient's level of health literacy. These concepts will be discussed later in this section. Specific communication skills that can be used to guide the practitioner through a productive patient interview include the following:

- Effective questioning by using open-ended questions
- Active listening
- Reflective responding
- Careful attention to body language
- Identifying cultural differences and disparities
- Understanding the patient's level of health literacy

Effective questioning techniques include both open- and closed-ended questions. To the extent possible, the practitioner should ask open-ended questions so that the patient is encouraged to explain and elaborate. Skilled use of these questions puts the practitioner in the role of observer, listener, recorder, and prompter and the patient in the role of storyteller. This technique also allows the practitioner to assess quickly the patient's depth of knowledge and understanding of his medications and health situation. For example, at the beginning of the interview, the practitioner may ask, "If there is one thing I can accomplish for you today, what would that be?" Or, perhaps during the interview when discussing adherence to a specific medication, the practitioner may ask, "How many times a day do you take this medication?" or "What time of day do you take this medication?" To conclude the interview, the practitioner may choose to ask, "Just to be sure we haven't missed anything important, what other medication issues have you had since your last visit?" Open-ended questions are asked one at a time with a pause in between each to allow the patient to answer. Closed-ended questions (e.g., those that can be simply answered "yes" or "no") can be used to prompt patients who know little about their health situation and to systematically minimize inadvertent omissions. If closed-ended questioning is used, all "yes or no" responses should be followed with additional questions such as, "Please explain what you experienced."

The patient should be encouraged to do most of the talking, while the practitioner utilizes active listening techniques. In order to be an effective active listener, distractions should be minimized. This may be difficult in certain settings, but finding a private area for the interview, ensuring that mobile phones

and pagers are off (or at a minimum set to the silent or vibrate mode), and not allowing interruption from the staff during the visit can all lead to enhanced communication. The active listening technique requires the interviewer to focus on what the patient is saying without interrupting. Providing verbal and nonverbal cues such as "Yes, please go on" or nodding affirmatively lets the patient know that the practitioner is listening.

Reflective responding allows the practitioner to periodically check in with the patient to ensure understanding of what the patient is communicating. This technique demonstrates caring and helps to build a rapport with the patient. An example of reflective responding may be, "From what you have told me, I understand that you are not taking your medications because they are too expensive" or "It seems like you are not having any difficulty taking your new cholesterol medication." By periodically summarizing the information obtained from the patient, the practitioner can clarify and bring closure to one segment of the interview before progressing further.

As the practitioner gains experience and becomes more sophisticated in interviewing patients, subtle clues (e.g., unusual information, observation, and body language) can be used to pursue a line of questioning that could explain an unexpected problem or clarify an existing problem. For example, a patient may become very nervous and fidget when asked to play back what was explained to her, or she may state, "I understood everything you said, and I don't need to waste your time repeating it." This may be a sign that the patient is hearing impaired or has cognitive difficulties that need to be addressed.

Cultural differences and health disparities must also be recognized and addressed for practitioners to achieve successful health outcomes. By definition, cultural competence is a set of congruent behaviors, attitudes, and policies that come together among a group of people, a system, or an agency that enables them to work effectively in cross-cultural situations.⁹ There are several core elements to cultural competence:

- Awareness and acceptance of difference
- Awareness of one's cultural values
- Development of knowledge of different cultures
- Understanding the dynamics of difference
- Ability to adapt skills to fit the cultural context of others

Health disparities refer to gaps in the quality of health and health care across racial, ethnic, and socioeconomic groups.¹⁰ These gaps result in worse clinical outcomes, and these differences persist after adjustment for known factors including, but not limited to, social determinants and access to health care. It is generally accepted that disparities can result from three main areas:^{11,12}

- From the personal, socioeconomic, and environmental characteristics of different ethnic and racial groups
- From the barriers encountered by certain racial and ethnic groups when trying to enter into the health care delivery system
- From the quality of health care that different ethnic and racial groups receive

In order to provide culturally competent care, practitioners must tailor care to meet the patient's linguistic, cultural, and social needs, recognizing that communication is directly linked to health outcomes. Linguistically, the patient and provider's spoken language, dialects, accents, and speed of the spoken language are important factors that will influence communication.

MEDICAL PROBLEMS: Have you experienced, or do you have: (circle Y or N)

| | | | | | |
|----------------------------------|---|---|-------------------------------|---|---|
| known kidney problems? | Y | N | sores on legs or feet? | Y | N |
| frequent urinary infections? | Y | N | known blood clot problems? | Y | N |
| difficulty with urination? | Y | N | leg pain or swelling? | Y | N |
| frequent urination at night? | Y | N | unusual bleeding or bruising? | Y | N |
| known liver problems/hepatitis? | Y | N | anemia? | Y | N |
| trouble eating certain foods? | Y | N | thyroid problems? | Y | N |
| nausea or vomiting? | Y | N | known hormone problems? | Y | N |
| constipation or diarrhea? | Y | N | arthritis or joint problems? | Y | N |
| bloody or black bowel movements? | Y | N | muscle cramps or weakness? | Y | N |
| abdominal pain or cramps? | Y | N | memory problems? | Y | N |
| frequent heartburn/indigestion? | Y | N | dizziness? | Y | N |
| stomach ulcers in the past? | Y | N | hearing or visual problems? | Y | N |
| shortness of breath? | Y | N | frequent headaches? | Y | N |
| coughing up phlegm or blood? | Y | N | rash or hives? | Y | N |
| chest pain or tightness? | Y | N | change in appetite/taste? | Y | N |
| fainting spells or passing out? | Y | N | walking/balance problems? | Y | N |

 Date

FIGURE 1-2 Patient history form (Continued).

Table 1-2 Behaviors Suggestive of Inadequate Health Literacy

- Asking for help
- Bringing someone along who can read
- Inability to keep appointments
- Making excuses like “I forgot to bring my glasses”
- Nonadherence with medications
- Poor adherence to recommended medical interventions
- Postponing making decisions
- Watching others and mimicking behaviors

Whether a personal or impersonal approach to the encounter is culturally acceptable will be important to know. Also, the degree of formality expected, appropriate subjects for conversation, directness, touch, and loudness of conversation may play a role in the success of the encounter. Often overlooked but critically important are health and healing beliefs that the patient and her family or community may have. It is only after these factors are recognized and acknowledged that a practitioner can make recommendations and negotiate a plan with the patient or her caregiver. From a communication standpoint, the practitioner must determine, at a minimum, the preferred mode of communication, the level of literacy, the preferred language, and whether an interpreter or a cultural broker (an individual who shares the cultural identity with the client/patient and can effectively mediate when cross-cultural communication is necessary) is needed.

Health literacy is a component of cultural competence. It was defined in the Institute of Medicine Report in 2004 as the *degree to which individuals have the capacity to obtain, process, and understand basic health information and services needed to make appropriate health decisions.*¹³ There are several behaviors or cues that may be suggestive of inadequate health literacy skills that a provider can look for when interacting with patients. These behavioral cues can be found in Table 1-2. There are several communication techniques that may be helpful in determining the level of health literacy and may aid the provider in addressing a patient with inadequate health literacy. These communication techniques are presented in Table 1-3.

In all interactions, the health care provider must treat the patient with respect as well as make every effort to ask questions and receive information in a nonjudgmental way (e.g., “Please tell me how you take your medications” as opposed to

Table 1-3 Communication Tips for Identifying and Addressing Inadequate Health Literacy

- Assess patient’s baseline understanding before providing extensive information
- Speak slowly
- Use lay language instead of medical terminology
- Emphasize only 1 to 3 points in any one encounter
- Encourage questions by using the open-ended question approach
- Show or draw pictures to enhance understanding and subsequent recall, if appropriate
- Use the teach-back or show-me method
- Write down important instructions
- Provide useful educational materials
- Be respectful, caring, and sensitive

“Do you take your medications exactly as prescribed?”). Practitioners who provide MTMS must keep in mind that patients hold them in trust and often share intimate details of their medical and social histories. Thus, practitioners must maintain the confidentiality of that information and share it only with those providers who need this information to provide patient care. Additionally, clinicians must adhere to the regulations set forth by the Health Insurance Portability and Accountability Act (HIPAA) of 1996, which provides standards to protect the security and confidentiality of individually identifiable protected health information (PHI). PHI includes information created during the provision of patient care that can be linked with a specific patient. Examples of PHI include the patient’s name, home address, date of birth, medical record number, medical diagnoses, treatment records, prescriptions, and laboratory and test results. Further discussion of the HIPAA regulations is beyond the scope of this chapter; consult the U.S. Department of Health and Human Services website for additional information.

OBTAINING A PATIENT HISTORY

Those who provide MTMS should develop standardized forms to record patient information obtained from the patient interview. Standardization facilitates quick retrieval of information, minimizes the inadvertent omission of data, and enhances the ability of other practitioners to use shared records.^{4,8}

For convenience, the patient interview and record can be divided into sections with subjective and objective data as well as an assessment and plan (including expected outcomes). Components of subjective and objective data are the medical history, drug history, and social history. In some situations, these histories can be supplemented by the generation of flowchart diagrams to monitor changes in specific parameters (e.g., blood glucose concentration, BP, weight) over time. These charts and documentation systems may be incorporated into the EMR, PIS, or a similar electronic platform.

Medical History

The medical history is essential to the provision of MTMS. It can be as extensive as the medical records that are maintained in an institution or physician’s office, or it can be a simple patient profile that is maintained in a community pharmacy. The purpose of the medical history is to identify significant past medical conditions or procedures; identify, characterize, and assess current acute and chronic medical conditions and symptoms; and gather all relevant health information that could influence drug selection or dosing (e.g., function of major organs such as the gastrointestinal tract, liver, and kidney, which are involved in the absorption and elimination of drugs; height and weight, including recent changes in either; age and gender; pregnancy and lactation status; and special nutritional needs). Not all interviews require the interviewer to ask for this much general information; however, in a data poor environment, more information is required directly from the patient. A more focused interview may be appropriate in settings where the information required is available electronically or is specific to a single disease state. For example, in an anticoagulation clinic, the information that is elicited from the patient is often specific to the patient’s anticoagulation therapy (e.g., bleeding incidents,

newly started medications, dietary changes, missed warfarin doses, etc.).

1. P.J., a 45-year-old woman of normal height and weight, states that she has diabetes. What questions might the practitioner ask of P.J. to determine whether type 1 or type 2 disease should be documented in her medical history?

Patients usually can enumerate their medical problems in a general way, but the practitioner often will have to probe more specifically to refine the diagnosis and assess the severity of the condition. Diabetes mellitus is used to illustrate the types of questions that can be used to gather important health information and assess drug therapy. The following questions should generate information that will help to determine whether P.J. has type 1 or type 2 diabetes mellitus.

- **How old were you when you were told you had diabetes?**
- **Do any of your relatives have diabetes mellitus? What do you know of their diabetes?**
- **Do you remember your symptoms? Please describe them to me.**
- **What medications have you used to treat your diabetes?**

When questions such as these are combined with knowledge of the pathophysiology of diabetes, appreciation of the typical presenting signs and symptoms of the disease, and understanding of the drugs generally used to treat both forms of diabetes, meaningful MTM can be provided. Even simple assessments such as the observation of a patient's body size can provide information useful for therapeutic interventions. For example, a person with type 2 diabetes is more likely to be an overweight adult (see Chapter 50).

Medication History

In the community pharmacy setting, patients generally present themselves in one of four ways: (a) with a self-diagnosed condition for which nonprescription drug therapy is sought; (b) with a newly diagnosed condition for which a drug has been prescribed; (c) with a chronic condition that requires refill of a previously prescribed drug or the initiation of a new drug; or (d) on referral from their health plan, provider or self-referral for focused medication therapy review (MTR). In the first and second situations, the practitioner must confirm the diagnosis by using disease-specific questions as illustrated in Question 1. In the third situation, the practitioner uses the same type of questioning as in the first two situations; however, this time the practitioner needs to evaluate whether the desired therapeutic outcomes have been achieved. The practitioner must evaluate the information gleaned during follow-up visits in the context of the history and incorporate it into his or her assessment and medication action plan (MAP). The fourth situation, in which patients require a focused MTR, the medication and medical history information are equally important. Without the medical history, it is not possible to evaluate whether the drug therapy is appropriate, and without an accurate medication history, it is not possible to determine if the patient has reached the desired goals of therapy for her condition. The goal of the medication history is to obtain and assess the following information: the specific prescription and nonprescription drugs that the patient is taking (the latter includes OTC medications, botanicals, di-

etary supplements, recreational drugs, alcohol, tobacco, and home remedies); the intended purpose or indications for each of these medications; how taken (e.g., route, ingestion in relation to meals), how much, and how often these medications are used; how long these agents have been taken or used (start and stop dates); whether the patient believes that any of these agents are providing therapeutic benefit; whether the patient is experiencing or has experienced any adverse effects that could be caused by each of these agents (idiosyncratic reactions, toxic effects, adverse effects); whether the patient has stopped taking any of the medications for any reason; and allergic reactions and any history of hypersensitivity or other severe reactions to drugs. This information should be as specific as possible, including a description of the reaction, the treatment, and the date of its occurrence.

The approach and process by which the medication history is obtained does not necessarily change based on the setting of the encounter. However, one primary difference in the inpatient setting is the Joint Commission requirement for medication reconciliation. A successful medication reconciliation process consists of a standardized systematic approach, with the initial step in this process involving the collection of the best medication history possible from every patient that enters any point in the health care system. The appropriate health care professional to obtain this information varies widely from one institution to the next, involving an array of individuals. Although pharmacists are uniquely qualified and have demonstrated increased accuracy in acquiring the medication history¹⁴, ultimately, medication reconciliation requires a multidisciplinary effort in which all available resources are integrated into each step of the process where appropriate.¹⁵ Shared accountability by utilizing key members of the health care team such as direct-care nurses, pharmacy technicians, pharmacists, and the prescriber is essential in this process. Once an accurate medication history is obtained, the information is used to ensure that any deviation from prescribing as the patient moves through the health care system is deliberate and based on acute changes in the patient's condition. If a discrepancy is an intended therapeutic decision by the prescribing clinician, appropriate documentation with either the reason for or intention to change, hold, or discontinue the medication should be completed in a manner that is clear to all members of the health care team. Unintentional variances in the lists should be considered as potential medication errors pending clarification from the prescribing clinician.

Since medication errors are most commonly seen at interfaces of care, the essential times to conduct medication reconciliation are when a patient is admitted to, transferred within (setting, service, practitioner, or level of care change), or discharged from a health care facility.^{16,17} A crucial final step in the reconciliation process and a vital piece of MTMS occurs at discharge to avoid therapeutic duplication, drug interactions, and omissions of medications that may have been discontinued or placed on hold during hospitalization. On departure from the health care facility, a complete list of the patient's medications must be communicated to the patient and the next provider of service regardless of whether it is within or outside the organization. It is important to realize that efforts to implement a medication reconciliation process should not focus simply on fulfilling a Joint Commission standard but that this process allows for informed prescribing decisions and creates

a safer environment for patients by improving the accuracy of medication administration throughout the continuum of care.

Perhaps the most important aspect of the medication history is to ensure that no assumptions related to medication use go unverified with the patient. The provider should ask questions related to how the current medication therapy is actually taken by the patient. The interviewer should then compare the use of medications as defined by the patient to the prescription information on the bottle or in the PIS/EMR. This information may identify discrepancies or misunderstandings between the prescriber and patient. As discussed previously, the patient may not have adequate health literacy, and the interpretation of the medication instructions printed on the bottle or described by a health professional may not be understandable to a patient. The review of the medication history is an opportune time to identify and clarify such misunderstandings.

2. P.J. has indicated that she is injecting insulin to treat her diabetes. What questions might be asked to evaluate P.J.'s use of and response to insulin?

The following types of questions, when asked of P.J., should provide the practitioner with information on P.J.'s understanding about the use of and response to insulin.

Drug Identification and Use

- What type of insulin do you use?
- How many units of insulin do you use?
- When do you inject your insulin in relationship to meals?
- Where do you inject your insulin? (Rather than the more judgmental question, "Do you rotate your injection sites?")
- Please show me how you usually prepare your insulin for injection. (This request of the patient requires the patient to demonstrate a skill.)
- What, if anything, keeps you from taking your insulin as prescribed?

Assessment of Therapeutic Response

- How do you know if your insulin is working?
- What blood glucose levels are you aiming for?
- How often and when during the day do you test your blood glucose concentration?
- Do you have any blood glucose records that you could share with me?
- Would you show me how you test your blood glucose concentration?
- What is your understanding of the hemoglobin A_{1c} blood test?
- When was the last time you had this test done?
- What were the results of the last hemoglobin A_{1c} test?

Assessment of Adverse Effects

- Do you ever experience reactions from low blood glucose?
- What symptoms warn you of such a reaction?
- When do these typically occur during the day?
- How often do they occur?
- What circumstances seem to make them occur more frequently?
- What do you do when you have a low blood glucose?

The patient's responses to these questions on drug use, therapeutic response, and adverse effects will allow a quick assess-

ment of the patient's knowledge of insulin and whether she is using it in a way that is likely to result in blood glucose concentrations that are neither too high nor too low. The responses to these questions also should provide the practitioner with insight about the extent to which the patient has been involved in establishing and monitoring therapeutic outcomes. Based on this information, the practitioner can begin to formulate the patient's therapeutic plan.

Social History

The social history is used to determine the patient's occupation and lifestyle; important family relationships or other support systems; any particular circumstances (e.g., a disability) or stresses in her life that could influence the MAP; and attitudes, values, and feelings about health, illness, and treatments.

3. A patient's occupation, lifestyle, insurance status, ability to pay, and attitudes often can determine the success or failure of drug therapy. Therefore, P.J.'s prescription drug coverage, nutritional history, her level of activity or exercise in a typical day or week, the family dynamics, and any particular stresses that may affect glucose control need to be documented and assessed. What questions might be asked of P.J. to gain this information?

Work

- Describe a typical work day and a typical weekend day.

Insurance/Cost

- What type of prescription drug coverage do you have? What are the copays for your insulin and diabetic supplies? How often do you go without your insulin or supplies due to cost?

Exercise

- Describe your exercise habits. How often, how long, and when during the day do you exercise? Describe how you change your meals or insulin when you exercise.

Diet

- How many times per day do you usually eat? Describe your usual meal times.
- What do you usually eat for each of your main meals and snacks?
- Are you able to eat at the same time each day?
- What do you do if a meal is delayed or missed?
- Who cooks the meals at home? Does this person understand your dietary needs?
- How often do you eat meals in a restaurant?
- How do you order meals in a restaurant to maintain a proper diet for your diabetes? (*Note:* This is asked of patients who frequently dine in restaurants.)

Support Systems

- Who else lives with you? What do they know about diabetes? How do they respond to the fact that you have diabetes? How do they help you with your diabetes management? Does it ever strain your relationship? What are the issues that seem to be most troublesome? (*Note:* These questions apply equally to the workplace or school setting. Often, the biggest barrier to multiple daily injections is refusal of the patient to inject insulin while at work or school.)

Table 1-4 Elements of the Problem Oriented Medical Record^a

Problem name: Each “problem” is listed separately and given an identifying number. Problems may be a patient complaint (e.g., headache), a laboratory abnormality (e.g., hypokalemia), or a specific disease name if prior diagnosis is known. When monitoring previously described drug therapy, more than one drug-related problem may be considered (e.g., nonadherence, a suspected adverse drug reaction or drug interaction, or an inappropriate dose). Under each problem name, the following information is identified:

| | |
|------------|---|
| Subjective | Information that explains or delineates the reason for the encounter. Information that the patient reports concerning symptoms, previous treatments, medications used, and adverse effects encountered. These are considered nonreproducible data because the information is based on the patient’s interpretation and recall of past events. |
| Objective | Information from physical examination, laboratory results, diagnostic tests, pill counts, and pharmacy patient profile information. Objective data are measurable and reproducible. |
| Assessment | A brief but complete description of the problem, including a conclusion or diagnosis that is supported logically by the above subjective and objective data. The assessment should not include a problem/diagnosis that is not defined above. |
| Plan | A detailed description of recommended or intended further workup (laboratory radiology, consultation), treatment (e.g., continued observation: physiotherapy, diet, medications, surgery), patient education (self-care, goals of therapy, medication use and monitoring), monitoring, and follow-up relative to the above assessment. |

^aSometimes referred to as the *SOAP* (subjective; objective, assessment, plan) note.

Attitude

- **How do you feel about having diabetes?**
- **What worries or bothers you most about having diabetes?** (*Note: Participate in the patient’s care. This approach is likely to enhance the patient–provider relationship, which should translate into improved care.*)

APPROACH TO AND ASSESSMENT OF PATIENT THERAPY

The provider–patient encounter will vary based on the location and type of services provided and access to necessary information. However, the general approach to the patient encounter should follow the problem-oriented medical record (POMR). Organizing information according to medical problems (e.g., diseases) helps to break down a complex situation (e.g., a patient with multiple medical problems requiring multiple drugs) into its individual parts.^{3,4} The medical community has long used a *POMR* or *SOAP note* to record information in the medical record or chart by using a standardized format (Table 1-4). Each medical problem is identified, listed sequentially, and assigned a number. *Subjective* data and *objective* data in support of each problem are delineated, an *assessment* is made, and a *plan* of action identified. The first letter of the four key words (subjective, objective, assessment, and plan) serve as the basis for the SOAP acronym.

The POMR is a general approach and helps to focus the encounter, which provides a structure for the documentation of the services provided. The following section will describe the POMR and SOAP note in more detail.

Problem List

Problems are listed in order of importance and are supported by the subjective and objective evidence gathered during the patient encounter. Each problem in the list can then be given an identifying number. All subsequent references to a specific problem can be identified or referenced by that number (e.g., “problem 1” or simply “1”). These generally are thought of in terms of a diagnosed disease, but they also may be a symptom complex that is being evaluated, a preventive measure (e.g., immunization, contraception), or a cognitive problem (e.g., nonadherence). Problems should be identified based on the practitioner’s level of understanding. For example, the symptoms of “difficulty breathing at night” or “two-pillow orthopnea” are consistent with the symptom complex of heart failure (HF); however, these symptoms could be assessed as individual problems if the student or practitioner is unaware of the association of these symptoms with HF. Any condition that requires a unique management plan should be identified as a problem to serve as a reminder to the practitioner that treatment is needed for that problem. Different settings and activities or clinical services will determine the priority of the problems identified.

Medical problems can be *drug related*, including prescribing errors, dosing errors, adverse drug effects, adherence issues, and the need for medication counseling. Drug-related problems may be definite (i.e., there is no question that the problem exists) or possible (i.e., further investigation is required to establish whether the problem really exists). The most commonly encountered types of drug-related problems are listed in Table 1-5.^{4,8}

The distinction between medical problems and drug-related problems sometimes is unclear, and considerable overlap exists. For example, a medical problem (i.e., a disease, syndrome, symptom, or health condition) can be prevented, cured, alleviated, or exacerbated by medications. When assessing drug therapy, several situations could exist: treatment is appropriate and therapeutic outcomes have been achieved; drugs that have been selected are ineffective or therapeutic outcomes are partially achieved; dosages are subtherapeutic or medication is taken improperly; an inappropriate drug for the medical condition being treated has been prescribed or is being used; or the condition is not being treated.

Likewise, a drug-related problem can cause or aggravate a medical problem. Such drug-related problems could include hypersensitivity reactions; idiosyncratic reactions; toxic reactions secondary to excessive doses; adverse reactions (e.g., insulin-induced hypoglycemia or weight gain); drug-drug, drug-disease, drug-laboratory test, and drug-lifestyle interactions; or polypharmacy (using multiple medications), which may increase the risk of adverse drug events.¹⁸

Subjective and Objective Data

Subjective and objective data in support of a problem are important because assessment of patients and therapies requires the gathering of specific information to verify that a

Table 1-5 Drug-Related Problems**Drug Needed (also referred to as no drug)**

- Drug indicated but not prescribed; a medical problem has been diagnosed, but there is no indication that treatment has been initiated (maybe it is not needed)
- Correct drug prescribed but not taken (nonadherence)

Wrong/Inappropriate Drug

- No apparent medical problem justifying the use of the drug
- Drug not indicated for the medical problem for which it has been prescribed
- Medical problem no longer exists
- Duplication of other therapy
- Less expensive alternative available
- Drug not covered by formulary
- Failure to account for pregnancy status, age of patient, or other contraindications
- Incorrect nonprescription medication self-prescribed by the patient
- Recreational drug use

Wrong Dose

- Prescribed dose too high (includes adjustments for renal and hepatic function, age, body size)
- Correct prescribed dose but overuse by patient (overadherence)
- Prescribed dose too low (includes adjustments for age, body size)
- Correct prescribed dose but underuse by patient (underadherence)
- Incorrect, inconvenient, or less-than-optimal dosing interval (consider use of sustained-release dosage forms)

Adverse Drug Reaction

- Hypersensitivity reaction
- Idiosyncratic reaction
- Drug-induced disease
- Drug-induced laboratory change

Drug Interaction

- Drug-drug interaction
- Drug-food interaction
- Drug-laboratory test interaction
- Drug-disease interaction

problem continues to exist or that therapeutic objectives are being achieved. Subjective data refer to information provided by the patient or another person that cannot be confirmed independently. This is the data most commonly obtained during a patient interview. Objective data refer to information observed or measured by the practitioner (e.g., laboratory tests, BP measurements). The objective data is most commonly obtained from the EMR or paper chart (data-rich-environment). However, some objective data can be obtained in data-poor-environments. In the absence of a medical record, weight, height, pulse, BP, blood glucose readings, and other objective information can be gathered during the provider–patient encounter.

4. P.N., a 28-year-old man, has a BP of 140/100 mmHg. What is the primary problem? What subjective and objective data support the problem, and what additional subjective and objective data are not provided but usually are needed to define this particular problem?

The primary problem is hypertension. No subjective data are given. The objective data are the patient's age, gender, and BP of 140/100 mmHg. Each of these is important in designing a patient-specific therapy plan. Because hypertension often is an

asymptomatic disease (see Chapter 13), subjective complaints such as headache, tiredness or anxiety, shortness of breath (SOB), chest pain, and visual changes usually are absent. If long-term complications such as rupturing of blood vessels in the eye, glomerular damage, or encephalopathy were present, subjective complaints might be blurring or loss of vision, fatigue, or confusion. Objective data would include a report by the physician on the findings of the chest examination (abnormal heart or lung sounds if secondary HF has developed), an ocular examination (e.g., presence of retinal hemorrhages), and laboratory data on renal function (blood urea nitrogen, creatinine, or creatinine clearance). To place these complications in better perspective, the rate of change should be stated. For example, the serum creatinine has increased from a level of 1 mg/dL 6 months ago to a value of 3 mg/dL today. Vague descriptions such as “eye changes” or “kidney damage” are of little value, because progressive damage to these end organs results from uncontrolled high BP, and disease progression needs to be monitored more precisely.

5. D.L., a 36-year-old construction worker, tripped on a board at the construction site 2 days ago, sustaining an abrasion of his left shin. He presents to the emergency department with pain, redness, and swelling in the area of the injury. He is diagnosed as having cellulitis. What is the primary problem? What subjective and objective data support the problem? What additional subjective and objective data are not provided but usually are needed to define this particular problem?

The primary problem is cellulitis of the left leg. Useful pieces of subjective information are D.L.'s description of how he injured his shin at a construction site and his current complaints of pain, redness, and swelling. The fact that he was at a construction site is indirect evidence of a possible dirty wound. Further information must be obtained about how he cleaned the wound after the injury and whether he has received a booster dose of tetanus toxoid within the past 10 years. Objectively, the wound is on the left shin. No other objective data are given. Additional data to obtain would be to document the intensity of the redness on a one-to-four-plus scale, the size of the inflamed area as described by an area of demarcation, the circumference of his left shin compared with his right shin, the presence or absence of pus and any lymphatic involvement, his temperature, and a white blood cell count with differential.

6. C.S., a 58-year-old woman, has had complaints of fatigue, ankle swelling, and SOB, especially when lying down, for the past week. Physical examination shows distended neck veins, bilateral rales, an S₃ gallop rhythm, and lower extremity edema. A chest radiograph shows an enlarged heart. She is diagnosed as having HF and is being treated with furosemide and digoxin. What is/are the primary problem(s)? What subjective and objective data support the problem(s)? What additional subjective and objective data are not provided but usually are needed to define this (these) particular problem(s)?

The primary problem is systolic HF. Subjectively, C.S. claims to be experiencing fatigue, ankle swelling, and SOB, especially when lying down. She claims to have been taking furosemide and digoxin. An expanded description of these symptoms and her medication use would be helpful. The findings on physical examination and the enlarged heart on chest

radiograph are objective data in support of the primary problem of HF. In addition, other objective findings that would help in her assessment would be the pulse rate, BP, serum creatinine, serum potassium concentration, and digoxin blood level and a more thorough description of the rales on lung examination, extent of neck vein distension, and degree of leg edema. Pharmacy records could be screened to determine current dosages and refill patterns of the medications.

In this case, a second primary problem may be present. Current recommendations for the management of HF include use of an angiotensin-converting enzyme (ACE) inhibitor before or concurrent with digoxin therapy. Thus, a possible drug-related problem is the inappropriate choice of drug therapy (“wrong drug”). The patient and/or prescriber should be consulted to ascertain whether an ACE inhibitor has been used previously, if any contraindications exist, or if possible adverse effects were encountered.

Assessment

After the subjective and objective data have been gathered in support of specific listed problems, the practitioner should assess the acuity, severity, and importance of these problems. She should then identify all factors that could be causing or contributing to the problem. The assessment of the severity and acuity is important because the patient expects relief from the symptoms that are of particular concern at this time. During the initial encounter with a patient, it might be discovered that the medical problem is only a symptom complex and that a diagnosis is needed to more accurately identify the problem and further define its severity.

The assessment is usually performed during or immediately following the data gathering while the provider keeps in mind evidence-based practices. For example, if diabetes is assessed and pertinent subjective data (medication history, social history, diet and exercise, etc.) and objective data exist (labs like glycosylated hemoglobin [A_{1c}], low-density lipoprotein cholesterol [LDL-C], BP, etc.), then the assessment of diabetes may be to determine if the patient is meeting the goals for the disease as defined by the ADA. If the patient is not at goal, then the explanation of the reasons why would be described in the assessment, and the plan would then be centered on helping that patient get to goal. Sometimes, the distinction between subjective information provided by the patient and assessments made by the practitioner are confused in the POMR. What the patient reveals belongs in the subjective data, and how the provider interprets it belongs in the assessment. For example, a patient stating that she is having difficulty affording her medications belongs in the subjective information. However, a patient appearing to have difficulty affording her medications belongs in the assessment, as it is the provider’s interpretation of what the patient has stated.

Drug Therapy Assessment

A responsibility of the practitioner is to monitor the response of patients to prescribed therapeutic regimens. The purpose of drug therapy monitoring is to identify and solve drug-related problems and to ensure that all therapeutic objectives are being achieved. Unless proven otherwise, the medical diagnosis should be assumed to be correct. On occasion, the diagnosis may not be readily apparent, or a drug-induced problem may have been diagnosed incorrectly as being a disease entity.

Nurses, pharmacists, physicians, physician assistants, and other health care practitioners share the responsibility to assess and monitor patient drug therapy. For the pharmacist, the drug therapy assessment may occur in many practice settings, including the community pharmacy while dispensing or refilling prescriptions or counseling patients, during MTMS encounters, assessing therapy for the hospitalized patient, through medication reconciliation, or as part of routine monthly evaluations of patients residing in long-term care facilities. Many states have enacted legislation allowing pharmacists to develop collaborative drug therapy agreements with physicians for disease state management of common disorders such as asthma, diabetes, dyslipidemia, and hypertension. Additional services commonly provided by pharmacists through collaborative drug therapy agreements include anticoagulation monitoring, emergency contraception, and immunizations.⁵ These services often involve more detailed drug therapy assessment and may occur within or outside the traditional pharmacy setting. Regardless, the patient’s need (this should be the primary consideration), time constraints, working environment (a determinant of the amount of patient information that is available), and practitioner’s skill level governs the extent of monitoring. Similarly, the exact steps used to monitor therapy and the order in which they are executed need to be adapted to a practitioner’s personal style. Thus, the examples given in this chapter should be used by the reader as a guide rather than as a recipe in a cookbook.

Plan

After the problem list is generated, subjective and objective data are reviewed, and the severity and acuity of the problems are assessed and prioritized, the next step in the problem-oriented (i.e., SOAP) approach is to create a plan, which at the minimum should consist of a diagnostic plan and a MAP that includes patient education. The plan is the action that was justified in the assessment. The plan is clear and direct and does not require explanation (this should be explained in the assessment). For example, if a patient is experiencing constipation while taking an opioid pain reliever, the plan would be to recommend a stool softener and stimulant laxative such as docusate sodium and bisacodyl. The plan should also include any follow-up that would be necessary related to the action taken.

Patient Education

Educating patients to better understand their medical problem(s) and treatment is an implied goal of all treatment plans. This process is categorized as the development of a patient education plan. The level of teaching has to be tailored to the patient’s needs, health literacy, willingness to learn, and general state of health and mind. The patient should be taught the knowledge and skills needed to achieve and evaluate his therapeutic outcome. An important component of the patient education plan emphasizes the need for patients to follow prescribed treatment regimens.

The POMR will allow the provider to focus the interview and encounter independent of the site or service offered. The POMR facilitates documentation of the provision of MTMS across multiple sites and services (across the continuum of care).

The next few sections will discuss how to approach MTMS in various clinical settings.

MEDICATION THERAPY MANAGEMENT SERVICES IN THE COMMUNITY PHARMACY/AMBULATORY SETTING

The core elements of MTMS have been described by the American Pharmacists Association (APhA) and the National Association of Chain Drug Stores.¹⁹ According to these organizations, the core elements of MTMS should include the following components:

1. Medication Therapy Review (MTR)
2. Personal Medication Record (PMR)
3. Medication Action Plan (MAP)
4. Intervention and referral
5. Documentation of services/Billing for services

Medication Therapy Review (MTR)

The MTR may be a comprehensive review in which the provider reviews all of the medications the patient is currently taking, or it may be a focused review of one medication-related issue such as an adverse event. Examples of services provided during the MTR are described in Table 1-6. MTR is dependent on the information that is available from the patient or other data sources. Community pharmacies may be a data-poor environment, and access to necessary information may be limited. In some ambulatory clinics, the provider may have access to the EMR (data-rich environment). Regardless of the setting, a necessary tool to help with the gathering of the medication information is the PMR. This medication record should be updated after any change in medication therapy and should be shared with other health care providers. The patient is responsible for the upkeep of the PMR, but the PMR requires periodic review by the pharmacist or other provider. The goal of this record is to promote self-care and ownership of the medication regimen.¹⁹ The PMR should be used at all levels of care, thereby facilitating the medication reconciliation process required across the continuum of care. An example of a PMR is shown in Figure 1-3.

Table 1-6 Examples of Services Provided During a Medication Therapy Review

- Assess the patient's health status
- Assess cultural issues, health literacy, language barriers, financial status, and insurance coverage or other patient characteristics that may affect the patient's ability to take medications appropriately
- Interview the patient or caregiver to assess, identify, and resolve actual or potential adverse medication events, therapeutic duplications, untreated conditions or diseases, medication adherence issues, and medication cost considerations
- Monitor medication therapy, including response to therapy, safety, and effectiveness
- Monitor, interpret, and assess patient laboratory values, especially as they relate to medication use/misuse
- Provide education and training on the appropriate use of medications
- Communicate appropriate information to other health professionals, including the use and selection of medication therapy

Adapted from reference 19.

Once the patient interview has occurred and the PMR has been updated, the provider may still require information to make an assessment. In such cases, the provider must do his best with the available information, or may obtain missing information such as the medical history or objective data from other providers. Lack of objective information is common in the community pharmacy setting, and the ability to address all problems effectively may be limited in this data-poor environment. In some encounters, obtaining the necessary information may take the entire visit, necessitating a follow-up encounter.

Medication Action Plan (MAP)

If adequate information is available to assess the current problem, a MAP should be developed. Because the MAP is patient centered and is prioritized based on the urgency of need, the provider and the patient should develop it together. An example of a MAP can be seen in Figure 1-4.

The MAP often describes the intervention performed in an MTM encounter and may serve as documentation that can be

| Patient: M.C. ALLERGIES: None Type of reaction: N/A | | Primary Physician: Dr. Sara Smith (555-3971) | | | | Pharmacist: Mary Doe (555-5551) | | Date Prepared: 4/2/08 | | Date Updated: 5/2/08 | |
|---|----------------------------------|--|----------|----------------------------------|-----------------------------------|---------------------------------------|---|------------------------------|-----------|-------------------------|--|
| Start Date | Medication (generic) | Dosage | Route | Times per Day | Scheduled Times | Purpose for Use | Remarks | Prescriber (Phone) | Stop Date | | |
| 1/2/08 | (lisinopril) | 40 mg | By mouth | Once | 9 a.m. | High blood pressure | | Sara Smith, MD (555-3971) | | | |
| 1/2/08 | (metoprolol) | 50 mg | By mouth | Twice | 9 a.m. and 9 p.m. | High blood pressure | | Sara Smith, MD (555-3971) | | | |
| 1/2/08 | (glipizide) | 5 mg | By mouth | Once | 9 a.m. | Diabetes | Take 30 minutes prior to breakfast | Sara Smith, MD (555-3971) | | | |
| 1/2/08 | (propoxyphene/ acetaminophen) | 100 mg/650 mg | By mouth | Up to four times a day if needed | 9 a.m., 2 p.m., 9 p.m., 2 a.m. | Back pain | Take with food. Do not take this medicine with other acetaminophen products (Tylenol®). Do not take this medication unless you have pain. | Sara Smith, MD (555-3971) | | | |
| 4/2/08 | Crestor® (rosuvastatin) | 40 mg | By mouth | Once | 9 a.m. | Cholesterol | | Ted Hart, MD (555-1234) | | | |

Bring this Personal Medication Record with you to all visits with health care providers and if you are admitted to a hospital. Contact your pharmacist regarding questions or updates.

FIGURE 1-3 Example of a Personal Medication Record (PMR).

| My Medication – Related Action Plan | |
|--|--------------------------------------|
| Patient: | M.C. |
| Provider (Phone): | Dr. Sara Smith (555-3971) |
| Pharmacy/Pharmacist (Phone): | RiteMart/Mary Doe, PharmD (555-5551) |
| Date Prepared: | May 2, 2008 |
| <p>The list below has important Action Steps to help you get the most from your medications. Follow the checklist to help you work with your pharmacist and providers to manage your medications AND make notes of your actions next to each item on your list</p> | |
| Action Steps → What I need to do... | Notes → What I did when I did it... |
| <input type="checkbox"/> For your muscle weakness and soreness Stop Crestor® (rosuvastatin) 40 mg. We asked Dr. Hart to change to a lower dose or different agent such as simvastatin. Obtain blood test from Dr. Hart's office. Follow-up with Dr. Hart in 2 days. | |
| <input type="checkbox"/> Medicine Cost We have asked Dr. Hart to stop Crestor® (rosuvastatin) as it is too expensive. A generic medicine such as simvastatin will cost you less and was recommended to Dr. Hart as an alternative. Continue to ask your pharmacist and doctor if the medications you are taking are covered by your Medicare Part D plan and if there are any alternatives that might be less expensive for you. | |
| <input type="checkbox"/> For Pain Talk to Dr. Sara Smith about other pain medicines because the Darvocet® (propoxyphene and acetaminophen) may not work as well as other choices. Some choices might include other medicines such as Vicodin® (hydrocodone and acetaminophen), over the counter acetaminophen, or medicines like naproxen or ibuprofen. | |
| My next appointment with my pharmacist is on: _____ (date) at _____ <input type="checkbox"/> AM <input type="checkbox"/> PM | |

FIGURE 1-4 Example of a Medication Action Plan (MAP).

shared with the patient and other health care providers (like the PMR). The primary purpose of the MAP is to make the action plan patient centered and to provide the patient with documentation of what they need to do next in the action plan. It also provides space for the patient to document what they did related to this action and when they did it. In some instances, the MAP may involve referral to another provider (a physician or pharmacist with additional qualifications) if the issue is beyond the scope of the intervening pharmacist. Some reasons for referral may include diabetes education by a certified diabetes educator, diagnosis of a new or suspected medical condition, or laboratory testing that may be beyond the scope of the pharmacist.

Coordination of care is a key element of MTMS and MTR.² This may include improving the communication between the patient and other health care providers, enhancing the patient's understanding of his health issues or concerns, maximizing health insurance coverage, advocating on behalf of the patient to get needed medications utilizing available resources and programs, and various other functions that will improve the patient's understanding of their health care environment and promote self-care. Coordination of care may be the primary

action taken on behalf of the patient and may be included in the MAP.

Documentation of Services

The development of a documentation process is a necessary component of MTMS.¹⁹ Documentation should be standardized and based on the POMR format. All appropriate records, including the PMR and MAP, should be shared with other providers to promote communication and continuity of care. If the encounter requires follow-up, the documentation should reflect the timing of the follow-up care, and any expectations of the patient and providers should be included. Thorough documentation of the encounter allows all providers to quickly assess the progress of the patient and determine that the desired outcome has been achieved.

Billing for Medication Therapy Management Services

Although billing for MTMS is not universally accepted by all payers, the introduction of the national provider identifier (NPI)

and pharmacist-specific current procedural terminology (CPT) codes may soon make this a reality.^{5,20} The implementation of Medicare Part D in 2006 allowed pharmacists in pharmacies contracted with prescription drug plans to provide MTMS to plan-identified Medicare recipients. Pharmacists bill these plans through the contracted pharmacy by using their individual NPI and one of three CPT codes. The NPI number designates the provider to be paid, and the CPT determines the amount of payment based on the services rendered. The CPT codes specific to pharmacists providing MTMS include the following:

CPT 99605: Initial face-to-face assessment or intervention by a pharmacist with the patient for 1 to 15 minutes

CPT 99606: Subsequent face-to-face assessment or intervention by a pharmacist with the patient for 1 to 15 minutes

CPT 99607: Each additional 15 minutes spent face-to-face by a pharmacist with the patient; used in addition to 99605 or 99606

Although the NPI number and CPT codes allow pharmacists to bill for MTMS, the reimbursement varies by plan and negotiated contract and is beyond the scope of this text. Pharmacists have also developed patient self-pay reimbursement strategies as well as contracts with self-insured employers and state-run Medicaid programs to provide services.^{21,22}

7. M.C. is a 76-year-old female who comes to an appointment at the community pharmacy with her daughter for a focused MTR. She has a Medicare Part D prescription drug plan and is asking for help with her medication costs. She indicates that she has type 2 diabetes, hypertension, back pain, and hyperlipidemia. Her medications include lisinopril 40 mg once daily, metoprolol 50 mg twice daily, glipizide 5 mg once daily, propoxyphene/acetaminophen 100 mg/650 mg one tablet every 6 hours as needed for pain, and rosuvastatin 40 mg once daily. M.C. tells you that she has trouble paying for her rosuvastatin (tier 3, \$60 copayment) and would rather have something generic that costs less (tier 1, \$5 copayment). Further, she complains of muscle soreness and weakness over the last 3 weeks. What objective information can be obtained in a community pharmacy setting? What is the primary problem? What additional information is necessary to determine the cause of her problem? How would a clinician assess and document her problem(s) in a SOAP format?

Although generally not considered a data-rich environment, increasing amounts of objective information can be gathered during the patient encounter at a community pharmacy. Specifically, information such as weight, BP, temperature, and finger-stick glucose and cholesterol levels can be measured if indicated for this patient. This information may be useful to the community pharmacist when performing the MTR in order to determine if the medications are achieving the desired therapeutic outcomes. Although the patient presented for MTR, the primary complaint is the patient's self-reported muscle weakness and soreness over the last 3 weeks. It is impossible to determine if this problem is a medication-related adverse event, because she did not provide a medication history or PMR. Assuming that M.C. is a patient of this pharmacy, the practitioner could gather the necessary medication history from the PIS.

Because the patient is present, this is a good opportunity to develop a PMR with M.C. While developing the PMR with the patient, the practitioner should gather additional information from M.C. about her medication use. For example, the name of one of M.C.'s medicines could be read with the practitioner continuing to ask open-ended questions such as, "How do you take this medication?" "What is your routine for taking your medication?" and "What types of problems, if any, have you had while using this medication?" This process will help to quickly identify any medication discrepancies between the pharmacy computer system and the patient's understanding of medication administration. If discrepancies are noted, the practitioner can clarify them with M.C. right away as part of the intervention. The PMR should also include a section to list medication allergies. The type of reaction should also be included on the PMR so that other providers will know the severity of the medication allergy (i.e., intolerance vs. anaphylactic reaction).

Based on data gathered from the pharmacy computer and M.C., a PMR (depicted in Fig. 1-3) could be developed. Once the PMR has been developed, the provider will have more information to determine if the current problem is medication related. Unfortunately, reviewing the medications alone often does not provide enough information to determine if M.C. is experiencing a medication-related event. Further questioning may be necessary. M.C. should be asked questions such as "How often do you experience muscle weakness and soreness?" "Which muscles are hurting?" "Show me where the problem is," "What do you think is causing the problem?" or "Describe the problem you are experiencing in more detail." Asking questions related to the onset of her symptoms of muscle soreness and weakness will help to determine whether this is a medication-related problem.

Based on this questioning and the PMR, the practitioner can develop an assessment of the current problem that she is experiencing. As indicated on the PMR, M.C. started rosuvastatin most recently. The initiation of this medication corresponds to the onset of her recent soreness and weakness. HMG-coA reductase inhibitors like rosuvastatin are known to cause myositis, or muscle breakdown, which may lead to weakness and muscle soreness. Furthermore, the prescribed dose is high for a female of M.C.'s age. Based on this information, an assessment of the problem can be pursued. If rosuvastatin is the suspected agent, the plan would include actions necessary to solve the problem or to determine if rosuvastatin is the cause of her muscle soreness and weakness. Unfortunately, all of the necessary information is not available (e.g., her baseline cholesterol, serum creatinine, liver function tests, or creatine kinase levels) to develop a formal plan of action to resolve the adverse medication event. However, part of the plan may be to obtain the labs necessary to identify or act on the adverse medication event. An example of the documentation of the SOAP note follows.

PRIMARY PROBLEM:

Muscle soreness and weakness (possible adverse medication event)

SUBJECTIVE:

M.C. reports weakness and soreness, predominantly in her legs over the past 3 weeks. She has difficulty rising from her chair after sitting for long periods and describes the

pain as aching. The patient reports taking her medications as prescribed and rarely misses a dose.

OBJECTIVE:

Total Cholesterol: 137 mg/dL; LDL-C: 56 mg/dL; HDL: 54 mg/dL; Triglycerides: 136 mg/dL

Temperature: 98.5°F

ASSESSMENT:

M.C. has muscle weakness and soreness in her large muscle groups. She is currently at the recommended LDL-C goal level for a person with diabetes and hypertension per NCEP ATP III guidelines (very-high-risk LDL-C goal is <70 mg/dL).²³ Her current lipid therapy is rosuvastatin 40 mg once daily, which was started by her cardiologist 4 weeks ago. The initiation of rosuvastatin 40 mg correlates to the timing of her muscle soreness and weakness. HMG-coA reductase inhibitors (i.e., rosuvastatin) are known to cause myositis/myalgias, and this patient is at particular risk given her age, gender, and starting dose. It is possible that the rosuvastatin could be causing her muscle soreness and weakness. Other lipid-lowering agents could be tried or the dose of rosuvastatin could be reduced, which might eliminate or reduce this adverse event. A creatine kinase level should be obtained to determine the severity of the myositis. A serum creatinine should also be measured, as myositis can lead to renal damage and rhabdomyolysis in severe cases; however, this is usually accompanied by fever and other symptoms that the patient is not currently experiencing.

PLAN:

- Discussed the possibility of an adverse medication event, which included the signs and symptoms of myalgias and myositis.
- Contacted Dr. Hart (M.C.'s cardiologist) to discuss the current problem with rosuvastatin.
- Per discussion with Dr. Hart, will obtain a creatine kinase level and serum creatinine.
- Discontinue rosuvastatin per the pharmacist recommendation. Dr. Hart agreed that M.C. should temporarily stop her rosuvastatin until her laboratory values are reviewed.
- Alternative dosing of rosuvastatin 5 mg or another equivalent agent (atorvastatin 10 mg or simvastatin 20 mg) was discussed with Dr. Hart.
- M.C. is to see Dr. Hart in the cardiology clinic in 2 days to discuss the laboratory values and alternative therapies.
- Discussed the entire plan with M.C., and she verbalized understanding of steps that she is to take with respect to her current medication-induced problem.

8. Based on M.C.'s medication profile, what other problems can be identified with her medication therapy? What can be done to address these issues?

There are three remaining issues that may need to be addressed. The first issue relates to the pain medicine (propoxyphene/acetaminophen) that M.C. is taking. It is well documented that propoxyphene is not an effective opioid pain reliever, and it may lead to increased adverse events in the elderly.²⁴ Other prescription medications such as hydrocodone/acetaminophen or nonprescription medication such as acetaminophen alone or nonsteroidal anti-inflammatory drugs could be used to help treat M.C.'s pain (see Chapters 8 and 99). Second, it is not clear from the current informa-

Table 1-7 Cost Containment Strategies

Patient with Prescription Drug Coverage

- Maximize generic drugs
- Maximize formulary coverage
 - Switch to agents covered on the least expensive formulary tier
- If patient has Medicare Part D, determine eligibility for low-income subsidy through the Social Security Administration
- Consider mail-order prescription programs

Uninsured Patient

- Use low-cost generic programs (e.g., Rx Outreach, Wal-Mart, Target generic programs)
- Switch to therapeutically equivalent lower-cost brand name drugs when generics are unavailable
- Consider tablet splitting, if appropriate
- Consider pharmaceutical industry-sponsored patient assistance programs
- Determine if the patient is eligible for Medicaid, Medicare, Medicare Part D, or other assistance programs

tion if the various providers are communicating. It is the responsibility of the pharmacist to help coordinate care between multiple prescribers as described by the APhA MTMS consensus document.² Therefore, it is important to be sure that both providers (Drs. Smith and Hart) receive a copy of the documentation of the issues addressed during the visit (SOAP note).

Finally, M.C. came into the pharmacy asking for help with her medication costs. In order to assess this problem, it is important to ask if there are specific cost issues with a particular drug or if it is her overall medication regimen that causes her concern. Another important question to ask is if she has stopped taking any medications or changed the way that she takes her medications due to cost. Many patients will discuss cost and adherence issues with their pharmacist, because the point of sale for medications occurs at the pharmacy. However, they may not discuss this problem with the prescriber. Cost and nonadherence due to cost may be medication-related problems that the pharmacist must communicate to the prescriber on behalf of the patient. In assessing drug cost, there are several steps that can be taken. First, determine the patient's ability to pay for medications; implement low-cost, medically appropriate interventions targeted to patient needs; facilitate enrollment into relevant benefit programs; and confirm medication changes with the patient and prescribers (Table 1-7).

For M.C., the rosuvastatin is her biggest concern, as it costs \$60 per month and her Medicare Part D plan lists it as a non-preferred (tier 3) agent on the formulary. With the possible discontinuation of her rosuvastatin, it is important for the pharmacist to anticipate her need for an alternative lipid-lowering agent and to determine if there are cost-effective formulary alternatives that may be appropriate. This information can then be relayed to the prescriber. Furthermore, the alternative lipid-lowering formulary choice can be integrated into the plan developed for the primary issue of muscle soreness and weakness (see Question 7 above). The integration of multiple problems is a complicated but important aspect of the MAP.

9. What additional information can be provided to M.C. at this time?

As discussed previously, an important part of MTMS involves the MAP. The MAP is a document that may empower the patient and promote self-care. The information on the MAP is important for both the patient and provider and facilitates communication among multiple providers. When a patient presents the PMR and MAP to all providers, complex medication information can be shared across the continuum of care. An example of M.C.'s MAP is included in Figure 1-4.

Because extensive information was communicated to the patient and other providers, follow-up (phone or face-to-face) would be appropriate and necessary to determine the resolution to the medication-related issues identified. Follow-up should occur in a timely manner, likely after M.C. has obtained the necessary labs and has been evaluated by her cardiologist as outlined in the plan. The follow-up should include questions related to the changes that were (or were not) made based on the practitioner recommendations and any new issues that have surfaced. Follow-up should be considered after any encounter in which an action plan is developed in order to determine if the medication-related problem has been resolved. Additionally, problems may be identified and prioritized during the initial visit but, due to time constraints, may not be addressed. A follow-up visit allows for assessment of these problems.

10. Assuming that the pharmacy provider had an NPI number and a contract with M.C.'s Medicare Part D prescription drug plan, how could the 30 minutes spent with M.C. be billed to her insurance?

Provided that M.C. was identified by her Medicare prescription drug plan as eligible for MTMS, the practitioner could bill for the 30-minute encounter. Using the practitioner's NPI number and the appropriate CPT codes, the practitioner could bill for one CPT 99605 (for the first 15 minutes of initial face-to-face MTM encounter) and one CPT 99607 (for an additional 15 minutes spent with the patient in a face-to-face MTM encounter). M.C.'s Medicare Part D plan may require the practitioner to bill the prescription drug plan initially, and then the plan would pay the community pharmacy directly instead of reimbursing the individual pharmacist. Documentation of the visit would need to be stored at the site of the encounter in case any information was requested from M.C.'s prescription drug plan.

MEDICATION THERAPY MANAGEMENT IN THE ACUTE CARE SETTING

11. M.C. has just been hospitalized in a large medical center for renal failure and urosepsis. The pharmacist has access to the medical chart, nursing record, MAR, and a computer that directly links to the clinical laboratory. The pharmacists at this facility assess the patient's drug therapy and routinely provide clinical pharmacokinetic monitoring. How would the pharmacist approach M.C. differently in this inpatient setting compared with the pharmacist in Question 7 who worked in a community pharmacy?

Similar to the outpatient setting, the SOAP format is often used when documenting the encounter of the hospitalized patient; however, obtaining the information needed poses unique challenges. In this setting, subjective information may be more

difficult to obtain at the time of assessment in those patients presenting with cognitive impairment resulting from their acute condition, such as the seriously ill or injured. Objective data, on the other hand, is more readily available and retrievable with access to pharmacy, laboratory, and other medical record information. On admission to the health care facility, the medication reconciliation process should be initiated to identify any variances in the admission orders when compared with the patient's home medication list. With acute medical problems superimposed on chronic conditions, it is not unusual to have new medications added and home medications held, changed, or discontinued.

Assessing the appropriateness of drug therapy requires a basic understanding of both pharmacokinetic (e.g., absorption, distribution, metabolism, and elimination of the drug) and pharmacodynamic (e.g., the relief of pain with an analgesic or reduction of BP with an antihypertensive agent) principles. This detailed assessment and monitoring is dependent on the availability of robust patient and laboratory data. The inpatient setting is a relatively data-rich environment where access to needed information is generally readily available. Knowledge of the patient's height, body weight, and hepatic and renal functions are essential for proper dosage considerations. The type of hospitalized patient will vary from the short-stay, otherwise healthy elective surgery patient to the critically ill, hemodynamically compromised patient. The pharmacist must be intimately aware of how pharmacokinetics and pharmacodynamics can be markedly altered throughout the hospitalization or disease-state process in each patient evaluated. This heightened awareness will allow for timely interventions and minimize medication errors resulting from improper or delayed dosage adjustments as the clinical status of the patient changes. Drug level monitoring may be suitable for certain medications and are of great clinical value; nevertheless, it is important to take into consideration clinical response to drug therapy along with the assessment of a specific laboratory value. Accurate interpretation of any drug level requires review of the nursing MAR (or eMAR), evaluating time of drug administration to that of serum sample acquisition. When serum drug levels are obtained, they must be reviewed for validity before alterations in medication regimens are made. If a serum drug concentration seems unusually high or low, the clinician must consider all of the various factors that might influence the serum concentration of the drug in that particular patient. When the reason for an unexpected abnormal serum drug concentration is not apparent, the test should be repeated before considering a dose change that may cause supra- or subtherapeutic concentrations resulting from erroneous data.

When M.C. was seen in the community pharmacy, the pharmacist assessed her chronic conditions (diabetes, hypertension, and hyperlipidemia and her cost issues), and her drug therapy. Monitoring in the community pharmacy-based MTM program will occur at regular time intervals and is less sensitive to the day-to-day changes of the patient. However, in the inpatient setting, M.C. has acute conditions (renal failure and urosepsis) superimposed on her chronic conditions. Monitoring of medication therapy will occur frequently, resulting in a dynamic treatment plan for her acute and chronic conditions.

Although the inpatient setting is relatively data rich, the information gathered and the assessment and plan formulated in

the facility must be communicated to other providers once the patient is discharged. At a minimum, communication of the patient's new medication therapy regimen (or PMR) should be communicated to the patient's primary care physician and pharmacist. This step in the process (medication reconciliation) is important to ensure appropriate medication use across the continuum of care.

CONCLUSION

Interventions in any setting require interdisciplinary communication, assessment of patient-specific needs, and documentation of the visit. The health care system is complicated, and it is often difficult for the patient to effectively navigate. Consistency and follow through are important to both patients and

other providers regardless of MTMS setting. As illustrated in Figure 1-1, communication to the patient, documentation by using the SOAP note and the MAP, and follow-up are all closely correlated. To develop a successful action plan, information must be gathered in an organized and concise fashion. This information, if properly documented and shared with other providers, will help in the provision of care to the patients served within the health care system.

PATIENT-DIRECTED MONITORING AND TESTING 2-22

This chapter provides the reader with an overview of laboratory tests commonly used in clinical medicine. Specialized laboratory tests, which are used to monitor specific disease states or specific drug therapies, are integrated into the case histories, questions, and answers in the disease-specific chapters of this book. Over-the-counter, or patient-directed laboratory tests, are briefly presented at the end of this chapter because these are being used to a greater extent. The most recent edition of a comprehensive laboratory textbook should be reviewed when comprehensive understanding of clinical laboratory tests is required.¹

GENERAL PRINCIPLES

Generally, laboratory tests should be ordered only if the results of the test will affect decisions about the care of the patient. The serum, urine, and other bodily fluids can be analyzed routinely;

however, the economic cost of obtaining these data must always be balanced by benefits to patient outcomes.

Normal Values

Clinical laboratory test results that appear within a predetermined range of values are referred to as “normal,” and those outside this range are typically referred to as “abnormal.” Laboratory findings, both normal and abnormal, can be helpful in assessing clinical disorders, establishing a diagnosis, assessing drug therapy, or evaluating disease progression. In addition, baseline laboratory tests are often necessary to evaluate disease progression and response to therapy or to monitor the development of toxicities associated with therapy.

Clinical laboratories can analyze sample specimens by different laboratory methods; therefore, each laboratory has its own set of normal values. Consequently, clinicians should rely

on normal values listed by their own clinical laboratory facility when interpreting laboratory tests.

Laboratory Error

A variety of factors can interfere with the accuracy of laboratory tests. Patient-related factors (e.g., age, gender, weight, height, time since last meal) can affect the range of normal values for a given test. Laboratory-based issues can also influence the accuracy of laboratory values. For example, a specimen can be spoiled because of improper handling or processing (e.g., hyperkalemia due to hydrolysis of a blood specimen); because it was taken at a wrong time (e.g., fasting blood glucose level taken shortly after a meal); because collection was incomplete (e.g., 24-hour urine collection that does not span a full 24-hour period); Errors also can arise due to faulty or poor quality reagents (e.g., improperly prepared, outdated); due to technical errors (e.g., human error in reading result, computer-keying error); due to interference from medical procedures (e.g., cardioconversion increases creatine kinase [CK] serum concentrations); due to dietary effects (e.g., rare meat ingestion can cause a false-positive guaiac test); and because medications can interfere either with the testing procedure or by their pharmacologic effects (e.g., thiazides can increase the serum uric acid concentration, β -agonists can reduce serum potassium concentrations). Clinicians might not be aware of when laboratory-related issues arise. As a result, laboratory findings must always be interpreted carefully, and the validity of a test result questioned when it does not seem to correlate with a patient's clinical status.

Units of Measure

The International System of Units (SI) reports clinical laboratory values using the metric system. For example, the basic unit of mass for the SI system, the *mole* is not influenced by the added weight of salt or ester formulations. The mole, therefore, is technically and pharmacologically more meaningful than the gram because each physiological reaction occurs on a molecular level. Nevertheless, efforts to implement the SI system internationally for laboratory test reports have been resisted in the United States. Despite adopting SI transition policies in the late 1980s,^{2,3} major American medical journals have since reverted back to the traditional units for laboratory test reporting. The “normal” values for common blood chemistry tests are presented in both conventional units and SI units, along with “conversion factors” to interchange traditional and SI units in Tables 2-1 (blood chemistry reference values) and 2-2 (hematologic laboratory tests). Formulas for converting conventional units to SI units are also available in the primary literature.^{4,5}

ELECTROLYTES AND BLOOD CHEMISTRIES

Sodium

Normal: 135–145 mEq/L or mmol/L

Sodium is the predominant cation of extracellular fluid (ECF). Only a small amount of sodium (~5 mEq/L) is in intracellular fluid (ICF). Along with chloride, potassium, and water, sodium is important in establishing serum osmolarity and osmotic pressure relationships between ICF and ECF. Dietary intake of sodium is balanced by renal excretion of sodium,

which is regulated by aldosterone (enhances sodium reabsorption), natriuretic hormone (increases excretion of sodium), and antidiuretic hormone (enhances reabsorption of free water). An increase in the serum sodium concentration could suggest either impaired sodium excretion or volume contraction. Conversely, a decrease in the serum sodium concentration to less-than-normal values could reflect hypervolemia, abnormal sodium losses, or sodium starvation. Although healthy individuals are able to maintain sodium homeostasis without difficulty, patients with kidney failure, heart failure, or pulmonary disease often encounter sodium and water imbalance. In adults, changes in serum sodium concentrations most often represent water imbalances rather than sodium imbalances. Hence, serum sodium concentrations are more reflective of a patient's fluid status rather than sodium balance.

Hyponatremia

Hyponatremia can result from dilution of the sodium concentration in serum or from a total body depletion of sodium. The finding of hyponatremia implies that sodium has been diluted throughout all body fluids because water moves freely across cell membranes in response to oncotic pressures. Dilutional hyponatremia occurs when the ECF compartment expands without an equivalent increase in sodium. Some clinical conditions (e.g., cirrhosis, congestive heart failure, renal impairment), as well as the administration of osmotically active solutes (e.g., albumin, mannitol), are commonly associated with dilutional hyponatremia. Hyponatremia that results from sodium depletion presents as a low serum sodium concentration in the absence of edema. Sodium-depletion hyponatremia can be caused by mineralocorticoid deficiencies, sodium-wasting renal disease, or replacement of sodium-containing fluid losses with nonsaline solutions.

Hypernatremia

Hypernatremia represents a state of relative water deficiency and, therefore, excessive concentrations of sodium in all body fluids (hypertonicity). Hypernatremia can be caused by the loss of free water, loss of hypotonic fluid, or excessive sodium intake. Free water loss is uncommon, except in the presence of diabetes insipidus. Gastroenteritis is the most common cause of hypotonic fluid loss in infants and the elderly. Increased retention of sodium in patients with hyperaldosteronism can also increase serum sodium concentrations. Excessive salt intoxication is usually accidental or iatrogenic and most commonly results from inappropriate intravenous administration of hypertonic salt solutions. Some β -lactam antibiotics (e.g., ticarcillin) contain a modest sodium load and can cause fluid overload when high dosages are administered.

The primary defense against hypertonicity is thirst and subsequent fluid intake. Hypernatremic syndromes, therefore, usually occur in patients who are unable to drink sufficient fluids. For example, infants who cannot demand fluid are at greatest risk for the development of hypernatremia. Similarly, patients, who are vomiting, comatose, or not allowed oral fluids are at risk for hypernatremia.

1. M.C., a 61-year-old woman with no known drug allergies (NKDA) is hospitalized with a chief complaint of increasing shortness of breath (SOB) and orthopnea over the past week. She has been treated previously for heart failure and has not taken any

Table 2-1 Blood Chemistry Reference Values

| Laboratory Test | Normal Reference Values | | Conversion Factor | Comments |
|-------------------------|-----------------------------|----------------------------|-------------------|--|
| | Conventional Units | SI Units | | |
| Electrolytes | | | | |
| Sodium | 135–145 mEq/L | 135–145 mmol/L | 1 | Low sodium is usually due to excess water (e.g., ↑ serum antidiuretic hormone) and is treated with water restriction. ↑ in severe dehydration, diabetes insipidus, significant renal and GI losses. |
| Potassium | 3.5–5 mEq/L | 3.5–5 mmol/L | 1 | ↑ with renal dysfunction, acidosis, K-sparing diuretics, hemolysis, burns, crush injuries. ↓ by diuretics, alkalosis, severe vomiting and diarrhea, heavy NG suctioning. |
| CO ₂ content | 22–28 mEq/L | 22–28 mmol/L | 1 | Sum of HCO ₃ and dissolved CO ₂ . Reflects acid–base balance and compensatory pulmonary (CO ₂) and renal (HCO ₃) mechanisms. Primarily reflects HCO ₃ . |
| Chloride | 95–105 mEq/L | 95–105 mmol/L | 1 | Important for acid–base balance. ↓ by GI loss of chloride-rich fluid (vomiting, diarrhea, GI suction, intestinal fistulas, overdiuresis). |
| BUN | 8–18 mg/dL | 2.8–6.4 mmol/L | 0.357 | End product of protein metabolism, produced by liver, transported in blood, excreted renally. ↑ in renal dysfunction, high protein intake, upper GI bleeding, volume contraction. |
| Creatinine | 0.6–1.2 mg/dL | 50–110 μmol/L | 88.4 | Major constituent of muscle; rate of formation constant; affected by muscle mass (lower with aging); excreted renally. ↑ in renal dysfunction. Used as a primary marker for renal function (GFR). |
| CrCl | 75–125 mL/min | 1.25–2.08 mL/sec | 0.01667 | Reflects GFR; ↓ in renal dysfunction. Used to adjust dosage of renally eliminated drugs. |
| Glucose (fasting) | 70–110 mg/dL | 3.9–6.1 mmol/L | 0.05551 | ↑ in diabetes or by adrenal corticosteroids. Important to obtain fasting glucose level. |
| Glycosylated hemoglobin | <5% | <5% | 1 | Used to assess average blood glucose over 1–3 months. Helpful for monitoring chronic blood glucose control in patients with diabetes. Values >8% seen in patients with poor glucose control. |
| Calcium–total | 8.8–10.2 mg/dL | 2.20–2.55 mmol/L | 0.250 | Regulated by body skeleton redistribution, parathyroid hormone, vitamin D, calcitonin. Affected by changes in albumin concentration. ↓ by hypothyroidism, loop diuretics, vitamin D deficiency; ↑ in malignancy and hyperthyroidism. |
| Calcium–unbound | 4.5–5.6 mg/dL | 1.13–1.4 mmol/L | 0.250 | Physiologically active form. Unbound “free” calcium remains unchanged as albumin fluctuates. Total calcium ↓ when albumin ↓. |
| Magnesium | 1.6–2.4 mEq/L | 0.8–1.20 mmol/L | 0.5 1 | ↓ in malabsorption, severe diarrhea, alcoholism, pancreatitis, diuretics, hyperaldosteronism (symptoms of weakness, depression, agitation, seizures, hypokalemia, arrhythmias). ↑ in renal failure, hypothyroidism, magnesium-containing antacids. |
| Phosphate ^d | 2.5–5 mg/dL | 0.8–1.60 mmol/L | 0.323 | ↑ with renal dysfunction, hypervitaminosis D, hypocalcemia, hypoparathyroidism. ↓ with excess aluminum antacids, malabsorption, renal losses, hypercalcemia, refeeding syndrome. |
| Uric acid | 2–7 mg/dL | 0.12–0.42 mmol/L | 0.06 | ↑ in gout, neoplastic, or myeloproliferative disorders, and drugs (diuretics, niacin, low-dose salicylate, cyclosporine). |
| Proteins | | | | |
| Prealbumin | 15–36 mg/dL | 150–360 mg/L | 10 | Indicates acute changes in nutritional status, useful for monitoring TPN. |
| Albumin | 4–6 g/dL | 40–60 g/L | 10 | Produced in liver; important for intravascular osmotic pressure. ↓ in liver disease, malnutrition, ascites, hemorrhage, protein-wasting nephropathy. May influence highly protein-bound drugs. |
| Globulin | 2.3–3.5 g/dL | 23–35 g/L | 10 | Active role in immunologic mechanisms. Immunoglobulins ↑ in chronic infection, rheumatoid arthritis, multiple myeloma. |
| Enzymes | | | | |
| CK | 0–150 units/L | 0–2.5 μkat/L | 0.01667 | In tissues that use high energy (skeletal muscle, myocardium, brain). ↑ by IM injections, MI, acute psychotic episodes. Isoenzyme CK-MM in skeletal muscle; CK-MB in myocardium; CK-BB in brain. MB fraction >5%–6% suggests acute MI. |
| CK-MB cTnI | 0–12 units/L <0.03 ng/mL | 0–0.2 μkat/L <0.03 μg/L | 0.01667 1 | More specific than CK-MB for myocardial damage, elevated sooner and remains elevated longer than CK-MB. cTnI >2.0 suggests acute myocardial injury. |

(continued)

Table 2-1 Blood Chemistry Reference Values (Continued)

| Laboratory Test | Normal Reference Values | | Conversion Factor | Comments |
|----------------------------|-------------------------|------------------|-------------------|---|
| | Conventional Units | SI Units | | |
| Enzymes (continued) | | | | |
| Myoglobin | <90 µg/L | <90 mcg/L | 1 | Early elevation (within 3 hr), but less specific for myocardial compared to CK-MB. |
| Homocysteine | 4–15 µmol/L | 4–15 µmol/L | 1 | Damages vessel endothelial, which may increase the risk for cardiac disease. Associated with deficiencies in folate, vitamin B ₆ , and vitamin B ₁₂ . |
| LDH | 100–190 units/L | 1.67–3.17 µkat/L | 0.01667 | High in heart, kidney, liver, and skeletal muscle. Five isoenzymes: LD1 and LD2 mostly in heart, LD5 mostly in liver and skeletal muscle, LD3 and LD4 are non-specific. ↑ in malignancy, extensive burns, PE, renal disease. |
| BNP | <100 pg/mL | <100 ng/L | 1 | BNP >500 ng/L indicates left ventricular dysfunction. Released from heart with ↑ workload placed on heart (e.g., CHF). |
| CRP | 0–1 mg/dL | 0–10 mg/L | 1 | Nonspecific indicator of acute inflammation. Similar to ESR, but more rapid onset and greater elevation. CRP >3 mg/dL increases risk of cardiovascular disease. |
| Liver Function | | | | |
| AST | 0–35 units/L | 0–0.58 µkat/L | 0.01667 | Large amounts in heart and liver; moderate amounts in muscle, kidney, and pancreas. ↑ with MI and liver injury. Less liver specific than ALT. |
| ALT | 0–35 units/L | 0–0.58 µkat/L | 0.01667 | From heart, liver, muscle, kidney, pancreas. ↑ negligible unless parenchymal liver disease. More liver specific than AST. |
| ALP | 30–120 units/L | 0.5–2.0 µkat/L | 0.01667 | Large amounts in bile ducts, placenta, bone. ↑ in bile duct obstruction, obstructive liver disease, rapid bone growth (e.g., Paget disease), pregnancy. |
| GGT | 0–70 units/L | 0–1.17 µkat/L | 0.01667 | Sensitive test reflecting hepatocellular injury; not helpful in differentiating liver disorders. Usually high in chronic alcoholics. |
| Bilirubin–total | 0.1–1 mg/dL | 1.7–17.1 µmol/L | 17.1 | Breakdown product of hemoglobin, bound to albumin, conjugated in liver. Total bilirubin includes direct (conjugated) and indirect bilirubin. ↑ with hemolysis, cholestasis, liver injury. |
| Bilirubin–direct | 0–0.2 mg/dL | 0–3.4 µmol/L | 17.1 | |
| Miscellaneous | | | | |
| Amylase | 35–120 units/L | 0.58–2.0 µkat/L | 0.01667 | Pancreatic enzyme; ↑ in pancreatitis or duct obstruction. |
| Lipase | 0–160 units/L | 0–2.67 µkat/L | 0.01667 | Pancreatic enzyme, ↑ acute pancreatitis, elevated for longer period than amylase. |
| PSA | 0–4 ng/mL | 0–4 mcg/L | 1 | ↑ in benign prostatic hypertrophy (BPH) and also in prostate cancer. PSA levels of 4–10 ng/mL should be worked up. Risk of prostate cancer increased if free PSA/total PSA <0.25. |
| TSH | 2–10 µunits/mL | 2–10 m units/L | 1 | ↑ TSH in primary hypothyroidism requires exogenous thyroid supplementation. |
| Cholesterol | | | | |
| Total | <200 mg/dL | <5.2 mmol/L | 0.02586 | Desirable = Total <200; LDL 70–160 (depends on risk factors); HDL >45 mg/dL; ↑ LDL or ↓ HDL are risk factors for cardiovascular disease. Consult NCEP and ATP guidelines for most current target goals and description of patient risk factors. |
| LDL | 70–160 mg/dL | <3.36 mmol/L | 0.02586 | |
| HDL | >45 mg/dL | >1.16 mmol/L | 0.02586 | |
| Triglycerides (fasting) | <160 mg/dL | <1.80 mmol/L | 0.0113 | ↑ by alcohol, saturated fats, drugs (propranolol, diuretics, oral contraceptives). Obtain fasting level. |

^aPhosphate as inorganic phosphorus.

ALP, alkaline phosphatase; ALT, alanine aminotransferase; AST, aspartate aminotransferase; ATP, Adult Treatment Panel; BNP, brain natriuretic peptide; BPH, benign prostatic hypertrophy; BUN, blood urea nitrogen; CHF, congestive heart failure; CK, creatine kinase (formerly known as creatine phosphokinase); CrCl, creatinine clearance; CRP, C-reactive protein; cTnI, cardiac troponin I; ESR, erythrocyte sedimentation rate; GFR, glomerular filtration rate; GGT, gamma-glutamyl transferase; GI, gastrointestinal; HDL, high-density lipoprotein; IM, intramuscularly; LDH, lactate dehydrogenase; LDL, low-density lipoprotein; MI, myocardial infarction; NCEP, National Cholesterol Education Program; NG, nasogastric; PE, pulmonary embolism; PSA, prostate-specific antigen; SI, International System of Units; TPN, total parenteral nutrition; TSH, thyroid-stimulating hormone.

Table 2-2 Hematologic Laboratory Values

| Laboratory Test | Normal Reference Values | | Comments |
|-----------------------------|--|-------------------------------|---|
| | Conventional Units | SI Units | |
| RBC count | | | |
| • Male | 4.3–5.9 × 10 ⁶ /mm ³ | 4.3–5.9 × 10 ¹² /L | |
| • Female | 3.5–5.0 × 10 ⁶ /mm ³ | 3.5–5.0 × 10 ¹² /L | |
| Hct | | | ↓ with anemias, bleeding, hemolysis. ↑ with polycythemia, chronic hypoxia. |
| • Male | 39%–49% | 0.39–0.49 I ^a | |
| • Female | 33%–43% | 0.33–0.43 I ^a | |
| Hgb | | | Similar to Hct. |
| • Male | 14–18 g/dL | 140–180 g/L | |
| • Female | 12–16 g/dL | 120–160 g/L | |
| MCV | 76–100 μm ³ | 76–100 fL ^b | Describes average RBC size; ↑ MCV = macrocytic, ↓ MCV = microcytic. |
| MCH | 27–33 pg | 27–33 pg | Measures average weight of Hgb in RBC. |
| MCHC | 33–37 g/dL | 330–370 g/L | More reliable index of RBC hemoglobin than MCH. Measures average concentration of Hgb in RBC. Concentration will not change with weight or size of RBC. |
| Reticulocyte count (adults) | 0.1%–2.4% | 0.001–0.024 I ^a | Indicator of RBC production; ↑ suggests ↑ number of immature erythrocytes released in response to stimulus (e.g., iron in iron-deficiency anemia). |
| ESR | | | Nonspecific; ↑ with inflammation, infection, neoplasms, connective tissue disorders, pregnancy, nephritis. Useful monitor of temporal arteritis and polymyalgia rheumatica. |
| • Male | 0–20 mm/hr | 0–20 mm/hr | |
| • Female | 0–30 mm/hr | 0–30 mm/hr | |
| WBC count | 3.2–9.8 × 10 ³ /mm ³ | 3.2–9.8 × 10 ⁹ /L | Consists of neutrophils, lymphocytes, monocytes, eosinophils, and basophils; ↑ in infection and stress. |
| ANC | >2,000 mm ³ | | ANC = WBC × (% neutrophils + % bands)/100; if <500 ↑ risk infection, if >1,000 ↓ risk infection. |
| Neutrophils | 54%–62% | 0.54–0.62 I ^a | ↑ in neutrophils suggests bacterial or fungal infection. ↑ in bands suggests bacterial infection. |
| Bands | 3%–5% | 0.03–0.05 I ^a | |
| Lymphocytes | 25%–33% | 0.25–0.33 I ^a | |
| Monocytes | 3%–7% | 0.03–0.07 I ^a | |
| Eosinophils | 1%–3% | 0.01–0.03 I ^a | Eosinophils ↑ with allergies and parasitic infections. |
| Basophils | <1% | <0.01 I ^a | |
| Platelets | 130–400 × 10 ³ /mm ³ | 130–400 × 10 ⁹ /L | <100 × 10 ³ /mm ³ = thrombocytopenia; <20 × 10 ³ /mm ³ = ↑ risk for severe bleeding. |
| Iron | | | |
| • Male | 80–180 mcg/dL | 14–32 μmol/L | Body stores two-thirds in Hgb; one-third in bone marrow, spleen, liver; only small amount present in plasma. Blood loss major cause of deficiency. |
| • Female | 60–160 mcg/dL | 11–29 μmol/L | ↑ needs in pregnancy and lactation. |
| • TIBC | 250–460 mcg/dL | 45–82 μmol/L | ↑ capacity to bind iron with iron deficiency. |

^aWith the SI, the concept of number fraction replaces percentage. Thus, for mass fraction, volume fraction, and relative quantities, the unit “I” is used to replace former units.

^bfL, femtoliter; femto, 10⁻¹⁵; pico, 10⁻¹²; nano, 10⁻⁹; micro, 10⁻⁶; milli, 10⁻³.

ANC, absolute neutrophil count; ESR, erythrocyte sedimentation rate; Hct, hematocrit; Hgb, hemoglobin; MCH, mean corpuscular hemoglobin; MCHC, mean cell hemoglobin concentration; MCV, mean cell volume; RBC, red blood cell; SI, International System of Units; TIBC, total iron-binding capacity; WBC, white blood cell.

medication over the past 2 weeks. M.C. has severe (4+) pedal edema and is in respiratory distress. Laboratory tests were ordered and reported back as follows: sodium (Na), 123 mEq/L (normal, 135–145); potassium (K), 4.1 mEq/L (normal, 3.5–5.0); chloride (Cl), 90 mEq/L (normal, 95–105); carbon dioxide (CO₂), 28 mEq/L (normal, 22 to 28); blood urea nitrogen (BUN), 30 mg/dL (normal, 8–18); serum creatinine (SCr), 1.3 mg/dL (normal, 0.6–1.2); and fasting glucose, 100 mg/dL (normal, 70–110). Why should M.C. not be given sodium chloride to return her serum sodium concentration to a normal value?

[SI units: Na, 123 mmol/L; K, 4.1 mmol/L; Cl, 90 mmol/L; CO₂, 28 mmol/L; BUN, 10.7 mmol/L; SCr, 115 μmol/L; glucose, 5.5 mmol/L]

All body fluids are in osmotic equilibrium, and changes in serum sodium concentration are associated with shifts of water into and out of cells. M.C. has 4+ pedal edema and heart failure; her serum concentration of sodium is probably

low because her plasma volume is increased relative to sodium. The serum sodium concentration in this case does not reflect total body sodium content. The usual treatment for this type of hyponatremia is salt and water restriction combined with diuresis in an attempt to remove the excess fluid associated with M.C.'s heart failure (see Chapters 11 and 18).

Potassium

Normal: 3.5–5.0 mEq/L or mmol/L

Sodium is the major cation in the ECF, and potassium is the major intracellular cation in the body. The potassium ion in the ECF is filtered freely at the glomerulus of the kidney, reabsorbed in the proximal tubule, and secreted into the distal segments of the nephron. Because the majority of potassium is sequestered within cells, a serum potassium concentration is not a good measure of total body potassium. Intracellular

potassium, however, cannot be measured easily. Fortunately, the clinical manifestations of potassium deficiency (e.g., fatigue, drowsiness, dizziness, confusion, electrocardiographic changes, muscle weakness, muscle pain) correlate well with serum concentrations. The serum potassium concentration is buffered and can be within normal limits despite abnormalities in total body potassium. During potassium depletion, potassium moves from the ICF into the ECF to maintain the serum concentration. When the serum concentration decreases by a mere 0.3 mEq/L, the total body potassium deficit is approximately 100 mEq. Serum potassium concentrations, therefore, can be misleading when interpreted in isolation from other considerations, and assumptions should not be made as to the status of total body potassium concentration based solely on a serum concentration measurement.

Hypokalemia

The kidneys are responsible for about 90% of daily potassium loss (~40–90 mEq/day), and the remaining 10% of potassium excretion each day is managed by the gastrointestinal (GI) system and the dermatologic system (i.e., sweating). The kidneys, however, only have a limited ability to conserve potassium. Even when potassium intake has ceased, the urine will contain at least 5 to 20 mEq of potassium per 24 hours. Therefore, prolonged intravenous therapy with potassium-free solutions in a patient unable to obtain potassium in foods (e.g., nothing by mouth [NPO] patient) can result in hypokalemia. Hypokalemia can also be induced by osmotic diuresis (e.g., mannitol, glucosuria), thiazide or loop diuretics, excessive mineralocorticoid activity, or protracted vomiting. Although the fluid secreted along most of the upper GI tract contains only modest amount of potassium (i.e., 5–20 mEq/L), vomiting can induce hypokalemia because of the combined effect from decreased food intake, loss of acid, alkalosis, and loss of sodium. The loss of large amounts of colonic fluid through severe diarrhea can cause potassium depletion because fluid in the colon is high in potassium content (i.e., 30–40 mEq/L). Insulin and stimulation of β_2 -adrenergic receptors can also induce hypokalemia because both increase the movement of potassium into cells from the extracellular fluid.

Hyperkalemia

Hyperkalemia most commonly results from decreased renal excretion of potassium, excessive exogenous potassium administration (especially when combined with a potassium-sparing diuretic), or excessive cellular breakdown (e.g., hemolysis, burns, crush injuries, surgery, infections). Metabolic acidosis also can induce hyperkalemia as hydrogen ions move into cells in exchange for potassium and sodium. Abnormal potassium concentrations in the serum primarily affect excitability of nerve and muscle tissue (e.g., myocardial tissue). As a result, arrhythmias can be induced by hyperkalemia or hypokalemia. Potassium also affects some enzyme systems, acid–base balance, as well as carbohydrate and protein metabolism.

2. J.S., a 17-year-old female (NKDA) with type 1 diabetes mellitus, is hospitalized for ketoacidosis. Her fasting blood glucose was 802 mg/dL (normal, 70–110), her urine output was 140 mL/hour (normal, 50), and her urine was positive (4+) for glucose and ketones. J.S.'s blood pH was 7.1 (normal, 7.4), and her serum potassium concentration was 4.1 mEq/L (normal, 3.5–5.0).

Although J.S.'s serum potassium concentration is normal, why is her serum potassium of concern?

[SI units: glucose, 44.5 mmol/L (normal, 3.9–6.1); K, 4.1 mmol/L]

Treatment of J.S.'s diabetic ketoacidosis without supplemental potassium could result in significant hypokalemia. When the pH of the blood is acidic, potassium shifts out of cells in response to increased concentrations of intracellular hydrogen ion. J.S.'s total-body potassium concentration is decreased as a result of both glycosuria and polyuria. Her serum potassium concentration, however, appears “normal” because acidosis has shifted potassium from intracellular storage sites into the circulating plasma volume. When her acidosis and hyperglycemia are treated, potassium ions will return intracellularly. If supplemental potassium is not provided, the serum potassium concentration will decrease dramatically. As a very general guideline, for every 0.1 decrease in pH from 7.4, the serum potassium concentration will be falsely elevated by about 0.6 mEq/L. Understanding J.S.'s pH is 7.1, her serum potassium concentration (4.1 mEq/L) will actually be closer to 2.3 mEq/L (i.e., 0.6 mEq/L \times three 0.1 units = 1.8 mEq/L) when the acidosis is corrected.

Carbon Dioxide Content

Normal: 22–28 mEq/L or mmol/L

The CO₂ content in the serum represents the sum of the bicarbonate concentration (HCO₃) and the concentration of dissolved CO₂ in the serum. The dissolved CO₂ represents a relatively small component of total CO₂ content, making CO₂ essentially a measure of the bicarbonate concentration in serum. Chloride and bicarbonate are the primary negatively charged anions that offset the positively charged cations (i.e., sodium, potassium).

Although several buffer systems (e.g., hemoglobin [Hgb], phosphate, protein) participate in regulating pH within physiological limits, the carbonic acid–bicarbonate system is the most important. From a clinical standpoint, most disturbances of acid–base balance result from imbalances of the carbonic acid–bicarbonate system. The importance of bicarbonate in maintaining physiological pH is presented in Chapter 10.

Chloride

Normal: 95–105 mEq/L or mmol/L

Chloride is the principal inorganic anion of the ECF; changes in chloride concentration are usually related to sodium concentration in an effort to maintain a neutral charge. The serum chloride concentration per se has no real diagnostic significance. In fact, the only real reason for measuring the serum chloride is to validate the serum sodium concentration. The relationship between serum concentrations of sodium, bicarbonate, and chloride is described by Equation 2-1, where *R* represents the anion gap:

As with bicarbonate, chloride contributes to maintaining acid–base balance. A decreased serum chloride concentration often accompanies metabolic alkalosis, whereas an increased serum chloride concentration may be indicative of a hyperchloremic metabolic acidosis. The serum chloride concentration, however, can also be slightly decreased in acidosis

if organic acids or other acids are the primary cause of the acidosis. *Hyperchloremia*, in the absence of metabolic acidosis, is seldom encountered because chloride retention is usually accompanied by sodium and water retention. *Hypochloremia* can result from excessive GI loss of chloride-rich fluid (e.g., vomiting, diarrhea, gastric suctioning, intestinal fistulas). Because chloride ions are renally excreted with cations, hypochloremia may also result from significant diuresis.

Anion Gap

The *R* factor, or anion gap (AG), represents the contribution of unmeasured acids, such as lactate, phosphates, sulfates, and proteins. As displayed in Equation 2-1, a patient's anion gap is determined by subtracting the primary anions (Cl and HCO₃) from the primary cation (Na). Some clinicians include potassium in this determination and subtract the anions from both major cations (Na and K). A normal anion gap is typically <12 mEq/mL if potassium is not incorporated in the calculation or <16 mEq/mL if potassium is considered.

An elevated anion gap may be indicative of a metabolic acidosis caused by an increase in lactic acids, ketoacids, salicylic acids, methanol, or ethylene glycol. A low anion gap may be the result of reduced concentrations of unmeasured anions (e.g., hypoalbuminemia) or from systematic underestimation of serum sodium (e.g., hyperviscosity of myeloma). Again, see Chapter 10 for a more detailed discussion of the clinical use of the anion gap.

Blood Urea Nitrogen

Normal: 8–18 mg/dL or 2.8–6.4 mmol/L

Urea nitrogen is an end product of protein metabolism. It is produced solely by the liver, is transported in the blood, and is excreted by the kidneys. The serum concentration of urea nitrogen (i.e., BUN) is reflective of renal function because the urea nitrogen in blood is filtered completely at the glomerulus of the kidney, and then reabsorbed and tubularly secreted within nephrons. Acute or chronic renal failure is the most common cause of an elevated BUN. Although the BUN is an excellent screening test for renal dysfunction, it does not sufficiently quantify the extent of renal disease. In addition, several nonrenal factors such as unusually high protein intake and conditions that increase protein catabolism (or upper GI bleeding) can increase the BUN concentration. A patient's hydration status will also influence BUN; a water deficit tends to concentrate the urea nitrogen, and a water excess dilutes the urea nitrogen. The ratio of BUN to SCr can also be of clinical use. A normal ratio is roughly 15:1. Ratios >20:1 are observed in patients with decreased blood flow to the kidney (e.g., prerenal disease such as dehydration or conditions involving reduced cardiac output) or conditions involving increased protein in the blood (e.g., dietary intake or an upper GI bleed). Situations where the BUN:SCr ratio is <15:1 are seen in patients with renal failure, significant malnourishment (decreased intake of protein), or severe liver disease where the liver is no longer able to form urea.

3. Why is the BUN abnormal for M.C. (from question 1)?

The BUN serum concentration in M.C. is somewhat increased, perhaps because of inadequate renal perfusion secondary to her heart failure. Her renal function could also be

more severely compromised than one would anticipate from her slightly increased BUN value because of dilution by increased ECF volume. Therefore, M.C.'s renal status should be further evaluated.

Creatinine

Normal: 0.6–1.2 mg/dL or 50–110 μmol/L

Creatinine is derived from creatine and phosphocreatine, major constituents of muscle. Its rate of formation for a given individual is remarkably constant and is determined primarily by an individual's muscle mass or lean body weight. Therefore, the SCr concentration is slightly higher in muscular subjects, but unlike the BUN, it is less directly affected by exogenous factors or liver impairment. Once creatinine is released from muscle into plasma, it is excreted renally almost exclusively by glomerular filtration. A decrease in the glomerular filtration rate (GFR) results in an increase in the SCr concentration. Thus, careful interpretation of the SCr concentration is used widely in the clinical evaluation of patients with suspected renal disease.

A doubling of the SCr level roughly corresponds to a 50% reduction in the GFR. This general rule of thumb only holds true for steady-state creatinine levels.⁵

4. M.C. was given digoxin 0.125 mg/day, and a SCr was ordered to further assess her renal function. The clinical laboratory determined her SCr was 1.2 mg/dL. Although this laboratory test result is within normal limits, why does it not clearly indicate normal renal function for M.C.?

[SI unit: SCr, 106 μmol/L]

A SCr of 1.2 mg/dL in M.C. does not necessarily reflect normal renal function. As patients become older, muscle mass represents a smaller proportion of total weight, and creatinine production is decreased. Furthermore, the SCr concentration in female patients is generally 0.2 to 0.4 mg/dL (85%–90%) less than for males because females have relatively smaller kidneys. Because M.C. is a 61-year-old woman, a creatinine clearance (CrCl) determination would more accurately reflect her renal function status.

Creatinine Clearance

Normal: 75–125 mL/minute or 1.25–2.08 mL/second

Because creatinine is cleared almost exclusively through the glomerulus in the kidney, CrCl can be used as a clinically useful measure of a patient's GFR. CrCl serves as a valuable clinical parameter because many renally eliminated drugs are dose adjusted based on the patient's renal function. To determine actual CrCl, the patient's urine is collected over a 24-hour period, and the concentration of urine creatinine (mg/dL), total volume of urine collected over the 24-hour period (mL/minute), and SCr (mg/dL) are determined. The patient-specific, measured CrCl is determined using Equation 2-2:

$$\text{Measured 24 hr CrCl}_{(\text{mL}/\text{min})} = \frac{[\text{Urine conc}_{(\text{mg}/\text{dL})}] \times [\text{Total urine volume}_{(\text{mL}/\text{min})}]}{\text{SCr}_{(\text{mg}/\text{dL})}}$$

2-2

Unfortunately, urine collections are time consuming and expensive, and incomplete collections can substantially underestimate renal function. In lieu of measuring actual CrCl,

simplistic equations are commonly used to estimate a patient's CrCl. The following Cockcroft-Gault⁷ formula incorporates age, body weight, and SCr. Typically, clinicians use ideal body weight (IBW) in the calculation of estimated CrCl; however, actual body weight (ABW) may be used when ABW is less than IBW. Equation 2-3 has the highest correlation and the greatest accuracy in patients with SCr concentrations <1.5 mg/dL⁸:

$$\text{Estimated CrCl for males (mL/min)} = \frac{(140 - \text{Age}) (\text{Body weight in kg})}{(72) (\text{SCr}_{(\text{mg/dL})})} \quad 2-3$$

The Cockcroft-Gault formula must be multiplied by 85% to calculate CrCl for females. Another commonly used approach to estimating CrCl is the Jelliffe method,⁹ shown in Equation 2-4:

$$\text{Estimated CrCl for Males (mL/min/1.73 m}^2) = \frac{98 - [(0.8) (\text{Age} - 20)]}{\text{SCr}_{(\text{mg/dL})}} \quad 2-4$$

This Jelliffe formula must be multiplied by 90% to calculate CrCl for females. The use of this method substantially underestimates CrCl for patients with SCr values <1.5 mg/dL,¹⁰ whereas Cockcroft-Gault appears to have the highest correlation and greatest accuracy in patients with SCr values <1.5 mg/dL.⁸ For patients with liver dysfunction, all methods of calculating CrCl from a SCr value are associated with significant overpredictions of CrCl.¹⁰ Thus, methods for predicting CrCl should be used cautiously when attempting to adjust drug dosages in patients with liver disease.

5. A 24-hour CrCl determination was ordered for E.S., a 63-year-old, 60-kg man. The following data were returned from the clinical laboratory: total collection time was 24 hours; total urine volume, 1,000 mL; urine creatinine concentration, 42 mg/dL; and SCr, 1.7 mg/dL. Determine both the measured and the estimated CrCl for E.S. based on the given data, and compare and contrast these results.

[SI units: SCr, 150 $\mu\text{mol/L}$]

Using Equation 2-2, E.S. has a 24-hour measured CrCl of approximately 17 mL/minute. His estimated CrCl is 38 mL/minute using the Cockcroft-Gault method (Equation 2-3). Based on both methods, E.S.'s ability to clear renally eliminated drugs is impaired. An incomplete collection of urine over the 24-hour period or possible mishandling of the specimen can be possible explanations for the lower value seen with the measured CrCl. Because E.S. had an elevated SCr of 1.7 mg/dL, the accuracy of the Cockcroft-Gault estimation might also be compromised.

Glucose

Normal: 70–110 mg/dL or 3.9–6.1 mmol/L

The fasting glucose concentration in the ECF is regulated closely by homeostatic mechanisms to provide body tissues with a ready source of energy. Insulin and glucagon play a critical role in this complex process. Because plasma glucose concentrations fluctuate in response to ingestion of meals, most glucose concentrations are measured in either the fasting state or the postprandial state, depending on the type of information desired. Generally, normal glucose values refer to the plasma glucose concentration in the fasting state. The specific labora-

tory assay of blood sugar determinations must also be considered because different assay methods vary in their specificity and sensitivity to glucose. Glucose testing using whole blood from capillary finger sticks is used in conjunction with blood glucose metering devices for patients with diabetes. Whole blood measurements using these devices are typically 15% lower than corresponding plasma glucose levels.

Glycosylated Hemoglobin

Hgb is the oxygen-carrying component of the red blood cell (RBC). Over the functional life span of RBCs (~4 months), glucose molecules irreversibly bind to Hgb which results in glycosylated Hgb (A1c). The concentration of Hgb A1c, therefore, reflects a patient's average blood glucose concentration over the life span of circulating RBCs. In contrast, fasting glucose serum concentrations can fluctuate acutely based on either meals or insulin use. As a result, measurement of Hgb A1c concentrations provides a much better tool for evaluating chronic diabetes therapy. In a patient without diabetes, about 5% of Hgb is glycosylated; however, poorly controlled patients with diabetes can have A1c values greatly exceeding 8%. In one study of patients with elevated A1c values, every 1% reduction in the elevated A1c reduced the risk of microvascular complications by 37% and reduced the risk of acute myocardial infection by 14%.¹¹ The interpretation of serum concentrations of plasma glucose, Hgb A1c, and other related laboratory tests is presented in Chapter 50.

Hyperglycemia and Hypoglycemia

Hyperglycemia and hypoglycemia are nonspecific signs of abnormal glucose metabolism. Diabetes mellitus is the most common cause of hyperglycemia. Insufficient carbohydrate intake because of a missed meal is the most common cause of hypoglycemia in a patient receiving insulin or another hypoglycemic medication.

6. T.C., a 68-year-old male, visits his endocrinologist to assess control of his type 2 diabetes. His average blood sugar over the past 90 days recorded via his blood glucose monitor is 217 mg/dL. However, T.C.'s Hgb A1c was 9%, which correlates with an average glucose concentration of roughly 240 mg/dL. T.C. is confused that these values are different because he routinely ensures his blood glucose machine is calibrated and coded properly. Why is the laboratory average different?

[SI units: glucose, 13.5 mmol/L]

T.C. should not be alarmed with the difference in these values. His blood glucose monitor is probably working properly and adequately measuring fluctuations in his plasma glucose concentrations. However, the monitor may be reflecting a lower average glucose concentration due to the timing of his daily testing for glucose. For example, measuring blood glucose in a fasting state more frequently than after mealtime could contribute to lower average concentrations because fasting values are typically lower than postprandial concentrations. The A1c is more indicative of his average blood sugar control over the past 90 days than the 90-day average recorded by his blood glucose monitor. A higher concentration of glucose in the blood positively correlates to a higher glycosylated Hgb. This value is typically reported as a percentage, with approximately 5% (100 mg/dL) considered as normal in a person without diabetes. As the A1c percentage increases, each point raises the

corresponding blood glucose value by about 35 mg/dL (e.g., 8% = 205 mg/dL, 9% = 240 mg/dL).

Osmolality

Normal: 280–300 mOsm/kg or mmol/kg

The osmolality of a solution is a measure of the number of osmotically active ions (i.e., particles present) per unit of solution. It is the total number of particles in the solution, not the weight of the particle or the nature of the particle that determines osmolality. Because one mole of a substance contains 6×10^{23} molecules, equimolar concentrations of all substances in the undissociated state exert the same osmotic pressure. A mole of an ionized compound such as NaCl contributes twice as many particles in solution as one mole of an undissociated compound such as glucose. In most situations, the primary determinants of serum osmolality in the ECF are sodium (and its accompanying anions), glucose, and BUN. If one corrects for the concentrations of glucose and BUN, the serum concentration of sodium closely mirrors the serum osmolality.

A simplified formula (Equation 2-5) useful for rule-of-thumb calculations is as follows:

$$\text{Osmolality}^* = 2[\text{Na}^+] + \frac{[\text{Glucose}]}{20} + \frac{[\text{BUN}]}{3} \quad 2-5$$

*Osmolality is measured in mOsm/kg H₂O

Serum osmolality is useful when evaluating fluid and electrolyte disorders, particularly sodium imbalances. An increase in the measured serum osmolality, relative to the calculated osmolality, can be attributed to an increase in the number of solutes, a reduction in the amount of free water (e.g., patients with significant dehydration), or perhaps laboratory error. The difference between the measured serum osmolality and the calculated serum osmolality is commonly referred to as the “osmol gap” (see Chapter 11).

MULTICHEMISTRY PANELS

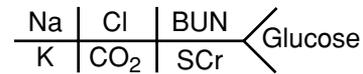

SMA-7, SMA-12, Chem Profile-20

7. What are the advantages and disadvantages of biochemical profiles such as the SMA-7, SMA-12, and Chem Profile-20 ordered for M.C. (from question 1)?

The SMA-7, SMA-12, and Chem Profile-20 are compilations of 7, 12, or 20 biochemical tests that analyze blood chemistries on large-volume, automated instruments. The abbreviation SMA refers to “sequential multiple analyzer.” Such tests are routinely obtained because they quickly provide basic information concerning organ function at relatively low cost. If abnormal values are noted, additional tests can be ordered to further investigate specific organ function. Nevertheless, routine use of biochemical profiles is controversial. When biochemical profiles are ordered without regard for the clinical evidence in an individual patient (i.e., routine testing is done on all patients on admission to a hospital), there is no evidence that these tests have improved patient care, lessened hospital costs, or shortened lengths of stay.

The SMA-7 panel typically analyzes a patient’s sodium, potassium, chloride, CO₂, BUN, SCr, and glucose concentrations. This particular blood chemistry panel provides rapid insight to a patient’s serum electrolytes, acid–base status, renal

function, and metabolic state. An abbreviated method to report the SMA-7 used commonly by clinicians is shown in the following figure.

If an SMA-12 is ordered instead of the SMA-7 panel, the additional tests usually include serum concentrations of albumin, total protein, bilirubin, alkaline phosphatase, and calcium. A Chem Profile-20 provides eight more tests, such as phosphorus, cholesterol, triglycerides, uric acid, iron, lactic dehydrogenase (LDH), aspartate aminotransferase (AST), and alanine aminotransferase (ALT). These eight tests provide additional information for a general evaluation of metabolism, cardiovascular risk factors, and liver function, not provided by the SMA-7 or SMA-12 profiles. The cost of a Chem Profile-20 is seldom much greater than that of an SMA-7 or SMA-12 because of the automated nature of these tests. The particular grouping of tests included in various chemistry panels may vary with different clinical laboratories.

Calcium

Normal: 8.8 to 10.2 mg/dL or 2.20 to 2.55 mmol/L

The total calcium content resides primarily in the bone, with only about 1% freely exchangeable with that in the ECF. This reservoir of calcium in bones maintains the concentration of calcium in the plasma constant despite pronounced changes in the external balance of calcium. If the homeostatic factors (i.e., parathyroid hormone, vitamin D, calcitonin) that regulate the calcium content of body fluid are intact, a patient can lose 25% to 30% of total body calcium without a change in the concentration of calcium ion in the plasma.

About 40% of the calcium in the ECF is bound to plasma proteins (especially albumin); 5% to 15% is complexed with phosphate and citrate; and about 45% to 55% is in the unbound, ionized form. Most laboratories measure the total calcium concentration, although it is the free, ionized calcium concentration that is important physiologically, and the form that is closely regulated physiologically. Most laboratories are also able to measure the ionized form of calcium (4.5–5.6 mg/dL or 1.13–1.4 mmol/L).

A reduced calcium concentration usually implies a deficiency in either the production or the response to parathyroid hormone or vitamin D. The abnormality in the parathyroid hormone system might result from hypomagnesemia, hypoparathyroidism, or pseudohypoparathyroidism. The abnormality in the vitamin D system can be caused by decreased nutritional intake; decreased absorption of vitamin D secondary to gastrectomy, chronic pancreatitis, or small bowel disease; decreased production of 25-hydroxycholecalciferol due to liver disease; increased metabolism of 25-hydroxycholecalciferol because of enzyme-stimulating drugs (e.g., phenobarbital, phenytoin, rifampin); or decreased production of 1,25-dihydroxycholecalciferol due to chronic renal disease. Patients with low concentrations of magnesium also typically have low serum concentrations of calcium, and hypomagnesemia must be corrected before the calcium concentration can be adequately addressed.

Elevated calcium concentrations are commonly associated with malignancy or metastatic diseases. Other causes of hypercalcemia include hyperparathyroidism, Paget disease, milk-alkali syndrome, granulomatous disorders, thiazide diuretics, and vitamin D intoxication.

8. V.C. is a 38-year-old man hospitalized because of obtundation, somnolence, and severe alcohol intoxication. He has NKDA, and his laboratory tests revealed the following: albumin, 2.0 g/dL (normal, 4–6); Ca, 6.8 mg/dL (normal, 8.8–10.2); total bilirubin, 10.8 mg/dL (normal, 0.1–1.0); serum AST, 280 units/L (normal, 0–35); and alkaline phosphatase, 240 units/L (normal, 30–120). Why is calcium treatment inappropriate despite V.C.'s apparent low serum concentration of calcium?

[SI units: albumin, 20 g/L; Ca, 1.7 mmol/L; total bilirubin, 184.6 μ mol/L; AST, 4.67 μ kat/L; alkaline phosphatase, 4 μ kat/L]

This case presentation provides insufficient patient data to make a conclusion concerning treatment. However, it does illustrate the importance of treating the patient as a whole, not as a specific laboratory value. Because calcium in the serum is partially bound to plasma proteins (mostly albumin), the serum calcium concentration is affected by the concentration of these plasma proteins. If the albumin concentration is low, the reported serum calcium will generally be less than the lower limit of normal. A useful method to estimate a corrected value for serum calcium in the presence of a low serum albumin is to use the following guideline: the total serum calcium will decrease by 0.8 mg/dL for each decrease of 1.0 g/dL in serum albumin concentration. V.C.'s serum albumin concentration is about 3.0 mg/dL less than "normal" (i.e., 5.0 mg/dL – 2.0 mg/dL = 3.0 mg/dL). Therefore, his correct serum calcium would be approximately 9.2 mg/dL (i.e., [3.0 mg/dL of albumin \times 0.8] added to his reported serum calcium of 6.8 mg/dL). The "corrected" serum calcium concentration falls within the normal range, and V.C. should not be treated with calcium based on the available data. Direct measurement of ionized calcium is independent of albumin concentration, making it unnecessary to correct calcium concentrations in the presence of hypoalbuminemia. Unfortunately, some clinical laboratories do not have the capability of measuring ionized calcium.

Magnesium

Normal: 1.6–2.4 mEq/L or 0.8–1.2 mmol/L

Magnesium is primarily an intracellular electrolyte that, together with potassium and calcium, helps maintain a neutral charge within the cell. Magnesium also serves an important metabolic role in the phosphorylation of adenosine triphosphate (ATP).

A primary cause of *hypomagnesemia* is malnourishment. Toxemia in pregnancy is associated with hypomagnesemia. Hypomagnesemia needs to be corrected before attempting to correct hypokalemia or hypocalcemia. Attempts to replace potassium or calcium in patients with hypomagnesemia will be ineffective until the low magnesium concentrations are adequately addressed. Excessive ingestion of magnesium-containing antacids can lead to *hypermagnesemia*. Increased concentrations of magnesium are also observed in patients with reduced renal function. Hypermagnesemia can slow conduction in the heart, prolong PT intervals, and widen the QRS complex.

Phosphate

Normal: 2.5 to 5.0 mg/dL or 0.80 to 1.60 mmol/L

The extracellular concentration of phosphate as inorganic phosphorus is the prime determinant of the intracellular concentration, which in turn is the source of phosphate for ATP and phospholipid synthesis. Intracellular phosphate is also important in the regulation of nucleotide degradation.

The ECF concentration of phosphate is influenced by parathyroid hormone, intestinal phosphate absorption, renal function, bone metabolism, and nutrition. Moderate *hypophosphatemia* is encountered by malnourished patients (especially when anabolism is induced), patients who excessively use antacids (aluminum-containing antacids bind phosphorus in the GI tract), chronic alcoholics, and septic patients. Clinical consequences of severe hypophosphatemia involve nervous system dysfunction, muscle weakness, rhabdomyolysis, cardiac irregularities, and dysfunction of leukocytes and erythrocytes. *Hyperphosphatemia* is most commonly caused by renal insufficiency, although increased vitamin D, hypoparathyroidism, and advanced malignancies are also significant causes.

Uric Acid

Normal: 2.0 to 7.0 mg/dL or 0.12 to 0.42 mmol/L

Uric acid is an end product of purine metabolism. It serves no biological function, is not metabolized, and must be excreted renally. Gout is usually associated with increased serum concentrations of uric acid and deposits of monosodium urate.

Increased serum uric acid concentrations can result from either a decrease in urate excretion (e.g., renal dysfunction) or excessive urate production (e.g., increased purine metabolism resulting from cytotoxic therapy of neoplastic or myeloproliferative disorders). Low serum uric acid concentrations are inconsequential and are usually reflective of drugs that have hypouricemic activity (e.g., high dosages of salicylates). The determinants of the serum concentration of uric acid, the clinical implications of hyperuricemia, and the therapeutic management of uric acid disorders are presented in Chapter 42.

PROTEINS

Prealbumin

Normal: 15 to 36 mg/dL or 150 to 360 mg/L

Prealbumin is one of the primary proteins in circulation, but it accounts for a relatively small percentage of the circulating proteins. It is also referred to as "thyroxine-binding prealbumin (TBPA)" due to its role as a transport mechanism for triiodothyronine (T₃) and thyroxine (T₄). However, prealbumin is most frequently used to monitor patients at risk for poor nutrition (e.g., patients with eating disorders, HIV, or patients receiving total parenteral nutrition). Compared to the relatively long half-life of albumin (about 3 weeks), the half-life of prealbumin is only 1 to 2 days. This shorter half-life provides a more accurate reflection of acute changes in protein synthesis and catabolism. Prealbumin, therefore, is an effective and useful marker of immediate nutritional status. Hepatic disease and malnutrition are associated with decreases in both albumin and prealbumin. Hodgkin disease, pregnancy, chronic renal disease, and corticosteroid use can increase prealbumin serum concentrations.

Albumin

Normal: 4 to 6 g/dL or 40 to 60 g/L

Albumin, produced by the liver, contributes approximately 80% of serum colloid osmotic pressure. As a result, hypoalbuminemic states are commonly associated with edema and transudation of ECF. A lack of essential amino acids from malnutrition or malabsorption, or impaired albumin synthesis by the liver, can result in decreased serum albumin concentrations. Most forms of hepatic insufficiency are associated with decreased synthesis of albumin. Albumin can be lost directly from the blood because of hemorrhage, burns, or exudates, or it may be lost directly into the urine because of nephrosis. Serum albumin concentrations seldom increase, but increases may be noted in volume depletion or shock, or immediately after the administration of large amounts of intravenous albumin. In addition to its diagnostic value, the serum albumin concentration is an important consideration in the therapeutic monitoring of drugs and electrolytes that are highly protein bound (e.g., phenytoin, digoxin, calcium). In cases of severe hypoalbuminemia, determination of the “free” or unbound concentration of these entities might be necessary for an accurate assessment of drug therapy.

Globulin

Normal: 2.3 to 3.5 g/dL or 23 to 35 g/L

In addition to albumin, globulin is another primary plasma protein. Whereas albumin principally functions to maintain serum oncotic pressure, globulins play an active role in immunologic processes. The globulins can be separated into several subgroups such as α , β , and γ . The γ -globulins can be separated further into various immunoglobulins (e.g., IgA, IgM, IgG). Chronic infection or rheumatoid arthritis can increase immunoglobulin levels, and fractionation of immunoglobulins can provide useful information in the evaluation of immune disorders. When immunoglobulins are separated by electrophoresis, elevations of one or several in a specific pattern can suggest a diagnosis of multiple myeloma, a plasma cell malignancy. Because globulin is not manufactured solely by the liver, the ratio of albumin to globulin (the A/G ratio) is changed in patients with liver disease. Changes in this ratio result from decreased albumin concentration and a compensatory increase in globulin concentration.

ENZYMES

Enzyme activity is typically expressed in terms of international units (IU), where one IU is the enzyme amount needed to catalyze the conversion of 1 μ mol of substrate per minute. The analogous expression in SI terms involves the term katal (kat). One katal is the amount of enzyme to catalyze 1 mol of substrate per second, making 1.0 μ kat the amount for 1.0 μ mol/second. Based on this information, the conversion between μ kat and IU is 1 μ kat = 60 IU.

Creatine Kinase

Normal: 0 to 150 units/L or 0 to 2.5 μ kat/L

The CK enzyme, formerly known as creatine phosphokinase, catalyzes the transfer of high-energy phosphate groups in tissues that consume large amounts of energy (e.g., skeletal

muscle, myocardium, brain). The serum concentration of CK can be increased by strenuous exercise, intramuscular injections of drugs that are irritating to tissue (e.g., diazepam, phenytoin), acute psychotic episodes, crush injuries, or myocardial damage.

CK is composed of M and B subunits, which are further divided into three isoenzymes: MM, BB, and MB. The CK-MM isoenzyme is found predominantly in skeletal muscle, the CK-BB in the brain, and the CK-MB in the myocardium. Myocardial CK activity consists of 80% to 85% CK-MM and 15% to 20% CK-MB. Noncardiac tissues that contain large amounts of CK have either CK-MM or CK-BB. The MB fraction is rare in tissues other than the myocardium.

CK-MB typically begins to increase 3 to 6 hours after an acute myocardial infarction (MI), peaks at 12 to 24 hours, and accounts for about 5% or more of the total CK.¹² Myocardial damage appears to correlate with the amount of CK-MB released into the serum (i.e., the higher the amount of CK-MB, the more extensive the myocardial injury). Although CK-MB levels >25 units/L are usually associated with an MI,¹³ the absolute amount can vary, depending on the assay method. Generally, if the amount of CK-MB exceeds 6% of the total, myocardial injury has presumably occurred. Analysis of CK-MB provides a rapid, sensitive, specific, cost-effective, and definitive means of detecting MI.¹⁴

9. S.G., a 44-year-old woman, appears at the emergency department of a local hospital, with complaints of sudden-onset chest pain, diaphoresis, and nausea that began about 1 hour ago. S.G. describes her pain as severe and not relieved by position change, antacids, or nitroglycerin. An electrocardiogram (ECG) reveals changes consistent with an acute MI. The total CK serum concentration is 118 units/L (normal, <150) and the CK-MB is 5 units/L (normal, <12). S.G. was admitted to the coronary care unit to rule out an acute MI. Why are the total CK and CK-MB serum concentrations within the normal range in S.G., despite clear evidence supporting an acute MI?

[SI units: CK, 1.97 μ kat/L; CK-MB, 0.08 μ kat/L]

The total CK and CK-MB are both within the normal range for S.G.; however, an MI cannot be excluded. CK serum concentrations usually do not rise above normal values until 4 to 8 hours after myocardial injury and usually peak in about 12 to 24 hours. About 10% of patients with suspected MIs fail to demonstrate an increase in the total CK, although serial CK-MB fractions will be increased. When CK-MB is >6% of total CK, an MI has probably occurred even if the total CK is not elevated.¹²

Troponin

Normal: 0 to 0.03 ng/mL or 0 to 0.03 mcg/L

10. How can myocardial enzymes be detected earlier than 4 to 8 hours after myocardial injury?

Troponins are proteins that mediate the calcium-mediated interaction of actin and myosin within muscles. There are two cardiac-specific troponins, cardiac troponin I (cTnI) and cardiac troponin T (cTnT). Whereas cTnT is present in cardiac and skeletal muscle cells, cTnI is present only in cardiac muscle.^{15,16} Compared with the detection of CK-MB, the presence of troponin I is a more specific and sensitive indicator of

myocardial damage.¹⁷ Furthermore, the concentration of cTnI increases within 2 to 4 hours of an acute MI, enabling clinicians to quickly initiate appropriate therapy. Troponin also remains elevated for about 10 days compared to the 2- to 3-day elevation typically observed with CK-MB. cTnI levels >2.0 ng/mL are suggestive of acute myocardial tissue injury. The use of troponin as a primary diagnostic test for acute MI is becoming widely accepted as a standard.¹⁷ (See Chapter 17.)

Myoglobin

Normal: 0 to 90 mcg/L

Myoglobin, a protein in heart and skeletal muscle cells, provides oxygen to working muscles. When muscle is damaged, myoglobin is released into the bloodstream. As a cardiac biomarker, myoglobin concentrations in serum rise within 3 hours after insult to the myocardial tissue, peak in about 8 to 12 hours, and return to normal in about a day. Because myoglobin serum concentrations rise more quickly than CK-MB after myocardial injury, it can be of value in helping rule out MI in the emergency department. Myoglobin serum concentrations, however, tend to be less specific for myocardial tissue compared to CK-MB. Trauma or ischemic injury to noncardiac tissue can increase serum myoglobin. Because troponin serum concentrations in serum also increase rapidly after myocardial damage, troponin is often preferred over myoglobin as a biomarker of cardiac damage.

Homocysteine

Normal: 4 to 15 $\mu\text{mol/L}$

Patients with deficiencies in folate, vitamin B₆, or vitamin B₁₂ tend to have elevated serum levels of homocysteine. Homocysteine is believed to have a destructive affect on vascular epithelium. Over time, patients with elevated homocysteine levels (>12 $\mu\text{mol/L}$) are believed to be at increased risk for cardiac disease.¹⁸ Screening individuals with a positive family history for elevated homocysteine or those with atherosclerosis without typical risk factors or increased lipids has been advocated. Understanding the association between increased homocysteine levels and specific vitamin deficiencies, supplementation of folate, B₆ and B₁₂ has been used clinically. However, data are too limited to suggest this approach reduces the incidence of acute MI or stroke.

Lactate Dehydrogenase

Normal: 100 to 190 units/L or 1.67 to 3.17 $\mu\text{kat/L}$

The enzyme, lactate dehydrogenase (LDH), is present in the heart, kidney, liver, and skeletal muscle. It is also abundantly present in erythrocytes and lung tissue. Because increased serum concentrations of LDH can be associated with diseases in many different organs and tissues, the diagnostic usefulness of an LDH determination is somewhat limited. There are, however, five isoenzymes of LDH. Although most tissues contain all five isoenzymes, some tissues have a predominance of one of the isoenzymes. LDH₁ and, to a lesser extent, LDH₂ predominate in the heart. Skeletal muscle and the liver have a predominance of LDH₅. LDH₃ and LDH₄ are found in a variety of tissues, including the lungs, RBCs, kidneys, brain, and pancreas. Consequently, identifying specific

isoenzymes can increase the diagnostic usefulness of serum LDH determinations. For example, the elevated serum LDH associated with MI consists mostly of LDH₁ and LDH₂, whereas with acute liver disease there is a greater proportion of LDH₄ and LDH₅. Unfortunately, these isoenzyme patterns are not necessarily typical of all myocardial or liver diseases. With the availability of other myocardial enzymes, LDH as a diagnostic tool is used less frequently.

Brain Natriuretic Peptide

Normal: 0 to 100 pg/mL or 0 to 100 ng/L

Brain natriuretic peptide (BNP) is released from the heart when increased demands are placed on the myocardial tissue. Elevations in BNP are indicative of patients with congestive heart failure (CHF). In an effort to reduce workload on the heart, BNP counteracts the renin-angiotensin-aldosterone system and causes vasodilatory effects, along with natriuresis (increased excretion of sodium), all geared at reducing blood volume. Patients with some degree of CHF typically have BNP levels >100 ng/L. BNP levels >500 ng/L represent definite left ventricular dysfunction, and further evaluation is warranted to more fully characterize the extent of impaired cardiac function.¹⁹ The beneficial aspects of endogenous BNP have prompted marketing the recombinant BNP product, nesiritide (Natreacor). Nesiritide is approved for the treatment of acute decompensated heart failure in patients with dyspnea at rest.²⁰

C-Reactive Protein

Normal: 0 to 1.0 mg/dL or 0 to 10 mg/L

C-reactive protein (CRP) is a nonspecific, acute-phase reactant that is helpful in the diagnosis and monitoring of inflammatory processes (e.g., rheumatoid arthritis) and infections. CRP is produced by the liver in response to an inflammatory process. Although an elevation in CRP indicates the presence of an acute inflammatory event, the nonspecific nature of the test does little to identify the cause or location of the inflammation. CRP is similar to an older test, erythrocyte sedimentation rate (ESR), but it tends to be more sensitive than ESR and is also associated with a more rapid and greater response to acute inflammation. A potential use of CRP is in the diagnosis of acute MI and as a risk factor for cardiovascular disease. Patients with CRP levels <1.0 mg/dL are considered to be at low risk, whereas patients with CRP levels >3.0 mg/dL are at increased risk for cardiovascular disease.²¹ Because viral infections do not typically increase in CRP serum concentrations, the use of CRP as a diagnostic tool to differentiate viral versus bacterial meningitis might be clinically helpful. For example, a CRP value within the normal range could help exclude a diagnosis of bacterial meningitis.

LIVER FUNCTION TESTS

Aspartate Aminotransferase

Normal: 0 to 35 units/L or 0 to 0.58 $\mu\text{kat/L}$

The AST enzyme, formerly called “serum glutamic oxaloacetic transaminase,” is abundant in heart and liver tissue and moderately present in skeletal muscle, the kidney, and the pancreas. In cases of acute cellular injury to the heart or liver,

the enzyme is released into the blood from the damaged cells. In clinical practice, AST determinations have been used to evaluate myocardial injury and to diagnose and assess the prognosis of liver disease resulting from hepatocellular injury. The serum AST level is increased in more than 95% of patients after an MI. However, the increase in AST does not occur until 4 to 6 hours after the onset of myocardial injury. Peak AST concentrations are seen in the serum after 24 to 36 hours, returning to the normal range in about 4 to 5 days. The magnitude of the peak AST levels approximate the extent of myocardial damage (see Chapter 17).

Serum AST values are elevated significantly in patients with acute hepatic necrosis, whether caused by viral hepatitis or a hepatotoxin (e.g., carbon tetrachloride). In these situations, the serum concentrations of both AST and ALT will be increased, even before the appearance of clinical symptoms (e.g., jaundice). The AST and ALT serum concentrations can be increased by as much as 100 times greater than the usual upper limits of normal in the presence of parenchymal liver disease. Patients with intrahepatic cholestasis, posthepatic jaundice, or cirrhosis usually experience more moderate elevations of AST, depending on the extent of cell necrosis. The AST serum concentration is usually higher than that of ALT in patients with cirrhosis, and the AST increase is usually about four to five times greater than the upper limit of normal.

Alanine Aminotransferase

Normal: 0 to 35 units/L or 0 to 0.58 $\mu\text{kat/L}$

The ALT enzyme, formerly called “serum glutamic pyruvic transaminase,” is found in essentially the same tissues that have high concentrations of AST. However, elevations in serum ALT are more specific for liver-related injuries or diseases. Although ALT is relatively more abundant in hepatic tissue versus cardiac tissue than AST, the liver still contains 3.5 times more AST than ALT. Serum concentrations of both AST and ALT increase when disease processes affect liver cell structure, but ALT concentrations are not significantly increased as a result of an acute MI. Evaluating the ratio of ALT to AST can be potentially useful, particularly in the diagnosis of viral hepatitis. The ALT/AST ratio frequently exceeds 1.0 with alcoholic cirrhosis, chronic liver disease, or hepatic cancer. However, ratios <1.0 tend to be observed with viral hepatitis or acute hepatitis, which can be useful when diagnosing liver disease.

Alkaline Phosphatase

Normal: 30 to 120 units/L or 0.5 to 2.0 $\mu\text{kat/L}$

The alkaline phosphatases (ALPs) constitute a large group of isoenzymes that play important roles in the transport of sugar and phosphate. These isoenzymes of ALP have different physiochemical properties and originate from different tissues (e.g., liver, bone, placenta, intestine). In normal adults, ALP is derived primarily from liver and bone. Although only small amounts of ALP are present in the liver, this enzyme is secreted into the bile, and substantially elevated ALP serum concentrations can be seen with mild intrahepatic or extrahepatic biliary obstruction. Thus, the presence of early bile duct abnormalities can result in elevated ALP before increases in the serum bilirubin are observed. Drug-induced cholestatic jaundice (e.g., chlorpromazine or sulfonamides) can increase

serum ALP concentrations. In mild cases of acute liver cell damage, ALP levels are seldom elevated. Even in cirrhosis, ALP concentrations are variable and depend on the degree of hepatic decompensation and obstruction. Serum ALP concentrations are an excellent indicator of space-occupying lesions in the liver, primarily due to disruption of biliary canaliculi within the liver.²²

The osteoblasts in bone produce large amounts of ALP, and marked serum elevations can be seen in Paget disease, hyperparathyroidism, osteogenic sarcoma, osteoblastic cancer metastatic to bone, and other conditions of pronounced osteoblastic activity. The serum ALP is increased during periods of rapid bone growth (e.g., infancy, early childhood, healing bone fractures) and during pregnancy because of the contributions of the placenta and fetal bones.

11. L.M., a 59-year-old female currently taking atorvastatin 40 mg daily for hypercholesterolemia, complains of fatigue and myalgia over the past week since her last prescription refill. On assessment, her primary care provider determines she has been taking an incorrect dose. Instead of cutting an 80-mg tablet in half, she has been taking the entire tablet, thereby effectively doubling her dose. The physician orders liver function tests (LFTs), CK, and SCr to evaluate her myalgia. Laboratory results indicate the following: AST, 51 units/L (normal, <35); ALT, 72 units/L (normal, <35); ALP, 82 units/L (normal, 30–120); CK, 216 units/L (normal, <150); and SCr, 1.4 mg/dL (normal, 0.6–1.2). Why are these laboratory results of sufficient concern to warrant discontinuation of atorvastatin?

[SI units: AST, 0.85 $\mu\text{kat/L}$; ALT, 1.2 $\mu\text{kat/L}$; ALP 1.37 $\mu\text{kat/L}$; CK, 3.6 $\mu\text{kat/L}$; SCr 123.8 $\mu\text{mol/L}$]

L.M.’s LFTs are elevated and are of concern, particularly in light of her other signs and symptoms. Statins have been implicated in causing elevations in LFTs on initiation of therapy and with dose increases. LFTs can be increased by up to three times the upper limit of normal. In the absence of jaundice or other clinical signs and symptoms, reduction of her atorvastatin dose will generally be sufficient in returning LFTs to normal values without adverse sequelae. L.M.’s values will likely return to baseline when her atorvastatin dose is reduced to 40 mg or discontinued. Additional monitoring after intervention would be indicated to confirm whether her LFTs stabilize or whether a trend of elevations is noted on multiple occasions. CK serum concentrations can also be increased in response to muscle injury or myalgia. When CK increases ten times the upper limit of normal, myopathy should be suspected. L.M.’s CK is mildly increased at this time, but not at an alarming value.

Gamma-Glutamyl Transferase

Normal: 0 to 70 units/L or 0 to 1.17 $\mu\text{kat/L}$

Although the enzyme gamma-glutamyl transferase (GGT) is found in the kidney, liver, and pancreas, its major clinical value is in the evaluation of hepatobiliary disease. An increase in the serum concentration of GGT parallels the increase of ALP in obstructive jaundice and infiltrative disease of the liver. However, increased ALP in the presence of a normal GGT is more suggestive of muscular or bone-related issues. GGT is one of the more sensitive liver enzymes for identifying biliary obstruction and cholecystitis. Because GGT is a hepatic

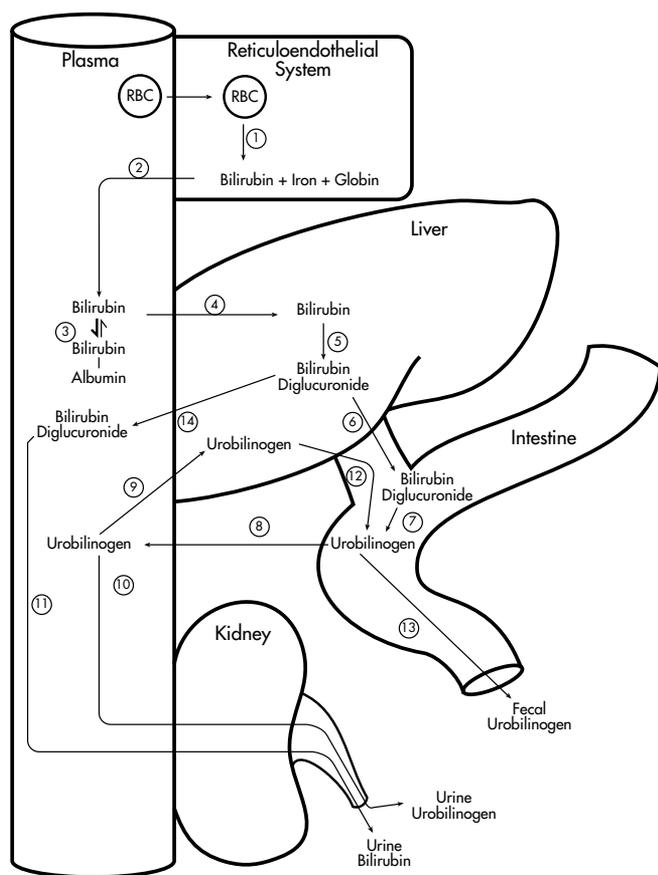

FIGURE 2-1 Bilirubin metabolism.

microsomal enzyme, tissue concentrations increase in response to microsomal enzyme induction by alcohol and other drugs (e.g., carbamazepine, phenobarbital, phenytoin). As a result, GGT is a sensitive indicator of recent or chronic alcohol exposure.

Bilirubin

Total Bilirubin—Normal: 0.1 to 1.0 mg/dL or 1.7 to 17.1 $\mu\text{mol/L}$

Direct (Conjugated) Bilirubin—Normal: 0 to 0.2 mg/dL or 0 to 3.4 $\mu\text{mol/L}$

Bilirubin is primarily a breakdown product of Hgb and is formed in the reticuloendothelial system (Fig. 2-1, step 1). It is then transferred into the blood (step 2), where it is almost completely bound to serum albumin (step 3). When bilirubin arrives at the sinusoidal surface of the liver cells, the free fraction is rapidly taken up into the cell (step 4) and converted primarily to bilirubin diglucuronide (step 5). A monoglucuronide is also formed that is metabolized predominantly to the diglucuronide. The conjugated bilirubin diglucuronide is then excreted into the bile (step 6) and appears in the intestine, where bacteria convert most of it to urobilinogen (step 7). The majority of urobilinogen is destroyed or excreted in the feces (step 13), but a small portion is reabsorbed into the blood (step 8) and either reabsorbed into the liver (step 9) and subsequently

excreted into the bile (step 12) or excreted into the urine (step 10). Urobilinogen is responsible for the straw color of the urine and the yellowish-brown color of the feces. The mechanism by which conjugated bilirubin in the liver cell is transferred to the blood (step 14) is not well understood. However, in many types of liver disease, conjugated (direct) bilirubin is present in increased concentrations in the blood. When this concentration exceeds 0.2 to 0.4 mg/dL, bilirubin will begin to appear in the urine (step 11). Unconjugated (indirect) bilirubin is water insoluble and is highly bound to serum albumin; both factors account for its lack of excretion in the urine.²³

Hyperbilirubinemia

12. A.R., a 42-year-old man with a 2-year history of hypertension controlled with hydrochlorothiazide and a 1-year history of Parkinson disease controlled by carbidopa/levodopa, is hospitalized after an episode of orthostatic hypotension. Admitting laboratory results show a hematocrit (Hct) of 27% (normal, 39–49). Because A.R. had a long history of alcoholism, additional laboratory tests were obtained. His results were as follows: total bilirubin, 3.5 mg/dL (normal, 0.1–1.0); direct bilirubin, 0.5 mg/dL (normal, <0.2); ALP, 40 units/L (normal, 30–120); AST, 32 units/L (normal, <35); and ALT, 27 units/L (normal, <35). Based on this information and Figure 2-1, what are three major causes of increased bilirubin in adults, and what might be the most logical cause of increased bilirubin in A.R.?

[SI units: Hct, 0.27; total bilirubin, 59.8 $\mu\text{mol/L}$; direct bilirubin, 8.6 $\mu\text{mol/L}$; ALP, 0.67 $\mu\text{kat/L}$; AST, 0.53 $\mu\text{kat/L}$; ALT, 0.45 $\mu\text{kat/L}$]

Increases in serum bilirubin can be categorized into three primary causes. First, hepatocellular injury interferes with the ability of the liver to conjugate bilirubin, leading to a disproportional increase of total bilirubin relative to the direct bilirubin (i.e., the indirect bilirubin will be increased). The normal AST and ALT values observed with A.R. indicate that hepatocellular damage is not likely the cause of the increased bilirubin. Therefore, a diagnosis of hepatocellular damage cannot be confirmed by the serum bilirubin concentrations alone. Second, hyperbilirubinemia can involve cholestatic or obstructive (posthepatic) causes. Blockage of the bile duct secondary to cholelithiasis (gallstone) or tumor will tend to increase conjugated (direct) bilirubin. In obstructive causes of hyperbilirubinemia, mild elevations in AST and ALT, as well as marked increase in ALP and GGT, are usually observed. Furthermore, increased excretion of excess conjugated bilirubin in the urine commonly results in dark brown-colored urine. Again, the clinical scenario illustrated with A.R. does not appear to support a cholestatic component as the cause of his increased bilirubin (ALP is within the normal range, and his direct bilirubin is only slightly elevated). The third primary cause of increased serum bilirubin involves hemolysis (prehepatic). In cases where erythrocytes are rapidly hemolyzed (e.g., sickle cell disease, drug-induced hemolysis), serum concentrations of indirect bilirubin increase. If the liver is conjugating and eliminating bilirubin normally, total bilirubin will increase out of proportion to the direct bilirubin, and the other LFTs will appear normal. This appears evident in A.R.'s case, making hemolysis the likely cause of his hyperbilirubinemia.

MISCELLANEOUS TESTS

Amylase and Lipase

Amylase (35–120 units/L or 0.58–2.0 μ kat/L) and lipase (0–160 units/L or 0–2.67 μ kat/L) are enzymes produced in the pancreas and secreted into the duodenum to assist in the digestive process. Amylase is responsible for breaking down complex carbohydrates into simple sugars and is also found in the saliva. Significant elevations in serum amylase are observed in patients with acute pancreatitis or pancreatic duct obstruction. Amylase levels tend to rise 6 to 48 hours after onset of the disease and usually return to normal 3 days after the acute event. In chronic pancreatitis or obstruction, amylase levels may remain elevated for longer periods. Other nonpancreatic conditions (e.g., bowel perforation, biliary disease, perforated peptic ulcer, ectopic pregnancy, mumps) can be associated with elevated serum amylase levels.

Lipase is responsible for breaking down triglycerides into fatty acids. Elevated serum lipase levels are also suggestive of pancreatic disease and tend to be more specific for pancreatic disease than amylase. The onset of lipase elevation is similar to amylase; however, lipase typically remains elevated for 5 to 7 days and can be useful in diagnosing patients in later stages of pancreatic disease. Narcotics (e.g., morphine) can constrict the sphincter of Oddi and increase serum concentrations of amylase and lipase.

Prostate-Specific Antigen

Normal: 0 to 4 ng/mL or 0 to 4 mcg/L

Prostate-specific antigen (PSA) is a protease glycoprotein produced almost exclusively by prostate epithelial cells. Serum concentrations of PSA are increased when the normal prostate glandular structure is disrupted by benign or malignant tumor or inflammation. More than half of the men with benign prostatic hyperplasia have elevated serum PSA concentrations. PSA is also a valuable parameter for staging and monitoring the progression and response to therapy of prostate cancer.²⁴

PSA serum concentrations increase after prostatic manipulation such as digital rectal examination (DRE), transrectal ultrasound, cystoscopy, or biopsy of the prostate. In addition, serum PSA will increase 24 to 48 hours following ejaculation. Although elevated serum concentrations of PSA can occur in men with benign prostatic hyperplasia, concentrations tend to be higher and encountered more often in men with cancer. As a result, the American Cancer Society²⁵ and the American Urological Association²⁶ currently recommend that health care providers offer a PSA blood test and DRE yearly to men older than 50 years. For men considered to be at high risk (family history or African American men), testing at age 45 years is suggested. Combination of both PSA and DRE were more effective in detecting prostate cancer than either test alone.

The serum half-life of PSA is 2 to 3 days, but serum PSA concentrations can remain high for several weeks after manipulation of the prostate. Men with PSA levels between 4 and 10 ng/mL should be evaluated further for potential prostate cancer. Circulating serum PSA is bound to plasma proteins, and the capability exists to measure both total and free (unbound) PSA concentrations. Increased risk of prostate cancer

has been observed in men with a free PSA-to-total PSA ratio of <0.25 .²⁷ An aggressive approach to localize prostate cancer for men with life expectancies more than 10 years is now favored.^{24,28} The diagnosis and treatment of prostate cancer is presented in Chapter 91.

Thyroid-Stimulating Hormone

Normal: 2 to 10 μ units/L or m units/L

Thyroid-stimulating hormone (TSH) is commonly used to monitor exogenous thyroid replacement therapy in individuals diagnosed with primary hypothyroidism. In addition, TSH may also be measured in conjunction with T_4 levels to diagnose this condition or secondary hypothyroidism. Causes of secondary hypothyroidism typically arise from damage, such as trauma or tumors, to the hypothalamus or pituitary gland. Secretion of thyroid-releasing hormone (TRH) and TSH are substantially impaired or absent due to this damage. Conversely, primary hypothyroidism occurs in response to low levels of T_3 and T_4 . Reduced levels stimulate TRH and TSH release in absence of the negative feedback typically exerted by normal levels of T_3 and T_4 ; as a result, increased TSH is noted.

Exogenous thyroid replacement therapy balances TSH secretion to achieve a euthyroid state. Individuals taking inappropriate replacement doses will exhibit alterations in TSH levels. In the absence of other clinical influences or interactions, a high TSH level indicates the need to supplement with additional thyroid medication, whereas a low TSH supports the reduction in exogenous supplementation. Causes of primary hypothyroidism include congenital defects, idiopathic hypothyroidism, thyroiditis (inflammation of the thyroid gland), or antithyroid medications. Chapter 49 provides a more detailed discussion of the clinical implications of altered thyroid laboratory findings.

Cholesterol and Triglycerides

A detailed discussion of hypercholesterolemia and lipid disorders is provided in Chapter 12. For convenience, the current range of desired values for total cholesterol (TC), low-density lipoproteins (LDLs), high-density lipoproteins (HDLs), and fasting triglycerides (TGs) has been incorporated in Table 2-1. The reader is referred to Chapter 12 or to National Cholesterol Education Program and Adult Treatment Panel guidelines for a detailed description on the topic.²⁹

HEMATOLOGY

There are several different hematologic cell types that originate from the hematopoietic stem cell. Each cell line has a defined role and unique contribution to the overall homeostatic process, and may be found in the bone marrow, lymph system, or blood. Typically, routine clinical laboratory testing involves measuring concentrations of mature myeloid cells found in the blood. Figure 2-2 illustrates the various lineages derived from the hematopoietic stem cell.³⁰ The cells derived via the myeloid lineage are the focus of the following discussion. Readers are encouraged to refer to Sections 18 (Chapters 86 and 87) and 19 (Chapters 88 to 92) to gain further understanding of the clinical relevance of lymphoid and myeloid cells (Fig. 2-2).

Bone Marrow

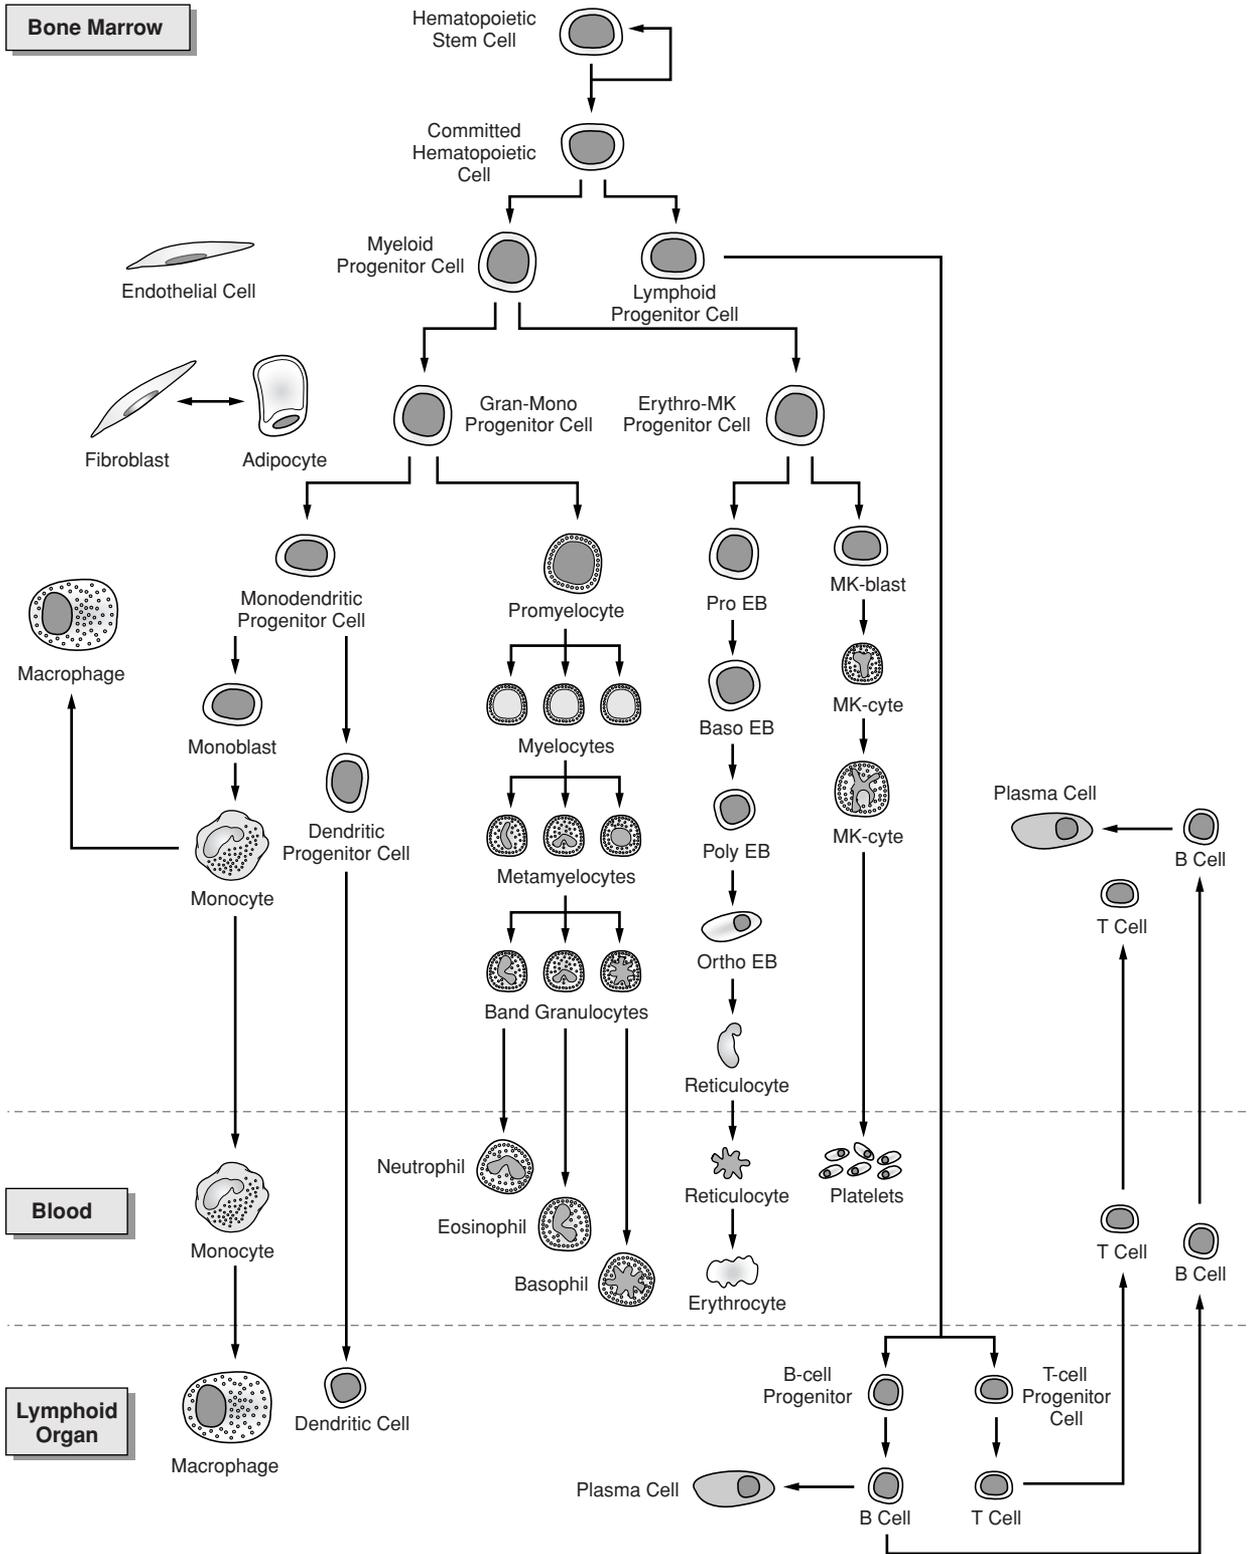

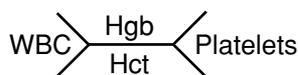

FIGURE 2-2 Hematopoietic stem cell lineage.

Complete Blood Count

The complete blood count (CBC) is one of the most commonly ordered clinical laboratory tests. A CBC measures the RBCs, Hgb, Hct, mean cell volume (MCV), mean cell Hgb concentration (MCHC), and total white blood cells (WBCs). Depending on the laboratory, an order for a CBC may also include platelets, reticulocytes, or leukocyte differential. An abbreviated method of noting hematologic parameters in clinical practice is noted in the following figure. In addition, a list of hematologic laboratory values is presented in Table 2-2.

Red Blood Cells (Erythrocytes)

Males—Normal: 4.3 to $5.9 \times 10^6/\text{mm}^3$ or 4.3 to $5.9 \times 10^{12}/\text{L}$
Females—Normal: 3.5 to $5.0 \times 10^6/\text{mm}^3$ or 3.5 to $5.0 \times 10^{12}/\text{L}$

Erythrocytes or RBCs are produced in the bone marrow, released into the peripheral blood, circulated for approximately 120 days, and cleared by the reticuloendothelial system. The primary function of RBCs is to transport oxygen to tissues. The concentration of RBCs in the blood can be measured to detect anemia, calculate RBC indices, or calculate the Hct. Hct and Hgb concentrations are generally used to monitor quantitative changes in RBCs.

Hematocrit

Males—Normal: 39% to 49% or 0.39 to 0.49 I
Females—Normal: 33 to 43% or 0.33 to 0.43 I

Hct (packed cell volume) is determined by centrifuging a capillary tube of whole blood and comparing the height of the settled RBCs to the height of the column of whole blood. The percentage of RBCs to the blood volume is the Hct. A decrease in Hct may result from bleeding, the bone marrow suppressant effects of drugs, chronic diseases, genetic alterations in RBC morphology, or hemolysis. An increase in Hct may result from hemoconcentration, polycythemia vera, or polycythemia secondary to chronic hypoxia.

Hemoglobin

Males—Normal: 14 to 18 g/dL or 140 to 180 g/L
Females—Normal: 12 to 16 g/dL or 120 to 160 g/L

Hgb is the oxygen-carrying compound contained in RBCs. Therefore, total Hgb concentration primarily depends on the number of RBCs in the blood sample. As mentioned with Hct, medical conditions that impact the number of RBCs will also affect Hgb concentration. As discussed previously, glycosylated Hgb (A1c) is a related test used to monitor diabetes mellitus.

Red Blood Cell Indices

RBC indices (also known as Wintrobe indices) are useful in the classification of anemias. These indices include the MCV, the mean cell hemoglobin (MCH), and the MCHC. These indices

are calculated in Equations 2-6 to 2-8:

$$\text{MCV} = \frac{\text{Hct} \times 1,000}{\text{RBC (in millions}/\mu\text{L})} = 76 - 100 \text{ (in } \mu\text{m}^3 \text{ or fL)} \quad 2-6$$

$$\text{MCH} = \frac{\text{Hgb (in g/dL} \times 10)}{\text{RBC (in millions}/\mu\text{L})} = 27 - 33 \text{ (in pg)} \quad 2-7$$

$$\text{MCHC} = \frac{\text{Hgb (in g/dL)}}{\text{Hct}} = 33 - 37 \text{ (in g/dL)} \quad 2-8$$

Mean Cell Volume

The MCV detects changes in cell size. A decreased MCV indicates a microcytic cell, which can result from iron-deficiency anemia. A large MCV indicates a macrocytic cell, which can be caused by a vitamin B₁₂ or folic acid deficiency. Underlying disease states (e.g., habitual alcohol ingestion, chronic liver disease, anorexia nervosa, hypothyroidism, reticulocytosis, hematologic disorders) may also present with an elevated MCV secondary to deficiencies in these vitamins.³¹ The MCV can be normal in a patient with a “mixed” (microcytic and macrocytic) anemia. Note that a direct assessment of a blood smear via microscopic examination is the gold standard for confirming RBC size.

Mean Cell Hemoglobin

The MCHC is a more reliable index of RBC Hgb than MCH. The former measures the concentration of Hgb, whereas the latter measures the weight of Hgb in the average RBC. In normochromic anemias, changes in the size of RBCs (MCV) are associated with corresponding changes in the weight of Hgb (MCH), but the concentration of Hgb (MCHC) remains normal. Changes in the Hgb content of RBCs alter the color of these cells. Thus, hypochromic refers to a decrease in RBC Hgb, reflected by reduced MCHC, and may indicate iron-deficiency anemia. Conversely, hyperchromic RBCs have an elevated MCHC due to the presence of greater amounts of Hgb. Hyperchromic cells are not commonly encountered.³²

13. C.U., a 58-year-old chronic alcoholic, was hospitalized after a barroom brawl. A CBC was ordered, and the following RBC indices were noted: MCV, 108 μm^3 ; MCH, 38 pg; and MCHC, 34 g/dL. How should these indices be interpreted in C.U.?

[SI units: MCV, 108 fL; MCH, 38 pg; MCHC, 340 g/L]

Usually, the MCH and MCV are both increased and the MCHC is normal in macrocytic anemias associated with vitamin B₁₂ or folic acid deficiency. The MCH is increased because the RBCs have increased in size; however, the concentration of Hgb (MCHC) has not changed. This characteristic picture is illustrated in the alcoholic patient, C.U., who is likely to have a dietary folic acid deficiency. If C.U.’s indices were normal (normocytic, normochromic) and if anemia was present (decreased Hgb or Hct), acute blood loss from injuries he sustained in the brawl should be considered. If the anemia seems to be more chronic in nature, alcohol-induced bone marrow suppression should be considered (see Chapters 28 and 84).

Reticulocytes

Adults—Normal: 0.1% to 2.4% of RBCs or 0.001 to 0.024 I

Reticulocytes are young, immature erythrocytes (RBCs). The reticulocyte count measures the percentage of these new cells in the circulating blood. An increase in the number of reticulocytes implies an increased number of erythrocytes are being released into the blood in response to a stimulus. Because erythrocytes regenerate rapidly, reticulocytosis can be noted within 3 to 5 days after hemolysis or after a hemorrhagic episode. Appropriate treatment of anemias caused by iron, vitamin B₁₂, or folic acid deficiencies should result in an increased reticulocyte count. Caution must be exercised in the interpretation of reticulocyte counts. Changes in the number of RBCs will result in proportional changes in the reticulocyte count because the latter is reported as a percentage of the number of RBCs.

Erythrocyte Sedimentation Rate

Males—Normal: 0 to 20 mm/hour

Females—Normal: 0 to 30 mm/hour

The ESR is the rate at which erythrocytes settle to the bottom of a test tube through the forces of gravity and in response to fibrinogen levels in the blood. The ESR is a nonspecific value and may be increased abnormally in acute and chronic inflammatory processes, acute and chronic infections, neoplasms, infarction, tissue necrosis, rheumatoid-collagen disease, dysproteinemias, nephritis, and pregnancy. Laboratory technique can affect the sedimentation rate substantially.²² Because many factors can enhance the settling rate of RBCs, moderate to marked elevation of the ESR merely indicates an inflammatory component to a disease state. An increased ESR in the setting of a normal physical examination is usually transitory and is rarely the harbinger of serious occult disease.³³

White Blood Cells

Normal: 3.2 to 9.8 × 10³/mm³ or 3.2 to 9.8 × 10⁹/L

Leukocytes or WBCs are comprised of five different types of cells. Neutrophils are the most abundant of the circulating WBCs, followed in order of frequency by lymphocytes, monocytes, eosinophils, and basophils. The neutrophils, eosinophils, basophils, and monocytes are formed from stem cells in the bone marrow. Lymphocytes are formed primarily in the lymph nodes, thymus, spleen, and, to a lesser extent, bone marrow (Fig. 2-2). Each WBC has unique functions, and it is best to consider them independently rather than collectively as “leukocytes.”³⁴ Ultimately, all WBCs contribute to host defense mechanisms. A convenient mnemonic for remembering the various types of WBCs is “Never Let Monkeys Eat Bananas” (N = neutrophils; L = lymphocytes; M = monocytes; E = eosinophils; and B = basophils).

Neutrophils

Normal: 54% to 62% of WBC

The terms “polys,” “segs,” “polymorphonuclear neutrophils,” and “granulocytes” are synonymous with the term “neutrophil” in clinical practice. The number of neutrophils is commonly increased during bacterial or fungal infections because these cells are essential in killing invading micro-

organisms. While the bone marrow increases production of new leukocytes, there is also an increase in the number of circulating immature neutrophils (e.g., bands); this phenomenon is commonly referred to as a “left shift,” which suggests bacterial infection.³²

However, neutrophils are also important in the pathogenesis of tissue damage in some noninfectious diseases, such as rheumatoid arthritis, inflammatory bowel disease, asthma, MI, or gout.³⁵ Increased neutrophils or neutrophilia can also be encountered during metabolic toxic states (e.g., diabetic ketoacidosis, uremia, eclampsia) and during physiological response to stress (e.g., physical exercise, childbirth). Drugs (e.g., epinephrine, corticosteroids) can also cause significant neutrophilia, primarily by demargination from blood vessel walls.

Agranulocytosis and Absolute Neutrophil Count

The condition involving decreased neutrophils, or neutropenia, is defined as a neutrophil count of <2,000 cells/mm³; agranulocytosis refers to severe neutropenia. The degree of neutropenia is often expressed by the absolute neutrophil count (ANC). The ANC is defined as the total number of granulocytes (polymorphonuclear leukocytes and band forms) present in the circulating pool of WBCs and can be calculated as WBC × (% neutrophils + % bands)/100. Generally, the risk of infection is low when the ANC exceeds 1,000/mm³; however, the risk of infection increases significantly when the ANC is <500/mm³. The risk of developing bacteremia is increased further as the ANC decreases to <100/mm³, a condition commonly referred to as “profound neutropenia” (see Chapter 68). The most common causes of neutropenia are metastatic carcinoma, lymphoma, and chemotherapeutic agents.

Lymphocytes

Normal: 25% to 33% of WBC

Lymphocytes constitute the second most common WBC in circulating blood. These leukocytes respond to foreign antigens by initiating the immune defense system. The vast majority of lymphocytes is located in the spleen, lymph nodes, and other organized lymphatic tissue. The lymphocytes circulating in blood represent <5% of the total amount in the body.

There are two major types of lymphocytes. T lymphocytes (thymic dependent) participate in cell-mediated immune responses, and B lymphocytes (bone marrow derived) are responsible for humoral antibody responses. Therefore, diseases affecting lymphocytes primarily manifest themselves as immune deficiency disorders that render the patient unable to defend against normal pathogens (see Chapter 69) or as autoimmune diseases in which immune responses are directed against the body’s own cells.³⁴

Increased numbers of lymphocytes on a white count differential sometimes accompany lymphoma (see Chapter 90) and viral infections such as infectious mononucleosis, mumps, and rubella. A relative lymphocytosis is sometimes encountered when the total lymphocytes have remained constant despite a decline in the total neutrophils.

Monocytes

Normal: 3% to 7% of WBC

Monocytes are formed in the bone marrow and are the precursors to macrophages and antigen-presenting cells (dendritic

cells), which are found in the body's tissues.³⁶ Macrophages and dendritic cells are phagocytic cells that engulf foreign antigens or dead or dying cells. Dendritic cells also present fragments of antigens to T and B lymphocytes. Monocytosis may be observed in mononucleosis, subacute bacterial endocarditis, malaria, and tuberculosis, as well as during the recovery phase of some infections.

Eosinophils

Normal: 1% to 3% of WBC

Because eosinophils have surface receptors that bind IgG and IgE, they can modify reactions associated with IgG- and IgE-mediated degranulation of mast cells. Primary lysosomal granules, small dense granules, and specific or secondary granules are the three types of granules found within eosinophils. The latter granules account for most of the biological activity of eosinophils and are toxic to parasites, tumor cells, and some epithelial cells.³⁷

Eosinophils have phagocytic activity, catalyze the oxidation of many substances, facilitate killing of micro-organisms, initiate mast cell secretion, protect against various parasites, and play some role in host defense. Eosinophilia is probably most commonly associated with allergic reactions to drugs, allergic disorders (e.g., hay fever, asthma, eczema), invasive parasitic infections (e.g., hookworm, schistosomiasis, trichinosis), collagen vascular diseases (e.g., rheumatoid arthritis, eosinophilic fasciitis, eosinophilic-myalgia syndrome), and malignancies (e.g., Hodgkin disease).³⁸⁻⁴⁰

Basophils

Normal: <1% of WBC

During infection or inflammation, basophils leave the blood and mobilize as mast cells to the affected site and release granules. These granules contain histamine, serotonin, prostaglandins, and leukotrienes. Degranulation results in an increased blood flow to the site and may compound inflammatory processes. An increase in basophils commonly accompanies allergic and anaphylactic responses, chronic myeloid leukemia, myelofibrosis, and polycythemia vera. A decrease in the number of basophils is generally not readily apparent because of the small number of these cells in the blood.³⁴

14. R.L., a 45-year-old man, is hospitalized with a sustained high fever of 39.4°C, SOB, and pleurisy. His cough is productive of rusty sputum, and he appears to be in acute distress. The results of the CBC and leukocyte differential are as follows: total WBC count, 18,000/mm³; neutrophils, 76%; bands, 13%; lymphocytes, 10%; monocytes, 0; eosinophils, 1%; and basophils, 0. On the basis of this laboratory report and other findings, a diagnosis of pneumococcal pneumonia is suspected. How is R.L.'s laboratory report consistent with bacterial infection?

[SI units: WBC, $1.8 \times 10^9/L$; neutrophils, 0.76; bands, 0.13; lymphocytes, 0.10; eosinophils, 0.01]

WBCs are the host's chief defense system, and the neutrophil is the main component of that system. During bacterial infections, the leukocyte count and the neutrophils are generally increased, and a left shift (increase in bands) may be noticeable. The percentage of other types of WBCs is decreased proportionately because the number of neutrophils is increased.

As the infection progresses, the percentage of band cells may decrease as a result of an increase in the number of neutrophils that have a longer half-life. This decrease in bands does not necessarily indicate improvement. A decrease in the percentage of neutrophils with a decrease in the total WBC count is characteristic of effective antibiotic therapy.

15. S.Q., a 35-year-old woman, was treated for 7 days with dicloxacillin for cellulitis of the left leg. On the eighth day, an allergic urticarial rash developed. The CBC showed a total leukocyte count of 10,000/mm³ with 6% eosinophils. What is the significance of this eosinophil count?

[SI units: WBC, $1.0 \times 10^9/L$; eosinophils, 0.06]

In the clinical setting, absolute leukocyte counts may be used in conjunction with normal reference values. Absolute counts are calculated by multiplying the percentage of each individual cell by the total leukocyte count. Eosinophils are usually increased in allergic reactions; therefore, a drug-induced hypersensitivity reaction is a strong probability in S.Q., with an absolute count of 600 eosinophils/mm³ (i.e., 6% of 10,000 leukocytes). The clinician should be suspicious of an allergic drug reaction when absolute eosinophil counts exceed 300 cells/mm³. Eosinophils may increase before, after, or concurrent with other evidence of allergy (e.g., rash). Eosinophilia without evidence of allergy is not sufficient cause to discontinue a suspected medication unless the eosinophilia is significant (i.e., >2,000 cells/mm³). In addition, the absence of eosinophilia certainly does not rule out an allergic diagnosis in a patient exhibiting clear clinical manifestations of an apparent allergic reaction.

Thrombocytes

Normal: 130 to 400 × 10³/mm³ or 130 to 400 × 10⁹/L

Appropriate platelet (i.e., thrombocyte) function is essential to blood clotting. Decreased platelet counts or thrombocytopenia may lead to petechiae, ecchymosis, and spontaneous hemorrhage. Causes include decreased platelet production, accelerated destruction, loss from excessive bleeding/trauma, dilution of blood samples secondary to blood transfusion, sequestration secondary to hypersplenism, disseminated intravascular coagulation, infection, or systemic lupus erythematosus. Malignancy, rheumatoid arthritis, iron-deficiency anemia, polycythemia vera, and postsplenectomy syndromes are the most common causes of elevated platelet counts or thrombocytosis.

Coagulation Studies

The control of bleeding depends on the formation of a platelet plug and the formation of a stable fibrin clot. The formation of this clot, the complex interactions of plasma proteins and clotting factors, and the clinical application of laboratory tests of coagulation are described in Chapter 15. The prothrombin time (PT), international normalized ratio (INR), and activated partial thromboplastin time (aPTT) are used to diagnose coagulation abnormalities or to monitor the effectiveness of patients receiving anticoagulation therapy. When used to assess drug therapy, achieving a value outside the "normal" range is in fact a therapeutically desirable outcome. These tests are described briefly in this chapter, with the understanding that the reader

will refer to Chapter 15 to gain the appropriate perspective on the clinical applicability of these tests.

Activated Partial Thromboplastin Time

aPTT measures the intrinsic clotting system, which depends on factors VIII, IX, XI, and XII and the factors involved in the final common pathway of the clotting cascade (factors II, X, and V). The typical control ranges from 35 to 45 seconds. aPTT is commonly used to monitor unfractionated heparin therapy.

Prothrombin Time

Prothrombin is synthesized in the liver and is converted to thrombin during the blood clotting process. Thrombin formation is the critical event in the hemostatic process because thrombin creates fibrin monomers that ultimately assemble into a clot and stimulates platelet activation. The PT test directly measures the activity of clotting factors VII, X, prothrombin (factor II), and fibrinogen. Automated laboratory instruments measure PT by recording the time required for the blood to clot after tissue thromboplastin has been added to the patient's blood sample. The reference range depends on the specific laboratory, but is usually between 10 and 12 seconds when rabbit brain thromboplastin is used.

International Normalized Ratio

Although INR is the recommended method to accurately monitor anticoagulant therapy, several potential problems have been identified with the INR system. Because of the variable sensitivity of thromboplastin reagents to decreases in specific clotting factors, there may be a lack of reliability of the INR system when it is used at the onset of warfarin therapy and for screening for a coagulopathy. Despite these potential problems with the INR system, the American College of Chest Physicians unanimously recommends using the INR system of reporting during initiation and maintenance of anticoagulant therapy.⁴¹ However, attempts to standardize laboratory reporting have not completely eliminated the variability observed between different laboratories, so clinicians must be cautious when interpreting coagulation parameters obtained for more than one institution.

The INR is calculated using Equation 2-9, where the prothrombin ratio (PTR) is the ratio between the patient's PT and the laboratory's control PT, and the ISI is the international sensitivity index. Commercial manufacturers quantify the ISI for the specific thromboplastin reagent used in each lot and report this information in the product package insert. For a thorough review on the monitoring of anticoagulant therapy, see Chapter 15.

$$\text{INR} = \left\{ \frac{\text{PT}(\text{patient})}{\text{PT}(\text{control})} \right\}^{\text{ISI}} = \text{PTR}^{\text{ISI}} \quad 2-9$$

URINALYSIS

A standard urinalysis begins with simple observation of the color and the gross general appearance of the urine specimen. The urine pH and specific gravity are then recorded. Formed elements in the urine are examined microscopically, and the urine is searched routinely for pathologically significant substances that are normally not present (e.g., glucose, blood, ketones, bile pigments).

Gross Appearance of the Specimen

The concentrated, first-morning urine specimen is usually analyzed to eliminate effects of undue dilution as a result of water intake. The color should be slightly yellow, depending on the degree of dilution, and the appearance should be clear. The appearance of the urine may reveal clouds of crystals, bilirubin, blood, porphyrins, proteins, food or drug colorings, or melanin. Discolored urine is abnormal. A red coloration of the urine may be imparted by blood, porphyria, or ingestion of phenolphthalein. A brown urine color may be caused by the acid hematin of blood or from melanin pigments. Excessive excretion of urobilinogen or the effects of drugs such as rifampin or phenazopyridine may cause a dark orange urine color. A blue to blue-green color of the urine may result from the systemic administration of methylene blue.

Specimen pH

When freshly produced, urine is normally mostly acidic (pH 4.6–8). Alkaline urine may indicate an aged specimen, systemic alkalosis, failure of renal acidifying mechanisms, or infection in the urinary tract.

Specific Gravity

A normal morning urine specimen should have a specific gravity of 1.020 to 1.025. The upper end of this range is close to the maximal concentrating ability of the kidney. Glomerular filtrate has a specific gravity of 1.010, and a urine of such a low specific gravity, under conditions of restricted water intake, would suggest failure of renal concentrating mechanisms. When water intake is not restricted, specific gravity readings are difficult to interpret.

Protein

Proteinuria is a classic sign of renal injury and a matter of concern. If proteinuria is found during the evaluation of a patient with a nonrenal illness, it suggests that the disease may also involve the kidneys (i.e., hypertension, diabetes).⁴² A healthy adult generally excretes 30 to 130 mg/day of protein into the urine.

Protein in a urine sample is generally tested qualitatively on a random urine sample by a dipstick method and is usually reported on a scale of 0 (<30 mg/dL), 1+ (30–100 mg/dL), 2+ (100–300 mg/dL), 3+ (300–1,000 mg/dL), and 4+ (>1,000 mg/dL). A positive qualitative test for urine protein should be repeated after a few days because transient proteinuria can accompany various physiological and pathological states, even when kidney function is normal. Therefore, patients with CHF, seizures, or febrile illnesses and normal renal function need not undergo invasive renal function tests if the proteinuria is modest and likely to be transient. Another qualitative evaluation of proteinuria can be performed in about 2 weeks to confirm the diagnosis of transient proteinuria.⁴³ If subsequent qualitative test results are positive, a 24-hour urine sample should be collected to quantitatively test for protein and creatinine (see Creatinine Clearance section). In patients with a normal 24-hour urinary protein concentration, previous positive qualitative test results probably represent either false-positive results or a transient phenomenon.⁴²

Microscopic Examination

The urine sediment is examined for RBCs, WBCs, casts, yeast, crystals, and epithelial cells.

RBCs should be absent in normal urine, although one or two RBCs per high-power field (HPF) would still be considered in the normal range. Bleeding or clotting disorders, some collagen diseases, and various bladder, urethral, and prostatic conditions may cause microscopic hematuria. In females, vaginal blood occasionally contaminates the urine specimen, but the presence of numerous squamous epithelial cells should be sufficient to alert clinicians to this artifact.

WBCs should be virtually absent in normal urine, although up to five WBCs/HPF would still be in the normal range. The presence of WBCs in the urine usually suggests an acute infection in the urinary tract (see Chapter 64). Some noninfectious inflammatory diseases of the kidney, ureter, or bladder may also contribute WBCs to the urine sediment.

Casts are composed of proteinaceous or fatty material that outlines the shape of the renal tubules where they were deposited. The presence of casts in the urine must be interpreted in light of other factors related to the kidney and its function; however, fatty casts, RBC casts, and WBC casts are always significant. RBC casts usually suggest glomerular injury, and WBC casts suggest tubular or interstitial injury. Lipid casts with proteinuria are characteristic findings in patients with the nephrotic syndrome.⁴⁴ The finding of hyaline casts alone in the presence of proteinuria suggests a renal origin for the protein. Hyaline or granular casts alone, however, only suggest some defect in factors that affect cast formation, and are therefore difficult to interpret.

Crystals may originally appear as a cloud in the urine. Their formation is pH dependent, and they often appear only as the urine cools to room temperature or in concentrated urine. In acid urine, crystals may be uric acid or calcium oxalate; in alkaline urine, they may be phosphates. Crystals per se are not highly significant, although they may reflect a tendency toward the formation of renal calculi (see Chapter 30).

16. R.C. is a 23-year-old man who was diagnosed with type 1 diabetes mellitus about 10 years ago; until now, his diabetes has been well controlled with an aggressive insulin regimen. His sister brings him to the emergency department with a 3-day history of fever, chills, dysuria, malaise, and some confusion. He also complains of nausea and vomiting and a poor appetite. Because he has not been able to keep any food down for about 48 hours, he has not taken his insulin. A finger stick blood glucose is 545 mg/dL, and a stat midstream urinalysis and Gram stain indicate the following: pH 5.2; appearance cloudy; specific gravity 1.033; urine protein 3+; urine glucose 4+; urine ketones positive; urine bacteria 4+; urine WBC, too numerous to count (TNTC); squamous epithelial, few per HPF; urine nitrite positive; and Gram stain, numerous gram-negative rods. What objective data from the urinalysis indicate that R.C. is critically ill?

[SI unit: glucose, 30.3 mmol/L]

The cloudy appearance of R.C.'s urine indicates the presence of bacteria, protein, and WBCs, which is substantiated by the data (4+ bacteria, 3+ protein, and TNTC WBCs). The lack of a significant amount of squamous epithelial cells, the presence of a significant amount of nitrite-producing bacteria, and the Gram stain indicate a clean-catch urine specimen

Table 2-3 FDA and Non-FDA-Approved Products Available for Patient-Directed Monitoring or Testing

Blood Chemistry

Blood glucose monitors
Glycosylated hemoglobin (A1c)
Lipids (TC, HDL, LDL, TG)
Prothrombin (PT, INR)

Screening for Disease or Infection

Middle ear monitor (otitis media)
Urinary tract infection
Urine dipsticks
 Glucose, ketones, specific gravity, blood, pH, protein, nitrite, leukocytes
Anemia (Hgb)
Hepatitis C
HIV
Kidney disease (microalbuminuria)
Thyroid (TSH)
Fecal occult blood test

Fertility—Male

Fertility tests (sperm counts)
Paternity testing (DNA)
Hormone tests (testosterone, DHEA)

Fertility—Female

Ovulation tests (LH)
Pregnancy tests (hCG)
Menopause tests (FSH)
Maternity testing (DNA)
Hormone tests (estrogen, progesterone, testosterone)

Drugs of Abuse

Alcohol
Nicotine
THC (marijuana)
Cocaine
Opiates
Amphetamines
Methamphetamines
PCP-phencyclidine
Barbiturates
Benzodiazepines
MDMA (ecstasy)

A1c, glycosylated hemoglobin; DHEA, dehydroepiandrosterone; FDA, U.S. Food and Drug Administration; FSH, follicle-stimulating hormone; hCG, human chorionic gonadotropin; HDL, high-density lipoprotein; Hgb, hemoglobin; INR, international normalized ratio; LDL, low-density lipoprotein; LH, luteinizing hormone; MDMA, 3',4-methylenedioxymethamphetamine; PCP, phencyclidine; PT, prothrombin time; TC, total cholesterol; TG, triglyceride; THC, tetrahydrocannabinol; TSH, thyroid-stimulating hormone.

and a urinary tract infection (UTI) involving gram-negative organisms. Because the renal threshold of glucose is typically 180 mg/dL, the presence of 4+ glucose in the urine indicates that the blood glucose concentration significantly exceeds this figure (substantiated by blood glucose of 545 mg/dL). Acidification of the urine and ketonuria occur after the release of ketone bodies into the bloodstream after the breakdown of fatty acids for energy utilization. It is likely that R.C. has a severe UTI and, most likely, diabetic ketoacidosis. (See Chapters 50 and 64 for thorough discussions of diabetes, diabetic ketoacidosis, and UTIs.)

PATIENT-DIRECTED MONITORING AND TESTING

Often patient-directed self-monitoring is an essential component to successful management of certain disease states such as blood pressure monitoring for hypertension and blood glucose monitoring for diabetes mellitus. When used appropriately, data obtained from these monitoring devices can be used by health care providers and consumers to initiate or modify therapies accordingly.

Additional laboratory, self-monitoring tests or devices are also available for consumers to purchase for independent testing or screening purposes at home (Table 2-3). Some products provide an immediate result, whereas others require submitting

a completed kit to a laboratory for analysis. Samples may be obtained from various sources, including urine, blood, saliva, stool, or hair samples. In 1992, sales of over-the-counter diagnostic tests in the United States were \$750 million. By 2002, sales jumped to \$2.8 billion annually.⁴⁵ The incidence of consumers using these products has significantly increased and likely will continue to climb due to increased access via the Internet as well as additional tests becoming available.

In the United States, some, but not all, patient-directed tests have been approved by the U.S. Food and Drug Administration (FDA). A current listing of approved products is available through the FDA's Office of In Vitro Diagnostic Device Evaluation and Safety (OIVD) and can be accessed online at <http://www.fda.gov/cdrh/oivd/>.⁴⁶ Consumers should be cautioned about the accuracy of tests that have not been approved and the validity of all test results, especially for diagnostic purposes, because many factors can impact or interfere with the sensitivity (probability of obtaining a positive result when sample is truly positive) and specificity (probability of obtaining a negative result when the sample is truly negative). Follow-up assessment with a health care provider should be encouraged to confirm or refute patient-directed test results. provides examples of tests available. Readers are encouraged to refer to the *Handbook of Nonprescription Drugs* for a detailed description of commonly used patient-directed tests.⁴⁷

INTRODUCTION

During the 1990s, the terms “alternative,” “complementary,” “unconventional,” and “integrative” described health care practices that were not commonly taught or practiced by health care providers in the United States.¹ Today, these practices are more widely accepted within the mainstream of care, so the terms “complementary” or “integrative” are most commonly used to describe them. These terms more accurately reflect the combined use of complementary therapies and conventional medicine. Some complementary therapies used today include homeopathy, massage therapy, aromatherapy, acupuncture, acupressure, herbs and supplements, reflexology, and chiropractic care. This chapter focuses on dietary supplements, one of the most common forms of complementary care.^{1,2}

In the United States, the popularity and use of herbs and dietary supplements has increased significantly since 1994. This has led to an estimated \$17.8 billion market for these products. The U.S. Food and Drug Administration (FDA) estimates that there are more than 29,000 different dietary supplements available to consumers, with an estimated 1,000 new products introduced to the market annually. Given the vast demand for these products, consumers need accurate information on their safety and effectiveness so they can make informed choices.

According to one national survey, consumers often do not discuss the use of dietary supplements with their health care providers because they believe their providers know little or nothing about these products and are biased against them.³ This practice can be hazardous if the consumer is self-treating a serious disorder with a dietary supplement for which more effective therapies exist, or if the supplement interacts with a particular medication or exacerbates a disease state. Indeed, nearly 16% of prescription drug users also report having taken a dietary supplement at the same time.⁴ Many consumers believe so strongly in the potential health benefits of certain dietary supplements that they would continue taking them even if they were proven to be ineffective.³ This emphasizes the importance of open communication with patients regarding their health care needs and beliefs and, in particular, their use of these products. One study found that consumers who use alternative health care practices were not necessarily dissatisfied with their medical care.⁵ Instead, alternative health care was more consistent with their way of life and attitudes toward health and living.

This chapter is designed to provide an evidence-based approach and critical analysis of the scientific literature on herbal and other supplements. The quality of the scientific literature in this area varies significantly, in that many studies suffer from flaws in study design, statistical analysis, small sample size, bias, and blinding. When possible, the recommendations made are designed to be in the best interest of the patient. Providing consumers with quality information will help them make educated decisions related to their care.

Although many products are available on the market, this chapter addresses some of the more common herbal and nutritional supplements. A summary of the products reviewed in this chapter appears in Table 3-1.

German Commission E

The prevalence of dietary supplement use in Europe far exceeds that of the United States. Therefore, it is not surprising that one

of the first groups to examine the safety and efficacy of herbal products was established in Germany. In 1978, the German Commission E, an expert panel composed of physicians, toxicologists, pharmacists, pharmacologists, biostatisticians, and others, was assembled by the German Federal Health Agency.⁶ Its purpose was to review the available clinical information on herbs and to determine which ones achieved “reasonable certainty of efficacy and absolute safety.”⁷ More than 300 herbs and herbal combinations were reviewed by the German Commission E, and its findings were published in the German *Bundesanzeiger*, which is similar to the *Federal Register*.⁷ This information was translated and published in English by the American Botanical Council. Today, the German Commission E monographs are used to a limited degree because much more evidence exists in the form of controlled trials for many of the popular dietary supplements.

Dietary Supplement Health and Education Act

In 1994, the U.S. Congress passed a bill that revolutionized the market for nonprescription drugs. The Dietary Supplement Health and Education Act (DSHEA) of 1994 (PL 103-417) was created to regulate dietary supplements: botanicals, vitamins, minerals, tissue extracts, and amino acids.⁸ The DSHEA has special provisions that regulate dietary supplements as foods, removing them from regulation as pharmaceuticals. Manufacturers of dietary supplements can make labeling claims without submitting evidence to the FDA, but they are responsible for the truthfulness of those claims. The FDA cannot remove a product from the market unless the product is proven to pose a serious or unreasonable risk to consumers. In contrast, pharmaceuticals must demonstrate a significant degree of safety and efficacy before they are approved for marketing. These differences have led to the rapid growth of the dietary supplement industry.

The terms used in this chapter to refer to dietary supplements differ from the FDA definition. Herbal remedy (botanical) is used to refer to any product derived from a plant source. Nutritional supplement is used to refer to vitamins, minerals, cofactors, enzymes, amino acids, and others. Despite the legal classifications and variations in nomenclature, dietary supplements are indeed drugs in that they do alter the structure and function of the body for the treatment or prevention of disease.

Product Labeling

Product labeling refers to both the label of the actual product and any accompanying written information. The labeling on a product must conform to the provisions in the Code of Federal Regulations for foods,⁸ which states that the principal display panel (PDP) must contain the name of the product and the contents in net weight. Other information about the product is located on the information panel, usually found to the right of the PDP. Currently, not all supplements on the market conform to these regulations, especially if they are imported from other countries. As of March 23, 1999, specific labeling requirements were required for all products sold as dietary supplements. The rules require manufacturers to include the terms “dietary supplement” as part of the name of the product. For example, vitamin C is sold as “Vitamin C Dietary Supplement.” Ingredient requirements also changed. Products are

Table 3-1 Summary of Herbal Products and Nutritional Supplements Reviewed

| <i>Herbal/Nutritional Supplement</i> | <i>Proposed Indication(s)</i> | <i>Authors' Interpretation of Level of Evidence for Use in a Clinical Setting^a</i> | <i>Dosing</i> |
|--|---|---|--|
| Garlic <i>Allium sativum</i> | Hyperlipidemia Hypertension Antiplatelet Antiatherosclerotic Cancer prevention Antitumor/antiproliferative Antimicrobial Diabetes/hypoglycemia | Promising Doubtful Promising Promising Investigational Unknown Investigational Doubtful | Standardized to contain 1.3% alliin or 0.6% allicin (600–900 mg powdered garlic/day in two to three divided doses) Equivalent to 1.8–2.7 g fresh garlic daily (one clove is approximately 3 g) |
| Ginkgo <i>Ginkgo biloba</i> | Dementia Peripheral vascular disease Stress/anxiety Short-term memory Tinnitus/hearing loss Sexual dysfunction | Promising Promising Unknown Doubtful Promising Investigational | Ginkgo biloba extract standardized to contain 22%–24% flavone glycosides and 5%–7% terpenoid lactones (120–240 mg/day in two or three divided doses) |
| St. John's wort <i>Hypericum perforatum</i> | Mild to moderate depression Antiviral Wound healing (topical) | Promising Investigational Unknown | Alcoholic extract standardized to contain at least 0.3% hypericin or 5% hyperforin (900 mg/day in three divided doses) |
| Echinacea <i>Echinacea purpurea</i> <i>Echinacea pallida</i> | Cold treatment Cold prophylaxis Urinary tract infection (supportive treatment) Wound healing | Promising Doubtful Unknown Unknown | 6–9 mL of <i>E. purpurea</i> fresh-pressed juice or 900 mg/day of <i>E. pallida</i> root (1:5 tincture, 50% ethanol); administer in divided doses (e.g., 15–30 drops of <i>E. purpurea</i> juice equivalent to 0.75–1.5 mL, two to five times daily) |
| Saw palmetto <i>Serenoa repens</i> <i>Panax ginseng</i> | Benign prostatic hyperplasia Adaptogen Ergogenic Immune modulation Anticancer/antitumor Diabetes/hypoglycemia Hyperlipidemia Hypertension/cardiovascular Erectile dysfunction/infertility | Promising Unknown Unknown Promising Promising Promising Unknown Unknown Investigational | Lipophilic extract standardized to contain 85%–95% fatty acids and sterols; 160 mg BID <i>P. ginseng</i> extract standardized to contain at least 7% ginsenosides; 1–2 g of the crude root or its equivalent (1 g of crude root is equivalent to 200 mg of the extract) |
| Glucosamine | Osteoarthritis Wound healing Antioxidant | Promising Doubtful Investigational | 500–1,000 mg TID; 1,500 mg once daily |
| Shark cartilage | Anticancer Antimicrobial | Doubtful Doubtful | 1 g/kg/day or 80–100 g/day given in three divided doses ZGG: 13.3 mg Q 2 hr while awake |
| Zinc | Common cold Allergic rhinitis | Promising Investigational | ZG: 23 mg Q 2 hr while awake ZA: 10 mg Q 2 hr while awake |
| Melatonin | Jet lag Insomnia Reproduction Antioxidant Immune modulation Anticancer Aging Depression | Doubtful Promising Investigational Investigational Investigational Investigational Doubtful Doubtful | <i>Jet lag</i> : 5–8 mg IR the evening of departure and for 3–5 days after <i>Insomnia</i> : 0.3–5 mg once nightly for sleep onset Higher dosages may be required for sleep maintenance |
| Coenzyme Q10 | Hypertension Heart failure | Promising Promising | 100–120 mg daily; given in two to three divided doses 50–150 mg daily in two to three divided doses |

HIV, Human immunodeficiency virus; IR, immediate release; ZA, zinc acetate; ZG, zinc gluconate; ZGG, zinc gluconate-glycine.

^aPromising: A sufficient number of double-blind, placebo-controlled studies have been conducted that indicate an effect may exist.

Investigational: Studies have indicated promising results in animal models or in epidemiologic studies. Small trials in humans may currently be underway.

Unknown: There is an equivalent amount of scientific evidence, which shows both positive and negative results of studies that have been conducted and indicates positive findings but was generally of poor study design, or there is a relative lack of trials that have been performed for this indication.

Doubtful: Studies that have been conducted have generally shown no effect.

required to include a “Supplement Facts” panel similar to the “Nutrition Facts” panels used for many processed foods. The labels contain information on as many as 14 ingredients when present in “significant amounts.” Examples include sodium, calcium, iron, ascorbic acid, and other vitamins and minerals. If the product was derived from a plant, the product identifies the part of the plant used and the Latin binomial. Similarly, for nonherbal dietary supplements, the source of the substance is listed: animal, human, and synthetic. When the ingredients exceed 100% of the dietary reference intake (DRI) for that vitamin or mineral, the product is referred to as high potency. DRI is a general term for nutrient requirements in a population. The DRI differs from the recommended dietary allowance (RDA) in that the RDA is based on individual nutrient requirements rather than population requirements.

The most significant labeling change requires that for each essential nutrient listed on a dietary supplement label, the “% Daily Value” must be provided. The “% Daily Value” is based on the RDA; for example, a supplement containing 60 mg vitamin C is considered to provide 100% of the daily value for adults. However, the problem is that the RDAs are based on 1968 nutrition recommendations. For example, the recommended calcium intake based on the RDA is too low for most adults, including postmenopausal women. For postmenopausal women, the National Institutes of Health recommends 1,200 mg of calcium daily, whereas the RDA for adults is 800 mg. In this example, an 800-mg dose represents 100% of the daily value for calcium. However, based on the new calcium requirements, the value is closer to 67%. The National Academy of Sciences is updating the human nutrient requirements for vitamins, minerals, and antioxidant dietary supplements. Substances such as choline, betaine, glutamic acid, inositol, and botanicals are considered nonessential nutrients for health. These products are added to supplements and are easily identified on a product label that states that the “% Daily Value” has not been established.

Structure-Function Claims

Manufacturers of dietary supplements can make only “structure-function” claims, which describe the role of a supplement intended to affect the structure or function in humans. These claims characterize the documented mechanism by which a supplement acts to maintain such structure or function, provided that such statements are not disease claims. For example, if a supplement claims to increase the release of macrophages, the structure affected is the “macrophage” and the function is “an increase in release.” In this way, the manufacturer is not claiming that the supplement is treating an upper respiratory tract infection. Under the DSHEA, manufacturers who make structure-function claims on product labels must also include the following disclaimer, “This statement has not been evaluated by the FDA. This product is not intended to diagnose, treat, cure or prevent any disease.” Consequently, a product can claim that it “enhances memory,” but it cannot claim that it “treats dementia.” Manufacturers who want to use a structure-function claim must inform the FDA no later than 30 days after the product is marketed. The manufacturer must be able to substantiate the claim, but is not required to submit supporting evidence to the FDA or make the evidence publicly available.

Fraudulent claims are common in the dietary supplement field. Phrases such as “miracle cure” suggest that the product is a cure for a disease, whereas terms such as “detoxify” and “purify” are vague and misleading. The most troubling labeling claims suggest that these products are free of side effects. If a dietary supplement is potent enough to cause a beneficial effect, it is also able to cause a side effect.

Supplement Labeling

Consumers may receive informational leaflets on a particular supplement at the time of purchase. The informational leaflets might consist of an article, a newsletter, a summary, or other written document. The quality of the information provided is not reviewed by the FDA, an expert panel, or other authority. The DSHEA specifies that dietary supplement labeling excludes accompanying written information from regulation when the information (a) is not false or misleading, (b) does not promote a particular manufacturer or brand, (c) is physically separate from the dietary supplement, and (d) does not have other information appended to it.⁸ It is difficult to enforce these provisions. Consequently, the information distributed to consumers may be false, biased, inaccurate, or misleading.

Product Formulations

Herbal remedies come in a variety of formulations, some of which include teas, extracts, oil macerations, and fresh expressed juice or tinctures.

Teas: Infusions, Decoctions, and Cold Maceration

Teas are prepared by drying the herb, which is then marketed in its coarse cut form or in tea bags. In general, tea formulations have not been studied in a randomized, controlled fashion because they are difficult to mask.⁷

Thus, empirical data have been used to establish indications for use.⁷ Teas can be prepared by infusion, decoction, or cold maceration. The most common preparation, infusion, involves steeping the herb in boiling hot water for up to 10 minutes and then straining. To prepare a decoction, the herb is placed in cold water and the combination is heated to a boil, steeped for up to 10 minutes, and then strained. Macerations are prepared by letting the herb stand in water at room temperature for many hours before straining.

Extracts

The term “extraction” is used when a portion of the herb or the entire herb is processed for the purpose of concentration. Extractions are formulated as fluids, powders, solids, and volatile oils. Extraction of the dried herb with ethanol, water, or both is used to make fluid extracts.⁷ Fluid extracts, which use alcohol as a solvent, are further classified as tinctures. Evaporation of the solvent is used to prepare solid and powder extracts.⁷ Either distillation or lipophilic extraction can be used to prepare volatile oils.⁷

Oil Maceration and Fresh-Pressed Juice or Tincture

Oil macerates can be prepared with fresh or dried herbs. In either case, similar to tea macerations, the herb is allowed to stand in oil (e.g., vegetable oil) to macerate at room temperature for many hours before straining. Fresh-pressed juice is prepared by macerating the herb in water and then squeezing

the juice from it.⁷ Fresh herbal tinctures can also be prepared by using an alcohol-based solvent.

Good Manufacturing Practices

In the United States, pharmaceutical manufacturers are required by law to conform to strict standards. Good manufacturing practices (GMPs) were designed to protect consumers from contamination and improper conditions during manufacturing. Dietary supplements are not required by law to conform to the same level of GMPs as pharmaceutical manufacturers. Under the DSHEA, dietary supplements are subject to current GMP in production, packing, or holding human food.⁸ These guidelines include maintenance of buildings and facilities, food handler requirements, and safety standards. Products imported from other countries are more difficult to regulate. Consequently, problems related to product purity, potency, and contamination have been documented in the scientific literature.⁹ Often, neither the distributor nor the consumer have any assurance that product content matches the labeling claims. Adulteration, whether intentional or accidental, is dangerous and puts the public health in jeopardy. In an attempt to begin addressing this issue, the U.S. Pharmacopeia (USP) established a program called the Dietary Supplement Verification Program (DSVP). This program helps establish ingredient quality and other standards unique to herbs and dietary supplements. Participation in the program is voluntary. Manufacturers who meet the DSVP criteria will be allowed to carry the USP-certified seal on their labels. This will help consumers distinguish a particular manufacturer's product as having the highest quality standards for content. Other organizations have established similar programs including Consumer Lab and the National Sanitation Foundation. Importantly, none of these programs address issues of pharmacologic safety or efficacy.

In 2007, more than 10 years after the DSHEA was enacted, the FDA issued a final rule on proposed changes to dietary supplement GMPs. The proposed changes in GMPs standards came after significant pressure from stakeholders and consumers. Among the various changes, dietary supplements must now be manufactured in a quality manner, without contaminants or impurities, and need to be labeled accurately. These changes in GMPs will indeed help better regulate manufacturing. To allow manufacturers time to comply, a long phase-in period has been developed. Larger supplement manufacturers are required to comply by June 2008 and smaller manufacturers by 2009 or later. In response, manufacturers have expressed concern regarding the cost of these changes, which may mean that these added costs are likely be passed on to the consumer.

One of the most important changes to the supplement industry involves the Dietary Supplement and Non-Prescription Drug Consumer Protection Act (PL 109-462), which was signed into law on December 22, 2006. This law requires manufacturers, packers, or distributors of dietary supplements to submit serious adverse event reports to the FDA based on specific information that they receive from the public. Under this law, serious adverse events may include death, a life-threatening situation, an inpatient hospitalization, a persistent or significant disability or incapacity, or a congenital anomaly or birth defect, or one that requires medical or surgical intervention to prevent such serious outcomes (based on reason-

able medical judgment). This law will help better characterize the frequency at which serious adverse events associated with herbs and supplements are reported. More important, it may help alert the FDA to serious adverse event trends so appropriate corrective action may be taken.

Given the popularity of dietary supplements, unscrupulous companies have attempted to cut costs through product adulteration. This is especially true of herbs that are expensive to acquire or that take years to cultivate. As a consequence of adulteration, the product could fail to have the desired effect, could cause serious side effects, or could interact with other drugs. Although some of the hazards may be mitigated by the new GMP requirements, some hazards may endure, including those related to the appropriate cultivation and accurate identification of botanicals.

Herbal Hazards

Consumers sometimes believe that "natural" products available without a prescription must also be safe.¹⁰ Often, this is not the case because hazards can be introduced during the collection and manufacturing process or, unknowingly, by the patient. Other hazards can result from toxic components within the herb.

Manufacturing Hazards (Adulteration)

In some cases, substances that do not appear on the package labeling may be introduced into a product, either deliberately or by accident. For example, plant misidentification resulted in renal failure in up to 100 women who ingested a Chinese herbal diet aid. In this case, *Stephania tetrandra* was replaced with a nephrotoxic herb, *Aristolochia fangchi*.¹¹ Similar cases of misidentification have resulted in digitalis poisoning.¹²

High levels of heavy metals (e.g., lead, mercury, arsenic) have been observed in some traditional Chinese and Ayurvedic (Indian) herbal remedies.^{13,14} A recent survey of 260 Asian products distributed in the United States revealed that high levels of heavy metals or adulterants were present in 83 products (32%).⁹ In these cases, the amounts exceeded the recommended maximum amounts set by the USP. Heavy metal toxicity has resulted in cases of anemia, hepatitis, and death.^{13,14}

There are many reports of toxicity caused by adulterated products. In the United States, an outbreak of eosinophilic myalgia syndrome occurred in patients using the nutritional supplement L-tryptophan.¹⁵ An aniline-derived contaminant was later found to be the cause. Cases of digitalis poisoning prompted the chemical analysis of an herbal product advocated for bowel cleansing. *Digitalis lanata* was isolated from the plantain (plantago) portion of the product.¹¹ Adulteration of herbal remedies with prescription drugs such as diazepam, non-steroidal anti-inflammatory drugs (NSAIDs), hydrochlorothiazide, and steroids has been observed as well.¹⁶

Direct Hazards: Products to Avoid or Use Cautiously

Products associated with severe adverse reactions are listed in Table 3-2.¹⁷⁻²⁶ Herbs containing pyrrolizidine alkaloids generally should be avoided because they are metabolized to pyrroles, which are hepatotoxic. Ephedrine and ephedrine-containing products can increase the risk of stroke, myocardial

Table 3-2 Hazards Associated With Some Nutritional Supplements

| Supplement/Latin Binomial | References | Associated Clinical Use ^a | Toxicity | Recommendation |
|---|---------------|---|---|--|
| Comfrey rhizome, roots, leaves <i>Symphytum</i> spp. | 6, 10, 17, 18 | Internal digestive aid External wound healing | Pyrrrolizidine alkaloids— hepatotoxicity | Avoid ingestion. External application only. Limit use to 4–6 wk. Do not use on unbroken skin. |
| Coltsfoot flower, leaves <i>Tussilago farfara</i> | 6, 10, 17 | Upper respiratory tract infections | Pyrrrolizidine alkaloids— hepatotoxicity | Avoid herb, root, or flower products. Leaf can be used as an external anti-inflammatory agent. Limit use to 4–6 wk. |
| Germander leaves, tops <i>Teucrium chamaedrys</i> | 10, 17, 19 | Diet aid | Hepatotoxicity | Avoid |
| Borage leaves, tops <i>Borago officinalis</i> | 6, 10, 17 | Anti-inflammatory, diuresis | Pyrrrolizidine alkaloids— hepatotoxicity | Avoid |
| Chaparral leaves, twigs <i>Larrea tridentata</i> | 10, 17, 20 | Anti-infective, antioxidant, anticancer | Hepatotoxicity | Avoid |
| Sassafras root bark <i>Sassafras albidum</i> | 17 | Tonic, blood thinner | Safrole oil— hepatocarcinogen in animal studies | Avoid |
| Aconite (found in some Chinese herbal remedies) <i>Aconitum</i> spp. | 21 | Analgesic | Alkaloids—cardiac and central nervous system toxicity | Avoid |
| Kava <i>Piper methysticum</i> | 22 | Anxiety | Hepatotoxicity | Avoid |
| Pennyroyal extract from <i>Mentha pulegium</i> or <i>Hedeoma pulegoides</i> | 10, 23 | Digestive aid, induction of menstrual flow, abortifacient | Pulegone and its metabolite—hepatic and renal failure | Avoid |
| Life root, whole plant <i>Senecio aureus</i> | 17 | Induction of menstrual flow | Pyrrrolizidine alkaloids— hepatotoxicity | Avoid |
| Poke root, root of plant <i>Phytolacca americana</i> | 17 | Antirheumatic | Hemorrhagic gastritis | Avoid |
| Jin Bu Huan (a Chinese herbal remedy) | 24 | Analgesic, sedative | Hepatotoxicity— mechanism unknown, but levotetrahydropalmatine is structurally similar to pyrrrolizidine alkaloids | Avoid |
| Aristolochic acid <i>Aristolochia</i> spp. | 24 | Weight loss | End-stage renal failure | Avoid |
| Ephedra ma huang, <i>Ephedra</i> spp. | 27 | Weight loss, stimulant, bronchodilation | Extension of pharmacologic effects | Avoid use in patients in whom stimulant effects could be harmful (e.g., hypertension, diabetes, heart disease, anxiety, hyperthyroidism) |
| Royal jelly from the honeybee (<i>Apis mellifera</i>) | 25 | Tonic | IgE-mediated bronchospasm, and anaphylaxis in patients with atopy or asthma | Avoid use in patients with history of asthma, atopy, or allergies |
| Guar gum <i>Cyamopsis psorabides</i> or <i>tetragonolobus</i> | 10, 26 | Weight loss, diabetes, hypercholesterolemia | Esophageal, small bowel obstruction | Avoid |

^a Associated clinical use is based on patient report at time of event or reported use in listed references.

infarction (MI), and seizures. Many cases of adverse events, including fatalities in otherwise healthy adults, have prompted several countries and individual states to ban the sale of ephedra-containing products. Currently, ephedra-containing products carry a warning indicating the risks in people with certain health conditions.²⁷

Hazards Introduced by the Consumer

Consumers should not exceed the doses recommended on the package label because overuse may lead to toxicity. Indirect toxicity can occur if consumers attempt to self-treat serious disorders. In general, dietary supplements should not be used to

treat cancer or serious infection if more effective therapies exist. However, if the patient is terminally ill and the supplement provides relief, use may be justified. Use during pregnancy, during lactation, or in children should also be avoided because the products have not been adequately studied for safety in these vulnerable patient populations.

Patient Recommendations

General recommendations regarding the use of herbal products are outlined in Table 3-3. These may be used when counseling patients on product selection and appropriate use. Many of

Table 3-3 Guidelines for Selecting or Recommending on Herbal Remedy or Dietary Supplement Product

- Read all labels carefully.
- Never share these products with others.
- Avoid using in children.
- Avoid if you are pregnant, nursing, or trying to become pregnant.
- Never take more than the recommended amount listed on the label.
- Do not select a product that does not have dosing recommendations on the label.
- Avoid products that do not carry a lot number or expiration date.
- Discard products 1 year from the date of purchase when no other expiration date present.
- Select products that list the manufacturer's name, address, and telephone number.
- Speak to your health care professional if you are trying to treat a life-threatening condition, such as cancer or HIV.
- If you are taking a prescription medicine, do not take an herbal remedy or dietary supplement for the same condition.
- Avoid taking multiple-ingredient preparations; select single-ingredient products that list the strength per dose.
- Do not store these products in a medicine cabinet or glove compartment; store them in a dry environment out of direct sunlight and humidity.
- The term "natural" does not mean safe; be diligent and report any unusual experiences to your doctor or pharmacist.
- Store products away from young children and pets.
- Always inform your health care provider of the products you are taking; keep a list if necessary or bring them with you to your appointment.
- Do not take these products with alcohol until you know it is safe to do so or are familiar with the effects.
- Check with your health care provider if you are taking "blood thinning" drugs; some products may interact.
- Never use these products in place of proper rest and nutrition; eat a balanced diet.
- Do not expect a cure or unrealistic results; these agents are not "cure-alls."
- If it sounds too good to be true, it probably is; use discretion when evaluating claims.

the recommendations are conservative because data on quality, safety, and efficacy of these products, specifically in special patient populations, are unavailable. These recommendations are not intended to promote use, but rather to educate patients and practitioners. Each decision should be made on an individual basis with the best interest of the patient in mind.

GARLIC (*ALLIUM SATIVUM*)

Garlic Formulations

1. M.J., a 65-year-old obese man, is concerned about his cholesterol and wants to start taking garlic. What types of commercial preparations are available, and how is garlic standardized? Which formulations are preferred?

Preparations of Garlic and Active Constituents

A variety of organosulfur compounds in garlic have been reported to have therapeutic effects. Fresh bulbs contain all of these compounds, but their potency varies depending on how the plant was grown, harvested, and stored. The type and amount of organosulfur compounds in commercial preparations also varies based on the manufacturing process.²⁸

Di-allyl-disulfide-oxide, or allicin, is responsible for the characteristic odor of garlic, and some garlic products (e.g., dried garlic powders) may be standardized to this ingredient or its precursor, alliin. Specifically, when bulb garlic is crushed, chewed, or chopped, the odorless precursor, S-allyl-L-cysteine sulfoxide, or alliin, is exposed to the enzyme allinase, and allicin and other thiosulfinates are formed.²⁹ Allinase is a very unstable enzyme that can be destroyed by heat and stomach acid.²⁸ Allicin is oil soluble and highly volatile, and is easily converted into the other odorous oil-soluble compounds: diallylsulfides (DASs), vinyl dithiins, and ajoenes.²⁸

There are four main types of commercial garlic products, and their content is based on how they are prepared. Dried garlic powders contain both water and oil-soluble organosulfur

compounds, and will likely be standardized to alliin content or state an allicin-generating capacity on the packaging.^{7,28} Enteric coating of powdered formulations may prevent allinase degradation in the stomach and improve allicin release into the small intestine, minimizing the odor.²⁹ Powdered formulations have been widely studied in clinical trials. The most common was standardized to 1.3% alliin or 0.6% allicin (based on allicin-releasing ability).⁶ Oil-based preparations that have been steam distilled contain oil-soluble DASs, but no water-soluble compounds.²⁸ Macerated oil preparations, which are made without heating, contain oil-soluble DASs, vinyl dithiins, and ajoenes.²⁸ Both steam-distilled oil preparations and macerated oil preparations have been poorly studied in clinical trials. Fermented or aged garlic extracts, which are odor free, predominantly contain water-soluble compounds such as S-allylcysteine (SAC) and may carry standardization for this compound.^{7,28} Aged garlic extracts have also been studied in clinical trials.

Consumers wanting to use garlic can begin by adding it to their diet. Those who want to use a supplement are best advised to choose a product that has been studied in clinical trials and demonstrated benefits in one or more therapeutic areas. These would include standardized powdered garlic or standardized aged garlic extract.

Antihyperlipidemic Effects

2. M.J. weighs 105 kg and is 6 ft tall. He rarely exercises and eats a diet high in fat; his medication profile indicates that he has been taking benazepril (Lotensin) 10 mg PO daily for 2 years. M.J.'s doctor has recommended a diet and exercise program. On questioning, he recalls his cholesterol values from last month: total cholesterol, 290 mg/dL; high-density lipoprotein cholesterol (HDL-C), 30 mg/dL; low-density lipoprotein cholesterol (LDL-C), 230 mg/dL; and triglycerides (TG), 150 mg/dL. Can garlic significantly improve M.J.'s lipid profile?

Many studies have examined the lipid-lowering effects of garlic, but only a few have included sample sizes of more

than 100 subjects.^{30,31} For this reason, the antihyperlipidemic properties of garlic are largely based on published meta-analyses.^{32,33}

A meta-analysis and systematic review suggests a small but favorable effect of garlic on hyperlipidemia, lowering total cholesterol by 4% to 6%. In the presence of dietary controls, however, this effect became insignificant.³² Trials varied in the type of garlic product used and in the duration of treatment. The most common formulation was a dried powdered preparation known as Kwai. Studies that lasted up to 12 weeks showed significant reductions in total cholesterol; however, these benefits became insignificant at 20 to 24 weeks.^{32,33} It was initially hypothesized that variations in efficacy seen in more recent trials may be related to the poor allicin-releasing ability of some powdered formulations marketed after 1993.²⁹ This notion, however, was dispelled with the results of a recent clinical trial.³⁰ This trial randomized 192 adults with a baseline LDL-C of 130 to 190 mg/dL to receive either 4 g of raw garlic, 1,400 mg of standardized powdered garlic with proven allicin-releasing ability (Garlicin), 1.8 g of aged garlic extract (Kyolic), or placebo for 6 months. None of the garlic groups had significant benefits on LDL-C as compared to placebo at the study end point.

Mechanism of Action

In vitro inhibition of hepatic 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase has been observed and is considered the primary mechanism for garlic's antihyperlipidemic action.³⁴ Inhibition of later steps in cholesterol synthesis has also been observed, but this effect requires garlic concentrations exceeding those achieved with normal or long-term human consumption.³⁴ Garlic also has multiple organosulfur compounds that act as antioxidants and could be beneficial in preventing oxidation of LDL-C.³⁵ Whether these mechanisms apply in humans remains uncertain.

3. Is M.J. a candidate for garlic?

M.J. should be advised that dietary modification and exercise are the best ways to reduce cholesterol without pharmacotherapy. His high total cholesterol and LDL-C and low HDL-C are not likely to be significantly lowered by the limited effect, if any, of garlic. As already noted, the benefits of garlic remain questionable because only small numbers of patients have been evaluated. Furthermore, its benefit in people who are already modifying their diets may be insignificant.

Hypotensive Activity

4. M.J. decides to purchase garlic and tells you that he will also begin the diet and exercise plan his doctor recommended. M.J. is taking benazepril (Lotensin) for hypertension. Do you have any additional questions or concerns?

Although there have been no drug–drug interactions reported for garlic and benazepril, M.J. should be aware that a few trials have reported a lowering of blood pressure (BP) following garlic use. Overall, however, it is unlikely that the effects of garlic on BP are clinically meaningful, so M.J. should not have to monitor his BP more often than usual after initiating a garlic supplement.

A review of 30 randomized controlled trials measuring BP outcomes concluded that although several trials reported significant reductions in BP using within group comparisons with at least 4 weeks of use, statistical significance was only achieved in three trials when compared to placebo. Among these three trials, the systolic blood pressure (SBP) was reduced by approximately 3% and the diastolic blood pressure (DBP) by 2% to 7%.³³ Stimulation of nitric oxide (NO) synthesis (a potent vasodilator), inhibition of angiotensin-converting enzyme, and reductions in intracellular calcium have all been observed in vitro and may be responsible for this effect.^{36–38}

Antiatherosclerotic Effects

5. T.L. is a 70-year-old man with a history of coronary artery disease (CAD) and peripheral vascular disease. He began taking warfarin (Coumadin) after a stroke 2 months ago. His other medications include metoprolol (Lopressor) 50 mg PO daily, simvastatin (Zocor) 20 mg PO daily, and isosorbide dinitrate (Isordil) 20 mg PO TID. T.L.'s friend told him that garlic might help his heart condition. Is there any evidence that garlic is beneficial in treating CAD?

The antiatherosclerotic effects of garlic are largely based on its potential to reduce coronary risk factors of hyperlipidemia, hypertension, platelet aggregation, LDL-oxidation, and fibrin formation (see question 6). Reductions in atherosclerotic lesions, atherosclerotic cell proliferation, aortic collagen accumulation, and vascular damage caused by oxidized LDL have been observed in garlic-treated animals fed a cholesterol-rich diet.³⁸

Only a few clinical trials have evaluated the effect of garlic in patients with CAD.^{39–41} A double-blind, placebo-controlled trial randomized patients with advanced atherosclerotic plaques and at least one risk factor for CAD to receive 900 mg/day of powdered garlic or placebo. At 2 years, plaque volume in the carotid and femoral arteries was significantly reduced by 5% to 18% in the treatment group.³⁹ A small pilot trial also demonstrated a reduction in the progression of coronary calcification (a marker of atherosclerosis progression) in patients who received aged garlic extract and statin therapy as compared to placebo and statin therapy over the course of 1 year.⁴⁰

Antiplatelet and Thrombolytic Effects

6. You inform T.L. that garlic may reduce coronary risk factors for CAD, but that its effectiveness in treating CAD has not been adequately studied in humans. Nevertheless, T.L. wants to take garlic. Do you have any concerns about T.L.'s use of garlic given his current medication profile?

Studies evaluating the effects of garlic on platelets have generally observed a decrease in platelet aggregation.^{33,38,41} Significant increases in fibrinolytic activity have also been observed in some trials with chronic ingestion of garlic for ≥ 14 days.^{33,38} Serum fibrinogen levels, however, do not appear to be significantly altered.³³ Small sample size, use of variable garlic preparations, and variable study duration have made drawing definitive conclusions from these studies difficult.

Mechanism of Action

Allicin and adenosine have antiplatelet effects *in vitro*.^{42,43} However, because both of these compounds are metabolized *in vivo*, antiplatelet effects have been attributed to DASs, particularly diallyltrisulfide (DATS) and ajoene,^{42,43} although ajoene is unlikely to play a role when fresh or powdered preparations are used.⁴² These metabolites may inhibit thromboxane formation and platelet aggregation in response to various activating factors, such as collagen, adenosine diphosphate, and epinephrine.^{41,43} Stimulation of NO synthesis may also play a role because NO is a potent inhibitor of platelet aggregation and adhesion.³⁶

In summary, T.L. should be told that garlic might increase his risk for bleeding. He should be advised not to initiate garlic supplements because he is currently taking warfarin. A few cases of increased international normalized ratios (INRs) have been reported in patients stabilized on warfarin who initiated garlic supplements. If T.L. still wants to try garlic, he should watch for signs and symptoms of bleeding, and have his INR tested within a few weeks of initiating the product.

Other Effects of Garlic

Anticarcinogenic/Antitumor Effects

Several epidemiologic case control studies have reported a reduced incidence of stomach, esophageal, and colorectal cancers in patients who consumed high amounts of raw, cooked, or both raw and cooked garlic as a food.⁴⁴ A meta-analysis also supported the effect of consuming garlic and a reduced incidence of both stomach and colorectal cancers with a relative risk estimate of 0.54 and 0.67, respectively.⁴⁵ Interestingly, one of the largest studies to examine the use of garlic supplements as opposed to garlic foods did not find a protective cancer benefit. Specifically, 120,852 Netherlanders, ages 55 to 69 years, were followed for 3.3 years for the development of cancer. Overall, there was no association between garlic supplement use and a lower risk of lung, breast, or colorectal cancer.⁴⁵

In vivo animal studies looking at the anticarcinogenic properties of garlic have focused on the water-soluble constituent, SAC, and the lipid-soluble diallylsulfide (DAS) constituents, particularly DAS, diallyldisulfides (DADS), and DATS.^{44,46} *In vivo* animal studies show inhibition of procarcinogens for multiple cancer types (e.g., colon, skin, breast, esophagus, lung, liver, renal) using DAS or DADS.⁴⁴ Mechanisms of cancer prevention observed for garlic constituents include enhanced activity of phase II detoxification enzymes such as glutathione-S-transferases, which aid in the detoxification of carcinogens, and decreased activity of phase I drug-metabolizing enzymes such as cytochrome P450, involved in carcinogen activation.^{44,46} Inhibition of DNA adduct formation, antioxidant effects, and induction of apoptosis are other mechanisms that have been observed.⁴⁴ *In vitro* garlic also inhibited the growth of *Helicobacter pylori*, a known risk factor in the development of stomach cancer.⁴⁶

Tumor growth inhibition has been observed *in vitro* and in animal models with garlic constituents.^{46,47} A review of studies involving the antiproliferative effects of garlic in animals speculated that usefulness in humans would be limited based on the difficulty in controlling the growth of established tumors and the small numbers of cells that could be inhibited.⁴⁷

Whether the concentrations of garlic constituents used to inhibit tumor growth could be achieved or tolerated in humans is also of concern.

Anti-Infective Effects

Garlic has antibacterial, antifungal, antiprotozoal, and antiviral properties *in vitro*.^{48,49} Allicin has been identified as the primary anti-infective component.⁴⁸ Today, the availability of potent antimicrobials limits the use of garlic as an anti-infective in industrialized countries.

Antidiabetic/Hypoglycemic Effects

Some studies have reported that garlic has a hypoglycemic effect.³³ However, others, including two trials in patients with type 2 diabetes mellitus, failed to find an effect.³³ Until further research confirms a consistent effect on blood glucose, garlic should not be used to treat diabetes. Furthermore, patients with diabetes who take garlic need not monitor their blood sugar more frequently than normal.

Adverse Drug Reactions/Drug Interactions

An observational study of 2,010 patients taking 900 mg/day of garlic for 16 weeks found the following incidence of side effects: 6% nausea, 1.3% hypotension, and 1.1% allergy.⁷ A dose-ranging study of the odiferous effects of enteric-coated garlic found that 14 days of garlic, 1,200 mg, resulted in a 50% incidence of perceived odor. Doses of 300 to 900 mg were associated with a 36% to 45% incidence of perceived odor, respectively.⁷

Contact dermatitis has been reported most often in people who frequently handle raw garlic (e.g., cooks, farmers).⁵⁰ The reaction is preceded by an eczematous rash, followed by the potential for desquamation and hyperkeratosis of the palms.⁵⁰ Rarely, allergic conjunctivitis, allergic rhinitis, and bronchospasm have been reported.⁷

The antiplatelet effects of garlic have been cited as a risk factor for postoperative bleeding.^{51,52} A case report of a spinal epidural hematoma in a previously healthy patient suggested that the patient's use of four cloves per day of raw garlic may have been the cause.⁵² Patients should be advised to avoid garlic 7 to 10 days before and after surgery.

There have been few reported drug-drug interactions between garlic and other medications. As already noted, patients taking anticoagulants and BP medications should be monitored closely. A 50% reduction in the bioavailability of saquinavir also has been reported.⁵³ Ritonavir, however, was not similarly affected.⁵⁴

Pharmacokinetics and Dosing

In healthy adults who consumed 500 mg of aged garlic extract (Kyolic), peak plasma SAC levels were detected 1 hour after administration. The half-life and excretion times for SAC were 10 and 30 hours, respectively.⁵⁵ In a separate study, N-acetyl-S-allyl-L-cysteine was detected in the urine of healthy adults who consumed 200 mg of powdered garlic extract (Kwai).⁵⁶

Patients wanting to reduce the possibility of garlic odor should purchase an enteric-coated formulation. A daily dosage of 600 to 900 mg of powdered garlic in two to three divided doses is recommended.⁷ A dose of 900 mg of powdered garlic

is equivalent to 2.7 g or 1 clove of fresh garlic per day. Products should be standardized for alliin or allicin content if they are powdered. The recommended standard is an alliin concentration of 1.3% or an allicin content of 0.6%. Aged garlic extracts may indicate that they are standardized by SAC content on the package label, but no accepted percentage standard has been established.

GINKGO (*GINKGO BILOBA*)

Neuroprotection

7. E.B., a 22-year-old woman, comes to the pharmacy to purchase *G. biloba* for her 80-year-old grandmother. E.B.'s grandmother has difficulty recalling past events and often becomes disoriented and anxious. Her grandmother was recently diagnosed as having cerebral insufficiency (CI) secondary to early Alzheimer disease (AD), but the neurologist suggested waiting before initiating donepezil (Aricept) because she has a history of low BP and dizziness when standing. E.B. heard that *G. biloba* may be helpful for patients with AD. Her grandmother's medications include aspirin 325 mg PO daily and buspirone (BuSpar) 2.5 mg PO TID. Do any clinical data demonstrate *G. biloba*'s efficacy in the treatment of AD?

CI includes a variety of clinical symptoms, some of which can include confusion, poor concentration and memory, forgetfulness, fatigue, depression, anxiety, vertigo, tinnitus, and hearing loss.⁵⁷ Many of these symptoms are said to be relieved by *G. biloba* extract (GBE). Studies using GBE for CI conducted before 1991 assessed efficacy based on improvements in clinical symptoms and tests designed to assess cognitive improvement.⁷ In 1991, the German Commission E developed new criteria for evaluation of nootropic (i.e., cognition-enhancing) therapies. It recommended that clinical improvement be based on three distinct levels of observation involving (a) patients' and families' impression of effect on daily living, (b) objective testing of cognitive performance, and (c) clinicians' impressions of symptomatic improvement.⁷ Newer clinical trials have met this recommendation by using the following standardized outcome measures, respectively: the Geriatric Evaluation by Relatives Rating Instrument, the standardized Alzheimer's Disease Assessment Scale for cognition (ADAS-cog), and the Clinical Global Impression of Change (CGIC) scale.⁷

The most recent systematic review and meta-analysis of ginkgo for patients with dementia or cognitive decline was published in 2002.⁵⁷ Only randomized, double-blind controlled trials that compared ginkgo to placebo and involved patients with acquired cognitive impairment or any severity of dementia were included. Thirty-three trials were included and ranged in length from 3 to 52 weeks. All but one study used a standardized ginkgo extract (i.e., 24% flavone glycosides and 6% terpene lactones), and most used a daily dose of 200 mg or less (range 80–600 mg/day). Small but significant improvements in the ADAS-cog were observed for doses <200 mg at 12 and 52 weeks and for any dose at 12 and 24 weeks. Small but significant improvements were also noted for activities of daily living (ADL) for doses <200 mg at 12, 24, and 52 weeks. The CGIC scale was associated with significant

benefits at doses <200 mg at 12 weeks and doses >200 mg at 24 weeks.

A large-scale trial comparing the efficacy of ginkgo to an acetylcholinesterase inhibitor for Alzheimer dementia has yet to be conducted. A small three-arm trial did compare 160 mg GBE, 5 mg donepezil, or placebo, and showed significant and equivalent benefits for both treatment arms compared to placebo.⁵⁸ However, a Cochrane Collaboration meta-analysis that looked at efficacy based on cognitive function changes, found that ginkgo was less effective than prescription donepezil, rivastigmine, and galantamine.⁵⁹

Current research is aimed at determining the preventative potential of ginkgo in dementia. Two large-scale prevention trials are underway with results expected in 2010: the Ginkgo Evaluation of Memory study and the GuidAge study.^{60,61} These studies will attempt to address whether use of a standardized ginkgo extract can delay the mean time to onset of Alzheimer dementia and delay the advancement of cognitive decline in persons age 70 years or older who have either mild cognitive impairment or have consulted a physician for a memory complaint. Both trials will include approximately 3,000 people and last 5 or more years.

8. Is E.B.'s grandmother a candidate for GBE? If so, how long should therapy be continued?

E.B.'s grandmother has been diagnosed with AD of mild severity. Clinical studies suggest that GBE may have some benefit for dementia of mild to moderate severity, but further research should be conducted to firmly establish efficacy. GBE is an option for E.B.'s grandmother, but her primary care provider should be informed if she initiates therapy. The optimal dosage and duration of therapy is unknown, but no significant adverse events have been noted in studies that have treated subjects with GBE for up to 1 year.⁵⁷

Mechanism of Action

9. What are the proposed mechanisms of action for the neuroprotective effects of *G. biloba*?

Cerebral ischemia, oxidative stress, and neuronal degeneration are believed to be involved in the pathogenesis of dementia and dementia of the Alzheimer's type. A prominent feature of AD is the development of neuritic plaques and neurofibrillary tangles in the areas of the brain that control cognition and emotion. Neurochemical imbalances also develop as cholinergic, adrenergic, and gamma-aminobutyric acid (GABA)-aminergic neurons are lost.⁶²

The mechanism of *G. biloba*'s action as a neuroprotective agent has been examined in many in vitro and some in vivo studies. Potential mechanisms include improved blood flow, antioxidant effects, antagonism of platelet-activating factor (PAF), alterations in neurotransmitter concentrations and binding sites, and inhibition of amyloid-beta (Aβ) fibrils.^{63–68} If GBE can decrease inflammation and improve blood flow through PAF antagonism, decrease oxidation through its antioxidant and radical scavenging properties, affect neurotransmission in humans as it does in animals, and inhibit the aggregation and toxicity of Aβ fibrils, it may be clinically meaningful for patients like E.B.'s grandmother who have AD.

Preparations and Active Constituents

10. E.B.'s grandmother loves tea. Will a tea formulation of *G. biloba* be beneficial?

G. biloba is prepared from the leaves of the Ginkgo tree.⁶ The active constituents include a flavonoid fraction (kaempferol, quercetin, and isorhamnetin) and a terpene fraction (ginkgolides A, B, C, J, and M, and bilobalide).⁶³ These compounds require concentration for optimal potency. The German Commission E recommends an herb:extract ratio of 50:1, which means that 50 parts of ginkgo leaf are used to generate 1 part of extract.⁷ Extracts should be standardized to contain 22% to 27% flavone glycosides and 5% to 7% terpene lactones.⁷ Although crude leaf teas are available, they are unlikely to be beneficial because of their low potency. Standardization for flavones and terpenes should be indicated on the package labeling.

Stress and Anxiety

11. E.B.'s grandmother is taking buspirone (BuSpar). Can GBE be used as a substitute for buspirone to treat her anxiety?

GBE has exhibited physiological stress-relieving properties in rodent models that differ from those of classic anxiolytics and antidepressants.⁶⁷ In rats, an 8-day treatment of GBE reduced corticosterone synthesis by reducing adrenal peripheral-type benzodiazepine receptor expression. This receptor has been linked to the stress response through enhanced steroid production.⁶⁷ In humans, exposure to physiological or psychological stress can result in steroid production. GBE may control the stress response by minimizing this elevation in steroids and promoting a more “normal” circulating corticosteroid level. GBE may improve cognitive deficiency, and anxiety is considered one of many symptoms associated with cognitive deficiency.

A recent randomized, double-blind, placebo-controlled study of GBE in generalized anxiety disorder (GAD) and adjustment disorder with anxious mood (ADWAM), also suggests significant benefits for both disorders.⁶⁹ In this study, 170 patients with GAD or ADWAM received placebo, GBE 480 mg, or GBE 240 mg for 1 month. Intention-to-treat analysis on the Hamilton Rating Scale for Anxiety (HAMA) showed significantly lower HAMA scores for both treatment groups compared to placebo and a significant dose–response effect.

Despite promising results of this former study, few trials have evaluated GBE as a monotherapy for GAD, and no trials have compared it to a benzodiazepine or buspirone. Therefore, GBE should not be used as a substitute for buspirone in E.B.'s grandmother. The potency and effectiveness of GBE as an anti-anxiety or antistress agent need to be studied further before it can be recommended for this indication.

Intermittent Claudication

12. E.B.'s grandmother has always had a problem with “poor circulation” in her legs, which limits her ability to walk. Will *G. biloba* help this problem?

Although GBE may improve vascular insufficiency through enhanced blood flow, there is less literature to support its

use for complications of peripheral arterial occlusive disease (PAOD) than there is for dementia.⁷ Two recent meta-analyses involving eight and nine randomized, double-blind, placebo-controlled trials evaluated GBE for intermittent claudication, a painful symptom of PAOD. Both concluded that GBE was more effective than placebo at improving pain-free walking distance.^{70,71} The weighted mean improvement in walking distance for GBE versus placebo was approximately 34 m. Effective dosing ranged from 120 to 160 mg/day for 24 weeks.

The clinical effect of GBE has been compared with the prescription drug, pentoxifylline (Trental). One meta-analysis suggested the improvement in pain-free walking distance was comparable, with an increase of 45% for GBE and 57% for pentoxifylline.⁷² However, this analysis is disputed by another one in which GBE improved pain-free walking distance by 32 m versus 138 m for pentoxifylline.⁷³ In summary, GBE may enhance E.B.'s grandmother's ability to walk longer distances.

Pharmacokinetics, Dosing, and Onset

13. What are the pharmacokinetic characteristics of GBE? What dose should be recommended for E.B.'s grandmother? When can beneficial effects be expected?

Pharmacokinetic parameters have been reported for the flavonoid fraction of ginkgo, ginkgolides A and B, and bilobalide.⁷⁴ Kinetics for the ginkgolides and bilobalide were determined following a single 80-mg oral dose of GBE. Single-dose kinetics for the flavonoid fraction were determined following the oral administration of equivalent doses of GBE (dose not stated) in capsules, drops, or tablets.⁷⁴ All GBE constituents studied were well absorbed (>60%) and reached peak concentrations within 1 to 3 hours. Half-life ranged from 2 to 6 hours for all constituents. Studies in animals identified many routes of clearance: 38% appeared in expired air, 22% in urine, and 29% in feces.

The recommended dosage of GBE is 120 to 240 mg/day taken orally in two to three divided doses.⁷ GBE is available as 40-, 60-, and 120-mg capsules or tablets. Studies in patients with CI suggest that clinical benefits may not be observed for 4 to 6 weeks.

Adverse Drug Reactions/Drug Interactions

14. Should E.B. be warned of any adverse effects or drug interactions with GBE?

Adverse effects associated with GBE are minimal. An evaluation of >10,000 individuals who took GBE for at least 3 months found that only 183 patients (1.69%) reported adverse events.⁷ All reported side effects occurred with a frequency of >0.5%. Ranked in order from the most to the least common, they included nausea, headache, stomach upset, diarrhea, allergy, anxiety, and insomnia.⁷

Case reports suggest an association between GBE use and the development of hemorrhage, especially when used in combination with aspirin or warfarin (Coumadin).^{75,76} Patients should be monitored for bleeding when taking antiplatelet or anticoagulant medications based on these case reports and discontinue ginkgo at least 7 to 10 days before or after surgery. E.B.'s grandmother should not use ginkgo in combination with

aspirin. Ginkgo should also be avoided in patients with a history of epilepsy or seizures. Case reports of seizures associated with ginkgo are likely due to product contamination with ginkgo seeds, which are known to contain an epileptogenic neurotoxin.⁷⁷ Coma has occurred following the use of ginkgo in combination with trazodone (Desyrel).⁷⁸

Short-Term Memory

15. C.S. is a college student and has a big test in 4 days. Can GBE improve her memory?

A number of randomized, double-blind, placebo-controlled studies in healthy young (age 20–30 years) and older (age older than 50 years) adults have looked at the effect of GBE on memory.^{79–82} In general, improvements were undetectable, inconsistent, and limited to a small fraction of cognitive tests.^{79–81} Some argue that beneficial effects, even though limited, seem more likely to occur following acute administration of very high doses of GBE (e.g., one 360–600-mg dose) in young adults or chronic administration of lower doses (<200 mg/day) in older adults. A recent systematic review involving seven single-dose and eight chronic-dose randomized clinical trials in healthy adults (without cognitive impairment) concluded that ginkgo was not effective for memory enhancement.⁸²

C.S. should be informed that GBE is unlikely to improve her memory for her upcoming examination. Its benefits on memory are limited to persons with mild cognitive impairment or Alzheimer dementia.

Other Indications

16. What other conditions might be improved by the use of GBE?

GBE has been used for several other conditions, but in most cases only a few studies have been conducted, or results have been conflicting. The use of GBE for tinnitus has been studied with conflicting results.⁸³ A review of five randomized trials (including four placebo-controlled trials) for this indication generally reported significant improvement in audiometry or the severity score.⁸³ A separate Cochrane review of GBE for tinnitus found that GBE is likely to be ineffective for primary tinnitus, which usually stems from a cochlear problem. However, it may be beneficial for tinnitus associated with cognitive insufficiency, which is caused by vascular insufficiency or a neural metabolic disorder.⁸⁴

GBE has been less well studied for use in macular degeneration, erectile dysfunction, antidepressant-induced sexual dysfunction, and acute mountain sickness.^{85–88} GBE cannot be recommended for these indications until more definitive clinical studies are completed. The most recently published, well-designed trials cast doubt on the efficacy of GBE for acute mountain sickness or erectile dysfunction of any etiology.^{86–88}

ST. JOHN'S WORT (*HYPERICUM PERFORATUM*)

Depression

17. G.C., a 47-year-old man, heard that St. John's wort can be used to treat depression. He is tired of the side effects associated with prescription antidepressants and wants to try this herb.

G.C. was diagnosed with major depression of moderate severity 2 years ago and was treated with fluoxetine (Prozac) 40 mg PO daily, which he discontinued after 2 months because it caused sexual dysfunction. G.C. never returned to the physician because he believed that his symptoms had improved. However, for the past few months, he has noted recurrent symptoms of lethargy, insomnia, poor appetite, a feeling of hopelessness, and a general disinterest in pleasurable activities. Assuming that G.C.'s depression is moderate in severity, is there any evidence that hypericum is a safe and effective alternative to prescription antidepressants for this indication?

Systematic reviews and meta-analyses evaluating the efficacy of hypericum or St. John's wort in the treatment of depression have been published.^{89–92} The Hamilton Depression Scale (HAMD) was the primary tool used to assess response in a majority of these studies.^{89–92} The HAMD score is based on a 17- to 21-item survey of the patient's somatic symptoms in which a score of 18 to 24 is indicative of modest depression.⁹⁰ Treatment response in these studies was typically defined as a HAMD score of <10 or a 50% drop in the HAMD score by the study end point.⁹⁰

The most recent systematic review and meta-analysis included 37 randomized, double-blind, controlled trials published from 1979 to 2002.⁹⁰ Most patients were defined as having mild to moderate depression and were treated with 900 mg/day of hypericum (range, 240–1,800 mg/day) for 4 to 12 weeks. Twenty-six trials compared hypericum to a placebo, while 14 compared it to a reference treatment (tricyclic antidepressant in 7 trials or serotonin reuptake inhibitor [SSRI] in 7 trials). Overall, hypericum was more effective than placebo. In the placebo-controlled trials, benefits tended to be greatest in studies that were smaller in sample size and not restricted to major depression (response rate, 6.13). In larger, more precise placebo-controlled trials that were restricted to major depression, benefits were smaller (response rate, 1.15). A subanalysis comparing hypericum to reference treatments demonstrated equivalence (response rate, 1.01), even when it was limited to comparisons to SSRIs (relative response, 0.98). All but one of these latter trials included patients with major depressive disorder. Adverse effects and study drop-outs were consistently more likely to occur with prescription antidepressants than with hypericum.

There have been three three-arm trials assessing the efficacy of hypericum in comparison to a placebo and an SSRI in patients with moderate to severe depression (baseline HAMD of at least 20).^{93–95} The largest trial compared 900 mg of hypericum to 20 mg of citalopram or placebo in 388 patients over 6 weeks. Equivalent, significant reductions in the HAMD score were observed for both treatment groups compared to placebo.⁹³ Surprisingly, in the other two trials, neither the hypericum arm nor the SSRI arm were superior to placebo in reducing HAMD scores at 4 to 8 weeks.^{94,95} CGIC scores, however, were significantly improved in one of these two trials for the SSRI arm,⁹⁴ while remission rates were significantly improved for both the hypericum and the SSRI arms in the other trial.⁹⁵

Additional two-arm trials comparing the efficacy of hypericum to either a placebo^{96,97} or an SSRI^{98,99} in moderate to severe depression have been published since the most recent systematic review and meta-analysis. Hypericum was significantly more effective than placebo and equally effective to its

SSRI comparison in these trials. Both SSRI comparator trials had a duration of 6 months, representing the longest treatment period to date.

In summary, hypericum is effective in mild to moderate depression and has a more tolerable side effect profile than prescription antidepressants. It may be an alternative for patients, such as G.C., who are unwilling or unable to tolerate the side effects of prescription antidepressants. The efficacy of hypericum in severely depressed patients is still uncertain and should be further studied before it is recommended. In addition, hypericum should not be recommended for patients who have experienced suicidal ideation, therapy resistance, or complicated depressive courses.

Mechanism of Action

18. What is the mechanism of action for St. John's wort in depression?

In vitro and animal studies have been conducted to evaluate the antidepressant mechanism for St. John's wort.^{100,101} Originally, the hypericin constituent was reported to have monoamine oxidase inhibitor qualities based on in vitro data, but this has not been affirmed.¹⁰⁰ Recent attention has focused on hyperforin and its structural analog, adhyperforin, as the primary antidepressant constituents in the extract.^{100,101} In vitro hyperforin equally inhibits the reuptake of serotonin, dopamine, norepinephrine, GABA, and L-glutamate.¹⁰⁰ Unlike other antidepressants, hyperforin does not act as a competitive antagonist at transmitter binding sites to decrease reuptake; instead, it attenuates the sodium gradient to alter neurotransmitter transport. This could also explain why its effects on neurotransmitters are less specific than with other antidepressants. Hypericum can also affect the density of neurotransmitter binding sites. In rats, chronic administration of hypericum results in a significant downregulation of cortical beta-receptors and an upregulation of serotonin 5HT₂ receptors.¹⁰⁰ Many prescription antidepressants also downregulate cortical beta-receptors, and electroconvulsive treatment, a highly effective antidepressant treatment, upregulates 5HT₂ receptors.¹⁰⁰

19. How should G.C. be advised regarding his request for St. John's wort?

G.C. should be advised against self-treatment of his depressive symptoms without first consulting his physician. Although G.C. did not tolerate fluoxetine, he did report temporary relief of symptoms, indicating that a reduction in dosage may be an option. In addition, there are a variety of other atypical antidepressants (e.g., bupropion [Wellbutrin], duloxetine [Cymbalta], venlafaxine [Effexor]) that G.C. may be able to tolerate. It is unclear what level of depression G.C. is currently experiencing. Although he was diagnosed as being moderately depressed 2 years ago, his relapse of symptoms is concerning, warranting re-evaluation of his depressive state. The long-term benefits of treatment with hypericum remain unknown because study durations typically lasted 8 to 12 weeks.^{89–92}

Adverse Drug Reactions/Drug Interactions

20. One month later, G.C.'s physician indicates that he has improved on a lower dosage of fluoxetine 20 mg PO daily. However,

G.C. still has complaints consistent with depression and wants to try St. John's wort. Is it safe to use St. John's wort in combination with a prescription antidepressant? Are there any adverse effects that G.C. should watch for?

There have been no clinical studies evaluating the combined use of prescription antidepressants and hypericum. Because the mechanism of action for hypericum is still unclear, it would be wise to avoid its combined use with agents that could enhance adrenergic or serotonergic neurotransmission (e.g., amphetamines, phenylephrine or phenylpropanolamine, antidepressants, triptans). There have been case reports of possible "serotonergic syndrome" in patients who began taking hypericum 600 to 900 mg/day in combination with prescription antidepressants, a prescription triptan, and buspirone (BuSpar).^{102–104} Almost all of these patients reported symptoms such as nausea, vomiting, dizziness, headache, restlessness/anxiety, and confusion within 2 to 4 days of initiating hypericum. All symptoms resolved with discontinuation of hypericum, and in two cases, cyproheptadine, a serotonin antagonist, was administered. In another case report, a patient developed sedative hypnotic symptoms when hypericum was used in combination with paroxetine (Paxil).¹⁰⁴ The latter is an unexpected reaction given the proposed mechanism for these agents.

Mania, hypomania, anxiety, autonomic arousal, and psychotic relapse have been reported in patients taking hypericum.¹⁰⁵ In most cases, patients had a history of psychiatric illness (e.g., panic disorder, posttraumatic stress disorder, mania, schizophrenia, severe depression) but were not taking psychiatric medications. One woman had initiated hypericum within 1 week of discontinuing sertraline, so an additive effect may have occurred.

Hypericum induces multiple cytochrome P450 isoenzymes (e.g., 3A4, 2D6, 2C8, 2C9, 2C19)¹⁰⁶ as well as the activity of the P-glycoprotein drug transporter, which is responsible for drug excretion from cells. The extent of enzyme induction may be related to the hyperforin constituent.¹⁰⁶ There are multiple case reports of patients who experienced a reduction in efficacy or serum drug concentration of digoxin, theophylline, cyclosporine, warfarin, indinavir, nevirapine, amitriptyline, midazolam, simvastatin, tacrolimus, oral contraceptives, and other medications after beginning hypericum therapy.¹⁰⁶ Patients using these medications or medications that are essential to their health should avoid hypericum or initiate therapy under the direction of a physician.

Few side effects have been reported in people taking standard doses of hypericum in postmarketing surveillance studies. It is estimated that hypericum is ten times less likely to elicit side effects as compared to standard antidepressants.¹⁰⁷ The most common side effects are gastrointestinal (GI) disturbances, sensitivity to light and other skin symptoms, and agitation.¹⁰⁷

Other adverse effects that have been observed in at least one case report and may have been caused by hypericum include hypertension and hypertensive crisis, sexual dysfunction, elevated thyrotropin levels, withdrawal symptoms after 1 month of use, cardiovascular collapse during anesthesia, delayed emergence from anesthesia, and seizures associated with an overdose attempt.^{104,108–110} Photosensitization is a rare side effect caused by the hypericin constituent in St. John's wort.¹⁰⁷ The effect has been observed more commonly in animals that

ingest large amounts of the plant and can include symptoms such as blisters, burns, restlessness, seizures, and death.¹⁰⁷ In humans, phototoxic reactions are rare at recommended doses up to 1,800 mg/day; they occur more often in patients with HIV who are receiving parenteral hypericin or taking the extract while undergoing laser treatment.^{111–113} Hypericin enhances the oxidation of lens proteins in the eye, which could lead to the formation of cataracts.¹¹⁴ Sunglass protection is therefore advisable. If high doses of hypericum are ingested acutely (e.g., in a suicide attempt), sun exposure should be avoided for 1 week because of hypericin's long half-life.⁷

Case reports of possible “serotonin syndrome” when St. John's wort was used in combination with other prescription antidepressants should be brought to the physician's attention. If he still wants to proceed with St. John's wort therapy, G.C. should monitor himself for symptoms of GI upset, anxiety/restlessness, and skin reactions. He should also wear sunscreen, sunglasses, and protective clothing, and avoid prolonged sun exposure. Warning patients to avoid tyramine-containing foods when taking hypericum is unnecessary based on *in vitro* data showing low levels of MAO inhibition.

Preparations and Active Constituents

21. What factors should G.C. consider when selecting a product? What type of product would you recommend?

St. John's wort is prepared from the dried above-ground parts of the plant.⁶ A variety of constituents have been isolated, including flavonoids, bioflavonoids, tannins and proanthocyanidins, xanthenes, phloroglucinols (e.g., hyperforin, pseudohyperforin), phenolic acid, volatile oils, naphthodianthrones (e.g., hypericin, pseudohypericin), sterols, vitamins, and choline.⁶ Products are typically standardized by the hypericin content, even though it is unlikely to be the sole active constituent.¹⁰⁰ Hyperforin, which represents 2% to 4% of the crude herbal drug, could be the primary antidepressant constituent,¹⁰⁰ although a combination of chemicals is likely involved.

A dried alcoholic extract can be prepared by extraction with ethanol or methanol and is the formulation most commonly used in the treatment of depression.⁷ Dried alcoholic extracts should contain no <0.3% hypericin or 1% to 6% hyperforin.^{7,100}

G.C. should be told that alcoholic extracts have been used most often in clinical studies reporting antidepressant efficacy.⁷ In addition, although the active constituents are unknown, total hypericin and hyperforin content are still considered markers of pharmaceutical quality and should be indicated on the package labeling.⁷

Pharmacokinetics and Dosing

22. What is known about the pharmacokinetics of hypericin and hyperforin? What dosage should be recommended, and when can G.C. expect to see a reduction in his symptoms for depression?

Pharmacokinetic parameters have been determined for the hypericin, pseudohypericin, and hyperforin constituents of hypericum.^{115–117} Results after single- and multiple-dose oral kinetics indicate an apparent linear relationship for hypericin

and pseudohypericin with doses up to 3.6 g of hypericum.¹¹⁵ Both hypericin and pseudohypericin are poorly bioavailable (14% and 21%, respectively).¹¹⁶ There is a 2-hour lag time in the onset of action for hypericin compared with 30 minutes for pseudohypericin.¹¹⁶ Time to peak levels are also delayed for hypericin compared with pseudohypericin (6.0–7.1 hours vs. 3.2–3.5 hours).¹¹⁵ At steady state, the half-life of hypericin is increased substantially from its single-dose value of 27.5 to 29.1 hours to 41.7 hours.¹¹⁵ The half-life of pseudohypericin is less affected and increased from 16.1 to 19.4 hours to 22.8 hours.¹¹⁵ Hypericin and pseudohypericin appear to be completely cleared by the liver because neither the primary compounds nor their glucuronide or sulfate metabolites have been detected in urine.¹¹⁶

Hyperforin demonstrates linear pharmacokinetics after single doses of up to 600 mg of hypericum.¹¹⁷ Larger doses of up to 1,200 mg resulted in serum concentrations that were less than what would have been expected with linear extrapolation. Pharmacokinetic parameters for hyperforin after a single dose of 300, 600, and 1,200 mg of hypericum (enriched to 5% hyperforin) revealed a lag time in the onset of action of 1 hour, a 9-hour half-life, and a time to peak of 3 hours. Half-life increased to 16 hours with multiple dosing of 900 mg of the extract for 8 days, but no accumulation occurred.

Hypericum extract 900 mg/day was the dosage most commonly used in clinical studies of mild to moderate depression.^{89–92} Each tablet is formulated to contain 300 mg of hypericum with 0.3% hypericin or 1% to 6% hyperforin and is administered three times daily.^{89–92} Although hyperforin is now considered a primary antidepressant constituent, most commercial preparations do not always bear this standardized marker. Patients should be told that 2 to 4 weeks is required for onset of effect.^{89–92}

Other Indications

23. What other conditions have been treated with hypericum?

In the past, hypericum was used as a topical agent for wound healing, an effect that was believed to be mediated by the astringent properties of the tannin constituents.⁷ The hyperforin constituent also inhibits the growth of various gram-positive bacteria *in vitro*.¹¹⁸ Despite these properties, the use of hypericum oil for wound healing is now considered obsolete.⁷

In vitro hypericin and pseudohypericin have demonstrated antiviral properties against enveloped viruses such as HIV-1, cytomegalovirus, and herpes simplex virus.¹¹⁶ The antiviral effect of St. John's wort is dose dependent and enhanced by exposure to light.¹¹⁶ The mechanism may involve the generation of singlet oxygen radicals and damage to the viral envelope.¹¹⁶ Antiviral efficacy has been assessed in patients with AIDS, but the dosages required for antiretroviral activity were generally high.¹¹¹ An intravenous (IV) formulation of the isolated hypericin constituent was used and caused phototoxicity in most patients.¹¹¹ Until more research is conducted, hypericin and hypericum extract cannot be recommended for the treatment of AIDS.

In vitro studies indicate that hypericin inhibits the growth of a variety of cancer cell types.¹¹⁹ Photoactivation is required to enhance its antiproliferative effects.¹¹⁹ Phase I trials in humans are currently underway. Hypericum extract has

also been studied in the treatment of seasonal affective disorder, depression with somatic symptoms, reactive depression, premenstrual syndrome, and neuropathy. Additional research is required before hypericum can be recommended for these indications.^{6,7,120}

ECHINACEA (*ECHINACEA PURPUREA*)

Preparations and Active Constituents

Many different factors have contributed to the variability in marketed echinacea products, including product content (e.g., parts used, addition of other non-*Echinacea* plant species), method of extraction, and the formulation most likely to trigger biological activity.¹²¹ Three species of *Echinacea* have been evaluated in clinical studies for their immune-stimulating effects: *Echinacea purpurea*, *Echinacea angustifolia*, and *Echinacea pallida*. Chemical studies conducted before 1990 often confused the botanical identity of these different species, especially *E. pallida* and *E. angustifolia*, making interpretation of therapeutic properties among individual species more difficult.⁷ Furthermore, *E. angustifolia* and *E. pallida* have been the predominant species evaluated in chemical analysis, whereas *E. purpurea* was most often used for testing in clinical trials.¹²¹

In 1992, the German Commission E approved the root of *E. pallida* and the above-ground parts of *E. purpurea* for clinical use.⁶ The commission recommends that the root of *E. pallida* be manufactured as a water-alcohol extract (1:5 tincture, 50% ethanol), whereas the above-ground parts of *E. purpurea* must be manufactured as a fresh-pressed juice in 22% ethanol by volume as a preservative (e.g., Echinacin, Echinaguard).⁶ Echinacea may stimulate the lymph tissue in the mouth.⁷ Although this mechanism of action remains to be proven, such an assumption would indicate preference for a liquid buccal tablet formation versus other formulations.⁷

Although chemically distinct, *E. purpurea*, *E. pallida*, and *E. angustifolia* share some common fractions; however, these common fractions can still vary in concentration and individual chemical components based on the plant parts used, the species being studied, and the type of formulation. All three species contain a lipophilic fraction (e.g., alkamides, polyacetylenes), water-soluble polysaccharides, caffeol conjugates (e.g., echinacoside, chicoric acid, caffeic acid), and flavonoids.^{6,122} The alkamides, chicoric acid, and polysaccharides have been recognized most often for possible immunomodulating effects.^{122,123} Alkamides are largely absent in the root of *E. pallida* while polyacetylenes are present.¹²² Among the caffeol conjugates, echinacoside is mainly found in the roots of *E. angustifolia* and *E. pallida*, while chicoric acid is found in the above-ground parts of *E. purpurea*.¹²² Various constituents have also been studied for possible anti-infective, antioxidant, and anti-inflammatory properties.^{121,122,124}

Cold Treatment

24. A.T. is an otherwise healthy 32-year-old man who wants to purchase echinacea. Over the past 2 days, A.T. has had symptoms consistent with a new onset cold: a sore throat, stuffy nose, and general body aches. He is not taking any other over-the-counter or

prescription medications and asks you if echinacea will shorten the duration of his cold symptoms.

Clinical trials evaluating the efficacy of echinacea in the relief of respiratory infections have been complicated by product heterogeneity (use of echinacea in combination with other herbs or vitamins and minerals, use of different *Echinacea* species, different methods of formulation, and whether cold symptoms were acquired naturally or following rhinovirus inoculation).^{125,126} Placebo control is also complicated by the distinctive flavor of liquid formulations of echinacea.

Fortunately, there have been recent reviews and meta-analysis to help differentiate which echinacea formulations are preferable. In one review, 14 randomized, placebo-controlled trials were evaluated.¹²⁵ All trials used either an echinacea monopreparation (10 studies) or a combination product (4 studies) that included echinacea for the prevention or treatment of the common cold. Five studies involved the use of Echinaguard or Echinacin (Madaus AG, Cologne, Germany), which are standardized ethanolic extracts of the above-ground parts of *E. purpurea*. Both persons who acquired the cold naturally (11 studies) or through inoculation (3 studies) were also included. Meta-analysis showed a 58% decrease in the incidence of cold and a reduction in cold duration of 1.25 days. Although there was heterogeneity among the trials, no significant publication bias was detected. The benefits of echinacea remained significant for cold incidence with a trend toward reduced duration, when only monopreparations were evaluated. Limiting the analysis to preparations involving Echinaguard or Echinacin also showed a significant 56% reduction in cold incidence.

The Cochrane Collaboration performed a separate review of echinacea in the treatment and prevention of the common cold (i.e., studies involving inoculation with rhinovirus were excluded).¹²⁶ Sixteen randomized trials with 22 comparisons of echinacea to placebo (19 trials), no treatment (2 trials), or another herbal preparation (1 trial) were included. No significant benefits were observed when echinacea was used prophylactically as a preventative agent. When echinacea was used as a treatment at the onset of cold symptoms, significant improvements were more frequently observed for echinacea compared to placebo. The authors concluded that there was evidence to support a beneficial effect of echinacea for cold treatment, specific to monopreparations involving the above-ground parts of *E. purpurea*.

A.T. should be informed that the use of echinacea in the treatment of cold symptoms is still under investigation. However, the evidence to date is positive when the above-ground parts of the *E. purpurea* plant are used. Cold symptoms and duration may be reduced when echinacea is taken early in the course of illness. Echinacea is not a cure for the common cold. Adequate hydration, proper nutrition, and rest are also important during this period.

Mechanism of Action

25. What is echinacea's purported mechanism of action in the abatement of cold symptoms?

Both in vitro and in vivo studies suggest that echinacea has an immune-modulating effect. In vitro studies have been conducted using murine and human macrophages. Using a purified

polysaccharide fraction of *E. purpurea*, significant increases in polymorphonuclear (PMN) cell activation; macrophage activation; macrophage cytotoxicity against tumor and bacterial target cells; and macrophage secretion of interleukin (IL)-1, IL-6, tumor necrosis factor- α (TNF- α), and reactive oxygen intermediates were observed.^{121,127} In vivo the polysaccharide fraction enhanced immune activation in mice against fungal and bacterial pathogens.¹²¹ In healthy volunteers, IV administration of the polysaccharide fraction enhanced PMN activity, macrophage activity, and migration of cells from bone marrow to peripheral blood.¹²⁷ Although the mechanisms described for the parenterally administered polysaccharide fraction of *E. purpurea* may not be applicable to the oral formulation used commercially, the water-soluble (polysaccharide-containing) fraction still seems to exert a superior immunostimulant response as compared to the fraction extracted with organic solvents.¹²³

Few studies have evaluated the mechanism of action of echinacea in its commercially available form. One in vitro study showed a significant increase in the production of IL-1, IL-6, IL-10, and TNF- α by human phagocytes in the presence of *E. purpurea* juice.¹²⁸ In vitro natural killer (NK) cell and antibody-dependent cell cytotoxicities were also enhanced by *E. purpurea* extract in both healthy and immunocompromised patients.¹²⁹ However, in vivo, only enhancement of phagocytic activity, total circulating white blood cells, monocytes, neutrophils, and NK cells has been noted with the use of *E. purpurea* formulations.^{121,130} Another study failed to find an effect of an orally administered *E. purpurea* juice on either cytokine expression or phagocytosis in 40 healthy volunteers over 14 days as compared to placebo.¹³¹

Echinacea's mechanism of action remains uncertain. Immune modulation or stimulation may play a role, but to date, only enhancement of phagocytic activity has been observed in humans. Future studies using the orally administered commercial formulations are required to determine if cytokine activity is enhanced in vivo as it is in vitro for humans.

Pharmacokinetics and Dosing

26. What is known about the pharmacokinetics of echinacea? What dose should be recommended for A.T.?

The pharmacokinetic parameters of echinacea indicate that the alkamide fraction is detectable in human plasma after oral administration of a combined *E. angustifolia* and *E. purpurea* combination root extract (liquid or tablet), while caffeic acid conjugates were not detectable in plasma and are likely not bioavailable.¹³² Pharmacokinetic parameters of some individual alkamides also have been documented.¹²²

Echinacea dosing for the supportive treatment of colds or upper respiratory infections is 6 to 9 mL/day of fresh-pressed juice preserved in ethanol prepared from the above-ground parts of *E. purpurea* (e.g., Echinaguard) or 900 mg/day of *E. pallida* root (1:5 tincture, 50% ethanol).⁷ Both preparations are administered in divided doses (e.g., 15–30 drops of *E. purpurea* juice, equivalent to 0.75–1.5 mL, two to five times daily). Appropriate dosing should be indicated on the package labeling. The German Commission E recommends that neither preparation be used for longer than 8 weeks because the mechanism for reported immune modulation is unclear.⁶ However, studies as

long as 12 weeks have been conducted without serious adverse effects.¹²¹ External preparations should contain no <15% *E. purpurea* fresh-pressed juice.⁶

Adverse Drug Reactions/Drug Interactions

27. Should A.T. be warned of any adverse effects caused by echinacea?

Toxic effects were not observed in animals given supratherapeutic parenteral and oral formulations of *E. purpurea* juice.¹³³ In vitro mutagenicity and carcinogenicity studies were also negative.¹³³ In humans, flu-like symptoms (e.g., fever, shivering, headache, vomiting) have been reported infrequently after parenteral administration.¹³⁴ This reaction may be caused by stimulation of phagocytes, cytokine production, or a transient decrease in lymphocyte counts immediately after parenteral administration.¹³⁵ Few adverse effects have been associated with oral dosing. Unpleasant taste and upset stomach have been reported infrequently.¹³⁴ Hypersensitivity reactions (anaphylactoid, bronchospasm, rash) have been reported more commonly in patients with pre-existing allergic rhinitis, atopy, or asthma, as well as in patients with no pre-existing allergic history.¹³⁴ One large-scale trial also found a significantly higher incidence of rash (~5%) in pediatric patients taking oral echinacea.¹²⁶

There are no reported drug–drug interactions for *E. purpurea* or *E. pallida*.⁶ Theoretically, however, echinacea should be avoided in patients taking immunosuppressive medications (e.g., cyclosporin, steroids). Because of the high alcohol content of certain preparations, patients taking drugs known to cause an Antabuse-like reaction (e.g., metronidazole [Flagyl], griseofulvin [Fulvicin], chlorpropamide [Diabinese]) should be warned of this effect.

Cold Prophylaxis

28. A.T. purchases a product called Echinaguard, a fresh-pressed juice formulation preserved in alcohol made from the above-ground parts of *E. purpurea*. Two days later, he indicates that his partner, who has had HIV for 6 years, wants to use echinacea to protect himself from A.T.'s cold. His partner's most recent CD4+ lymphocyte count was 300 cells/mm³, and his viral load is undetectable. How would you advise A.T.?

Randomized, double-blind, placebo-controlled trials have generally failed to observe a prophylactic benefit of echinacea in reducing the frequency of the common cold.^{125,126} A.T.'s partner should be informed that the prophylactic benefit of echinacea has not been established. Instead, he should be advised to wash his hands frequently and avoid close contact with A.T. while he is symptomatic.

States of Immune Deficiency

29. Could echinacea have other beneficial or harmful effects on A.T.'s partner who is HIV positive? What are the contraindications to its use?

Because the immune-modulating effects of echinacea are still being evaluated, it is unclear how this herb will affect the immune status of patients with HIV infection. On the one hand, echinacea may enhance immune function, and this could be viewed as beneficial. In vitro analysis using cells from patients with AIDS showed enhancement of NK cell activity by *E. purpurea* extract.¹²⁹ NK cells, in turn, can have a cidal effect on HIV-infected cells.¹²⁹ On the other hand, replication of HIV may also be stimulated by other effects of echinacea: enhancement of TNF- α levels and T-lymphocyte activation.¹²¹ Therefore, until the effects of echinacea are clearly defined, it should not be used by patients who have HIV for any prolonged length of time. Short-term use of echinacea for 7 to 10 days at the onset of cold symptoms, however, is unlikely to be harmful.

Additional disorders have been cited by the German Commission E as contraindications to echinacea use. Many of these disorders could be activated by immunostimulation, such as multiple sclerosis, tuberculosis, leukosis, collagen disorders (i.e., rheumatoid arthritis), and other autoimmune disorders.⁶ As further clinical research is conducted, these contraindications may be removed.

Other Indications

30. What other conditions have been treated with echinacea?

Echinacea has been used to enhance hematologic recovery after chemotherapy, but this use is investigational. Two studies used intramuscular *E. purpurea* juice in combination with thymostimulin (an immune-enhancing thymic hormone) after low-dose cyclophosphamide (Cytosan) therapy.^{136,137} In both studies, patients had advanced stage hepatocellular or colorectal cancer, and sample sizes were small. Although certain immune parameters were significantly increased, it was unclear whether thymostimulin or echinacea was predominantly responsible. A pilot study investigated the effect of *E. purpurea* polysaccharides on leukocyte counts before and during chemotherapy. Patients had advanced gastric cancers, and no benefits were observed from the intervention.¹³⁸

The German Commission E recommends *E. purpurea* but not *E. pallida* for the “supportive treatment of lower urinary tract infections.”⁶ This indication is largely based on (a) studies performed in the 1950s using parenteral echinacea preparations and (b) unpublished studies performed by the manufacturer (Madaus) using echinacea lozenges in patients with respiratory and urinary tract infections (UTIs).¹³⁵ Despite support by the German Commission E, the use of echinacea for UTIs requires further clinical study. To date, most clinical trials have used injectable formulations of echinacea, which are not commercially available, and have lacked high-quality study design.¹³⁵

Echinacea has also been evaluated for the treatment of recurrent vaginal candidiasis and recurrent genital herpes. In a nonrandomized, open-label study involving 203 women with recurrent vaginal candidiasis, patients received 6 days of topical econazole (Spectazole) with or without a 10-week course of subcutaneous, IV, intramuscular, or oral fresh-pressed juice of *E. purpurea*.^{121,135} Recurrence rates in patients receiving echinacea versus econazole alone were significantly lower, 5%

to 16.7% versus 60%, respectively. The other trial was randomized and double-blinded and evaluated 50 patients with recurrent genital herpes. Patients received 6 months of an *E. purpurea* extract (Echinaforce) or placebo, but no benefits were observed at the end of the study.¹³⁹

Historically, echinacea has been used for wound healing by Native Americans.⁷ The German Commission E has approved *E. purpurea* for the topical treatment of “poorly healing wounds and ulcerations.”⁶ In vitro echinacea has many effects that are compatible with a variety of possible anti-inflammatory effects. These include inhibition of enzymes involved in the inflammatory process (e.g., cyclo-oxygenase, 5-lipo-oxygenase, hyaluronidase) and a reduction in free radical formation.¹²¹ In animals, echinacea reduces skin inflammation in response to chemical irritants.¹²¹ Although topical anti-inflammatory effects have been demonstrated, there are no well-designed published trials in humans supporting this indication.¹²¹ Thus, the use of echinacea for wound healing requires further research.

SAW PALMETTO (*SERENOA REPENS*)

Background

Prostate growth is largely dependent on the enzymatic conversion of testosterone to dihydrotestosterone (DHT) by 5 α -reductase. Elevated DHT levels have been observed in patients with benign prostatic hyperplasia (BPH).¹⁴⁰ Prostatic growth factors, focal inflammation, and upregulation of androgen receptors may also be involved in the hyperplasia of prostatic stroma.¹⁴⁰ Prostatic enlargement can lead to physical obstruction of the urethra and symptoms of urinary hesitancy, dribbling, incomplete bladder emptying, straining, and decreased urinary flow.¹⁴¹ In addition, α -mediated adrenergic innervation of the prostate smooth muscle and bladder neck can lead to vasoconstriction and further compression of the urethra.¹⁴¹ This dynamic component of BPH can account for up to 40% of the prostatic tone exerted on the urethra and can contribute to urinary symptoms.¹⁴¹ Disease progression may lead to UTIs, urinary retention, hematuria, renal insufficiency, and bladder dysfunction from poor detrusor contractility or instability.^{140,141}

The American Urological Association (AUA) Symptom Index is the standard scale for prostate symptom assessment.¹⁴² Using this validated symptom scale, seven questions are scored from 0 to 5, and the total sum is used to classify disease progression as mild (0–7), moderate (8–18), or severe (19–35).¹⁴² The International Prostate Symptom Score (I-PSS) is the European equivalent of the AUA Symptom Index and is also used to assess BPH.¹⁴³ Prostatic enlargement may often be detected by digital rectal examination; a prostate size >20 g is considered abnormal.¹⁴¹ Urinary flow rate is the most frequent objective test used to assess bladder outlet obstruction.¹⁴² Although peak flow rate can vary with age or voided volume, a guideline for classification of prostatism is mild (15–20 mL/second), moderate (10–14 mL/second), and severe (<10 mL/second).¹⁴² Prostate-specific antigen (PSA) values, produced by both benign and malignant prostate cells, can be used to detect prostate abnormalities.¹⁴¹ Normal PSA values range between 0 and 4 ng/mL. However, PSA values may also be within normal limits in patients with BPH or prostate cancer; therefore, they are

not a truly specific marker for either disease.¹⁴¹ The reader is referred to Chapter 101 for more information.

31. B.F. is a 70-year-old man who presents to the ambulatory care clinic for a follow-up visit with his primary care provider. B.F. was recently referred to the urology clinic for symptoms of frequent urination, urgency, dysuria, and decreased urinary flow. Additional objective tests performed by the urologist included a urinalysis and a peak urinary flow rate. Prostate cancer was ruled out on rectal examination. Results of B.F.'s examination included: AUA score, 12 out of 35; PSA, 3.2 ng/mL; estimated prostate weight, 32 g; peak urinary flow, 12 mL/second; normal urinalysis; BP, 110/60 mm Hg; heart rate (HR), 70 beats/minute; and normal renal function. B.F. has no other medical problems and is not taking any other prescription medications. How would you rate the severity of B.F.'s BPH? What objective parameters contribute to this rating?

Based on B.F.'s AUA score, his disease is of moderate severity. Objective parameters include his increased prostate size of 32 g and a restricted urinary flow of 12 mL/second. Subjective symptoms of dysuria, urgency, and frequent urination should not be used as tools to assess disease severity because both obstructive and irritative symptoms of BPH often wax and wane.¹⁴¹

Treatment Options for Benign Prostatic Hyperplasia

32. B.F. is extremely bothered by his symptoms and wants to know the treatment options available besides the minimally invasive procedures and surgical procedures described by his urologist. What are these options?

Because B.F. has moderate disease, a number of treatment options are available. Generally, patients with mild to moderate disease are afforded the “watchful waiting” option, which means that the patient’s symptoms are monitored for disease progression.¹⁴¹ This option is recommended because over a 5-year period, 45% of patients will have no deterioration, 40% will improve, and 15% will deteriorate.¹⁴² The dynamic nature of BPH also has been noted in placebo studies of 2 to 24 weeks’ duration in which 42% of patients improved, 46% had no change, and 12% had worsening of symptoms.¹⁴² Patients such as B.F. who are significantly bothered by their symptoms and are requesting nonsurgical treatments are candidates for prescription medications such as alpha-adrenergic antagonists (e.g., terazosin [Hytrin], doxazosin [Cardura], tamsulosin [Flomax], alfuzosin [Uroxatral]) and 5 α -reductase inhibitors (e.g., finasteride [Proscar], dutasteride [Avodart]).¹⁴² Dutasteride inhibits isoenzyme types 1 and 2 of 5 α -reductase and has been shown to reduce serum DHT levels more effectively (93% vs. 70%) than finasteride, which only inhibits isoenzyme type 2 of 5 α -reductase.¹⁴⁴ Saw palmetto, a phytotherapeutic agent, has also been advocated for the treatment of BPH by many physicians in Europe.¹⁴⁰

Finasteride is most effective in patients with prostate volumes >40 mL and may be no more effective than placebo in patients with prostate volumes <30 mL, which is why the drug class of 5 α -reductase inhibitors is often reserved for persons with moderate to severe BPH.¹⁴⁴ B.F.'s prostate volume of 32 mL makes him a poor candidate for finasteride. His BP of 110/60 mmHg is also a concern if α -blockers are

prescribed, because they reduce BP in both hypertensive and nonhypertensive patients.¹⁴² Terazosin and doxazosin carry a slightly greater risk of orthostasis as a side effect than the other α -blockers.¹⁴⁴ If alpha-blockers were initiated, B.F.'s BP would have to be monitored closely. Tamsulosin is more specific for the α -1a- and α -1d-receptor subtypes and is less likely to result in orthostasis. The α -1a-receptor subtype is very specific to the prostate (~70% of the adrenergic receptor mRNA).¹⁴⁵ If B.F. is initiated on α -blockers, he should be counseled about first-dose syncope and monitoring his BP when beginning therapy. B.F. should arise slowly from the sitting or lying position, especially when getting out of bed in the morning.

Preparations and Active Constituents

33. Because terazosin was covered under B.F.'s health plan, his doctor started him on this as a first-line agent. B.F. returns to the clinic 1 week later complaining of intolerable dizziness. The primary care physician is considering switching B.F.'s prescription to tamsulosin. This prescription would cost more, so B.F. is considering saw palmetto due to his financial constraints. What are the active ingredients and mechanism of action of saw palmetto?

Saw palmetto berry is composed of many constituents; the active ingredients, however, are as yet unknown.¹⁴³ Permixon, the brand most commonly used in Europe, contains 90% free and 7% esterified fatty acids.¹⁴³ Phytosterols (i.e., β -sitosterol, campesterol, stigmasterol, cycloartenol, lupeol, lutenone, methylcycloartenol), aliphatic alcohols, polyphenolic compounds, and flavonoids also are present.^{143,146} Reported pharmacologic activity may reside in the lipophilic fraction.¹⁴⁰ Saw palmetto is commercially formulated as a concentrated fat-soluble extract that is standardized to contain 85% to 95% fatty acids and sterols.

Mechanism of Action

Early in vitro studies suggested that saw palmetto had antiandrogenic properties. In human foreskin, fibroblasts, and rat prostate cell lines, saw palmetto competitively inhibited DHT binding to cytosolic and nuclear receptors.^{140,146} Unlike finasteride, which inhibits 5 α -reductase type 2, saw palmetto inhibited type 1, and, in some cases, both isoforms of the enzyme in vitro.^{140,146} Additional mechanisms that have been observed in vitro include inhibition of prostatic growth factors and inflammatory mediators produced by the 5-lipo-oxygenase pathway (e.g., leukotrienes) and α -1-adrenoreceptor antagonism.^{140,146}

In vivo, saw palmetto reduced estrogen- and androgen-stimulated prostate growth in rats.¹⁴⁷ However, in healthy males, 1 week of treatment failed to influence 5 α -reductase activity, DHT levels, and testosterone levels when compared with finasteride.¹⁴⁰ Eight days of treatment also had no effect on α -1-adrenoreceptor antagonism in healthy men.¹⁴⁸ In men with BPH, saw palmetto failed to influence plasma levels of testosterone, follicle-stimulating hormone (FSH), and luteinizing hormone after 1 month of treatment.¹⁴⁰ PSA levels were also unaffected by saw palmetto after 6 months of treatment, suggesting a lack of 5 α -reductase activity.¹⁴³ Contrary to these reports, some studies in men with BPH report significant reductions in epidermal growth factor, DHT

production, and antiestrogenic activity with 3 months of treatment.¹⁴⁹ These reductions were comparable to that observed with 3 months of finasteride therapy. In summary, the mechanism of action of saw palmetto on the prostate remains unclear, but it is likely to involve a number of different processes. More clinical research is required to confirm previously published reports.

34. B.F.'s primary care physician is still unsure whether to initiate tamsulosin or saw palmetto. Are there any clinical trials that have evaluated the efficacy of saw palmetto in the treatment of BPH? How does the effect of saw palmetto compare with the other prescription drugs for BPH? Would it benefit B.F.? If so, what dosage should be used?

A meta-analysis looked at 21 randomized controlled trials conducted between 1966 and 2002 involving saw palmetto for BPH.¹⁵⁰ There were more than 3,000 participants: 1,408 in trials of saw palmetto versus placebo and 1,701 in trials of saw palmetto versus another treatment medication. Urinary symptom scale scores were reported in 13 studies and revealed an absolute improvement of 28% for saw palmetto versus placebo. The weighted risk ratio for patient- and physician-rated symptomatic improvement was 1.76 and 1.72, respectively. The weighted mean difference for nocturia and peak urine flow between saw palmetto and placebo were 0.76 times/evening and 1.86 mL/second. Saw palmetto and finasteride produced similar absolute improvements in urinary peak flow and I-PSS scores. Saw palmetto was typically administered at a dose of 320 mg/day for a mean of 13 weeks.

In contrast, a newer double-blind clinical trial randomized 225 men with moderate to severe symptoms of BPH to 320 mg of saw palmetto daily or placebo. After 1 year, there were no significant differences between groups on either the AUA Symptom Index or any secondary outcomes such as prostate size, urinary flow, quality of life, or residual urinary volume.¹⁵¹

Small comparative trials of saw palmetto versus prazosin and alfuzosin have been conducted in patients with mild to moderate BPH.^{152,153} The prazosin study was not analyzed statistically, but in both treatment groups symptoms improved at 3 months. Improvements were slightly greater for prazosin 2 mg orally twice a day versus saw palmetto 320 mg/day in the 41 patients studied.¹⁵² A shorter 3-week trial compared saw palmetto 320 mg/day with alfuzosin 2.5 mg PO TID in 63 patients.¹⁵³ A standardized scale, the Boyarsky rating scale, was used for symptomatic assessment. Improvements in symptom score (38.8% vs. 26.9%), obstructive score (37.8% vs. 23.1%), and peak urinary flow (71.8% vs. 48.4%) all favored alfuzosin over saw palmetto.

A large double-blind, randomized comparative trial of saw palmetto and tamsulosin also exists.¹⁵⁴ This 1-year trial compared 320 mg/day of saw palmetto to 0.4 mg/day of tamsulosin among 811 men with moderate BPH. The primary end points were the I-PSS score and maximal urinary flow. All outcomes were significantly improved in both groups to a similar degree. Approximately 80% of those treated had improved I-PSS scores. A smaller 6-month open-label comparative trial also showed tamsulosin 0.4 mg, saw palmetto 320 mg, and tamsulosin plus saw palmetto to be of comparable efficacy in

improving I-PSS scores in patients with moderate to severe BPH.¹⁵⁵

A large comparative trial of saw palmetto 320 mg/day and finasteride 5 mg/day was conducted in 1,098 patients.¹⁴³ The 6-month trial used the I-PSS rating scale to evaluate BPH symptoms in patients with mild to moderate disease. Objective parameters included peak urinary flow, prostate volume, and PSA levels. Quality of life and sexual dysfunction were also assessed. Both treatment groups had significant improvements in I-PSS score, quality of life, and peak urinary flow on study completion. PSA was reduced by 41% by finasteride but was unaffected by saw palmetto. Finasteride significantly reduced prostate volume (18%) compared with saw palmetto (6%). Sexual dysfunction was significantly more frequent with finasteride (+9%) than with saw palmetto (−6%).

Although impressive in size, the latter trial had methodologic shortcomings. There was no placebo control, and the study lasted only 6 months. Because clinical improvement with finasteride continues for 6 to 12 months into treatment, a longer follow-up period of 1 year may have revealed a significant difference between treatment groups.¹⁵⁶ In addition, enrollment in this comparative study required a prostate volume >25 mL. As previously noted, finasteride is generally reserved for patients with a prostate volume >40 mL and may be no more effective than placebo in patients with a prostate volume <30 mL.¹⁴⁴ Therefore, without a placebo arm, the clinical response observed in both treatment groups may be no greater than placebo. Saw palmetto had a lower incidence of sexual dysfunction, which was significant but not of substantial magnitude. Absolute percentages for side effects of erectile dysfunction and decreased libido, respectively, were 2.8% and 3.0% for finasteride and 1.5% and 2.2% for saw palmetto.

In summary, saw palmetto may improve overall urinary tract symptoms by approximately 28% compared with placebo.¹⁵⁰ In comparative trials, saw palmetto demonstrated similar efficacy to finasteride at 6 months, tamsulosin at 1 year, and a slightly reduced efficacy versus other α -blockers at 1 and 3 months.^{143,152–154,156} The benefits of saw palmetto extending beyond 1 year remain uncertain because of short study durations. B.F. may benefit from saw palmetto because it has a quick onset of action (4 weeks) that is similar to α -blockers (4–6 weeks) but shorter than finasteride (6 months).^{142,146} B.F.'s low BP and financial constraints also make saw palmetto a reasonable choice. The dose of saw palmetto used most often in trials of patients with BPH was 320 mg/day, taken as 160 mg orally twice a day. The German Commission E recommends 1 to 2 g of saw palmetto berry or 320 mg of lipophilic extract.⁶ The lipophilic extract is available as 80- and 160-mg tablets and capsules.

If B.F. does not achieve any symptomatic relief by 6 weeks, another therapy should be instituted. Saw palmetto is not indicated for severe BPH or prostate cancer. B.F. should continue to schedule regular follow-up visits with his primary care physician to continuously assess the need for saw palmetto.

Adverse Drug Reactions/Drug Interactions

35. B.F. begins saw palmetto therapy. Two days later, he complains of stomach upset after ingesting the herb. What adverse effects and drug interactions are associated with saw palmetto?

Is stomach upset a common reaction, and is there anything that can be done to minimize it?

To date, no drug–drug interactions have been reported for saw palmetto, but a small number of side effects have been observed in clinical trials. In the comparative study involving 1,098 patients, saw palmetto–associated side effects occurring with an incidence of 1% to 3% included hypertension, decreased libido, abdominal pain, erectile dysfunction, back pain, urinary retention, and headache.¹⁴³ Additional complaints that occurred with an incidence of <1% were diarrhea, flulike symptoms, nausea, constipation, and dysuria.¹⁴³

B.F. should be assured that this type of reaction has occurred before in patients taking saw palmetto. To minimize stomach upset, B.F. can try taking the herb with food. If his stomach upset does not resolve, he should inform his primary care physician so another treatment can be considered.

Pharmacokinetics

36. What is known about the pharmacokinetics of saw palmetto? Will administration with food affect the absorption or the overall efficacy of the herb?

Few pharmacokinetic trials have been performed with saw palmetto. Single-dose kinetics were evaluated in 12 fasting men who ingested 320 mg of the herb. Peak plasma levels were reached in 1.5 hours, and the elimination half-life was 1.9 hours.¹⁴⁰ No trials have been conducted evaluating the effect of food on bioavailability or efficacy. Tissue distribution of saw palmetto has been studied in rats.¹⁴⁰ Saw palmetto supplemented with oleic acid, lauric acid, or β -sitosterol revealed tissue concentrations that were greater in the prostate than other genital organs or the liver.

GINSENG (PANAX SPP.)

Preparations and Active Constituents

37. A.J., an overweight 55-year-old man with type 2 diabetes mellitus, hypercholesterolemia, and hypertension, has come to the pharmacy to purchase a dietary supplement to boost his energy. His current medications include simvastatin (Zocor) 10 mg PO daily, metformin (Glucophage) 750 mg PO BID, and benazepril (Lotensin) 10 mg PO daily. His current laboratory values are total cholesterol, 225 mg/dL; LDL-C, 185 mg/dL; HDL-C, 30 mg/dL; TG, 110 mg/dL; and BP 150/80 mmHg. There have been no changes to A.J.'s medication regimen in the past year. A.J. has no family history of coronary heart disease. He states that he has been under a lot of stress lately and has not been feeling as energetic as he normally does. He selects two herbal products, both of which claim to enhance energy. The first is a combination herbal product containing bitter orange as the primary ingredient; the other is labeled “Siberian ginseng.” There are so many ginseng products that A.J. asks you if there is any difference between his current selection and the other bottles labeled “Panax.”

There are a variety of species of ginseng, many of which are distinguished by their country of origin. Some of these include *Panax ginseng* C.A. Meyer (Chinese or Korean variety), *Panax quinquefolius* (American variety), *Panax japonicus* C.A. Meyer (Japanese variety), and *Panax notoginseng* (Sanchi

variety).¹⁵⁷ Thirty different triterpenoid saponin glycosides known as “ginsenosides” have been isolated from ginseng.¹⁵⁷ Additional constituents include polysaccharides, flavonoids, daucosterin, mucilaginous substances, amino acids, bitter substances, vitamins, choline, pectin, fatty oil, and ethereal oil.¹⁵⁸ Composition may vary between different species or within the same species when cultivated at different locations. The ginsenosides are believed to be responsible for many of the reported effects and can be subdivided into three main categories based on their chemical structure: oleanolic acid, panaxadiol, and panaxatriol types.¹⁵⁷ Individual saponins have been further classified and are chemically designated by the letter “R” followed by a subscript letter, number, or both.⁷ It is generally the root of the plant that is used for commercial manufacturing; the length of time required for maturation of ginseng root and optimal ginsenoside levels is 5 to 6 years.¹⁵⁸ For this reason, and due to overharvesting, commercial supply can be scarce, leading to higher prices and a greater risk of plant substitution or suboptimal ginsenoside content.¹⁵⁹ Rg₁ and Rb₁ are considered standardized markers of ginsenoside content in both American and Chinese or Korean *P. ginseng* roots; however, the ratio of Rg₁:Rb₁ is higher in Asian ginseng than in American ginseng, which leads to different pharmacologic properties between these two species.¹⁶⁰ Both *P. ginseng* extract and crude herb formulations are recommended by the German Commission E.⁶ Ginseng extract should be standardized to contain at least 4% ginsenosides.⁶ Crude herb products are available as fresh ginseng (younger than 4 years of age), peeled and dried white ginseng (4–6 years of age), or steamed and dried red ginseng (older than 6 years of age).¹⁵⁸ The latter products may be further processed into powder, extract, or tea formulations.

Other plants that have been reported to have similar clinical effects to ginseng but are not of the *Panax* species include *Eleutherococcus senticosus* (Siberian ginseng) and *Pfaf-fia paniculata* (Brazilian ginseng).¹⁶¹ Both species lack the characteristic ginsenosides of the *Panax* species but contain eleutherosides and pfaffosides, respectively.¹⁶¹ Siberian ginseng was developed as a substitute for the *Panax* species by the former Soviet Union. Many of the clinical studies for Siberian ginseng have been published in the Russian language, making them less available to the scientific community.⁶ Both the *Panax* species and *Eleutherococcus* are approved by the German Commission E as “a tonic to counteract weakness and fatigue, as a restorative for declining stamina and impaired concentration, and as an aid to convalescence.”⁶

Therefore, A.J. should be informed that Siberian ginseng is not part of the *Panax* species and contains no ginsenosides. However, both preparations are approved for the treatment of similar conditions in Europe. In general, *P. ginseng* C.A. Meyer may be a superior choice because it has been studied more thoroughly by the scientific community and carries a marker of standardization based on its ginsenoside content.

38. Given A.J.'s clinical presentation, what concerns would you have before recommending a ginseng product?

A.J.'s fatigue may be a symptom of poor glucose control. Thus, his recent blood glucose measurements should be reviewed, and his glycosylated hemoglobin (A1c) level should be checked. In addition, A.J. should be asked about other symptoms that can cause a loss of energy such as depression (e.g.,

Table 3-4 Adaptogenic Mechanisms Reported for Ginseng and Its Constituents Based on In Vitro and Animal Studies

| References | Mechanism | Adaptogenic Quality |
|------------|--|--|
| 162 | ↓ Adrenal catecholamine release | Antistress |
| 163 | ↑ Adrenocorticotropin hormone and corticosterone release, agonist at glucocorticoid receptor | Antistress |
| 162 | Centrally mediated enhancement of GABA _A , inhibition of substance P | ↓ Psychological and pain-mediated stress |
| 157, 162 | ↑ Central levels of acetylcholine, increase serotonin, norepinephrine, and dopamine in the cerebral cortex | Nootropic |
| 158, 162 | Reversal of tolerance and dependence to morphine by decreasing dopamine receptor supersensitivity | ↓ Narcotic tolerance and dependence |
| 157 | Anti-inflammatory, possibly mediated through anticomplement activity | ↓ Acute and chronic inflammation |
| 157 | Antioxidant | ↓ Cellular damage in states of hypoxia |
| 157 | Promotes neurite growth, increase proliferation of neuronal progenitor cells, protects against agents causing neuronal cell death, inhibits N-methyl-D-aspartate (NMDA) and non-NMDA glutamate receptors | Neuronal protection |
| 157 | ↑ Endothelial nitric oxide and inhibits prostacyclin production | Vasoregulatory effect |
| 157, 158 | ↓ Platelet aggregation, ↓ (TXA ₂), and platelet-activating factor (PAF); ↑ effect of aggregation inhibitors; cGMP, cAMP | Antiplatelet activity |
| 157 | ↑ Insulin release, number of insulin receptors, and insulin sensitivity | Improved glucose homeostasis |
| 157 | Induced mRNA expression for IL-2, IL-1 α IFN- γ , and GM-CSF; activated B and T cells, NK cells, and macrophages | Immunomodulation |
| 157 | ↓ Tumor angiogenesis, ↑ tumor cell apoptosis (death) | ↓ Tumor metastasis |

GM-CSF, granulocyte-macrophage colony-stimulating factor; IL, interleukin; NK, natural killer.

appetite, quality of sleep), a cold (e.g., congestion, runny nose, sore throat), or hypothyroidism (e.g., constipation, cold intolerance, weight gain).

Mechanism of Action

39. A.J. states that his most recent A1C was 8% (normal, 4%–6%). He performs fingerstick blood glucose measurements twice daily and values range between 130 and 160 mg/dL. He has no other symptoms suggestive of hyperglycemia or other conditions associated with fatigue. A.J. asks for your assistance in choosing between the supplements he has selected. What claims are made for each of these supplements, and how does the proposed mechanism of action for each of these agents affect your recommendation?

A.J. has selected a combination product that contains bitter orange (*Citrus aurantium*) as its primary ingredient. Bitter orange contains synephrine, a sympathomimetic that is similar to ephedrine and has the potential to increase HR and BP. Sympathomimetics act as central nervous system (CNS) stimulants to boost energy; they also constrict blood vessels and raise glucose levels. Because these effects could worsen A.J.'s hypertension and diabetes, he should avoid the use of this combination supplement.

Ginseng has been labeled as an “adaptogen,” which refers to the body's ability to normalize itself when exposed to stressful or noxious stimuli. Adaptogenic properties that have been reported for ginseng include stress relief, improved mood and cognitive function, enhanced physical performance, immune modulation, improved cardiovascular function, antidiabetic activity, anticancer effects, and protection against liver damage.⁶ The postulated mechanism of action in humans is based on the results of in vitro and animal studies. This extrapolation may be premature because many studies used formulations (e.g.,

individual ginsenosides or polysaccharides) and routes of administration (e.g., parenteral) that differ from commercially available formulations. Some of the mechanisms reported for ginseng are listed in Table 3-4.^{157,158,162,163} Based on these mechanisms, A.J. has no contraindications to ginseng and may or may not benefit from its reported homeostatic effects on glucose control and BP. Of the two supplemental products A.J. has selected, *P. ginseng* would be the preferred agent.

Ergogenic and Nootropic Effects

40. A.J. agrees to avoid the ephedra-containing supplement but wants to know what types of benefits he can expect once he initiates ginseng.

The effects of ginseng on physical (ergogenic) and mental (mood, nootropic) performance have been inconsistent. In 83 healthy patients, 200 to 400 mg/day of *P. ginseng* extract (Ginsana, G115) or placebo for 8 weeks failed to show a significant benefit on positive affect, negative affect, or total mood disturbance.¹⁶⁴ A larger 9-week, double-blind study in 127 healthy patients using 400 mg/day of standardized *P. ginseng* extract (Gerimax) failed to show consistent enhancement of cognitive function.¹⁶⁵ A series of tests were used to assess psychomotor function, attention and concentration, learning and memory, and abstraction. Significant improvements occurred for the abstraction test and the auditory reaction test (one of three tests designed to assess psychomotor function). Studies evaluating an acute dosing effect of ginseng (Ginsana, G115) have also produced inconsistent findings. In a double-blind, placebo-controlled, crossover study, the cognitive benefits of ginseng in doses of 200, 400, or 600 mg were evaluated in 20 healthy young adults. Only the 400-mg ginseng arm showed significant improvements at 1, 2.5, 4, and 6 hours after dosing.¹⁶⁶

Many human studies evaluating the ergogenic effects (i.e., parameters of muscular oxygen utilization and workload) of ginseng have been criticized for their poor methodology.¹⁶⁷ Well-designed trials involving small numbers of healthy patients (8–38) have been performed. *P. ginseng* extract (Ginsana, G115) at dosages of 200 to 400 mg/day or 8 to 16 mg/day of *P. quinquefolius* extract for 1 to 8 weeks failed to improve parameters of oxygen consumption, blood lactic acid concentration, or respiration under conditions of submaximal or maximal exercise.^{168–170} Many studies reporting positive ergogenic effects were not placebo controlled.¹⁶⁷ Those that were blinded and reported benefit were of small sample size (12–30 patients) and conducted in athletes; significant improvements in oxygen uptake, recovery heart rate, and endurance were noted.¹⁶⁷

Combination products of *P. ginseng* extract (G115) complexed with vitamins, minerals, and trace elements also have been used to assess adaptogenic properties.^{171–174} The dosage of ginseng extract used in these studies ranged from 40 to 80 mg/day for up to 12 weeks. Unfortunately, only one study used a control group, which accounted for the effects of vitamins, minerals, and trace elements.¹⁷⁴ Without such a control, the effects of ginseng cannot be distinguished from the other nutritional elements in the product. Ergogenic benefits were observed in one of these studies.¹⁷² In two other studies, quality of life was assessed.^{171,174} In 390 patients, 80 mg/day of extract significantly improved one of three scales used to assess quality of life.¹⁷¹ A subgroup analysis revealed that patients with the lowest quality of life scores had the greatest benefit. In contrast, 80 mg/day of extract in 49 sick and geriatric patients failed to influence cognitive function or somatic symptoms.¹⁷³ The only study that used an appropriate control group was conducted in 625 patients, 501 of whom completed the trial. Ginseng extract (40 mg/day) significantly improved quality of life based on an 11-item questionnaire.¹⁷⁴

A.J. should be told that the reported ergogenic, cognitive, and quality of life benefits of ginseng have not occurred with any consistency. Some studies reported significant effects, whereas others demonstrated no effect. Dosages of *P. ginseng* extract ranged from 40 to 600 mg/day.

Glucose Homeostasis

41. To what degree will A.J.'s diabetes, hypertension, and hyperlipidemia be affected by ginseng?

Both *P. quinquefolius* L, American ginseng, and *P. ginseng*, Korean or Chinese variety, have been studied in small randomized clinical trials for their effects on glucose in diabetic or nondiabetic patients.^{175,176} In 19 patients with type 2 diabetes mellitus, use of red *P. ginseng* 6 g/day (divided doses three times daily 40 minutes before meals) resulted in significant reductions ($p < 0.05$) in two of three fasting indices and five of seven indices following a 75-g oral glucose tolerance test compared to placebo. The primary outcome, A1C was not significantly altered versus placebo and averaged 6.5% in both groups over the 12-week study.¹⁷⁶ A separate trial evaluated American ginseng for its effect on postprandial blood sugar levels.¹⁷⁵ Both nondiabetic subjects and subjects with type 2 diabetes mellitus had significant drops in postprandial blood sugar values when 3 g of ginseng was taken 40 minutes before

a meal, compared with placebo. A significant drop also was observed in patients with diabetes, but not in healthy subjects, when ginseng was taken at the time of the meal. A recent systematic review also suggests that both American ginseng and *P. ginseng* can reduce blood glucose. Fifteen studies (13 randomized and 2 nonrandomized were included), sample sizes were small (36 or less patients in 14 trials), and overall 9 of the 15 trials showed significant reductions in blood glucose using either American or *P. ginseng* monopreparations.¹⁷⁷ A.J. should continue to check his blood glucose regularly and report any changes to his doctor.

Cardiac and Lipid Homeostasis

Some studies suggest that ginseng may have a beneficial effect on blood pressure (BP) and lipid profiles, but results are inconclusive.¹⁷⁷ Although vasodilatory effects of *P. ginseng* have been observed in animal models, effects in humans have been less consistent. A systematic review of 12 studies (7 randomized, 5 nonrandomized) primarily involving *P. ginseng* ($N = 11$) and its effects on BP showed largely insignificant reductions. Dosing among all trials varied from 40 mg to 4.5 g/day of ginseng. When benefits were observed, they were limited to small changes in systolic or diastolic blood pressure (SBP or DBP) of less than 4% among the randomized trials, which is also unlikely to be clinically meaningful in persons with hypertension.

In contrast, a rise in BP was reported after chronic ingestion (>1 month) of ginseng and Siberian ginseng products.¹⁷⁸ Patients developing hypertension typically consumed an average of 3 g of ginseng root per day,¹⁷⁸ but many of these patients also consumed caffeinated beverages, which may have contributed to the hypertension. Furthermore, no chemical analysis was performed for product content.

The effects of ginseng on serum lipid levels have also been the subject of a recent review.¹⁷⁷ Nine studies (four randomized, five nonrandomized) were included. A majority involved monopreparations of *P. ginseng* ($N = 6$) and variable dosing (80 mg to 9 g/day), and were of small sample size (24 patients or less in six trials). A majority of trials ($N = 5$) showed a significant improvement in one or more lipid parameters, but given the heterogeneity among the trials, it is unclear if these effects are reproducible or clinically meaningful.

A.J. should be informed that hypotensive and antihyperlipidemic effects of ginseng have not been clearly demonstrated. A.J.'s current BP and lipid values are elevated despite prescription therapy, and he has several other cardiovascular risk factors, including his age, diabetes, hypertension, and low HDL-C. A.J.'s dosages of simvastatin and benazepril should be increased, and he should monitor his BP more frequently after initiating ginseng. Any episodes of hypotension or hypertension should be discussed with his physician.

Immune Modulation

42. A.J. has received his flu shot already. Will taking ginseng further decrease his risk of catching the flu this season?

Ginseng is under investigation as an immune modulator. In vitro ginseng appeared to have a greater effect on stimulating lymphocyte proliferation in elderly versus young patients.¹⁷⁹ A lack of effect on leukocyte and lymphocyte counts was also

observed in vivo when 300 mg/day of *P. ginseng* extract was studied for 8 weeks in young and healthy adults.¹⁸⁰ However, other research has shown significant enhancement of immune function in healthy patients.¹⁸¹ Eight weeks of aqueous or standardized *P. ginseng* extract significantly increased PMN cell chemotaxis, phagocytosis fraction and index, intracellular killing, total lymphocytes (T3), T-helper (T4) subset, suppressor cells (T8), and NK cell activity.¹⁸¹ Both time to effect and degree of immune stimulation were superior in the standardized versus the aqueous extract group.¹⁸¹ The largest study to date using a *P. ginseng* product as a cold preventative was performed in 227 patients. Influenza vaccine was administered with and without 100 mg/day of *P. ginseng* extract (Ginsana). Forty-two cases of influenza were reported in the vaccination-only group versus 15 in the vaccination and ginseng group at 12 weeks. Antibody titers and NK cell activity were also significantly enhanced at 8 and 12 weeks in the ginseng group.¹⁸²

Two recent randomized, double-blind trials have shown a similar and significant preventative effect on cold frequency and duration among seniors taking American ginseng 400 mg for 4 months (1 month prior and 3 months after receiving the flu shot).^{183,184} Benefits may not just be limited to taking the herb while receiving the flu shot, however, as a separate randomized, double-blind study ($N = 279$ persons) of American ginseng 400 mg over 4 months also found significant benefits. The total number of colds was reduced overall and significantly so in persons with at least two colds over the 4-month study period.¹⁸⁵ A significant reduction in cold duration (34.5% less) and symptom severity (31% less) was also observed among all ginseng users who contracted a cold. Thus, ginseng may indeed decrease A.J.'s risk for catching the flu this season.

43. J.L. is a 32-year-old woman with a history of multiple sclerosis who last had an exacerbation 6 months ago. She would like to initiate ginseng to improve her athletic performance in an upcoming race. How would you advise J.L.?

Multiple sclerosis is an autoimmune disorder, and ginseng may enhance cytokine expression and stimulate the immune system. Although the German Commission E does not contraindicate the use of ginseng in patients with autoimmune disorders, it is reasonable to avoid ginseng in patients with multiple sclerosis and other immune system disorders (AIDS, collagen vascular disease, etc.), given the possibility of immune activation.

Anticarcinogenic/Antitumor Effects

44. R.B. is a 32-year-old woman who has a strong family history of stomach cancer. She has heard that ginseng can prevent cancer. Is there any evidence of this effect?

Animal studies have demonstrated anticarcinogenic properties for ginseng. In long-term experiments, ranging in duration from 28 to 56 weeks, ginseng significantly reduced procarcinogen-induced lung adenoma and hepatoma in mice.¹⁸⁶ The incidence and proliferation of tumors was also reduced.¹⁸⁶

In humans, two large-scale epidemiologic trials observed reductions in the incidence of cancer in patients consuming ginseng.¹⁸⁶ Evaluation of 921 cancer patients and 605 controls on an oncology service in Korea found a direct correlation be-

tween ginseng intake and the risk for cancer development.¹⁸⁷ The odds ratio with no ginseng intake was 1.0. This was reduced to 0.6 in patients who consumed ginseng one to three times per year, and to 0.36 if consumption was increased to once per month or more. Duration of ginseng use also correlated to cancer development. At 1, 3, and 5 years of use, the odds ratio for cancer development was 0.64, 0.36, and 0.31, respectively. Fresh ginseng juice or slices and white ginseng tea had no influence on cancer risk, but fresh and white ginseng extract, white ginseng powder, and red ginseng did. Types of cancers that were reduced included oral, pharyngeal, esophageal, gastric, colorectal, hepatic, pancreatic, laryngeal, pulmonary, and ovarian. There were no reductions in breast, cervical, bladder, or thyroid cancer.

A larger prospective study of 4,634 patients compared the quantity of ginseng ingested to future cancer development.¹⁸⁷ The relative risk of cancer development was significantly lower in individuals who consumed ginseng more often. The relative risk for consumption once per month or more was 0.34. Stomach and lung cancers were significantly reduced. In both epidemiologic studies, other patient-specific variables could have influenced cancer development. Although smoking was taken into account, diet, environmental carcinogen exposure, and sexual behavior were not.

In summary, R.B. can be told that ginseng extract or powder may reduce her risk of developing stomach cancer. However, it should not be considered a cure for cancer. The greatest benefit is associated with frequent consumption (once or more per month) and long duration of use. If a fresh formulation is used, it should be manufactured as an extract because other formulations showed no benefit.

Erectile Dysfunction, Fertility, and Sex Hormones in Men

45. B.J. is a 45-year-old man with a history of mild alcohol-induced liver dysfunction, bipolar disorder, and recent intermittent episodes of erectile dysfunction. B.J. has been alcohol free for 2 years, and clinically his bipolar disorder has been stabilized with lithium (Lithobid) for 10 years. He has never been evaluated for sexual dysfunction. His current laboratory values include lithium, 1.0 mEq/L; AST, 80 U/L (normal, 5–40 U/L); ALT, 60 U/L (normal, 7–35 U/L); alkaline phosphatase, 100 U/L (normal, 30–120 U/L); albumin, 3.0 g/dL (normal, 4–6 g/dL); and an INR of 1.3. B.J. read that ginseng can alleviate symptoms of sexual dysfunction; he wants to purchase a bottle. How would you instruct this patient?

Ginseng may enhance fertility and erectile dysfunction in men. In one study, 46 patients with oligoasthenospermia and 20 controls were treated with 4 g/day of *P. ginseng* extract.¹⁸⁸ Sperm number and motility were significantly enhanced, and testosterone, dihydrotestosterone, FSH, and luteinizing hormone levels were increased compared with controls after 3 months of use. In another placebo-controlled, double-blind, crossover study of 45 men, 2,700 mg of red *P. ginseng* extract significantly enhanced parameters of erectile dysfunction compared with placebo (60% vs. 20%, respectively) after 8 weeks of treatment.¹⁸⁹ Nitrogen oxide release has been suggested as a possible mechanism of action.¹⁵⁷

Although preliminary studies suggest that ginseng might improve fertility and erectile dysfunction, more research is

needed. Because B.J.'s erectile dysfunction is of recent onset, he should be evaluated by his physician before initiating any treatment. If ginseng is initiated for sexual dysfunction, patients should be informed that efficacy cannot be assured.

Adverse Drug Reactions/Drug Interactions

46. B.J.'s physician was unable to find any physical abnormalities to explain his temporary erectile dysfunction. Therefore, he would like to try ginseng to alleviate his symptoms. What are the side effects and drug–drug interactions that have been associated with ginseng? Are any of these of concern in B.J.?

CNS stimulation, insomnia, hypertension, and nervousness have been reported in patients using ginseng and Siberian ginseng products.¹⁷⁸ Additional case reports of irritability, sleeplessness, and manic behavior have been observed in patients with a history of psychiatric illness taking ginseng in combination with other psychiatric medications (i.e., lithium, neuroleptics, phenelzine [Nardil]).¹⁹⁰ In these cases, product analysis was not performed, and adulteration could have occurred. However, in animal studies ginseng has altered corticosterone release, neurotransmitter function, and pain modulation (Table 3-4). Because B.J. has a history of bipolar disorder, he and his physician should be informed of these reports. If B.J. initiates ginseng, he should be alert for changes in mood and discuss these with his physician if they occur.

Additional drug–drug interactions that have been reported include a case report of diuretic resistance in a patient using a germanium-containing ginseng product.¹⁹⁰ Germanium, which has been associated with renal dysfunction, was considered to be the cause.¹⁹⁰ Elevated digoxin levels were observed in a patient consuming Siberian ginseng.¹⁹¹ This may have been the result of contamination of Siberian ginseng products with *Periploca sepium* (silk vine), which contains cardiac glycosides.¹⁹² In another case report, ginseng was associated with a probable reduction in warfarin efficacy,¹⁹⁰ and in animals, antiplatelet properties have been observed (Table 3-4). Antiplatelet properties could increase bleeding risk in patients taking other antiplatelet or anticoagulant medications, so this combination should be avoided. Preoperative and postoperative patients should also be advised to discontinue ginseng 7 to 10 days before and after surgery. Case reports of Stevens-Johnson syndrome and cerebral arteritis have occurred after standard and suprathreshold (25 g fresh root) ginseng doses, respectively.¹⁹⁰ Finally, because ginseng has been shown to possibly enhance the immune system response, persons with autoimmune disorders should not use ginseng chronically.¹⁸¹

The German Commission E lists no drug–drug interactions, contraindications, or adverse events associated with the use of *P. ginseng*.⁶ However, high BP has been listed as a contraindication to the use of Siberian but not *P. ginseng*.⁶ Adulteration cannot be ruled out in most adverse events and drug interactions that have been reported. Product analyses were not performed.

Sex Hormones in Women

47. Does ginseng have any “hormonal effects” in women?

In women, ginseng has been reported to have weak estrogenic activity.¹⁹⁰ In vivo case reports of vaginal bleeding and

mastalgia have occurred after the acute or chronic use of ginseng products.¹⁹⁰ In one of these cases, rechallenge with the ginseng product resulted in a return of the bleeding and a reduced plasma FSH level.¹⁹⁰ Neonatal androgenization was reported after a mother's use of Siberian ginseng.¹⁹³ This was later discredited when product analysis revealed the presence of *P. sepium* (silk vine) as a contaminant.¹⁹⁴

Pharmacokinetics and Dosing

48. What is known about the pharmacokinetics of ginseng? What doses are generally recommended?

After oral dosing of red, white, and *P. ginseng* extract, urinary excretion of 20(S)-protopanaxadiol and 20(S)-protopanaxatriol ginsenosides was >2%.¹⁹⁵ Elimination half-life ranged between 13.5 and 17.0 hours based on urinary excretion data.¹⁹⁵ After single-dose administration, a linear relationship was observed between the amount of ginseng ingested and the rate of ginsenoside excretion. Steady-state excretion of ginsenosides after multiple daily doses was achieved in 5 days.¹⁹⁵ These data provide some information regarding the absorption and excretion of ginsenosides in humans, but the primary route of metabolism and excretion of ginsenosides requires further investigation.

The dose of *P. ginseng* recommended by the German Commission E is 1 to 2 g of the crude root or its equivalent; 1 g of crude root is equivalent to 200 mg of the extract.¹⁶⁹ Ginsana is a standardized extract of *P. ginseng* that has been used in some clinical trials and can be found in the United States. Dosing for Siberian ginseng is 2 to 3 g of crude root or its equivalent. The commission recommends limiting the continuous use of these agents to 3 months.⁶

GLUCOSAMINE/CHONDROITIN

Background

Glucosamine has been promoted for use alone and in combination with chondroitin to treat and prevent osteoarthritis (OA). Both glucosamine and chondroitin were used in veterinary medicine for years prior to their use in humans. Glucosamine is said to strengthen cartilage, and chondroitin is commonly advocated as a product that decreases cartilage breakdown. Both products have been studied clinically as a way to prevent cartilage breakdown, specifically in knee osteoarthritis.

Human Cartilage

Human cartilage is a connective tissue composed of cartilage cells (chondrocytes) and the extracellular matrix. The extracellular matrix accounts for nearly 90% of articular cartilage¹⁹⁶ and is predominantly avascular. Chondrocyte nutrients and waste products are transported by diffusion through the blood supply of trabecular bone, blood, synovial fluid, and the perichondrium.¹⁹⁷ Chondrocyte nutrients help build the extracellular matrix.

The extracellular matrix of cartilage serves as the anchor for chondrocytes and imparts structural stability. Fibronectin, produced by fibroblasts, is also found within the extracellular matrix and is responsible for many cell repair processes.

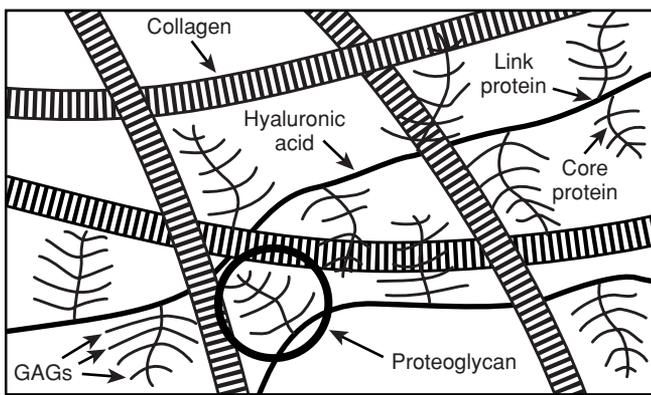

FIGURE 3-1 GAG and PG structures in human cartilage.

The extracellular matrix is a mesh of connective tissue that is composed of collagen, hyaluronic acid, and proteoglycans (PGs).

PGs are macromolecules composed of a protein core covalently linked to sulfated glucosaminoglycan (GAG) side chains. The PG structure resembles a “bottle brush” appearance. In articular cartilage, two types of GAGs are linked to the protein core: chondroitin sulfate and keratan sulfate. Hyaluronate serves as a link protein, which is bound to the PG subunit ionically (Fig. 3-1). The strength of articular cartilage largely depends on collagen, hyaluronate, and the GAGs of the PG aggregates (mostly chondroitin). Chondroitin imparts tensile strength, whereas PGs impart compressive strength. During cartilage synthesis, cations and water are bound to PG. This forms a viscous layer, which cushions and lubricates the joint.

Pharmacology

Glucosamine is an amino monosaccharide and is a product of glucose metabolism via the hexosamine pathway. Glucosamine is found in many human tissues and is a substrate for PG synthesis. Glucosamine is the rate-limiting step in GAG synthesis (Fig. 3-2). Glucosamine increases sulfate uptake, increases production of PG synthesis, and blocks matrix metalloprotease enzymes, which are catabolic enzymes.¹⁹⁸ Exogenous glucosamine sulfate is taken into cells and enters the extracellular matrix through diffusion, where it is incorporated into cartilage.¹⁹⁷ The sulfate salt component, as well as glucosamine, is necessary for the production of PG. Although the exact mechanism of glucosamine uptake has not been determined, PG channels have been suggested as a pathway of entry into the synovial fluid and chondrocytes.¹⁹⁷

Osteoarthritis (OA)

OA is characterized by a loss of PGs and GAGs and an increase in cartilage degradation, leading to joint stiffness and decreased elasticity.¹⁹⁹ In early OA, GAG synthesis increases.²⁰⁰ PG aggregates, consisting of noncovalently linked PGs to a single monomer of hyaluronic acid, tend to be smaller and contain a lower proportion of PGs than that found in patients without OA.²⁰¹

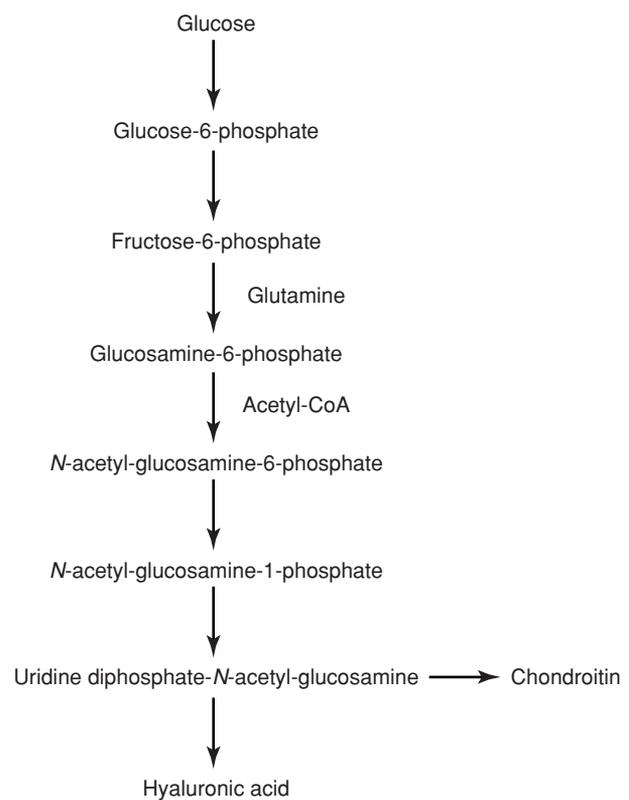

FIGURE 3-2 Biosynthesis of glucosamine, chondroitin, and hyaluronic acid.

Pharmacokinetics

Approximately 26% of oral glucosamine is absorbed after first-pass metabolism.²⁰² Glucosamine displays linear pharmacokinetics at oral doses of 750 mg, 1,500 mg, and 3,000 mg daily.¹⁹⁸ It is distributed into tissues (kidneys, liver, articular cartilage) and incorporated into plasma proteins and other structures. The volume of distribution approaches 2.5 L, and the elimination half-life following oral glucosamine administration averages 15 hours.^{198,202} Unmetabolized and unbound glucosamine is predominantly eliminated in the urine. Unabsorbed glucosamine is largely eliminated by the fecal route. Although the exact amount has not been quantified, glucosamine is also metabolized to carbon dioxide and excreted through the lungs as expired air.²⁰²

49. K.E. is a 66-year-old obese woman with type 2 diabetes (managed with diet) who has had OA of the left knee for 10 years. She is 5 ft 4 in. and weighs 95 kg (ideal body weight, 55 kg). Five years ago, her knee pain responded to maximum doses of acetaminophen (Tylenol), but it has progressively worsened over the past 2 years. Radiographic examination of the left knee reveals osteophyte formation and articular space narrowing. K.E. is currently taking ibuprofen 400 mg TID, which provides only moderate relief of her pain. She would like to try glucosamine because a friend told her that it would help alleviate knee pain and increase her mobility. What is the clinical evidence for using glucosamine in osteoarthritis?

Glucosamine is widely used by many adults with OA, including older adults. The scientific literature is replete with

many poorly designed studies evaluating the safety and efficacy of glucosamine for OA; most of these conclude there is a benefit. One meta-analysis found an overall improvement in symptoms of 30%, which was deemed to be an overestimation of the beneficial effects of glucosamine and chondroitin.²⁰³ Since the publication of this meta-analysis, several well-designed studies have been published, some demonstrating a benefit, and others suggesting no effect. Reasons for these differences may involve inadequate concealment of allocation and significant heterogeneity among the patients enrolled, particularly in industry-funded trials.²⁰⁴ Other reasons include the use of differing glucosamine formulations. For example, one of the largest and very well-designed placebo-controlled trials compared the effects of placebo, glucosamine, chondroitin sulfate, and the combination at standard doses on painful knee OA over 6 months.²⁰⁵ The study found that neither glucosamine nor chondroitin sulfate alone reduced pain effectively, and the combination seemed to be slightly better in those with moderate to severe pain. Unfortunately, the investigators used the glucosamine hydrochloride formulation, which has been shown in previous research to be ineffective.²⁰⁶

Two well-designed, randomized, double-blind, placebo-controlled trials have demonstrated improvements in symptom scores and pain after 2 to 3 months of glucosamine administration.^{207,208} Both trials used once daily dosing of 1,500 mg glucosamine sulfate for 3 years. The Lequesne index, a tool used to measure pain, minimum walking distance, and movement limitation in ADL, was used to measure efficacy. The Western Ontario and McMaster Universities knee osteoarthritis index (WOMAC) was used to assess severity of joint pain, stiffness, and physical function. Patients enrolled had similar baseline OA disease of mild to moderate severity, as measured by radiograph and the Lequesne and WOMAC rating scales. Statistically significant improvements in symptoms and joint space narrowing were observed in patients receiving glucosamine sulfate. Improvements in joint space narrowing were observed at 1 year and continued to improve at 3 years. The patients receiving placebo experienced progression of joint space narrowing and worsening symptom scores. In both studies, the use of rescue medications (e.g., acetaminophen, NSAIDs) was variable and inconsistent between the glucosamine and placebo groups. Interestingly, there was little correlation between structural joint improvements (as seen on radiograph) and symptom improvement. This finding is commonly accepted in the treatment of OA; symptom relief can occur independently of structural changes.

One study compared the effects of glucosamine 500 mg TID to ibuprofen 400 mg TID.²⁰⁹ Hospitalized patients were treated for active OA of the knee for 4 weeks. Pain scores were significantly lower in those patients receiving ibuprofen at week 1; by week 2, pain score improvements were similar for both groups. Ibuprofen resulted in fast-onset pain relief, but glucosamine had a slower onset of action. Because the study was only 4 weeks long, it is unclear how long efficacy would be maintained in both groups. Nearly 35% of patients taking ibuprofen experienced GI side effects compared to 6% taking glucosamine.

K.E. should be advised that oral glucosamine may help prevent the breakdown of cartilage and may alleviate some of her pain long term, but it will not cure OA. It is unlikely that she will experience a 30% improvement in her symptoms; however, it is possible. A more realistic goal would be to see a

reduction in pain and an increase in mobility of about 10%. The most important thing K.E. should do is to keep a diary of her pain, indicating the time when it occurs, its duration, and its severity. She should also indicate her daily walking distance and factors that trigger her pain. This will help determine whether glucosamine is having an effect because it can take 1 to 2 months before a response is observed clinically. Because glucosamine may take longer to work than ibuprofen (months vs. hours, respectively), the duration of pain relief from glucosamine may last longer simply because tolerability seems to be better as compared to ibuprofen. Weight loss and physical therapy should also improve her joint mobility.

Nonsteroidal Anti-Inflammatory Drug Combination Therapy

50. Can glucosamine be used in conjunction with NSAIDs to treat OA pain?

Combined glucosamine and NSAID therapy has not been studied, but because there are significant side effects associated with NSAID use in elderly patients like K.E., the decision to use them should be weighed against her risks for GI bleeding or ulceration, renal dysfunction, and pain severity. Because the analgesic effects of glucosamine are not seen immediately,²⁰⁷ combined use with ibuprofen may help alleviate acute pain. She should be instructed to use the lowest effective dose of ibuprofen and to take it with food or milk. After 7 to 21 days, K.E. may consider discontinuing NSAID therapy while continuing glucosamine monotherapy. In any case, she should review her treatment decision with her primary care provider.

Product Selection

51. K.E. is concerned that some glucosamine sulfate formulations pose a risk to people with shellfish allergies. Is this true?

Glucosamine is predominantly derived from chitin, which is found in yeast, fungi, and marine invertebrates. In the United States, the primary source is from shellfish such as shrimp, scallops, and lobster. Because quality control issues have been a real concern in the purity of supplements in the United States, people with shellfish allergies have been told to avoid products derived from chitin. Interestingly, no reports of allergic reactions have been reported in shrimp-allergic individuals taking glucosamine sulfate. Many people believe that the allergens are found in the meat of crustaceans rather than in the exoskeleton and that this may account for the lack of allergic reactions. Other explanations may involve the method of glucosamine purification and formulation, suggesting that proper manufacturing would ultimately destroy allergenic constituents. One study compared the potential for allergic reactions in shrimp-allergic adults who ingested 1,500 mg of shrimp-derived or synthetic-derived glucosamine.²¹⁰ The study concluded that no subjects experienced immediate or delayed allergic reactions (24 hours) following the ingestion of either product. This suggests that allergenicity from properly formulated glucosamine products should not pose a risk in susceptible adults.

52. K.E. is determined to try glucosamine but is confused about which product to select because the ingredients vary. Which glucosamine product should K.E. use?

In the United States, glucosamine is widely available in grocery stores, health food stores, and pharmacies as an over-the-counter dietary supplement. Many salts of glucosamine are available, including glucosamine sulfate, glucosamine hydrochloride, and glucosamine hydroiodide. Glucosamine sulfate is the preferred product because the sulfate salt is required for GAG synthesis and is the most widely studied.²¹¹ The formulations of glucosamine sulfate that have been used in clinical trials are Dona, Viartril-S, or Xicil, all of which are manufactured by Rottapharm in Italy. Dona can be purchased directly from the manufacturer's website. Several other formulations have proven to be of high quality and purity; look for products with the USP seal of approval on the package labeling. Glucosamine hydroiodide may be problematic in patients with undiagnosed thyroid disease or in those taking thioamides and therefore should be avoided. Glucosamine hydrochloride has been studied for OA knee pain for 3 months and was found to be ineffective in improving mobility and joint function as compared with placebo.²⁰⁶ The only statistically significant improvements noted were in subjective pain relief and objective knee improvements on radiographic examination. Therefore, the value of glucosamine hydrochloride remains unknown. Many oral preparations also contain *N*-acetylglucosamine (NAG), which is a GAG intermediate. However, exogenous NAG is poorly used by cells and is believed to be a poor substrate for kinase phosphorylation, which is needed for GAG synthesis.²¹² The role of NAG in preventing OA has not been determined.

Other ingredients added to glucosamine products include herbs, amino acids, sodium, selenium and potassium salts, zinc, copper, manganese, and vitamins. Some of these ingredients are added to make the product more attractive to consumers. Others are added because they are essential cofactors for GAG synthesis. For example, manganese is added because nutritional deficiencies have been associated with bone and joint malformations. Ascorbic acid is added because it is an essential cofactor for collagen synthesis; the objective is to ensure that collagen synthesis occurs at an effective rate.²¹³ There is no evidence, however, that these added ingredients are necessary in patients who eat a balanced diet. Sodium and potassium are added to increase glucosamine stability.

Chondroitin Sulfate

Dietary supplement manufacturers often combine chondroitin sulfate with glucosamine because it is believed to inhibit cartilage-destroying enzymes called "matrix metalloproteinases." Chondroitin sulfate is the most abundant GAG in articular cartilage and consists of repeating units of glucosamine and aminosugars. Whether chondroitin is absorbed intact from the GI tract remains controversial. Chondroitin is likely broken down into individual glucosamine monomers and absorbed via the GI tract. Clinical evidence supports this mechanism.^{214–216} In one study, chondroitin (400 mg orally TID) appeared to be as effective as diclofenac sodium (Voltaren), 50 mg orally TID, in relieving the pain associated with OA.²¹⁴ Patients experienced a recurrence of pain when either therapy was discontinued. Patients receiving chondroitin appeared to have better long-term control of pain, but they were allowed to continue therapy for 3 months versus 1 month for diclofenac (Voltaren) therapy. A recent meta-analysis supports chondroitin efficacy. However,

the authors concluded that chondroitin effectiveness was overestimated in clinical studies.

In summary, the benefits of these combination products have not been adequately studied in clinical trials. One of the largest multicenter studies mentioned previously set out to assess the value of adding chondroitin sulfate to glucosamine.²⁰⁵ Specifically, this study compared the effects of placebo to glucosamine, chondroitin sulfate, glucosamine with chondroitin sulfate, and celecoxib. Unfortunately, the investigators used glucosamine hydrochloride instead of glucosamine sulfate, making the study outcome less than ideal. The group of patients using chondroitin sulfate alone did experience a small but insignificant improvement in knee OA pain. The group receiving both glucosamine hydrochloride and chondroitin sulfate experienced a similar insignificant outcome. In a subgroup analysis, the authors concluded that the combination may be effective in patients with moderate-to-severe knee pain rather than those with milder disease. This finding is contrary to what many experts have advocated: beginning therapy in early disease to help preserve cartilage form and function as compared to beginning therapy in the later stages when little to no functional cartilage remains. Whether to begin glucosamine/chondroitin in early disease or late disease is still unclear. Until more information is known, K.E. should select a product containing glucosamine sulfate, chondroitin sulfate, or both. Any of these products may help her symptoms. Keep in mind that the addition of other ingredients might increase the potential for adverse effects and may add to the cost of the product.

Dosing

53. What is the most effective dose for glucosamine/chondroitin?

Dose-response studies have not been conducted. The most commonly studied oral daily glucosamine dose is 1,500 mg/day. The most commonly studied dose for chondroitin sulfate is 1,200 mg/day. In clinical trials, glucosamine has been administered as either 500 mg TID or 1,500 mg given once daily with or without meals. Chondroitin sulfate has also been administered as 400 mg TID or 1,200 mg/day. Given that adherence is better with once daily administration as compared to three times daily, K.E. should consider taking either supplement or both once daily.

Adverse Drug Effects

54. K.E. has been experiencing stomach upset while taking ibuprofen. Will glucosamine cause stomach upset or other serious side effects?

Although adverse effects of glucosamine have not been systematically studied, information can be gleaned from patient reports in four clinical trials^{207,208,217,218} and one uncontrolled study.²¹⁹ Overall, glucosamine appears to be well tolerated and better tolerated than NSAIDs. The most commonly reported adverse symptoms involve the GI tract and include constipation, epigastric pain, tenderness, heartburn, diarrhea, and nausea.^{207,208,217,218,220} Therefore, K.E. should be told that glucosamine is well tolerated compared with NSAIDs, but it may also produce symptoms of GI irritation. Taking glucosamine with food may prevent GI irritation. Because K.E. already is

complaining of stomach upset while taking ibuprofen and is at high risk for GI bleeding secondary to NSAID use, she should be referred to her primary care provider for further evaluation before she adds glucosamine to her regimen.

Animal studies suggest glucosamine increases blood glucose and insulin resistance. This finding raised serious concerns for adults with diabetes using glucosamine for OA. Many studies have been carried out using both oral and IV formulations. Oral glucosamine administration is unlikely to affect blood sugar, particularly in patients who do not have diabetes.²²¹ Glucosamine acts intracellularly and not extracellularly, which may explain why blood glucose levels are unaffected. In those patients with undiagnosed disease or impaired glucose tolerance, it is possible that glucosamine may contribute to abnormal blood glucose values.²²² Until more information is available, patients like K.E. with diabetes mellitus or glucose intolerance who use glucosamine should monitor their blood sugar regularly.

55. Are there any known drug interactions with glucosamine?

Although drug–drug interactions have not been formally evaluated, no significant drug interactions have been reported to date. One case report exists that suggests an interaction between warfarin and glucosamine/chondroitin.²²³ In this case, a 69-year-old patient with atrial fibrillation was stable on 47.5 mg of warfarin weekly with an INR between 2 and 3. After 4 weeks of self-initiated 3,000 mg of glucosamine and 2,400 mg of chondroitin daily (six capsules of Cosamin DS), the patient's INR increased from 2.58 to 4.52. The dose of Cosamin DS is twice what is recommended in the literature and what is typically used in clinical trials. Because glucosamine is a component of heparin and chondroitin is a small component of danaparoid (a low-molecular-weight heparinoid), it is possible that there may be an additive pharmacodynamic effect. However, this does not explain the increase in INR, which is not affected by heparin-like activity. Whether these higher-than-normal doses enhanced warfarin action is not known. More research is needed to assess the effect of this high dose on warfarin pharmacology. Finally, the purity of the Cosamin DS product was not assessed to rule out contaminants as the cause. At this point, the use of glucosamine/chondroitin with warfarin is not contraindicated, but the INR should be monitored at the start of therapy and during any dose adjustments.

SHARK CARTILAGE

Background

Shark cartilage has been advocated for many disorders, including cancer, psoriasis, diabetic retinopathy, neurovascular glaucoma, inflammation, Kaposi sarcoma, and arthritic pain. It has also been said to have antimicrobial properties²²⁴ and antioxidant effects,²²⁵ neither of which is well studied. Shark cartilage is derived from the elastic cartilage found in the endoskeleton of sharks. The spiny dogfish shark (*Aqualus acanthias*) is the primary source of commercial shark cartilage products in the United States. Native shark cartilage contains three components: chondrocytes (cartilage cells), water, and an extracellular matrix. Shark cartilage dietary supplements contain various proteins, including collagen, proteoglycans (PGs), phospholipids, sterols, and a variety of minerals (calcium, phospho-

rus, sodium, magnesium, potassium, zinc, iron). Chondroitin-6-sulfate appears to be one of the primary PGs found in shark cartilage, although it is not known whether this is the active ingredient. Various angiogenesis inhibitors have been identified and extracted from native shark cartilage. It is unknown if these are present or active in commercially available shark cartilage supplements.

Two popular brands of shark cartilage advocated for their antineoplastic effects include BeneFin and Neovastat, the latter being the most studied. The proposed antineoplastic activity of shark cartilage or its glycoprotein extracts is based on its ability to block two main pathways that contribute to angiogenesis: matrix metalloproteases and the vascular endothelial growth factor signaling pathway. Results have been inconsistent, however.^{226–235} Angiogenesis, or the development of new blood vessels, is an important process in wound healing, building of the corpus luteum, embryonic development, and solid tumor growth and metastases. Unfortunately, whether commercially available dietary supplements actually contain active angiogenesis inhibitors is not known.

Most disturbing is that in June 1997, the FDA sent a warning letter to Lane Labs, the manufacturer of BeneFin, to stop promoting BeneFin for the treatment of cancer. Despite the warnings, the company persisted, and in 1999, FDA was granted the authority to impose a permanent injunction against Lane Labs to stop selling the supplement for the treatment of cancer. Lane Labs had to refund consumers for the cost of the supplement. Shark cartilage, however, is available today and is marketed for its proteoglycan (glucosamine and chondroitin) and calcium content.

56. S.N., a 51-year-old woman, was recently diagnosed with stage III colon cancer. She has had two previous adenomatous polyps removed, and her recent colonoscopy revealed adenocarcinoma of the colon. S.N. recently watched a television news program that claimed shark cartilage is a cure for cancer. She is currently awaiting surgery and will be receiving adjuvant chemotherapy, fluorouracil (Acrucil), and levamisole (Ergamisol). She would like to start taking shark cartilage. Is shark cartilage effective as an anticancer agent?

There is limited information on the effectiveness of shark cartilage or its extracts in the prevention or cure of cancer. Shark cartilage is available in liquid, powder, tablets, and a variety of unique capsule formulations. Each formulation of shark cartilage requires unique processing. Two common methods of processing shark cartilage involve creating an aqueous extract or a dry powder formulation. Among the commercially available shark cartilage dietary supplements, little information is provided to consumers about the type of extract or the extent of the processing. This is important because dosing recommendations vary among the various formulations, and limited data exist regarding an effective dose. One aqueous extract derived from shark cartilage (Neovastat AE-941) has been studied in a phase II renal cell carcinoma study.²³⁶ In this study, Neovastat was given to 22 patients as a twice daily oral preparation. The study began using 60 mL/day; subsequently, some patients received a higher dose, 240 mL/day, based on tolerability. The only responders included two patients receiving 240 mL/day who survived 14 months compared with 7 months for those taking 60 mL/day. Although this study suggests that Neovastat had a favorable effect, the

degree of improvement was minimal. Furthermore, the open label design makes these findings difficult to interpret. In one preliminary 16-week study in Cuba, only 3 of 29 patients with cancer responded to an unknown formulation of shark cartilage. Although the findings were not published, the National Cancer Institute reviewed the data and concluded that the results were “incomplete and unimpressive.”²³⁷ One unpublished clinical trial evaluated the effect of 80 to 100 g of shark cartilage powder self-administered orally or rectally daily in 70 subjects with cancer (type of cancer and other concomitant therapy unspecified). After 8 weeks, 10 of 20 patients who had been evaluated reported an improvement in quality of life, pain, and appetite; 4 showed partial or complete responses to therapy.²³⁷

Another study described the use of shark cartilage in 60 adult patients with advanced cancers (16 breast, 16 colon, 14 lung, 8 prostate, 3 lymphoma, 1 brain, 2 unknown) that were resistant to conventional therapies and had objective measurable disease.²³⁸ Life expectancy was ≥ 12 weeks, and none of the patients had received recent or concomitant cancer chemotherapy. All patients received shark cartilage 1 g/kg/day given in three divided doses. After 12 weeks, 47 patients were evaluated for efficacy and toxicity. Five patients dropped out due to GI side effects. Quality-of-life scores did not improve after 12 weeks of therapy, and no complete or partial responses were noted. Based on these findings, shark cartilage did not alter disease progression.

The current scientific literature does not support the use of commercially available shark cartilage dietary supplements for the treatment of any type of cancer, including colon cancer. More importantly, many of the commercially available shark cartilage dietary supplements contain only binding agents or fillers. Therefore, without reliable dose–response data and bioavailability studies, it is difficult to determine whether these products have true antiangiogenic activity. If S.N. decides to use shark cartilage in combination with her chemotherapy, she should be told that it is not a cancer cure. Furthermore, the effect of shark cartilage on the activity of any other drugs she may be taking or the course of her disease is unknown.

Product Selection, Dosage, and Administration

57. If S.N. chooses to use shark cartilage, what type of product should she use and how should she be advised to take it?

There is no evidence that one formulation or source of shark cartilage is superior to another. However, the product selected should not have been exposed to excessive heat during the manufacturing process because this may denature any active proteins.^{239,240} This information can be obtained only by contacting the manufacturer directly because dietary supplement labels often do not disclose the specific formulation type.

Clinically, shark cartilage has been administered orally and rectally. The most commonly recommended oral dose is 1 g/kg/day.^{238,239} The GI absorption of shark cartilage has not been studied, and skeptics suggest that substantial oral absorption of its macromolecular constituents (40% proteins; 5%–20% GAGs) is unlikely because they will be destroyed by GI enzymes. However, others argue that the active ingredient is unknown, and one GAG, chondroitin, has been shown to undergo significant intestinal absorption.²⁴¹ For these reasons,

some advocate using products that have been pulverized to the finest particle size.²³⁹ To avert enzymatic degradation, maximize absorption, and minimize GI irritation, shark cartilage has also been administered as a retention enema for 25 minutes. The recommended mixture is 20 g of bulk shark cartilage powder diluted in 20 mL of tepid water. In the lay press, “colonic cleansing” has been recommended before the retention enema to clear the bowel of fecal material and to enhance absorption. This practice is dangerous, can cause dehydration, and should not be used.

Adverse Effects

58. Are there any adverse effects associated with this product? Does S.N. have any contraindications to its use?

S.N. should be warned to watch for GI upset, the most common dose-limiting side effect of shark cartilage.²³⁹ Diarrhea, constipation, indigestion, and taste disturbances have also been observed. Most striking, however, is the unpleasant “fishy” odor of the supplement. Shark cartilage may also contain calcium; therefore, patients taking calcium supplements along with shark cartilage may need to adjust their calcium supplementation. Two cases of hepatitis have also been reported.²⁴² In one case, the patient was also taking oral comfrey, which is known to be hepatotoxic. Use of other hepatotoxic agents, including alcohol, acetaminophen, and prescription medications, was not described. While taking shark cartilage, S.N. should report any changes in stool or urine color, flulike symptoms, and fatigue. Because the cause of these effects is unknown, S.N. should discontinue use and discard any product that has changed in color, odor, or consistency.

S.N. does not have any contraindications to the use of this product. These include situations in which neovascularization is crucial for tissue growth and repair, such as fetal development (pregnancy), wound healing, and normal growth (infants and children). Drug interactions with shark cartilage have not been identified or reported.

59. Does shark cartilage interact with other medicines?

No formal drug interaction studies have been conducted with shark cartilage, and no interactions have been reported to date. Shark cartilage should be used cautiously in patients receiving anticoagulants because certain proteins isolated from shark cartilage resemble the structure of heparin and other endogenous human proteins that enhance the effects of tissue plasminogen activator.²⁴² Similar to glucosamine/chondroitin, the potential for a pharmacodynamic interaction with warfarin exists, although no studies are currently available. At this point, there is no contraindication to using shark cartilage along with warfarin because close INR monitoring is implemented at the start of therapy and during any dose adjustments.

ZINC

Background

Zinc is a trace element that serves as an enzymatic cofactor and protects cell membranes from lysis through complement activation and toxin release.²⁴³ Many salt forms of zinc are available, including acetate (2A), gluconate (2G), gluconate-glycine (2GG), ascorbate, aspartate, orotate, sulfate, and chloride.

Each formulation varies in solubility, palatability, and zinc ion (Zn^{2+}) release characteristics. Zn^{2+} in zinc acetate (ZA), zinc gluconate (ZG), and zinc gluconate-glycine (ZGG) has been studied clinically for its role in treating the common cold.

Mechanism of Action

The mechanism of action of Zn^{2+} ions is controversial but may involve a combination of several actions. In vitro studies have shown that Zn^{2+} ions interfere with the formation of rhinoviral capsid proteins, preventing viral replication.^{244–246} Zn^{2+} ions also block binding of human rhinovirus to intracellular adhesion molecule-1 (ICAM-1), which subsequently interferes with the inflammatory process.²⁴⁷ ICAM-1, an immunoglobulin present on the surface of endothelial and epithelial cells, serves as a receptor for the human rhinovirus. However, Zn^{2+} ions do not seem to affect mature rhinoviruses.²⁴⁵ Other research suggests that Zn^{2+} induces interferon- γ production in human white blood cell cultures.²⁴⁸ At physiological serum concentrations, zinc has been shown to inhibit histamine release from mast cells and basophils.²⁴⁹ An astringent or drying effect on mucus-producing goblet cells may contribute to the efficacy of Zn^{2+} in treating the common cold.²⁵⁰ Finally, Zn^{2+} ions have been shown to inhibit depolarization and impulse transmission in the trigeminal and facial nerves, leading to cold symptom relief in 1 to 3 minutes.²⁵¹

The role for zinc lozenges in the symptomatic relief of the common cold is based on Zn^{2+} release characteristics. Once released into the oral and nasal passages, Zn^{2+} ions are at supra-physiological concentrations, causing an osmotic gradient.²⁴⁷ This gradient is believed to cause the transfer of Zn^{2+} ions from the mouth to the nasal and mucosal passages, sometimes referred to as a biological closed electric circuit (BCEC), where they prevent rhinoviral binding and activation.^{247,252} The Zn^{2+} cation appears to be the most effective form of zinc for the common cold because it may interact with the electronegative cell surfaces in the oropharyngeal cavity. The administration of zinc products that release neutral or negatively charged Zn has been associated with a worsening of symptoms.^{253,254} Neutral zinc may decrease transport through the BCEC, and negatively charged zinc may be repelled by mucosal cell surfaces.

Common Cold

The discovery that zinc may help treat the common cold occurred in 1979. A 3-year-old girl with acute lymphocytic leukemia suffering from a cold was taking ZG tablets to help stimulate lymphocyte responses after chemotherapy. Instead of swallowing the tablet whole, she let it dissolve in her mouth. The next day, her cold symptoms were gone.²⁵⁵ This finding led researchers to begin studying ZG for the treatment and prevention of the common cold.^{256,257}

Many studies have been conducted on the effects of zinc and the common cold.²⁵⁸ These studies have generated controversy and received a great deal of scrutiny. In addition to study design flaws, much of the criticism involves limitations in the nature of common cold. Study design flaws include poor placebo matching (blinding), lack of randomization information and power analysis, small sample size, variations in dosage, frequency of administration, time of first dose, varying patient populations, lack of patient follow-up, and disparity in excipients or flavor-

ing agents used. Other drawbacks that limit the applicability of the results involve a lack in documentation of rhinovirus infection, variations in the time of year studied, variations in location of study, differences in inoculum, and concomitant medication use.

Systematic Review

One comprehensive systematic review analyzed 14 placebo-controlled studies on the use of zinc for the treatment of the common cold.²⁵⁸ The review focused on explicit criteria necessary to ensure valid experimental study design. The criteria included validated case definition (cold symptoms), quantifiable hypotheses, sample size, randomized allocation, double-blinding, proof of blinding, adherence, drop-out rates, intent-to-treat analyses, methods of statistical analysis, and measurements of probability. These criteria are critical because many of the zinc studies had been criticized for not following appropriate study design methods. The authors identified that seven studies found a positive effect for zinc, and seven studies reported no effect. Among the studies concluding zinc had a positive effect on the common cold, only one study met all 11 criteria listed previously. This is concerning because it implies that the benefits observed with zinc may have been due to chance or possibly due to flawed study design. The most common study design flaw was not using an intent-to-treat analysis. Among the zinc lozenge and nasal spray studies, two fulfilled all study criteria; however, one found a positive effect, and one found no effect of zinc. Other research suggests that the inclusion of citric acid, tartaric acid, mannitol, and sorbitol may prevent Zn^{2+} release. In all, drawing any conclusions from these studies is very difficult given study heterogeneity, lack of consistent study design, and variations in zinc delivery and zinc formulation. Explaining these variables to consumers may be overwhelming; therefore, consumers should know that more studies are needed. The formulation of zinc and the delivery method may all play a role in effectiveness.

60. C.D. is a 32-year-old woman suffering from a “cold.” She complains of a sore throat, runny nose, and nasal stuffiness that began yesterday and has worsened since. Today, she developed watery eyes and sneezing. She is taking pseudoephedrine tablets (30 mg Q 8 hr PRN) for her nasal stuffiness. She is not immunocompromised and states that she does not have any other medical problems. She denies headaches, nausea, vomiting, cough, or myalgias and fever. An oral temperature taken at home is 98°F (37°C). She would like to try zinc lozenges for her cold symptoms. Are zinc lozenges appropriate for this patient?

Although many viruses are associated with the common cold, rhinovirus is involved in 30% to 50% of community-acquired colds.^{259,260} C.D.’s symptoms began yesterday and have worsened today. The rapid onset is consistent with rhinovirus infections because the majority of viral replication is complete 1 day before symptom onset.²⁶¹ Peak symptoms usually appear 2 to 3 days after infection. C.D. is not complaining of headache, sinus pain, fever, fatigue, or myalgias, symptoms that are typically associated with influenza or respiratory syncytial virus. These symptoms usually develop more slowly over the course of ≥ 5 days. C.D. should see an improvement in her symptoms within 1 to 2 weeks because the common cold is self-limiting. C.D.’s symptoms began yesterday, so she is

still a candidate for zinc therapy. In studies that have documented efficacy, improvements in cold symptoms have been seen when zinc therapy is started within 1 to 2 days of symptom onset.^{252,256,262} C.D. states that she wants rapid relief of her cold symptoms. Zinc may help relieve these symptoms, but the onset of relief varies. In clinical trials, zinc therapy appeared to shorten the subjective duration of respiratory symptoms by 1 to 2 days. Remind C.D. that zinc lozenges are not a cure for the common cold. They also do not replace rest, proper nutrition, and hydration.

Product Selection and Dosing

61. C.D. wants to know which product to select. Many formulations of zinc are available. What should C.D. know about zinc dosing and administration for the common cold?

Various zinc formulations have been used to deliver Zn^{2+} , including zinc lozenges; nasal gels delivered as nasal sprays; and zinc nasal swabs, gum, and oral chews.

Clinical trials have used oral ZA, ZG, and ZGG, but adequate study blinding has been a problem because zinc lozenges have a characteristic taste that is difficult to mask. Various excipients and fillers have been used to overcome the flavor: citrate, tartaric acid, and mannitol-sorbitol mixtures. These products resulted in a tightly bound zinc complex, as measured by high stability constants, preventing the release of Zn^{2+} .²⁴⁷ Based on its theoretical Zn^{2+} release characteristics, ZGG was studied. Some research suggests ZGG releases approximately 90% to 93% of the available Zn^{2+} in the mouth,²⁶³ whereas other investigators have found that ZGG does not release any Zn^{2+} in the mouth at physiological pH as measured by zinc ion availability (ZIA).²⁶⁴ The ZIA method was developed to measure the amount of Zn^{2+} released under physiological conditions in the mouth and oropharyngeal areas.²⁶⁴ Based on this principle, the ZIA values were estimated for each formulation used in clinical trials and varied based on rate of lozenge dissolution, dosage, and excipients used. ZIA values do not correspond to statistically significant treatment outcomes or to statistically significant changes in the duration of common colds. The clinical relevance of this method is controversial and is currently being evaluated.

Four randomized, double-blind, placebo-controlled trials have examined the effects of zinc gluconate nasal gel on the duration and severity of common cold symptoms.^{265–268} Three studies have used the same formulation called Zicam. One study inoculated healthy volunteers with the rhinovirus,²⁶⁷ and the other two studies evaluated efficacy in naturally acquired colds. All patients were instructed to begin using the spray within 24 to 48 hours of the onset of cold symptoms. They were further instructed to spray one dose into each nostril every 4 hours for as long as they experienced cold symptoms. In all but one study, zinc nasal gel significantly reduced the duration of cold symptoms. The average symptom duration was 2 to 4 days in the zinc group versus 6 to 9 days in the placebo. Side effects were reported equally in the zinc and placebo groups and included a slight tingling or burning sensation. Other side effects included nasal tenderness, dry nose, dry mouth, dysgeusia, and epistaxis.

Another similar trial used a nasal spray containing 0.12% zinc (as zinc sulfate heptahydrate).²⁶⁸ Patients were instructed

to administer two inhalations into each nostril four times daily until the symptoms resolved, up to a maximum of 14 days. After the treatment period, there were no differences in the time to symptom resolution or cold duration; however, the zinc group did have a lower symptom score compared to placebo. The efficacy of zinc nasal spray appears similar to oral zinc lozenges, although zinc lozenges have been studied to a greater extent than zinc nasal spray. More research is needed to determine the best zinc formulation and method of administration in the common cold. Currently, both oral lozenges and nasal sprays appear to be equally effective.

In summary, C.D. should select a zinc formulation that has been shown to release Zn^{2+} readily in the mouth and oropharyngeal areas, but it is currently unclear which of the zinc products can best accomplish this. Oral ZGG, ZG, and ZA as well as nasal sprays seem to be somewhat effective; however, concerns regarding nasal sprays and permanent anosmia make the nasal sprays undesirable. C.D. should select an oral product that she finds the most palatable, convenient, and affordable.

Dosage

The commercially available zinc nasal spray (Zicam) has been administered as one spray in each nostril four times daily while awake. All zinc lozenges studied have been administered every 2 hours while awake. Although the most effective ZGG oral dose has not been established, 13.3-mg lozenges were used in clinical trials. C.D. may benefit from taking one 13.3-mg ZGG lozenge every 2 hours while awake. A higher ZGG dosage may be used, but may be associated with poor palatability. If C.D. chooses to take a ZA formulation, she should select a product with at least 10 mg of ZA per lozenge. If she prefers to take a ZG formulation, each lozenge should contain at least 23 mg of elemental zinc. For any zinc lozenge product selected, C.D. should let the lozenges dissolve completely in her mouth without chewing or swallowing them. C.D. should continue taking the lozenges every 2 hours while awake for the duration of her cold symptoms. Most clinical studies have continued Zicam for up to 10 days and zinc lozenge therapy from 5 to 10 days, or until symptoms have completely resolved. C.D. should be reminded that neither zinc nasal spray nor zinc lozenges are a cure for the common cold. If she does not see an improvement in her symptoms after 10 days or if she develops a fever, purulent sputum, vomiting, or diarrhea, she should stop taking the zinc product and seek medical care.

Adverse Effects

62. What are the side effects of zinc lozenges? What should C.D. expect?

The most common side effects associated with zinc lozenges are related to poor palatability, often resulting in poor adherence and sometimes discontinuation. Other common side effects include nausea, taste disturbances, and mouth irritation. Vomiting, diarrhea, mouth sores, and stomach distress have also been reported. These symptoms are more likely to occur with higher doses of zinc (23 mg every 2 hours).^{253,254,256} One acute overdose of ZG resulted in nausea and vomiting and an elevated serum zinc level.²⁶⁹ Despite a total ingestion of 4.2 g, no caustic effects were observed. If C.D. develops nausea, she should try taking the lozenges after a meal.

63. Are the zinc nasal sprays, gels, and swabs tolerated better than zinc lozenges?

Zinc nasal sprays have been associated with permanent anosmia (loss of smell), which has also led to taste disturbances. The reaction has been described as follows: the solution is applied to the nares and sniffed, a burning sensation lasting minutes to hours occurs. Nearly 48 hours later, anosmia has developed.²⁷⁰ In October 2004, the FDA received more than 100 complaints about zinc nasal sprays and anosmia. The manufacturers of zinc nasal sprays argue that there is no evidence their products cause anosmia and that anosmia may be caused by many other factors. Given the severity of this side effect, zinc nasal sprays, gels, and swabs that are applied directly to the nasal passages cannot be recommended at this time. If C.D. is interested in trying zinc nasal gel, she should be discouraged and directed to any of the other oral formulations.

Long-Term Safety**64. C.D. returns to the pharmacy 1 month later. She wants to take zinc lozenges again to treat another cold. Is it safe for C.D. to reinstate zinc lozenges? What are the long-term concerns associated with zinc?**

In clinical trials, the average duration of therapy for zinc lozenges has varied between 5 and 10 days or until symptom resolution. Zinc lozenges should be used only for colds of short duration. Currently, there is no information documenting the degree of systemic absorption, resistance to treatment, or cumulative effects of zinc lozenges. Because the amount of elemental zinc absorbed from zinc lozenges has not been measured, the consequences of long-term use are unclear. Studies of elemental zinc supplementation at oral dosages of 150 mg twice daily for 6 weeks did not have adverse consequences.²⁷¹ However, with chronic use, oral zinc has resulted in copper and other nutrient imbalances because zinc is an effective copper chelator.²⁷² C.D. may begin another course of zinc therapy if she follows the same treatment recommendations mentioned previously and does not exceed the dosing recommendations.

Pregnancy and Lactation**65. The following year, C.D. wants to know if she can safely take zinc lozenges for her cold if she is pregnant. What should C.D. know about the safety of zinc lozenges during pregnancy or lactation?**

Women who are pregnant or nursing should avoid zinc lozenges because subjects who were pregnant or lactating were excluded from study enrollment. C.D. should attempt to manage her cold symptoms without medications if possible. A humidifier may help her congestion, and adequate hydration is especially important.

Efficacy in Children**66. L.P. is a 5-year-old girl who has caught a cold from her brother. L.P.'s mother wants to give her child zinc lozenges. Has the efficacy of zinc lozenges been evaluated in children?**

Only two prospective studies to date have assessed the value of zinc lozenges in children.^{256,273} Dosing in these trials was estimated based on the empiric adult dose. For children weighing <27 kg, a dose of 11.5 mg (as ZG) was given every 2 hours while awake.²⁵⁶ ZGG doses were estimated based on average body surface area and corresponding year in school (at the expected age). Children in school grades 1 to 6 received 10 mg ZGG five times per day. Children in school grades 7 to 12 received 10 mg six times per day.²⁷³ Unfortunately, variations in both the formulation and the dose produced conflicting results. The 11.5-mg ZG lozenge, although higher in dose, resulted in a higher incidence of withdrawals because of taste disturbances and poor mucosal tolerability. The ZGG lozenges were better tolerated, but did not shorten the duration of cold symptoms in children. In children, lozenge flavor is especially important in ensuring medication adherence. Macknin et al. attempted to characterize the amount of time missed from school because of colds.²⁷³ Although children taking zinc lozenges returned to school sooner than those taking placebo, this difference was not statistically significant. Because a dose–response relationship in children has not been established, dosing of zinc lozenges in children is empiric; adverse effects are similar for both children and adults.

Various formulations of zinc specifically marketed to children are now available. These formulations include zinc gluconate bubble gum, zinc lollipops, and sugarfree zinc lozenges. None of these formulations have been specifically studied in children for the relief of the common cold and should not be recommended. L.P.'s mother should be advised to ensure that L.P. gets adequate hydration and nutrition, and to monitor her temperature.

Zinc Deficiency**67. Can zinc lozenges be used to supplement the normal dietary intake of zinc?**

Zinc is an essential component in hundreds of cellular and enzymatic processes. The recommended dietary allowance for adult males is 15 mg.²⁷⁴ Some researchers suspect that zinc lozenges correct an underlying zinc deficiency and therefore strengthen the immune response. In developing countries, zinc deficiencies have been documented in both children and adults.²⁷⁵ In the United States, zinc deficiencies have been described in the elderly and in premenopausal women.^{276,277} Many of the clinical manifestations of zinc deficiency (growth retardation, poor appetite, mental lethargy, delayed wound healing, susceptibility to infection) are reversible after supplementation. Therapeutic zinc supplementation at dosages of 150 mg/day for 1 to 3 months reverses these effects. The amount of elemental zinc delivered in a 7-day course of zinc lozenges given at the maximum recommended dose is about 1.9 g, but because it is unknown how much of the dose is absorbed systemically, these lozenges should not be used to correct nutritional deficiencies. The average U.S. diet provides 10 to 15 mg of zinc.²⁷⁸ Patients should eat a balanced diet containing foods rich in zinc: red meats, eggs, whole grains, legumes, oysters, and other shellfish.²⁷⁹ Otherwise, a multiple vitamin with minerals should be adequate to prevent zinc deficiency.

Allergic Rhinitis

68. S.L. is a 38-year-old man who read on the Internet that zinc lozenges alleviate the symptoms of allergic rhinitis. S.L. knows that zinc has been studied for the common cold to relieve nasal congestion and rhinitis. Currently, he is taking loratadine (Claritin) 10 mg PO daily. Should S.L. take zinc lozenges for his allergic rhinitis symptoms?

Some patients enrolled in the clinical trials for the common cold experienced “antiallergic effects” after zinc lozenge administration,^{251,252} but there are no studies that have evaluated this effect in people with allergic rhinitis. Some literature suggests that Zn²⁺ interferes with the inflammatory process by inhibiting leukocyte migration. The expression of ICAM-1, an adhesion molecule, is increased during an allergic response, and its expression has been correlated with an increased migration of neutrophils and eosinophils.²⁵¹ Because Zn²⁺ can prevent ICAM-1 expression, it may therefore inhibit the inflammatory process; Zn²⁺ also may have antihistaminic effects.²⁴⁹ If S.L. decides to take zinc lozenges for his allergic rhinitis, he should be told that Zn²⁺ has antihistaminic properties. Although the degree of systemic antihistaminic effects has not been measured clinically, S.L. should be made aware of possible additive effects with his antihistamine.²⁵¹ Symptoms to look for include excessive dryness and irritation of the oral and nasal passages and headache. Because there is no clinical information on the use of zinc lozenges for allergic rhinitis, it cannot be recommended.

MELATONIN

Background

Melatonin is an endogenous hormone that is secreted by the pineal gland, located at the base of the brain. Melatonin secretion is primarily controlled by daylight and darkness and corresponds to typical sleep–wake hours. Darkness stimulates melatonin release. Secretion increases progressively after the onset of darkness, usually between 9 PM and 4 AM; peak melatonin levels occur between 2 AM and 4 AM.

Melatonin has received orphan drug status to regulate the sleep cycle in blind patients who have no light perception.²⁸⁰ In the United States, it is sold as a dietary supplement as 0.1-, 0.3-, 1-, 5-, and 10-mg oral tablets or capsules in immediate-release (IR) and various sustained-release (SR) formulations. Synthetic formulations of melatonin are available and should be used exclusively. Animal-derived or human-derived products carry a risk for viral transmission, contamination, and variable potency. Melatonin has been used for jet lag, insomnia, aging, depression, reproduction, HIV, and a variety of cancers. Other uses include cluster headache prophylaxis and use in nightshift workers and children. Possible antianxiety and analgesic-like effects have led to an increased use of melatonin before and after medical and surgical procedures, including abdominal hysterectomy. Melatonin is being investigated aggressively for use in children undergoing magnetic resonance imaging (MRI) and computed tomography (CT) scans and in children with neurodevelopmental disabilities. Many studies evaluating the effects of melatonin for sleep are limited by small sample size, incomplete information, and inadequate laboratory monitoring. In addition, short treatment duration and variable dosing

schedules make treatment recommendations difficult. Many treatment recommendations are based on pharmacologic principles, rather than clinical evidence.

Pharmacokinetics

The effects of several medications on melatonin levels have been studied, as have the pharmacokinetics of endogenous and exogenous melatonin (Tables 3-5 and 3-6). After administration of an 80-mg oral dose, melatonin levels peaked between 60 and 150 minutes and returned to normal in 8 to 19 hours. Melatonin disposition is characterized by a rapid distribution phase followed by an elimination phase. The initial half-life is

Table 3-6 Mean Nocturnal Levels of Circulating Melatonin

| Age | Mean Melatonin Levels |
|--------------------|---------------------------|
| First 6 mo of life | 27.3 pg/mL (0.12 nmol/L) |
| 1–3 yr | 329.5 pg/mL (1.43 nmol/L) |
| 15–20 yr | 62.5 pg/mL (0.27 nmol/L) |
| 70–90 yr | 29.2 pg/mL (0.13 nmol/L) |

estimated to be 2 minutes, and the elimination half-life is 20 to 50 minutes.²⁸¹ Other research has shown that doses of 0.05, 0.5, and 5 mg have mean elimination half-lives of 65, 43, and 70 minutes, respectively.^{282,283}

Endogenous melatonin is metabolized in the liver to 6-hydroxy-melatonin and excreted as sulfate and glucuronide conjugates.²⁸¹ In 22 patients with liver cirrhosis, endogenous melatonin serum levels were significantly elevated compared with age-matched controls.²⁸⁴ A positive correlation between total bilirubin and daytime melatonin level was also seen.²⁸⁴ As expected, the elimination half-life of exogenous melatonin increased from 44 to 97 minutes, on average, in people with liver cirrhosis.²⁸⁵ Competition with bilirubin for elimination, decreased liver blood flow, or decreased activity of the enzyme, 6- β -hydroxylase, may also contribute to these observations.²⁸⁴ Other research has suggested that the endogenous production rate of melatonin appears to be reduced in patients with liver cirrhosis.²⁸⁵

The oral bioavailability of melatonin ranges between 40% and 70% for dosages that vary from 2.5 to 100 mg. Food may enhance the absorption somewhat, resulting in higher mean plasma levels compared with those achieved when taken in the fasting state.²⁸⁵

Jet Lag (Rapid Time Zone Change)

Transmeridian air travel results in dysregulation of the sleep–wake cycle until the circadian secretion of melatonin adjusts to the new time zone (2–14 days). Adaptation is generally more difficult or slower for older patients when traveling eastward and when multiple time zones are crossed. The most common symptoms of jet lag include GI disturbances and insomnia, particularly daytime sleepiness and frequent awakenings during the night. Maximizing exposure to daylight can enhance symptom recovery.²⁸⁶

69. S.T., a 33-year-old female flight attendant, complains of sleep disturbances, loss of mental alertness, and daytime drowsiness. Every 2 weeks, she travels from Los Angeles, California, to London, England, and on to Auckland, New Zealand. A friend recommended melatonin. How should S.T. manage her symptoms? Can melatonin help?

S.T. is experiencing the classic symptoms of rapid and multiple time zone changes, which have caused an abrupt shift in her sleep–wake cycle. Usually, time to adjust to the new time zone and proper sleep hygiene is the only treatment necessary. However, because S.T. is a flight attendant and has to repeat this schedule on a regular basis, her body has little time to adapt, and she is likely to suffer from jet lag symptoms on a more long-term basis.

Clinical trials have evaluated 5 to 8 mg of IR melatonin for jet lag.^{287–291} Although these studies included a small number of participants, patients reported subjective improvements in symptoms, including decreased daytime fatigue, normal sleep patterns, energy, alertness, and mood. Subjects who took 5 mg of IR melatonin up to 3 days before departure seemed to have a worse recovery of jet lag symptoms (decreased energy and alertness) than those who began taking the medication on arrival in the new time zone. This difference was not statistically significant. The largest study assessed the effects of melatonin in 257 patients traveling across six time zones.²⁹² Subjects were randomized to receive placebo or one of three melatonin regimens. Melatonin was administered as 0.5 mg at bedtime, 5 mg at bedtime, or 0.5 mg on a “shifting schedule.” The shifting schedule was designed to mimic the circadian release of melatonin throughout the sleep–wake cycle; one dose was taken on the evening of departure and then at 1 hour earlier each night for 6 days. By day 6, the melatonin dose corresponded to the natural melatonin peak time. No differences were observed at all time points among patients receiving any melatonin dosage or placebo. No statistical differences were observed in total sleep time, napping, sleep onset, or other symptoms. Melatonin possesses some hypnotic effects, which may help S.T. However, improvement in jet lag symptoms seems to be more closely related to resynchronization by regular light–dark stimuli. Therefore, S.T. should also maximize her exposure to daylight and implement proper sleep hygiene techniques, which include going to bed at the same time each night and avoiding caffeine and daytime naps.

The optimal dose and timing of melatonin administration have not been determined, but S.T. may benefit from 5 mg of the IR formulation beginning on the evening of departure and then for the next 1 to 3 days after arrival at the destination.

Although melatonin is relatively well tolerated, she should be advised to watch for daytime drowsiness, tachycardia, dysrhythmia, and headache.^{287–290,293} One case of acute psychosis, one case of retrograde amnesia, and two cases of melatonin-induced erythematous plaques have been reported.^{294–296} Because melatonin can cause drowsiness, S.T. should use caution when performing tasks that require full alertness 30 minutes to 2 hours after a dose, and she should avoid alcohol or other CNS depressants. The long-term effects of melatonin administration have not been studied.

70. S.T. is trying to become pregnant. Is it safe for her to continue taking melatonin now or when she becomes pregnant? Should S.T. take melatonin while breast-feeding?

Melatonin has been shown to inhibit ovulation when administered in combination with a progestin. Therefore, S.T. should avoid taking melatonin while trying to conceive because high dosages (75–300 mg/day) may inhibit ovulation.²⁹⁷ Although it is unknown whether lower dosages (0.5–5 mg daily) can alter conception or pose a threat to the fetus, she should avoid taking any drugs while trying to become pregnant and during her pregnancy. Instead, she should try to control her jet lag symptoms through sleep hygiene.

S.T. also should avoid taking melatonin while breast-feeding because it may suppress prolactin secretion and diminish the production of breast milk.²⁹⁸

Insomnia

71. T.X. is a 75-year-old woman who complains of insomnia and daytime fatigue. On further questioning, it becomes clear that T.X. falls asleep early (around 9 PM) and wakes up at about the same time each morning (6 AM). However, she wakes up two to three times each night and has difficulty getting back to sleep. Will melatonin help?

Insomnia is a subjective awareness of inappropriate sleep. Patients may complain of difficulty falling asleep (sleep onset), staying asleep, sleep maintenance (as in T.X.'s case), or arising too early (early morning awakening). Melatonin has been studied in the treatment of various sleep disorders, including delayed sleep-phase syndrome (DSPS) and insomnia. Many studies have documented the hypnotic effect of melatonin in improving sleep onset, duration, and quality when administered to healthy volunteers.^{299–303} Increases in rapid eye movement sleep have also been documented.²⁹⁹ One study demonstrated that peak hypnotic effects vary based on the time of day melatonin is ingested, suggesting that light is an important factor for efficacy. Melatonin 5 mg orally caused peak hypnotic effects within 3 hours when taken at noontime compared to 1 hour when taken at 9 PM.²⁹⁹

However, these studies are limited by small sample size, inadequate monitoring, and poor study design. Dosing, patient age, timing of drug administration, randomization, study duration, and type of monitoring have varied greatly. Many of the clinical studies failed to establish a relationship between low endogenous melatonin levels and insomnia at study onset. In addition, the cause of the sleep disorder is often not defined or stated, or is confounded by other disease states. Some patients with DSPS, for example, also had a diagnosis of depression, and sleep disturbances often subside in this population once antidepressant therapy is initiated. Larger studies are needed to determine the effect of patient age, dosage, duration of therapy, and sleep disorder etiology on melatonin efficacy. According to one meta-analysis that combined these studies, pooled data from melatonin trials were found to be significantly heterogeneous. Despite this, statistically significant improvements in sleep quality have been observed.³⁰³ Improvements in sleep-onset latency (time to fall asleep), sleep efficiency, and sleep duration have all been reported in patients taking melatonin.

Insomnia in the Elderly

As illustrated by T.X., sleep maintenance is the most prevalent sleep-related disorder in patients older than 65 years of age, occurring in approximately 30% of the elderly population.²⁸³ Sleep-onset insomnia is less common (19%), followed by early morning awakening (18.8%).²⁸³ Because melatonin serum levels can be low in elderly patients who suffer from insomnia, some have theorized that use of a SR formulation will correct the low levels and prevent sleep maintenance insomnia. Although elderly patients taking 0.5 mg of SR or IR products experienced significant improvements in sleep onset, the SR formulation did not improve total sleep time. In fact, the effectiveness of melatonin administration on improving total sleep time (sleep maintenance) has been inconsistent. In older ambulatory adults between 55 and 80 years of age, consistent improvements have been seen in sleep quality, sleep latency, and morning alertness with the 2-mg SR formulation.^{304,305}

Interestingly, there is no evidence of rebound insomnia or withdrawal effect on discontinuation of melatonin.³⁰⁵ It is unknown which formulation of melatonin is superior for sleep maintenance insomnia; however, subjective improvements have been consistent across all studies. Because melatonin may improve morning alertness and quality of sleep, and given that there are few risks associated with its use, T.X. can try the lowest dose of melatonin (either IR or SR) at bedtime to see if it will maintain her sleep. The dosage can be gradually escalated to 5 mg.

72. R.R. is a 28-year-old male medical student who has been having trouble falling asleep for the past week. He attributes his insomnia to stress because he has to take his medical licensing examination in 2 weeks. He wants to know if melatonin will help him get to sleep without feeling “hang-over” the next day. Will melatonin help?

Melatonin has not been systematically studied in people with insomnia caused by stress, even though it is a common etiology. R.R. wants to achieve adequate rest but also wants to avoid the “hang-over” effects associated with antihistamines contained in over-the-counter sleep medications or prescription sedative-hypnotics. R.R. will likely benefit from melatonin because it has been shown to improve sleep onset. Because he does not experience early morning awakenings, an IR formulation of melatonin should be sufficient. IR melatonin has a short half-life and has not been associated with significant daytime drowsiness or a “hang-over” effect. R.R. should start with the lowest effective dose, 0.3 mg, if possible. If he has no response in 30 to 60 minutes, he may take a repeat dose as needed. Although melatonin is considered relatively safe with few dose-related side effects, using the minimal effective dose is best. Melatonin should only be used 30 minutes before the desired bedtime. There is some evidence that up to 6 months of continuous melatonin use may decrease semen quality in otherwise healthy males. Thus, if R.R. is planning to start a family, he may want to avoid using melatonin. Instead, he should try to follow proper sleep hygiene techniques. For example, he should avoid staying up all night studying, and he should try to maximize his exposure to daylight while awake.

Anticancer Effects

73. J.T. is a 47-year-old woman who currently is taking tamoxifen for breast cancer. She recently read that melatonin may have antitumor effects. What evidence exists for this claim? Would melatonin be effective in her case?

The antitumor effects of melatonin have been studied in vitro and in small clinical trials involving patients with metastatic breast cancer, malignant melanoma, and glioblastoma.³⁰⁶ In all these cancers, some beneficial effect has been observed, which may be related to melatonin's immunomodulating or antioxidant effects. With regard to breast cancer, in vitro studies have shown that melatonin decreases estrogen-binding capacity and the expression of estrogen receptors in the MCF-7 breast cancer cell line; it also inhibits the growth of epithelial breast cancer cells.³⁰⁶ In a clinical trial, patients with metastatic breast cancer refractory to tamoxifen displayed a slower progression of disease when given melatonin than patients receiving tamoxifen alone, regardless of

estrogen-receptor status.³⁰⁷ Melatonin also may lessen the cytotoxicity associated with chemotherapy or radiation therapy.³⁰⁶ These effects are linked to neurohormonal changes at the level of the cell (e.g., modulating membrane excitability, increasing cellular repair, conserving ATP, blocking nitric oxide synthesis). Nonetheless, more study is needed to better define the effects of melatonin based on the severity and type of cancer as well as on duration of disease. Melatonin may have some beneficial effects in J.T.'s case, but she should add this therapy only in consultation with her oncologist, who is in the best position to evaluate its effects on her disease progression. Dosages of 20 to 40 mg/day have been used.

COENZYME Q10

Background

Coenzyme Q10 is a cofactor found in cell membranes, serum, and lipoproteins. It is also known as ubiquinone or, in its reduced form, ubiquinol. As its name implies, it is ubiquitous, being found in small amounts in soybeans, walnuts, almonds, oils, fruits, and spinach. It is also found in various organ meats (heart, liver, kidney, spleen, pancreas) and skeletal muscle. Biochemically, coenzyme Q10 protects mitochondrial proteins and DNA from free-radical damage and serves as an electron carrier of the electron transport chain in the inner mitochondrial membrane. This is an important process in that it is the last step in aerobic respiration that results in ATP generation. For this reason, coenzyme Q10 has been studied for its role in many different conditions, including cardiovascular disorders, Alzheimer's disease (AD), breast cancer, gum disease, and Parkinson disease, among others.

Pharmacokinetics

Coenzyme Q10 is absorbed slowly from the GI tract because it has a high molecular weight and low water solubility.³⁰⁸ For this reason, many coenzyme Q10 formulations have been designed to maximize absorption often by including a lipophilic vehicle such as vitamin E. Following a single dose, there is a two-peak pattern at 6 and 24 hours. The first peak corresponds to the parent compound, and the second peak corresponds to the metabolite, ubiquinol. Typical adult serum concentrations vary from 0.7 to 1 mcg/mL; the clinical significance of these levels is unknown.³⁰⁹ Coenzyme Q10 is best absorbed when taken with food, and higher levels have been observed when it is chewed with a high-fat food such as peanut butter.³¹⁰ Within cells, most of the coenzyme Q10 (40%–50%) is found in mitochondria within the inner mitochondrial membrane. Whether coenzyme Q10 is metabolized is unknown; however, it is distributed to the liver and incorporated into very low density lipoprotein. Coenzyme Q10 is predominantly excreted via the biliary tract and, therefore, more than 60% of an oral dose is recovered in the feces.³⁰⁸

Prevention of Statin-Induced Myopathy

74. J.S. is a 55-year-old male in otherwise good health diagnosed with “high cholesterol” 3 years ago. He states that his LDL cholesterol was 149 mg/dL at the time of diagnosis, but now, after

starting simvastatin (a statin drug), his LDL cholesterol is 95 mg/dL. His LDL is under control, but he wants to know if he should begin taking coenzyme Q10 to help prevent statin-related myopathy.

Statins reduce cholesterol production by inhibiting the enzyme HMG-CoA reductase, which is also involved in the synthesis of coenzyme Q10. Initiating statin therapy has been associated with a decrease in coenzyme Q10 serum concentrations, which may block the critical steps in muscle cell energy generation, possibly leading to statin-related myopathy.³¹¹ A reduction in serum concentrations does not always correlate with a reduction in intramuscular concentrations, which may play a greater role in statin-related myopathy. It is unknown whether the reduction in intramuscular coenzyme Q10 leads to statin myopathy or if the myopathy itself causes cellular damage that reduces intramuscular coenzyme Q10. In addition, the type of statin used and the dose of the statin may also play a role. In one small double-blind study, the effect of coenzyme Q10 supplementation was evaluated in patients taking various statins who also had developed myopathy symptoms.³¹² Patients received either coenzyme Q10 100 mg/day or vitamin E 400 IU/day for 30 days. After 30 days, the patients taking coenzyme Q10 had statistically significant reductions in muscle pain intensity, whereas the vitamin E group had no change in muscle pain intensity. Although this study suggests a benefit, larger studies are needed to determine when to initiate coenzyme Q10 (e.g., preventative treatment compared to active treatment once myopathy has developed). Given that coenzyme Q10 is relatively safe, however, there is no clinical harm in J.S. using it while taking simvastatin, although the cost may be significant. It is important to let J.S. know that myopathy may still occur rarely with a statin, even while taking coenzyme Q10. He should be instructed that the risk for myopathy from statin therapy is very low compared to the beneficial reduction of morbidity and mortality that has been demonstrated in large, well-designed studies. He should be instructed to report any unusual or unexplained muscle pain to his provider.

Hypertension

75. F.T. is a 75-year-old male with stage 1 hypertension. F.T. measures his blood pressure at home, and since beginning enalapril 20 mg and hydrochlorothiazide 25 mg, his BP readings have improved from 150/95 to 130/85 mmHg. His provider has encouraged him to implement lifestyle modifications to further improve his BP, in particular to increase his physical activity and to minimize his daily consumption of alcohol. F.T. drinks a six-pack of beer after dinner at least nightly while watching television. A friend of his heard that taking coenzyme Q10 can help lower BP, and F.T. wants to try it.

Adults with hypertension have been found to have lower levels of endogenous coenzyme Q10. This has led to speculation that a deficiency in endogenous coenzyme Q10 levels may lead to the development of hypertension. There are many causes of hypertension; however, low endogenous coenzyme Q10 levels have not been studied well enough to make this link. In early clinical trials, small but significant reductions in SBP and DBP (7–10 mmHg) were observed after 8 to 10 weeks of coenzyme Q10 supplementation.³¹³ This led researchers to

believe that coenzyme Q10 possessed antihypertensive properties because of its antioxidant and vasodilatory effects.³¹³ One large meta-analysis of 12 clinical trials included 362 hypertensive patients and found a BP-lowering benefit of coenzyme Q10. Although this meta-analysis included both well-designed and poorly designed trials (open-labeled, uncontrolled, with and without concomitant antihypertensive therapy), the reductions in blood pressure were consistent across all studies. In three well-designed randomized, controlled trials, coenzyme Q10 supplementation significantly lowered SBP (17 mmHg) and DBP (8 mmHg) compared to no change in the placebo groups.

F.T. should be informed that coenzyme Q10 has the potential to further lower his BP; however, whether this reduction will help him reach his goal (<120/80 mmHg) is still unknown. More research is needed to assess the true value of using coenzyme Q10 either alone or in combination with other antihypertensive medications. More importantly, F.T. should be encouraged to decrease his daily alcohol consumption and increase his physical activity. These lifestyle modifications will not only improve his hypertension but may also contribute to a healthier lifestyle. Finally, because F.T. is not at his goal BP, he should continue his regular doctor appointments because small-dose adjustments to his medications may be necessary. He should continue to self-monitor his BP at home and maintain a log of his BP readings.

Heart Failure

76. S.A. is a 54-year-old male with nonischemic cardiomyopathy diagnosed in 2005. He has never had an MI but does have a history of dyslipidemia and is a current smoker (1 pack per day for 20 years) and heavy drinker (beer and spirits on most days of the week). S.A. was diagnosed to have New York Heart Association (NYHA) Class I disease (left ventricular ejection fraction [LVEF] = 25%) and is currently asymptomatic. He is taking ramipril 5 mg PO twice daily. S.A. read about the benefits of coenzyme Q10 in heart failure (HF) and would like to initiate therapy. What are the benefits of coenzyme Q10 in HF?

Studies have suggested that patients with HF have decreased levels of coenzyme Q10, so a deficiency may contribute to its progression. Early studies have demonstrated improvements in hemodynamic parameters (increases in ejection fraction and end diastolic volume) following coenzyme Q10 therapy.³¹⁴ Other studies demonstrated improvements in subjective signs and symptoms of heart failure, including edema, liver enlargement, resting dyspnea, and heart palpitations.³¹⁵ Unfortunately, many of these studies are outdated in that enrolled patients were not taking ACE inhibitors or β -blockers, which have been shown to improve morbidity and mortality in patients with HF. In addition, many studies used nonstandard or noninvasive methods to assess disease progression. Coenzyme Q10 may offer a small benefit to patients with mild to moderate heart disease (NYHA Class II–III) without ischemia. Initiating coenzyme Q10 later at more severe stages of disease appears to have little to no effect.³¹⁵ Because S.A. does not have ischemia and is still asymptomatic, it is unknown just how much subjective or objective benefit he may experience. When data from studies are combined, a statistically significant improve-

ment in ejection fraction of 4% has been suggested.³¹⁵ Because his disease is in the early stages, it is possible that coenzyme Q10 may offer him some benefit because he still has adequate functional heart muscle.

Dosing

There is no established dosing for coenzyme Q10; however, clinical trials have used varied doses, depending on the indication. For most indications, the typical daily dose averages 100 mg/day. For the treatment of hypertension, daily doses ranged from 100 to 120 mg daily.³¹³ In patients with HF, 50 to 150 mg daily in two or three divided doses have been used.³¹⁴ Dosing recommendations may vary among manufacturers; this depends on the formulation and the lipid vehicle used to deliver the coenzyme Q10. For most products, however, multiple daily doses are required to ensure adequate replacement. If S.A. wants to use coenzyme Q10 for his HF, a dose of 100 mg daily in divided doses is appropriate. More importantly, S.A. should limit his alcohol intake and if motivated to quit smoking, he should enroll in a smoking cessation program. S.A. should continue taking ACE inhibitors because they are recommended for patients who are asymptomatic and have an LVEF <40%.

Side Effects

Coenzyme Q10 is very well tolerated with very few side effects reported. In clinical trials, the most common side effects were GI discomfort, including diarrhea, nausea, heartburn, and appetite suppression, occurring with an incidence of <1%.³¹⁶ These side effects abated when the dose was reduced or coenzyme Q10 was discontinued. Other side effects included irritability, agitation, headache, and dizziness.³¹⁶ Thrombocytopenia, skin rash, and pruritus have also been reported in <0.5% of patients. Ascribing many of these infrequent side effects to coenzyme Q10 is very difficult because many of the studies were conducted when the purity of these products was unknown. Other rare case reports of flu-like symptoms, photophobia, and thrombocytopenia have not been definitely linked to the supplement.

Drug Interactions

Coenzyme Q10 may interact with warfarin leading to a subtherapeutic INR. Coenzyme Q10 is structurally related to menaquinone, also known as vitamin K2. As a result, coenzyme Q10 is believed to have procoagulant effects. Several case reports describe a subtherapeutic INR in patients taking stable doses of warfarin after beginning coenzyme Q10 therapy.³¹⁷ Because the potential interaction may have undesirable effects on coagulation, patients should be advised to avoid coenzyme Q10 while taking warfarin. In some patients, the combination may be safely used, provided the patient agrees to more frequent monitoring of INR values, especially during the first month of therapy. In addition, adherence to both warfarin and coenzyme Q10 should be encouraged and maintained throughout the course of therapy.

Because coenzyme Q10 has purported antihypertensive effects, it is reasonable to consider additive antihypertensive effects when combined with prescription antihypertensives.

The most significant effects would be encountered during therapy initiation or following antihypertensive dose increases.

77. D.P. is a 66-year-old woman with a history of atrial fibrillation and no history of bleeding. She has been taking warfarin 7 mg once daily for 2 months, and her INR values have been therapeutic, ranging from 2 to 2.5 (target 2–3). She arrives in clinic today asking whether she should begin coenzyme Q10 for its antioxidant effects to help with her atrial fibrillation.

In D.P.'s case, the desire to initiate coenzyme Q10 is based on its antioxidant effects. Engaging D.P. in a discussion about the need for antioxidant effects would be helpful. If D.P. is committed to using coenzyme Q10 while continuing warfarin, she should be informed that her INR may become subtherapeutic, placing her at risk for a thromboembolic event unless adjustments are made to her warfarin. More frequent monitoring and a change in warfarin dose may be required. D.P. should also know that the antioxidant contributions from coenzyme Q10 have not been studied in patients with atrial fibrillation.

Adverse drug reactions occur in approximately 30% of hospitalized patients, and 3% of all hospitalizations are a result of adverse drug reactions. Allergic drug reactions account for 5% to 20% of all observed adverse drug reactions.^{1–4} In one study of >36,000 hospitalized patients, 731 adverse events were identified, with 1% being severe, life-threatening, allergic reactions.⁵ The potential morbidity and mortality associated with allergic drug reactions is great, although they occur infrequently.

Definition

The appropriate diagnosis and treatment of a patient experiencing an allergic reaction necessitates differentiation between *allergic reactions* from other *adverse drug reactions*. One approach divides adverse reactions into those that are “predictable, usually dose dependent, and related to the pharmacologic actions of the drug” and those that are “unpredictable, often dose independent, and are related to the individual’s immunologic response or to genetic differences in susceptible patients.”¹ Under this classification, drug allergy or drug hypersensitivity is an unpredictable adverse drug reaction that is immunologically mediated.^{1,2,6}

Predisposing Factors

Factors known to affect the incidence of allergic reactions can be categorized as being drug or patient related.⁷

Age and Gender

Children are less likely to become sensitized than adults, presumably because younger age is likely to be associated with less cumulative drug exposure.^{6–9} More female than male patients experience allergic reactions (up to 2.3:1), although this may vary by type of reaction, drug, patient age, and setting.^{10,11}

Genetic Factors

Patients with histories of allergic rhinitis, asthma, or atopic dermatitis who develop a systemic drug reaction tend to react more severely than others.^{7,8,12} Familial occurrences of allergic reactions, although rare, have been reported. For example, erythema multiforme was described in three of five siblings treated with thiabendazole.¹³ Ethnic predisposition to drug allergy is increasingly recognized. Whites are more likely to develop hypersensitivity reactions to abacavir than non-whites, and blacks are more susceptible to angioedema from angiotensin-converting enzyme (ACE) inhibitors than are other ethnic groups.^{14,15} A patient’s ability to metabolize a drug is influenced by his or her genetic makeup and may affect the incidence of allergic reactions. *Pharmacogenetics* (i.e., the study of genetically determined variability to drug response) often centers on drug-metabolizing enzymes because many drugs are metabolized by enzymes that are encoded by variations in DNA sequences or genetic polymorphisms.¹⁶

Acetylator phenotype (e.g., fast acetylator or slow acetylator) is genetically determined, and several variations in the gene encoding for *N*-acetyltransferase (NAT) are recognized.¹⁶ The

slow acetylator phenotype is an autosomal recessive trait. Slow acetylators are at risk for sulfonamide hypersensitivity and also are more likely to develop antinuclear antibodies (ANA) and symptoms of systemic lupus erythematosus (SLE) when treated with procainamide or hydralazine.¹⁷ Drug-induced lupus can be considered an allergic reaction because of its association with an immune response, as evidenced by an increase in ANA.

Anticonvulsant hypersensitivity syndrome, characterized by fever, generalized rash, lymphadenopathy, and internal organ involvement, is most associated with aromatic anticonvulsants (e.g., phenytoin, phenobarbital, and carbamazepine) and is more common in patients with a heritable deficiency in epoxide hydrolase.¹⁸ This syndrome also is known as *drug hypersensitivity syndrome* and as *DRESS syndrome* (**d**rug **r**ash with **e**osinophilia and **s**ystemic symptoms). A genetic defect also might be responsible for a serum sicknesslike reaction to cefaclor.¹⁸

Numerous polymorphisms are known for the CYP isoenzyme family that catalyzes the oxidative metabolism of hundreds of drugs. The best studied of these are variations in genes that encode for CYP2D6, CYP2C9, CYP2C19, and CYP3A4. Examples of the phenotypic expression of these variations include poor metabolizers (who possess nonfunctional alleles and have reduced metabolic activity) and ultrarapid metabolizers (who have multiple copies of functional genes and have enhanced metabolic activity).¹⁶ Genetic differences in CYP-metabolizing enzymes might explain the predisposition to drug allergy and hypersensitivity of some individuals, as well as other forms of drug toxicity and drug response.

Whereas genetic polymorphism in drug-metabolizing enzymes is responsible for some allergic reactions, gene variations in the major histocompatibility complex (MHC) perhaps are more significant.¹⁴ For example, dermatologic reactions and thrombocytopenia to gold and toxicity to penicillamine are linked to the presence of the HLA-DR3 allele in the MHC; severe cutaneous reactions to allopurinol are linked to presence of the HLA-B*5801 allele in the Han Chinese population, and the potentially life-threatening hypersensitivity syndrome seen with abacavir is strongly associated with the HLA-B*5701, HLA-DR7, and HLA-DQ3 haplotype.^{14,17–21} In the latter case, presence of this haplotype in patients predicted abacavir hypersensitivity 100% of the time, whereas its absence had a 97% negative predictive value.¹⁹ This haplotype appears more commonly in whites than in other ethnic groups and explains the predisposition of whites to this severe reaction. Genetic screening of patients for this haplotype before initiating abacavir therapy has significantly reduced the occurrence of hypersensitivity reactions.²² In the future, it is hoped genes that are involved in life-threatening hypersensitivity reactions (e.g., anaphylaxis, hepatotoxicity, blood dyscrasias, Stevens-Johnson syndrome, toxic epidermal necrolysis) will be identified.

Associated Illness

Although genes clearly play a role in hypersensitivity reactions, environmental factors (e.g., concomitant illness) also are implicated. For example, the incidence of maculopapular rash with ampicillin therapy is significantly higher in patients with Epstein-Barr virus infections (e.g., infectious mononucleosis), lymphocytic leukemia, or gout.^{2,7} Infection with herpes virus or Epstein-Barr virus also has been linked

to DRESS syndrome;^{23,24} and the occurrence of reactions to trimethoprim-sulfamethoxazole in patients who are HIV positive is about 10-fold higher than in the HIV-negative population.¹⁴

Previous Drug Administration

A previous history of an allergic reaction to a drug being considered for treatment, or one that is immunochemically similar, is the most reliable risk factor for development of a subsequent allergic reaction.^{6,7} A commonly encountered example is the patient with a history of penicillin allergy, in whom all structurally related penicillin compounds should be avoided, and in whom the possibility of a hypersensitivity reaction should be considered when using other β -lactam antibiotics.⁷

Drug-Related Factors

The dose, frequency of exposure, and route of administration can influence the incidence of drug allergy. For example, penicillin-induced hemolytic anemia (see Question 6 in Chapter 87: Drug-Induced Blood Disorders) requires high and sustained drug concentrations.⁹ In β -lactam antibiotic IgE sensitivity, frequent intermittent courses, rather than continuous therapy, are more likely to result in drug sensitization.¹⁶ The route of administration is important in terms of the risk of both sensitization and allergic reaction in a previously sensitized person. Topical administration carries the greatest risk of sensitization, whereas the oral route is the least sensitizing. Intramuscular administration is more sensitizing than the intravenous (IV) route. In a patient who is already sensitized to a specific medication, the risk of an allergic reaction to that medication is greatest when it is given IV and least when given orally. This is thought to be a function of the rate of drug delivery.⁷

Pathogenesis

Allergic drug reactions cannot be attributed to a single immunopathologic mechanism. Traditionally, an allergic drug reaction was thought to occur in two phases: initial sensitization and subsequent elicitation.²⁵ Most drugs are small molecules (<1000 Da) and are unable to stimulate an immune response. Sensitization occurs as a result of covalent binding of a drug or a metabolite to a carrier protein in a process referred to as *haptenization*.^{2,3,6,12,25} This drug-protein (or drug-metabolite-protein) complex is sufficiently large to induce the production of drug-specific T or B lymphocytes and IgM, IgG, and IgE. On re-exposure to the drug, the patient is likely to present with allergic symptoms.¹⁶ Allergic reactions to β -lactam antibiotics occur by this mechanism. This theory, however, cannot explain several allergic phenomena. For instance, some chemically inert drugs (i.e., drugs that cannot form stable covalent bonds and do not have reactive metabolites) can still elicit an allergic response. Lidocaine and mepivacaine are examples. Furthermore, some patients have a strong allergic reaction to a drug on initial exposure, and some allergic reactions rapidly occur following drug exposure, a time period shorter than expected for the development of new antibodies. To account for some of these observations, other models for explaining allergic reactions have been proposed. The direct *pharmacological interaction* or P-I concept offers one explanation for these observations. This model suggests that some drugs are

able to bind directly to T-cell receptors in a reversible, non-covalent manner. The drug–T-cell receptor complex interacts with MHC molecules, leading to activation and expansion of T cells that are directed against the drug.²⁶ On the other hand, the *danger hypothesis* proposes idiosyncratic drug reactions are the result of damaged or stressed cells that release “danger signals.” Danger signals may be cytokines (e.g., interleukins, tumor necrosis factors) that act as co-stimulants to trigger an immune response once released. Similar to the P-I concept, neither covalent binding of drug to a carrier protein nor prior drug exposure is a prerequisite for an allergic response with the danger hypothesis. Rather, the drug itself, or a reactive metabolite, directly induces cell injury or stress, causing the release of danger signals. Once the drug is discontinued, generation of danger signals cease, and the clinical manifestations of the allergic reaction resolve.²⁷ Undoubtedly, the processes involved in allergic reactions are complex and might include some combination of each theory. Interested readers are referred to more in-depth reviews.^{28,29}

Drugs as Allergens and Immunologic Classification

Allergic drug reactions can be classified into one of four types (Table 4-1).^{6,7}

TYPE I: ANAPHYLACTIC REACTIONS

Anaphylactic reactions are acute, generalized reactions that occur when a previously sensitized person is re-exposed to a particular antigen. Reactions range in severity from pruritus and urticaria to bronchospasm, respiratory distress, laryngeal edema, circulatory collapse, and death. Anaphylactic reactions to antibiotics and radiographic contrast media reportedly occur in 1 in every 5,000 exposures, 10% of which are fatal.³⁰ Initial exposure to an antigen results in production of specific IgE antibodies. On re-exposure, antigen interacts with antibodies bound to the surface of mast cells or basophils, causing the release of histamine and other mediators.²⁵ A period of several weeks is required after initial exposure and sensitization before an anaphylactic reaction can be elicited; once sensitized, however, an anaphylactic response can be elicited within minutes as a result of existing antibodies. In addition, an anaphylactic response can occur on re-exposure to small amounts of drug administered by any route.^{25,30–32} Reactions that clinically re-

semble anaphylaxis, but do not involve immunologic mediators (antibodies), are termed *anaphylactoid reactions*.

TYPE II: CYTOTOXIC REACTIONS

Cytotoxic reactions involve the interaction of IgG or IgM and can occur by three different mechanisms (Table 4-1). Common clinical manifestations of cytotoxic reactions include hemolytic anemia, thrombocytopenia, and granulocytopenia. Penicillin-induced hemolytic anemia is the best-known example of a cytotoxic drug reaction (see Question 6 in Chapter 87: Drug-Induced Blood Disorders). This reaction typically appears after 7 days of high-dose therapy.^{9,33,34}

TYPE III: IMMUNE COMPLEX–MEDIATED REACTIONS

Immune complex-mediated reactions result from the formation of drug–antibody complexes in serum, which often deposit in blood vessel walls, resulting in activation of complement and endothelial cell injury.³⁰ Also referred to as *serum sickness*, these reactions typically manifest as fever, urticaria, arthralgia, and lymphadenopathy 7 to 21 days after exposure.^{9,35}

TYPE IV: CELL-MEDIATED (DELAYED) REACTIONS

In cell-mediated (delayed) reactions, antigen binds with sensitized T cells. Contact dermatitis is the most common manifestation of cell-mediated reactions, although systemic reactions can occur. The variety of clinical manifestations of delayed hypersensitivity has been attributed to distinct patterns of cytokine release and effector-cell recruitment, based on the type of T cells stimulated. For example, hypersensitivity reactions involving T-helper 1 cells are induced by interferon- γ and interleukin-2, whereas reactions involving T-helper 2 cells employ interleukins 4 and 5. Each pattern of cytokine release recruits specific effector cells, such as macrophages, neutrophils, or other T cells, and is responsible for the unique clinical manifestations of the reaction. Based on this new understanding, type IV reactions have been reclassified as type IVa, type IVb, type IVc, and type IVd, corresponding to four unique patterns of T-cell and effector-cell involvement.³⁶

An understanding of the immunologic mechanism can be helpful in the diagnosis and treatment of an allergic reaction; however, the exact immunologic mechanism is unknown for many allergic reactions to drugs. In addition, patients often

Table 4-1 Immunopathologic Classification of Allergic Drug Reactions

| Immunologic Class | Antibody | Mechanism | Common Clinical Manifestations |
|----------------------------|----------|--|--------------------------------|
| Type I (anaphylactic) | IgE | Drug-hapten reacts with IgE antibody on the surface of mast cells and basophils, resulting in the release of mediators | Anaphylaxis |
| Type II (cytotoxic) | IgG | <i>Hapten–cell reaction:</i> Drug interacts with cell surfaces, resulting in the formation of an immunogenic complex and the production of antibodies | Hemolytic anemia |
| – | IgM | <i>Immune complex reaction:</i> Drug reacts with antibody in circulation, forming a complex that with complement binds to the cell, resulting in injury (hematologic reactions only) | Granulocytopenia |
| – | – | <i>Autoimmune reaction:</i> Drug induces autoantibody production against red blood cells | Thrombocytopenia |
| Type III (immune complex) | IgG | Same as type II immune complex reactions (nonhematologic reactions) | Serum sickness |
| Type IVa-d (cell mediated) | – | Interaction of sensitized T lymphocytes with drug antigen | Contact dermatitis |

Adapted from reference 6, with permission.

Table 4-2 Clinical Features of Allergic Drug Reactions

- Have no correlation with known pharmacologic properties of the drug
- Require an induction period on primary exposure but not on readministration
- Can occur with doses far below therapeutic range
- Often include a rash, angioedema, serum sickness syndrome, anaphylaxis, and asthma
- Occur in a small proportion of the population
- Disappear on cessation of therapy and reappear after readministration of a small dose of the suspected drug(s) of similar chemical structure
- Desensitization may be possible

Reprinted from reference 2, with permission.

present with several symptoms characteristic of more than one of the reactions described above. The use of many drugs concurrently also makes it difficult to identify the drug responsible for the reaction. Therefore, a careful drug history and diagnostic tests (e.g., wheal and flare, *in vitro* detection of drug-specific IgE antibodies) often are necessary for an appropriate diagnosis and treatment of a patient.

Diagnosis

Distinctive Features of Allergic Reactions

The first step in the diagnosis of an allergic drug reaction is to recognize and differentiate it from other adverse drug reactions. This can be accomplished by having a good understanding of the distinctive features of allergic drug reactions (Table 4-2).^{2,6}

1. J.A., a 73-year-old woman, is admitted from a nursing home with an infected decubitus ulcer. Cultures reveal *Staphylococcus aureus*, which is sensitive to oxacillin, cefazolin, and vancomycin. On questioning, J.A. reports having experienced a rash to penicillin in the past. Her current medications include oral docusate 100 mg twice daily (BID), oral enalapril 5 mg every morning, oral prednisone 20 mg daily, and oral ibuprofen 800 mg three times daily (TID). What information should be obtained to determine whether J.A.'s rash represents an allergic drug reaction?

The single most informative diagnostic procedure for allergic drug reactions is a detailed drug history (Table 4-3), which is helpful in obtaining the information necessary to determine whether a reaction represents a drug allergy and in identifying

Table 4-3 Detailed Drug History

- Prior allergic and medication encounters
- Nature and severity of reaction
- Temporal relationships between drugs and reaction (dose, date initiated, duration)
- Prior exposure to the same or structurally related medications subsequent to the reaction
- Effect of drug discontinuation
- Response to treatment
- Prior diagnostic testing or rechallenge
- Route of administration
- Other medical problems (if any)

From references 3 and 32, with permission.

the culprit drug. In inquiring about prior allergic and medication encounters, it is important to document the drugs to which the patient has or has not previously reacted. This can sometimes alert the clinician about certain types of compounds to which the patient is likely to react. In addition, the acquired information allows the clinician to characterize the drug reaction and to appreciate how such a reaction might be manifested in the patient on exposure to the same, or an immunologically similar, compound in the future.

The temporal relationship between drugs and reactions often is the strongest piece of evidence implicating an allergic reaction to a particular agent. Drugs that the patient has received for long continuous periods before the onset of a reaction are less likely to be implicated than drugs that have been recently initiated or restarted.³⁷ Equally important is to determine when an adverse reaction has occurred. Many compounds have been reformulated over the years, resulting in removal of sensitizing impurities (e.g., penicillin, vancomycin). Therefore, it is possible that re-exposure to the agent will not result in an adverse event. Inquiring about whether the patient has received the drug since the first episode by asking the patient about other brands or names of other drugs in the same class (e.g., amoxicillin, ampicillin) will assist in determining whether the patient is likely to react to the drug on re-exposure. It usually is helpful to chart all the drugs the patient is currently taking, their dose, and start and stop dates of use. This can be compared with the onset and disappearance of the reaction.

2. On further questioning, J.A. reports having experienced an urticarial rash in the past when given ampicillin for a kidney infection approximately 2 years ago. The rash developed over her entire body less than a day after starting the antibiotic and disappeared 2 days after discontinuation. Her treatment course was completed with ciprofloxacin. She denies having had a viral infection at the time of the rash to ampicillin. She does not recall having experienced any adverse effects when she received penicillin before this reaction. No other recent changes in her treatment regimen were made before the occurrence of the rash. Why is it likely that J.A. is allergic to penicillin?

Several useful pieces of information gleaned from the drug history obtained from J.A. can be used to determine the likelihood of an allergic reaction to penicillin. J.A.'s rash appeared less than a day after initiation of ampicillin and other drugs had not been added; therefore, the rash probably was caused by ampicillin.

Another important method of identifying a potential drug-induced allergic reaction is to examine the patient's medication list to determine whether the patient is receiving an agent that commonly is implicated in causing the exhibited allergic manifestation. For example, amoxicillin and ampicillin are two of the top three drugs implicated in drug-induced rash.¹⁰

J.A. received penicillin previously without experiencing any adverse effects until an urticarial rash (a relatively common allergic manifestation) developed on subsequent exposure. This sequence of events follows the typical pattern of an allergic reaction. Allergic reactions require an induction period to sensitize the person to the antigen; however, once sensitized, allergic symptoms typically occur immediately on re-exposure.³⁷

Therefore, a prior exposure to the same or structurally related compounds needs to be documented.

Finally, it is important to evaluate other medical problems that can elicit or mimic a reaction resembling drug allergy (see above section “Associated Illness”). Rashes to ampicillin commonly occur in patients with concurrent Epstein-Barr virus infection.¹⁹ J.A. denies having a viral infection at the time of her rash, thereby, strengthening the case that the rash was likely a manifestation of an allergic reaction.

Skin Testing

3. Why might skin testing for penicillin allergy be appropriate (or inappropriate) for J.A.?

Although J.A.’s elicited medication history strongly suggests that she is allergic to penicillin, a skin test and a drug rechallenge would more firmly establish her drug allergy. For many years, skin-testing antigen for penicillin was commercially available as penicilloyl polylysine (Pre-Pen). Although the manufacturer (Hollister-Stier, Spokane, Washington) of penicilloyl polylysine voluntarily withdrew it from the market in 2004, AllerQuest (West Hartford, CT) obtained the legal rights and has been working to market it in the United States and Canada.³⁸ Penicillin skin testing using Pre-Pen (also known as PPL [penicilloyl polylysine]) is a safe and effective procedure (Table 4-4), with <1% of positive responders developing systemic reactions.³⁴ In those in whom a false-negative response occurred, reactions were mild and, in most cases, did not require drug discontinuation.^{33,34} Skin testing with PPL identifies 80% of patients allergic to penicillin. When the penicilloyl derivative is supplemented with skin tests for the minor determinants of penicillin,³³ 99.5% of penicillin-allergic patients can be iden-

tified. When 34 purportedly “penicillin-allergic patients,” who subsequently tested negative to penicillin skin-tests, needed β -lactam antibiotics during hospitalization, no allergic drug reactions occurred.³⁹

Penicilloyl, the primary metabolite of penicillin, is referred to as the major determinant. The other derivatives, including the parent compound (penicillin), are referred to as minor determinants. The terms *major determinant* and *minor determinant* refer to the frequency of antibody formation to these antigenic penicillin metabolite-protein complexes. These terms do *not* describe the severity of the allergic reaction. Indeed, the major determinant is thought to be responsible for accelerated reactions, but not anaphylaxis. The minor determinants are responsible for anaphylaxis and immediate systemic reactions.

Penicillin and its metabolites become antigenic when combined with proteins and can precipitate a hypersensitivity reaction in a patient on re-exposure. In patients with a history of penicillin hypersensitivity, skin test reactivity is affected by the length of time since the allergic reaction and by the nature of the past reaction. Skin test positivity is greatest 6 to 12 months after a reaction and decreases with time. Skin test positivity in one study was found to be only 40% of patients with a history of anaphylaxis, 17% with urticaria, and 7% for maculopapular rashes.³³ Skin testing should not be performed in patients receiving antihistamines because they block the response to the antigen and can result in misinterpretation. In patients receiving antihistamines (i.e., H₁- or H₂-receptor antagonists) or when skin testing is not possible because of severe skin disease, *in vitro* assays to detect drug-specific IgE antibodies have been developed for the major and minor determinants of penicillin.

Table 4-4 Penicillin Skin Testing Procedure

| Agent | Procedure | Interpretation |
|---|--|--|
| Penicilloyl polylysine (Pre-Pen) Major determinant | Scratch test one drop of full-strength solution (6 to 10 ⁻⁵ mol/L) ^a | <i>No wheal or erythema after 10 minutes:</i> proceed with intradermal test. <i>Wheal or erythema within 10 minutes:</i> choose alternative agent, desensitization if no other alternatives exist |
| Penicilloyl polylysine (Pre-Pen) | Intradermal test: 0.01 to 0.02 mL PPL (Pre-Pen). ^a Saline: negative control Histamine: positive control (optional; useful if it is suspected that patient may be anergic) | Negative response: induration size similar or less than saline control Positive response: induration 14 mm or more greater than saline control with or without erythema: choose alternative agent, desensitization if no other alternatives exist |
| Penicillin G potassium (>1 week old) most important of the minor determinants | Scratch test one drop of 10,000 U/mL solution | Same as scratch test with PPL (see above) |
| Penicillin G potassium – | Intradermal test: 0.002 mL 10,000 U/mL solution Serial testing with 10, 100, or 1,000 U/mL solutions can be performed in those with strong history or serious reactions | Same as intradermal test with PPL (see above) |

^aThe penicilloyl derivative of penicillin conjugated to polylysine (PPL) is administered initially as a scratch test. If no wheal or erythema develops, then intradermal testing is performed.

From Schwarz Pharma Kremers Urban Company, Milwaukee, WI, with permission.

Note: as of 2004, Pre-Pen is no longer commercially marketed in the United States. It is anticipated that Pre-Pen will be re-introduced in 2008. From reference 38.

To determine whether skin testing is appropriate for J.A., the risks and benefits must be weighed. Because the time of the last reaction was approximately 2 years ago, J.A. may still retain some skin test positivity if the previous reaction was truly an allergic reaction to ampicillin. Testing with PPL (major determinant) and penicillin (minor determinant) could be useful in determining whether J.A. is likely to develop an urticarial or anaphylactic reaction to penicillin or its derivatives. That J.A. is currently receiving prednisone should not alter the interpretation of the skin test results because the corticosteroids minimally affect the IgE-mediated immediate hypersensitivity reactions. The risks of developing serious systemic reactions to penicillin skin testing are minimal.

The benefit of penicillin skin testing for J.A., however, is questionable because she could be treated with an antibiotic other than a penicillin. The most practical approach to penicillin-allergic patients is simply to avoid the drug. Therefore, the patient's drug history should always be evaluated carefully. In the unlikely situation in which treatment with a penicillin is essential, penicillin skin testing would be useful.

Cross-Reactivity

4. J.A. received a scratch test with PPL, which was negative; however, an intradermal test was positive. What treatment options are available to J.A. for her infection?

All penicillin derivatives should be avoided because J.A. had a positive skin-test reaction. Skin tests are not commercially available for cephalosporins and other β -lactam antibiotics. Although cephalosporin-skin testing (i.e., prick followed by intradermal instillation) using 0.01 mL of a concentration of 2 mg/mL of the cephalosporins in normal saline has been proposed by some, no prospective studies have evaluated this approach.⁴⁰ Therefore, clinicians must rely on cross-reactivity data to determine whether a nonpenicillin β -lactam antibiotic (e.g., a cephalosporin) can be used in a penicillin-allergic patient.

In one study, about 50% of patients with a history of penicillin allergy exhibited hypersensitivity reactions to the β -lactam antibiotic, imipenem (Primaxin).³³ Cross-reactivity (i.e., cross-antigenicity) occurs between penicillin and cephalosporins in 5% to 15% of patients,^{33,34} however, the true incidence of cross-reactivity is considerably less because these percentages were derived based on the recollection of patients of an allergic history rather than by objective skin tests.

The cross-reactivity between penicillins and cephalosporins formerly was attributed primarily to their common β -lactam chemical-ring structure; however, side-chain-specific reactions are now recognized to be responsible for a significant portion of allergic reactions within and between the penicillin and cephalosporins families.^{40–42} In a study of 30 patients with immediate allergic reactions to cephalosporins, <20% reacted to penicillin determinants (i.e., skin test positivity, radioallergosorbent testing [RAST] positivity, or both).⁴¹ (RAST is a radioimmune test to detect IgE antibodies responsible for hypersensitivity.) This cross-reactivity between penicillin and cephalosporins is significantly less than earlier reports (up to 50%); however, the results of this study could be attributable to the greater use of third-generation, rather than the first-generation cephalosporins, which share

more chemical structure similarities with the penicillins. Additional support for the importance of side-chain-specific reactions of β -lactams comes from observational data noting that 30% of patients with immediate reactions to penicillins were selective for amoxicillin.⁴³ These data suggest relatively low cross-reactivity between penicillins and third-generation cephalosporins. The risk of a serious allergic reaction with the use of an advanced-generation cephalosporin in a penicillin-allergic patient might be no greater than the risk of any alternative antibiotic.⁴² Some patients also have multiple drug allergies and could manifest an allergic reaction to these drugs (and others that are not β -lactams) in a manner similar to their penicillin reaction.³³

Although desensitization with an appropriate cephalosporin is a potential option for J.A., her infection is not life-threatening, and the organism is probably sensitive to other antimicrobial agents. In this case, it would be more prudent to treat J.A. with a non- β -lactam antibiotic. If J.A.'s skin tests to cephalosporin were undertaken, and had been negative, she could receive a cephalosporin despite her positive history beginning with a cautiously administered small (i.e., "test") initial dose.³³

GENERALIZED REACTIONS

Drug allergies can be grouped into three categories: generalized reactions, organ-specific reactions, and pseudoallergic reactions. Generalized reactions involve multiple organ systems and variable clinical manifestations. Anaphylactic reactions, serum sickness reactions, drug-induced fever, drug-induced vasculitis, and autoimmune drug reactions are the generalized drug reactions presented in this chapter.

Anaphylaxis

5. L.P., a 43-year-old man, is brought to the emergency department (ED) with a chief complaint of a hand wound received while defending himself during an attempted robbery. Physical examination reveals a man in moderate distress with a 3.5-inch laceration on the palm of his right hand, requiring sutures. L.P.'s history is notable for migraine headaches, which are managed with atenolol 25 mg once daily; adult-onset diabetes, controlled with diet; and multiple scars from wounds obtained during a bar-room brawl 2 years before admission. He has no known allergies. The wound is cleansed and 1% lidocaine is infiltrated around the laceration in preparation for suturing. Four minutes after the lidocaine injections, L.P. notes tingling and pruritus of both his hands and feet, and appears flushed. Three minutes later he complains of light-headedness, difficulty breathing, and a lump in his throat. His vital signs at this time are blood pressure (BP) 80/40 mmHg (nl, 130/85); heart rate 75 beats/minute (normal, 60); and respiratory rate 27 breaths/minute (normal, 12). Chest auscultation reveals restricted airflow and stridor. Anaphylaxis is the diagnosis and emergency treatment is started. What subjective and objective evidence support the diagnosis of anaphylaxis in L.P.?

Anaphylaxis is an acute, clinical syndrome that results from the rapid release of immunologic mediators from tissue mast cells and peripheral blood basophils. The symptoms of anaphylaxis vary widely, depending on the route of exposure, rate of exposure, and dose of allergen.^{30,32,44,45} Symptoms usually

begin within minutes of exposure, as in L.P., and most reactions occur within 1 hour. On rare occasions, anaphylaxis can appear several hours after exposure and late phase or biphasic attacks have occurred 8 to 12 hours after the initial attack. In general, the severity of the anaphylaxis is directly proportional to the speed of onset. L.P. displays symptoms in many of the organs commonly involved in anaphylaxis. Although almost any organ system can be affected, the cutaneous, gastrointestinal (GI), respiratory, and cardiovascular systems are involved most frequently, either singly or in combination.^{30,32,44,45} These “shock organs” contain the largest number of mast cells and are the most highly affected.

L.P. exhibits erythema (flushed appearance) and complains of pruritus of his hands and feet, both common initial symptoms of anaphylaxis; the groin also is commonly affected. These symptoms can progress to urticaria and angioedema, especially of the palms, soles, periorbital tissue, and mucous membranes. L.P. describes the early manifestations of angioedema (laryngeal edema) with complaints of a lump in his throat (this also may be described as throat tightness or constriction by some patients).

The upper and lower respiratory tracts also can be involved during an anaphylactic event. L.P. exhibits stridor, indicating upper airway involvement. Hoarseness is another sign of upper respiratory tract involvement. In addition, L.P. is tachypneic with poor airflow, suggesting his lower airway also is affected. L.P. does not display wheezing or acute emphysema, which are further clues of lower airway involvement. Respiratory symptoms can lead to suffocation and death.⁴⁴ In one autopsy series, laryngeal edema accounted for 25% of the fatalities and acute emphysema for another 25% of the deaths.⁴⁶ Cardiovascular symptoms also are ominous. Cardiovascular collapse and hypotensive shock (anaphylactic shock) are caused by peripheral vasodilation, enhanced vascular permeability, leakage of plasma, low cardiac output, and intravascular volume depletion. Thus, hypotension, as seen with L.P., is a common cardiac manifestation. Tachycardia also commonly occurs in patients with cardiac complications of anaphylaxis. L.P. does not show a significant increase in heart rate, however, he is taking the β -blocker atenolol. Other cardiac manifestations of anaphylaxis include a direct cardiodepressant effect and various electrocardiographic changes, including arrhythmias and ischemia.

Although not demonstrated by L.P., common GI manifestations such as abdominal cramping, diarrhea (which can be bloody), nausea, and vomiting also are manifested during an anaphylactic reaction.^{30,32,44} In summary, L.P.’s rapid onset and progression of symptoms involving multiple organ systems (i.e., cutaneous, respiratory, and cardiovascular systems) are consistent with an anaphylactic reaction. L.P.’s anaphylaxis is a severe reaction given its speed of onset, the number of organ systems involved, and the degree of involvement. In particular, his respiratory and cardiovascular symptoms indicate a potentially life-threatening reaction.

6. What is the likely cause of L.P.’s anaphylactic event?

Anaphylaxis occurs through one of three mechanisms.³⁰ In the first type of reaction, exposure to a foreign protein, either in its native state or as a hapten conjugated to a carrier protein, causes IgE-antibody formation. The IgE antibodies

then bind to receptors on mast cells and basophils. On re-exposure, the antigen stimulates cellular degranulation through both antigen-IgE antibody formation and cross-linking, which result in massive release of preformed immunologic mediators from the mast cells and basophils. Histamine is the major mediator of anaphylaxis and the primary preformed cellular constituent. Histamine has multiple effects and is likely responsible for vasodilation, urticaria, angioedema, hypotension, vomiting, abdominal cramping, and changes in coronary flow.³² Leukotrienes (e.g., leukotrienes C₄ and D, also known as slow-reacting substance of anaphylaxis [SRS-A]), platelet activating factor, and prostaglandins are generated rapidly as a result of cellular degranulation, and other mediators of anaphylaxis (e.g., tryptase, chymase, heparin, and chondroitin sulfate) are released as well.^{30,44} Anaphylactic reactions to *Hymenoptera* venom (e.g., bee stings), insulin, streptokinase, penicillins, cephalosporins, local anesthetics, and sulfonamides occur through this IgE-mediated mechanism.

Anaphylaxis also can occur via a second mechanism. This involves the formation of immune complexes that activate the complement system and the subsequent formation of anaphylatoxins C3a, C4a, and C5a. Such anaphylatoxins can directly stimulate mast cell and basophil degranulation and mediator release.

The third mechanism by which substances, such as radiocontrast media and other hyperosmolar agents, can cause anaphylaxis is by the direct stimulation of mediator release (primarily histamine). The pathway by which this occurs is as yet unknown, but it is independent of IgE and complement.

Lastly, when no distinct mechanism can be associated with an anaphylactic event, the term *idiopathic recurrent anaphylaxis* is applied.^{30,45}

L.P.’s anaphylactic episode, most likely, is related to the first mechanism (i.e., IgE-antibody formation). Specifically, L.P. probably received lidocaine when the wounds he sustained 2 years ago were sutured. Exposure to lidocaine at that time probably stimulated IgE-antibody formation. Following re-exposure to lidocaine during this admission, antibody-antigen complexes were formed, resulting in cellular degranulation and anaphylaxis. The temporal relationship of L.P.’s anaphylactic reaction to the administration of lidocaine also strongly implicates lidocaine as the precipitating agent. Furthermore, L.P. was not exposed to agents known to cause anaphylaxis by one of the other known mechanisms.

7. Given L.P.’s signs and symptoms and the presumed cause of his anaphylactic reaction, how should he be treated?

Effective management of anaphylaxis requires quick recognition and aggressive therapeutic intervention because of the immediate life-threatening nature of the reaction, as illustrated by L.P. The severity of the anaphylactic reaction must be assessed quickly, the probable causative agent determined, the administration of the offending substance discontinued, and the absorption of the offending agent minimized. All of these interventions must be undertaken promptly and the clinical status of the patient closely monitored. Vital signs, cardiac and pulmonary function, oxygenation, cardiac output, and tissue perfusion in particular must be immediately and continuously assessed.^{30,44} In an attempt to minimize further systemic absorption of the anaphylaxis-inducing drug, L.P.’s wound should

be thoroughly flushed with normal saline because the lidocaine that was infiltrated around his wound is the probable cause of his anaphylactic reaction.

L.P. is showing signs of anaphylactic shock and peripheral vasodilation, which must be managed immediately. Epinephrine is the drug of choice for the pharmacologic management of anaphylaxis and for all major or severe allergic reactions. It also can be used for the symptomatic relief of minor adverse allergic reactions. The α -adrenergic effects of epinephrine increase systemic vascular resistance and increase blood pressure. These actions counter the vasodilating and hypotensive effects of histamine and the other mediators of anaphylaxis. In addition, the β -adrenergic effects of epinephrine promote bronchodilation and increase cardiac rate and contractility. Epinephrine also inhibits the release of mediators from basophils and mast cells.

The route of epinephrine administration is important. If anaphylaxis is not severe or life threatening, or if vascular access cannot be readily obtained, epinephrine can be administered intramuscularly (IM) or subcutaneously (SC). Although IM epinephrine injections into the thigh achieve higher epinephrine concentrations more rapidly than do SC or IM injections into the arm,⁴⁷ the rate and extent of absorption from IM and SC routes of epinephrine administration have not been studied in patients undergoing an anaphylactic reaction.⁴⁸ Epinephrine should be administered IV in cases of anaphylaxis that progress to shock because low cardiac output and intravascular volume depletion from shock decrease tissue perfusion and possibly the absorption of SC or IM injections. In animal studies, the benefits of intermittent IV boluses of epinephrine are short lived and a continuous infusion of epinephrine provides optimal results.⁴⁹ In L.P.'s case, an IV line should be placed immediately and an epinephrine infusion prepared by mixing 1 mg (1 mL) of a 1:1000 dilution of epinephrine in 250 mL of normal saline to make a concentration of 4 mcg/mL. The infusion should start at 1 to 4 mcg/min and be titrated to clinical response, with a maximal rate of 10 mcg/min.⁴⁸

At the same time, another IV line should be established and normal saline infused at a rate sufficient to maintain perfusion to vital organs. Normal saline is the preferred crystalloid because it stays in the intravascular space longer than does dextrose and does not contain lactate (e.g., Lactated Ringer's solution), which could worsen metabolic acidosis. Circulating blood volume can decrease by as much as 50% in the first 10 minutes of anaphylactic shock because of vasodilation and fluid shifting from the intravascular to the extravascular space.⁴⁸ Therefore, vigorous fluid resuscitation might be necessary (e.g., 1 to 2 L of normal saline at a rate of 5 to 10 mL/kg in the first 5 minutes). Cerebral perfusion, as evidenced by adequate mentation, must always take precedence over BP readings when managing shock. Some evidence suggests poor outcomes in patients who are in an upright position during anaphylactic shock. Pumphrey⁵⁰ studied 38 deaths from anaphylactic shock and, in 10 cases where postural information was documented, patients died after being moved to an upright position. Four deaths occurred immediately after changing position. Movement of the patient from a supine to an upright position during shock possibly worsened already poor venous return, causing a sudden decrease in cardiac filling and subsequent circulatory collapse.⁵⁰ Thus, placing a patient in the Trendelenburg position (patient supine, inclined approxi-

mately 45 degrees with head at the lower end and legs at the upper end) might improve survival by enhancing perfusion to vital organs.

The effect of L.P.'s atenolol also must be considered. Patients taking a β -blocker, whether cardioselective or not cardioselective, could experience more severe episodes and more refractory episodes of anaphylaxis than patients not taking a β -blocker. This effect might be caused by a blunted response to epinephrine when given to treat anaphylaxis, resulting in refractory hypotension, bradycardia, and bronchospasm.⁴⁸ If L.P.'s BP and heart rate do not substantially improve shortly after initiating epinephrine, IV glucagon, which can stimulate heart rate and cardiac contractility independent of β -adrenergic blockade, should be given (Table 4-5). Inhaled β -agonists, H₁- and H₂-receptor antagonists, corticosteroids, and aminophylline commonly also are used to supplement the actions of epinephrine. In light of L.P.'s severe pulmonary reaction, he should receive oxygen as well as a nebulized β -agonist (e.g., albuterol). If L.P.'s respiratory status fails to improve after pharmacologic intervention, intubation must be considered. Atenolol would not be expected to diminish the effect of albuterol because atenolol is a β 1 cardioselective β -blocker and the dose is low. Because histamine is the primary mediator of anaphylaxis, IV administration of an antihistamine such as diphenhydramine, 50 mg every 6 hours until the reaction resolves, is warranted. Similarly, giving an H₂-receptor antagonist is reasonable. Because L.P. is not receiving any drugs known to interact with cimetidine and because he has no diseases that require dose adjustment, cimetidine may be given as outlined in Table 4-5.

Lastly, given the severity of his reaction and his pulmonary involvement, L.P. is a candidate for IV corticosteroids. Methylprednisolone, 125 mg every 6 hours for four doses, might be beneficial and is associated with minimal risk. Although commonly used, the indications and doses for corticosteroid administration in the treatment of anaphylaxis are not well defined. The effect of methylprednisolone on L.P.'s diabetes is not a factor because his clinical status is life-threatening. Once stabilized, L.P. should be transferred to a critical care setting and monitored for a minimum of 24 hours because relapses of the anaphylactic reaction can occur.^{30,32,44,45}

Serum Sickness

Serum sickness is a type III hypersensitivity reaction that results from the production of antibodies directed against heterologous protein or drug haptens with subsequent tissue deposition. The typical presentation of serum sickness (Table 4-6) includes fever, cutaneous eruptions (95%), lymphadenopathy, and joint symptoms (10%–50%).^{51–54} Symptoms usually occur 1 to 2 weeks after exposure, but accelerated reactions can occur within 2 to 4 days in previously sensitized persons. Laboratory data are relatively nonspecific and are of little diagnostic value. For example, the erythrocyte sedimentation rate (ESR) and the serum concentration of circulating immune complexes usually are increased. Complements C3 and C4 are often low, while activation products C3a and C3a desarginine are elevated. Urinalysis might reveal proteinuria, hematuria, or an occasional cast.^{51–54}

In most cases, serum sickness reactions are mild and self-limiting and resolve within a few days to weeks after

Table 4-5 Drug Therapy of Anaphylaxis

| Drug | Indication | Adult Dosage | Complications |
|--------------------------------------|--|---|---|
| Initial Therapy | | | |
| Epinephrine | Hypotension, bronchospasm, laryngeal edema, urticaria, angioedema | 0.3 to 0.5 mL of 1:1,000 IM or SC Q 5 min PRN 3–5 mL of 1:10,000 IV over 5 min Q 10–20 min PRN. 1 mL of 1:1,000 in 250 mL of normal saline IV at a rate of 1–10 mcg/min (preferred over intermittent injections) 3 to 5 mL of 1:10,000 intratracheally Q 10–20 min PRN | Arrhythmias, hypertension, nervousness, tremor |
| Oxygen | Hypoxemia | 40%–100% | None |
| Metaproterenol | Bronchospasm | 0.3 mL of 5% solution in 2.5 mL of saline via nebulizer (i.e., 15 mg) | Arrhythmias, hypertension, nervousness, tremor |
| <i>Or</i> Albuterol | – | 0.5 mL of 0.5% solution in 2.5 mL of saline via nebulizer (i.e., 2.5 mg) | – |
| <i>Or</i> Isoetharine | – | 0.5 mL of 1% solution in 2 mL of saline via nebulizer (i.e., 5 mg) | – |
| IV fluids | Hypotension | 1 L of normal saline Q 20–30 min PRN (rates as high as 1–2 mL/kg/min may be necessary) | Pulmonary edema, CHF |
| Secondary Therapy^a | | | |
| Antihistamines | Hypotension, urticaria | – | – |
| H ₁ -receptor antagonists | – | Diphenhydramine 25–50 mg IV, IM, PO Q 6–8 h PRN Hydroxyzine 25–50 mg IM or PO Q 6–8 h PRN | Drowsiness, dry mouth, urinary retention; may obscure symptoms of continuing reaction |
| H ₂ -receptor antagonists | | Cimetidine 300 mg IV over 3–5 min or PO Q 6–8 h PRN Ranitidine 50 mg IV over 3–5 min Q 8 h PRN or 150 mg PO BID PRN | – |
| Corticosteroids | Bronchospasm; patients undergoing prolonged resuscitation or severe reaction | Hydrocortisone sodium succinate 100 mg IM or IV Q 3–6 h for two to four doses or Methylprednisolone sodium succinate 40–125 mg IV Q 6 hrs for two to four doses | Hyperglycemia, fluid retention |
| Aminophylline | Bronchospasm | 6 mg/kg loading dose (if necessary) IV over 30 min followed by 0.3–0.9 mg/kg/hr as a maintenance dose ^b | Arrhythmias, nausea, vomiting, nervousness, seizures |
| Norepinephrine | Hypotension | 4 mg in 1 L dextrose 5% IV at a rate of 2–12 mcg/min | Arrhythmias, hypertension, nervousness, tremor |
| Glucagon ^c | Refractory hypotension | 1 mg IV over 5 minutes, followed by 5–15 mcg/min in fusion | Nausea, vomiting |

^a Although not effective during acute anaphylaxis, these agents may reduce or prevent recurrent or prolonged reactions.

^b Doses are for aminophylline; to convert to theophylline, multiply by 0.8. Lower rates may be required in elderly patients, those taking medications that reduce aminophylline metabolism, those with hepatic dysfunction, and those with HF. Higher doses may be required in younger patients or cigarette smokers.

^c Glucagon may be particularly useful in patients taking β -adrenergic blockers, because it can increase both cardiac rate and contractility regardless of β -adrenergic blockade.

Choice of agent and starting doses should be patient-specific, weighing safety and efficacy.

HF, heart failure; IM, intramuscularly; IV, intravenously; Q, every; PO, orally; PRN, as needed; SC, subcutaneously.

withdrawal of the inciting agent. Antihistamines and aspirin can be used to relieve pruritus and arthralgias. In severe cases, corticosteroids might be used and can be tapered over 10 to 14 days.^{51,52–54} Serum sickness reactions are rare because of the infrequent use of foreign serum today;⁵² however, reactions to specific agents continue to be reported (Table 4-7).

Drug Fever

8. M.M., a 47-year-old ill-appearing woman, is hospitalized with a 3-day history of difficulty breathing, left-sided chest pain on inspiration, fever, chills, and a productive cough. Her medical history is significant only for hypertension, well controlled on

Table 4-6 Hypersensitivity Reactions to Drugs: Serum Sickness

| | |
|-------------------------|---|
| Clinical Manifestations | Fever, cutaneous eruptions (95% of cases), lymphadenopathy, and joint systems (10%–50%). Onset 1–2 weeks after exposure, 2–4 days in sensitized individuals. Laboratory data relatively nonspecific: elevated ESR and circulating immune complexes. Complements C3 and C4 are often low, whereas activation products C3a and C3a desarginine are elevated. RF sometimes present. UA may reveal proteinuria, hematuria, or an occasional cast. |
| Prognosis | Usually mild and self-limiting. Most resolve within a few days to weeks after withdrawal of inciting agent. |
| Treatment | Aspirin and antihistamines can relieve arthralgias and pruritus. Corticosteroids may be required for severe cases and tapered over 10–14 days. |

hydrochlorothiazide; she has no known drug allergies. M.M.'s physical findings on admission are temperature 38°C; respirations 20 breaths/minute; left-sided crackles heard on auscultation; oxygen saturation 85% on room air; and heart rate 85 beats/minute. A chest radiograph reveals an infiltrate in her left lower lobe. Her white blood cell (WBC) count is 17,500 cells/mm³ (normal, 5,000–10,000) with the following differential: polymorphonuclear neutrophil leukocytes (PMN), 83% (normal, 45%–79%); bands, 12% (normal, 0%–5%); lymphocytes, 10% (normal, 16%–47%); basophils, 0% (normal, 0%–1%); and eosinophils, 1% (normal, 1%–2%). Community-acquired pneumonia is the diagnosis, and M.M. is empirically started on ceftriaxone 1 g IV daily, azithromycin 500 mg IV every 24 hours, and oxygen at 2 L/minute. Other medications include oral acetaminophen 325 mg every 4–6 hours as needed for temperature >38°C, oral famotidine 20 mg twice daily, and oral hydrochlorothiazide 12.5 mg daily. Seventy-two hours later, M.M. is breathing without pain at a respiratory rate of 12 breaths/minute, her lungs are clear to auscultation, and her oxygen saturation is 98% on room air. She appears much better and offers no new complaints. Her temperature over the previous 48 hours has ranged from 38.6°C–40°C, her pulse has ranged from 90–100 beats/minute, and her WBC count is 22,000 with the following differential: PMN, 89%; bands, 5%; lymphocytes, 12%; basophils, 0%; and eosinophils, 7%. Drug-induced fever is considered. What evidence supports this diagnosis? What is the mechanism for drug fever?

Drug fever is described as a febrile reaction to a drug without cutaneous symptoms and is estimated to occur in 3% to 5% of inpatients.⁵⁵ Drug fever can be challenging to identify and can be misinterpreted as a new infectious process or failure of an existing infection to respond to treatment. Such failure to recognize a drug fever can lead to prolonged hospitalization and unnecessary tests or medications. Table 4-8 lists the characteristics of hypersensitivity drug-induced fever. The most important finding in the case of M.M. is her clinical improvement with respect to her pulmonary status despite a high-grade fever and persistent leukocytosis; she also appears healthier than expected if she had an untreated infection. Whereas a drop in her WBC count would be anticipated given

her improving respiratory function, her WBC count remains elevated, consistent with hypersensitivity drug fever. Notably, her eosinophil count is increased, a frequent sign of hypersensitivity reactions. Despite her high-grade fever, she has a relative bradycardia; that is, her heart rate is not as elevated as expected

Table 4-8 Hypersensitivity Reactions to Drugs: Drug-Induced Fever^{56–58,60–62,65,66}

| | |
|-------------------------|--|
| Frequency | True frequency is unknown because fever is a common manifestation and almost any drug can cause fever. estimate is that 3%–5% of hospitalized patients experiencing adverse drug reaction suffer from drug fever alone or as part of multiple symptoms. |
| Clinical Manifestations | Temperatures may be 38°C or higher and do not follow a consistent pattern. Although patients may have high fevers with shaking chills, patients generally have few symptoms or serious systemic illness. Skin rash (18%), eosinophilia (22%), chills (53%), headache (16%), myalgias (25%), and bradycardia (11%) can occur in patients with drug fever. Onset of fever after exposure to the offending agent is highly variable, ranging from an average of 6 days for antineoplastics to 45 days for cardiovascular agents. Occurrence of fever is independent of the dose of the offending agent. |
| Treatment | Although drug fever can be treated symptomatically (e.g., with antipyretics, cooling blankets), stopping the offending agent is the only therapy that will eliminate fevers. Patients generally defervesce within 48–72 hours of stopping the suspect drug. |
| Prognosis | Drug fever is usually benign, although one review (57) found a mean increased length of hospitalization of 9 days per episode of drug fever. Rechallenge with the offending drug usually results in rapid return of the fever. Although re-exposure to the suspect drug was previously thought to be potentially hazardous, there is little risk of serious sequelae. |

if an infectious process were ongoing. Further, the timing of the symptoms favors a drug-induced fever (i.e., within days of starting a new medication). A definitive diagnosis can be made only by stopping the suspected offending agent, however, because fever generally resolves within 48 to 72 hours if a rash is not present. When a rash is present, however, the fever may persist for several days after stopping the implicated drug.

Drug fever can be caused by various mechanisms, although it is ascribed most commonly to a hypersensitivity reaction. Other mechanisms include the pharmacologic action of the drug (e.g., cell destruction from antineoplastic agents releases endogenous pyrogens); altered thermoregulatory function (e.g., increased metabolic rate from thyroid hormone); decreased sweating from drugs with anticholinergic properties (e.g., atropine, tricyclic antidepressants, phenothiazines); drug-administration-related fever (e.g., amphotericin B, bleomycin); and idiosyncratic reactions (e.g., neuroleptic malignant syndrome from haloperidol, malignant hyperthermia from inhaled anesthetics).^{55,56}

9. What agent is the most likely cause of drug fever in M.M.?

Most of the information available on drug fever is based on case reports or small case series, and the only critical appraisal of the literature⁵⁷ is not consistent with information found in other reports. Furthermore, the literature is inconsistent with regard to the frequency of drug fever (e.g., very common, common, uncommon) and such descriptions are not supported by good clinical data. Nevertheless, some drugs are more commonly associated with drug fever than others. These include anti-infectives as a class (especially β -lactam antibiotics), antiepileptics (especially barbiturates and phenytoin), and antineoplastics. Other causes of drug fever include amphotericin B; antihistamines (except diphenhydramine); anticholinergics and drugs with anticholinergic properties (e.g., tricyclic antidepressants, phenothiazines); asparaginase; bleomycin; hydralazine; interferon; methyl dopa; muromonab CD-3; para-aminosalicylic acid; procainamide; quinidine; quinine; and drugs containing a sulfonamide moiety (including antibiotics, stool softeners, and diuretics).^{55–66} A more complete listing of drugs associated with fever is presented in Table 4-7.

In M.M.'s case, ceftriaxone or the macrolide, is the most likely cause of her ongoing fever, given the timing of the reaction relative to beginning the antibiotics and the frequency of febrile reactions attributed to them, especially to β -lactam antibiotics. Febrile reactions have not been associated with ac-

etaminophen, and famotidine is rarely a cause of fever without other symptoms of an allergic reaction. Although diuretics such as hydrochlorothiazide can cause fever, M.M. was taking this medication before admission without any ill effects, making this drug an unlikely culprit.

10. How should M.M.'s drug fever be treated? Can M.M. receive cephalosporins in the future?

Because M.M. has responded clinically, her antibiotics should be discontinued and her fever curve, WBC count, heart rate, and respiratory status followed. An oral antibiotic from another drug class (e.g., a fluoroquinolone) should be started to complete a 7- to 10-day antibiotic course of therapy. Acetaminophen and other antipyretics should be avoided unless M.M. becomes uncomfortable from the fever because they can mask the response to the discontinuation of her antibiotics.

As with any hypersensitivity reaction, rechallenge with the offending drug can cause a similar, or sometimes greater, response. In M.M.'s case, re-exposure to ceftriaxone (or another β -lactam antibiotic) or a macrolide might cause a febrile reaction. It is unclear, however, how large the risk of re-exposure truly is. Although drug fever sometimes precedes more serious hypersensitivity reactions, evidence suggests there may be little risk to re-exposure. Should M.M. require ceftriaxone (or another β -lactam or macrolide antibiotic) in the future, it would be prudent to administer the drug in a setting where M.M. can be monitored, at least initially, to ensure prompt treatment if an immediate hypersensitivity reaction develops.

Hypersensitivity Vasculitis

11. M.G., a 26-year-old woman with cystic fibrosis, is admitted for treatment of pneumonia. Sputum cultures obtained before admission reveal *Alcaligenes xylosoxidans* sensitive only to minocycline and chloramphenicol. M.G. is initiated on appropriate doses of these two antibiotics for a 2-week course. On day 8 of therapy, M.G. begins to complain of a rash on her legs. Physical examination reveals palpable purpura and a maculopapular rash on both lower extremities. Laboratory data reveal an elevated ESR and leukocytosis. What is the likely cause of M.G.'s rash and laboratory abnormalities?

M.G.'s presentation is suggestive of a diagnosis of hypersensitivity vasculitis. Hypersensitivity vasculitis, also called *cutaneous leukocytoclastic angiitis* (CLA), is characterized by

Table 4-9 1990 Criteria for the Classification of Hypersensitivity Vasculitis

| Criteria ^a | Definition |
|---------------------------------------|---|
| Age at disease onset > 16 yrs | Development of symptoms after age 16 |
| Medication at disease onset | Medication was taken at the onset of symptoms that may have been a precipitating factor |
| Palpable purpura | Slightly elevated purpuric rash over one or more areas of the skin; does not blanch with pressure and not related to thrombocytopenia |
| Maculopapular rash | Flat and raised lesions of various sizes over one or more areas of the skin |
| Biopsy including arteriole and venule | Histologic changes showing granulocytes in a perivascular or extravascular location |

^aThe diagnosis of hypersensitivity vasculitis can be made if a patient exhibits at least three of these criteria.

Adapted from reference 248, with permission.

inflammation of the small blood vessel walls. These reactions occur when immune complex deposition within the small veins and arterioles activates complement, causing the release of chemotactic factors. These factors attract polymorphonuclear cells that cause vessel damage.^{67–69}

Drug-Induced Vasculitis

Approximately 20% of cases of cutaneous vasculitis are believed to be drug-related.⁷⁰ Table 4-7 lists the more commonly implicated drugs; interested readers are referred to more in-depth reviews.^{71,72} The diagnosis of hypersensitivity vasculitis is based on five clinical criteria (Table 4-9), three of which must be present.⁷³ M.G. meets three of the five criteria, including age > 16 years, palpable purpura, and a maculopapular rash. In addition, minocycline, a medication that she was taking at the onset of the rash, has been associated with serum sickness and vasculitic-type reactions. Onset of symptoms typically occurs 7 to 10 days after initiation of drug therapy, but can occur sooner on re-exposure. Purpuric papules and macular eruptions, the most commonly observed findings, are usually symmetric and occur on the extremities (Table 4-10).⁶⁸ Hyper-

Table 4-10 Hypersensitivity Reactions to Drugs: Clinical Manifestations of Drug-Induced Vasculitis

- Palpable purpura and maculopapular rash occurring symmetrically on the extremities
- Multiple organ systems may be involved:
Renal: microscopic hematuria to nephrotic syndrome and acute renal failure
Liver: enlarged liver, elevated enzymes, and arthralgias
- Laboratory data usually show nonspecific abnormalities of inflammation: elevated erythrocyte sedimentation rate and leukocytosis. Peripheral eosinophilia may be present and serum complement concentrations can be low. Histologic findings on biopsy reveal granulocytes in venule or arteriole walls
- Onset typically 7–10 days after initiation of therapy

From references 51, 177, 241, 237, with permission.

sensitivity vasculitis can involve multiple organ systems. Renal damage, ranging from microscopic hematuria to nephrotic syndrome and acute renal failure, is common in patients with disseminated disease.⁶⁸ An enlarged liver with elevated enzymes is indicative of hepatocellular involvement. Although the lungs and ears can be involved as well, clinical manifestations are usually mild.⁶⁸ Arthralgia also is commonly observed. Laboratory examinations usually show nonspecific abnormalities of inflammation such as an elevated ESR and leukocytosis. In patients with cystic fibrosis experiencing acute pneumonia, these laboratory abnormalities already could be present and, therefore, will not be helpful in establishing the diagnosis of hypersensitivity vasculitis in M.G.

12. What additional workup could be performed to confirm the diagnosis of drug-induced vasculitis in M.G.?

In addition to the previous workup, other laboratory and diagnostic procedures might demonstrate peripheral eosinophilia and low serum complement concentrations. A biopsy, which typically reveals granulocytes in the wall of a venule or arteriole and eosinophils at any location, would provide more definitive information.⁷³

13. How should M.G.'s hypersensitivity vasculitis be treated?

The first step is to discontinue the minocycline therapy. Drug-induced vasculitic reactions typically resolve on their own without additional interventions. If the reaction is severe, corticosteroids can be used.

Autoimmune Drug Reactions

14. R.F., a 24-year-old white male medical student, has been treated for 5 months with isoniazid because of a positive skin test for tuberculosis. He now is in clinic with complaints of new-onset myalgias and arthralgias. Laboratory values obtained the morning of the visit are within normal limits except for a positive ANA titer and an elevated ESR. What is the likely cause of R.F.'s symptoms and laboratory abnormalities?

Some drugs can induce an autoimmune process characterized by the presence of autoantibodies and, in some instances, clinical features of an autoimmune disorder. A drug-induced syndrome resembling SLE usually is characterized by myalgias, arthralgias, positive ANA titers, and an elevated ESR (Table 4-11). All of these characteristics are manifested by R.F.

Drug-induced SLE was first recognized over 50 years ago in a group of patients taking hydralazine for antihypertensive therapy.⁷⁴ Subsequently, isoniazid, chlorpromazine, anticonvulsants, β -adrenergic blockers, quinidine, methyl dopa, penicillamine, and sulfasalazine also have been implicated (Table 4-7); however, hydralazine and procainamide have been the drugs most frequently associated with this syndrome.^{75–78} An exact incidence of drug-induced lupus is difficult to ascertain because of changing patterns of drug use.

15. How can the diagnosis of drug-induced lupus be differentiated from SLE in R.F.?

In contrast to idiopathic SLE, drug-induced lupus is less likely to affect females and blacks.⁷⁶ Individuals with a slow

Table 4-11 Hypersensitivity Reactions to Drugs: Autoimmune Drug-Induced Lupus

| | |
|-------------------------|---|
| Frequency | Less likely to affect females and blacks than idiopathic SLE. Drug-induced lupus is more common in individuals with slow acetylator phenotype. |
| Clinical Manifestations | Milder disease than idiopathic SLE. Arthralgias, myalgias, fever, malaise, pleurisy, and slight weight loss. Mild splenomegaly and lymphadenopathy. <i>Onset</i> : usually abrupt, occurring several months to years after continuous therapy with the offending drug. <i>Appearance</i> : Classic butterfly malar rash, discoid lesions, oral mucosal ulcers, Raynaud's phenomenon, and alopecia are unusual features with drug-induced lupus as opposed to idiopathic SLE. <i>Laboratory studies</i> : positive ANA (predominantly single-stranded DNA and antihistone antibodies), anemia, and elevated erythrocyte sedimentation rate. Many patients demonstrate ANA without development of lupus disease. It is, therefore, not necessary to discontinue therapy in asymptomatic patients with positive ANA. |
| Treatment | Clinical features subside and disappear days to weeks after discontinuation of the offending drug. Serologic tests resolve more slowly. ANA may persist for a year or longer. |
| Prognosis | Drug-induced lupus does not predispose to development of idiopathic SLE. Lupus-inducing drugs do not appear to increase the risk of exacerbation of idiopathic SLE. Long-term treatment with interferon- λ may, however, worsen pre-existing SLE. |

ANA, antinuclear antibody; SLE, systemic lupus erythematosus.
From references 74–88, 249, with permission.

acetylator phenotype have a greater tendency to develop drug-induced lupus; ANA following exposure to lupus-inducing drugs also appear more rapidly.^{79,80} In general, drug-induced lupus is a milder disease than idiopathic SLE. Many patients with drug-induced lupus, however, could fulfill the diagnostic criteria for SLE according to the American Rheumatism Association.⁸¹ Arthralgias or myalgias accompanied by a positive ANA test can be the only clinical features for some patients with drug-induced lupus. Symptoms usually appear abruptly after several months to years of continuous therapy with the offending drug. Common complaints include fever, malaise, arthralgias, myalgias, pleurisy, and slight weight loss. Mild splenomegaly and lymphadenopathy have been reported occasionally. The classic butterfly malar rash, discoid lesions, oral mucosal ulcers, Raynaud's phenomenon, and alopecia are unusual features in drug-induced lupus in contrast to idiopathic SLE. In addition, the central nervous system and kidneys rarely are affected.⁷⁶ Laboratory abnormalities commonly include anemia and an elevated ESR. The evidence supporting a diagnosis of drug-induced lupus in R.F. includes white male predominance, abrupt onset and relatively mild symptomatology, and lack of the classic butterfly malar rash. More definitive tests include determining whether antibodies to single-stranded (indicative of drug-induced lupus) or double-stranded DNA (indicative of SLE) are present.

16. Should ANA have been monitored in an effort to detect drug-induced lupus at an earlier stage in this patient?

No. Although all patients with symptomatic drug-induced lupus test positive for ANA (which consist predominantly of single-stranded DNA and antihistone antibodies),⁷⁶ many patients taking lupus-inducing drugs become ANA positive without going on to develop lupus. In patients treated with procainamide, about 50% to 75% are positive for ANA after 12 months and 90% after 2 years or more of continuous therapy; only 10% to 20% of those patients actually develop lupus symptoms.^{82–84} Similarly, up to 44% of patients are ANA positive after 3 years of hydralazine therapy, but drug-induced lupus occurs in only 6.7% of patients after 3 years of treatment.⁸⁵ It is not necessary to discontinue therapy in asymptomatic patients

with positive ANA because most of them will never develop clinical symptoms.⁷⁶

17. How should R.F.'s drug-induced lupus be treated?

Musculoskeletal complaints can be treated with aspirin or nonsteroidal anti-inflammatory drugs (NSAID). More severe symptoms from pleuropulmonary or pericardial involvement may require the use of corticosteroids.⁷⁷ Clinical features of drug-induced lupus usually subside and disappear in days to weeks with discontinuation of the offending drug. Occasionally, these symptoms linger or recur over a course of several months before eventually disappearing. Serologic tests tend to resolve more slowly: ANA may persist for a year or longer.^{76,86} Drug-induced lupus does not predispose patients to the subsequent development of idiopathic SLE.⁸⁷ In most instances, lupus-inducing drugs do not increase the risk of exacerbation of idiopathic SLE⁸⁸; however, long-term treatment with isoniazid may worsen pre-existing SLE.⁸⁹ R.F. has not yet completed his 6- to 9-month course of isoniazid therapy. An alternative agent should be prescribed for R.F. for at least an additional month and preferentially for up to 4 more months (see Chapter 61: Tuberculosis).

ORGAN-SPECIFIC REACTIONS

The drug allergies in this chapter have been grouped into categories of generalized reactions, organ-specific reactions, and pseudoallergic reactions. The generalized reactions have been described above, the organ-specific hypersensitivity drug reactions affecting the blood, liver, lung, kidney, and skin are described next, and pseudoallergic reactions follow.

Blood: Immune Cytopenias

Drug-induced immune cytopenias (e.g., granulocytopenia, thrombocytopenia, hemolytic anemia) result from type II-mediated allergic reactions (Table 4-1). A drug or drug metabolite binds to the surface of blood elements such as granulocytes, platelets, and red blood cells. IgG or IgM antibodies are formed and are directed against the drug or drug metabolite bound

to the cell (i.e., hapten-cell reaction).⁹ The immune complex and autoimmune mechanisms for hemolytic anemia are presented in Chapter 87, Drug-Induced Blood Disorders. Typical symptoms associated with immune thrombocytopenia include chills, fever, petechiae, and mucous membrane bleeding. Granulocytopenia generally manifests with chills, fever, arthralgias, and a precipitous drop in the leukocyte count. Symptoms of hemolytic anemia can be subacute or acute and can be sufficiently severe to cause renal failure. Coombs' test is useful in identifying antibodies bound to red cells or circulating immune complexes directed against red cells. Antibiotics are the most commonly implicated class of drugs causing either neutropenia or hemolytic anemia. (See Chapter 87 for a more complete description of the immune cytopenias.)

Liver

Hypersensitivity reactions involving the liver can be classified as cholestatic or cytotoxic. Jaundice is usually the first sign of a cholestatic reaction, in addition to pruritus, pale stools, and dark urine. Cholestatic reactions usually are reversible on discontinuation of the offending agent.

Cytotoxic reactions can involve hepatocellular necrosis or steatosis and can result in irreversible damage if not recognized early. (See Chapter 29: Adverse Effects of Drugs on the Liver, for a discussion of hypersensitivity reactions involving the liver.)

Lung

Pulmonary manifestations of drug hypersensitivity include asthma and infiltrative reactions. Asthma typically occurs as part of a generalized systemic reaction. Most reactions to drugs that involve asthma alone represent a pharmacologic side effect rather than a true allergic reaction.

Infiltrative reactions typically develop 2 to 10 days after exposure and manifest with cough, dyspnea, fever, chills, and malaise.⁶ Infiltrative reactions vary in presentation from eosinophilic pneumonitis to acute pulmonary edema. (See Chapter 25: Drug-Induced Pulmonary Disorders, for a discussion of hypersensitivity reactions to specific drugs.)

Kidney

The most common hypersensitivity reaction involving the kidney is interstitial nephritis. Typical findings include fever, rash, and eosinophilia. Methicillin is the drug most commonly associated with interstitial nephritis, however, penicillins, sulfonamides, and cimetidine also have been implicated in renal hypersensitivity reactions.^{6,9} (See Chapter 30: Acute Renal Failure, for an analysis of hypersensitivity reactions to specific drugs that adversely affect the kidney.)

Skin

Adverse reactions involving the skin are the most common clinical manifestation of drug allergy. Although several different types of cutaneous reactions are possible, most drug-induced skin eruptions can be classified as erythematous, morbilliform, or maculopapular in appearance.⁹ In a surveillance study of drug-induced skin reactions, amoxicillin was the most com-

mon cause, followed by trimethoprim-sulfamethoxazole and ampicillin. Overall, allergic skin reactions were identified in 2% of hospitalized patients.¹⁰

Treatment of skin reactions includes discontinuation of the offending drug and general supportive care. (See Chapter 38: Dermatotherapy and Drug-Induced skin disorders.)

PSEUDOALLERGIC REACTIONS

18. C.C., a 37-year-old man with no known allergies, is hospitalized for treatment of methicillin-resistant *S. aureus* (MRSA) bacteremia associated with an infected central line. His medical history is significant for short-bowel syndrome requiring parenteral nutrition and one previous episode of MRSA line infection successfully treated with vancomycin. Similar to his last admission, vancomycin 750 mg IV over 60 minutes every 12 hours is begun. A trough level taken after the fifth dose, however, is 5 mg/L and the vancomycin dose is doubled to 1,500 mg IV every 12 hours, to be administered at the same rate. Fifteen minutes after the new dose of vancomycin is begun, C.C. experienced hypotension (100/70 mmHg), tachycardia (85 beats/minute), generalized pruritus, and facial flushing. C.C. is diagnosed as having a pseudoallergic reaction to vancomycin. What subjective and objective data in C.C. are important in differentiating vancomycin pseudoallergic reaction from a true allergic reaction?

Pseudoallergic reactions are drug reactions that exhibit clinical signs and symptoms of an allergic response, but are not immunologically mediated.⁹⁰ They can manifest as relatively benign symptoms or as severe, life-threatening events indistinguishable from anaphylaxis (Table 4-12).⁹⁰ The latter response is described as an anaphylactoid reaction because it resembles true anaphylaxis, but does not involve IgE-antibody formation.^{9,90} The risk of such potentially severe reactions needs to be considered when prescribing agents known to be associated with anaphylactoid reactions. For example, the prophylactic use of antibiotics such as ciprofloxacin to prevent meningococcal infections during an outbreak was associated with a relatively high rate (1:1,000) of serious anaphylactoid reactions.⁹¹ This would be of potentially greater importance in the setting of a mass prophylaxis program to combat exposure to anthrax. Unlike true allergic reactions, which require an induction period during which a patient becomes sensitized to an antigen, pseudoallergic reactions can occur on the first exposure to a drug. The development of pseudoallergic reactions can be dose related, manifesting when large doses of the drug are administered, when the dose is increased, or when the rate of IV administration is increased.⁶

C.C. has experienced a common pseudoallergic reaction to vancomycin, usually referred to as the “red man syndrome” or “red neck syndrome,” which primarily occurs when large doses of vancomycin are administered rapidly. Differentiating between a true allergic response and a pseudoallergic response can be difficult because the signs and symptoms can be indistinguishable. For example, each of the symptoms experienced by C.C. (flushing, tachycardia, pruritus, and hypotension) is caused by histamine release and can occur during an anaphylactic episode. To conclusively determine the cause of the reaction would require immunologic testing for antibodies to the suspect drug or agent, which is not always possible or practical. In this case, C.C. had uneventfully received vancomycin

Table 4-12 Hypersensitivity Reactions to Drugs: Pseudoallergic Reactions

| | |
|-------------------------|---|
| Frequency | Highly variable, depending on the agent involved. For example, up to 30% of patients taking aspirin develop a cutaneous pseudoallergic response. On the other hand, pseudoallergic reactions to other agents, such as phytonadione and thiamine, are rare. |
| Clinical Manifestations | Range from benign reactions (e.g., pruritus and flushing) to a life-threatening clinical syndrome indistinguishable from anaphylaxis |
| Treatment | Pseudoallergic reactions are treated the same as true allergic reactions (i.e., according to the clinical presentations of the patient). Thus, some reactions simply may require removal of the suspect agent, whereas some anaphylactoid reactions may require aggressive therapy (e.g., epinephrine, antihistamines, corticosteroids). |
| Prognosis | As with true allergic reactions, patients who have experienced a pseudoallergic drug reaction may have a similar reaction on re-exposure. The severity of response may lessen, however, with repeated administration. Furthermore, for some drugs, the frequency and severity of the reaction also may be influenced by the dose or rate of intravenous (IV) administration. Pretreatment regimens to reduce the frequency and the severity of responses have been developed for some drugs well known to cause pseudoallergic reactions (e.g., radiocontrast media). |

From references 5, 9, 90, 91, 93, 94, 100, 111, 250–257, with permission.

previously and has tolerated five doses during this hospitalization; therefore, it is unlikely that the reaction is immunologically mediated (i.e., a true allergic reaction). Furthermore, the reaction occurred after an increase in his vancomycin dose, which further supports the diagnosis of a pseudoallergic reaction.

19. Why did vancomycin cause a pseudoallergic reaction in C.C.?

Two general mechanisms have been proposed for pseudoallergic reactions: complement activation and direct histamine release.³⁰

Complement activation is secondary to immune complex formation, leading to the production of C3a, C4a, and C5a. These anaphylatoxins directly stimulate tissue mast cell and basophil degranulation and the subsequent release of neurochemical mediators. Radiocontrast media, whole blood and blood products, and protamine cause pseudoallergic reactions via this mechanism of complement activation.⁹⁰

Pseudoallergic reactions from *direct drug-induced histamine release* occur through an as yet unknown pathway. Direct drug-induced release of histamine does not involve complement activation or IgE-antibody formation. Several drugs (e.g., vancomycin, protamine, radiocontrast media, opiates, pentamidine, phytonadione, deferoxamine) are known to directly stimulate histamine release.^{6,90}

Some drugs (e.g., radiocontrast media and protamine) cause pseudoallergic reactions via both complement activation and direct-histamine release mechanisms. Furthermore, some drugs (e.g., vancomycin, quaternary ammonium muscle relaxants, and ciprofloxacin) can cause both true allergic reactions and pseudoallergic reactions.³

20. How should C.C.'s pseudoallergic reaction be treated? Does treatment of pseudoallergic reactions differ from that of true allergic reactions?

The first step in treating C.C.'s reaction is to eliminate the underlying cause. Thus, his vancomycin infusion should be held until the reaction resolves. Because the reaction is histamine mediated, administration of an antihistamine such as diphenhydramine 50 mg IV is warranted. Observation of his BP and heart rate is mandatory. IV fluids should be adminis-

tered if his BP continues to fall or fails to stabilize. Patients with allergic reactions should be treated based on their clinical signs and symptoms, regardless of the mechanism behind the reaction. Thus, for all intents and purposes, pseudoallergic reactions are treated in the same manner as true allergic reactions.

21. Can C.C. continue to receive vancomycin? How can future reactions be prevented?

It is not necessary to discontinue vancomycin therapy in C.C. This reaction can be prevented by administering smaller doses of the drug more frequently (e.g., 1,000 mg every 8 hours rather than 1,500 mg every 12 hours) or infusing the dose over a longer interval, typically 2 hours. Alternatively, pretreatment with an antihistamine 1 hour before vancomycin administration is effective. In addition, tachyphylaxis to vancomycin-induced red man syndrome is independent of pretreatment with antihistamine and is another characteristic that differentiates a pseudoallergic reaction from a true allergic reaction. Pretreatment regimens to prevent pseudoallergic reactions to various other drugs (e.g., radiocontrast media) also are well described and can be effective.

22. What other drugs are commonly associated with pseudoallergic reactions?

Many other agents have been associated with pseudoallergic reactions, as shown in Table 4-13. Some of the agents more commonly associated with pseudoallergic reactions are described next.

Aspirin/Nonsteroidal Anti-inflammatory Drugs (NSAIDs)

After penicillins, aspirin is the drug most commonly reported as causing “allergic” reactions. Reactions to aspirin can be divided into three broad categories: respiratory reactions, cutaneous manifestations, and anaphylaxis. None of these reactions has been consistently associated with IgE.⁹²

Respiratory. The prevalence of bronchospasm with rhinoconjunctivitis is 0% to 28% in children with aspirin sensitivity. In adult asthmatics, the prevalence of aspirin sensitivity ranges from 5% to 20%. The prevalence of aspirin sensitivity during aspirin challenge in adult asthmatics with a history of aspirin-induced respiratory reaction ranges from

Table 4-13 Pseudoallergic Reactions

| | | |
|--|-----------------------------------|---|
| Acetylcysteine ²⁵⁴ | Immune globulin ⁹⁰ | Phytonadione ⁹⁰ |
| ACE inhibitors ¹⁰⁰ | Iron dextran ²⁶⁰ | Polyoxyethylated castor oil (Cremophor EL, a solubilizing agent used in parenteral drugs such as cyclosporine, paclitaxel) ^{258,259} |
| Angiotensin II–receptor blocking agents ^{101–109} | Iron sucrose ²⁶¹ | Protamine ⁹ |
| Aspirin ^{93,94} | Methotrexate ²⁶² | Quaternary ammonium muscle relaxants ^{5,90} |
| β -Adrenergic blockers ⁹⁰ | Minocycline ²⁶³ | Radiocontrast media ¹¹¹ |
| Ciprofloxacin ^{5,252,255,256} | Narcotic analgesics ⁹⁰ | Reserpine ⁹⁰ |
| Cisplatin ²⁶⁴ | NSAID ^{92,93} | Sodium ferric gluconate ²⁶⁵ |
| Corticosteroids ^{266,267} | Ondansetron ^{253,257} | Thiamine ⁹² |
| COX-2 inhibitors ⁹⁵ | Paclitaxel ²⁶⁸ | Vancomycin ^{9,251} |
| Deferoxamine ⁹⁰ | Pentamidine ⁹⁰ | |

66% to 97%.^{93,94} Symptoms usually occur within 30 minutes to 3 hours of ingestion. The triad seen in many sensitive patients is aspirin sensitivity, nasal polyps, and asthma. All potent inhibitors of cyclooxygenase can cause respiratory symptoms in aspirin-sensitive patients. Thus, patients who react to aspirin should be considered sensitive to NSAIDs, and vice versa. Weak cyclooxygenase inhibitors, such as acetaminophen, choline magnesium salicylate, propoxyphene, salicylamide, salsalate, and sodium salicylate, are generally well tolerated in patients with aspirin sensitivity.⁹²

Cutaneous. The prevalence of cutaneous reactions to aspirin depends on the type of reaction and the population studied. For example, urticaria-angioedema occurs in 0.5% of children, 3.8% of the general adult population, and in 21% to 30% of patients with a history of chronic urticaria. Disease activity at the time of aspirin challenge plays an important role in those with a history of chronic urticaria. In one study, 70% of patients whose urticaria was active at the time of challenge reacted to aspirin, compared with only 6.6% of patients whose urticaria was not active at the time of challenge. Furthermore, aspirin or NSAID may aggravate preexisting urticaria.^{92–94} Other dermatologic reactions to aspirin occur with less frequency: for example, eczema, purpura, and erythema multiforme occur in 2.4%, 1.5%, and 1% of the population, respectively.

Anaphylaxis. The true prevalence of aspirin or NSAID-induced anaphylaxis is unknown, but may range from 0.07% of the general population to 10% of patients with anaphylactic symptoms. Although IgE is not consistently associated with aspirin or NSAID-related reactions (including anaphylaxis), aspirin- or NSAID-induced anaphylaxis shares three characteristics with immune-mediated anaphylaxis that point to IgE as a cause. First, the reaction occurs after two or more exposures to the offending agent, suggesting that preformed IgE antibodies are responsible. Second, patients do not have underlying nasal polyposis, asthma, or urticaria. Third, the patient who reacts to aspirin or a single NSAID can tolerate a chemically unrelated NSAID, suggesting that a drug-specific IgE antibody has been formed.^{92,95}

The NSAIDs that selectively inhibit cyclooxygenase-2 (COX-2) while sparing cyclooxygenase-1 (COX-1) include celecoxib, rofecoxib, and valdecoxib, among others. Celecoxib is the only COX-2 inhibitor or “coxib” currently marketed in the United States. Selective inhibition of COX-2 provides anti-inflammatory effects while minimizing the renal effects, GI toxicity, and antiplatelet effects seen with inhibition of COX-1. Aspirin and older NSAIDs are nonselective inhibitors of cyclooxygenase, inhibiting both COX-1 and COX-2. Anaphyl-

actoid or hypersensitivity reactions have been reported with celecoxib and it appears that the rate of hypersensitivity is comparable to that of traditional NSAIDs.⁹⁵ Notably, celecoxib prescribing information states that, as with any NSAID, use is contraindicated in patients who have experienced asthma, urticaria, or allergic-type reactions after taking aspirin or other NSAIDs. Several reports, however, describe successful administration of celecoxib and other COX-2 selective agents to patients with aspirin-sensitive asthma or a history of hypersensitivity reactions to traditional NSAIDs, and evidence suggests that inhibition of COX-1 rather than COX-2 is key to initiating these events.^{96–99} Nevertheless, COX-2 selective agents can still elicit allergic responses by other means (e.g., IgE-mediated hypersensitivity). Thus, appropriate precautions and monitoring should be followed when initiating therapy in any patient with a history of allergic reactions to aspirin or other NSAIDs.

Angiotensin-Converting Enzyme Inhibitors and Angiotensin II–Receptor Blockers

23. K.J., a 48-year-old woman, seeks care at an urgent care center. She presents with impaired speech, but is able to swallow; she has red and swollen lips and tongue, and puffy eyes. Her medical history includes hypertension, atrial fibrillation, and a new diagnosis of hypercholesterolemia (plasma cholesterol 290 mg/dL). Although her BP had been well controlled on hydrochlorothiazide, her diuretic was discontinued about 3 weeks ago because of its effect on cholesterol, and enalapril 5 mg daily was started. K.J. also takes a multivitamin (one tablet each day) and warfarin (5 mg daily). Her physical examination shows BP 130/87 mmHg; heart rate 70 beats/minute; lungs clear to auscultation and percussion; respirations 12 breaths/minute; and skin without rash or urticaria. Her condition is attributed to angioedema induced by enalapril. What is angioedema, and what evidence supports this diagnosis? What is the mechanism behind angioedema?

Angioneurotic edema (angioedema) manifests as local erythematous edema, which frequently involves the tongue, lips, eyelids, and mucous membranes of the mouth, nose, and throat. Drugs can cause this anaphylactoid reaction. For example, ACE inhibitors have been associated with this adverse effect in about 0.1% to 0.2% of individuals treated with this drug. It is not dose related and occurs with all ACE inhibitors. K.J. presents with classic symptoms of angioedema and does not have symptoms of a true anaphylactic reaction, further strengthening the diagnosis of drug-induced

angioedema. Symptoms of angioedema usually occur within the first week of starting therapy, although they can occur at any time. Thus, although angioedema developed 3 weeks after K.J. began enalapril, the temporal relationship is reasonable.

The precise mechanism of angioedema remains unclear. Studies suggest, however, that increased concentrations of bradykinin, elevated levels of complement 1-esterase inactivator (an enzyme that inhibits complement activation), histamine-mediated reactions, and deficiencies in carboxypeptidase N, α_1 -antitrypsin, and complement C4 may be involved.^{92,100,101} (See Chapter 18: Heart Failure.)

24. How should K.J. be treated? Would an angiotensin receptor blocker (ARB) be an appropriate substitute for her ACE inhibitor?

Although angioedema can be life-threatening, symptoms are usually mild and resolve within hours to days of stopping the offending drug. More severe reactions can progress to laryngospasm, laryngeal swelling, and airway obstruction and must be treated emergently with appropriate measures to maintain airway patency. Antihistamines and corticosteroids are commonly prescribed, but the validity of this treatment needs substantiation. K.J. does not need to be hospitalized because her respirations are not compromised and she is not experiencing swallowing difficulty; however, she should be kept under observation at the urgent care center to ensure that her angioedema does not worsen. After this is established, she can be sent home with a prescription for diphenhydramine 25 mg orally every 6 hours for 24 hours, with instructions to seek emergent help if her breathing or swallowing becomes difficult. She should be instructed to discontinue her enalapril, follow up with her primary physician as soon as possible, and to request her community pharmacist to record this adverse reaction to enalapril into her drug profile at the pharmacy. Because angioedema occurs with all ACE inhibitors, K.J. must avoid all drugs in this class.

Angioedema with ARB also has been reported,^{102–109} although with less frequency than with ACE inhibitors. Many of the cases of ARB-induced angioedema involved patients with a history of ACE inhibitor-induced angioedema, but this is not consistently the case. Similar to the ACE inhibitors, angioedema to ARB can occur at any time during treatment. In K.J.'s case, it would be best to avoid ARB and ACE inhibitors. Instead, other antihypertensive agents that have little effect on cholesterol (e.g., calcium channel blockers) should be used.

25. Are there other pseudoallergic reactions that occur with ACE inhibitors and ARB?

Besides angioedema, cough is a pseudoallergic reaction caused by ACE inhibitors. It may occur in up to 39% of patients after 1 week to 6 months of therapy. Interestingly, it is more common in nonsmokers than in smokers; the incidence does not increase in patients with chronic airway disease or asthma. Cough is more common in women than men, is not dose related, and, as with angioedema, occurs with all ACE inhibitors.^{92,100,101,110} Several mechanisms appear to be responsible, including inhibition of the breakdown of bradykinin in the lung and increases in local mediators of inflammation such as prostaglandins and substance P. Although many approaches to the management of ACE-induced cough have been

proposed,¹⁰¹ angiotensin II-receptor blocking agents are the most promising alternative. Cough can occur with ARB, but the frequency appears to be no more than that of placebo. Furthermore, most direct comparative trials between ARB and ACE inhibitors demonstrate that the frequency of cough with ARB is much lower than with ACE inhibitors.¹⁰¹

Radiocontrast Media

Radiocontrast media are widely used diagnostic agents, exceeding 10 million administrations annually.⁹² Adverse reactions to radiocontrast media include nausea, flushing, BP changes, bronchospasm, urticaria, angioedema, cardiac arrhythmias, convulsions, angina, and symptoms indistinguishable from true anaphylaxis. The cause of radiocontrast media reactions remains unknown, although histamine release, complement activation, and direct toxic effects on end organs might all play a role. These adverse effects are classified as pseudoallergic reactions because evidence does not support IgE mediation of these reactions. The overall incidence of reaction to radiocontrast media is 0.7%–13%, depending on the type of agent selected and whether the patient was pretreated before administration.¹¹¹ Conventional, ionic, high-osmolality contrast media produce reactions in 4%–13% of recipients, whereas nonionic, low-osmolality agents produce fewer reactions (0.7%–3.1%). Estimates of the mortality rate associated with the administration of contrast media varies widely from 1:15,000–1:117,000.^{92,111}

Patients with a history of a pseudoallergic reaction to contrast media are at increased risk for future reactions with repeat exposure. Several pretreatment regimens have been developed to minimize such occurrences. For example, 32 mg of oral methylprednisolone given 12 and 2 hours before a procedure involving a high-osmolality contrast medium can reduce the reaction rate by up to 45% in some patients.¹¹¹ Another pretreatment regimen uses oral prednisone 50 mg taken 13 hours, 7 hours, and 1 hour before the procedure, plus diphenhydramine 50 mg orally or intramuscularly 1 hour before the examination.¹¹² This latter regimen lowers the occurrence of pseudoallergic reactions to high-osmolality contrast media, even in high-risk patients (i.e., those with a history of severe anaphylactoid reactions).

Narcotic Analgesics

Some opiates stimulate histamine release and, thereby, cause hypotension, tachycardia, facial flushing, increased sweating, or pruritus. Severe reactions are uncommon, however. In many cases, the opiate can be continued with administration of an antihistamine to treat the symptoms. If the reaction is significant, a non-narcotic alternate analgesic may be considered, or an opiate that does not cause histamine release can be substituted. Morphine and meperidine cause the greatest histamine release in both *in vitro* and *in vivo* studies. Codeine, hydromorphone, oxycodone, and butorphanol stimulate histamine release less commonly; and levorphanol, fentanyl, sufentanil, methadone, and oxymorphone have little to no effect on histamine levels. One of the more frequent reactions to epidurally or intrathecally administered opiates is pruritus, which does not appear to be mediated by histamine because narcotics that do not release histamine (e.g., fentanyl, sufentanil) still cause pruritus

after spinal administration. Furthermore, the pruritus tends to develop several hours after the opiate has been administered, when serum levels of histamine are insignificant. The cause of pruritus from spinal opiates remains unclear. The reaction can be managed with antihistamines and low-dose naloxone or nalbuphine, while continuing with the spinal narcotic.⁹⁰

Protamine

Protamine sulfate, a low-molecular weight protein that is a component of some insulin preparations, is used extensively to neutralize heparin during cardiac procedures. In one study, 11% of patients receiving protamine during cardiac surgery experienced an adverse reaction (e.g., angioedema, wheezing, erythema, urticaria). Severe hypotension and shock leading to death have also been reported. The mechanism of these severe reactions is unknown, but might be pseudoallergic and IgE mediated.^{9,92}

Iron-Dextran Injection

Iron-dextran injection is a solution of ferric hydroxide (InFeD) or ferric oxyhydroxide (Dexferrum) complexed with low-molecular weight dextran. Iron dextran is used in the treatment of iron deficiency when oral iron preparations cannot be used or are ineffective. This is most commonly seen in patients with anemia of chronic renal failure, particularly those treated with epoetin alfa or darbepoetin and undergoing hemodialysis (Chapter 31: Chronic Kidney Disease). Iron-dextran injection is associated with a wide spectrum of adverse events (e.g., chest pain, hypotension, hypertension, abdominal pain, nausea, vomiting, weakness, syncope, backache, arthralgias, myalgias, hypersensitivity reactions). Hypersensitivity reactions can be manifested as urticaria, sweating, dyspnea, rash, fever, and as anaphylactoid reactions, which can be fatal. Consistent with a nonimmunologic mechanism, hypersensitivity reactions to iron dextran are not dose related and can occur with the first drug exposure.¹¹³ Serious life-threatening anaphylactoid reactions occur in 0.6% to 0.7% of patients treated with iron dextran; serious reactions that prevent further administration occur in 2.47% of recipients.¹¹⁴ Although the cause of the hypersensitivity reactions from iron dextran is unclear, it is attributed to the dextran component. Anaphylaxis from dextran, when used as a volume expander, has been reported.¹¹⁴ A test dose of iron dextran should be administered to assess tolerance, before administration of the full dose. Nevertheless, hypersensitivity reactions have been reported despite successful tolerance to a test dose, rendering this practice unreliable.

Two nondextran parenteral iron products are available in the United States: sodium ferric gluconate (Ferrlecit) and iron sucrose, also known as iron saccharate (Venofer). Both agents have a better safety profile than iron dextran. Baile et al.¹¹⁵ reviewed abstracted reports of adverse reactions made to the U.S. Food and Drug Administration (FDA) between 1997 and 2002 to compare adverse event reporting rates between all parenteral iron products. These researchers categorized reactions according to the standard adverse event dictionary used by FDA. Because of differences between dosing of the products, results were reported per 100-mg dose equivalents (DE). The

researchers found the reporting rate for all adverse reactions was 29.2, 10.5, and 4.2 reports per million 100 mg DE for iron dextran, sodium ferric gluconate, and iron sucrose, respectively. The reporting rate for anaphylactoid reactions was 0.87, 0.46, and 0.0 per million 100 mg DE, respectively. There were 0.6 reports of anaphylaxis per million 100 mg DE of iron dextran; no reports exist of anaphylaxis for sodium ferric gluconate or iron sucrose.¹¹⁵ Another study used data reported to the FDA MedWatch program between 2001 and 2003 to determine the odds of adverse events between all four parenteral iron products. Relative to the InFeD brand of iron dextran, patients receiving sodium ferric gluconate or iron sucrose were half as likely to experience an allergic reaction or any adverse drug event (ADE). An equal risk existed of experiencing an allergic reaction, or any ADE, between sodium ferric gluconate and iron sucrose. Odds ratios between the Dexferrum brand of iron dextran and sodium ferric gluconate or iron sucrose were not reported. Although sodium ferric gluconate and iron sucrose were safer than iron dextran, at least one death and five life-threatening ADE were reported with each of the four agents studied, underscoring that risks are associated with any parenteral iron product.¹¹⁶

Both sodium ferric gluconate and iron sucrose cause fewer hypersensitivity reactions, including anaphylactoid reactions, and appear to be safer than iron dextran. The decision to give patients who are to receive parenteral iron preparation a test dose will depend on the product used. All patients receiving iron dextran should receive a test dose to assess tolerance. Neither sodium ferric gluconate nor iron sucrose requires a test dose per their prescribing information. It appears iron dextran-tolerant patients have little risk of experiencing a serious hypersensitivity or anaphylactoid reaction to sodium ferric gluconate or iron sucrose injection and can safely be given one of these products without a prior test dose. Similarly, patients who have never received any parenteral iron product can be administered sodium ferric gluconate or iron sucrose for injection without a prior test dose. Although studies support the safety of both sodium ferric gluconate and iron sucrose for injection in iron dextran-sensitive patients, such patients may be at increased risk for an anaphylactoid reaction or other serious hypersensitivity response, and test dosing in this population may be reasonable. Regardless of whether a test dose is administered for any of the parenteral iron products, close monitoring of the patient following drug administration is necessary and the availability of resuscitative medication and personnel trained to evaluate and address anaphylaxis is prudent.

LATEX ALLERGY

Natural latex is a milky fluid consisting of extremely small particles of rubber obtained from the rubber tree. Natural rubber includes all products made from, or containing, natural latex.¹¹⁷ Many products commonly used in health care (e.g., gloves, BP cuffs, catheters, injection ports, rubber stoppers of medication vials) are made wholly or in part of latex. Over the past several years, the significance of latex allergy has become clear as cases of allergic reactions, some life-threatening, have been reported.¹¹⁷ Health professionals must recognize the types of reactions latex can cause and must know how to minimize patient exposure to latex. Also, preparing parenteral

drugs for latex-allergic patients can be difficult because of the number of materials involved that may contain latex.

Health professionals are at significant risk for developing latex allergy because of their frequent exposure to latex products. Other groups at risk for developing latex allergy are workers in businesses that manufacture latex products, patients with spina bifida; and people with allergies to avocado, potato, banana, tomato, chestnuts, kiwi fruit, and papaya.¹¹⁷

Three types of reactions to latex have been described: irritant contact dermatitis, allergic contact dermatitis (chemical sensitivity dermatitis), and immediate hypersensitivity.^{117,118}

Irritant contact dermatitis is the most common reaction to latex and manifests as dry, itchy, irritated areas of the skin. This is not a true allergic reaction to latex.¹¹⁷

Allergic contact dermatitis is a delayed hypersensitivity reaction caused by exposure to chemicals added during the processing and manufacturing of latex. A rash, similar to that seen with poison ivy, usually begins 24 to 48 hours after exposure and may progress to oozing blisters.¹¹⁷

Immediate hypersensitivity to proteins in the latex is an IgE-mediated allergic response. The reaction can begin within minutes of exposure to latex or occur hours later. Symptoms vary from mild skin redness, hives, and itching to respiratory involvement (runny nose, sneezing, itchy eyes, trouble breathing, asthma). Rare cases of anaphylactic shock have been described.¹¹⁷ Reports of the prevalence of latex allergy vary from 1% to 6% of the general population and 8% to 12% of health care workers. Latex allergy is diagnosed by obtaining an accurate description of the reaction and establishing a temporal relationship to latex exposure. Diagnostic kits are available to detect latex antibodies as well as to aid in the diagnosis of allergic contact dermatitis.^{117,118}

Health care practitioners, particularly those in settings in which IV or intramuscular medications are administered, may be faced with preparing parenteral products for a latex-allergic patient. This often poses a challenge because latex is in many of the materials used to prepare parenteral products (e.g., rubber stoppers on medication vials, injection ports on IV bags, rubber plungers for syringes, IV transfer sets).^{117,118} Many manufacturers are now preparing products in a latex-free form, which simplifies drug preparation. Furthermore, manufacturers of medical devices are now required to identify on their labels which products have natural latex and which have dry natural rubber.¹¹⁹ Many institutions have instituted policies on the preparation of parenteral products for the “latex-sensitive” person. Readers are referred to these references for the details of these procedures.^{118,120–123}

PREVENTION AND MANAGEMENT OF ALLERGIC REACTIONS

26. A.M., a 40-year-old woman, is hospitalized with a diagnosis of community-acquired pneumonia. Her medical history is noncontributory except for an uneventful course of ampicillin 6 months before admission for an ear infection. A.M. is empirically treated with cefuroxime 0.75 g IV every 8 hours. On day 2 of therapy, she develops a raised pruritic maculopapular rash on her back, abdomen, and upper extremities. Antacid, docusate sodium, albuterol by metered-dose inhaler, and multivitamins were initi-

ated on the same day as the cefuroxime. How should A.M.’s allergic reaction be managed? How might her allergic reaction have been prevented?

When examining methods to prevent allergic reactions, three possibilities exist: (a) the patient has unknowingly been sensitized to a drug and experiences an allergic reaction on receiving the same or a similar drug again; (b) the patient has a history of an allergic reaction to a medication and mistakenly receives the same or a similar medication a second time and again develops an allergic reaction; and (c) the patient has a history of an allergic reaction to a medication and intentionally receives the same or similar medication again. As in the first situation, A.M.’s allergic reaction was unpredictable and, therefore, could not be prevented. To prevent future allergic reactions (i.e., the second situation), however, A.M.’s reaction should be well documented in the medical chart and pharmacy records. In addition, all patients should undergo a thorough drug history on hospitalization. Careful attention should be paid to differentiating drug intolerance (e.g., stomach upset) from true allergic reactions, and any allergic reactions elicited during an interview should be documented appropriately. Adequate communication of allergic reactions is the single most important method of preventing their occurrence.

As described earlier, the first step in managing an allergic reaction is to determine its cause. Given A.M.’s history of exposure to ampicillin, the timing of the reaction, and the low frequency of allergic reactions to her other medications, cefuroxime are the most likely candidates. Second, a decision regarding whether to stop the suspect drug should be made. This decision must be based on the severity of the reaction, the condition being treated, and the availability of suitable alternatives. When possible, an equally effective alternative drug should be substituted for the suspect agent, preferably one that is immunologically distinct to avoid cross-sensitivity (see Question 4 for a discussion of cross-reactivity).¹²⁴ If a suitable alternative exists, the offending agent should be stopped and the reaction treated symptomatically if necessary. In the case of A.M., another antimicrobial (e.g., azithromycin, clarithromycin, trimethoprim-sulfamethoxazole) could be substituted for cefuroxime (Chapter 60: Respiratory Tract Infections) and her symptoms treated with an oral or parenteral antihistamine, as well as a low-potency topical corticosteroid if necessary.

Some cases are described by the third situation: a patient develops an allergic reaction (or has a well-documented history of drug allergy), and it is inappropriate or not possible to change to an alternative drug. If the sensitivity reaction is severe or life-threatening, desensitization should be considered (Questions 27 to 30); premedication to prevent or minimize anaphylaxis is not effective.³ If the reaction is minor (e.g., pruritus, rash, or GI symptoms), premedication or management of the reaction with antiallergy medications (e.g., antihistamines) might be sufficient to allow completion of therapy. It is rare in such cases for the reaction to progress to more serious allergic symptoms such as anaphylaxis;¹²⁴ however, suppression of allergic symptoms should be undertaken cautiously because many immunologic reactions are not IgE mediated and may progress to serious reactions, despite treatment. In general, allergy suppression should be reserved for prevention of mild reactions that are known or strongly suspected to be IgE mediated.^{3,124}

Desensitization

β-Lactams

27. K.A. is a 24-year-old primigravida in her eighth week of pregnancy with a history of angioedema secondary to penicillin. Her initial pregnancy screening revealed a positive Venereal Disease Research Laboratory (VDRL) reaction and a fluorescent treponemal antibody absorption (FTA-Abs) titer of 1:64. K.A. denies a history of genital lesions, currently does not exhibit clinical signs or symptoms of syphilis, and denies previous treatment for syphilis. Based on the serologic evidence and her history, a diagnosis of early latent syphilis is made. Current treatment guidelines indicate that penicillin is the drug of choice for K.A. How can a possible reaction to penicillin be prevented in K.A.? Is premedication an alternative to preventing a reaction?

Acute desensitization (or hyposensitization) is the process of administering gradually increasing doses of a drug over hours or days in an effort to develop clinical tolerance.^{1,3,6,34,124} This process has been used successfully to reintroduce drugs to patients with known allergic reactions in situations in which no alternatives exist. It is most commonly used in patients with IgE-mediated hypersensitivity and is well described for penicillin-allergic patients. Desensitization, however, is not useful in preventing late penicillin reactions and should not be attempted in patients who have experienced severe dermatologic reactions such as exfoliative dermatitis.³⁴ Because K.A.'s reaction to penicillin may be potentially severe, premedication is not an option and desensitization to penicillin should be started. (See Chapter 65: Sexually Transmitted Diseases, for alternative therapy.)

28. How should K.A. be desensitized? Why should she be skin tested before desensitization?

If possible before desensitization is begun, K.A. should be skin tested (see Questions 3 and 4) to confirm her penicillin allergy.^{3,34,124} Patients who have a positive history of penicillin allergy, but whose skin tests are negative, can receive full therapeutic doses without desensitization with little risk of developing an allergic reaction. One author, for example, reported only one case of acute anaphylaxis in a skin test-negative patient given full therapeutic doses of penicillin in >1,500 skin tests; similar results have been reported by other investigators.^{34,124} If skin testing cannot be performed or if K.A.'s skin test is positive, desensitization should be initiated. Acute oral desensitization to penicillin and other β -lactam antibiotics is well established; one such protocol is outlined in Table 4-14, although others have been used successfully.^{125–128}

The oral route for β -lactam desensitization is preferred to the parenteral route because (a) exposure by the oral route is less likely to cause a systemic allergic reaction than parenteral exposure; (b) fatal anaphylaxis from oral β -lactam drug therapy is rare; (c) preformed polymers and conjugates of penicillin major and minor determinants to penicillium proteins are not well absorbed after oral administration; (d) blood levels rise gradually, favoring univalent haptentation (appearance of multivalent haptent-carrier conjugates, on the other hand, is gradual); and (e) fatal or life-endangering reactions have not occurred using current methods. In addition, oral desensitization can be accomplished over several hours.³ If oral desensitization is not

Table 4-14 β -Lactam Oral Desensitization Protocol

| Stock Drug Concentration (mg/mL) ^a | Dose No. | Amount (mL) | Drug Dose (mg) | Cumulative Drug (mg) |
|---|----------------|-------------|----------------|----------------------|
| 0.5 | 1 ^b | 0.05 | 0.025 | 0.025 |
| 0.5 | 2 | 0.10 | 0.05 | 0.075 |
| 0.5 | 3 | 0.20 | 0.10 | 0.175 |
| 0.5 | 4 | 0.40 | 0.20 | 0.375 |
| 0.5 | 5 | 0.80 | 0.40 | 0.775 |
| 5.0 | 6 | 0.15 | 0.75 | 1.525 |
| 5.0 | 7 | 0.30 | 1.50 | 3.025 |
| 5.0 | 8 | 0.60 | 3.00 | 6.025 |

Dosing for the oral protocol is arbitrary and should be adjusted for individual patients based on the clinical sensitivity and the desired drug dose end point.

possible (e.g., if oral absorption is questionable), parenteral desensitization can be instituted. Although the subcutaneous and intramuscular routes have been used, the IV route is quicker and allows better control over the rate and concentration of drug administered, and any untoward reaction can be detected promptly and treated rapidly.^{3,6,9} Table 4-15 outlines an IV β -lactam desensitization protocol. Oral and parenteral desensitization methods have not been compared formally, however. Patients should not be premedicated before desensitization, because this may prevent detection of minor allergic responses that may precede more serious reactions. In addition, desensitization should be performed in a setting where emergency resuscitative equipment and personnel are readily available.¹²⁴ Thus, K.A. should undergo oral desensitization as outlined in Table 4-14 if her skin test is positive or if skin testing cannot be performed.

29. Is K.A. at risk for an allergic reaction during desensitization? If desensitization is successful, is she at risk for a reaction during full-dose penicillin therapy?

Acute β -lactam desensitization, regardless of the route or protocol chosen, is not without risk. Approximately 5% of patients experience mild cutaneous reactions during desensitization, although one study reported reactions in 20% of patients during oral desensitization.^{3,128} If a reaction occurs during the desensitization procedure itself, the reaction may be treated and desensitization continued using lower doses, increased intervals between doses, or both, after the reaction has abated. Severe, fatal reactions during desensitization are rare.³

Uneventful β -lactam desensitization, however, does not guarantee patients will be without reaction during full-dose therapy. Approximately 25% to 30% of patients experience a mild reaction during therapy, whereas 5% experience

Table 4-15 β -Lactam Intravenous Desensitization Protocol

| Stock Drug Concentration (mg/mL) ^a | Dose No. ^b | Amount per 50 mL (mg/mL) ^c | Cumulative Drug (mg) |
|---|-----------------------|---------------------------------------|----------------------|
| 0.005 | 1 | 0.0001 | 0.005 |
| 0.025 | 2 | 0.0005 | 0.030 |
| 0.125 | 3 | 0.0025 | 0.155 |
| 0.625 | 4 | 0.0125 | 0.780 |
| 3.125 | 5 | 0.0625 | 3.905 |
| 15.625 | 6 | 0.3125 | 19.530 |
| 31.25 | 7 | 0.625 | 50.780 |
| 62.50 | 8 | 1.25 | 113.280 |
| 125.00 | 9 | 2.5 | 238.280 |
| 250.00 | 10 ^d | 5.0 | 488.280 |

^aStock drug solutions are prepared using serial dilutions of the desired goal (e.g., 500 mg of β -lactam). Doses one through five represent fivefold dilutions; doses six through ten represent twofold dilutions.

^bInterval between doses is 1 to 30 minutes. If desensitization is interrupted for >2 half-lives of the β -lactam, desensitization should be repeated.

^cMix 1 mL of stock drug solution in 50 mL 5% dextrose/0.225 normal saline or other compatible solution. Infuse each dose over 20–45 minutes. Dilution volume may vary with patient age and weight.

^dIf all 10 doses are administered and tolerated, the remainder of a full therapeutic dose of the β -lactam should be administered.

Adapted from reference 269, with permission.

Dosing for the IV protocol is arbitrary and should be adjusted for individual patients based on the clinical sensitivity and the desired drug dose end point.

more severe reactions, including drug-induced serum sickness, hemolytic anemia, or nephritis.³ Reaction rates are no different in severely ill or pregnant patients compared with stable or nonpregnant patients, although those with cystic fibrosis may be more difficult to desensitize because of their high frequency of allergic reactions.^{3,128,129} Despite the occurrence of reactions, full-dose therapy is possible for most desensitizations, but suppression of the reaction (e.g., by diphenhydramine) may be required.³

30. If K.A. requires penicillin at a later date, will she need to undergo desensitization again? What is chronic desensitization?

The desensitized state, once achieved, will persist for approximately 48 hours after the last full dose of antibiotic; after this time, drug sensitivity will return.³ Thus, if K.A. requires future courses of penicillin, she will need to undergo desensitization once again. In some cases, those requiring long-term antibiotic therapy (e.g., for endocarditis), those who may require β -lactams at a future date (e.g., those with cystic fibrosis), or those who have occupational exposure to β -lactams, maintenance of the desensitized state can be considered. Chronic twice-daily dosing of oral penicillin has safely resulted in “chronic desensitization.” Similar to acute desensitization, once therapy is interrupted, the allergic state returns.^{3,9}

Table 4-16 Oral Trimethoprim-Sulfamethoxazole Desensitization Protocol

| Hour | Trimethoprim Component (Concentration or Tablet) | Volume | Dose of TMP-SMZ |
|------|--|----------|-----------------|
| 0 | 0.0008 mg/mL | 5 mL | 0.004/0.02 mg |
| 1 | 0.008 mg/mL | 5 mL | 0.04/0.2 mg |
| 2 | 0.08 mg/mL | 5 mL | 0.4/2 mg |
| 3 | 0.8 mg/mL | 5 mL | 4/20 mg |
| 4 | 8 mg/mL | 5 mL | 40/200 mg |
| 5 | 160 mg | 1 tablet | 160/800 mg |

Stock solution of trimethoprim-sulfamethoxazole (TMP-SMZ) may be prepared by appropriate dilutions of the commercially available suspension (8 mg trimethoprim/40 mg sulfamethoxazole per mL) with simple syrup or distilled water.

Adapted reference 151, with permission.

This protocol should serve as a guide only. Obtaining informed consent from the patient before initiating desensitization is advisable.

Other Drugs

31. Have patients allergic to drugs besides β -lactams been desensitized successfully?

Although most experience with desensitization is with penicillin and other β -lactams, desensitization also has been accomplished with various other drugs, including rifampin,¹³⁰ isoniazid,¹³⁰ acyclovir,¹³¹ sulfasalazine,^{132–135} aminoglycosides,¹²⁹ vancomycin,^{136,137} and several others.^{138–150} Interestingly, not all of these cases represent IgE-mediated hypersensitivity reactions. Acute desensitization, which has until recently been used to manage only IgE-mediated reactions, appears to be effective in other forms of immunopathology.³ For example, reactions to trimethoprim-sulfamethoxazole commonly occur in patients infected with HIV and may not be IgE mediated. Yet, successful desensitization to trimethoprim-sulfamethoxazole is increasingly common, given its role in treating and preventing *Pneumocystis jiroveci* pneumonia.³

One procedure for trimethoprim-sulfamethoxazole desensitization¹⁵¹ is outlined in Table 4-16, although several other protocols have been used successfully.^{9,152–157} Although mild to moderate reactions can occur (e.g., fever, mild skin rash), patients may complete desensitization successfully by suppressing the reaction with antihistamines, reducing the dose to the highest level previously taken without a reaction until the reaction subsides, or both.^{152,154,155} As with the β -lactams, before desensitization for any medication is undertaken, alternative therapies should be sought and used if possible. Furthermore, desensitization is contraindicated if the reaction is a serious dermatologic response, such as toxic epidermal necrolysis or Stevens-Johnson syndrome. Last, desensitization should be undertaken only in an appropriate setting by experienced personnel, because severe reactions can develop.¹⁵⁸

SUMMARY 5-22

This chapter reviews common strategies for the evaluation and management of drug overdoses and poisonings. Information for the management of specific drug overdoses is best obtained from a poison control center (reached by dialing 1-800-222-1222 anywhere in the United States).

Epidemiologic Data

American Association of Poison Control Centers and Drug Abuse Warning Network

Toxicity secondary to drug and chemical exposure commonly occurs in children; however, the incidence of exposure to specific agents and the severity of outcomes varies based on the population studied (Table 5-1).¹⁻³ The number of reported toxic exposures in the United States in 2005 was approximately 2.42 million, according to the American Association of Poison Control Centers (AAPCC).³ In most cases, little or no toxicity was associated with the exposure. About 22% received treatment at a health care facility, only 5.6% reported moderate or severe symptoms, and 1,261 resulted in fatalities. According to the Drug Abuse Warning Network (DAWN), 1.4 million U.S. emergency room visits involved drug misuse or abuse in the year 2005. Of those cases, 56% involved illicit drug use.⁴

These disparate statistics from two national sources underscore the difficulty in determining the true incidence of poisoning and overdoses.⁵ Nevertheless, epidemiologic data are useful in identifying trends and in instigating public health interventions. For example, from 2001 to 2002, the number of inhalant abuse cases reported by DAWN increased 187%, identifying the need for additional education about inhalant abuse toxicity.⁶ From 2004 to 2005, after inhalation education programs, inhalant abuse decreased by 54%.⁴

Age-Specific Data

Stratifying patients by age can be useful in assessing the likelihood of severe toxicity from an exposure. For example, most unintentional ingestions by children 1 to 6 years of age occur because children are curious, becoming more mobile and beginning to explore their surroundings, and often putting objects

or substances into their mouths. According to AAPCC data, 50.9% of all reported poisonings occur in children younger than 6 years of age.³ Fortunately, exposures usually involve the ingestion of relatively small amounts of a single substance. In one report, only 10.5% of pediatric poisoning cases were treated in a health care facility; the remaining cases were managed at home.³ In actuality, severe toxicities in young children from ingestions are relatively uncommon.

AAPCC epidemiologic data also report medication errors, which in the pediatric population, commonly result from confusing units of measurement (e.g., teaspoons vs. milliliters or tablespoons vs. teaspoons), incorrect formulation or concentration administered, dispensing cup errors, and incorrect formulation or concentration dispensed from the pharmacy.³

In children younger than 6 years of age, the reasons for toxic exposure to medications are less clear.⁷ Adolescent children generally have poor knowledge of the toxicity of medications and can overdose themselves unintentionally.⁸ The potential for suicide attempts or intentional substance abuse, however, should not be ignored in older children or adults. These intentional overdoses commonly involve mixed exposures to illicit drugs, prescribed medications, or ethanol, and are associated with more severe toxicity and death than unintentional toxic exposures.

In geriatric patients, overdoses tend to have a greater potential for severe adverse effects, compared with overdoses in other age groups, because the elderly are more likely to have underlying illnesses, and more often have access to a variety of potentially dangerous medications.¹⁰ More than 40% of patients age 65 or older take five medications per week and 12% use ten or more medications weekly.¹¹ In 2005, 16% of fatalities from toxic ingestions involved patients older than 60 years.³

Information Resources

Computerized Databases

A vast number of substances can be involved in a poisoning or overdose, and reliable data about the contents of products,

Table 5-1 Substances Most Frequently Involved in Poisoning Exposures^a

| All Ages | Children Younger Than 6 Years | Adults Older Than 19 Years | Fatalities |
|--------------------------------------|--------------------------------------|--------------------------------------|-----------------------------------|
| Analgesics | Cosmetics and personal care products | Analgesics | Analgesics |
| Cosmetics and personal care products | Cleaning substances | Sedative/hypnotics/antipsychotics | Sedative/hypnotics/antipsychotics |
| Cleaning substances | Analgesics | Cleaning substances | Antidepressants |
| Sedative/hypnotics/antipsychotics | Foreign bodies | Antidepressants | Stimulants and street drugs |
| Foreign bodies | Topical products | Bites, envenomations | Cardiovascular drugs |
| Cold and cough preparations | Cough and cold preparations | Cardiovascular drugs | Alcohols |
| Topical preparations | Plants | Alcohols | Anticonvulsants |
| Pesticides | Pesticides | Pesticides | Antihistamines |
| Antidepressants | Vitamins | Cosmetics and personal care products | Fumes/gases/vapors |
| Bites, envenomations | Antihistamines | Food products/food poisoning | Muscle relaxants |
| Cardiovascular drugs | Antimicrobials | Hydrocarbons | Hormones and hormone antagonists |
| Antihistamines | GI preparations | Chemicals | Chemicals |
| Alcohols | Arts, crafts, office supplies | Fumes/gases/vapors | Unknown drug |
| Plants | Hormones and hormone antagonists | Anticonvulsants | Cleaning substances |
| Antimicrobials | Electrolytes and minerals | Antihistamines | GI preparations |

^aDespite a high frequency of involvement, these substances are not necessarily the most toxic, but may reflect ready access. Adapted from reference 3. These poisoning exposures are listed in order of frequency encountered.

toxicities of substances, and treatment approaches need to be readily accessible. POISINDEX, a computerized database,¹² provides information on thousands of drugs by brand name, generic name, and street name, as well as foreign drugs, chemicals, pesticides, household products, personal care items, cleaning products, poisonous insects, poisonous snakes, and poisonous plants. Annual subscriptions to POISINDEX, updated quarterly, are expensive and are generally available only in large medical centers.¹³

Printed Publications

Textbooks and manuals also provide useful clinical information about the presentation, assessment, and treatment of toxicities. *Goldfrank's Toxicologic Emergencies*¹⁴ and the pocket-size *Poisoning & Drug Overdose*¹⁵ are valuable, inexpensive alternatives to computerized database programs. Books, however, are less useful than computerized databases because information must be condensed and cannot be updated as frequently. Some drug package inserts also refer to treatment of acute toxicities; however, the information can be inadequate or inappropriate.¹⁶

Poison Control Centers

Poison control centers provide the most cost-effective and accurate information to health care providers and to the general public.^{17,18} Poison centers are usually staffed by trained poison information specialists who have a pharmacy, nursing, or medical background. Physician backup is provided 24 hours a day by board-certified medical toxicologists. The nonphysician clinical toxicologists, pharmacists, and nurses who staff poison control centers are certified as specialists in poison information by the AAPCC or as clinical toxicologists by the American Board of Applied Toxicology.¹⁹

The poison information specialist must accurately and efficiently assess event-specific toxicity by telephone, without the benefit of direct observation of the patient; and communicate this assessment along with treatment information quickly, accurately, and professionally in a reassuring manner. Subsequent to the telephone consultation, the poison control center staff should initiate follow-up calls to determine the effectiveness of the recommended treatment, the need for additional evaluation or treatment, and the outcome.^{20,21}

Effective Communication

Effective communication is essential to the assessment of potential poisonings. In most situations, the person seeking guidance on the management of a potentially toxic exposure is the parent of a small child who may have ingested a substance. The caller is usually anxious about the child and may feel guilty about the exposure. To calm the caller, the health care provider should quickly reassure the parent that telephoning for assistance was appropriate and that the best assistance possible will be provided.²⁰ If English is not the first language of the caller, or if there are other communication barriers, solutions must be found to enhance outcomes. Most poison centers subscribe to translation services or have bilingual staff to communicate with non-English-speaking callers. Poison centers also have TTY equipment to serve the hearing and speech impaired populations.

Once calm, effective communication is established, the health care provider should first determine whether the patient is conscious and breathing and has a pulse. If life-threatening

symptoms have occurred, the caller should call for emergency services. If the health care provider does not have the knowledge or resources to provide poison information, he or she should refer the caller to the closest poison control center. Information on the location and phone number of the nearest poison control center can be found on the Internet at www.aapcc.org or by calling 1-800-222-1222. The call is automatically transferred to the poison center that serves the caller's area in the United States.

GENERAL MANAGEMENT

Supportive Care and "ABCs"

Management of poisoned or overdosed patients is primarily based on symptomatic and supportive care. Specific antidotes exist only for a small percentage of the thousands of potential drugs and chemicals that could cause a poisoning. The first aspect of patient management should always be basic support of airway, breathing, and circulation (the "ABCs"). The assessment and treatment of the potentially poisoned patient can be separated into seven primary functions: (a) gathering history of exposure, (b) evaluating clinical presentation (i.e., toxidromes), (c) evaluating clinical laboratory patient data, (d) removing the toxic source (e.g., gastrointestinal [GI] decontamination), (e) considering antidotes and specific treatment, (f) enhancing systemic clearance, and (g) monitoring outcome.^{22–24}

Gathering History of Exposure

Comprehensive historical information about the toxic exposure should be gathered from as many different sources as possible (e.g., patient, family, friends, prehospital health care providers). This information should be compared for consistency and evaluated relative to clinical findings and laboratory results. The patient's history of the exposure is often inaccurate and should be confirmed with objective findings.^{22,23,25} For example, a patient who presents at the emergency department (ED) with a supposed hydrocodone and carisoprodol overdose is expected to be lethargic or comatose. If the patient arrives wide awake with tachycardia and agitation, the caregiver should suspect exposure to other substances. This would be the case whenever the patient's symptoms are not consistent with the history presented.

Specific information should be sought concerning the patient's state of consciousness, symptoms, probable intoxicant(s), maximum amount and dosage form(s) of substance ingested, as well as when the exposure occurred. Medications, allergies, and prior medical problems also should be ascertained to facilitate development of treatment plans (e.g., a history of renal failure may indicate the need for hemodialysis to compensate for decreased renal drug clearance).^{22,23}

Evaluating Clinical Presentation and Toxidromes

A thorough physical examination is needed to characterize the signs and symptoms of overdose, and should be conducted serially to determine the evolution or resolution of the patient's intoxication. An evaluation of the presenting signs and symptoms can provide clues on the drug class causing the toxicity, confirm the historical data surrounding the toxic exposure, and suggest initial treatment.^{26,27} The patient may be asymptomatic on presentation, even though a potentially severe exposure has

occurred, if absorption of the drug or toxic substance is incomplete or if the substance has not yet metabolized to a toxic substance.²⁸

Characteristic toxidromes (i.e., a constellation of signs and symptoms consistent with a syndrome) can be associated with some specific classes of drugs.^{23,26,27} The most common toxidromes are those associated with anticholinergic activity, increased sympathetic activity, and central nervous system (CNS) stimulation or depression. The *anticholinergic* drugs can increase heart rate, increase body temperature, decrease GI motility, dilate pupils, and produce drowsiness or delirium. *Sympathomimetic* drugs can increase CNS activity, heart rate, body temperature, and blood pressure (BP). *Opioids, sedatives, hypnotics, and antidepressants* can depress the CNS, but the specific class of CNS depressant often cannot be easily identified by a specific constellation of symptoms. Classic findings may not be present for all drugs within a therapeutic class. For example, opioids generally induce miosis, but meperidine can produce mydriasis. Furthermore, the association of symptoms with a particular class of toxic substances is difficult when more than one substance has been ingested. Practitioners should not focus only on the specific clinical findings associated with a toxidrome; rather, they should consider all subjective and objective data gathered from the history of exposure, the patient's medical history, physical examination, and laboratory findings.

Interpretation of Laboratory Data

DRUG SCREENS

A urine drug screen can be useful in identifying the presence of drugs and their metabolites in selected patients. Although a urine drug screen is not indicated in all cases of drug overdose, it can be useful in a patient with coma of unknown etiology, when the presented history is inconsistent with clinical findings, or when more than one drug might have been ingested.^{24,29,30}

PHARMACOKINETIC CONSIDERATIONS

The absorption, distribution, metabolism, and elimination of drugs in the overdosed patient can be quite different than when the drug is taken in usual therapeutic doses.³¹ The pharmacodynamic and pharmacokinetic behavior of drugs can be substantially altered by large drug overdoses, especially with drugs that exhibit dose-dependent pharmacokinetics. The rate of drug absorption is generally slowed by large overdoses, and the time to reach peak serum drug concentrations can be delayed.³² For example, peak serum concentrations of phenytoin can be delayed for 2 to 7 days after an orally ingested overdose.^{33,34} The volume of distribution of an overdosed drug can be increased, and when usual metabolic pathways become saturated, secondary clearance pathways can be important. For example, large overdoses of acetaminophen saturate glutathione mechanisms of metabolism, resulting in hepatotoxicity.³⁵

When the pharmacokinetic parameters of an overdosed drug are altered, serial plasma concentration measurements can better define the absorption, distribution, and clearance phases of the ingested substance. Pharmacokinetic parameters that have been derived from therapeutic doses should not be used to predict whether absorption is complete or to predict the expected duration of intoxication caused by large overdoses.^{31,36–38}

Decontamination

After the airway and the cardiopulmonary system are supported, efforts should be directed toward removing the toxic substance from the patient (i.e., decontamination).^{22,39} Decontamination presumes that both the dose and the duration of toxin exposure are important in determining the extent of toxicity and that prevention of continued exposure will decrease toxicity.²⁸ This intuitive concept is clearly relevant to ocular, dermal, and respiratory exposures, when local tissue damage is the primary problem. Respiratory decontamination involves removing the patient from the toxic environment and providing fresh air or oxygen to the patient. Decontamination of skin and eyes involves flushing the affected area with large volumes of water or saline to physically remove the toxic substance from the surface.^{22,23}

GASTROINTESTINAL DECONTAMINATION

Because most poisonings and overdoses result from oral ingestions, measures to decrease or prevent continued GI absorption have commonly been used to limit the extent of exposure.^{22,23,28,40} GI decontamination should be considered if the ingestion is large enough to produce potentially significant toxicity, or if the potential severity of the ingestion is unknown and the time since ingestion is <1 hour. The following methods have been used: (a) evacuate gastric contents by emesis or gastric lavage, (b) administer activated charcoal as an adsorbent to bind the toxic substance remaining in the GI tract, (c) use cathartics or whole bowel irrigation (WBI) to increase the rectal elimination of unabsorbed drug, or (d) combine any of these methods.

The efficacy of GI decontamination varies, depending on when the process is initiated relative to the time of ingestion, dose ingested, and other factors. Furthermore, ipecac-induced emesis, gastric lavage, cathartics, and activated charcoal are not directly associated with improved patient outcomes.^{41–46}

The most appropriate method for GI tract decontamination remains unclear because sound comparative data for different methods of GI decontamination are unavailable. Clinical research in healthy subjects, by necessity, must use nontoxic doses of drugs. Studies using nontoxic doses are not applicable to the overdose situation because alterations in GI absorption can occur with large doses. In addition, low-dose studies generally rely on pharmacokinetic end-points such as peak plasma concentrations, area under the plasma concentration-time curve, or quantity of drug recovered from the urine.^{41,42,44–46} In contrast, clinical studies of GI decontamination methods in patients who have ingested toxic doses of a substance use clinical outcomes or a directional change in serum drug concentrations.^{41,42,45,46} These latter trials are not standardized with respect to the dose ingested or to the time interval between drug ingestion and GI decontamination.

Ipecac-Induced Emesis and Gastric Lavage

Ipecac-induced emesis and gastric lavage primarily remove substances from the stomach; and their efficacy is affected significantly by the time the ingested substance remains in the stomach. Gastric lavage or ipecac-induced emesis is most effective when implemented within 1 hour of the ingestion (i.e., before the substance moves past the stomach into the intestine).^{41,42}

The commonly used adult gastric lavage tube (36F) has an internal diameter too small to allow recovery of large tablet or capsule fragments and an even smaller diameter lavage tube is used for children.⁴² Gastric lavage may be useful only if large amounts of a liquid substance were ingested and the patient arrived within 1 hour of the ingestion.⁴² Unfortunately, most patients arrive in the ED more than an hour after ingestion, when absorption of the toxic substance from the stomach has most likely already occurred. As a result, the efficacy of these procedures in overdose situations is minimal. Studies have not confirmed that use of gastric lavage or ipecac-induced emesis improves the outcome of the patient.^{40–42}

Established Guidelines

The American College of Emergency Physicians has published guidelines for the initial evaluation, diagnosis, stabilization, and management of patients who present with acute toxic ingestions,²² and the American Academy of Clinical Toxicology (AACT), along with the European Association of Poisons Centres and Clinical Toxicologists (EAPCCT) and other organizations, have published position papers on GI decontamination.^{41–46}

The AACT and EAPCCT clinical guidelines state that ipecac syrup and gastric lavage should not be routinely used.^{41,42} In addition, the American Academy of Pediatrics no longer supports the use of ipecac syrup routinely as a home treatment of poisoning and advocates that ipecac syrup already in the home should be discarded safely.⁴⁷ As a result, the use of ipecac to induce vomiting in both the home and the health care setting has been curtailed significantly.

Activated Charcoal

In 1963, a review article concluded that activated charcoal was the most valuable agent available for the treatment of poisoning.⁴⁸ This conclusion was based only on studies in fasting patients who had nontoxic exposures. Nevertheless, data from those studies were extrapolated to poisoned patients. Since then, activated charcoal has become the preferred method of GI decontamination for the treatment of toxic ingestions.^{22,27,40,43,49–51} If administered within 1 hour of the ingestion, the adsorption of substances to charcoal prevents absorption. It is assumed that adsorption of the toxin prevents toxicity and improves patient outcome, especially if the risk to the patient is low.⁴³

Vomiting with aspiration of activated charcoal occurs in about 5% of patients who receive activated charcoal.^{43,51–53} The resulting pulmonary problems can be due to aspiration of acidic stomach contents and/or the charcoal. Decreased oxygenation can occur immediately, or pulmonary effects can occur later.^{54–56} Adult respiratory distress syndrome has resulted after the unintentional instillation of charcoal into the lung.⁵¹ Aspiration of charcoal can result in chronic lung disease or fatalities, whereas the toxic exposure, for which the charcoal was administered, is often not lethal or even serious.^{53,57}

Cathartics

Sorbitol (a cathartic) was often administered with the activated charcoal to enhance passage of the charcoal-substance complex through the GI tract. However, decreased transit time through the bowel has not been proven to decrease absorption, probably because drug absorption does not take place in the

large bowel.⁴⁴ Sorbitol is also associated with an increased incidence of vomiting and aspiration.¹⁹ Hyponatremia can also develop subsequent to the administration of repeat doses of activated charcoal with sorbitol.^{58,59} Currently, most EDs use aqueous activated charcoal mixtures rather than charcoal-sorbitol combinations. Cathartics are not effective as GI decontaminants, and their use is no longer advised.^{22,43,44}

Whole Bowel Irrigation

Whole Bowel Irrigation (WBI) with a polyethylene glycol-balanced electrolyte solution (e.g., Colyte, GoLYTELY) can successfully remove substances from the entire GI tract over several hours. WBI is effective with ingestions of sustained-release dosage forms, as well as substances that form bezoars (concretions of tablets or capsules), such as ferrous sulfate or phenytoin.^{23,45,60} WBI is also indicated when the toxic agent is not adsorbed by activated charcoal (e.g., body-packer packets, lithium, iron, potassium).^{22,23,45,60} This method of GI decontamination takes much longer to complete and is associated with poor patient adherence because large volumes of fluid (2 L/hour for adults until the effluent is clear) need to be ingested for this to be effective.⁶⁰ A nasogastric (NG) tube, however, can be inserted, and the WBI fluid mixture can be administered via this NG tube.⁴⁵

Antidotes and Specific Treatments

An antidote, a drug that neutralizes the toxicity of another substance, is useful if it does not produce even greater hazards for the patient. Some antidotes can displace a drug from receptor sites (e.g., naloxone for opioids, flumazenil for benzodiazepines),^{61,62} and some can inhibit the formation of toxic metabolites (e.g., *N*-acetylcysteine [NAC] for acetaminophen, fomepizole for methanol). Some treatments are highly effective for the management of individual drug overdoses, but they do not meet the definition of an antidote. For example, sodium bicarbonate is used to treat the cardiotoxicity arising from tricyclic antidepressant (TCA) overdoses, and benzodiazepines are used to treat CNS toxicity associated with cocaine and amphetamine overdoses.^{23,63–65}

Enhancing Systemic Clearance

Hemodialysis and manipulation of urine pH can enhance the clearance of substances. Hemodialysis can successfully treat some specific intoxications (e.g., methanol, ethylene glycol, aspirin, lithium). Hemodialysis can also be used in patients with severe acid-base or renal dysfunction.⁴⁰ Alkaline diuresis can enhance the elimination of drugs such as aspirin and phenobarbital.⁶⁶

Monitoring Outcome

Selecting the appropriate parameters and length of time to monitor a patient who has been exposed to a toxic agent requires knowledge of toxic effects and the time course of the intoxication.²⁸ Most patients who are at risk for moderate or severe toxicity should be monitored in an intensive care unit (ICU) with careful assessments of cardiac, pulmonary, and CNS function.⁶⁷

ASSESSMENT OF SALICYLATE INGESTION

Gathering a History

1. M.O., the mother of a 4-year-old child, states that her daughter, D.O., has ingested some aspirin tablets. What additional information should be obtained from or given to M.O. at this time?

Obtaining an initial assessment of the patient's status is essential. The caller's telephone number should be obtained in the event that the call is disconnected, initial recommendations need to be modified, or subsequent follow-up is needed. The health care provider should ask for patient-specific information with questions that are nonthreatening and nonjudgmental. The caller should be reassured that calling for help was the right thing to do.

Evaluating Clinical Presentation

2. On further questioning, M.O. states that D.O. is crying and complaining of a stomachache. Otherwise, the child appears to be normal. The daughter was found sitting on the bathroom floor with an aspirin bottle in her hand and some partially chewed tablets on the floor next to her. The child had the same look on her face that she does when she eats things that she does not like. M.O. reports that she can see white tablet material gummed on the child's teeth. The mother was gone no more than 5 minutes and had asked her 5- and 6-year-old sons to watch their sister. What additional information is needed to correctly assess the potential for toxicity?

To determine the potential toxicity for an unintentional ingestion, it is important to assess the presence of symptoms and to identify the substance ingested. Inquiries should begin with open-ended questions to determine the facts that the caller is certain of versus what may have been assumed. The answers usually point to more specific information that is needed to accurately assess the exposure.²⁰

D.O.'s symptoms presently are not life threatening. Her behavior is consistent with being scared in response to the mother's anxiety. Once it has been established that the child does not need immediate life-saving treatment, the caller is generally more willing and able to answer additional questions.

M.O. already has provided information about the child's symptoms; however, more information is needed to determine the identity of the ingested substance, the time of ingestion, the brand of aspirin (to ensure that the product is not an aspirin-combination or even an aspirin-free formulation), the dosage form, the number of dosage units in a full container, and the number of remaining dosage units in the container. The parent should be careful to look for tablets under beds, rugs, or other locations out of sight (e.g., wastepaper baskets, toilets, pet food dishes, pockets). The dosage forms in the container should be identical in appearance, and the contents should be what are stated on the label. Information concerning the child's weight and health status, as well as whether the child is taking other medications, is also important. The child's weight is useful in determining the maximum mg/kg dose of aspirin that was ingested.

When more than one child is present during an ingestion incident, the caller should be questioned as to whether other children also could have participated in the ingestion. In this

situation, the children could have shared equally in the missing dosage units of drug, all of the drug could have been fed to one child, or all of the drug could have been ingested by the oldest or most aggressive child. When it is unclear how many missing dosage units of a substance might have been ingested among a group of children, each child should be evaluated and managed as if he or she may have ingested the total missing quantity.

Triage of Call

3. The caller, M.O., has now determined that a total of five tablets each containing 325 mg/tablet of aspirin are missing from the bottle. Because M.O. recalls having taken two aspirin tablets from this bottle, it is not likely that her daughter took more than three tablets. M.O. states that D.O. weighs 36 lb. What treatment is needed for this child?

The maximum dose of aspirin ingested by this child is likely to be much less than the minimum dose required to produce significant symptoms based on an assumption that this 4-year-old girl is of average weight for her age (i.e., 36 lb or ~16 kg). A dose of 150 mg/kg of aspirin is the smallest dose at which treatment or assessment at a health care facility is necessary.^{68,69} D.O. is likely to have ingested a maximum of 975 mg of aspirin (i.e., three 325-mg tablets), which is about 60 mg/kg (975 mg divided by 16 kg). If this child is healthy, takes no medications, and is not allergic to aspirin, the child does not need any treatment. With this history of ingestion, the only adverse effect that might occur is some mild nausea. Providing information to the mother that her child had not ingested a toxic amount will be reassuring.

For many years, aspirin was the most common cause of unintentional poisoning and poisoning deaths among children.^{69–71} However, safety closure packaging and reduction of the total aspirin content in a full bottle of children's aspirin to approximately 3 g has steadily reduced the frequency of pediatric aspirin poisoning and deaths.^{70–72} Although acute aspirin poisoning remains a problem, the largest percentage of life-threatening intoxications now results from therapeutic overdose.⁶⁸ Therapeutic overdoses occur when a dose is given too frequently, when both parents unknowingly dose the child with the drug, or when too large a dose is given. Therapeutic overdoses are especially a problem if the situation continues for a period of time and the drug is able to accumulate.⁶⁸

Outcome for M.O.

Follow-up telephone consultations on toxic ingestions is important to identify children who unexpectedly develop symptoms that might need to be treated. A telephone call to M.O. 6 to 24 hours after her initial call would be appropriate to follow up on the child. On a call back to M.O., the parent stated that she gave D.O. lunch at the appropriate time. D.O. then watched cartoons, took her usual nap, and remained asymptomatic.

Acute and Chronic Salicylism

Signs and Symptoms

4. V.K., a 65-year-old, 55-kg woman with a history of chronic headaches has taken 10 to 12 aspirin tablets a day for several months. On the evening of admission, she became lethargic,

disoriented, and combative. Additional history revealed that she ingested up to 100 aspirin tablets on the morning of admission (about 10 hours earlier) in a suicide attempt. She complained of ringing in her ears, nausea, and three episodes of vomiting. Vital signs were BP 140/90 mmHg, pulse 110 beats/minute, respirations 36 breaths/minute, and temperature 102.5°F. V.K.'s laboratory data obtained on admission were as follows: serum sodium (Na), 148 mEq/L (normal, 135–153); potassium (K), 2.8 mEq/L (normal, 3.5–5.5); chloride (Cl), 105 mEq/L (normal, 95–105); bicarbonate, 10 mEq/L (normal, 24–31); glucose, 60 mg/dL (normal, 70–110); blood urea nitrogen (BUN), 35 mg/dL (normal, 5–25); and creatinine, 2.2 mg/dL (normal, 0.5–1.4). Arterial blood gas (ABG) values (room air) were as follows: pH, 7.25; PCO₂, 20 mmHg; and PO₂, 95 mmHg. A serum salicylate concentration measured approximately 12 hours after the acute ingestion was 88 mg/dL. Her hemoglobin was 9.6 g/dL (normal, 12–16 g/dL for females) with a hematocrit of 28.9% (normal, 37%–47% for females) and a prothrombin time (PT) of 16.4 seconds (normal, 10–13 seconds). Is her ingestion high risk?

The symptoms and severity of salicylate intoxication depend on the dose consumed; the patient's age; and whether the ingestion was acute, chronic, or a combination of the two.^{71,73,74} This case illustrates an acute ingestion in someone who has also chronically ingested aspirin. Acute ingestion of 150 to 300 mg/kg of aspirin is likely to produce mild to moderate intoxication, >300 mg/kg indicates severe poisoning, and >500 mg/kg is potentially lethal.^{68,69} V.K., who ingested approximately 600 mg/kg, has taken a potentially lethal dose. Chronic salicylate intoxication is usually associated with ingestion of >100 mg/kg/day for more than 2 days.^{68,69} V.K. has been taking 70 mg/kg/day for her headaches in addition to her acute ingestion. V.K. demonstrates many of the findings typical of severe acute salicylism (see next two questions and answers). Her outcome does not look good because she is elderly and has taken a potentially lethal amount of aspirin.

Pathophysiology of Salicylate Intoxication

5. Describe the pathophysiology and clinical features of acute and chronic salicylism.

Toxicity from salicylate exposure results in direct irritation of the GI tract, direct stimulation of the CNS respiratory center, stimulation of the metabolic rate, lipid and carbohydrate metabolism disturbances, and interference with hemostasis.^{68,69,71,73,74} Toxic doses of salicylate directly stimulate the medullary respiratory center leading to nausea, vomiting, tinnitus, delirium, tachypnea, seizures, and coma, and influence several key metabolic pathways.^{68,71–75} Direct stimulation of the respiratory drive increases the rate and depth of ventilation, which can result in primary respiratory alkalosis. The respiratory alkalosis causes increased renal excretion of bicarbonate, resulting in decreased buffering capacity. The patient usually presents with a partially compensated respiratory alkalosis.^{68,72,73,75} Hypokalemia can result from increased GI and renal losses of potassium, as well as from systemic alkalosis.^{68,73,74}

Although marked metabolic and neurologic abnormalities are most commonly observed in young children with advanced salicylate intoxication, adolescents or adults acutely poisoned with a large dose can develop these symptoms as well.^{68,72,73} Acute salicylism in a young child often takes a more severe

course than that typically seen in adults. After acute ingestion, children quickly pass through the phase of pure respiratory alkalosis. Renal bicarbonate loss secondary to respiratory alkalosis reduces the buffering capacity more profoundly in a child and facilitates the development of metabolic acidosis.^{68,71,73,75}

Salicylates have toxic effects on several biochemical pathways that contribute to metabolic acidosis and other symptoms.^{68,73–75} Mitochondrial oxidative phosphorylation is uncoupled and results in an impaired ability to generate high-energy phosphates, increased oxygen use and carbon dioxide production, increased heat production and hyperpyrexia, increased tissue glycolysis, and increased peripheral demand for glucose. Salicylates also inhibit key dehydrogenase enzymes within the Krebs cycle, resulting in increased levels of pyruvate and lactate. The increased demand for peripheral glucose causes increased glycogenolysis, gluconeogenesis, lipolysis, and free fatty acid metabolism. The latter results in enhanced formation of ketoacids and ketoacidosis.^{71,75}

The patient may become severely volume depleted through several mechanisms.^{68,73–75} Hyperthermia and hyperventilation produce increased insensible water loss, vomiting may promote GI fluid losses, and the solute load caused by altered glucose metabolism results in an osmotic diuresis. Depending on the patient's acid–base balance and net fluid and electrolyte intake and output, serum sodium and potassium concentrations may be normal, elevated, or decreased. Hypernatremia and hypokalemia are most common.^{71,73}

Blood glucose concentration is usually normal or slightly elevated, although hypoglycemia may accompany chronic salicylism (e.g., as illustrated by V.K.) or occur late in acute intoxication. CNS glucose levels can be markedly reduced in the presence of normal blood glucose concentrations because increased CNS glucose utilization to generate high-energy phosphate exceeds the rate at which glucose can be supplied.^{68,71,73,75}

Other manifestations of severe acute salicylism include a variety of neurologic signs and symptoms: disorientation, irritability, hallucinations, lethargy, stupor, coma, and seizures.^{67,71} Hyperthermia may be marked and can result in the inappropriate administration of aspirin as an antipyretic. Coagulopathy can occur because of impaired platelet function, hypoprothrombinemia, reduced factor VII production, and increased capillary fragility, especially when taken chronically.^{73–75} Pulmonary edema and acute renal failure also can occur, but the former occurs more commonly after chronic intoxication.^{73,75,76}

Chronic salicylism symptoms are similar to acute intoxications. However, patients with chronic exposures may have less GI symptoms but generally appear more ill and have more CNS symptoms.^{69,77} In both adults and children, the principal signs of chronic salicylism are a partially compensated metabolic acidosis, increased anion gap, ketosis, dehydration, electrolyte loss, hyperventilation, tremors, agitation, confusion, stupor, memory deficits, renal failure, and seizures.^{71,73,74,78} The severity of CNS manifestations is related to the cerebrospinal fluid (CSF) salicylate concentration.^{72,73} This may increase in the presence of systemic acidosis because a greater fraction of salicylate is unionized and can cross the blood–brain barrier. Therefore, metabolic acidosis is especially dangerous in a salicylate-intoxicated patient.^{71,73}

Unless the history of salicylate intake is specifically sought, the problem may not be immediately apparent, especially in

the elderly in whom such findings are likely to be attributed to other causes (e.g., encephalitis, meningitis, diabetic ketoacidosis, myocardial infarction).^{24,73,77} Delay in diagnosis has been associated with increased mortality.^{24,68,73,77} Unfortunately, plasma salicylate concentrations do not correlate well with the degree of poisoning in chronically intoxicated patients, and it is more important to treat the patient's clinical status than his or her salicylate concentration.⁶⁸ Death in patients with salicylism, whether acute or chronic, results from CNS and/or cardiac dysfunction, or pulmonary edema.^{71,73,77}

Assessment of Toxicity

6. What signs, symptoms, and laboratory values in V.K. are consistent with salicylate intoxication?

V.K. demonstrates many of the findings typical of severe acute salicylism. Hyperventilation has resulted from the direct respiratory stimulant effects of salicylate and as compensation for her metabolic acidosis (PCO₂, 20 mmHg; pH, 7.25; serum bicarbonate, 10 mEq/L; respiratory rate, 36 breaths/minute). Hypokalemia (2.8 mEq/L) in the presence of metabolic acidosis represents severe potassium depletion because of increased renal and possibly GI losses. Hyperpyrexia caused by salicylate is present in V.K., although an infectious cause also must be considered. Her neurologic symptoms of lethargy, disorientation, and combativeness, as well as tinnitus, nausea, and vomiting, are commonly seen in severe salicylate intoxication. In addition, being elderly and taking a lethal amount of aspirin bodes ill for this patient's outcome.

Laboratory Evaluation

7. What objective evaluations should be assessed in a patient with presumed salicylate intoxication?

V.K.'s workup illustrates a thorough initial patient evaluation. Laboratory evaluation should include ABG values, serum electrolytes, BUN, serum creatinine, blood glucose, and a complete blood count (CBC).^{71,73,74} Urine should be tested for specific gravity and pH.⁷¹ In symptomatic patients, a prothrombin (PT), international normalized ratio (INR), and partial thromboplastin times (PTT) are useful to assess the presence of salicylate-induced coagulopathy. Vitals signs should be monitored for an increased respiratory rate and hyperpyrexia.^{72,73} Physical examination should include an evaluation of chest x-ray, cardiopulmonary and neurologic function, and measurement of urine output.⁷³

A salicylate blood concentration should be obtained 6 hours after an acute ingestion at a known time, immediately and 6 hours after an acute ingestion of an unknown time, and immediately and every 2 to 6 hours in symptomatic patients.^{24,65,71,73,79} Repeat a serum salicylate measurement every 4 to 6 hours to verify that the original concentration represented a peak level and that the salicylate level is decreasing rather than increasing.^{24,68,71,74,79} Obtaining the units of measurement on salicylate serum concentrations is essential because different laboratories report concentrations in different units (e.g., mg/dL, mcg/mL, mmol/L). An incorrect interpretation of the salicylate unit of measurement can result in overestimates or underestimates of the severity.²⁴

Historically, the Done-nomogram was used to determine the degree of toxicity from a known single acute salicylate in-

gestion by plotting the serum salicylate concentration by time since the ingestion.⁸⁰ However, clinical symptoms and laboratory findings are more useful in identifying the degree of acute intoxication, assessing patient prognosis, and guiding therapy.⁷⁹ In case of chronic ingestions, the nomogram is not useful, and other parameters such as acid-base and electrolyte balance should be used to determine severity of the case.^{68,71}

The Done-nomogram is also not useful in certain situations such as ingestion of enteric-coated or sustained-release salicylate products, when the time of ingestion is unknown, or when the patient is acidemic or has renal failure.^{71,73,74,79–81} The nomogram is probably not useful when salicylate serum concentrations are measured more than 12 hours after ingestion. Serum concentrations obtained less than 6 hours after ingestion in acute ingestion situations are also difficult to interpret because the drug level has not yet peaked and can result in an underestimation of the eventual degree of intoxication.^{68,71,78,81} Salicylate concentrations can continue to rise over approximately 24 hours if a large amount has been taken or if enteric-coated tablets have been ingested. Enteric-coated tablets can clump together forming a bezoar that slowly releases drug into the gut.^{73,79} The Done-nomogram is no longer used because of these difficulties in interpreting salicylate concentrations.²⁴

Management

8. What would be a reasonable management plan for V.K.?

Management of salicylate intoxication depends on the degree of acid-base and electrolyte disturbances.^{68,71,73} Activated charcoal is not indicated for V.K. because the ingestion occurred about 10 hours ago and she has a somewhat altered mental status.⁴³ The risk of aspiration is greater than the value of possibly adsorbing any remaining aspirin from the GI tract. In addition, V.K. already has symptoms of salicylate poisoning, indicating that the aspirin has already been absorbed. V.K.'s hypokalemia, acidosis, and hypoglycemia must be corrected, and is probably best accomplished through the administration of intravenous (IV) hypotonic saline-dextrose solutions combined with potassium supplementation. This solution is administered at a rate that replaces the patient's deficits and keeps pace with continued losses.^{68,71,73–75} Care should be taken to avoid overzealous fluid therapy, which can predispose the patient to cerebral or pulmonary edema.^{73,75} Administration of an IV dextrose bolus is also indicated because V.K. is also hypoglycemic (60 mg/dL).^{71,73,75}

SODIUM BICARBONATE

It is important to correct V.K.'s acidosis because acidosis will increase CSF salicylate concentrations.^{72,73} Correction of acidosis can be accomplished by adding sodium bicarbonate to her IV fluids.^{68,71–74} V.K.'s serum sodium and potassium concentrations should be monitored closely.⁸⁰ It is essential to provide adequate ventilation to prevent respiratory alkalosis. With a respiratory rate of 36 breaths/minute, placing the patient on a ventilator to assist with breathing might be considered. However, forced mechanical ventilation can interfere with the patient's need to compensate to maintain the serum pH. Patients on ventilators can become severely acidotic, which can result in death because of an inability to compensate adequately.^{71,82}

SEIZURES

Seizures are not evident in V.K. but can be encountered in cases of severe salicylate poisoning. Seizures generally carry a poor prognosis and are indicative of severe salicylate intoxication that requires hemodialysis.⁷¹ Other treatable causes of seizures (e.g., marked alkalosis, hypoglycemia, hyponatremia) can be present in individuals such as V.K. and should be ruled out. If seizures occur, benzodiazepines are the drugs of choice for treatment.⁷¹

COAGULOPATHY AND HYPERTHERMIA

Coagulopathy generally responds to vitamin K₁, which should be given if the PT or INR is prolonged.⁷¹ GI bleeding or other hemorrhage can occur, but not commonly.^{71,73,74} Mild hyperthermia usually does not require therapy, but cooling fans and mist may be required for extremely elevated temperatures.^{71,75}

PULMONARY EDEMA

Noncardiogenic pulmonary edema commonly occurs in salicylate intoxications, especially when the overdose is attributable to chronic ingestions.^{71,73,76} Pulmonary edema is associated with a high incidence of neurologic symptoms in patients and can occur even without fluid overload.^{73,76} Increased alveolar capillary membrane permeability, prostaglandin effects, and a metabolic interaction with platelets releasing membrane permeability substances are the primary mechanisms for the cause of pulmonary edema associated with salicylate overdose.⁷⁶ Treatment is aimed at reducing salicylate levels via alkalization or hemodialysis.⁷⁶

ALKALINE DIURESIS

9. What measures will enhance salicylate elimination? Which of these may be indicated in V.K.?

Forced alkaline diuresis and hemodialysis can enhance the excretion of salicylate in overdose situations.⁶⁸ Hemodialysis is preferred because it can also correct fluid and electrolyte imbalances.^{73,76,78} Sodium bicarbonate is recommended for alkaline diuresis to reduce the arterial pH with the goal of minimizing salicylate transport into the CNS.^{72,73,75}

Although large doses of sodium bicarbonate together with forced fluids can enhance the renal elimination of the weak acid and shorten its half-life, this treatment does not favorably influence the morbidity or mortality of patients with salicylism. Alkaline diuresis can also place the patient at risk for sodium and fluid retention, as well as pulmonary edema, if too much fluid is given too quickly.^{71,73,74,76} Furthermore, whether the urine can be adequately alkalinized (pH > 7) in severely intoxicated pediatric patients has been questioned because of the large acid load that is excreted.^{68,71,72} Nevertheless, urine alkalization with sodium bicarbonate should be attempted in severely salicylate-intoxicated adult patients such as V.K.

Potassium replacement in patients receiving alkaline diuresis is essential.^{71,73,75} These patients may require large amounts of potassium supplementation due to renal wasting of potassium. The risk for pulmonary edema can be minimized if this is done without forcing fluids.^{71,73,74,75}

Hemodialysis should be considered in patients who show progression of severe salicylate intoxication and seizure activity, renal failure, or plasma salicylate concentrations in the

potentially fatal range.^{68,73,74,76,78} Patients with a chronic exposure, with acidosis, or CNS symptoms, and who are elderly or ill, are high-risk patients and should be considered for early dialysis.^{73,78} Because V.K. has many of the risk factors, she is a candidate for emergent hemodialysis.

Clinical Outcome of Patient V.K.

A repeat salicylate level 6 hours later (18 hours after ingestion) had increased to 93 mg/dL. Her chemistry panel revealed serum sodium (Na), 144 mEq/L (normal, 135–153); potassium (K), 2.1 mEq/L (normal, 3.5–5.5); chloride (Cl), 100 mEq/L (normal, 95–105); bicarbonate, 9 mEq/L (normal, 24–31); glucose, 78 mg/dL (normal, 70–110); creatinine, 4.8 mg/dL (normal, 0.5–1.4); and BUN, 42 mg/dL (normal, 5–25). Her hemoglobin was now 8.5 g/dL (normal, 12–16 for females) with a hematocrit of 23% (normal, 37%–47% for females) and a PT of 16.6 seconds (normal, 10–13 seconds). V.K.'s pH on blood gases remained in the 7.2 to 7.3 range. Urinary alkalization was attempted with a high-dose IV sodium bicarbonate infusion in an attempt to reach a urine pH of 7.5. However, her urine pH never increased above pH 5.6. V.K. became fluid overloaded and developed dyspnea. She was placed on a ventilator with worsening of her symptoms. A chest radiograph showed pulmonary edema. V.K. became confused and agitated, pulling at her IV lines and trying to get out of bed. Nephrology was consulted to provide emergent hemodialysis to correct the acidosis, electrolyte abnormalities, and fluid overload. As the catheter was being placed, the patient had a tonic-clonic seizure. Diazepam 10 mg IV was administered, and the seizure stopped. At this time, the patient was unresponsive. The NG tube revealed the presence of copious amounts of bright red blood. She was rushed to surgery for an emergency laparotomy. On the way to the operating room, she had another seizure, went into respiratory arrest, coded, and could not be resuscitated.

ASSESSMENT OF IRON INGESTION

Gathering History and Communications

10. The grandmother of R.F., a 20-month-old boy, calls the ED of a nearby hospital because her grandson is vomiting and appears to have been playing with some green tablets. The child was left alone in his room for about 15 minutes to take a nap. Why might the consultation with this grandmother be expected to be more difficult than the consultation in question 1?

Phone calls to a health care provider, a health care facility, or a poison control center from individuals other than the parent are usually more difficult to manage. The caller may not be able to provide all patient-specific information needed (e.g., patient weight, chronic medications) to accurately assess the drug ingestion. Supplemental information is often needed from a parent. Furthermore, nonparent callers tend to be more upset over an unintentional ingestion and may have more difficulty than a parent in taking decisive action.

Triage of Call

11. Despite additional questioning, the grandmother cannot identify the tablets and cannot find any labeling or empty medicine containers that could help in the tablet identification. R.F. is still

vomiting, and some of the vomitus is green-colored like the tablets. There are three children in the household and two adults who take medications for various chronic illnesses. According to the grandmother, R.F. is healthy, and no one else in the household currently has the “flu” or other GI illness. The child’s mother gave birth 3 weeks ago and is now at her obstetrician’s office for a postnatal visit. What recommendations could be provided to this grandmother at this time?

With this history, the practitioner should consider whether the information presented by R.F.’s grandmother is consistent with a drug ingestion and whether this incident is likely to be associated with a significant adverse outcome. Most 2-year-old children experience limited toxicity with unintentional drug ingestions because only a relatively small amount of substance is usually ingested. Nevertheless, some substances (e.g., methanol, ethylene glycol, nicotine, caustic substances, camphor, chloroquine, clonidine, diphenoxylate-atropine, theophylline, oral hypoglycemic agents, calcium channel blockers, tricyclic antidepressants [TCAs]) can produce significant toxicity when only small amounts are ingested.^{83,84}

Although the history of drug ingestion in R.F. is somewhat vague, the description of a green tablet, the vomiting of green material, and the recent pregnancy of his mother suggests possible ingestion of prenatal iron tablets. Because this exposure would be categorized as an unknown toxicity with a realistic potential for severe toxicity if iron tablets were ingested, R.F. should bring the child to the ED for evaluation. Depending on the distance to the hospital and the anxiety level of the grandmother, the practitioner might want to instruct the grandmother to call for emergency medical services transportation rather than relying on other means of transportation. She should be instructed to take the green tablets to the ED along with the child so the tablets can be identified. Other medications that are in the house should also be taken to the ED, and the mother should be contacted at the obstetrician’s office.

Substance Identification

12. R.F.’s mother has been contacted and has confirmed that the only green tablets in the house are her prenatal iron supplements. She is in close proximity to the hospital and will await the arrival of her son. R.F. arrived 20 minutes later along with one green tablet and an empty prescription container that was found by his older brother. R.F. is still vomiting but is awake and alert with a heart rate of 125 beats/minute, a respiratory rate of 28 breaths/minute, a temperature of 99.1°F, and pulse oximetry of 99%. How can the maximum potential severity of this ingestion be estimated at this time?

R.F.’s vital signs, when corrected for age, are normal. Attention should now focus on identifying the ingested substance and the maximum potential severity of the ingestion. Although this case involves an unknown ingestion, with a possibility of being a severe iron intoxication, the identity of the tablets still has not been verified. Therefore, R.F. must be carefully assessed, and the ingestion history reaffirmed.

All solid dosage prescription drugs are required by the U.S. Food and Drug Administration (FDA) to have identification markings. Reference books (e.g., *Facts and Comparisons, Physicians Desk Reference*),⁸⁵ computerized databases (e.g., IDENTIDEX),⁸⁶ and the product manufacturers can assist in identifying solid dosage forms. The imprint code markings on

the green tablet brought to the ED with R.F., the empty medication container, and the mother’s assistance should be sufficient to correctly identify the tablet. The identification of this green tablet will most likely establish the toxicity potential because most childhood ingestions usually involve only one substance. Once the tablet has been identified, the maximum number of tablets ingested should be estimated. The label on the empty medication container should provide information on the identity and number of tablets dispensed. If the medication container is unlabeled, the date the prescription was obtained, the number of estimated doses taken, and the number currently remaining in the medication container can be used to approximate the maximum number of tablets that were ingested.

R.F.’s vital signs and symptoms should be monitored at frequent intervals to evaluate whether his clinical status is consistent with expectations based on the suspected ingestion. Nausea, vomiting, diarrhea, and abdominal pain are commonly encountered early in the course of iron intoxication.^{87–92} The absence of symptoms, however, should not be interpreted as an indication that a poisoning has not occurred, especially if the patient is being evaluated within a short time after the presumed ingestion.^{87,89–92}

Evaluating Severity of Toxicity

13. R.F. weighs 22 lb, appears to be in no apparent distress, and has stopped vomiting. About 30 mL of dark-colored vomitus was recovered, but no tablets are seen, and testing demonstrates that no blood is present in the vomitus. A maximum of 11 tablets were ingested based on the bottle label and the mother’s recall. What degree of toxicity should be expected in R.F.?

The potential severity of ingestion can be estimated for commonly ingested drugs such as acetaminophen,⁹³ salicylates,⁶⁹ iron,⁸⁷ and TCAs⁹⁴ because of well-established dose–toxicity relationships. Acute elemental iron ingestions of <20 mg/kg are usually nontoxic, 20 to 60 mg/kg doses result in mild to moderate toxicity, and >60 mg/kg doses are severe and potentially fatal.^{88,90,92}

The label on the prescription medication container, as well as independent verification of the tablet by R.F.’s mother and the tablet imprint, indicate that each tablet contained 300 mg of ferrous sulfate in an enteric-coated formulation. Because the dose–toxicity relationship of iron is based on the amount of elemental iron ingested, knowledge of the specific iron salt is important in calculating the ingested dose. Ferrous sulfate contains 20% elemental iron, ferrous gluconate contains 12%, and ferrous fumarate contains 33%.^{87,88,90,91} Therefore, each 300-mg ferrous sulfate tablet contains 60 mg of elemental iron. R.F. ingested a maximum of 11 enteric-coated ferrous sulfate 300-mg tablets and he weighs 22 lb (10 kg); therefore, his ingestion of ~66 mg/kg of iron places him at risk of severe toxicity. Although R.F.’s only symptom is vomiting at this time, absorption could be delayed because he ingested an enteric-coated formulation.

Abdominal Radiographs

14. R.F. is expected to experience potentially severe toxicity from his ingestion of iron. Why would an abdominal radiograph

(x-ray) be useful to verify the number of iron tablets that were actually ingested?

Radiodense substances (e.g., iron, enteric-coated tablets, chloral hydrate, phenothiazines, heavy metals), theoretically, can be visualized in the GI tract by an abdominal radiograph.⁹⁴ The ability of a radiograph (x-ray) to demonstrate the presence of a radiodense substance, however, depends on the dosage form, concentration, and the molecular weight of the substance. The intact dosage form can often be detected if the tablet has not already disintegrated or dissolved.⁹⁵ Less than one-third of pediatric abdominal radiographs show positive evidence of tablets or granules after iron poisoning.⁹⁶

Keep in mind that children are more likely than adults to chew tablets rather than swallow them whole, and false-negative results can occur even when whole tablets have not already started to disintegrate. If the tablets were chewed, an abdominal radiograph to verify the number of ingested iron tablets is not likely to be useful. However, an abdominal radiograph after the completion of GI decontamination can help assess whether additional decontamination is needed.⁹⁵

Gastrointestinal Decontamination

15. Why would gastric lavage and/or activated charcoal not be indicated for the management of R.F.'s iron ingestion?

When selecting a GI decontamination method, one should consider the substance ingested, maximum potential toxicity expected from the drug dosage form, potential time course of toxicity, time elapsed between ingestion and the initiation of treatment, symptoms, and physical examination findings. Decontamination with activated charcoal is not indicated because R.F. has ingested iron tablets, which do not adsorb to activated charcoal.^{50,87,97} Gastric lavage would also not be effective because the removal of large undissolved iron tablets from the stomach is limited by the small internal diameter of the gastric lavage tube, especially in pediatric patients.^{97,98}

Whole Bowel Irrigation

16. What other method of GI decontamination should be considered for R.F.?

WBI with a polyethylene glycol electrolyte solution can be considered in this case. WBI fluid can be administered orally, or infused by NG tube at a rate of 1.5 to 2 L/hour for adults and at a rate of 500 mL/hour for children.^{99,100} Although the large volume of fluid to be ingested over a short period of time (several hours) and the frequent association of the nausea and vomiting often result in poor patient compliance, R.F. is hospitalized and the fluid can be infused by NG tube if needed. WBI should be continued until the rectal effluent is clear, which may take many hours.^{99,100}

Monitoring Effectiveness of Treatment

17. How should the effectiveness of GI decontamination be assessed in the ED?

The simplest method of assessing GI decontamination is to visually inspect the return fluid from the WBI. Increasing serum iron concentrations, deteriorating clinical status, or ev-

idence of radiodense tablets in the GI tract on abdominal radiograph would warrant more aggressive treatment.^{88–90,96}

Serum Iron Concentrations

18. At this time, R.F. has no evidence of CNS or cardiovascular symptoms that can occur with toxic iron ingestions. He did have one large dark-colored diarrheal stool that tested negative for blood. A serum iron concentration, obtained about 3 hours after the ingestion, was 470 mcg/dL (normal, 60–160 mcg/dL). What conclusions as to severity or likely clinical outcome can be derived from this serum concentration?

The serum iron concentration provides an indication as to whether more aggressive therapy is needed.^{92,96,101} The higher than normal serum iron concentration confirms the suspicion that R.F. has ingested iron tablets despite both his current lack of serious symptoms and the absence of tablet evidence in the rectal effluent or abdominal radiograph.

The time course of absorption is probably the most difficult pharmacokinetic parameter to evaluate with toxic ingestions. For example, drug concentrations can continue to rise after an overdose despite GI decontamination.^{89,91,92,101} This prolongation of absorption time is even further complicated when sustained-release or enteric-coated dosage formulations have been ingested because the onset of symptoms is unpredictable.⁹⁰

R.F.'s serum iron concentration of 470 mcg/dL at this time suggests a serious ingestion because peak serum iron concentrations >500 mcg/dL are usually predictive of significant toxicity.^{89–92,96,101} This single serum iron concentration, however, does not provide information as to whether the serum concentration is rising or declining nor when the serum iron concentration will peak as a result of his iron ingestion.¹⁰² Iron tablets may also clump together and form a concretion or bezoar. Bezoar formation can result in prolonged absorption and delay the onset of toxicity.^{89,92} Samples for peak serum iron concentration should be obtained 4 to 6 hours after ingestion.^{90–92} Although R.F.'s serum iron concentration was measured approximately 3 hours after ingestion, another serum iron measurement in 2 to 4 hours is needed because he ingested an enteric-coated formulation.

Blood Glucose, White Blood Cell Count, and Total Iron Binding Capacity

19. R.F. had WBI administered through the NG tube for 4 hours until the rectal effluent was clear. At this time, R.F. began to vomit numerous times and became drowsy and fussy. A second serum iron concentration was ordered (i.e., 6 hours after ingestion). What other laboratory tests could be helpful in assessing the potential toxicity of iron in R.F.?

Blood glucose concentrations and white blood cell (WBC) counts usually are increased when serum iron concentrations are >300 mcg/dL. A WBC count >15,000/mm³ and a blood glucose concentration >150 mg/dL within 6 hours of an ingestion generally suggest a greater likelihood of severe iron intoxication.⁸⁸ These tests provide supplemental confirmation of iron intoxication and can be useful in medical facilities in which serum iron concentrations cannot be obtained. Sensitivity of these tests are low (about 50%), and treatment should not

be based on a WBC and glucose concentration alone.^{89–91,96} These laboratory tests are not routinely monitored in iron poisoning because of the poor sensitivity.⁹⁰

It was once believed that if the serum iron concentration exceeded the total iron binding capacity (TIBC) concentration, it would be a substantiate iron toxicity. The correlation between the TIBC concentration and iron toxicity, however, has not held up, and the TIBC test is no longer used to monitor iron toxicity.⁹²

Stages of Iron Toxicity

20. It is now 6 hours since R.F. ingested the iron tablets. His second serum iron concentration is not yet available. He continues to be fussy and drowsy but has missed his usual afternoon nap. He has several more episodes of vomiting. Why is R.F.'s relatively mild course at this time not particularly reassuring?

The time between the ingestion of an overdose of drugs and the development of severe toxicity is often delayed. It is unclear in some cases why there is an asymptomatic period, but it may be secondary to delayed absorption of the ingested drug, the time required for the drug distribution, or the time needed to form a toxic metabolite. Consequently, R.F. may still develop further symptoms of severe toxicity. Four distinct stages of symptoms can be encountered with iron toxicity.^{87–92}

Stage I

Stage I symptoms usually occur within 6 hours of ingestion. During this time, nausea, vomiting, diarrhea, and abdominal pain are encountered and are probably secondary to the erosive effects of iron on the GI mucosa. The caustic effects of free iron can cause bleeding as evidenced by blood in the vomitus and stool. In more severe intoxications, CNS and cardiovascular toxicity can be present during Stage I.^{89–92}

Stage II

The second stage of iron toxicity is characterized as a period of decreasing symptoms and an apparent improvement in the clinical condition. This stage can last for up to 12 to 24 hours after the ingestion and could be misinterpreted as resolving toxicity. This stage might represent the time needed for the absorbed iron to distribute throughout the body before systemic symptoms develop.⁸⁷ Alternatively, this stage might merely reflect patients who did not receive treatment early in the course of intoxication and appeared to be well before systemic effects developed.⁸⁶ It is unknown why this stage of apparent improvement occurs with iron toxicity. In most severe cases, Stage II is not encountered and the patient's condition continues to progressively deteriorate.^{89,92}

Stage III

Stage III generally occurs 12 to 48 hours after iron ingestion and is characterized by CNS toxicity (e.g., lethargy, coma, seizures) and cardiovascular toxicity (e.g., hypotension, shock, pulmonary edema). Metabolic acidosis, hypoglycemia, hepatic necrosis, renal damage, and coagulopathy can be experienced at this stage.^{89–92}

Stage IV

The final stage is apparent 4 to 6 weeks after acute iron ingestion and consists of late-appearing GI tract sequelae that

are secondary to the initial local toxicity. In this stage, prior tissue damage can progress to gastric scarring and strictures at the pylorus, resulting in permanent abnormalities of GI function.^{89–92}

Patients can present to the health care facility in any stage of iron toxicity and can have a fatal outcome in any stage. Assigning a stage of toxicity should not be based on time since ingestion, but instead should be based on clinical symptoms.⁹¹

Deferoxamine Chelation

21. The clinical laboratory has reported that the second serum iron concentration that was obtained 6 hours after ingestion from R.F. has increased from 470 to 553 mcg/dL. He has continued to vomit. R.F.'s mother states that the child looks "pale" to her. What criteria are most important in determining whether the antidote deferoxamine should be administered to R.F.?

[SI units: 84.18 and 99.04 $\mu\text{mol/L}$, respectively]

Deferoxamine (Desferal) chelates iron by binding ferric ions in plasma to form the iron complex ferrioxamine.⁹⁰ Deferoxamine prevents iron toxicity at a cellular level by removing iron from mitochondria.⁸⁸ Unfortunately, a relatively small amount of iron is bound (approximately 9 mg of iron to 100 mg of deferoxamine).^{102,103} The iron-deferoxamine complex primarily is excreted renally as ferrioxamine.^{88,90,91} Renal elimination of the ferrioxamine usually results in a pinkish-orange urine, often described as "vin rose."^{88,90,91} Deferoxamine therapy should be initiated when serum iron concentrations exceed 500 mcg/dL and when symptoms of iron toxicity (e.g., GI symptoms, hemorrhage, coma, shock, seizures) are present.^{88–91} R.F. is experiencing symptoms, he presumably ingested up to 66 mg/kg of elemental iron, and iron absorption appears to be ongoing based on the increase in his serum iron concentration. Therefore, R.F. should be treated with deferoxamine.

Deferoxamine Dose

22. What dose of deferoxamine should be prescribed for R.F., and how should it be administered?

Deferoxamine is more effective when administered intravenously as a constant infusion due to the short half-life of the deferoxamine (76 ± 10 minutes).^{89,91,102} Clinically, a slow IV infusion is preferred over intramuscular (IM) administration because the dose administered can be better controlled, is less painful, and is better absorbed than an intramuscularly administered dose.^{91,92} Deferoxamine 15 mg/kg/hour is usually administered in a continuous IV infusion; however, doses up to 45 mg/kg/hour have been used in patients with severe iron poisoning.^{89–92,102} Hypotension can result from administering IV boluses of deferoxamine too rapidly.^{89,90,92,102,103} According to the manufacturer, the total deferoxamine dose should not exceed 6 g every 24 hours when administered to adults or children, but adverse effects have not been seen in patients who received more than 6 g every 24 hours.^{91,103}

If IV access is not readily available or if the patient is transported to another medical facility for treatment, deferoxamine should be administered intramuscularly.^{88,103} The usual IM dose of deferoxamine for the treatment of acute iron intoxication is 90 mg/kg, not to exceed a maximum of 1 g per dose.¹⁰³

The dose can be repeated every 4 to 12 hours, depending on the clinical status of the patient.¹⁰³ Pain at the injection site, as well as induration, is common after IM administration.^{91,103}

Deferoxamine should be initially administered to R.F. at a rate of about 8 mg/kg/hour, and his clinical status should be monitored closely. If the dose is tolerated, the rate can be increased every 5 minutes until the desired dose of 15 mg/kg/hour is achieved.⁸⁹

Monitoring and Discontinuation

23. R.F. is admitted to the pediatric ICU 1 hour after the initiation of a deferoxamine infusion at 8 mg/kg/hour. How should deferoxamine therapy be monitored, and when should it be discontinued?

The rate of deferoxamine infusion should be increased if symptoms of severe iron toxicity develop, and the dosage should be decreased if adverse effects develop.^{89,90,92,103} The infusion of deferoxamine should be continued until the serum iron concentration is <100 mcg/dL and symptoms of iron toxicity are no longer present.¹⁰³ Patients will require chelation therapy for about 1 to 2 days, depending on the severity of symptoms.^{89–91} Chelation therapy that continues longer than necessary should be avoided because deferoxamine infusion for more than 24 hours has been associated with the development of acute respiratory distress syndrome.^{89–91}

The urine color change to “vin rose” indicates ferrioxamine in the urine.^{88,82} The disappearance of the “vin rose” color should not be used as a reliable marker of adequacy of deferoxamine therapy because not all patients experience vin rose urine.^{88,92} There is no correlation between amount of iron ingested, serum iron concentration, and the urine color change.⁸⁸

Deferoxamine can interfere with some laboratory methods used to measure serum iron concentrations and cause falsely low values.^{88,89,101,104} To monitor serum iron concentrations when deferoxamine has been started, using atomic absorptive spectroscopy is recommended.¹⁰³ When deferoxamine is initiated, the clinical laboratory should be contacted to clarify whether deferoxamine will interfere with their serum iron analysis.

Outcome of Patient R.F.

R.F. was admitted to pediatric ICU overnight and treated with a constant infusion of deferoxamine at 15 mg/kg/hour for 13 hours. His GI symptoms were no longer apparent, he became more alert, and his vital signs were stable. An analysis of a free iron blood sample the next morning revealed a serum iron level of 67 mcg/dL. He was discharged home that afternoon.

[SI units: 11.99 $\mu\text{mol/L}$]

ASSESSMENT OF CENTRAL NERVOUS SYSTEM DEPRESSANT VERSUS ANTIDEPRESSANT INGESTION

Validation of Ingestion

24. T.C., a 34-year-old unconscious woman, was found lying on the couch with a suicide note. The note stated that she had ingested 25 of her pills. On discovering T.C. unresponsive, T.C.’s 15-year-

old daughter called paramedics. When the paramedics arrived, T.C.’s heart rate was 145 beats/minute, BP was 105/65 mmHg, and respirations were 12 breaths/minute and shallow. T.C. was found in a pool of vomitus. T.C. responded only to painful stimuli. The paramedics immediately started an IV line after completing their assessment of her ABCs. Why should the drug overdose information from this suicidal patient be validated?

Assessing the accuracy of historical information in adult drug exposures is difficult, and many health care professionals question the validity of information, especially from suicidal patients.^{22–26} The ingestion history could be inaccurate because the patient’s altered mental status might prevent accurate recollection of what occurred. She may also try to intentionally mislead health care providers to minimize appropriate care. The supposition that the drug overdose history from a patient is unreliable is based on studies demonstrating poor correlation between stated drug ingestions and urine drug test results.^{23–26,29,30,105}

Urine drug screens generally detect all recent drug and substance use, rather than just an overdosed drug. Urine drug screen results, therefore, are not reliable indicators of acute exposures. Every effort should be made to validate the history with information from other sources. In suicidal patients, one should consider all drugs that may have been available to the patient, as well as the patient’s presenting symptoms, laboratory tests, and information obtained from family members, police, paramedics, and other individuals who know the patient.^{22–26}

Interventions by Protocol

25. In addition to managing the ABCs, what pharmacologic interventions should be authorized for the paramedics to administer to T.C. in addition to the initiation of an IV solution?

Glucose and Thiamine

Emergency medical service personnel often have protocols directing them to treat patients who are unconscious from an unknown cause. These protocols generally include administration of glucose, thiamine, and naloxone.^{23,26,61,106} If paramedics cannot measure a blood glucose concentration immediately, T.C. should be given 50 mL of 50% dextrose to treat possible hypoglycemia. The risks of hyperglycemia from this dose of glucose are negligible relative to the significant benefits if the patient is hypoglycemic. Thiamine should be administered concurrently with glucose because glucose can precipitate the Wernicke-Korsakoff complex in thiamine-deficient patients¹⁰⁷ (see Chapter 84). Wernicke’s encephalopathy is a reversible neurologic disturbance consisting of generalized confusion, ataxia, and ophthalmoplegia. Korsakoff’s psychosis is believed to be irreversible and is associated with a more prolonged deficiency of thiamine.^{107,108}

This unconscious patient should also be evaluated for blood loss, hypoxia, and evidence of head trauma.²²

Naloxone

The pure opiate antagonist, naloxone, is indicated for the treatment of respiratory depression induced by opioids,^{106,109} but many emergency medical service protocols authorize paramedics to routinely administer naloxone to all patients with decreased mental status.¹⁰⁹ Naloxone reportedly has reversed

coma and acute respiratory depression in intoxicated patients who have no evidence of opiate use.^{60,108} The response of these patients to naloxone might have been secondary to opioids that were not detected by the urine toxicology screens (e.g., oxycodone, fentanyl). Drug-induced CNS depression usually waxes and wanes, and reports of naloxone success in patients who have not used opioids could also have been the result of responses to needle sticks, movement, or other stimuli rather than to naloxone.

Administering naloxone to an opioid-addicted patient can result in withdrawal symptoms (e.g., agitation, combativeness, vomiting, diarrhea, lacrimation, rhinorrhea) that can further complicate the intoxication picture.⁶¹ Small doses of naloxone should be administered initially to determine the patient's response to this medication. Violent and aggressive behavior can be precipitated when sudden increased consciousness is induced by naloxone.²⁴ This can complicate emergency care in an emergency transport vehicle and put caregivers and patients at risk for trauma.⁶¹

Initial Treatment

26. The paramedics arrive at the ED with T.C. 30 minutes after her daughter called them. T.C.'s heart rate in the ED is 148 beats/minute, BP is 90/55 mmHg, and respirations have decreased from 12 breaths/minute, spontaneous and shallow, to 7 breaths/minute, with assisted ventilation from a bag-valve mask. T.C. remains unresponsive. The paramedics were unable to find any prescriptions or other medications in the house. Her daughter believed that her mother was taking medication for depression, but she could not be more specific. The police will notify T.C.'s husband and try to obtain additional information about the ingested substance. What initial treatment should be provided for T.C. in the ED?

T.C. should be intubated and mechanically ventilated with 100% oxygen because of her shallow, slow respirations and the likelihood that vomitus could have been aspirated into her lungs. The blood pressure taken by the paramedics was 105/65 mmHg and now is 90/55 mmHg. A bolus of IV fluid should be administered to T.C. to determine whether an increase in her intravascular fluid volume will increase her blood pressure and improve her mental status.^{22,39}

Antidotes

27. T.C.'s husband reports that T.C. is under the care of a psychiatrist for depression and two previous suicide attempts. He does not know the identity of her medication, but attempts are underway to contact T.C.'s psychiatrist. What antidotes can be administered in the ED for diagnostic purposes? Should flumazenil (Romazicon) be administered?

Theoretically, antidotes such as naloxone, flumazenil, de-feroxamine, and antidigoxin FAB fragments could be administered in a hospitalized setting to identify an unknown toxin.^{24,59,110} However, the costs, time required for administration, and increased risks from these antidotes preclude their use for diagnostic purposes without some plausible suspicion of a specific drug ingestion. Although naloxone and flumazenil can reverse CNS depression caused by opioids and benzo-

diazepines, respectively, their use is not appropriate without historical, clinical, or toxicologic laboratory findings, which suggest that one of these drugs is a cause of T.C.'s intoxication.

Organ System Evaluations

28. How can the initial physical assessment, using an organ systems approach, help in identifying the drugs ingested by T.C.?

The patient's ABCs and CNS and cardiopulmonary functions should be assessed with special attention to clinical manifestations that suggest ingestion of a specific class of drugs.^{26,39} For example, T.C.'s history of depression suggests that antidepressants, antipsychotics, lithium, and/or benzodiazepines are candidates for ingestion in her case. An organ system evaluation will help determine whether these (or other) drugs might have been ingested. Nonprescription medications such as aspirin, acetaminophen, decongestants, and antihistamines, which are commonly available in most households, should also be considered because adult drug ingestions usually involve more than one drug.

Central Nervous System Function

Changes in CNS function are probably the single most common finding associated with drug intoxication.²⁶ CNS depression or stimulation, seizures, delirium, hallucinations, coma, or any combination of these can be manifested in intoxicated patients. CNS changes can be the direct result of an ingested drug or may be additive to other underlying CNS processes or medical conditions. Many drug overdoses can produce different clinical manifestations at various times during the intoxication and different doses can produce different effects as well.^{26,65}

Drugs with anticholinergic properties can produce disorientation, confusion, delirium, and visual hallucinations early in the course of the intoxication; coma can become apparent as toxicity progresses. Generally, overdoses with anticholinergic drugs do not produce true hallucinations, but rather pseudo-hallucinations. When a patient with an intact baseline mental status presents with psychosis, paranoia, or visual hallucinations, CNS stimulants such as cocaine or amphetamines should be considered.^{26,63} Drug intoxication-induced alterations in CNS function are initially difficult to distinguish from those caused by underlying psychiatric disorders, trauma, hypoxia, or metabolic disorders, such as hepatic encephalopathy or hypoglycemia. However, with the passage of time, decreased CNS function secondary to drug toxicity is more likely to wax and wane in severity in contrast to the more constant CNS depression that occurs with significant trauma or metabolic disorders. Drug toxicity also rarely produces focal neurologic findings. Changes in pupil size, reflexes, and vital signs can provide insights into the pharmacologic class of drug involved in the intoxication.^{24,26,27}

CNS depression, seizures, disorientation, and other CNS changes that are commonly associated with drugs likely to be prescribed by psychiatrists should be evaluated carefully in T.C. For example, T.C.'s pupil size would most likely be dilated if she had ingested a TCA because of the anticholinergic effects of these drugs. TCA intoxications can also cause myoclonic spasms.²⁶ These spasms are often difficult to differentiate from

seizure activity caused by TCA overdoses, although the spasms are often asymmetric and more persistent.¹¹¹

Cardiovascular Function

Assessment of heart rate, rhythm, conduction, and measurements of hemodynamic function can also be used to help identify the type of drug ingested. For example, overdoses of sympathomimetic drugs usually increase heart rate. Overdoses of cardiac glycosides or beta-blockers can slow the heart rate. Although drugs can increase or decrease heart rate directly, indirect cardiac effects (e.g., reflex tachycardia in response to hypotension) also need to be considered. Abnormal heart rates produced by drug overdoses are usually not treated unless hypotension or severe dysrhythmias are precipitated.^{26,39}

Pulmonary Function

Evaluating the rate and depth of respiration and the effectiveness of gas exchange in an intoxicated patient can also help identify drugs that might have been ingested. For example, a decrease in respiratory rate is commonly associated with the ingestion of CNS depressants. An increased respiratory rate and depth is generally associated with CNS stimulant toxicity. An increase in respiratory rate can also be secondary to respiratory compensation for a drug-induced metabolic acidosis.²⁶ Aspiration of gastric contents after vomiting is a common event in drug ingestions. Aspiration pneumonitis is the most common pulmonary abnormality associated with significant intoxications.⁴³ Noncardiogenic acute pulmonary edema has been associated with drug overdoses of salicylates^{75–78} (especially with chronic intoxications) and the use of drugs of abuse (e.g., cocaine and heroin).^{112–119}

Temperature Regulation

Body temperature is an important and sometimes overlooked parameter when assessing potential intoxications.^{24,39} Decreased mental status is often associated with a loss of thermoregulation, and this results in a body temperature that falls or increases toward the ambient temperature. Increased body temperature (hyperthermia) caused by overdoses of CNS stimulants (e.g., cocaine, amphetamines, ecstasy), salicylates, hallucinogens (e.g., phencyclidine), or anticholinergic drugs or plants (e.g., jimsonweed) can have serious consequences.^{24,26,39} Body temperature should be measured rectally to obtain an accurate representation of core body temperature.¹²⁰

Hyperthermia caused by drug overdoses is commonly encountered in hot, humid environments or when the intoxication is associated with physical exertion, increased muscle tone, or seizures. In these patients, it is important to obtain renal function tests (e.g., BUN, serum creatinine) and a serum creatine kinase (CK) measurement to determine whether rhabdomyolysis has occurred secondary to breakdown of muscle tissue.^{24,39,120}

Gastrointestinal Function

The GI tract should be assessed for decreased motility because drug absorption can be delayed or prolonged.^{26,121} When this is the case, decontamination may be beneficial after an oral ingestion even if a long period of time has elapsed since the ingestion. The presence of blood in either emesis or stool may signal ingestion of a GI irritant or caustic substance.¹²²

Skin and Extremities

The physical examination should include a thorough evaluation of the body surfaces. Look for causes of trauma that may also explain the patient's condition. Examination of the skin and extremities can provide evidence of drug intoxication, especially with IV or subcutaneous drug injection needle marks.²⁴ Drugs can be hidden in the rectum or vagina.²⁴ Look for drug patches (e.g., fentanyl) on hidden areas of the body such as the back of the neck or scrotum. Fluid-filled bullae at gravity-dependent sites that have been in contact with hard surfaces for a long time suggest prolonged coma.²⁶ Muscle tone also should be assessed.²⁶ Increased tone or myoclonic spasms can be caused by some drug overdoses (e.g., TCAs) and can produce rhabdomyolysis or hyperthermia.^{26,120} Dry, hot, red skin may also be an indication of anticholinergic toxicity.^{26,39}

In summary, an organ system assessment of T.C. can provide useful insights into the identity of drugs that might have been ingested, the viability of organ function that might have been adversely affected, and the treatment that should be instituted.

Laboratory Tests

29. What laboratory tests should be ordered for T.C.?

The laboratory assessment of an intoxicated patient should be guided by the history of the events surrounding the ingestion, clinical presentation, and past medical history.^{22,123} The status of oxygenation, acid–base balance, and blood glucose concentration must be determined, especially in patients with altered mental status such as T.C.³⁹ Oxygenation can be assessed initially by pulse oximetry, and acid–base status by ABGs and serum electrolyte concentrations.^{23,123,124} T.C. was given oxygen and a bolus of IV fluid on her arrival at the ED. Paramedics administered glucose during her transportation to the ED.

A medical history of organ dysfunction or medical disorders (e.g., diabetes, hypertension) that can damage organs of elimination (e.g., kidney, liver) will also guide the need for laboratory tests. A serum creatinine concentration and liver function tests (e.g., aspartate aminotransferase [AST], alanine aminotransferase [ALT]) should be ordered. Other more specific tests reflective of her past medical history can be ordered subsequent to dialogue with her psychiatrist. A CBC, complete chemistry panel, serum osmolality, and other baseline laboratory tests should be obtained.²⁶ Pregnancy tests should be considered in female patients of childbearing age because unwanted pregnancies are common causes of overdose.¹²⁴

A baseline electrocardiogram (ECG) should be obtained when exposure to a cardiotoxic drug is suspected or whenever the cardiovascular or hemodynamic status is altered.^{23,39,124} A 12-lead ECG should be ordered because T.C. is likely to have ingested a psychotropic agent. Continuous cardiac monitoring should be instituted because of the significant cardiotoxicity associated with overdoses of these agents. Patients with severe TCA overdoses frequently present with symptoms of coma, tachycardia with a prolonged QRS segment, seizures, hypotension, and respiratory depression.^{125–128}

A chest radiograph is useful when the potential exists for either direct pulmonary toxicity or aspiration.²³ A chest radiograph is indicated because T.C. had vomitus in her mouth and

TCAs are associated with the development of acute respiratory distress syndrome and pulmonary edema.^{125,129,130}

Qualitative Screening

30. Why should (or should not) T.C.'s urine and blood be screened to assist in identifying the ingested substance?

Toxicology laboratory testing can be used to identify the substances involved in a toxic exposure, to exclude substances, or to measure the concentration of substances in serum or other biological fluids.^{24,123,124} The identification and quantification of compounds should be considered as two distinct types of toxicologic testing.^{24,131} *Qualitative* screening, intended to identify unknown substances, must be able to identify which substance or class of substances, is involved in the toxic exposure. *Quantitative* testing is similar to therapeutic drug monitoring in that the presence of the substance usually is known, and the question being answered is how much is present.²⁴

Screening various biological fluids suspected of having high concentrations of a parent drug and its metabolites can identify unknown substances. Urine is screened much more commonly than blood, whereas gastric fluid is rarely evaluated. A urine drug screen is preferred to a blood drug screen because urine generally contains a higher concentration of a drug and its metabolites than other body fluids.¹³²

When reviewing the results of urine screening panels for drugs and other substances, one must remember that the presence of a substance in urine is not necessarily related to a concurrent toxicity. A positive result on a urine screening panel merely indicates that the patient has ingested or has been exposed to the substance, but it does not differentiate between toxic and nontoxic doses. If a drug and its metabolites are eliminated slowly into the urine over a prolonged period of time, and if the testing methodology detects small concentrations of the substance, urine drug screening could identify the presence of a substance days, weeks, or even months after the exposure (e.g., marijuana).^{24,124}

It is important to know which drugs/substances are tested at a given laboratory. Many laboratories restrict the number of drugs for which they test because 15 drugs account for more than 90% of all drug overdoses.²⁹ Some urine toxicology screens only detect common drugs of abuse (e.g., amphetamines, barbiturates, benzodiazepines, cocaine, marijuana, opioids).¹²⁴ Some drugs of abuse are not detected on routine drug screening (e.g., gamma hydroxybutyrate, ketamine, flunitrazepam).²⁴ Some analyses detect only antibodies to drug metabolites. For example, a benzodiazepine screen detects oxazepam, a common benzodiazepine metabolite. However, alprazolam and lorazepam are not metabolized to oxazepam and will not be detected in a urine screen. Likewise, an opioid screen may not detect the synthetic opioids such as fentanyl and methadone.¹²⁴

Results of qualitative toxicology screening tests are difficult to interpret. False negatives, false positives, cross-reactivity with related drugs, chronicity of exposure, and length of time since last exposure all complicate results.¹²⁴ Urine toxicology screen results rarely change clinical management of the patient. Monitoring mental status, cardiovascular and respiratory status, and other laboratory parameters provide better clues than the results of a urine toxicology screen.^{23,24,123,124,131}

Toxicology screening can be appropriate when the history of a suspected toxic exposure is unavailable, inaccurate, or inconsistent with the clinical findings.²⁴ However, it is important to know which drugs are detected on a given toxicology screen.¹²⁴ A comprehensive qualitative urine drug screen can be considered for T.C. because information about the substance(s) she ingested is not yet known.

Quantitative Testing

31. Why should a quantitative toxicology laboratory test be ordered (or not ordered) for T.C. as well?

Following a qualitative urine analysis for drugs, a quantitative analysis of drug concentration in blood can help determine the severity of toxicity and the need for aggressive interventions (e.g., hemodialysis).^{24,30,124,131} Quantitative tests are especially useful when assessing the potential toxicity of drugs with delayed clinical toxicity or when the toxicity primarily is caused by metabolites (e.g., ethylene glycol, methanol). Furthermore, the concentration of a drug in serum is sometimes much more predictive of end-organ damage than clinical findings (e.g., acetaminophen effect on the liver).

Quantifying the amount of drug in serum is useful when (a) the concentration of the substance correlates with toxic effects, (b) the turnaround time for results is rapid, and (c) treatment can be guided by the serum concentration.^{29,123,131} To aid in the care of poisoned patients, quantitative serum concentrations of acetaminophen, carbamazepine, carboxy-hemoglobin, digoxin, ethanol, ethylene glycol, iron, lithium, methanol, methemoglobin, phenobarbital, and theophylline should be available at laboratories of large health care facilities.^{23,24,30,123,131}

When blood samples are collected to quantitate potentially intoxicating substances, as much information as possible should be obtained about the time course of events to determine whether absorption and distribution of the substance is complete. Serial samples may be needed to determine whether significant absorption is still occurring.²⁸ In contrast to the interpretation of therapeutic serum concentrations of chronically administered drugs, the serum concentration of a substance ingested in an overdose will not be at steady state.

Quantitative toxicologic testing will not benefit T.C. at this point in time because the identity of the ingested substance is unknown. Nevertheless, a serum ethanol concentration could be useful in this case because alcohol is often ingested concurrently in overdose situations.¹²³ Most poison centers also recommend obtaining a quantitative acetaminophen level on all intentional ingestions because serious hepatotoxicity can occur if acetaminophen ingestion is missed.^{24,123,124}

Assessment

32. T.C.'s clinical status has not changed over the past 10 minutes. A urine toxicology screen, blood acetaminophen, blood alcohol, and ABGs have been ordered. The 12-lead ECG shows a prolonged QRS interval of 0.14 seconds (normal, <0.1 seconds). No antidotes have been administered. T.C.'s physical examination did not detect any evidence of trauma to her head. Her pupils were dilated and slowly responsive to light, and her bowel sounds were

hypoactive. What conclusions can be made at this time with regard to the likely substance ingested by T.C.?

Although the ingested substance still has not been specifically identified, the available data provide some clues as to the likely pharmacologic class of drug that was ingested. The presence of CNS depression (T.C. is unresponsive), slowed ventricular conduction (prolonged QRS on ECG), tachycardia (heart rate, 148 beats/minute), hypotension (BP, 90/55 mmHg), decreased GI motility (hypoactive bowel sounds), and the history of a possible depressive illness (history from husband and daughter) are all consistent with a TCA drug overdose. The antidepressant could have been ingested alone or with other agents.

Antidepressant Toxicities

33. How would the different toxicities of the various available antidepressants affect the treatment of T.C.?

The major pharmacologic effects and toxicities of the antidepressants are similar for all drugs within the same class. When a specific drug within a therapeutic class has not yet been identified, the overdose should be managed as if the ingested drug can produce the most severe toxicity of any drug in the class. In this light, T.C.'s presumed antidepressant drug overdose should be evaluated and managed initially as TCA (e.g., amitriptyline) ingestion.^{127,133} Antidepressants with different structures and actions (e.g., trazodone [Desyrel], fluoxetine [Prozac], sertraline [Zoloft]) generally do not produce toxicity as severe as that of the TCAs.^{127,133,134}

Gastrointestinal Decontamination

34. If a TCA ingestion is presumed, why might GI decontamination be appropriate at this time?

The longer GI decontamination is delayed relative to the time of ingestion, the less effective it is likely to be because drug absorption will already have occurred. Because the time of ingestion is unknown and T.C. is unresponsive, she probably already has absorbed significant amounts of the drug, making her more vulnerable to aspiration. Furthermore, T.C. might already have aspirated because she was found in a pool of vomitus. TCA overdoses can also induce seizures, which would be a relative contraindication to GI decontamination. In consideration of these concerns, some would not support GI decontamination for T.C.^{41,42,43,44,52–55}

Others might support GI decontamination because TCAs have strong central and peripheral anticholinergic properties that slow GI emptying, which could result in erratic absorption and delayed toxicity. Furthermore, TCAs have a large volume of distribution (10–50 L/kg), and both the parent drug and its metabolite undergo enterohepatic recirculation. The half-life of TCAs in overdose situations is 37 to 60 hours.⁹⁴ For those reasons, activated charcoal could be reasonably administered in an effort to adsorb any drug that may not yet be absorbed from the GI tract.⁵⁰

Repeated doses of activated charcoal have been used to increase the elimination of TCAs because of the long half-life of TCAs and the enterohepatic recirculation. In clinical studies, multiple-dose activated charcoal has increased the elimination

of amitriptyline, but the data are insufficient to support or exclude the use of this therapy.⁴⁶

Monitoring Efficacy

35. How should the effectiveness of GI decontamination be monitored in T.C.?

If activated charcoal is administered, T.C. must first be intubated to protect her airway, and the charcoal must be administered via NG tube because she is unconscious. The insertion of the NG tube could stimulate the gag reflex; thereby, causing emesis and possible aspiration. T.C.'s lung sounds should be monitored closely to determine if aspiration pneumonitis is developing, particularly because T.C. was found unconscious and had already vomited.

Activated charcoal, especially in multiple doses, can produce ileus, GI obstruction, or intestinal perforation, especially when administered to patients who have ingested drugs that slow GI motility.^{46,50,97} Bowel sounds must be monitored frequently to determine that an ileus is not developing. Once the patient passes a charcoal-laden stool, the activated charcoal can be considered to have successfully passed through the GI tract.

Sodium Bicarbonate and Hyperventilation

36. According to T.C.'s psychiatrist, he prescribed amitriptyline 100 mg at bedtime for her severe depression. How does this new information alter T.C.'s treatment plan?

This information confirms the assumptions that a TCA was ingested, and it also specifically identifies the probable ingested drug. In TCA ingestions, severe toxicity has been associated with doses of 15 to 25 mg/kg.⁹⁴ T.C. ingested a total of 2,500 mg based on her suicide note that said she took 25 tablets. If she weighs about 60 kg and was truthful about the amount taken, she ingested a significantly toxic dose (about 42 mg/kg).

On the ECG, TCA toxicity will exhibit as tachycardia with prolongation of the PR, QTc and QRS intervals, ST and T wave changes, and abnormalities of the terminal 40-millisecond vector.^{94,111,125,128,135–138} TCAs have anticholinergic, adrenergic, and quinidinelike membrane effects on the heart.^{111,125,127,133,136} It is believed that the anticholinergic effect causes the tachycardia and the quinidinelike effect causes the ECG changes.

In addition, TCAs are sodium channel blockers.¹³⁹ Sodium channel blockade slows the maximum uptake stroke of phase 0 of the action potential and decreases automaticity. Blockade decreases conduction velocity in the Purkinje fibers, which increases the QRS interval.¹³⁶ Myocardial depression, ventricular tachycardia, and ventricular fibrillation are the most common causes of death from TCAs.¹²⁸ Therefore, admission to the ICU with continuous cardiac monitoring is essential for T.C.¹³⁵

The primary therapy for reversing ventricular arrhythmias and conduction delays is alkalinization of the serum and sodium loading by administering IV hypertonic sodium bicarbonate.^{111,125,127,128,136,137,140} Indications for sodium bicarbonate include hypotension, prolonged QRS segment (longer than 100 milliseconds), right bundle branch block, and wide complex tachycardia.^{127,137} Alkalinization increases

serum protein binding of the TCAs and thereby reduces the amount of free active drug (probably a minor consideration).^{111,125,128,137} Correction of the serum pH is beneficial because underlying acidosis increases TCA cardiotoxic effects.¹³⁷ Furthermore, sodium bicarbonate has been found useful even in patients with a normal pH because sodium bicarbonate purportedly overcomes the sodium channel blockade and decreases cardiotoxicity.^{137,139}

Based on T.C.'s tachycardia and a widened QRS segment on ECG, she should be treated with IV sodium bicarbonate with the goal of achieving an arterial pH of 7.5 to 7.55.^{128,137} Sodium bicarbonate could have been administered earlier because the suspicion of an antidepressant overdose was strong initially, her ECG demonstrated QRS prolongation and worsening myocardial conduction, and her BP continued to decline from the time she was first seen by the paramedics. The use of IV sodium bicarbonate could introduce the risk of sodium overload and subsequent pulmonary edema, if not monitored closely.^{94,138} An alternate is to hyperventilate the patient to a pH of 7.5 by adjusting her ventilator setting, and in this manner, decrease the cardiotoxicity of the TCA.^{125,128,138}

The combination of IV bicarbonate and mechanical ventilation is more likely to produce severe alkalemia. Careful and frequent monitoring of the serum pH of patients on dual therapy is essential.^{125,139}

Monitoring Efficacy

37. How should the sodium bicarbonate therapy in T.C. be monitored?

Many patients intoxicated with TCAs present with severe acidosis. Large doses of sodium bicarbonate may be required to normalize the arterial pH. The efficacy of sodium bicarbonate administration can be evaluated by monitoring acid–base status using ABGs, especially if the patient is also being ventilated mechanically.^{125,139,140}

A bolus of sodium bicarbonate (1 mEq/mL) should be administered IV as a bolus of 1 to 2 mEq/kg over a 1- to 2-minute period. Continuous ECG monitoring is needed to monitor results of the bolus on cardiac abnormalities. Repeat bolus doses are administered as needed until the QRS interval narrows and tachycardia slows. Blood pH should be tested after several boluses to determine if a target pH of 7.5 to 7.55 has been obtained.¹³⁷ At a minimum, ABGs should be determined within an hour of starting sodium bicarbonate therapy to determine pH response to the bicarbonate.¹⁴⁰ Bolus bicarbonate can be followed by a constant sodium bicarbonate infusion of 150 mEq sodium bicarbonate per liter to maintain an alkaline pH.¹³⁷ ABGs must be monitored frequently to ensure a response.^{125,139,140} Serial ECGs to measure the QRS interval can evaluate the efficacy of sodium bicarbonate. A prolonged QRS interval will generally narrow to normal after the systemic pH has been increased to about 7.5.¹⁴⁰

Seizures

38. T.C. gradually developed more severely altered mental status and became comatose, not responding even to painful stimuli. She suddenly experienced a tonic-clonic seizure, which lasted

about 2 minutes and terminated spontaneously. Should anticonvulsant therapy be initiated for T.C. at this time?

CNS toxicity is common in TCA overdoses. Symptoms include agitation, hallucinations, coma, myoclonus, and seizures.^{111,125–128} Seizures can cause significant increases in acidosis and increase cardiotoxicity. Indeed, seizures are often seen immediately prior to cardiopulmonary arrest. Due to the severe consequences of prolonged seizures, aggressive drug treatment with rapid onset of action is indicated, and benzodiazepines are the drugs of choice to treat these seizures.^{125,128}

Drug overdose–induced grand mal seizures are most commonly single seizures that terminate before drug therapy can be administered.¹²⁷ Seizure activity is not expected to persist; therefore, instituting long-term anticonvulsant therapy is not indicated. However, if her seizure did not stop within 1 to 2 minutes, a benzodiazepine would have been indicated.^{111,125,127} The onset of action of phenobarbital is too delayed for managing acute seizures, and phenytoin is usually ineffective in treating drug toxicity–related seizures.¹¹¹ After a seizure, the patient may become more acidotic and hypotensive.¹²⁸ Blood gases and ECG changes should be monitored immediately after a seizure.

Interpretation of Urine Screens

39. T.C.'s BP fell to 88/42 mmHg and dopamine was started. Her pH on repeat ABGs was 7.26. T.C.'s ECG normalized after the administration of 150 mL of sodium bicarbonate by IV bolus. After dopamine, her BP increased to 102/68 mmHg, and seizure activity ceased. The urine drug screen results were positive for amitriptyline and nortriptyline. Acetaminophen and alcohol were not detected in her blood. Does the presence of nortriptyline indicate that T.C. has ingested other drugs in addition to her combination of amitriptyline?

Nortriptyline is a metabolite of amitriptyline and, therefore, was identified on the urine drug screen. Metabolites, as well as the parent compound, are often identified on comprehensive urine drug screens.¹²⁴

Duration of Hospitalization

40. How long should T.C. be monitored?

T.C. should be admitted to the ICU and monitored until all evidence of CNS and cardiovascular toxicity has been reversed.¹¹¹ There is some controversy over how long symptomatic patients should be observed. Some believe symptomatic patients need cardiac monitoring for 24 hours post ingestion.¹²⁷ Some believe TCA overdose patients need to be monitored until they are symptom free for 24 hours because of a few reports of late development of symptoms.¹²⁸ However, 98% of signs of cardiotoxicity and arrhythmias are seen within the first 24 hours post TCA ingestion.^{111,126} Because the incidence of late-occurring symptoms is rare, most patients are discharged after they are fully awake.¹²⁵ After the toxicity has completely resolved, T.C. should be evaluated by a psychiatrist to determine whether she should be admitted for inpatient treatment of her suicidal tendencies.^{125–127}

Outcome of Patient T.C.

T.C. had no further seizure activity. She remained on a dopamine infusion for 8 hours and required several more boluses of IV sodium bicarbonate. The next afternoon, she started to awaken with her family at the bedside. She was tearful and expressed regret that her suicide attempt was not successful. She repeatedly told her family that they would be better off without her. Her psychiatrist saw her, and arrangements were made to transfer her to an in-patient psychiatric hospital once she was medically cleared.

ASSESSMENT OF ACETAMINOPHEN INGESTION

Mechanism of Hepatotoxicity

41. L.P., a 23-year-old woman who is about 32 weeks pregnant, presents to the ED 5 hours after ingesting 50 acetaminophen 500-mg tablets. She is depressed and hoped to end her pregnancy by ingesting acetaminophen. Her pregnancy was unplanned, and she has received no prenatal care. L.P. has vomited spontaneously four times since the ingestion and is complaining of abdominal pain; her heart rate is 100 beats/minute, BP is 100/70 mmHg, and temperature is 97.5°F. L.P. does not have any chronic diseases, and the remainder of her medical history is unremarkable. How does an overdose of acetaminophen cause toxicity?

Acetaminophen is metabolized in the liver by glucuronidation and sulfation. The mixed-function oxidase system cytochrome P450(CYP)2E1 metabolizes a portion of the acetaminophen to the highly reactive metabolite N-acetyl-p-benzoquinoneimine (NAPQI). In therapeutic doses, this metabolite is detoxified in the liver by glutathione. At toxic serum acetaminophen concentrations, the glucuronidation and sulfation metabolic pathways become saturated. Usually, NAPQI is detoxified by conjugation with glutathione, but increased amounts of the toxic metabolite deplete hepatic glutathione stores. When glutathione stores are decreased to about 30% of normal, the toxic metabolite binds to liver cells, resulting in the characteristic centrilobular hepatic necrosis seen in acetaminophen overdoses.^{141–144}

Complication of Pregnancy

42. How does L.P.'s pregnancy change the management of her acetaminophen ingestion?

Pregnancy does not alter the initial approach to the assessment or treatment of potentially toxic ingestions, and assessment should focus initially on the mother.^{144,145} Overdoses during pregnancy are often associated with attempted abortions, depression, prior loss of a child/children, potential loss of a lover, and/or economic reasons.^{146,147} Intentional ingestions of analgesics, prenatal vitamins, iron, psychotropics, and antibiotics account for 74% of the overdoses during pregnancy.

The fetus is at risk when the mother overdoses on acetaminophen because acetaminophen crosses the placenta. The fetal liver can oxidize acetaminophen to its hepatotoxic metabolite by 14 weeks of gestation.¹⁴¹ However, the ability of the fetal liver has only about 10% of the capability of the adult liver to metabolize acetaminophen. The fetal liver can conjugate acetaminophen with both glutathione and sulfate,

but detoxification by glutathione conjugation appears to be decreased.^{148,149}

In studies of maternal acetaminophen toxicity, most of the pregnant women survived without damage to themselves or their babies. However, there were also maternal and fetal deaths as a result of the overdoses.^{148,150} Acetaminophen overdoses during pregnancy did not appear to increase the risk for birth defects or adverse pregnancy outcome unless the mother suffered severe toxicity, emphasizing the need to treat the mother promptly.^{141,148}

Gastrointestinal Decontamination

43. What GI decontamination should be initiated for L.P.?

L.P.'s acetaminophen ingestion occurred 5 hours ago; therefore, the drug is likely to be totally absorbed, and no GI decontamination should be initiated.

Estimating Potential Toxicity

44. How should the potential toxicity of the acetaminophen ingestion be assessed in L.P.?

Serum acetaminophen concentrations better predict acetaminophen-induced hepatotoxicity than the dose of acetaminophen acutely ingested.^{151,152} The Matthew-Rumack nomogram (Fig. 5-1) is used in the United States to assess the potential for hepatotoxicity from acute overdoses of acetaminophen.¹⁵² The treatment line is defined by a serum acetaminophen concentration of 200 mcg/mL at 4 hours after acetaminophen ingestion and 30 mcg/mL at 15 hours post ingestion on a semilogarithmic graph.¹⁴⁴ The serum acetaminophen concentration is plotted on a graph against the time of ingestion.¹⁵² The nomogram predicts the probability that the AST or ALT will be >1,000 IU/L and can be used to guide therapy by indicating whether a specific acetaminophen

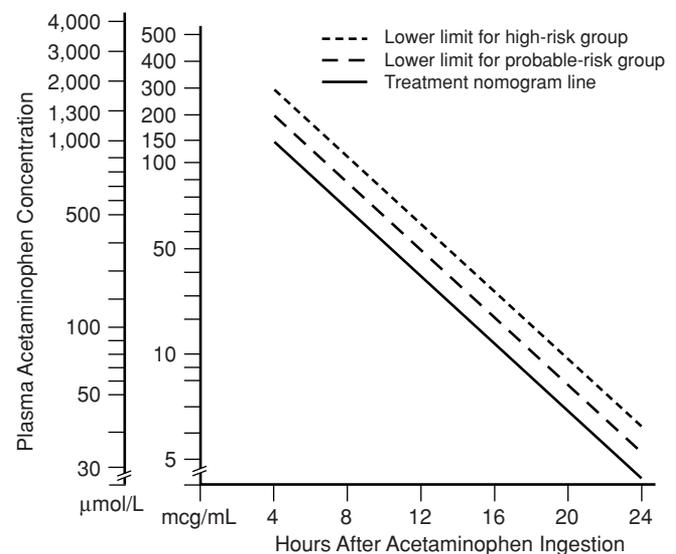

FIGURE 5-1 Nomogram for interpretation of severity of acetaminophen poisoning. (Copyright © 2001 Massachusetts Medical Society. All rights reserved.)

concentration is in the toxic range.¹⁵³ The nomogram is useful only for acute ingestions because it underestimates the potential for toxicity in chronic acetaminophen ingestions. It should be noted that although the nomogram is used to plot acetaminophen concentrations for all patients, it has been validated only in healthy nonalcoholic adult patients.¹⁴⁴

Acetaminophen Treatment Nomogram

45. When is the preferred time to measure a serum acetaminophen concentration?

Acetaminophen absorption generally is complete within 1.5 to 2.5 hours after ingestion of solid or liquid dosage forms.¹⁵² The Matthews-Rumack nomogram is not applicable before 4 hours post ingestion because it is based on complete drug absorption.¹⁵³ Most clinical laboratories can complete their assays and report acetaminophen serum concentration results within 2 hours.

Stages of Acetaminophen Toxicity

46. What are the clinical signs and symptoms of acetaminophen toxicity?

Early detection of an acetaminophen overdose is difficult because there are no characteristic early diagnostic findings. Toxicity appears in stages that may overlap and are not clear cut. About 30 minutes to 24 hours post ingestion, the patient may exhibit anorexia, nausea, vomiting, malaise, and diaphoresis that can easily be attributed to other causes. The second stage of acetaminophen toxicity occurs about 24 to 48 hours post ingestion and is the stage in which hepatotoxicity develops. Hepatotoxicity is universal by 36 hours post ingestion. An AST measurement is the most sensitive measure of hepatotoxicity. AST abnormalities always precede evidence of actual liver impairment.^{144,154,155}

In the third stage, 72 to 96 hours post ingestion, maximum liver dysfunction is evident with the return of anorexia, nausea, vomiting, and malaise. Symptoms can range from mild to fulminant liver failure with hepatic encephalopathy, coma, and hemorrhage. AST and ALT serum concentrations can be >10,000 IU/L. There are also increases in bilirubin and INR measurements, as well as abnormalities in glucose and pH readings. Death, if it occurs, is usually a result of multiorgan failure or hemorrhage caused by hepatic failure. Most deaths occur 3 to 5 days after exposure. Patients who survive this stage go into the last stage, which is recovery.^{144,154,155}

Antidotes

47. What is the antidote, how does the antidote work, and when is it most effective?

Toxicity is determined by the results of a serum acetaminophen concentration measured at least 4 hours post ingestion.¹⁵² NAC is the antidote for acetaminophen toxicity. NAC is a sulfhydryl donor that converts to cysteine, which is subsequently converted to glutathione.^{141,155,156} NAC acts as a glutathione substitute and directly combines with the toxic acetaminophen metabolite, NAPQI, reducing it to a nontoxic

cysteine conjugate.¹⁵⁴ NAC can also substitute for sulfation, which increases the nontoxic metabolism through that route as well. NAC increases intrahepatic microcirculation and is believed to possess hepatoprotective properties showing some value even after liver damage has already occurred.^{141,155}

Instituting therapy early with NAC is essential. When NAC is started within 8 to 10 hours of the ingestion, hepatotoxicity resulted in only 1.6% of cases. If NAC treatment is delayed, especially longer than 16 hours post ingestion, the efficacy of NAC treatment declines dramatically.^{141,144,148,155–157} In patients who were started on NAC more than 10 hours after ingestion, 53% developed liver damage.^{144,156,157}

Safety of *N*-Acetylcysteine in Pregnancy

48. Is NAC safe to use during pregnancy?

Acetaminophen overdose in pregnant women should be managed in the same manner as in nonpregnant patients.^{141,144,148} If the life of the mother is not saved, the fetus will not survive (unless the child is near term and is emergently delivered); therefore, attention to the mother must be foremost. NAC therapy is not contraindicated in pregnant patients and might be helpful because it crosses the placenta and can protect the fetus from hepatotoxicity.^{141,148}

NAC therapy appears to be protective for both mother and fetus.^{141,144,155,157} When used as an antidote for acetaminophen overdose in pregnancy, NAC did not appear to result in toxic effects to the fetus.^{141,144,158} The probability of fetal death was increased with the delay in NAC treatment after overdose and with acetaminophen overdose early in gestation.^{144,148,155}

Route of Administration of *N*-Acetylcysteine

49. The 6-hour acetaminophen concentration in L.P. was 245 mcg/mL. By what route should NAC be administered?

This concentration of acetaminophen at 6 hours is above the treatment line on Figure 5-1. Because there is some delay from the time of ingestion to presentation at the emergency department and L.P. has already had vomiting, it will be more difficult for L.P. to tolerate oral NAC. For this reason, IV NAC is recommended.

A FDA-approved sterile, pyrogenfree formulation of NAC is available in the United States as Acetadote.^{156,159} The use of IV NAC is not completely risk free because of a possible anaphylactoid reaction during the first dose of the IV NAC. The incidence of adverse reactions ranges from 14.3% to 23%. Asthmatic patients and patients with ectopy should receive the drug slowly and carefully, watching for symptoms of a reaction.¹⁵⁹

A majority of the adverse reactions included nausea, vomiting, urticaria, flushing, and pruritus. Bronchospasm, angioedema, hypotension, and death have occurred, although rarely so, and must be carefully monitored for when the IV route is being used.^{156,160,161} Most reactions occur during or just after the first 15 minutes of the antidote infusion and appear to be dose related.¹⁶¹ The first dose of IV NAC is usually administered over 60 minutes instead of 15 minutes, even though a study comparing adverse reactions in the two infusion rates did not show clinically significant differences.^{159,162}

Intravenous *N*-Acetylcysteine

50. How is NAC given intravenously?

The FDA-approved IV NAC protocol is the same 20-hour dosing regimen used in Europe, known as the Prescott protocol.^{156,157,159} A 150 mg/kg loading dose of NAC in 5% dextrose is infused intravenously slowly over 60 minutes while watching for symptoms of a possible anaphylactoid reaction. This is followed by a maintenance dose of 50 mg/kg infused over 4 hours, and then followed with a 100 mg/kg dose infused over 16 hours. This regimen provides a total of 300 mg/kg NAC over the 20 hours after the loading dose.¹⁵⁹ As soon as the patient is able to tolerate oral administration, the patient can be switched to oral NAC therapy. Oral therapy is as effective as IV therapy as long as it is started early in the course. In addition, oral therapy is much less expensive.¹⁶³

Oral *N*-Acetylcysteine

51. What should be the dosing regimen for oral NAC?

The standard oral NAC protocol is based on the original clinical studies.¹⁵³ The loading dose of NAC is 140 mg/kg orally using either the 10% or 20% mucolytic solutions that were formulated for inhalation therapy. Seventeen additional maintenance doses of 70 mg/kg of NAC are administered at 4-hour intervals after the initial dose for a total of 72 hours of therapy. This provides a total of 1,330 mg/kg NAC over 72 hours.^{156,164} Because oral NAC contains a sulfhydryl group, the substance has a very disagreeable taste and smell (like rotten eggs) that commonly results in nausea and vomiting for the patient. To mask the unpleasant taste and odor, NAC is diluted to a concentration of 5% using a carbonated beverage or fruit juice.¹⁵³ Because the entire dose of oral NAC passes through the liver, high concentrations are produced, which is seen as an advantage of oral therapy.¹⁵⁶

Shorter oral NAC regimens are currently being used based on the efficacy of IV therapy.^{165,166} Short course oral NAC follows the same 20-hour time course as IV NAC. Patients receive the usual 140 mg/kg oral loading dose of NAC, followed by 70 mg/kg every 4 hours for 5 additional doses (20 hours of therapy). Serum acetaminophen, liver function tests, and INR are repeated at 20 hours after the loading dose, which is after the fifth maintenance dose. If 20-hour liver function tests and coagulation studies are normal and the acetaminophen level is below the lower limits of detection, NAC can be stopped. A repeat set of liver function tests is recommended at 36 hours after ingestion. In other versions of the 20-hour NAC therapy, the dosage regimen is the same, but the laboratory studies are measured initially, at 16, 36, and 48 hours post ingestion.¹⁶⁶

Efficacy of *N*-Acetylcysteine

52. Which route of NAC administration is more effective?

There has been no proven evidence that one route of NAC administration is superior.^{155,156,167} Patient outcome after an acetaminophen overdose depends more on the time after the ingestion that treatment begins rather than on the route of administration of NAC. Patients who are started on NAC within 8 to 10 hours post ingestion, regardless of the route, rarely

develop hepatotoxicity. Patients who present late or have a delay in the time of NAC treatment have higher rates of hepatotoxicity.^{141,155,156,163,164,168}

In one comparative study of IV NAC to oral NAC therapy, both were effective in reducing hepatotoxicity when therapy was initiated within 10 hours after ingestion. Vomiting delayed oral administration of the drug, but IV administration resulted in significantly longer delays in instituting therapy.¹⁶⁸ IV NAC avoids the problems of the vomiting patient, but oral NAC is safer. Oral NAC is associated with nausea and vomiting, whereas IV NAC is associated with bronchospasm, urticaria, and angioedema during administration.^{141,155}

Starting oral NAC may take less time to prepare than IV NAC therapy and is less expensive. If the patient presents early after an acetaminophen ingestion and does not have nausea and vomiting, oral therapy would be indicated. If the patient presents late (more than 10 hours post ingestion) with signs and symptoms of hepatotoxicity along with intractable nausea and vomiting, IV NAC should be instituted at once.^{156,164}

Monitoring Efficacy of *N*-Acetylcysteine

53. How should the efficacy of NAC therapy be monitored in L.P.?

The effectiveness of NAC intervention in L.P. should be monitored by daily assessment of her acetaminophen concentration (as long as it is still measurable), AST, ALT, total bilirubin, glucose, and INR. The AST and ALT serum concentrations typically increase within 36 hours (range: 24–72 hours) after ingestion.^{155,168} As the hepatic damage continues, the liver enzymes may peak at several thousand units, even with NAC therapy. In most patients, AST and ALT begin to decline after 3 days and then return to baseline values.¹⁵⁵

In a small number of patients, usually those who presented late after the ingestion, fulminant hepatic failure may develop. In general, symptoms of severe or persistent acidosis, coagulopathy, a significantly increased serum creatinine, and grade III to IV encephalopathy are consistent with fatal outcomes in patients with fulminant hepatic failure. Liver transplantation might be a consideration for these patients.^{144,169–172}

Duration of *N*-Acetylcysteine Therapy

54. How long should NAC administration be continued?

The original NAC dosing protocol was based on an assumption that the half-life of acetaminophen was 4 hours. After five half-lives (20 hours), the acetaminophen should be metabolized and NAC could be discontinued. A NAC dose of 6 mg/kg/hour was determined to be necessary based on the rate of glutathione turnover relative to NAPQI production. To ensure that patients received an adequate NAC dose, the FDA recommended that this dose be changed to 18 mg/kg/hour for 72 hours.¹⁷³ This recommendation serves as the basis for the traditional 72-hour oral course of NAC therapy.

When using the traditional 72-hour oral course of NAC, therapy can be discontinued if the liver function tests are trending toward normal, other laboratory tests (i.e., coagulation studies, glucose, pH, bilirubin) are within normal ranges, and acetaminophen is no longer present in the serum. As long as

acetaminophen is present, it can be metabolized to NAPQI and cause further toxicity.^{155,165,173} Continued NAC will not be harmful to the patient and can be beneficial.

When using the shorter 20-hour course of oral NAC, if liver function tests and coagulation studies are normal and the 20-hour acetaminophen concentration can no longer be measured in the serum, NAC therapy can be stopped.¹⁶⁶ However, if 20-hour liver function tests or coagulation studies are abnormal, or if the 20-hour acetaminophen concentration measurement reveals acetaminophen still present in the serum, NAC therapy should be continued for at least another 24 hours. These laboratory tests should be repeated every 24 hours, and the patient's progress must be monitored closely. If the patient is not improving, NAC should be continued until the patient recovers, receives a liver transplant, or dies.¹⁴⁴

At this time, there is no consensus as to the best route of NAC administration, optimal dosage regimen, or optimal length of therapy.^{155,156,173} There is consensus, however, that NAC therapy must be instituted within 10 hours post ingestion.^{141,155,156,163,164,168} For patients who do not exhibit any signs of hepatotoxicity, shorter-course NAC therapy reduces the amount of NAC administered to the patient, decreases the quantity of laboratory tests, shortens hospital stay, and is less costly.^{156,165,173}

N-Acetylcysteine Toxicity

55. How should the toxicity of NAC therapy be monitored in L.P.?

With the exception of vomiting, oral NAC is remarkably safe and has not been associated with toxicity.^{141,155,156} Oral NAC must be retained for a minimum of 1 hour post ingestion to be successfully absorbed. If L.P. vomits within an hour after her oral NAC dose, the dose should be repeated. If she experiences protracted vomiting, administration of antiemetic drugs (e.g., ondansetron, metoclopramide) or placement of a duodenal feeding tube can improve GI tolerance.^{156,174,175} If the patient cannot tolerate oral liquids, NAC therapy should continue via IV administration.

IV NAC therapy has been associated with anaphylactoid reactions in up to 14% of the patients. Although most reactions

are not severe, bronchospasm, angioedema, and respiratory arrest have been reported.^{141,155,156,173} Patients should be monitored for allergic and anaphylactoid reactions when NAC is administered intravenously. Most reactions can be avoided by infusing the NAC loading dose slowly over 1 hour.^{141,155,156}

Outcome of Patient L.P.

L.P. continued to have nausea and vomiting and had difficulty tolerating liquids. IV NAC was continued. An obstetrics consultation was requested to evaluate L.P.'s pregnancy. Fetal monitoring was instituted during her hospital admission. A sonogram was taken of the baby. Once L.P. saw her baby's image from the sonogram, her depressed mood seemed to lift. Approximately 36 hours post ingestion, her acetaminophen level was no longer detectable, and her liver function tests showed a mild elevation of her AST at 274 U/L and an ALT of 188 U/L (normal AST and ALT values, 8–45 U/L). Her INR and total bilirubin values were normal at 0.7 seconds (normal INR time, 8–1.2) and 0.8 mg/dL (normal total bilirubin in adults, 0.3–1.0 mg/dL), respectively.

L.P. was seen by a psychiatrist. She was scheduled for counseling and prenatal classes. L.P. seemed eager to attend the classes, and she talked enthusiastically about the baby when family members came to visit. Because of L.P.'s pregnancy, the decision was made to continue NAC for a full 72-hour course with the goal of protecting the fetal liver as much as possible. Six weeks later, she had a normal delivery of a healthy 6-lb, 1-oz baby girl.

SUMMARY

Unfortunately, there is no “cookbook” method to treat all poisoned patients. Each exposure is unique: the patients, substances, symptoms, time of exposure, and circumstances differ in each case. Treatment of the poisoned patient often involves controversy because solid, evidence-based science to support a given decision is frequently lacking. When challenged with a poisoning exposure, consult with a poison control center. By calling 1-800-222-1222, the call will be connected to the poison center nearest your location. Consultation is available 24 hours a day nationwide.

RESOURCES FOR HOSPICE AND PALLIATIVE CARE 6-10**HOSPICE AND PALLIATIVE CARE****Terminology**

Hospice care and *palliative care* are similar, but distinct, terms sharing the common belief that, “the relief of suffering is a long standing, central, and fully legitimate aim of medicine.” *End-of-life care* refers to both hospice care and palliative care. The basic principle of end-of-life care is to optimize the quality of life for the patient and family in the last weeks and months of life, as well as to provide support beyond the end of life into bereavement.

Palliative care, which includes hospice care, is ideally introduced early in the disease progression to provide support to patients with a serious chronic or life-threatening illness. The word “palliation,” derived from the Latin word “pallium” (a cloak), has been defined as “treatment to reduce the violence of a disease.”¹ The World Health Organization defines palliative care as an approach that improves the quality of life of patients and their families who are facing a life-threatening illness, by preventing and relieving suffering through early identification and impeccable assessment and treatment of pain and other physical, psychosocial, and spiritual problems.² Palliative care

- Affirms life and regards dying as a normal process
- Provides relief from pain and other distressing symptoms
- Intends neither to hasten nor postpone death
- Integrates the psychological and spiritual aspects of patient care
- Offers a support system to help patients live as actively as possible until death
- Uses a team approach to address the needs of the patient and his or her family during the patient’s illness and to provide bereavement counseling when indicated³

The provision of palliative care by interdependent health team members composed of physicians, nurses, pharmacists, social workers, and others has been successful in meeting the unique needs of patients with difficult or terminal illnesses.^{4–10}

Hospice, originally a place or way station for people making a pilgrimage, is considered both a philosophy of care and a place to deliver care. *Hospice care* can be delivered in a building designated as a hospice, in the patient’s home, or in a facility where the patient resides. As a programmatic model for delivering palliative care, hospice care provides a team approach to the individualized symptom management (e.g., pain), as well as psychosocial, emotional, and spiritual support for the patient and his or her family and caregivers during the last months of life.¹¹

Medicare Hospice Benefit

According to estimates of the National Hospice and Palliative Care Organization, there were approximately 4,100 hospice programs in the United States in 2005. In that year, more than 1.2 million patients received hospice services, with approximately 800,000 deaths, or one-third of all deaths, in the United States occurring under hospice care. Hospices provided care for patients with various terminal illnesses (e.g., cancer [46% of all admissions], heart disease [12%], dementia [9.8%], debility [9.2%], lung disease [7.5%]). Pediatric patients accounted for <1% of the hospice population, although the number of pediatric programs is growing. About 80% of hospice patients were 65 years of age or older, and one-third were 85 years or older. Under the Medicare Hospice Benefit, 82.4% of hospice patients received coverage in 2005.¹¹

The Medicare Hospice Benefit, implemented in 1983, is funded from Part A (the hospital portion) of Medicare.¹² Patients are eligible for this benefit if, in the opinion of two

From references 15 and 16.

physicians (i.e., patient's primary care physician and hospice medical director), the natural course of their disease will result in death within 6 months. Other insurance payers generally follow this criterion. In electing this benefit, patients must agree to relinquish their regular Medicare benefits, as they relate to the terminal illness, and agree not to seek curative treatment. This benefit links all care related to the terminal illness to the selected hospice program, which coordinates and provides the care. Hospice programs, therefore, have some latitude to establish policy on what they will and will not pay for within the context of the Medicare Hospice Conditions of Participation.¹³ Hospice care is provided at four levels as follows, all of which can be modified based on a patient's condition or caregiving needs:

- Routine level of care (day-to-day care in the home)
- Continuous level of care used when more skilled care in the home is required
- General inpatient care (reimbursement for a hospital stay related to symptoms that cannot be managed in the home)
- Respite care (up to 5 days in a skilled nursing facility) to give the caregiver a break or respite

Patients may freely visit their primary care provider (i.e., physician or nurse practitioner) for any reason, including reasons unrelated to their terminal illness. The primary care provider will be paid directly by Medicare. Patients may choose to use their Medicare benefits for other unrelated illnesses or to revoke their election to the Medicare Hospice Benefit at any time (e.g., to pursue curative treatment or seek treatment outside the hospice plan of care). Patients may at a later date, choose to return to hospice care or change to a different hospice program, without restrictions or loss of benefits.¹⁴

Hospice programs receive a fixed daily payment to provide all care related to the terminal diagnosis (e.g., medications, supplies, durable medical equipment, procedures, home health aides, provider visits, spiritual care, bereavement services). The reimbursement rates for the four levels of hospice care under the Medicare Hospice Benefit are established each summer for the following fiscal year, effective October 1.¹⁵ A baseline reimbursement rate is set, along with an adjustment for wage differentials based on the local cost of living.¹⁶ As an example, Table 6-1 shows the different reimbursement rates for the provision of routine level of care in San Francisco, California, and Jefferson City, Missouri.

Historically, hospice reimbursement rates have been low and have not kept pace with rising costs. Programs generally have high costs at the start of care because of personnel costs involved in the admission, assessment, and development of the initial plan of care, and obtaining medications, medical equip-

ment, and medical supplies. High costs are also encountered nearer to the end of life, when new problems can appear and symptoms often intensify. In addition, it is becoming more common for patients to be referred to hospice when death is imminent. Median lengths of stay have declined, from 71.8 days during the Medicare demonstration project (1980–1982) to 26 days in 2005 (i.e., half of all patients in 2005 were on service <26 days, half were on longer).^{11,17–19} Furthermore, drug costs have outpaced increases in hospice reimbursement by at least a factor of two based on the average wholesale price (AWP) and wholesale acquisition cost (WAC). These variables (i.e., referrals to hospice later in the course of terminal illness, higher costs at the start of care, shortened lengths of stay, higher drug costs) have placed intense pressure on hospice programs to manage expenses.

Management of Drug Costs

Because it is difficult to influence the time when patients are referred to hospice, the duration of time in hospice care, or the inherently higher costs when patients are first enrolled into hospice, the management of drug costs has taken a high priority in providing cost-effective hospice care. Table 6-2 illustrates historical reimbursement rates and how drug costs have proportionately consumed a larger portion of the Medicare reimbursement received by hospice programs since the inception of the Medicare Hospice Benefit.

Most hospices pay for prescriptions obtained from retail pharmacies based on the AWP of a drug. The AWP is determined by pharmaceutical manufacturers and is published as RED BOOK products²⁷ or by First Databank.²⁸ Although widely used, the AWP is often criticized as an inflated, artificial index, with drug markups as high as 1,000% over true acquisition costs.²⁹ In 2001, drug costs consumed 13.4% of hospice reimbursement, and, presumably, this percentage has increased since that year given the disparity in the rise of drug costs compared to hospice reimbursements.³⁰ Controlling drug costs, therefore, is a critical component of fiscal management for hospice programs.

Well-trained clinical pharmacists can affect the fiscal margins of hospice programs by discouraging inappropriate use of medications, establishing evidence-based formularies, promulgating prior authorization policies for specific targeted drugs, establishing policies for adhering to the use of generic drugs, and managing the quantities of medications to be dispensed. In addition to managing drug expenditures, pharmacists provide drug information both to patients and providers, and work integrally with other members of the hospice health care team to improve the safe and effective use of medications.

Table 6-2 Drug Costs in Relation to Hospice Reimbursement (Routine Level of Care)

| Year | Unadjusted Daily Reimbursement ^{15,20–26} | % Annual Rate Increase | Average Annual Price Increase for Most Widely Used Brand Name Drugs ^{31–33} | | Hospice Per Diem Drug Costs ³⁰ | Drug Costs as % of Reimbursement ³⁰ |

| 2005 | \$121.98 | 3.3% | 6.0% | (21.6%, 2001–2004) | | |
| 2006 | \$126.49 | 3.7% | 6.2% | | | |
| 2007 | \$130.79 | 3.4% | | | | |
| 2008 | \$135.11 | 3.3% | | | | |

WAC, wholesale acquisition cost (manufacturer's list price to wholesalers); AWP, average wholesale price (determined by manufacturer).

*For a 16-year period.

Referral to Hospice

Eligibility

1. M.P. is an 89-year-old woman referred to hospice for end-stage Alzheimer's dementia (AD). She lives in a residential care home for the elderly with a hired caregiver. Her husband has been unable to care for her at home for some time because she requires full assistance with all activities of daily living. She was recently hospitalized with aspiration pneumonia and a urinary tract infection, and completed a course of intravenous vancomycin and Zosyn. Her past medical history includes osteoporosis, coronary artery disease, chronic obstructive pulmonary disease (COPD), hypercholesterolemia, and hypothyroidism. She is not oriented to person, place, or date. Her speech is unintelligible or nonsensical. She cannot feed herself, but will eat the thick pureed food that is fed to her. She is bed-bound and incontinent of urine and stool. She is agitated at times, especially at night. Her Palliative Performance Scale (PPS) is 30%. Weight is 112 lb, decreased from 135 lb a year ago, and a recent serum albumin is 2.2 g/dL. What criteria does M.P. meet for eligibility for hospice services under the Medicare Hospice Benefit?

Patients with chronic diseases (e.g., Alzheimer disease, Parkinson disease, stroke, heart failure, lung disease) can be sufficiently ill and debilitated to need custodial care, but might not be sufficiently ill to meet the definition of a terminal illness. This differentiation between terminally ill versus chronically ill requiring custodial care is important because in order to qualify for hospice services under the Medicare Hospice Benefit, patients must be at a stage where death is expected within the next 6 months. For cancer diagnoses, the presence of widespread metastatic disease may make this prognosis more easily evident. However, for other chronic diseases, this is not as clear.

The Medicare fiscal intermediaries have issued criteria to assist in the determination of eligibility for hospice care, as well as criteria to meet a 6-month terminal prognosis for a number of diseases. These criteria, or local coverage determinations (LCDs), provide guidelines for meeting an overall decline in clinical status, for meeting non-disease-specific data

to establish a baseline, for establishing the effect of comorbidities (e.g., renal failure, liver disease), and for the submission of documentation for having met criteria. Criteria have been established for patients with cancer and noncancer diagnoses, and these criteria are used in the determination of eligibility for service and reimbursement.^{14,34} Criteria for the noncancer diagnoses have been developed for amyotrophic lateral sclerosis, dementia due to Alzheimer's disease and related disorders, heart disease, HIV disease, liver disease, pulmonary disease, stroke, coma of any etiology, and acute and chronic renal disease.

The determination of whether M.P. meets eligibility requirements for Medicare Hospice Benefits must be based on the established LCDs for dementia due to Alzheimer's disease. These criteria are as follows:

- Stage 7 or beyond, according to the Functional Assessment Staging Scale
 - Stage 7A: Can speak six or fewer intelligible words in a day or during an interview
 - Stage 7B: Speech ability limited to the use of a single intelligible word in a day or during an interview
 - Stage 7C: Cannot ambulate without assistance
 - Stage 7D: Cannot sit up without assistance
 - Stage 7E: Loss of ability to smile
 - Stage 7F: Loss of ability to hold head up independently
- Unable to ambulate without assistance
- Unable to dress without assistance
- Unable to bathe without assistance
- Urinary and fecal incontinence, intermittent or constant
- No consistently meaningful verbal communication; stereotypical phrases only or the ability to speak is limited to six or fewer intelligible words
- One of the following within the past 12 months: aspiration pneumonia; pyelonephritis or upper urinary tract infection, septicemia, decubitus ulcers (multiple, stages 3 and 4), fever (recurrent after antibiotic treatment)
- Inability to maintain sufficient fluid and caloric intake with 10% weight loss during the previous 6 months or serum albumin <2.5 g/dL

Table 6-3 Palliative Performance Score (PPSv2) version 2

| PPS Level | Ambulation | Activity and Evidence of Disease | Self-Care | Intake | Conscious Level |
|-----------|-------------------|---|----------------------------------|-------------------|-------------------------------|
| 100% | Full | Normal activity and work No evidence of disease | Full | Normal | Full |
| 90% | Full | Normal activity and work Some evidence of disease | Full | Normal | Full |
| 80% | Full | Normal activity with effort Some evidence of disease | Full | Normal or reduced | Full |
| 70% | Reduced | Unable to do normal job/work Significant disease | Full | Normal or reduced | Full |
| 60% | Reduced | Unable to do hobby/house work Significant disease | Occasional assistance necessary | Normal or reduced | Full or Confusion |
| 50% | Mainly sit/lie | Unable to do any work Extensive disease | Considerable assistance required | Normal or reduced | Full or confusion |
| 40% | Mainly in bed | Unable to do most activity Extensive disease | Mainly assistance | Normal or reduced | Full or drowsy ± confusion |
| 30% | Totally bed-bound | Unable to do any activity Extensive disease | Total care | Normal or reduced | Full or drowsy ± confusion |
| 20% | Totally bed-bound | Unable to do any activity Extensive disease | Total care | Minimal to sips | Full or drowsy ± confusion |
| 10% | Totally bed-bound | Unable to do any activity Extensive disease | Total care | Mouth care only | Drowsy or coma ± confusion |
| 0% | Death | | | | |

From reference 35; adapted with permission of the Victoria Hospice Society.

The PPS score (Table 6-3) gradates the extent of disability and can be used to assist in the determination of hospice eligibility.³⁵ M.P. meets the previous criteria and is eligible for hospice because of her Alzheimer disease. She clearly is debilitated. She is unable to speak intelligently, cannot feed herself, is not oriented to time or place, incontinent of urine and stool, has lost about 20% of her weight during the past year, has a serum albumin of 2.2 g/dL, and has a PPS rating of 30% (i.e., totally bed-bound, unable to do any activity, confused). In addition, she has a number of comorbidities, experienced a recent episode of aspiration pneumonia, and finished a course of antibiotic therapy.

Medication Management

2. M.P. has no known allergies. Her current medications are memantine (Namenda) 10 mg BID, aspirin 81 mg once daily, alendronate (Fosamax) 10 mg daily, esomeprazole (Nexium) 20 mg daily, lovastatin (Mevacor) 20 mg with dinner, megestrol 40 mg/mL (Megace) 5 mL (200 mg) BID, levothyroxine (Synthroid) 0.1 mg daily, multivitamin daily, beclomethasone (Vanceril) metered-dose inhaler (MDI) one puff daily, albuterol 2.5 mg/ipratropium 0.5 mg (DuoNeb) via nebulizer Q 4 hr PRN for wheezing or shortness of breath, acetaminophen 325 to 650 mg Q 6 hr PRN for mild pain or fever, olanzapine (Zyprexa) 5 mg HS PRN for agitation, milk of magnesia 30 mL PO daily for constipation, and a bisacodyl (Dulcolax) suppository 10 mg Q 3 days PRN if no bowel movement. What is your assessment of M.P.'s medication regimen? Which medications are the hospice required to provide, and which might be discontinued?

Hospices are required to provide (pay for) medications related to the terminal diagnosis for the palliation of symptoms within the hospice plan of care (POC). The POC is the individualized plan of treatment developed for each patient formulated at the start of care and updated regularly by the interdisci-

plinary group (IDG). The Conditions of Participation mandate that the IDG be composed of a physician, registered nurse, social worker, and a pastoral or other counselor.¹³ A registered nurse coordinates the implementation of the POC. Some hospice program IDGs have incorporated a pharmacist into the group to review medication issues.

The large array of medications being taken by M.P. is similar to the lists of medications of many hospice patients. These patients are often elderly, have a long history of several chronic medical conditions, and have been taking multiple medications for past and present medical conditions. In most cases, the medication lists of patients who are admitted into a hospice program have seldom been reviewed, updated, or modified in light of the present medical situation. Admission to a hospice program represents a change in the level of care and is a most appropriate time for a review of all medications to ascertain the necessity of each, with the goal of optimizing efficacy and minimizing the potential for adverse effects, medication errors, and inappropriate costs.

Because M.P. is to be enrolled into a hospice program, her care should not be focused on curative treatments, but rather on the management of discomforting symptoms and on improving her quality of life in the time remaining. M.P.'s medications should be analyzed with the goal of simplification. Unnecessary medications should be discontinued and alternatives added to manage two or more symptoms concurrently. The following changes should be considered:

Acetaminophen. This analgesic is often helpful in relieving mild pain, particularly in immobile elderly patients. A trial of around-the-clock acetaminophen could be helpful.

Albuterol/ipratropium combination. The hospice program is not required to pay for medications related to M.P.'s COPD because it is not related to her LCD for Alzheimer's disease. Nevertheless, this combination inhalation formulation should

be continued if she is able to participate in her nebulizer treatments and they improve her breathing.

Alendronate. This bisphosphonate drug can be discontinued because the treatment of osteoporosis is not an important consideration at this terminal stage of her life nor is it in the hospice plan of care. Thus, hospice would not cover it. Furthermore, M.P. is bed-bound; alendronate should be ingested in the upright position, and patients should remain upright after taking the medication to decrease the risk of alendronate-induced esophageal irritation. Pain that she may experience from osteoporosis can be treated with analgesics.

Aspirin. The low-dose aspirin is intended to decrease the risk of cardiovascular clotting. The aspirin will not increase M.P.'s comfort or quality of life. Although the aspirin would not be covered by her Medicare benefit, it can be continued unless her primary care provider prefers its discontinuation.

Beclomethasone MDI. This patient is not functioning well cognitively (i.e., not oriented to time, person, or place) and would be unable to effectively time the inhalation of a breath to the actuation of her MDI. A systemic corticosteroid (e.g., prednisone) might improve her COPD symptoms and also improve her appetite and sense of well-being. The potential for adverse effects is modest with short-term corticosteroid use.

Bisacodyl, Milk of Magnesia. Constipation in hospice patients is common because of decreased gastrointestinal motility with advanced age, decreased physical activity, lack of adequate fiber and fluid intake, and use of constipating medications (e.g., opioids, anticholinergics, psychotropic agents).³⁶ The milk of magnesium, with an occasional bisacodyl suppository, is a good laxative regimen for this patient. If an opioid is later prescribed for M.P., a mild stimulant laxative (e.g., senna) with a stool softener (e.g., Colace) would be indicated. If stool softeners, stimulants, and saline laxatives are ineffective in resolving opioid-induced constipation, oral sorbitol or lactulose (10 g/15 mL) in 30-mL dosages can be prescribed up to four doses a day if needed. (Sorbitol would be preferred because it is more cost effective.) Mineral oil 30 mL daily is an option if the stool is hard; however, mineral oil would not be optimal for M.P. because of her recent history of aspiration pneumonia. In cases of refractory constipation, the oral ingestion of naloxone, an injectable opioid antagonist, can reverse opioid-induced constipation by antagonizing opioid effects within the gastrointestinal tract without affecting systemic analgesic because naloxone is poorly absorbed orally. The usual starting dose of naloxone for the management of opioid-induced constipation is 0.4 to 0.6 mg PO Q 6 hr. Naloxone doses of 2.4 mg PO Q 6 hr have been used, but have been associated with opioid withdrawal symptoms.³⁷

Esomeprazole. This proton-pump inhibitor (PPI) would probably be unnecessary because alendronate-induced esophageal-gastrointestinal irritation would not be an issue subsequent to its discontinuation. If a PPI, however, is needed, nonprescription generic omeprazole is preferred because it is <20% of the cost of Nexium.³⁸

Levothyroxine. This thyroid medication should be continued until M.P. is no longer able to swallow. This medication, however, would not be covered under her hospice Medicare benefit, which is based on her Alzheimer's disease, rather than other thyroid end-of-life disease (e.g., cancer).

Lovastatin. Cholesterol-lowering agents are not necessary during the last 6 months of life and should be discontinued. Lovastatin would not improve the quality of life of M.P. at this

stage of her terminal illness and would not be covered by her hospice benefit.

Megestrol. The progesterone derivative, megestrol, in doses of 400 to 800 mg daily, can substantially stimulate appetite.³⁹ If undernourished hospice patients have a desire to eat more, many hospice patients will provide megestrol, regardless of whether it will be covered by the Medicare hospice benefit. It is unclear, however, whether stimulation of appetite in a cognitively impaired patient will result in weight gain or improved nutritional status. Because the benefits in this situation are unclear, the potential of adverse effects (e.g., venous thrombosis) of megestrol needs to be considered, especially in M.P., who is not ambulatory and had been taking low-dose aspirin for prevention of cardiovascular clotting.

Memantine. Because the NMDA (N-methyl-D-aspartate) antagonist, memantine, has been modestly effective in improving performance in patients with moderate-to-severe Alzheimer's disease,^{40,41} it is probably of limited utility for M.P. It would be reasonable to discontinue M.P.'s memantine subsequent to discussion with appropriate hospice team members and M.P.'s family.

Multivitamins and other nutritional supplements are unlikely to improve M.P.'s comfort or quality of life. The discontinuation of these drugs would simplify medication administration, decrease the potential for medication errors, and decrease costs.

Olanzapine. An antipsychotic (e.g., olanzapine, haloperidol, chlorpromazine) is often prescribed to manage the agitation and confusion encountered by patients with dementia. At the time of admission to hospice, patients may be receiving atypical agents (e.g., olanzapine). Small doses of the more typical antipsychotics, such as haloperidol (Haldol) and chlorpromazine (Thorazine), can also be very useful in treating opioid-induced nausea and vomiting⁴² and would be covered by M.P.'s Medicare Hospice Benefit. Chlorpromazine would be preferable when more sedation is desired.

SYMPTOM MANAGEMENT

The American College of Physicians has developed clinical guidelines, based on a systematic review of evidence and on a report by the Agency for Healthcare Research and Quality, to improve palliative care at the end of life. These guidelines provide strong recommendations for the regular assessment of patients at the end of life for symptoms of pain, dyspnea, and depression, and for therapies of proven effectiveness for these symptoms. For patients with cancer, these include the use of opioids, nonsteroidal anti-inflammatory drugs, and bisphosphonates for pain; tricyclic antidepressants, selective serotonin reuptake inhibitors, and psychosocial interventions for depression; and opioids for unrelieved dyspnea and oxygen for short-term relief of hypoxemia. The guidelines do not address other variables of palliative care at the end-of-life or the management of other matters (e.g., nutritional support) because the quality of evidence is limited rather than because other issues or symptoms are unimportant.⁴³

3. As soon as the hospice admission and assessment is completed, the nurse develops a plan for symptom management and orders a comfort kit for M.P. Why are the components in this kit useful?

Table 6-4 Symptom Prevalence in Advanced Cancer

NR, not reported.

Some hospices use a general comfort kit that contains specific medications to manage symptoms commonly encountered by most hospice patients, or they order medications to treat anticipated symptoms for a specific patient. These medications are placed in the home or facility in which the patient resides. This facilitates the availability of medications to patients who encounter anticipated symptoms and are convenient when caregivers are instructed by the patient's primary care provider to provide the medication to the patient. Patients living with a life-threatening illness or nearing the end-of-life can encounter as many as 53 symptoms.⁴⁴ In one study, patients ($n = 176$) experienced an average of 6.6 to 6.8 distressing symptoms during the last week of life.⁴⁵ In general, the prevalence of each symptom is difficult to measure and demonstrates a high degree of variability. The prevalence of pain (43%–80%) in cancer patients, for example, varies with the primary site of advanced cancer.⁴⁵ Patients with terminal illnesses also experience nausea and vomiting (4%–44%), dyspnea (15%–79%), constipation (4%–65%), insomnia (7%–28%), delirium (4%–85%), anorexia (6%–74%), weight loss (58%–77%), and fatigue (13%–91%).^{45–47} The disparity in symptom prevalence (Table 6-4) may be attributed to a host of variables (e.g., study design, patient population, underlying disease, inconsistent definitions). The occurrence of symptoms, however, can vary significantly, even within the last week of life, and the need for frequent assessments of patients cannot be overemphasized. Morphine, lorazepam, haloperidol, prochlorperazine suppositories, and an anticholinergic agent are commonly ordered for hospice patients.

Morphine. Every hospice cancer patient should have a short-acting opioid available for the palliation of unrelieved dyspnea and pain. Although morphine can cause respiratory depression, small doses are very effective in controlling dyspnea by multiple mechanisms: vasodilation, reduced peripheral vascular resistance, inhibition of baroreceptor responses, reduction of brainstem responsiveness to carbon dioxide (the primary mechanism of opioid-induced respiratory depression), and lessened reflex vasoconstriction caused by increased blood PCO_2 levels.

Opioids can also reduce the anxiety associated with dyspnea and might also act directly on opioid receptors present in the airways^{49–51} (Table 6-5).

Hospice patients generally do not have an easily accessible port (i.e., an IV line) into which medications can be easily administered. As a result, medications are primarily administered orally and, occasionally, by sublingual, buccal, transdermal, rectal, or subcutaneous (if an infusion is warranted) routes of administration. When patients lose the ability to swallow near

More cumbersome and expensive due to use of nebulizer and nonpreserved parenteral products.</p> <p>Agents: morphine 2.5–10 mg in 2 mL 0.9% NaCl hydromorphone 0.25–1 mg in 2 mL 0.9% NaCl fentanyl 25 mcg in 2 mL 0.9% NaCl Generally given Q 2–4 hr PRN for breathlessness.</p> <p>Benzodiazepines are useful for the anxiety associated with breathlessness.</p> |

From references 49–51.

the end of life (or have a condition that precludes swallowing), the sublingual or buccal routes of administration are the most useful, especially if drugs are lipophilic. Morphine is hydrophilic, and although some of it might be absorbed across the mucous membranes, the primary clinical effect probably results from gastrointestinal absorption after the drug has trickled down the back of the throat.

Oral morphine sulfate (OMS), in a concentration of 20 mg/mL, is commonly packaged in a 30-mL bottle at the beginning of hospice care. This bottle of morphine can provide sixty 10-mg doses, and at this concentration, only 0.5 mL of morphine needs to be administered. Oxycodone or hydro-morphone, in comparable adjusted doses, can be substituted for morphine when needed.

Lorazepam. A short-acting benzodiazepine (e.g., lorazepam 0.5 mg Q 4 hr PRN) is useful for the treatment of anxiety. Patients, especially those with respiratory symptoms, can experience episodes of extreme anxiety near the end-of-life. Caution should be used in not overusing these drugs in the elderly because they can increase the risk of falling or cause paradoxical reactions and worsen delirium or restlessness.

Haloperidol. Small doses of haloperidol (e.g., 0.5–1 mg) are useful for the treatment of restlessness, delirium, or nausea and vomiting.

Prochlorperazine. When patients cannot take oral medications to manage nausea and vomiting, rectal suppositories of prochlorperazine are often effective. Although drug therapy needs to consider the etiology of the nausea and vomiting, prochlorperazine is generally a good initial agent.

Anticholinergic. As death approaches, patients can have difficulty in clearing pharyngeal secretions, and as a result, generate a sound commonly known as a death rattle.⁵² Although patients are often unconscious at this point, this sound can be very distressing to those nearby. An anticholinergic (e.g., glycopyrrolate, hyoscyamine, scopolamine, atropine) can be administered in an attempt to dry these pharyngeal secretions. This treatment modality is usually initiated after the patient has become obtunded; if begun too early, patients might develop problems with thickened bronchial or pulmonary secretions, tachycardia, delirium, dry mouth, or other adverse anticholinergic effects. Glycopyrrolate, available in a tablet or injectable formulation, is a good choice for an anticholinergic because it minimally crosses the blood–brain barrier. The 1-mg tablets could be crushed and placed under the tongue Q 8 hr. Hyoscyamine is available as oral tablets, capsules, oral sustained-release tablets, sublingual tablets, oral liquid, oral solution, and injection. Either the sublingual tablets or oral solution of hyoscyamine can be given in a 0.125- to 0.25-mg dose sublingually Q 4 hr PRN. Scopolamine-transdermal patches have a slow onset of action (blood levels are detected 4 hours after application)⁵³ and are of limited utility in this situation. The oral administration of atropine ophthalmic solution 1% is convenient to administer and is cost effective. Assuming that 20 drops is approximately equivalent to 1 mL, patients can be given 0.5 to 1 mg (1–2 drops) of the atropine ophthalmic solution PO Q 4 hr PRN. Families and caregivers must be instructed not to use this in the eye.

4. The patient's nurse has difficulty finding OMS available from a pharmacy and difficulty in finding a pharmacy willing to accept a faxed prescription. Why is morphine so difficult to obtain?

Providing relief for pain or other symptoms with opioids is often difficult due to numerous barriers. Patients and caregivers are often fearful of opioids, or mistakenly believe these medications will cause addiction or hasten death.⁵⁴ Pharmacists can create barriers by not having opioids in the pharmacy, sometimes due to fear of robbery, fear of investigation by drug regulatory agencies, or insufficient appreciation of the usefulness of opioids in pain management and palliative care.⁵⁵ Pharmacists, who are inexperienced in providing service to hospice patients, might not be knowledgeable of federal regulations governing the provision of controlled substances to hospice patients. Federal statutes, as well as most state statutes, permit prescriptions for Schedule II controlled substances for hospice patients to be faxed. According to the Code of Federal Regulations (21CFR1306.11) paragraph (g): “A prescription prepared in accordance with Sec. 1306.05 written for a Schedule II narcotic substance for a patient enrolled in a hospice care program certified and/or paid for by Medicare under Title XVIII or a hospice program which is licensed by the state may be transmitted by the practitioner or the practitioner's agent to the dispensing pharmacy by facsimile. The practitioner, or the practitioner's agent, will note on the prescription that the patient is a hospice patient. The facsimile serves as the original written prescription for purposes of this paragraph (g) and it shall be maintained in accordance with Sec. 1304.04(h).”⁵⁶

The process of ordering controlled substances for use by hospice patients at home can take many hours, and sometimes as much as an entire day. Hospice providers should anticipate possible difficulties when placing orders for Schedule II controlled-substance medications.

PAIN MANAGEMENT

5. G.G., a 40-year-old woman, is admitted to hospice with stage IV ovarian cancer, metastatic to pelvis, liver, and lungs. She was diagnosed after many months of nonspecific complaints of gastric distress and bloating. On laparotomy, she was staged as stage III and underwent a total abdominal hysterectomy and bilateral salpingo-oophorectomy and tumor debulking at that time. She has undergone subsequent chemotherapy and repeated tumor debulkings. In the past 6 months, her weight has decreased from 175 lb to 153 lb (she is 52 in. tall). Her primary complaints are constant nausea, constipation, and gripping abdominal pain, which she characterizes as burning and twisting. She quantifies the pain as 8/10 (on a 0- to 10-point scale) and describes the pain as one that moves into her groin and leg. Her family is unhappy about the drowsiness she experiences from her medications; they believe she is overmedicated. She has no known allergies. Current medications are Duragesic transdermal system 75 mcg/hour Q 72 hr, Kadian 50 mg PO once daily (sustained-release morphine intended for once daily administration), DSS 250 mg daily, Prevacid 30 mg PO daily, and lorazepam 0.5 mg Q 4 hr PRN nausea and anxiety. What is your assessment of her pain management regimen?

G.G. is currently using two long-acting opioids (i.e., Duragesic, Kadian), but is still unable to achieve relief of her pain, which is probably neuropathic pain (burning and twisting). The use of two long-acting agents is duplicative and should be replaced with one opioid. Methadone would be a better long-acting agent because it has activity against neuropathic pain (see Chapter 8). When converting the fentanyl (i.e., Duragesic

transdermal) and Kadian to methadone, the following should be considered: (a) patient compliance and ability to follow prescription directions, (b) use of an appropriate conversion formula, (c) converting a transdermal formulation of fentanyl to an oral opioid formulation, and (d) a supplemental opioid for breakthrough pain.

Due to its long and variable elimination half-life, the dose of methadone should generally be adjusted only once every 4 to 6 days, and patients must be able and willing to precisely follow directions for its use. Although formulas and tables are available to assist practitioners in the conversion of a short-acting morphine formulation to long-acting methadone, these have caused problems.^{57,58} A better, safer conversion plan is to use the methadone prescribing information⁵⁹ and to follow a general rule of thumb not to exceed 30 mg of morphine as an initial oral dose.⁶⁰

| <i>Total Daily Baseline Oral Morphine Dose (i.e., Dose of Morphine Equivalents)</i> | <i>Estimated Daily Oral Methadone Requirement (as % of Total Daily Morphine Dose)</i> |
|---|---|
| <100 mg | 20%–30% |
| 100–300 mg | 10%–20% |
| 300–600 mg | 8%–12% |
| 600–1,000 mg | 5%–10% |
| >1,000 mg | <5% |

Once the conversion is made, the calculated dose is adjusted and the dosing interval is set at every 12, 8, or 6 hours, based on patient age, previous use of opioids, and current clinical status. Clinical judgment is vital in individualizing a regimen for each patient based on his or her needs.

Before calculating the conversion to methadone for G.G., an important consideration in patients using transdermal fentanyl is an assessment of its absorption.⁶¹ The fentanyl from the transdermal system is absorbed through several layers of the skin and deposited in the subcutaneous fat, from which it is absorbed into the systemic circulation. It is generally observed that transdermal fentanyl is not effective in very thin, cachectic patients. In those cases, the conversion would be made without including the fentanyl. The patch would be removed at initiation of the first methadone dose and supplemented with medication for breakthrough pain if needed. In patients using multiple patches, one patch can be removed every 3 days. Despite weight loss, G.G. (52 in. and 153 lb) is not cachectic, and the fentanyl should be included when calculating the conversion of her current opioid dose to a comparable methadone dose. In this patient, her sustained morphine formulation (i.e., Kadian 50 mg PO TID) is equivalent to 150 mg/day of oral morphine. Her fentanyl transdermal system 75 mcg/hour is equivalent to about 150 mg of oral morphine equivalent/day. Her total morphine equivalents (MEs) per day = 150 mg + 150 mg = 300 mg. Using a 1:5 ratio for conversion of MEs to methadone, the calculated dose of oral methadone for this patient should be about 60 mg/day.

Although G.G. is relatively young, has been using opioids for some time, and has severe pain (quantified at 8/10), a methadone dose of 20 mg Q 8 hr (i.e., 60 mg/day) might be excessive. She should be treated with 15 mg of methadone PO Q 8 hr (45 mg/day), and the dose increased, if needed, based on her clinical response. This smaller initial dose would accommodate for some incomplete cross-tolerance from the morphine

and fentanyl, and for any fentanyl that remains in her system over the next several days. Patients who have been on much higher doses of opioids, alternatively, can be converted over a period of several days (e.g., converting one-third of the previous daily dose of opioid every 3 days). This is an especially useful method for converting opioid doses for thin, cachectic patients who have been on multiple transdermal patches. A clinician should be in touch with G.G. frequently during the first several days after her conversion to methadone. A telephone call should be made 2 to 4 hours after the first dose to assess for efficacy and toxicity (primarily somnolence, confusion, or nausea). If pain relief does not last for the entire dosing interval, it can be adjusted, or G.G. can be instructed to take an extra dose of methadone.

An added benefit in changing to methadone for G.G. is a financial one for the hospice. Outpatient prices for long-acting opioids based on AWP are very steep and significantly add to hospice costs. The prudent use of methadone can improve overall pain management and keep costs in check. When methadone is not appropriate, generic extended-release morphine is a good second choice. Transdermal fentanyl should be reserved for patients who cannot take oral medication or for when there are significant compliance issues. OxyContin should be used only when patients cannot tolerate morphine or have other contraindications to its use. By converting to methadone, G.G.'s daily cost for the opioid alone will decrease from \$33.41/day (i.e., \$16.86 for Kadian and \$16.55 for Duragesic) to \$0.48 or less based on the AWP prices listed in the table.

Average Wholesale Price (AWP) of Long-Acting Opioids³⁸ for 1-Day Supply (Equivalent to Oral Morphine 150 mg/day)

| | |
|---|---------|
| OxyContin 120 mg (40-mg tablets × 3) | \$17.61 |
| Kadian 150 mg (50-mg capsules × 3) | \$16.86 |
| Duragesic 75 mcg (\$49.65/patch ÷ 3 = 1 day's dose) | \$16.55 |
| Avinza 150 mg (60 mg + 90 mg, one capsule of each) | \$15.63 |
| Fentanyl transdermal 75 mcg (\$40.23 ÷ 3) | \$13.41 |
| MS Contin 75 mg BID (15 mg + 60 mg, two of each) | \$10.94 |
| Morphine-ER 75 mg BID (15 mg + 60 mg, two of each) | \$8.40 |
| Methadone 30 mg (10 mg × 3) | \$0.48 |

From RED BOOK for Windows, Thompson Micromedex, Vol. 44, April 2007.

G.G. will also need something for breakthrough pain. Some practitioners use small doses of methadone, 2.5 mg or 5 mg, as often as Q 3 hr. This is a good choice in a well-supervised (i.e., inpatient) setting with nurses familiar with the use of methadone. However, if caregivers treat methadone as if it were morphine, which is much more commonly used for breakthrough pain, the risk of overmedicating the patient is very real. This can have disastrous consequences, especially in frail, elderly patients. Because G.G. tolerated morphine well in the past, 30 mg or 1.5 mL of OMS 20 mg/mL can be prescribed Q 2–4 hr PRN for breakthrough pain because she is not in an inpatient setting.

Aggressive Symptom Management and Palliative Sedation

6. D.V., a 35-year-old man with gastric cancer metastasized to the esophagus with periaortic involvement is hospitalized. He

was diagnosed 10 months ago, and his disease has progressed despite multiple courses of chemotherapy (most recently, irinotecan and Erbitux). A double-lumen peripherally inserted central catheter line has been inserted. He has lost 65 lb since diagnosis, weighs 150 lbs at 6 ft tall, and presents with abdominal pain, severe nausea, vomiting, obstipation (intractable constipation), and general malaise. D.V. describes his pain as a 7/10 in intensity and as “burning like a knife through my stomach.” He uses 50 to 75 patient-controlled analgesia (PCA) bolus doses Q 24 hr. He has no other medical problems. D.V. is referred to hospice care because he and his wife have agreed to stop chemotherapy and do not want to go back to the hospital. He states a history of allergic reactions to morphine, ondansetron, and diphenhydramine, although these reactions are not noted. He is presently receiving hydromorphone 2 mg/hour in an IV infusion with 1 mg PCA bolus dose Q 5 min, hydromorphone 4 mg PO Q 4 hr PRN pain, fentanyl transdermal 275 mcg/hour Q 3 day, ketamine 20 mg PO Q 3 hr, senna two tablets PO BID, docusate sodium 250 mg PO BID, MiraLax 17 g PO daily, lactulose 15 mL PO PRN constipation, lorazepam 2 mg PO Q 4 hr PRN nausea or vomiting, metoclopramide 10 mg Q 6 hr PRN nausea or vomiting, promethazine 25 mg IV Q 4 hr PRN nausea or vomiting, baclofen 10 mg Q 8 hr as needed for hiccups, and Protonix 40 mg once daily. What is your assessment of his medication regimen?

D.V.’s drug regimen is unnecessarily complicated for a patient at home. It may be possible to simplify it by looking at each problem anew. His pain is poorly managed as evidenced by his complaint of pain intensity at 7/10 (on a scale of 0–10), the use of multiple opioids, and the use of excessive PCA boluses. Once an infusion with PCA dosing is started, there is no need to continue other long-acting opioids (i.e., transdermal fentanyl), or oral agents for breakthrough pain. The PCA doses are serving as the rescue doses for breakthrough pain, and pain relief should be titrated using this method alone. Once pain is well controlled, an oral long-acting agent can be considered if the patient is able to swallow. To do otherwise creates a chaotic approach. Patients reporting allergic reactions to opioids should be carefully asked to describe the precise nature of the purported allergic reaction. True allergies to opioids are rare; patients often refer to an adverse reaction as an allergy or have experienced an effect from the histamine release that is associated with opioids. Hydromorphone, especially injectable hydromorphone, is much more expensive than morphine and is best reserved for use in patients who have a genuine allergy to morphine.

Although D.V. had been prescribed ketamine Q 3 hr in the hospital, it is unrealistic to expect that this can be continued in the home setting. D.V. and his wife would probably be glad to discontinue it and replace it with an alternative due to his need to be dosed Q 3 hr.

D.V.’s constipation is currently treated with multiple medications within the same therapeutic class. It would be more prudent to maximize the use of a single agent within a category, rather than using two at less than the maximally recommended dose. D.V. can use a higher dose of senna (up to four tablets BID), and then, if necessary, add sorbitol (which is more cost effective than lactulose).

D.V. also takes multiple medications for his nausea and vomiting. The injectable promethazine can be converted to suppositories for use at home. He had also been directed to

take lorazepam for his nausea and vomiting; however, benzodiazepines are not effective antiemetics. They are given to manage the anxiety associated with nausea and vomiting, and are particularly useful in managing the anticipatory nausea and vomiting that is commonly encountered during chemotherapy administration. Metoclopramide can be useful for D.V.’s nausea and vomiting if his physical examination reveals hypoactive bowel sounds. It is also useful for treating hiccups, and the need for baclofen can be reassessed.

7. A few days after arriving home, D.V. asks his hospice nurse, “Can’t you just give me something to end it all?” He has not been sleeping well, is tired of taking so many medications, and wants to alleviate the burden he feels he is imposing on his wife.

In patients who are terminally ill, suffering may continue despite maximal palliative efforts. As a result, practitioners continually encounter patients’ requests for the ending of their lives because of overwhelming suffering. Although controversial, most clinicians are significantly averse to this practice both ethically and legally.^{62–67} State and national professional organizations have not been helpful in providing guidance for managing this ultimate end-of-life decision. Each clinician, therefore, must rely on his or her own ethics to decide whether to participate in facilitating a patient’s death. Although substantial numbers of clinicians can imagine situations in which assisted suicide would be acceptable, few are willing to actively participate in the ending of a patient’s life.^{68,69}

In a small number of patients, it may be desirable to reduce suffering by the thoughtful use of medications to induce sedation. It is not appropriate to increase opioid doses to achieve the desired sedated state. Medications used successfully to induce sedation for these patients include benzodiazepines, barbiturates, and phenothiazines. No drug or drug class is superior to any other for this use.⁷⁰

A trial of palliative sedation with lorazepam could be initiated at a rate of 2 mg/hour and gradually increased if needed to as much as 6 mg/hour. Although palliative sedation has a small potential to shorten life, the need to relieve terminal agitation could justify this risk. Palliative sedation should only be initiated as a last resort in severe cases not responsive to other palliative measures, and only after thorough discussion of the important clinical and ethical issues with the patient, family, and other clinical team members.

8. Repeated increases in the hydromorphone infusion basal rate (he is now at 25 mg/hour) had little effect on managing D.V.’s pain, and his consistent use of up to 120 PCA attempts over 24 hours reflects his continued pain. He describes the intensity of his pain as 8/10 (on a 0–10 scale). Before considering palliative sedation, what other therapeutic interventions can be implemented for D.V.?

Before considering palliative sedation, patients should be thoroughly assessed for insomnia and depression. Underlying reasons for insomnia should be explored and treated. Poor pain management is often to blame. In this patient, lidocaine 0.5 to 1 mg/kg/hour administered intravenously or subcutaneously might be useful to assist in the management of his severe neuropathic pain.^{71–75} Lidocaine purportedly interrupts pain transmission by blocking sodium channels (see Chapter 8).

Clinical Result. D.V. was started on lidocaine 1 mg/kg/hour intravenously. A bolus dose was not given due to the short

half-life of lidocaine. Overnight, his use of hydromorphone boluses dropped to one. He now reported his pain as 1/10 and slept through the night for the first time in months. Over the next 2 days, the hydromorphone basal rate was tapered to 5 mg/hour. He did not develop any toxicity, such as perioral numbness, metallic taste, or somnolence. D.V. continued on lidocaine, using no hydromorphone boluses for the next 2 weeks until he died at home, surrounded by his family.

Postoperative Nausea and Vomiting 7-9

Nausea and vomiting are unpleasant symptoms caused by self-limiting disorders or serious conditions such as cancer. These symptoms can range from mild, short-lived nausea to continuing severe emesis and retching. In addition to the suffering involved, uncontrolled vomiting can lead to dehydration, electrolyte imbalances, malnutrition, aspiration pneumonia, and esophageal tears. Nausea and vomiting often reduce food intake and can impair a person's ability to care for themselves. Significant reductions in quality-of-life scores have been demonstrated in cancer patients with chemotherapy-induced nausea and vomiting compared with patients who did not have those symptoms. Clinicians can improve the care of patients by recommending appropriate preventive medications in situations where nausea and vomiting can be predicted (e.g., postoperative, chemotherapy-induced and radiation-induced symptoms). In addition, by assuring appropriate use of rescue antiemetics, clinicians can help reduce existing symptoms.

PATHOPHYSIOLOGY AND NEUROTRANSMITTERS

The neurophysiology of the emetic response is complex, with multiple organs and neurotransmitters involved. The emetic response can be described in three phases: nausea, vomiting, and retching. *Nausea* is the subjective feeling of the need to vomit. It includes an unpleasant sensation in the mouth and stomach and can be associated with salivation, sweating, dizziness, and tachycardia. *Vomiting* is the forceful expulsion of the stomach contents through the mouth, but is preceded by the relaxation of the esophageal sphincter, contraction of the abdominal muscles, and temporary suspension of breathing. *Retching* is the rhythmic contraction of the abdominal muscles without actual emesis. It can accompany nausea, or occur before or after emesis.

Nausea and vomiting are caused by many disorders. Central nervous system (CNS) causes include increased intracranial pressure, migraine, brain metastases, vestibular dysfunction, alcohol intoxication, and anxiety. Infectious disease causes include viral gastroenteritis, food poisoning, peritonitis, meningitis, and urinary tract infections. Metabolic causes include hypercalcemia, uremia, hyperglycemia, and hyponatremia. Gastrointestinal disorders, such as gastroparesis, bowel obstruction, distention, and mechanical irritation, can cause

nausea and vomiting. Among the many medications that can cause nausea and vomiting are cancer chemotherapy, antibiotics, antifungals, and opiate analgesics.

The CNS, the peripheral nervous system, and the gastrointestinal (GI) tract are all involved in initiating and coordinating the emetic response. In the CNS, the vomiting center (VC) receives incoming signals from other parts of the brain and the GI tract and then coordinates the emetic response by sending signals to the effector organs. The VC is located in the medulla oblongata of the brain, near the nucleus tractus solitarius (NTS). The VC is stimulated by neurotransmitters released from the chemoreceptor trigger zone (CTZ), the GI tract, the cerebral cortex, the limbic system, and the vestibular system (Fig. 7-1). The major neurotransmitter receptors associated with the emetic response include serotonin (the 5-hydroxytryptamine type 3) receptors, neurokinin-1 receptors, and dopamine receptors. Other receptors involved include corticosteroid, acetylcholine, histamine, cannabinoid, gabaminergic, and opiate receptors. Many of these receptors are targets for antiemetic therapy.

In the CNS, the CTZ is located in the area postrema on the floor of the fourth ventricle in the brainstem; it lies outside the blood-brain barrier. When the CTZ senses toxins and noxious substances in the blood and cerebrospinal fluid, it triggers the emetic response by releasing neurotransmitters that travel to the VC and the NTS. The major neurotransmitter receptors involved in this pathway include serotonin, dopamine, and neurokinin-1.

The GI system also plays a large part in the initiation of the emetic response. The GI tract contains enterochromaffin cells in the GI mucosa. When these cells are damaged by chemotherapy, radiation, or mechanical irritation, serotonin is released, which can stimulate the vagal afferents as well as directly stimulate the VC and NTS. The vomiting center then propagates the emetic response.

The cerebral cortex and limbic system can stimulate the emetic center in response to emotional states such as anxiety, pain, and conditioned responses (anticipatory nausea and vomiting). The neurotransmitters involved in this pathway are less well understood. Disorders of the vestibular system, such as vertigo and motion sickness, stimulate the VC through acetylcholine and histamine release.

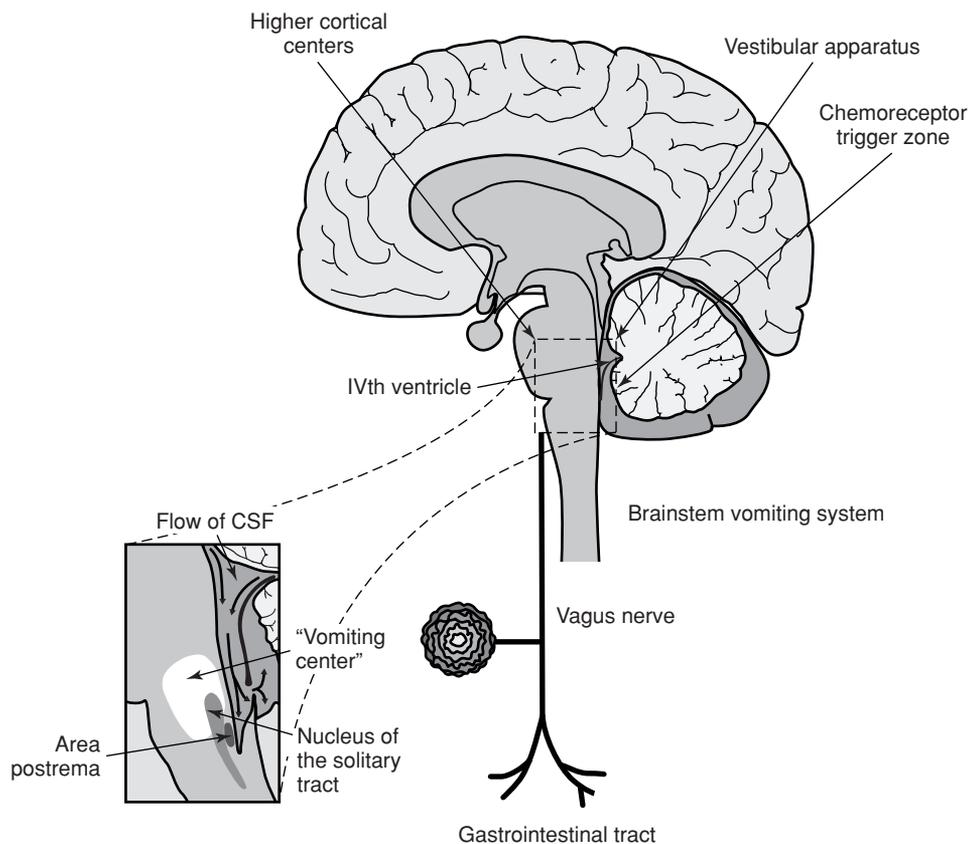

FIGURE 7-1 Vomiting center.

Pharmacotherapy of Emesis

The initial evaluation of the patient with nausea and vomiting should include the onset of symptoms; the severity and duration of symptoms; hydration status; precipitating factors; current medical conditions and medications; and food and infectious contacts. The etiology of the nausea and vomiting should be determined, if possible, so that underlying conditions can be treated specifically. Supportive treatment should be initiated, if needed, including fluid and electrolyte replacement. If the nausea and vomiting is mild and self-limited, antiemetic therapy may not be required. For others, however, the appropriate antiemetic therapy will depend on the patient and the etiology of the nausea and vomiting.

Motion Sickness

1. P.C. is a 27-year-old woman who has no significant medical history, with the exception of moderate dysmenorrhea and motion sickness associated with travel by air. Previously, she has taken dimenhydrinate before airplane trips with moderate success. She is engaged to be married, and she and her fiancé have decided on a week-long Caribbean cruise for their honeymoon. P.C. is concerned that she may also develop sea sickness and that dimenhydrinate may not control her symptoms, particularly in the event of rough weather at sea. Will P.C. be at higher risk for motion sickness?

The symptoms of motion sickness occur in response to an unusual perception of real or apparent motion. In these situa-

tions, there is sensory conflict about body position or motion through the visual, vestibular, or body proprioceptors. Acetylcholine is thought to be the primary neurotransmitter involved in signaling the VC, as is histamine, to a lesser extent. Adrenergic stimulation can block this transmission. Symptoms begin with stomach discomfort and progress to salivation changes, sweating, dizziness, lethargy, retching, and emesis. The risk of motion sickness is low in children <2 years of age. The risk is highest in children and adolescents, and higher in females than males. In some individuals, sensitivity to motion sickness diminishes over time. Travel by boat is most likely to cause symptoms; air, car, and train travel is less likely.^{1,2} Because of P.C.'s history and her travel plans, she is at high risk for recurrence of her motion sickness symptoms.

Nonpharmacologic measures or natural remedies may be useful for reducing motion sickness. These include riding in the middle of the boat or plane where the motion is less dramatic; lying in a semirecumbent position; fixing the vision on the horizon; avoiding reading; and closing the eyes if below deck or in the cabin. Many people recommend keeping active on a ship to "get their sea-legs" faster through habituation. The effectiveness of acupressure at the P6 point of the wrist (about three fingerbreadths above the wrist) is unclear. A controlled-stimulus trial compared two brands of wristbands with placebo; neither band was more effective than placebo in preventing symptoms of motion sickness.³ Studies of ginger preparations also are equivocal. The action of ginger may be of promotion of gastric emptying and not on the vestibular system.^{4,5}

2. For P.C., what medications are available to prevent and treat motion sickness symptoms?

Anticholinergic agents and antihistamines that cross the blood–brain barrier effectively prevent and treat motion sickness.^{1,2} In general, these medications are more effective in preventing than treating established symptoms. 5-hydroxytryptamine 3 (5-HT₃) receptor antagonists and neurokinin-1 (NK-1) receptor antagonists have not been shown to be effective in preventing motion sickness^{6,7} and are very costly. Nonsedating antihistamines are not as effective as other antihistamines because they do not sufficiently cross the blood–brain barrier.¹ Scopolamine has been well studied for the prevention of motion sickness and is highly effective.⁸ In a controlled trial, scopolamine was more effective than promethazine and both were more effective than placebo, meclizine, or lorazepam.⁹ Scopolamine is available as a topical patch, which bypasses the problem of GI symptoms associated with motion sickness. Scopolamine is less likely than dimenhydrinate to effect psychomotor performance.¹⁰ Table 7-1 describes medications effective for motion sickness, including the recommended use and the adult doses. The severity of the stimulus is highly dependent on the individual and also varies with the weather and with position in the plane or boat.

Because P.C. is a susceptible individual in a moderate-severe stimulus situation, prevention with a scopolamine patch applied behind the ear every 3 days, starting 6 to 8 hours before departure should be recommended. If she experiences breakthrough symptoms, dimenhydrinate or promethazine can be recommended as well. She should be advised about the poten-

tial adverse effects of these agents, which include drowsiness, confusion, and dry mouth.

Chemotherapy-Induced Nausea and Vomiting

3. M.C., a 54-year-old woman with breast cancer, is in the clinic today to receive her first cycle of “AC” (doxorubicin and cyclophosphamide) chemotherapy. She will receive paclitaxel and trastuzumab after the completion of the AC. Her chemotherapy doses will be intravenous (IV) doxorubicin 60 mg/m² plus cyclophosphamide 600 mg/m² IV for one dose on day 1 of each cycle. This will be repeated every 21 days for four cycles. M.C. does not drink alcohol or smoke. Her only other medical condition is adult onset diabetes, which is controlled with metformin and diet. She has had four children, now all grown, and had substantial morning sickness with each of her pregnancies. M.C.’s neighbor has told her that all chemotherapy causes severe nausea and vomiting. How likely is M.C. to experience nausea and vomiting?

Chemotherapy-induced nausea and vomiting (CINV) occurs in many patients receiving chemotherapy for cancer. The mechanisms of the emetic response described at the beginning of this chapter apply to CINV as well. The major neurotransmitter receptors involved in these pathways include serotonin, NK-1 and dopamine receptors. CINV can occur in different patterns. Acute phase CINV symptoms occur within a few hours after the administration of the chemotherapy. These symptoms often peak several hours after administration and can last for

Table 7-1 Medications for Prevention or Treatment of Motion Sickness in Adults

| Medication (Trade name) | Dosage | Recommended Use | Adverse Effects |
|----------------------------------|---|--|---|
| Scopolamine (Transderm-Scop) | 1.5 mg TOP behind the ear Q 3 days. Apply at least 3 hrs (preferably 6–8 hrs) before exposure | Long term exposure (>6 hrs) of moderate-intense stimulus. Alternative treatment for shorter or milder stimulus. | Dry mouth, drowsiness, blurred vision, confusion, fatigue, ataxia |
| Dimenhydrinate (Dramamine) | 50–100 mg PO Q 4–6 h (max 400 mg/day). May be taken PRN or on scheduled basis if required. | Short- or long-term exposure to mild to moderate stimulus. Alternative for other situations. | Drowsiness, dry mouth, thickening of secretions, dizziness |
| Promethazine (Phenergan) | 25 mg PO Q 4–6 h. May be taken PRN or on scheduled basis if required. 25–50 mg IM Q 4–6 h for established severe symptoms. May be taken PRN or on scheduled basis if required. | In combination with dextroamphetamine for short exposure of intense stimulus. Alternative for other situations. | Drowsiness, orthostatic hypotension, dry mouth |
| Meclizine (Antivert, Bonine) | 12.5–50 mg PO Q 6–24 h. May be taken PRN or on scheduled basis if required. | Alternative for mild stimulus or in combination for moderate to severe stimulus | Drowsiness, dry mouth, thickening of secretions, dizziness |
| Dextroamphetamine (Dexedrine) | 5–10 mg PO Q 4–6 h. May be taken PRN or on scheduled basis if required. | In combination with promethazine for short exposure of intense stimulus. | Restlessness, abuse potential, insomnia, overstimulation, tachycardia, palpitations, hypertension |
| Cyclizine (Marezine) | 50 mg PO Q 4–6 h (max 200 mg/day). May be taken PRN or on scheduled basis if required. | Alternative for mild stimulus situations. | Drowsiness, dry mouth, |

IM, intramuscular; PO, oral; PRN, as needed; Q, every; TOP, topically.

drug use. The factors associated with increased delayed CINV included age, type of antiemetics used, prior nausea and vomiting, including that with pregnancy, increasing number of chemotherapy cycles, previous acute CINV, and nonprescription drug use.

Chemotherapy-related factors also predict the likelihood of symptoms. Factors, such as shorter infusion time, higher dose, and more chemotherapy cycles, increase the risk of CINV. With multiday chemotherapy regimens, the symptoms usually peak on about the third to fourth day of chemotherapy, when the acute symptoms caused by the later days' doses are overlapping with the delayed symptoms from the first days' doses. The most predictive factor, however, is the chemotherapy agent's inherent ability to cause CINV, or its emetogenicity.^{11–14} Antineoplastics that are most likely (>90% of patients) to cause symptoms are classified as highly emetogenic chemotherapy. Agents that cause nausea and vomiting in 30% to 90% of patients are classified as moderate-risk agents. Low emetogenicity agents cause symptoms in 10% to 30% of patients. Other chemotherapy agents have a minimal risk, causing CINV in <10% of patients. Table 7-2 lists selected chemotherapy agents in the various emetogenicity classes. References differ in the estimation of emetic risk for some antineoplastic agents. Note, for some agents, that the emetogenicity depends on the dosage used.

Certain antineoplastic agents are more likely to cause delayed CINV symptoms. These include cisplatin, carboplatin, cyclophosphamide, doxorubicin, epirubicin, and ifosfamide. Patients receiving more than one of these agents are at high risk for delayed symptoms.

Most chemotherapy agents are given in combinations, rather than as single agents. Estimating the emetogenicity of chemotherapy combinations has always been difficult. One method¹⁵ using a mathematical formula for estimating the total effect, is based on a five-level classification of emetogenicity. No method has been prospectively evaluated or unanimously accepted, however. Chemotherapy regimens that contain cyclophosphamide and an anthracycline, such as doxorubicin, are highly emetogenic (symptoms in >90% of patients.) The primary literature should be examined for the incidence of nausea and vomiting for established chemotherapy combination regimens. In the absence of specific information regarding the risk of CINV in certain combinations, the antiemetic regimen should be geared toward the chemotherapy agent with the highest emetogenicity level given on that day.^{11,14,16} For example, for a chemotherapy combination with one agent with a high risk and one with a moderate risk, the antiemetic regimen should be appropriate for the high-risk chemotherapy agent.

Antiemetic efficacy, or complete emetic response, is usually defined as no emesis and no nausea or only mild nausea in the first 24 hours after chemotherapy administration. With currently recommended antiemetic regimens, most but not all patients will be protected from emesis in the acute phase (first 24 hours). Nausea, however, is more difficult to control. In addition, delayed CINV symptoms are more difficult to prevent.

4. Our patient, M.C., is at high risk for acute CINV. Her personal risk factors include female gender, history of morning sickness with pregnancy, and being a nondrinker. The chemotherapy

regimen she will receive (cyclophosphamide and doxorubicin) is highly emetogenic in the acute phase and also has a high risk of delayed symptoms. What antiemetics are available for M.C.?

Appropriate antiemetic therapy is based on the emetogenicity of the chemotherapy regimen and patient risk factors. Because the pathophysiologic response of nausea and vomiting involves many neurotransmitters, combinations of antiemetics from different therapeutic classes will be more effective in most situations than a single agent. The predominant classes of antiemetics used for CINV include serotonin (5HT3) antagonists, the neurokinin-1 antagonist and corticosteroids.

5-HT3 Antagonists

The 5-HT3 antagonists inhibit the action of serotonin in the GI tract and the CNS and thereby block the transmission of emetic signals to the VC. Serotonin antagonists are both highly effective and have minimal side effects. Several agents in this class are now available: ondansetron, granisetron, dolasetron, and palonosetron. Dosages of these agents are shown in Table 7-3. These agents have been widely studied and some commonalities have emerged. All of these agents have a threshold effect and so a sufficiently large dose must be given to block the relevant receptors. The dose-response curve is relatively flat, such that escalating doses do not enhance efficacy. When given in appropriate doses, all of these agents have similar efficacy for acute CINV, with response rates ranging from about 60% to 80%, depending on study design.^{11,14,17–19} The effectiveness of each of these agents is enhanced by the addition of dexamethasone. The response rate increases by about 15% to 20% in regimens that include dexamethasone and a 5-HT3 antagonist.^{20,21} Oral and IV 5-HT3 administration are equally effective assuming the patient can take oral medications. The side effects of the 5-HT3 antagonists are similar and fairly mild and include headache, constipation, diarrhea, and transient elevations of liver function tests. These agents are one component of optimal antiemetic prophylaxis for acute CINV, but are not more effective than agents from other classes (notably dexamethasone, aprepitant, or prochlorperazine) for delayed CINV.^{22–25} Serotonin antagonists, therefore, are not recommended for delayed CINV.

Palonosetron, the newest member of the serotonin antagonist family, is distinguished by its longer elimination half-life than others in its class. Palonosetron was compared with single doses of ondansetron or dolasetron in two trials of moderately emetogenic chemotherapy and in one trial of highly emetogenic chemotherapy.^{26–28} In each of these trials, palonosetron resulted in the same or higher complete response rate (no emesis and no use of rescue medication in the acute or delayed phase) than that of the comparator agents, but methodologic concerns limit the conclusions. In two of these trials, corticosteroid administration was allowed, but not required, although dexamethasone is recommended for prophylaxis for moderately and highly emetogenic chemotherapy. Prophylaxis with dexamethasone for delayed symptoms was not included. These trials essentially compared palonosetron with placebo for the delayed phase, because the comparator was not continued for the 3 days. Palonosetron has not been compared with other serotonin antagonists where dexamethasone dosing was included for both the acute and delayed phase.¹⁴ In addition, it has

Table 7-3 Antiemetic Agents for Chemotherapy-Induced Nausea and Vomiting (CINV)

| Medication (Trade name) | Class | Indication/Phase | Dose in Adults (doses should be given 30–60 minutes before chemotherapy) | Dose in Pediatrics |
|------------------------------|-------------------------------|--|--|--|
| Aprepitant (Emend) | NK-1 antagonist | Acute/Delayed | 125 mg PO on day 1, 80 mg PO on days 2,3 | |
| Dexamethasone (Decadron) | Corticosteroid | Acute (high emetogenicity) | 12 mg (if with aprepitant) or 20 mg IV or PO | |
| | | Acute (moderate emetogenicity) | 8 mg IV or PO | |
| | | Acute (low emetogenicity) | 4–8 mg IV or PO | |
| | | Delayed | 8 mg PO daily days 2–4 (when with aprepitant) | |
| Dolasetron | Serotonin antagonist | Acute | IV: 100 mg or 1.8 mg/kg PO: 100–200 mg | 1.8 mg/kg IV or PO |
| Dronabinol (Marinol) | Cannabinoid | Breakthrough | 2.5–10 mg PO TID to QID | |
| Droperidol (Inapsine) | Butyrophenone | Breakthrough | 0.625–1.25 mg IV Q 4–6 h PRN | 50–60 mcg/kg/dose |
| Granisetron (Kytril) | Serotonin antagonist | Acute | IV: 1 mg or 0.01 mg/kg PO: 2 mg | 0.01 mg/kg/dose |
| Haloperidol (Haldol) | Butyrophenone | Breakthrough | 0.5–1 mg PO, IV, or IM Q 6 h PRN | |
| Metoclopramide (Reglan) | Dopamine antagonist | Breakthrough | 10–20 mg PO or IV Q 6 h PRN | 0.1 mg/kg/dose |
| Lorazepam (Ativan) | Benzodiazepine | Breakthrough | 0.5–2 mg PO, IV, IM, or SL Q 6 h PRN | 0.05 mg/kg/dose |
| Nabilone (Cesamet) | Cannabinoid | Refractory CINV | 1–2 mg PO BID (max 2 mg PO TID) | |
| Olanzapine (Zyprexa) | Serotonin/dopamine antagonist | Acute/delayed/breakthrough | 2.5–10 mg PO QHS | |
| Ondansetron (Zofran) | Serotonin antagonist | Acute (moderate or high emetogenicity) | IV: 8–12 mg or 0.15 mg/kg PO: 16–24 mg PO | 0.15 mg/kg Q 4 h ×3 doses or 0.45 mg/kg single dose |
| Palonosetron (Aloxi) | Serotonin antagonist | Acute/delayed | IV: 0.25 mg | |
| Prochlorperazine (Compazine) | Dopamine antagonist | Breakthrough | 5–10 mg (up to 20 mg) PO, IV, IM Q 4–6 h PRN | >2 yo: 0.1–0.15 mg/kg/dose |
| Promethazine | Dopamine antagonist | Breakthrough | 12.5–25 mg PO, IV, IM, PR Q 4–6 h PRN | >2 yo: 0.25–1 mg/kg/dose |

BID, twice daily; IM, intramuscular; IV, intravenous; PO, oral; PR, rectal; PRN, as needed; QHS, every night; QID, four times daily; TID, three times daily. Adapted from references 11, 14, 16, with permission.

not been compared with regimens containing other 5-HT₃ antagonists (in the delayed setting), dexamethasone, and aprepitant. One group of researchers described a three-drug combination of palonosetron, dexamethasone, and aprepitant in a noncomparative, phase II study, and found that the three-drug combination was safe and effective.²⁹ Whether palonosetron is equivalent or superior to other 5-HT₃ antagonists will be determined by trials that compare palonosetron with a 5-HT₃ antagonist, with both treatment arms consisting of dexamethasone and aprepitant in the acute and delayed phases.

Palonosetron is normally administered as a single 0.25 mg IV dose before chemotherapy. Repeated dosing within 1 week is not approved by the U.S. Food and Drug Administration (FDA). With its long elimination half-life, palonosetron should be effective for at least a few days, but little data are published regarding repeated doses. Palonosetron has been studied in a three-dose regimen (administration on days 1, 3, 5) for multiday chemotherapy in a noncontrolled trial published only in abstract form.³⁰ This regimen appeared to be safe and effective, but was not compared with any other regimen.

Other serotonin antagonists, including tropisetron, ramosetron, lerisetron, and others,^{31,32} are under development and study.

It is difficult to identify the serotonin antagonist with the highest overall cost-effectiveness because drug acquisition costs vary between the inpatient and outpatient clinics and from institution to institution. Costs of the different agents should be compared at each practice site to determine the preferred agent.

Corticosteroids

The mechanism of action of corticosteroids as antiemetics has not been fully determined. Some suggest that corticosteroids may decrease serotonin release, antagonize serotonin receptors, or activate corticosteroid receptors in the NTS of the medulla in the CNS.²⁰ Many studies validate the effectiveness of corticosteroids in the prophylaxis of CINV symptoms. Efficacy with both dexamethasone and methylprednisolone has been described, but dexamethasone is much more widely studied and utilized. Dexamethasone improves the antiemetic

control of serotonin antagonists by about 15% to 20%.^{20,21} In addition, dexamethasone is one of the cornerstone agents used to prevent delayed CINV. It is inexpensive and available in both IV and oral formulations.

The optimal dose of dexamethasone with different emetic stimuli has been studied in two controlled trials. For moderately emetogenic chemotherapy in the acute phase, a single 8-mg dose was as effective as larger doses or prolonged administration.³³ In the setting of highly emetogenic cisplatin-based chemotherapy, higher doses of 12 or 20 mg were superior to doses of 4 and 8 mg.³⁴ If used with aprepitant, the lower 12-mg prechemotherapy dose is recommended because of inhibition of steroid metabolism by aprepitant (see the neurokinin-1 receptor antagonist section).¹⁴ For prevention of delayed CINV symptoms, the most commonly used dose of dexamethasone is 8 mg twice daily on days 2 and 3 after chemotherapy without aprepitant. The dose should be reduced to 8 mg daily when used with aprepitant.

Corticosteroids are sometimes underutilized because of the potential risk of side effects. The adverse effects of corticosteroids include insomnia, jitteriness, increased appetite, GI distress, and perineal irritation if the IV dose is infused too quickly.²⁰ For most patients, however, dexamethasone is well tolerated, especially because the therapy is typically short term at lower doses. Hyperglycemia can occur, especially in patients with pre-existing diabetes. These patients should be advised to monitor their glucose levels more frequently and contact their practitioner if the levels remain elevated. In the nondiabetic patient, hyperglycemia is rare. Tapering the corticosteroid dose after the end of treatment for CINV is usually unnecessary because the duration of therapy is short. Rare patients who have withdrawal-like symptoms may, however, benefit from a short taper.

Corticosteroids also have antitumor properties and are a part of the antineoplastic regimen for some malignancies, such as lymphoma, lymphoid leukemia, and myeloma. In these cases, no need is seen to administer additional dexamethasone for the antiemetic protection; however, the corticosteroid should be administered before the rest of the chemotherapy to provide antiemetic activity. If aprepitant is part of an antiemetic regimen in a situation where the corticosteroid is given for antitumor reasons, the dose of the corticosteroid should not be reduced.¹⁴

Neurokinin-1 Receptor Antagonists

The potential use of NK-1 receptor antagonists as antiemetics became apparent when the role of substance P in the peripheral and CNS was recognized in the emetic stimulus pathway. Aprepitant, the first NK-1 receptor antagonist available, has been studied for the prevention of CINV caused by moderately and highly emetogenic chemotherapy. Aprepitant is usually given as a 3-day oral regimen 125 mg on day 1 and 80 mg on days 2 and 3. Early trials determined that aprepitant could not replace a serotonin antagonist, but that it would be used best in conjunction with corticosteroids and a serotonin antagonist.

Aprepitant was studied in two phase III trials for the prevention of CINV with highly emetogenic cisplatin-based chemotherapy.^{35,36} In both of these trials, aprepitant (or placebo) was added to a standard antiemetic regimen of ondansetron on day 1 and dexamethasone on days 1 through 4. The patients treated with aprepitant showed improved complete

response rates (no emesis, and no use of rescue medications) by about 20%, in both the acute and delayed phases. In a recent reanalysis,³⁷ investigators found that the aprepitant-containing regimens were more effective in women than in men, which is fortunate because women have more acute and delayed symptoms than men.

Aprepitant was also studied in the prevention of CINV caused by moderately emetogenic chemotherapy.³⁸ Patients in the treatment arm were given aprepitant, ondansetron, and dexamethasone on day 1 plus aprepitant on days 2 and 3. The patients in the control arm were given ondansetron and dexamethasone on day 1, plus ondansetron on days 2 and 3. The rate of complete response (no emesis and no use of rescue medications) was higher in the aprepitant arm in both the acute and delayed phases. Dexamethasone, however, is one of the most effective agents for delayed CINV symptoms and it was not used in either arm for the delayed phase. In essence, aprepitant was not compared with the standard of care for the delayed phase. The results may not have been significant if a proper comparator had been used.

The effects of aprepitant seem to be maintained over four cycles of chemotherapy in patients receiving moderately emetogenic chemotherapy.³⁹ The addition of aprepitant to the antiemetic regimen on cycle 2 (even when it was omitted from cycle 1) also seems to improve control of CINV symptoms.^{40,41} For patients who have had inadequate response to an antiemetic regimen that did not include aprepitant, it may be useful to add it in later cycles.

The efficacy of aprepitant for the control of delayed CINV symptoms was confirmed in a trial that included 489 patients comparing a standard aprepitant regimen (aprepitant, ondansetron, and dexamethasone on day 1, followed by aprepitant and dexamethasone on days 2 and 3, and dexamethasone on day 4) to a nonaprepitant regimen (ondansetron and dexamethasone on days 1 through 4) in patients receiving highly emetogenic chemotherapy.⁴² The aprepitant-containing regimen offered superior control of CINV in the acute, delayed, and overall time periods. The study confirmed that aprepitant is a better choice than a serotonin antagonist during the delayed phase of CINV.

Aprepitant is generally well tolerated with mild side effects, including fatigue, hiccups, headache, and diarrhea.^{35,36,38,42} The overall adverse effects in standard aprepitant-containing regimens are not appreciably different from regimens without aprepitant.^{35–38,42} A potential disadvantage of aprepitant is the unavailability of an IV formulation.

Aprepitant is metabolized by the CYP3A4 enzyme system. It is a moderate inhibitor and inducer of CYP3A4, and an inducer of CYP2C9.^{11,43,44,45} Consequently, several drugs potentially interact with aprepitant. The most commonly encountered interaction is with the corticosteroids. Aprepitant increases the area under the curve of dexamethasone such that the dexamethasone dose (when used as an antiemetic) should be reduced by about one-half of the usual dose when these drugs are used together.⁴⁶ The effect is greatest when the corticosteroid is administered orally.^{11,43–47} When the corticosteroid is also given as part of the antitumor regimen, however, the dose should not be reduced because of concern that the antineoplastic activity might be compromised.¹⁴ Aprepitant may also enhance warfarin metabolism by inducing CYP2C9. International normalized ratio (INR) values in patients treated

with warfarin and the standard aprepitant regimen are significantly reduced, especially on day 8 of the chemotherapy cycle.⁴⁸ The patient's coagulation status after aprepitant administration should be monitored, especially during the 7- to 10-day time period. The dosage of warfarin should be adjusted if the INR is high or low. Several chemotherapy agents (paclitaxel, etoposide, paclitaxel, ifosfamide, irinotecan, imatinib, vinca alkaloids, and others) are metabolized by the CYP3A4 enzyme system and the metabolism of these agents may be altered by aprepitant. Aprepitant was used in clinical trials with some of these agents. Caution is warranted, however, because the clinical relevance of this effect is not known.¹⁸ Other drugs that may interact with aprepitant include oral contraceptives, itraconazole, terfenadine, and phenytoin.^{43,44,47}

A new investigational NK-1 receptor antagonist, casopitant, has been studied for the prevention of CINV symptoms in patients receiving moderately and highly emetogenic chemotherapy in preliminary phase II/III trials using doses of 50 to 150 mg daily.^{49,50} The initial results suggest that further trials with this agent are warranted.

Other Antiemetics

Medications from other drug classes have also been used as antiemetics for CINV. These include dopamine antagonists (prochlorperazine, promethazine), benzodiazepines (lorazepam), butyrophenones (droperidol, haloperidol), benzamides (metoclopramide), and cannabinoids. Many of these agents were used widely until more effective antiemetic agents became available. These agents remain useful for breakthrough symptoms or for patients who are refractory to standard therapy. The appropriate dosages and indications for these agents are shown in Table 7-3. Many of these agents have more side effects than standard agents, especially sedation and extrapyramidal side effects, such as dystonia and akathisia. Lorazepam is commonly used as a rescue antiemetic. Its mechanism of action as an antiemetic is not completely understood, but it may involve disruption of the cortical impulses to the VC, as well as anxiolytic activity. Because each patient has an individualized response to medicines, additional options for rescue antiemetics are needed.

Olanzapine is an atypical antipsychotic agent that antagonizes several serotonin and dopamine receptors as well as other neurotransmitter receptors. Its antiemetic action was first described in patients with refractory nausea or vomiting and advanced cancer.⁵¹⁻⁵³ Preliminary studies have shown that olanzapine prevents acute and delayed CINV associated with moderately and highly emetogenic chemotherapy.⁵⁴⁻⁵⁷ In these trials, the complete response rate to antiemetic regimens containing olanzapine with dexamethasone plus either granisetron or palonosetron was 100% in the acute phase and 75% to 80% in the delayed phase. The usual dose of olanzapine ranges from 2.5 to 10 mg daily for control of refractory symptoms. The dose used in the CINV studies was 5 to 10 mg daily starting up to 2 days before the chemotherapy cycle. The common side effects of olanzapine include sleepiness, dry mouth, and dizziness, although these were not significant in the preliminary reports. Olanzapine is a good choice for control of refractory CINV symptoms, but further study is warranted before it should be routinely recommended for prophylaxis of CINV.

Cannabinoids have long been used for refractory nausea and vomiting. This is based on the effect of the CNS cannabinoid

receptors on the CTZ, the NTS, and the VC.⁵⁸ Small trials have shown conflicting effectiveness in the prevention of CINV.^{59,60} A new oral cannabinoid, nabilone, has recently been approved for the treatment of CINV in patients who do not respond adequately to other antiemetics.⁵⁸ Cannabinoids are associated with side effects, such as drowsiness, dry mouth, dysphoria, vertigo, and euphoria. Although some patients have a clear preference for, and good response to, cannabinoids, side effects and a lack of pronounced efficacy limit their use in the general population of chemotherapy patients. These agents are usually reserved for patients who do not have adequate relief from other rescue medications, such as phenothiazines, benzodiazepines, or olanzapine.

Another agent being investigated for the control of CINV is gabapentin in doses of 300 to 900 mg daily for 5 days or more, combined with standard antiemetic regimens.^{61,62} In preliminary studies, gabapentin improved control of CINV symptoms and was well tolerated. Further studies are needed to define the role of gabapentin in CINV.

5. M.C. is at high risk for acute nausea and vomiting and for delayed symptoms as well. What would be the most appropriate antiemetic regimen for M.C.?

The optimal prophylactic antiemetic regimens depend on the emetic risk of the chemotherapy regimen. Treatment guidelines have been developed by several groups, including the American Society of Clinical Oncology (ASCO), the National Comprehensive Cancer Network (NCCN), and the Multinational Association of Supportive Care in Cancer (MASCC). These evidence- and consensus-based guidelines, which are largely in agreement with their recommendations, are summarized in Table 7-4.

For multiday chemotherapy regimens, prophylaxis with a serotonin antagonist and dexamethasone should be offered for each day that moderately or highly emetogenic chemotherapy is administered.^{11,14,16} Aprepitant might be useful in these situations, although it has not been studied in this context. Preliminary studies indicated that aprepitant was safe to administer for a total of 5 days. If multiday chemotherapy regimens have a high risk of delayed symptoms, then therapy for the delayed symptoms should be continued for at least 2 to 3 days after the last chemotherapy administration.

For M.C., the best regimen would include a single dose of a serotonin antagonist plus dexamethasone 12 mg oral or IV plus oral aprepitant 125 mg on day 1, then oral dexamethasone 8 mg on days 2 through 4 and oral aprepitant 80 mg on days 2 and 3. She should be offered medications for breakthrough CINV symptoms, such as prochlorperazine and lorazepam. She should be warned of the potential adverse effects of dexamethasone, especially hyperglycemia, and counseled to check her blood sugars more frequently and contact her physician if they remain elevated. M.C. should be advised to maintain a record of her symptoms and contact her physician if the breakthrough medications are not working or if she cannot keep fluids down.

Modern antiemetic regimens can achieve complete emetic control in about 70% to 90% of patients, but the response rate is lower for delayed CINV symptoms. If CINV symptoms are not adequately controlled, alterations in the antiemetic regimen should be made for the next cycle. Suggestions include

Table 7-4 Recommended Antiemetic Regimens by Emetogenicity of Chemotherapy Regimen

| <i>Emetogenicity Potential</i> | <i>Acute Phase (doses should be given 30–60 min before chemotherapy)</i> | <i>Delayed Phase</i> | <i>Breakthrough</i> |
|---|--|--|--------------------------------------|
| High (>90% of patients) | Day 1: single dose 5-HT3 antagonist + dexamethasone + aprepitant | Dexamethasone days 2–4 + aprepitant days 2–3 | One to two agents for PRN use |
| Moderate (30%–90% of patients) with high risk of delayed CINV (i.e., cyclophosphamide plus doxorubicin) | Day 1: single dose 5-HT3 antagonist + dexamethasone + aprepitant | Dexamethasone days 2–4 + aprepitant days 2–3 | One to two agents for PRN use |
| Other moderate regimens (30%–90% of patients) | Day 1: single dose 5-HT3 antagonist + dexamethasone | None | One agent for PRN use |
| Low (10%–30% of patients) | Single dose dexamethasone or metoclopramide or prochlorperazine | None | Either none or one agent for PRN use |
| Minimal (<10%) | None | None | Usually none |

5-HT3, 5 hydroxytryptamine type 3; CINV, chemotherapy-induced nausea and vomiting; PRN, as needed. Adapted from references 11, 14, 16, with permission.

upgrading to the next higher emetogenicity level recommendation, adding aprepitant if not already given, and scheduling agents from other pharmacologic classes.

Many patients may benefit from nondrug therapy for CINV symptoms, especially for anticipatory nausea and vomiting and anxiety. Techniques include guided imagery, hypnosis, relaxation techniques, systematic desensitization, and music therapy.⁶³ Acupuncture and acupressure techniques have been investigated for use in CINV and some patients benefit from their use. The use of acupressure devices that stimulate the P6 point on the wrist have been proposed; however, in a controlled trial in patients with breast cancer, it was not found to be helpful.⁶⁴ If patients are troubled by CINV symptoms, it is recommended that they refrain from heavy meals for 8 to 12 hours before the chemotherapy. They should also avoid heavy, greasy foods and food with strong aromas. Chewing gum can mask the metallic taste, which some patients perceive. Dry, salty foods can also help settle the stomach.

Radiation-Induced Nausea and Vomiting

6. E.G. is a 54-year-old man with newly diagnosed head and neck cancer who will receive radiation therapy concurrently with chemotherapy containing cisplatin and fluorouracil. His daily (Monday through Friday) radiation treatments will last for 6 weeks. He has a heavy smoking history (35 pack-years) and “quit” last week, although it is not going well. After E.G.’s nausea and vomiting from the chemotherapy subsides, is he at risk for developing radiation-induced nausea and vomiting?

Radiation therapy can cause nausea and vomiting through the same basic pathways that chemotherapy does. Radiation induced nausea and vomiting (RINV) affects 40% to 80% of patients receiving radiation therapy. The risk of RINV depends on several factors, namely the size and area to be irradiated. Patients whose radiation areas >400 cm² are more likely to have significant RINV symptoms. Total body irradiation (associated with hematopoietic stem cell transplantation) causes RINV in >90% of patients. Patients receiving radiation to the upper abdominal area experience nausea and vomiting about 50% to 80% of the time. Radiation to other areas of the body is less likely to cause nausea and vomiting. E.G is not at high

risk for developing RINV, because his radiation site will be in the head and neck region.

Just as with CINV, symptoms caused by radiation can be prevented with serotonin antagonists, corticosteroids, or both. Evidence- and consensus-based recommendations have been published by several multidisciplinary groups and are shown in Table 7-5. High-risk RINV is best treated with a combination of a serotonin antagonist and a corticosteroid.^{65,66,67} Patients receiving radiotherapy in the moderate risk group can receive either prophylaxis or rescue therapy with a serotonin antagonist. Because E.G. is unlikely to develop radiation-induced symptoms, he does not need prophylaxis with a serotonin antagonist. If he develops symptoms later, rescue therapy with a dopamine antagonist or a serotonin antagonist should be offered.

Postoperative Nausea and Vomiting

7. E.W. is a 48-year-old woman who is scheduled for a laparoscopic cholecystectomy. The scheduled duration of her surgery is less than an hour. Her medical history includes hypertension. She does not have a history of motion sickness and she is a nonsmoker. E.W. has never had surgery before. Her sister-in-law had severe

Table 7-5 Prophylaxis for Radiation-Induced Nausea and Vomiting

| <i>Emetic Risk</i> | <i>Radiation Area</i> | <i>Recommendation</i> |
|--------------------|---|---|
| High (>90%) | Total body irradiation | Prophylaxis with a serotonin antagonist + dexamethasone |
| Moderate (60%–90%) | Upper abdomen | Prophylaxis with a serotonin antagonist |
| Low (30%–60%) | Lower thorax, pelvis, cranium (radiosurgery), craniospinal region | Prophylaxis or rescue with a serotonin antagonist |
| Minimal (<30%) | Head or neck, extremities, cranium, breast | Rescue with a dopamine antagonist or a serotonin antagonist |

Adapted from references 11, 14, 16, 65, with permission.

nausea and vomiting after an outpatient surgical procedure last year and E.W. is worried that it might happen to her. What is E.W.'s risk of having postoperative nausea and vomiting? What can be done to reduce her risk and how can symptoms be treated if they occur?

Postoperative nausea and vomiting (PONV) is a common complication of surgery, affecting 25% to 30% of all patients, but up to 80% of patients in high risk groups. In surgical patients, PONV can lead to hospitalizations, stress on the surgical closure, hematomas, and aspiration pneumonitis. Patient-related, surgical and anesthetic factors can increase the risk of PONV.^{68,69} Some of the patient risk factors include female gender, history of motion sickness, nonsmoking status, obesity, and a history of PONV. Some surgical risk factors for PONV include long duration of surgery and type of surgical procedure (e.g., laparoscopy, ear-nose-throat procedures, gynecologic surgeries, and strabismus repair). Anesthetic risk factors include the use of volatile anesthetics or nitrous oxide (as opposed to IV propofol) and the use of intraoperative or postoperative opioids. Children are twice as likely to develop PONV as adults.^{68,70} The risk increases with the child's age but declines after puberty.^{68,70}

Certain anesthesia practices may reduce the risk of PONV. These include use of regional anesthesia (instead of general anesthesia), use of intraoperative oxygen, hydration and avoidance of nitrous oxide, and volatile anesthesia therapy.^{68–70,72}

Several risk factor models have been studied to correlate these factors into recommendations for prevention and therapy. One model is both simple and practical.^{69,71} This model uses the following risk factors: female gender, history of PONV or motion sickness, nonsmoking status, surgery >60 minutes in duration, and the use of intraoperative opioids. If the patient has none or one risk factor, the risk of PONV is about 10% to 20%; no prophylaxis is necessary unless there is a medical

risk for emesis. If the patient has two or more risk factors, the incidence increases to 40% to 80%; prophylaxis with one or two medications is warranted. E.W. has at least two risk factors (female, nonsmoker) and may have more if her surgery lasts longer than expected or if she receives intraoperative or postoperative opioids. She has a moderate to high risk of PONV.

An optimal prophylactic regimen for PONV matches medication choice with the patient's risk level.^{68–70,72} Appropriate choices for monotherapy include droperidol, a serotonin antagonist, or dexamethasone. Patients at the highest risk for PONV should be given prophylaxis with a combination of two to three antiemetics. Dual therapy choices include a serotonin antagonist plus either droperidol or dexamethasone. Triple therapy would combine a serotonin antagonist plus dexamethasone plus droperidol. Because E.W. has a moderate to high risk for PONV, a combination of a serotonin antagonist and dexamethasone would be a good choice for prophylactic therapy.

The most effective and commonly used medications for the prevention of PONV include serotonin antagonists, dexamethasone, droperidol, and combinations of these agents. No appreciable difference is found in efficacy or adverse effects between the serotonin antagonists; therefore, the costs of the different agents should be taken into consideration when selecting therapy. Droperidol has long been used for PONV, but concerns have been raised about the rare occurrence of QT prolongation and *torsades de pointes*.^{72,73} Most clinicians believe droperidol to be a safe, especially when doses are not excessive (up to 1.25 to 2.5 mg/dose for adults and up to 75 mcg/kg/dose for children).^{68,73,74} The mechanism by which dexamethasone protects against PONV is unclear, but its efficacy has been shown in many trials.^{68,70,72} Combinations of medications with different mechanisms of action are more effective than monotherapy. Aprepitant, has been studied in the prevention of PONV. Two studies recently compared oral aprepitant

Table 7-6 Medications for Prevention and Treatment of Postoperative Nausea and Vomiting (PONV)

| Medication | Prophylactic Dose | Treatment or Rescue Dose |
|------------------|--|---|
| Aprepitant | Adults: 40 mg PO within 3 hrs before induction of anesthesia | |
| Dexamethasone | Adults: 4–10 mg at the start of induction of anesthesia Pediatrics: 0.15 mg/kg/dose | Adults: 2–4 mg IV |
| Dolasetron | Adults: 12.5 mg IV at end of surgery Pediatrics: 0.35 mg/kg/dose | Adults: 12.5 mg IV |
| Droperidol | Adults: 0.625–1.25 mg IV at end of surgery Pediatrics: 50–75 mcg/kg/dose | Adults: 0.625–1.25 mg IV or IM Q 4–6 h Pediatrics: 10–30 mcg/kg/dose (max 100 mcg/kg/dose) |
| Metoclopramide | Adults: 10 mg IV at end of surgery | Adults: 10–20 mg IV or IM Q 6 h |
| Granisetron | Adults: 0.35–1 mg IV at end of surgery | Adults: 0.1 mg |
| Ondansetron | Adults: 4–8 mg IV at end of surgery Pediatrics: 0.05–0.1 mg/kg/dose | Adults: 1 mg IV Q 8 h Pediatrics: 0.05–0.1 mg/kg/dose |
| Prochlorperazine | Adults: 5–10 mg IV at end of surgery | Adults: 5–10 mg IV or IM Q 4–6 h Pediatrics: 0.13 mg/kg/dose |
| Promethazine | Adults: 12.5–25 mg IV at end of surgery | Adults: 12.5–25 mg IV or IM Q 4–6 h Pediatrics (>2 yrs): 0.25–0.5 mg/kg/dose |
| Scopolamine | Adults: 1.5 mg TOP evening before or at least 4 hrs before end of surgery | |

Adapted from references 68–70, 72, with permission.

40 mg or 125 mg with IV ondansetron 4 mg.^{45,74} These trials showed equivalency between the two doses of aprepitant and slight superiority over ondansetron in the proportion of patients without nausea, vomiting, or the use of rescue medications. Aprepitant, however, is significantly more expensive than generic ondansetron or dexamethasone, which is a consideration. Aprepitant's role in PONV has yet to be determined. Dexamethasone and serotonin antagonist combinations have been well studied and are highly effective.^{68,70,72,74} Dosages for the prophylaxis and treatment of PONV are shown in Table 7-6. 5-HT₃ antagonists and droperidol seem to be more effective when given at the end of surgery. Corticosteroids are best given before the induction of anesthesia.^{68,72}

Several methods for nonpharmacologic techniques for the prevention of PONV have been studied and have been shown to be effective, at least in some patient populations. These include acupuncture, transcutaneous nerve stimulation, acupressure at the P6 wrist point, hypnosis, and aroma therapy with isopropyl

alcohol. Ginger remedies were not found to be more effective than placebo for PONV.⁶⁸

Even with appropriate prophylaxis for PONV, some patients will experience breakthrough symptoms and require rescue therapy. Patients who have not received prophylaxis with a serotonin antagonist can be offered a low dose of a serotonin antagonist for rescue. For rescue, only about one-quarter of the prophylaxis dose is needed.⁶⁸ Serotonin antagonists have a fairly flat dose response and larger doses (ondansetron 4 to 8 mg) have not been found to be more effective for treatment of PONV than lower doses (ondansetron 1 mg).^{68,74} For all patients who have breakthrough symptoms, it is important to choose an antiemetic from a different pharmacologic class than the agents used for prophylaxis.^{69,72} Droperidol, promethazine, metoclopramide, and prochlorperazine are commonly used as rescue medications. If E.W. had breakthrough nausea, droperidol would be a good choice for rescue therapy.

Pain is an unpleasant sensation that can negatively affect all areas of a person's life, including comfort, thought, sleep, emotion, and normal daily activity. Chronic, untreated pain can disturb quality of life and social functioning and disrupt employment. The pain sensation results from complex phenomena that involve physical perception as well as the emotional reaction to the perception. Physiologic variables (e.g., tissue injury) and psychological variables (e.g., anxiety) influ-

ence a person's reaction to pain. Ascending neural pathways transfer electrochemical pain signals from the periphery to the central cortex where perception occurs, whereas descending pathways may attenuate or modulate signaling back to the site where the pain is felt. The pain sensation is therefore the net effect of complicated interactions of ascending and descending neural pathways with biochemical and electrochemical processes.

Pain is categorized according to its cause, location, duration, and clinical features. The most simplistic categorization involves differentiating brief-duration (acute) pain from long-lasting (chronic) pain syndromes. Acute pain serves a useful purpose of alerting an individual to an injury and initiating a reflex withdrawal from a noxious or offensive stimulus. In contrast, persistent (chronic) pain serves no biologic protective purpose and can cause undue stress and suffering. Pain was formerly believed to be merely a symptom and not a diagnosis. Recent advances in molecular biology and the understanding of neural mechanisms have demonstrated, however, that chronic pain can lead to long-lasting changes in the nervous system, a phenomenon known as *neural plasticity*. This concept is particularly important to the understanding of chronic pain because it helps explain difficulties observed in treating various painful conditions. Although initially considered static, pain processes are now realized to be plastic. Such changes therefore define a disease or process that induces physiologic change in the body. Regardless of its origin, however, pain requires a thorough evaluation to determine the underlying cause. By definition, pain is a subjective experience. Therefore, the patient is the only person who can best describe the intensity and character of pain. Pain is whatever the experiencing person says it is, existing wherever he or she says it does.

Because pain is a variable and personal experience, it is difficult to describe completely and measure objectively. The clinician, therefore, must guard against personal biases, which can interfere with treatment. It is important also to rely on tools, such as pain scales, to communicate with patients and understand the extent of their pain. Such tools allow clinicians to objectively measure the clinical results of their interventions. Most often with chronic painful conditions, total pain elimination is not a realistic goal, owing to the nervous system changes described above. Instead, a more attainable objective is reducing pain to a tolerable predetermined level as agreed on by consensus of the patient and clinician. A person with chronic pain should expect to achieve pain reduction with the ultimate objective of increasing daily function (e.g., activities of daily living) and minimizing suffering.

Mechanisms of Pain

Transduction, Transmission, Modulation, and Perception

Pain sensation involves a series of complex interactions between peripheral nerves and the central nervous system (CNS). This process is modulated by excitatory and inhibitory neurotransmitters released in response to stimuli. Such stimuli can be physical, psychological, or both. An example of a physical stimulus is a burn or cut to the skin. In a short time, local reactions occur in the damaged area that initiate the release of chemical mediators involved in inflammation. This is followed by sensitization of the nerve endings, which ultimately send signals to the sensory cortex of the brain. Nociception, or the sensation of pain, is composed of four basic processes: transduction, transmission, modulation, and perception (Fig. 8-1).¹

Transduction is the process by which noxious stimuli are translated into electrical signals at peripheral receptor sites. This begins when nociceptors (free nerve endings located throughout the skin, muscle, and viscera) are exposed to a

sufficient quantity of mechanical, chemical, or thermal noxious stimuli.^{2,3} In addition, a variety of chemical compounds (e.g., histamine, bradykinin, serotonin, prostaglandins and substance P) are released serially from damaged tissues and can activate or sensitize nociceptors.^{2,3} Serotonin has the additional action of modulating the peripheral release of primary afferent neuropeptides that are responsible for neurogenic inflammation. These neuropeptides include substance P, calcitonin gene-related peptide, and neurokinin A.^{2,3}

Transmission involves the propagation of an electrical signal along neural membranes. Stimuli, such as prostaglandins and inflammatory mediators, change the permeability of the membrane, producing an influx of sodium and an efflux of potassium, thereby depolarizing neuronal membranes. Electrical impulses are transmitted to the spinal cord via two primary afferent nerve types: myelinated A-fibers and unmyelinated C-fibers. The A-delta fiber is responsible for rapidly conducting electrical impulses associated with thermal and mechanical stimuli to the dorsal horn of the spinal cord. A-delta fibers release excitatory amino acids, such as glutamate, which activate α -amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptors located on dorsal horn neurons.^{2,4} Transmission of signals along these fibers results in sharp or stabbing sensations that alert the subject to an injury or insult to tissue. CNS input rapidly produces reflex signals, such as musculoskeletal withdrawal, to prevent further injury.⁵

The smaller, unmyelinated C-fibers respond to mechanical, thermal, and chemical stimuli and conduct electrical impulses to the spinal cord at a much slower rate compared with myelinated A-delta fibers. C-fibers, which also terminate in the dorsal horn, release the excitatory amino acids, glutamate and aspartate. Unlike A-fibers, C-fibers also release peptides, such as substance P, neurokinin A, somatostatin, galanin, and calcitonin gene-related peptide (CGRP).⁵ The role of these peptides is not completely understood. Substance P is known to activate neurokinin-1 receptors, which may play a role in increasing excitability of spinal cord neurons.^{5,6} Transmission of electrical impulses via C-fibers results in pain that is dull, aching, burning, and poorly localized or diffuse. This type of pain is known as *second* pain because it is perceived after the first pain sensation.

Once dorsal horn receptors are activated, electrical signals are further propagated to the thalamus, primarily via the spinothalamic tract. From the thalamus, signals are sent to the cortex and other regions of the brain for processing and interpretation.

Modulation of nociceptive information occurs quickly between descending inhibitory pathways from the thalamus and brainstem and interneurons in the dorsal horn. Neurons from the thalamus and brainstem release inhibitory neurotransmitters, such as norepinephrine, serotonin, γ -aminobutyric acid (GABA), glycine, endorphins, and enkephalins, which block substance P and other excitatory neurotransmitter activity on primary afferent fibers.⁷

The conscious awareness, or *perception*, of pain is the end result of this complex cascade of actions. The perception of pain involves not only nociceptive processes, but also physiologic and emotional responses, which contribute significantly to the sensation that is ultimately experienced by the person.⁷ The perception of pain may be influenced by abnormal generation or processing of electrical pain signals and by the

psychological framework created by the patient's temporal affective state or from previous painful experiences. Therefore, treatment that includes drug therapy to alter the nociceptive and physiologic responses, in addition to cognitive-behavioral strategies (e.g., distraction, relaxation, and imagery) to alter the psychological response, may be more effective together than if either intervention is used alone.⁸

Peripheral and Central Sensitization

Under normal homeostatic conditions, a balance exists between excitatory and inhibitory neurotransmission. Changes in this balance may occur both peripherally and centrally, however, leading to exaggerated responses and sensitization.^{8,9} Examples often observed in chronic pain states include hyperalgesia (enhanced pain to a given noxious stimulus) and allodynia (pain in response to a normally non-noxious mechanical stimulus, such as light touch). Peripheral and central nociceptors can be functionally heterogeneous and can change through processes of sensitization. Peripherally, certain nociceptors respond to strong mechanical stimuli, whereas other normally "silent" nociceptors can undergo sensitization from exposure to prostaglandins, bradykinin, serotonin, histamine, adenosine triphosphate (ATP), and cytokines.¹⁰ These sensitized nociceptors then become highly responsive to weak mechanical stimuli.¹¹

Centrally, two types of nociceptors have been identified. Nociceptive-specific neurons respond only to noxious stimuli, such as heat, whereas wide dynamic range neurons respond to noxious stimuli, but also may be excited by peripheral mechanostimulation.^{11,12} In chronic pain conditions, populations of these neurons can shift, so that normally inactivated neurons become highly responsive to various weak stimuli.^{2,11} The person affected notices that many types of stimuli elicit pain, including light touch or minor changes in ambient temperature.

On stimulation, AMPA receptors are the first to be activated, followed by neurokinin peptide receptors. The *N*-methyl-D-aspartate (NMDA) receptor does not participate in normal transmission and is blocked by magnesium.^{5,13} If the stimulus continues, NMDA receptors may become activated, leading to chronic painful conditions. For this to take place, several conditions must occur.⁵ First, input from primary afferent fibers must be of sufficient intensity and duration. When peripheral damage occurs, the synthesis and release of substance P is increased. The increased release of substance P, along with other peptides and neurokinins is thought to enhance glutamate activation of the NMDA receptor. Second, for glutamate to activate NMDA receptors, a coagonist, glycine, must be present. The last step in activating NMDA receptors requires the removal of the magnesium channel block. Tachykinins, such as substance P released along with glutamate, stimulate neurokinin receptors and depolarize the neuron. The magnesium block is removed only when there is sufficient repeated depolarization. When these conditions have been met, the receptor channel opens, allowing large amounts of calcium and sodium to enter the neuron. This produces excessive excitability and amplification of signals.

This initial activation of the NMDA receptor is known as *wind-up*. Wind-up progressively increases the number and response of nociceptive neurons in the dorsal horn without any change of input to the spinal cord.^{5,13} In fact, this process can continue after peripheral input has stopped. With continued

nociceptive input, spread occurs activating nearby receptors, known collectively as *metabotropic glutamate receptors*.^{4,7} Central sensitization occurs when NMDA and neurokinin receptors are activated, along with increases of cyclic nucleotides and nitric oxide, and activation of several protein kinases within.¹¹

Treatment Implications

If all these processes are considered, then the goal of pain therapy is to reduce peripheral sensitization, thereby decreasing central stimulation and the amplification associated with wind-up, spread, and central sensitization. This often requires multiple modalities to interrupt transmission at different levels. For example, the management of a chronic painful condition may include treatment with an opiate (e.g., morphine) to reduce ascending pain transmission, a nonsteroidal anti-inflammatory drug (NSAID) (e.g., ibuprofen) to reduce prostaglandin formation, and a membrane-stabilizing agent (e.g., carbamazepine) to alter ion flux in nerve membranes and blunt depolarization.

New targets will be identified for effective drug therapy as additional information is learned about the complex interactions and adaptations of neurotransmitters and receptors. However, it is unlikely that a single effective "magic bullet" will be developed because of the complex relationships between neurotransmitters and interpatient variability in the perception of pain. Such variability can arise from genotypic differences in receptor function, metabolic enzymes, and protein transporters that convey substances across cellular membranes. Therefore, continued understanding of the mechanisms of pain transmission will be important in allowing clinicians to most effectively use available agents.

Mode of Analgesic Action

Nonsteroidal Anti-Inflammatory Drugs

Nonsteroidal anti-inflammatory drugs (NSAID) are presumed to exert their analgesic effects by inhibiting prostaglandin synthesis in the periphery; however, this probably is an oversimplified view of their action. In the periphery, various chemical mediators, such as serotonin, substance P, bradykinin, and histamine, are released in addition to prostaglandins in response to tissue injury, and the physiologic response to these chemicals is complex. These substances do not all produce pain when experimentally injected as individual substances. Instead, the combined effects of multiple chemicals are required before a pain response is produced. For example, when histamine, prostaglandin E₂, or bradykinin is administered alone, pain does not result; when all the agents are given together, the combination produces intense pain. Therefore, prostaglandins probably induce hyperalgesia (excessive sensitivity to pain) in the local sensory nerve receptors when other chemical mediators exert their effects. The analgesic efficacy of an NSAID, however, does not correlate entirely with its capacity for prostaglandin inhibition in the periphery. Acetaminophen, which exhibits its analgesic action by inhibiting prostaglandin synthesis, also can produce analgesia at concentrations that do not inhibit peripheral cyclooxygenase activity and prostaglandin formation. Salicylates also can produce analgesia at concentrations that do not inhibit peripheral cyclooxygenase activity and prostaglandin formation. Therefore, the exact mechanism of NSAID analgesia has yet to be elucidated; however, the analgesic effect of NSAID is likely central

in origin and involves substance-P receptors of the neurokinin-1 type and glutamate receptors of the NMDA type in addition to central prostaglandin inhibition. Because spinal administration of NSAIDs reduces the hyperalgesia evoked by spinal substance P and NMDA, the action of the NSAID appears to be independent of peripheral inflammation. NSAID actions through GABAergic pathways, arachidonic acid byproducts, and AMPA receptors also are being studied. Aspirin, the prototypical NSAID, has demonstrated synergistic activity with endogenous opioids at opioid receptors as well as enhancing serotonin's effects in the central nervous system.^{14,15}

Opiates

Opiates can attach to one or more of five opioid receptors: the μ -, δ -, ϵ -, κ -, and σ -receptors. These receptors can be differentiated further into subtypes (e.g., μ_1 , μ_2 , δ_1 , δ_2 , κ_1 , κ_2 , and κ_3). Animal models suggest that as many as seven subtypes of μ -receptors may exist, but it is not known how many of these can be found in humans. Stimulation of μ_1 -receptors may be responsible for the desired effects of supraspinal analgesia, and stimulation of μ_2 -receptors may lead to unwanted consequences such as respiratory depression, euphoria, constipation, and physical dependence. Some κ -receptors, as well as δ - and ϵ -receptors, also mediate analgesic response, although the role of ϵ -receptors is not fully understood. Autonomic stimulation, dysphoria, and hallucinations may be caused by σ -receptors. These are not considered true opioid receptors, but may interact with some opioid-like agents.

The effect of opiates on these receptor subtypes is gradually being discovered. Morphine can stimulate μ_1 -, μ_2 -, and κ -receptors, and perhaps this ability to stimulate multiple receptors accounts for morphine's mixed analgesic and side effect profile. Pure opiate antagonists (e.g., naloxone) occupy opiate receptors without eliciting a direct response and block the access of opiate agonists, such as morphine, to these receptors. As a result, pure narcotic antagonists block both the desired and undesired opiate effects. Pentazocine and butorphanol (both mixed agonist-antagonists) produce analgesia through stimulation of κ -receptors, but cause unwanted dysphoria and hallucinations through their effect on σ -receptors. Pentazocine and butorphanol also block access of morphine to μ -receptors, leading to withdrawal symptoms in individuals who are physically dependent on morphine or its analogs.

In the spinal cord, the highest concentration of opioid receptors is located around the C-fiber terminal zones in the lamina I of the dorsal horn and the substantia gelatinosa. The μ -opioid receptors constitute approximately 70% of the total receptor population; δ - and κ -receptors account for 24% and 6% of the population, respectively. μ -Receptors also are located in the afferent terminals. Because morphine has a 50 times higher affinity for the μ -receptor than for the δ - or κ -receptors, it is a very effective analgesic. The pharmacologic action of opioids depends on the availability of opioid receptors, and the cutting of peripheral nerves leads to degeneration and loss of opioid receptors in the nerve itself. As a result, postamputation pain often is not relieved by morphine or other opioids.

Opioids produce analgesia by three main mechanisms¹⁶:

- Presynaptically, opioids reduce the release of inflammatory transmitters (e.g., tachykinin, excitatory amino acids, and peptides) from the terminals of afferent C-fiber neurons after activation of opioid receptors.

- Opioids also can reduce the activity of output neurons, interneurons, and dendrites in the neuronal pathways by means of postsynaptic hyperpolarization.
- Opioids also inhibit neuronal activity via GABA and enkephalin neurons in the substantia gelatinosa.

Analgesic Adjunctive Agents

Analgesic medications often are prescribed concurrently with other drugs to enhance analgesia or to treat pain exacerbations. These adjunctive medications are most often used in the management of chronic pain, particularly when the dose of the primary analgesic has been optimized or when the underlying condition has progressed and is no longer adequately controlled by the primary analgesic agent. Other adjuvant agents may be added to analgesic therapy to reduce side effects, such as excessive sedation, nausea and vomiting, or constipation. The most common drug classes used as adjunctive analgesic agents are corticosteroids, anticonvulsants, heterocyclic antidepressants, α_2 -adrenergic agonists, NMDA receptor antagonists, local and oral anesthetics or antiarrhythmics, antihistamines and neuroleptics. Adjunct analgesic agents may be used as the primary analgesic agent in the treatment of neuropathic pain syndromes, where the usefulness of opioids is under debate. Neuropathic pain syndromes do not respond to NSAIDs.

Corticosteroids, such as dexamethasone, are useful in reducing pain associated with cerebral and spinal cord edema and in treating refractory neuropathic pain and bone pain, particularly metastatic bone pain. Corticosteroids may also provide other beneficial effects, such as mood elevation, antiemetic activity, and appetite stimulation.¹⁷

Antidepressants are commonly used to treat neuropathic pain (e.g., diabetic neuropathy, postherpetic neuralgia) and pain associated with insomnia or depression.¹⁸ They are used to treat fibromyalgia, a syndrome characterized by diffuse muscle and joint pain, which is thought to result from central dysregulation. Their analgesic effect is independent of their antidepressant effect. Postulated mechanisms of action involve blockade of norepinephrine reuptake, antagonism of histamine and muscarinic cholinergic receptors, α -adrenergic blockade, or suppression of C-fiber evoked activity in the spinal cord.¹⁹

Anticonvulsants; antiarrhythmics; α_2 -adrenergic antagonists; and the NMDA receptor antagonists, ketamine and dextromethorphan, also have been used to manage neuropathic pain with varying degrees of success. Antihistamines, such as hydroxyzine and promethazine, are often prescribed postoperatively to augment the analgesic effects of opioid agents. Hydroxyzine may provide minimal analgesia, whereas little evidence exists to confirm analgesic action for promethazine.²⁰ The addition of phenothiazines and antihistamines may be useful in alleviating opioid-induced nausea and vomiting; however, these agents may potentiate orthostatic hypotension, respiratory depression, sedation, and extrapyramidal side effects.²¹ Use of these agents should not be a substitute for appropriate doses of opioid analgesics.

Classification of Pain

Acute Pain

Pain immediately following an injury to the body is considered to be *acute pain*, whereas pain lasting beyond the expected healing time, or persistent pain that does not respond to usual

pain control methods, is defined as *chronic pain*. Acute pain serves a useful purpose in minimizing the extent of injury by causing an organism to recoil from a noxious or harmful stimulus. In most cases, the objective physical findings associated with acute pain can be localized directly to the site of injury. Injury to nerves on visceral organ systems can present as diffuse, poorly differentiated, referred pain.

Acute pain is usually self-limiting and typically subsides when the injury heals. Untreated or inadequately treated pain can evoke physiologic hormonal responses that alter circulation and tissue metabolism; these can also produce tachypnea, tachycardia, widening of the pulse pressure, and increased sympathetic nervous system activity. Inadequately treated pain can produce significant psychological stress responses and compromise the body's immune system by provoking release of endogenous corticosteroids. Decreased range of motion, diminished pulmonary vital capacity, and a compromise in the overall well-being of a person secondary to poorly treated pain can delay recovery after surgery or trauma. Acute pain is often exacerbated by anxiety and secondary reflex musculoskeletal spasms.

Acute pain should always be aggressively managed, even before a definitive cause is known. In patients with traumatic head injury, medications should be withheld until a full neurologic workup can be performed because they can interfere with cognitive function. Patients with acute abdominal pain also may have pain medications withheld until a diagnosis is made; however, several studies support early pain management.^{22,23} When pain is relieved, the patient is more comfortable and better able to cooperate with the history, physical examination, and diagnostic procedures. Postoperative and other acute pain syndromes often are ignored or inadequately treated, however. Part of the tendency to undertreat pain is the reluctance of caregivers to prescribe opiates for fear of causing addiction. Addiction to opioids is essentially nonexistent when these drugs are prescribed for acute pain, and withholding appropriate pain treatment causes needless patient suffering.

Chronic Pain

The origins of chronic pain may be neurogenic, nociceptive, psychiatric, or idiopathic. As will be presented later, it is important to further differentiate chronic pain syndromes into those that are associated with malignancy from those that are not. All forms of chronic pain share some common characteristics, however. Unlike acute pain, which prompts the afflicted individual to avoid further injury or seek help, chronic pain usually serves no benefit to the individual. Chronic pain can be episodic or continuous, or a combination of both. A patient may feel constant pain and also experience exacerbations of more intense pain at various times. Chronic pain can cause a person to feel "trapped" inside of his or her body, distinguished only by more painful and less painful days. Chronic pain often is destructive to the host by deteriorating quality of life, functional ability, spiritual and psychological well-being, interpersonal relationships, and financial status.¹⁷ Chronic pain also can cause changes in appetite, psychomotor retardation, irritability, social withdrawal, sleep disturbances, and depression. The patient often cannot remember an existence free of pain and is convinced that the pain will be present until death. In short, chronic pain can become an all-consuming focus of the patient's life.

The key to successful chronic pain management rests on prevention and elimination of unnecessary suffering and despair. Chronic pain management should consider the applicability of cognitive interventions (relaxation technique, self-hypnosis, psychiatric therapy) as well as physical manipulations (local application of heat, cold, massage, electrical nerve stimulation, acupuncture, and physical therapy). Pharmacologic agents (antidepressants, antiarrhythmics, anticonvulsants, major tranquilizers, and longer-acting opioids), regional anesthesia (local anesthetic blocks with or without corticosteroids or chemical neurolysis), surgical interventions (spinal decompression, release of nerve entrapment), and spinal analgesia (intraspinous opioids or local anesthetic agents) are also warranted.^{24,25}

PAIN ASSOCIATED WITH MALIGNANCY (CHRONIC MALIGNANT PAIN)

Chronic malignant pain can have a combination of acute, intermittent, or constant components. Although the pain is chronic, it can have elements of acute pain when tissue damage continues from tumor infiltration. Nerve destruction, chemotherapy, radiation therapy, and surgery also contribute to malignant pain. Occasionally, chronic malignant pain has only minimal or no associated objective clinical physical findings, and may be erroneously dismissed by inexperienced clinicians.

Anticipation by the patient that malignant pain will be continuous leads to anxiety, depression, and insomnia.²⁶ These destructive feelings can accentuate the patient's perception of pain. Inadequately treated chronic malignant pain can become progressively more severe and cause relentless suffering. Persistent pain can accelerate the deterioration of the patient's physical and psychological condition more than the malignancy itself.

The most important aspect of chronic malignant pain management is a logical and systematic approach with the goal of pain alleviation (or minimization) and prevention. A primary element of this approach is patient access to health care and pain management information. It is the duty of all health care providers to effectively assess their patients' pain management needs and to make appropriate referrals or therapeutic changes.

CHRONIC NONMALIGNANT PAIN

Pain not associated with a malignant disease and lasting >6 months or beyond the healing period is considered to be chronic nonmalignant pain. This pain also has been called *chronic benign pain*, an obvious misrepresentation, because pain is never benign when it causes patient suffering. Chronic nonmalignant pain is recognized as a serious health problem that affects millions of people worldwide and carries far-reaching social implications.²⁷ The development of treatment guidelines is difficult because of the heterogeneity of causes. For most types of chronic pain, initial therapy is often conservative. Failure of conservative therapy may necessitate the use of more potent analgesics. The use of opiates in this patient population is controversial; however, increasing data support opiate use in psychologically healthy patients.^{28,29} Because chronic pain affects many aspects of a patient's life, a multidisciplinary approach that addresses effective drug therapy and comprehensive rehabilitation often provides greater relief to the patient than drug therapy alone.

Much of the difficulty encountered in pain management arises when clinicians are not sufficiently educated or trained in dealing with the complex pharmacologic and psychosocial

Table 8-1 Common Causes of Analgesic Treatment Failure

| Problem | Potential Impact on Pain Management | Example |
|---|--|--|
| 1. Inappropriate or unknown diagnosis | Improper medication selection | Using a nonsteroidal anti-inflammatory drug (NSAID) for abdominal pain that may be related to a gastrointestinal bleed |
| 2. Misunderstanding of pharmacology or pharmacokinetics | Overestimating potency or half-life | Dosing an opioid less frequently than necessary to provide adequate relief |
| 3. Inadequate management of adverse effects | Patient may discontinue therapy or misuse over-the-counter remedies | Patient suffers constipation from antidepressants and uses daily bisacodyl |
| 4. Fear of addiction | Physician or patient or caregiver may withhold medications | Evidence of tolerance after chronic use of opioids may be mistaken for addiction |
| 5. Unrealistic goals for therapy | Patient will not be satisfied with pain management regimen and may seek other care | Patient states a desire to be “pain free” following significant nerve injury |
| 6. Irrational polypharmacy | Over- or under-use of appropriate therapies | Patient with neuropathic pain using three different opioids without any adjuncts in the regimen |
| 7. Patient barriers | Patient cannot understand appropriate medication use or other pain management modalities | <ul style="list-style-type: none"> • Language or comprehension deficits • Cognitive deficits: patient cannot remember regimen • Physical impediments to using medicines appropriately • Cultural barriers (e.g., stoicism) |
| 8. Lack of understanding of pathophysiology of pain | Limitations of health care providers’ ability to adequately relieve pain | Drugs that show benefit in animal models are not useful for human pain conditions |

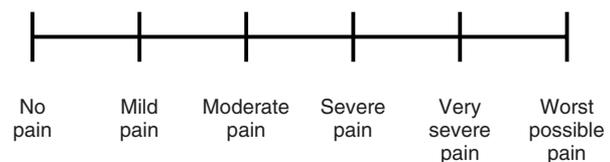

problems associated with chronic pain. Often the clinician fails to listen to the patient or fails to recognize clues to the subtle nature of the patient’s pain complaints. Drug selection often is irrational and doses are frequently inadequate. An unfortunate tragedy occurs when clinicians occasionally withhold adequate analgesia because of a misunderstood fear of addiction, or when a patient refuses medications because of a similar fear of addiction.^{30,31}

General Treatment Principles

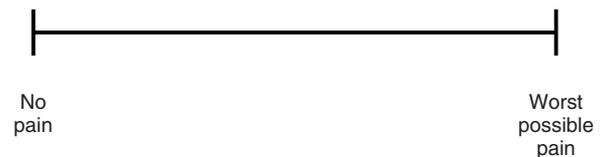

Pain is one of the most common reasons for which patients seek medical attention, yet it remains significantly undertreated despite the availability of effective medications and other therapies.^{32,33}

Table 8-1 lists eight common causes of treatment failure when using analgesics.³⁴ In general, the reasons include a lack of understanding of pain management principles or the pharmacologic properties of the drugs; an overestimation of the risk of addiction by both patients and caregivers; or poor communication between the patient and medical personnel. A number of steps to overcome these barriers are described in the succeeding section.

Effective analgesic therapy begins with an accurate assessment of the patient. The Pain Intensity and Pain Distress Scales (Figures 8-2 and 8-3, respectively) can help clinicians assess pain. When obtaining a pain history, it is important to gather details about the pattern, duration, location, and character of the pain. Pain intensity should be measured using an appropriate pain scale (Figs. 8-2 and 8-3) according to the patient’s ability to communicate.^{17,24} Factors that exacerbate or relieve pain should be assessed. The names and amounts of all analgesics that the patient is taking should be documented as well as their effectiveness. In addition, other medical problems and medications should be documented, including over-the-counter and nonprescription remedies. A patient fearful of being accused of analgesic abuse might be reluctant to give an accurate drug use history unless a trusting relationship can be established.

Effective treatment considers the cause, duration, and intensity of pain and matches the appropriate intervention to the situation. The goal of therapy is to eliminate or reduce the pain to the lowest tolerable intensity and prevent it from recurring, rather than waiting to treat the pain when it becomes unbearable. The patient should predetermine this lowest tolerable

level with the health care provider based on a pain scale that is mutually understood. Guidelines from the World Health Organization, summarized in Table 8-2, can be useful when choosing initial therapy.³⁵ It is also important to consider the clinical situation when determining analgesic selection or whether the painful condition requires analgesic therapy. For example, it would be irrational to use morphine to treat the severe abdominal cramping pain associated with constipation, because morphine can worsen the constipation. If pain is the result of a fracture, then stabilization and immobilization, in addition to appropriate analgesics, will reduce pain in the affected bone. Once a pain regimen is initiated, frequent reassessment will determine whether the goals of therapy are being met and whether they address any emerging side effects. Drug selection, doses, routes of administration, and dosing frequency should be adjusted as needed until the goals of therapy are met. In treating acute, severe postoperative pain, it may be necessary to begin with a potent opiate analgesic and then gradually reduce the dose based on the patient's clinical response.

When treating chronic pain, elimination and prevention of pain is best accomplished by using analgesics at fixed time intervals (“time-contingent”) rather than on an as-needed basis. The traditional as-needed analgesic dosing schedule is inadequate much of the time, leading to greater 24-hour drug intake and a pattern of stepwise increases in dosage. Therefore, most pain management specialists now administer, or at least offer, analgesics to their patients on a schedule, at least for the first few days until pain requirements can be adequately assessed. In patients with severe acute or malignant pain, however, scheduled analgesics alone may not be adequate without additional

Table 8-2 Example Initial Regimens for Different Pain Levels Based on Guidelines From the World Health Organization (WHO)

| <i>Pain Level Description</i> | <i>Typical Corresponding Numerical Rating (0 to 10 Scale)</i> | <i>WHO Therapeutic Recommendations</i> | <i>Example Medicines for Initial Therapy</i> | <i>Comments</i> |
|-------------------------------|---|---|--|---|
| “Mild” pain | 1–3 | Nonopioid analgesic: taken on a regular schedule, not as needed (prn) | <ul style="list-style-type: none"> Acetaminophen 650 mg every 4 hr Acetaminophen 1,000 mg every 6 hr Ibuprofen 600 mg every 6 hr | <ul style="list-style-type: none"> Consider adding adjunct analgesic or using an alternate regimen if pain not reduced in 12 days Consider step up if pain not relieved by two different regimens |
| “Moderate” pain | 4–6 | Add opioid for moderate pain (e.g., moderate potency analgesic). Use on a schedule, not prn | <ul style="list-style-type: none"> Acetaminophen 325 mg/codeine 60 mg every 4 hr Acetaminophen 325 mg/Oxycodone 5 mg every 4 hr Tramadol 50 mg every 6 hr | <ul style="list-style-type: none"> Consider adding adjunct analgesic or using an alternate regimen if pain not reduced in 12 days Consider step up if pain not relieved by two different regimens |
| “Severe” pain | 7–10 | Switch to a high potency (strong) opioid; administer on a regular schedule | <ul style="list-style-type: none"> Morphine 15 mg every 4 hr Hydromorphone 4 mg every 4 hr Morphine controlled release 60 mg every 8 hr | <ul style="list-style-type: none"> Consider alternate regimen (e.g., different strong opioid) if pain not reduced in 12 days Consider increased dose of strong opioid, or addition of nonopioid agents, if pain not adequately relieved by two regimens |

analgesics for breakthrough episodes. Until the dosage is stabilized, all patients who are receiving analgesics should be monitored closely for efficacy of analgesia as well as untoward side effects. Successful pain management can also include the use of nonpharmacologic measures, such as ensuring that the patient receives adequate rest and emotional support. Physical and occupational therapy may be useful to help improve strength or mobility and to ensure that no barriers at home or work exist that can interfere with the patient's activities of daily living.²⁸

Anxiety and guilt often complicate the management of pain. Patients sometimes become anxious, fearing that their pain will become uncontrollable or that they will become addicted to opiates. Also, patients sometimes feel guilty about taking opioids for their pain because of the negative social connotations associated with these drugs. They may feel that they have failed their clinicians' expectations. Therefore, patient education about the rational use of analgesics is imperative. Pain can be managed best when trust and communication exist between the caregiver and the patient, known as a *therapeutic alliance*. Patients must feel comfortable telling caregivers whenever their pain needs arise, and caregivers must respond appropriately and in a timely fashion. Good communication between caregivers and patients can alleviate anxiety and guilt regarding patients' pain needs.

Patient-specific characteristics (e.g., age, gender, race, organ dysfunction, and comorbidities) play an important role in the response to pharmacotherapy, ranging from subtherapeutic effect to toxicities. A genetic polymorphism of the cytochrome P450 system significantly contributes to inconsistency of patient response to drug therapy.³⁶ Based on CYP 450 enzymatic activity, patients may be classified as poor metabolizers, intermediate metabolizers, extensive metabolizers, and ultrarapid metabolizers. Such variations in drug metabolism have been correlated to a range of effective doses and occurrence of toxicities. This has been observed with different drug classes, including opioids.³⁶

Codeine is a prodrug that is metabolized to morphine, a more potent analgesic, by CYP2D6. This particular enzyme is known to have variable presence among individuals, leading to insufficient analgesia in poor metabolizers.³⁷

Tramadol, a synthetic opioid, exerts its full analgesic effect when the parent compound is converted to O-desmethyltramadol via CYP2D6. Consequently, it has been demonstrated that, in the postoperative setting, poor metabolizers do not exhibit equal analgesia when compared with extensive metabolizers.³⁷

Polymorphism of CYP 450 is not the only target of pharmacogenomic research. Genetic variations that contribute to opioid, cannabinoid, NMDA, dopamine, and serotonin receptor expression, as well as drug transporters, are also subjects of further research. Their effect on response to pharmacotherapy has not yet been elucidated.³⁷

In the near future, when genetic testing becomes economically feasible for widespread use, clinicians will utilize this information in their decision process to prevent toxicities and optimize pharmacotherapy.³⁷

Analgesic Selection

The selection of an analgesic must be individualized for each patient, depending on the cause and chronicity of the pain

as well as the patient's age and concomitant medical conditions that may alter drug response. Furthermore, the clinical response of the patient dictates future dose adjustment, route, and desired dosing interval. The selection of an opioid for the management of severe acute and chronic malignant pain must always include consideration of morphine or one of the other potent opioids; however, the role of NSAID should not be overlooked. Adjunctive analgesic medications, such as antidepressants or anticonvulsants, are often added because chronic non-malignant pain can be associated with sympathetic dysfunction and neuropathies. An NSAID is the analgesic of choice in the management of mild to moderate pain involving musculoskeletal tissues and also are extremely effective in the management of pain from bony neoplastic metastasis. Neurogenic pain often responds better to tricyclic antidepressants (TCA) than to opioids. Neuropathic pain may not be relieved by opioids until the dose is high enough to also cause significant side effects.

If the maintenance dose of an opioid analgesic is too high, the patient can become oversedated and less functional. In extreme cases, patients may become bedridden from excessive opiate use. When given the choice of eliminating the last trace of discomfort at the cost of some sensorial clouding, patients invariably select full alertness and the continued presence of some pain.^{38,39} Patients who are receiving opioids also need to be monitored for deterioration in vital signs (pulse and respiratory rate), constipation, and urinary retention. Stool softeners and other prophylactic measures, such as stimulant laxatives, may be required. Similarly, a patient who is receiving NSAID or adjunctive analgesics should be monitored for possible untoward side effects associated with such medications.

Orally or transdermally administered analgesics allow a patient a greater degree of independence and control over daily activities than parenteral administration by maximizing mobility. Similar advantages can be obtained with an intravenous (IV) infusion device, particularly a portable programmable infusion pump. Regular parenteral administration by other routes can be difficult and painful in cachectic patients.

Low to Moderate Potency (Mild) Analgesics

The nonsteroidal anti-inflammatory analgesics have a relatively flat dose-response effect when contrasted with opioids, reaching maximal analgesia at low to moderate doses. In contrast to opiate analgesics, higher doses of NSAIDs do not produce greater analgesia. These drugs are frequently prescribed at doses in excess of the effective maximal analgesic dose, however, because the duration of analgesia can increase with higher doses. For example, ibuprofen given 600 mg every 6 hours produces a similar analgesic effect as 400 mg given every 4 hours. The total daily dose is the same, but side effects are experienced more often with larger doses. Although NSAIDs have both analgesic and anti-inflammatory properties, it is often difficult to differentiate between these effects in published studies or during clinical use in patients, as the time courses of each effect overlap.

All of the NSAIDs, including ibuprofen (Motrin), naproxen (Naprosyn), naproxen sodium (Anaprox), diflunisal (Dolobid), diclofenac (Voltaren), diclofenac potassium (Cataflam), nabumetone (Relafen), ketoprofen (Orudis), flurbiprofen (Ansaid), ketorolac (Toradol), and others, provide analgesia

equivalent or superior to that of aspirin^{40,41} or acetaminophen codeine 60 mg combined with a variety of mild to moderate painful conditions.^{42,43} As with the opioid analgesics, the duration of action of an NSAID does not correlate well with the serum half-life of the drug. Likely, this is because the analgesic effect arises from central mechanisms, and is related to the exposure of the CNS to adequate drug levels. Patient response should guide the clinician in selecting dosing intervals of these agents, especially when they are combined with opioids.

Opioid Analgesics

In general, opioids are more effective for treating severe pain than nonopioid analgesics such as NSAIDs, although the range of potencies is wide with this class of medicines. They are generally recommended for moderate to severe pain intensity and are used in chronic pain syndromes that are refractory to other classes of agents.

An intramuscular (IM) dose of 10 mg/70 kg of morphine sulfate provides significant analgesia in approximately 70% of patients with severe pain. The remaining 30% of patients require higher doses,⁴⁴ which not only increase the intensity and duration of analgesia, but also the incidence of side effects. Morphine dosage requirements also vary with the severity of pain, individual perceptions of pain, age, opioid tolerance or previous exposure, and the presence of concomitant diseases. Thus, single parenteral analgesic doses of morphine ranging from 4 to >20 mg are used to treat acute pain and parenteral doses as high as 200 mg/hour have been required to treat end-stage malignant pain in patients who have developed tolerance.

A 10-mg parenteral dose of morphine is the historical reference standard by which all other opioid analgesics are compared. Therefore, morphine equivalents are often used when calculating analgesic doses for other opioids. The duration of analgesia of an opioid correlates partially with its serum half-life, but also with the dose, route of administration, and the distribution characteristics of the drug.⁴⁵ For example, methadone has a very long serum half-life of 24 hours, but its duration of analgesia is only about 6 hours. On the other hand, single daily doses of methadone are retained on opiate receptors in the brain long enough to prevent abstinence symptoms for 24 hours in opiate abusers. When used for pain management, the long half-life of methadone may contribute to cumulative effects and drug toxicity such as QTc prolongation. When methadone is administered epidurally, its duration of analgesia is short because of its high lipophilicity that promotes rapid redistribution from the epidural space into systemic circulation, and consequently, metabolic clearance. Conversely, morphine has a relatively short duration of analgesia when administered parenterally, but when it is administered epidurally, it has a long duration of analgesia because of its low lipophilicity, which inhibits its redistribution from the epidural space.

The administration of opioid analgesics is frequently complicated by the need to convert between different routes of administration or different opioid formulations. The approximate equianalgesic doses of parenteral and oral opioid analgesics are listed in Table 8-3. The specific oral-to-parenteral ratios of these drugs also are listed in Table 8-3; however, the precision of these ratios is controversial, in part because of the methodologies used to infer these “equivalencies.” For example, most

investigators maintain that the oral-to-parenteral ratio for morphine is 6:1, but some hospice clinicians maintain that morphine’s oral-to-parenteral ratio is closer to 2:1. Such confusion may result from differences in the design of single-dose versus multiple-dose clinical trials. First-pass hepatic metabolism may be greater in single-dose clinical studies than in multiple-dose studies because first-pass metabolic pathways can become saturated with repeated doses. Furthermore, the accumulation of the active metabolite morphine-6-glucuronide after chronic dosing may contribute to the clinically observed differences. When all factors are taken into account, the bioavailability of oral morphine varies from 17% to 70% of a dose; therefore, it is reasonable to expect individual patient response to be highly variable.^{46,47} No matter which ratio the clinician uses, the dosing must be guided by the patient’s clinical response and frequent clinical reassessment.

If an opioid analgesic is to be substituted with another opioid, the equivalent doses as listed in Table 8-3 can be used as an approximate guide to dosage conversions unless the patient has developed tolerance. Cross-tolerance between opioid analgesics exists, but is often not complete. Therefore, calculated doses may be reduced by as much as 50% when interchanging different opioids. This is especially true when switching to methadone from other opioids.⁴⁸ Patient comfort is the goal, and the response of the patient should always be the basis for dosage adjustments. Whenever a new opioid analgesic is initiated, the patient’s response should be assessed within the first few hours because the initial dose of the new analgesic is only correctly estimated about half the time. Frequent reassessment of clinical responses should facilitate dosage adjustments and control the patient’s pain more quickly.

The analgesic efficacy of propoxyphene and combinations of acetaminophen with propoxyphene 65 mg remains controversial. Most double-blind studies demonstrate no advantage of propoxyphene alone over aspirin, acetaminophen, or codeine in relieving various types of pain.^{49,50} This lack of benefit conflicts with the observation that propoxyphene in combination with acetaminophen remains a commonly prescribed regimen in the United States. This may be partially explained by an additive or synergistic effect when opioids are combined with nonopioid analgesics. Another possible explanation is the tendency of many patients to take more than the prescribed doses. Because propoxyphene has a 13-hour half-life, repeated doses taken every 4 to 6 hours for several days can result in significant drug accumulation. Furthermore, analgesic assessments of propoxyphene efficacy have been based primarily on single-dose studies,⁵¹ while most patients take as many as 10 to 12 tablets daily. Propoxyphene has significant CNS effects. At lower dosages, propoxyphene can produce mild CNS depressant effects. At higher dosages, however, it can have an amphetaminelike stimulant effect and, in overdoses, propoxyphene can produce seizures. As with other opioid analgesics, propoxyphene can produce physical dependence.

As with all opioid analgesics, patients taking propoxyphene need to be warned about the risks of concurrent alcohol use, the operation of equipment or machinery requiring mental acuity, and the potential for agitation and sleeplessness when the medication is discontinued abruptly after prolonged use. In addition to effects on the CNS, propoxyphene has been associated with hypoglycemia in patients with renal dysfunction.⁵²

Table 8-3 Properties of Opioid Analgesics

| | Parenteral Dose (mg) | Oral Equivalent | Routes | Onset (min) | Duration (hr) | t _{1/2} (hr) | Notes |
|--|-------------------------|--------------------|---------------------------|-----------------|------------------|-----------------------|---|
| Opioid Agonists for Moderate to Severe Pain (mu Receptor Agonists) | | | | | | | |
| Phenanthrenes | | | | | | | |
| Morphine (various) | 10 | 30 | PO, parenteral, PR | IV: 5 PO: 60 | 3–6 | 2–3 | Sustained release PO preparations available |
| Hydromorphone (Dilaudid) | 1.5 | 7.5 | PO, parenteral, PR | See morphine | 3–6 | 2–4 | |
| Levorphanol (Levo-Dromoran) | 2 | 4 | PO, SC, IM | 30–90 | 4–6 | 4–16 | Accumulates with chronic dosing |
| Oxymorphone (Numorphan) | 1.5 | N/A | Parenteral, PR | 10–90 | 3–6 | 3–4 | |
| Phenylpiperidines | | | | | | | |
| Fentanyl (Sublimaze) | 0.1 | N/A | IV, spinal, buccal, patch | 10 | 1–2 | 3–4 | Nonlinear kinetics with repeat dosing |
| Sufentanil (Sufenta) | 10 mcg | N/A | Parenteral, spinal | 10 | 2–4 | | Duration may be dose-related |
| Diphenylheptanes: | | | | | | | |
| Methadone (Dolophine) | 10 | 5 | PO, SC, IM | 60 | 6–8 | 21–25 | Accumulates with chronic dosing |
| Opioids for Mild to Moderate Pain (mu Agonists) | | | | | | | |
| Phenanthrenes | | | | | | | |
| Codeine (various) | 120 | 200 | PO, parenteral, PR | See morphine | 3–6 | | |
| Hydrocodone (various) | N/A | 30 | PO | | 30–60 | 3–4 | |
| Oxycodone (various) | N/A | 20 | PO | | 30–60 | 4–6 | |
| Dihydrocodeine (various) | N/A | 30 | PO | | 30–60 | 4–6 | |
| Phenylpiperidines | | | | | | | |
| Meperidine (Demerol) | 100 | 400 | PO, parenteral | 15–60 | 1–3 | 3–4 | Normeperidine is a CNS irritant |
| Partial Agonists/Antagonists (mu and/or Kappa Agonists With or Without mu Antagonism) | | | | | | | |
| Buprenorphine (Buprenex) | 0.3 | N/A | SC, IV, IM | 1–5 | 4–6 | 2–3 | Not naloxone reversible |
| Butorphanol (Stadol) | 2 | N/A | SC, IV, IM, intranasal | 15–45 | 3–4 | | Dysphoric |
| Nalbuphine (Nubain) | 10 | N/A | SC, IV, IM | 1–5 | 4–6 | 2–3 | Respiratory ceiling |
| Opioid Antagonists | | | | | | | |
| Naloxone (Narcan) | 0.40.8 | N/A | IV | 10 | 2–3 | 1–1.5 | |
| Naltrexone (Trexan) | N/A | 50 | PO | 30–60 | 24–72 | 9–17 | Duration dose-dependent |

NOTE: Most analgesic equivalents were derived from single dose studies.

CNS, central nervous system; IM, intramuscular; IV, intravenous; N/A, not applicable; PO, orally; PR, by rectum; SC, subcutaneously.

Differentiating Between Clinical Opioid Use and Drug Abuse

When using opiates to treat severe pain lasting more than a few days, several phenomena can occur. The terms used to describe these phenomena are *tolerance*, *physical dependence*, and *pseudoaddiction*. Clinicians must understand the differences and the context in which these phenomena occur to differentiate between expected developments and drug abuse. Much of the fear and reluctance to use opioid analgesics result from misunderstandings of these natural events by clinicians, patients, and caregivers.

Tolerance to the analgesic effects of opiates is a common physiologic finding that results from neuroadaptation by the body during chronic use.⁵³ It may be seen after several days of therapy and can be first recognized by a decrease in the duration of analgesia. Patients who develop tolerance require an increase in the opiate dose to achieve the same level of analgesia. Tolerance to opiates occurs fairly slowly, but should be anticipated in all patients requiring continuous opiate therapy, such as critical care patients or patients with chronic painful conditions. These types of patients should be informed that the need for increasing doses is an expected occurrence and does not indicate addiction.

Physical dependence is a natural physiologic process that occurs with chronic opioid administration.⁵³ Signs and symptoms of physical dependence are summarized in Table 8-4 and are seen only when opiates are stopped abruptly or the

Table 8-4 Signs and Symptoms of Opiate Physical Dependence

1. Rhinorrhea (runny nose)
2. Lacrimation (tearing)
3. Hyperthermia, chills
4. Muscle aches (myalgia)
5. Emesis, diarrhea, gastrointestinal cramping
6. Anxiety, agitation, hostility
7. Sleeplessness

Symptoms begin within 6 hours for short-acting opioids (e.g., morphine) and generally peak in approximately 36–48 hours. Symptoms of abstinence usually subside within 3 to 7 days (average, 5 days). With methadone, however, abstinence syndrome develops more slowly, and is less severe, but protracted. Opioid antagonists or mixed agonist–antagonist drugs can precipitate abstinence in some patients after chronic or subchronic opioid exposure.

dose is markedly decreased. Physical dependence does not indicate addiction, and the difference should be made clear to patients and their caregivers. The symptoms of physical dependence may be observed in critical care patients who have their doses of opioid analgesics tapered too rapidly or in patients requiring chronic opioid therapy who are unable to obtain an adequate supply of medication or who are undertreated. Unintentional physical withdrawal can also occur if metabolic enzyme inducers, such as phenytoin, are added to a chronic pain regimen. Early symptoms of abstinence can include irritability and restlessness, and onset occurs within 6 to 24 hours of the time the last opioid dose was administered. Later, a person develops chills, sweating, joint and muscle pains, and gastrointestinal (GI) distress, including emesis and diarrhea with abdominal cramping. The time of onset is correlated to the drug's half-life, to the average doses required by an individual, and to the pattern and history of opioid dosing. For example, abstinence induced by tolerance to hydrocodone (a drug with a short half-life) can be anticipated to develop in 4 to 6 hours after the last dose, whereas with methadone it may not occur for 24 to 48 hours after the last dose. Similarly, the abstinence syndrome can last longer when associated with long-acting agents. For short-acting agents (e.g., hydrocodone or oxycodone), abstinence may resolve within 48 to 72 hours, whereas for drugs such as methadone, it may last as long as several days. Mood swings, myalgia, and arthralgia can persist for as long as several weeks after the last dose of an opioid.

Addiction to opioid analgesics is characterized by a dysfunctional pattern of use for purposes other than alleviation of pain. It may involve adverse consequences of opioid use, loss of control over their use, and preoccupation with obtaining opioids despite the presence of adequate analgesia. It is important to realize that tolerance and physical dependence may or may not be present in addiction and that the presence of tolerance and physical dependency does not imply addiction. *Pseudoaddiction* is an important type of behavior that clinicians must understand and recognize because it can easily be misinterpreted as addiction.⁵³ Pseudoaddictive behaviors may be seen in patients with severe, unrelieved pain. These behaviors can mimic those seen with addiction. Patients become preoccupied with obtaining opioids; however, their underlying focus is on finding relief for their pain. Their fear of not having an adequate amount of medication available to control their pain may result in medication hoarding. When patients with pseudoaddiction are provided adequate analgesia, the behaviors that mimic addiction resolve, the medications are used as prescribed, and the patient's daily functioning increases.⁵³

If opioid misuse is suspected, pharmacists can help both patients and prescribers develop appropriate care plans by being vigilant for warning signs that the patient is not adhering to a care plan. These include prescriptions from multiple physicians or phone calls from unknown prescribers; rapid or unsanctioned escalation of dosing requirements, particularly for nonmalignant pain syndromes; frequent excuses for running out of medication early or requests for "vacation" supplies; lack of requests for adjunct analgesic refills (e.g., antidepressants, anticonvulsants); extreme polypharmacy with multiple CNS depressants or multiple habituating substances; and injecting oral medicines or chewing matrix formulations. Persons demonstrating these traits may require referral to an appropriate substance abuse program.⁵⁴

ACUTE PAIN

Analgesic Goals

1. E.T. is a 36-year-old woman recovering from the surgical repair of a left tibia fracture following a motor vehicle accident. She is otherwise healthy, with no other medical conditions. Her medication history reveals no drug allergies or history of recreational drug use, and occasional use of oral ibuprofen 400 mg every 6 hours as needed for menstrual cramps. Postoperatively, E.T. received acetaminophen 325 mg with codeine 30 mg, two tablets orally every 3 hours for pain; however, this analgesic regimen was inadequate for controlling her pain. After extensive complaints, E.T.'s analgesic medication was replaced with two tablets of hydrocodone 5 mg with acetaminophen 500 mg every 4 hours. Despite these changes, E.T. continues to complain of pain. Vital signs indicate the following: respiratory rate, 24 breaths/minute; heart rate, 110 beats/minute; blood pressure (BP), 140/85 mmHg. She rates the intensity of her pain as 8 on a 10-point scale. What is your assessment of E.T.'s pain and what are reasonable analgesia goals for E.T.?

The current analgesic regimen has not provided E.T. with adequate pain relief based on her pain evaluation rating of 8 on a 10-point scale. Physiologic responses to pain include autonomic findings, such as increased respirations, heart rate, and BP. The apparent analgesic failure in E.T. can be attributed to several factors. First, the choice of medication may not be effective for her level of pain, or she may simply require more analgesics than anticipated. Standard analgesic dosage recommendations are only conservative estimates of average initial doses. Ultimately, analgesic dosing must be tailored to the specific needs of the patient. Patients with compromised metabolic function may need smaller doses, whereas patients with extensive injuries may require larger doses. Acute pain always should be aggressively treated.

After an initial analgesic has been administered, the patient should be assessed frequently, and doses should be adjusted quickly in response to inadequate pain control or excessive sedation. The dose of an analgesic should be modified before a patient feels the need to express significant discomfort from pain. E.T.'s complaints of significant pain intensity may also be influenced by anxiety that commonly accompanies inadequate pain relief. E.T.'s possible anxiety over the current surgical outcome could intensify her pain because pain and anxiety are reinforcing phenomena. For most patients, pain is synonymous with injury. When an injury has been repaired and the patient continues to experience pain, the patient's anxiety and fear can intensify pain sensations. The use of pain distress scales, as shown in Figure 8-3, may be more useful for evaluating pain in patients with significant anxiety.²⁴ The use of distraction or relaxation techniques can also help make E.T. more comfortable.

The goal for managing acute pain is to keep the patient as comfortable as possible while minimizing possible untoward adverse effects from the analgesic. It is important for the clinician to discuss the pain management plan with the patient, establish goals of therapy, address patient concerns, and evaluate patient understanding. Use of pain rating scales, as shown in Figure 8-2, should be reviewed with the patient, and a pain rating goal that is acceptable to the patient should be determined. The importance of factual reporting should be emphasized to the patient. This helps eliminate behaviors of stoicism

or exaggeration.²⁴ Appropriate goals for E.T. would be a pain rating of <4 of 10-point scale, a return of vital signs toward her baseline values, and reduced anxiety. Only appropriate analgesic selection, careful follow-up evaluations, and rational analgesic dosage adjustments can accomplish these goals.

Combination Analgesics

2. Is the choice of acetaminophen with hydrocodone appropriate for E.T.?

Acetaminophen and opioid analgesics provide pain relief by different mechanisms of action and it is reasonable to use both for their additive or synergistic effects when managing pain. Acetaminophen with hydrocodone is a fixed-dose combination, however, and these combination drug formulations decrease dosing flexibility and frequently lead to unintended toxic side effects. The combination of acetaminophen 500 mg and hydrocodone 5 mg given two tablets every 4 hours can result in the patient receiving 6 g of acetaminophen in a 24-hour period. Chronic administration of acetaminophen in doses exceeding 5 g/day has been associated with hepatic enzyme changes. Short-term use of 6 g of acetaminophen daily for a few days in patients without risk factors (e.g., alcoholism, malnutrition, concurrent administration of hepatic-enzyme inducers) is usually safe.⁵⁵ If patients need to use acetaminophen-containing combination analgesics frequently throughout the day, then it is important to consider products that contain lower amounts of acetaminophen. Several NSAIDs also have been associated with hepatotoxicity.⁵⁶ Acetaminophen and NSAIDs should be avoided in patients who have severe liver disease, as evidenced by elevated liver transaminases, a low serum albumin, or a prolonged prothrombin time. If acetaminophen is to be used at all in patients with impaired hepatic function, doses must be limited to <2 to 3 g/24 hours.

E.T. should have been initiated on a more potent analgesic to control her pain. Analgesic combinations of acetaminophen with either codeine 30 mg or hydrocodone 5 mg are effective for mild to moderate pain (e.g., 5 on a 10-point scale), but these combinations are less than adequate for moderately severe to severe pain, unless the opioid dose is increased. Because E.T.'s pain has not been successfully controlled with either acetaminophen with codeine or acetaminophen with hydrocodone, it would be reasonable to start her on oral morphine 30 mg every 4 hours. If she is unable to tolerate oral medications following surgery, then morphine 4 mg IV every 2 to 3 hours can be used instead. Although the use of IM administration is often prescribed, many clinicians discourage the use of this route because of erratic or unpredictable absorption with some opiates and additional pain caused from the injection itself.

After initiation of morphine, E.T. should be evaluated in a few hours for pain relief and adverse effects. The dose or dosing interval should be adjusted if either is found to be inadequate. Sometimes, changing to an alternative opiate may be indicated if analgesia is still inadequate or unwanted side effects are experienced. Until an individual's response to a particular opioid is known, it is wise for the clinician to formulate a back-up plan with an alternative opiate regimen.

An NSAID such as ibuprofen or naproxen also may be used adjunctively for E.T.'s pain. Although an NSAID alone usually is inadequate for controlling moderate to severe pain, they

have additive analgesic effects when combined with opiates. In E.T., the prescriber should also consider the risk of bleeding after surgical intervention owing to the antiplatelet effect of NSAIDs. The cyclooxygenase-2 (COX-2) NSAIDs appear to have minimal antiplatelet effects, and may be considered if surgery or trauma presents a high risk of bleeding.

Equianalgesic Dosing of Opioid Analgesics

3. How should E.T.'s hydrocodone dose be converted to oral morphine?

Hydrocodone 20 mg orally is approximately equal to morphine 30 mg (Table 8-3). Therefore, 10 mg of hydrocodone as originally ordered for E.T. is equal to an oral morphine dose of approximately 15 mg, or 5 mg of morphine by injection. This dose of morphine would likely be inadequate for E.T. because her pain is not controlled by this equivalent dose. Thus, E.T. should be started on oral morphine 30 mg every 4 hours around-the-clock for the first 24 hours, then changed to as-needed dosing afterward. Inflammation caused by trauma often peaks around 48 to 72 hours following the inciting event, so pain is expected to decrease dramatically after this period.

Managing Side Effects of Opioid Analgesics

4. E.T. complains of itching after three doses of morphine, but shows no sign of rash. What can be done to alleviate the problem?

Opioid analgesics infrequently cause pruritic rashes due to true allergic-type reactions. In contrast, when administered parentally they commonly stimulate local histamine release from mast cells and cause a local wheal, burning, itching, and erythema at the site of injection. Similarly, systemic release of histamine after both oral and parenteral administration of opioids can produce either localized or generalized flushing and itching. Although histamine related reactions occur frequently and may be confused with an allergic reaction, true opioid allergies are infrequent. When they do occur, they are IgE-dependent.⁵⁷ Coadministration of diphenhydramine (Benadryl) or hydroxyzine (Vistaril) prevents histamine-induced itching and also provides antianxiety effects that may add to morphine's analgesic benefit.

Chemically, there are three distinct structural categories of opioids: the *phenanthrenes* (morphine, codeine, hydrocodone, hydromorphone, dihydrocodeine, oxycodone, oxymorphone, levorphanol, nalbuphine, butorphanol, dezocine, and dihydrocodeine), the *phenylpiperidines* (meperidine, fentanyl, alfentanil, sufentanil, and remifentanil), and the *phenylheptanones* or *diphenylheptanes* (methadone, levomethadyl, and the weak analgesic, propoxyphene). Allergic reactions may cross-manifest within the same chemical structural class, but are less likely between classes. Thus, in patients with true allergic reactions, treatment can be instituted with a product from one of the other chemical groups. For example, if E.T. was allergic to morphine, she could be switched to fentanyl.

5. What other adverse effects from morphine should be monitored for in E.T.? What preventive measures should be considered?

The most common side effects reported with the use of opioid analgesics are nausea, vomiting, itching, and constipation.

These are expected untoward opioid effects and, with some care, they can be managed or minimized. These first three symptoms of nausea, vomiting, and itching can all be minimized by antihistamines, such as diphenhydramine or hydroxyzine 25 to 50 mg orally every 6 hours as needed. If drowsiness from the antihistamine is excessive when used in combination with the opioid, a nonsedating antihistamine such as fexofenadine can be substituted. Persistent and more problematic symptoms may require switching to an alternative opioid analgesic.

The best method for treating opioid-induced constipation is prevention. Postsurgical patients are especially susceptible to this effect because their GI motility is already slowed from decreased physical activity and from anesthetic agents received during surgery. Morphine and other opioids suppress the propulsive peristaltic action of the colon, increase colonic and anal sphincter tone, and reduce the reflex relaxation response to rectal distention. These actions, combined with decreased normal sensory stimuli for defecation because of their CNS-depressant actions, contribute to opioid-induced constipation. Stool softeners are effective in keeping the bowel contents moist, but do not stimulate bowel peristaltic propulsion. Only the stimulant laxatives and prokinetic agents can increase bowel propulsive activity. When opioid analgesics are initiated, a stimulant laxative plus stool softener should also be given. E.T. will be receiving morphine orally around the clock and would probably benefit from two tablets of senna 8.6 mg daily in combination with docusate sodium 200 mg twice daily. If constipation persists, osmotic laxatives, such as lactulose or sodium phosphate enema, may be added to draw water into the lumen of the bowel, which would cause distention and peristalsis.

Postoperative ileus frequently is exacerbated by opioid analgesics, but opioids rarely produce ileus or bowel obstruction alone without other underlying physiologic causes. Oral naloxone 0.4 to 1.2 mg every 6 hours has been used with some success in preventing opioid-induced constipation. Unlike parenteral naloxone, oral naloxone is poorly absorbed systemically (25%) and, therefore, will not interfere with analgesic effect unless doses are high.^{58,59} An oral naloxone formulation is not yet commercially available, but the parenteral preparation can be administered orally if needed. The oral naloxone requirement rarely exceeds 2.4 mg every 6 hours. At higher dosages, systemic antagonist effects can occur, resulting in decreased analgesia in addition to the local intestinal effects. Other opioid antagonists, such as methylnaltrexone, are currently being investigated and may provide an alternative to oral naloxone.⁶⁰

6. On the third day of her morphine treatment, E.T. appears agitated. Could her agitation be attributed to her morphine?

Although opioids are CNS depressants, they can cause CNS excitation, especially if the patient receives large doses for a prolonged period. Anxiety, agitation, irritability, motor restlessness, tremors, involuntary twitching, and myoclonic seizures have been associated with meperidine, morphine, and hydromorphone, but not methadone, although methadone may rarely cause myoclonus. For meperidine and morphine, the CNS toxicity correlates to accumulation of their active metabolites, normeperidine and morphine-6-glucuronide, respectively. Because both of these metabolites are cleared renally, patients with renal insufficiency are at greatest risk,

but toxicity can also occur when high doses are administered frequently in patients with normal renal function.^{59,61} With meperidine, the problem is compounded by the 17-hour half-life of normeperidine. In patients with normal renal function, avoiding doses in excess of 60 mg/hour of meperidine, 100 mg/hour of morphine, or 40 mg/hour of hydromorphone minimizes CNS toxicity.

The treatment of opioid-induced CNS irritability should include discontinuation of the opioid analgesic and treatment with a benzodiazepine. Myoclonic seizures resulting from meperidine administration are sometimes preceded by involuntary twitching in the extremities and can be averted by discontinuing the meperidine. Seizures induced by meperidine are resistant to naloxone, but respond to anticonvulsants such as phenytoin or diazepam. Because E.T. has normal renal function and her morphine dose is not excessive, it is unlikely that she is suffering from morphine-induced CNS effects. It is more likely that she is starting to recover from her surgery and is anxious from her environment. Nevertheless, it may be time to start reducing her morphine dose if her pain is well controlled.

Ketorolac

7. Could parenteral ketorolac (Toradol) be given to E.T. instead of the morphine?

For patients such as E.T. with acute severe pain, an opioid such as oral or parenteral morphine or hydromorphone should be the first-line agent for pain management. As E.T.'s pain severity decreases, however, an NSAID may be considered for treating mild to moderate pain.

Because it is the only available injectable NSAID in the United States, ketorolac is sometimes used as an alternative to opioids. Although ketorolac is indicated for the short-term management of moderate to severe pain, it should not be substituted for appropriate opioid analgesics for the management of acute postoperative pain.^{62,63} Ketorolac is most beneficial in postoperative pain if it is used in combination with the opioids instead of as monotherapy. Parenteral formulations of NSAIDs are no more effective than oral formulations given in equivalent doses (e.g., ibuprofen 600 mg orally every 6 hours is equally as effective as 15 to 30 mg parenteral ketorolac).⁶⁴ Ketorolac also has been associated with several cases of serious postsurgical bleeding. Although ketorolac could be effective in relieving E.T.'s pain, it is no more effective than morphine. Patients receiving ketorolac should be monitored for typical NSAID side effects, especially postsurgical bleeding.

The NSAIDs cause sodium retention and can also block prostaglandin-induced vasodilation in patients with compromised renal blood flow. Thus, NSAIDs should be used with caution in patients with heart failure, hypovolemia, dehydration or any other conditions that compromise renal blood flow and increase the risk of developing renal toxicity.

Nonsteroidal Anti-Inflammatory Drug Selection

8. Two days later, E.T. is ready to be discharged from the hospital. Although her pain is much improved, she still has mild to moderate intermittent pain. The pain management team is planning to send her home with an NSAID to treat her pain. Is any one NSAID analgesic superior to the others?

In all probability, all NSAIDs, not just those with an approved indication for the treatment of mild to moderate pain, have analgesic properties. The superiority of any particular NSAID for a particular patient cannot be predicted, and no one NSAID has been demonstrated to have superior analgesia over any other. Nevertheless, patients who fail to benefit from one NSAID can respond to a different NSAID. Therefore, an NSAID should be selected based on the patient's previous history of response, efficacy, safety, and cost. Ibuprofen and other propionic acids have a long history of safety and are available as less costly generic products. (See Chapter 43, Rheumatic Disorders, for a more detailed discussion of the clinical use of NSAIDs.)

When selecting one of these agents, the clinician must be aware of the considerable risk of systemic side effects. Although GI side effects are the most common, NSAIDs have caused undesirable nervous system, otic, ocular, hematologic, renal, hepatic, and cardiovascular adverse effects.

Several large randomized, controlled trials prompted the U.S. Food and Drug Administration (FDA) in 2004 to withdraw rofecoxib, a selective COX-2 inhibitor, from the market because of increased cardiovascular risk associated with a prolonged period of use. At the same time, questions were also raised about the safety of nonselective NSAIDs. When compared with the selective COX-2 inhibitor, celecoxib, naproxen was linked to increased risk for cardiovascular events after approximately 3 years of therapy. This emerging knowledge, on a previously unrecognized problem, prompted the FDA to emphasize a warning for all NSAIDs regarding an increased risk for cardiovascular events. Until further data are available, these drugs should be initiated at the lowest effective dose for the shortest period of time.⁶⁵

9. If E.T. had a history of asthma, would an NSAID be safe to use?

Aspirin and essentially all other NSAIDs can induce bronchospasm and other allergic manifestations in patients with a history of asthma, allergic rhinitis, and nasal polyps. An asthma history alone is not a reason to withhold an NSAID. If, however, a patient describes an asthma-like response (shortness of breath, wheezing, cough, laryngospasm) following aspirin or other NSAID ingestion, no drugs from this class should be used in the future.

The risk of using aspirin or other NSAID in patients with chronic bronchitis, emphysema, or in asthmatics without nasal polyps or history of drug-induced bronchospasm is less clear. If E.T. had a history of asthma, then an NSAID should be used cautiously.^{64,66} Acetaminophen does not induce bronchospasm and is safe to give to patients with obstructive airways disease, including a history of NSAID induced asthma.

Analgesic Nephrotoxicity

10. What are the risks of analgesic nephropathy from NSAID use in E.T.?

Analgesic overuse is a common cause of chronic interstitial nephritis (CIN) and may account for approximately 5% of the cases of chronic renal failure in the United States. Historically, aspirin and phenacetin in combination were thought to be the causative agent for most cases of CIN; however, acetaminophen, aspirin,⁶⁷ and other NSAIDs^{68,69} also have been implicated. Acetaminophen-induced renal toxicity is almost al-

ways accompanied by concomitant serum hepatic transaminase changes and generally is associated with acute acetaminophen intoxication.⁷⁰ Most cases of interstitial nephritis seem to be related to both dose and duration of NSAID therapy.^{71,72} (Also see Chapter 30, Acute Renal Failure.)

The NSAID's effect on renal function may be twofold. NSAIDs can directly damage renal tubules and can also reduce renal blood flow by inhibiting prostacyclin. Prostacyclin modifies renal function in response to the effects of endogenous vasoconstrictors (e.g., norepinephrine and angiotensin II), especially if the patient is volume depleted, has been taking diuretics, or is elderly. Renal insufficiency may occur in 20% of patients with one or more of these identifiable risks who also take NSAIDs.^{73,74} Patients with cirrhosis and ascites⁷⁵ and patients with significantly altered hemodynamic status can experience as much as a 50% decrease in creatinine clearance (ClCr) when treated with indomethacin (Indocin)^{76,77} or ibuprofen (Motrin). Some subjects with normal renal function experience profound changes in glomerular filtration rate when taking indomethacin concurrent with triamterene (Dyrenium).⁷⁸

For E.T., who is fairly young and healthy without risk factors, the potential for NSAID-induced renal toxicity is quite low. Her renal function still should be monitored, however, if she is to be placed on an NSAID for more than a few days because she has recently undergone surgery and may have relative volume depletion.

NSAID Use in Renal Disease

11. If E.T. was currently exhibiting renal dysfunction, what NSAID could be used?

Sulindac (Clinoril) and nabumetone (Relafen) have been reported to cause less renal insufficiency because of the absence of active urinary nephrotoxic metabolites. These two NSAIDs can still decrease renal blood flow in patients at risk and can cause renal dysfunction via hypersensitivity reactions unrelated to their effects on renal blood flow. Although sulindac and nabumetone appear to be preferred over other NSAIDs in patients with renal dysfunction, clinical experience is not as great with these two drugs relative to other NSAIDs.

Possible drug-induced nephrotic syndrome has been reported with indomethacin (Indocin), ibuprofen (Motrin), naproxen (Naprosyn), phenylbutazone (Butazolidin), fenoprofen (Nalfon), sulindac (Clinoril), and tolmetin (Tolectin). In particular, fenoprofen was implicated in 71% of 31 cases.⁷⁹ The prognosis for recovery of renal function is excellent, although some patients require treatment with corticosteroids.⁸⁰ It is unclear whether patients with pre-existing renal dysfunction are at any greater risk of developing further drug-induced abnormalities, but most clinicians consider it a relative contraindication.

Opioids

Patient-Controlled Analgesia

12. T.J., a 52-year-old woman, has had posterior spinal fusion with instrumentation because of severe scoliosis that compromised her respiratory function and quality of life. She has just been transferred to the ward from the postanesthetic recovery critical care unit. She is now crying and complaining of

severe pain not relieved by intramuscular meperidine 75 mg every 3 hours. T.J. has no known drug allergies. She has a history of taking acetaminophen 500 mg with hydrocodone 7.5 mg two tablets every 3 hours before admission. Why would a patient-controlled analgesia (PCA) device be useful for T.J.?

The current dose of meperidine is high and carries the risk of CNS side effects. PCA is a technique whereby patients self-administer narcotics by using a preprogrammed mechanical infusion device attached to tubing that delivers the drug to the patient through an IV or subcutaneous needle or catheter. Basically, the patient depresses a button to activate the PCA controller to deliver a preset dose of opiate medication. This prevents the need to call a nurse or other caregiver when pain arises and also obviates the problem of drug doses that are not ordered sufficiently frequently. The controller is preprogrammed to establish “lock-out” periods that prevent the pump from delivering a dose if the patient presses the button too often. Safeguards against accidental overdose are instituted by adjusting the concentration of drug in the controller or the duration of the lock-out period. Either of these variables can be adjusted to fit the patient’s analgesic needs. Caution must be taken to instruct parents of children or adolescents appropriately on the use of the PCA device, lest they inadvertently administer an excess amount of medication. In general, family members should not act as “surrogates” in helping patients control their pain with a PCA device.

Numerous programmable PCA devices are available, most of which provide intermittent self-boluses of drug, with or without continuous infusion. Some systems use syringe pump technology and others an IV pump system. Compact devices

are convenient for ambulatory use. T.J.’s pain can be managed with a PCA device for as long as she is able to comprehend the operation of the device. Most postoperative patients require a basal continuous IV infusion of opioid in addition to intermittent boluses during the first 24-hour period. The need for continuous basal infusion usually diminishes after 24 to 48 hours. PCA is most useful in the first 3 to 5 postoperative days when the patient has the most severe pain. After this initial critical period, the pain can readily be managed with oral analgesic doses. The PCA allows T.J. to have control over her pain. She will determine how often and when the opioid analgesic is delivered, and she can titrate the dose to a level of comfort or side effects that is acceptable to her.

OPIOID SELECTION FOR USE IN PCA

13. What opioid analgesics could be used in T.J.’s PCA device?

Most of the commonly prescribed parenteral opioids can be used in a PCA, but fentanyl, hydromorphone, and morphine are used most frequently. Meperidine is used less frequently because of the problems with the normeperidine metabolite discussed earlier. (See Table 8-5 for dosing guidelines.) Morphine usually is recommended first, followed by hydromorphone, fentanyl, and meperidine. If the patient has a history of morphine intolerance (e.g., itching or nausea), alternative agents, such as hydromorphone, should be initiated. Most of the opioids used for PCA have a broad range of acceptable doses with the exception of meperidine, which has a narrow dosing range because the active normeperidine metabolite can

Table 8-5 Recommended Doses of Opioid Analgesics

| <i>Initial Doses</i> | <i>Adult Oral Dose (mg)</i> | <i>Child Oral Dose (mg/kg)</i> | |
|---|--------------------------------|--------------------------------|-----------------------------|
| Opioid Agonists for Moderate to Severe Pain (mu Receptor Agonists) | | | |
| Morphine (various) | 15–30 | 0.30 | |
| Hydromorphone (Dilaudid) | 4–8 | 0.06 | |
| Levorphanol (Levo-Dromoran) | 2–4 | 0.04 | |
| Methadone (Dolophine) | 5–10 | 0.20 | |
| Opioids for Mild to Moderate Pain (mu Agonists) | | | |
| Codeine (various) | 30–60 | 0.51 | |
| Hydrocodone (various) | 5–10 | N/A | |
| Oxycodone (various) | 5 | 0.1 | |
| Tramadol (Ultram) | 50–100 | NR | |
| Meperidine (Demerol) | Not recommended (NR) | | |
| Patient Controlled Analgesia (PCA) (Parenteral) | | | |
| | <i>Usual Initial Dose (mg)</i> | <i>Dose Range (mg)</i> | <i>Interval Range (min)</i> |
| Morphine | 1.0 | 0.5–2.0 | 6 (5–10) |
| Hydromorphone | 0.2 | 0.04–0.4 | 6 (5–10) |
| Fentanyl | 0.01 (10 g) | 0.01–0.05 | 6 (5–10) |

Example: A morphine PCA with a 1.0-mg initial dose that allows a patient to self-administer an additional 1 mg every 6 minutes provides a dosing range of 1–11 mg/hr available medication.

accumulate, even at normal therapeutic doses. Meperidine also has only a 3-hour half-life and perhaps an even shorter duration of action as an analgesic.⁸¹ Therefore, meperidine is unsuitable for treatment of acute severe pain when the analgesic requirement is exceedingly high or when patients have impaired renal function. Fentanyl can be a safer alternative to meperidine.

Patient controlled analgesia is used most commonly for administering opioids IV and, on rare occasions, subcutaneously. Subcutaneous opioid administration is limited by the fluid volume needed to deliver the drug. A subcutaneous infusion of 1 mL/hour is universally accepted; however, slightly larger volumes is acceptable in some patients. Highly concentrated morphine solutions (e.g., 60 mg/mL) must be compounded to permit maximal doses for these patients. Alternatively, hydromorphone (Dilaudid HP) at concentrations of 10 mg/mL can be used. When necessary, hydromorphone powder can be purchased and higher concentrations can be prepared (maximal concentration of 40 mg/mL can be achieved), but it is unknown whether concentrations that exceed those of commercial products increase local tissue irritation or other untoward effects.^{82,83} Because no contraindications exist, T.J. should be started on IV morphine in her PCA pump.

14. What dosing regimen should be recommended for use for T.J.'s PCA pump?

An appropriate order for PCA must include the name of the drug, solution concentration, dose for self-bolus, lock-out period, continuous basal dose, hourly maximal dose limit, and dose and frequency for breakthrough pain. An example of a PCA order for T.J. would include the following:

| | |
|-----------------------|---|
| Morphine sulfate | 1 mg/mL |
| Self-dose | 1 mg (1 mL) IV |
| Lock-out time | 6 minutes |
| Basal dose | 1 mg/hour (1 mL/hour) IV |
| Dose for breakthrough | 1 mg IV every 20 minutes as needed for pain |
| 1-hour limit total | 12 mg IV |

15. How often should monitoring occur for T.J.'s PCA therapy?

Although T.J. has a history of opiate use, it is imperative that appropriate monitoring tools be in place to assess her response to therapy. Even at therapeutic doses, opiate analgesics can depress respiration, alter heart rate, and lower blood pressure. Therapeutic monitoring should be more frequent within the first 24 hours, when opioid effects are less predictable. Typical assessments include blood pressure, pulse, respiratory rate, oxygen saturation, and visual analog and sedation scale scores. An appropriate monitoring pattern for T.J. may include the following:

| | |
|-----------------------------|------------------------|
| Holding parameters for PCA: | |
| Respiratory rate | <10 breaths/minute, OR |
| Systolic blood pressure | <90 mmHg |

T.J. should be assessed at the initiation of the PCA dose and then at regular intervals (every 30 minutes, twice; every hour, twice; then every 4 hours) unless she becomes unstable or pain increases.

DOSE CONVERSION BETWEEN OPIOID ANALGESICS

16. T.J. has requested another analgesic agent because of excessive sedation. She currently needs 10 mg of morphine per hour

from her PCA. How should T.J. be converted to another PCA opioid analgesic?

The IV equivalent of morphine 10 mg/hour is approximately equal to hydromorphone 2 mg/hour, meperidine 100 mg/hour, or fentanyl 100 mcg/hour (Table 8-3). Meperidine is not a viable alternative for T.J. because the equivalent meperidine dose of 100 mg/hour exceeds the maximal recommended dose of 60 mg/hour. The remaining options are either hydromorphone or fentanyl PCA. Examples of options for PCA orders include either of the following:

| | |
|---|--|
| Fentanyl | 10 mcg/mL |
| Self-dose | 10 mcg (1 mL) IV |
| Lock-out dose | 6 minutes |
| Basal dose | 10 mcg/hour (1 mL/hour) IV |
| Breakthrough pain | 10 mcg intravenously every 20 minutes as needed for pain |
| 1-hour limit total | 120 mcg IV |
| Hold parameters for PCA: Respiratory rate <10 breaths/minute or, systolic blood pressure <90 mmHg | |
| OR | |
| Hydromorphone | 0.2 mg/mL |
| Self-dose | 0.2 mg (1 mL) IV |
| Lock-out dose | 6 minute |
| Basal dose | 0.2 mg/hour (1 mL/hour) IV |
| Breakthrough pain | 0.2 mg IV every 20 minutes as needed for pain |
| 1-hour limit total | 2.4 mg IV |
| Hold parameters for PCA: Respiratory rate <10 breaths/minute or, systolic blood pressure <90 mmHg | |

As always, T.J. should be re-evaluated in 2 hours after changing the PCA, and doses should be adjusted at that time.

CONVERSION FROM PCA TO ORAL OPIOIDS

17. Forty-eight hours later, T.J.'s requirement for hydromorphone has decreased significantly. Her requirement has averaged 0.5 mg hydromorphone/hour in the last 12 hours. How should T.J. be converted to oral opioid analgesics?

Patient controlled analgesia is rarely used beyond 72 hours postoperatively,⁸⁴ and continuous basal infusions frequently are discontinued after the first 24 hours. Transition to oral opioid analgesics from PCA should occur as soon as the patient is able to tolerate oral intake of solids. Oral opioid analgesia usually is given every 3 to 4 hours for convenience, as well as allowing time for drug absorption. Conversion to oral from parenteral opioids is best achieved based on the total opioid requirement during the previous 24-hour period. For T.J., the total 24-hour IV hydromorphone (0.5 mg/hour) required was 12 mg, which is roughly equivalent to IV morphine 60 mg, methadone 18 mg, or levorphanol 12 mg. Alternatively, the 24-hour oral equivalent doses are as follows: morphine 180 mg, methadone 18 mg, levorphanol 24 mg, or hydromorphone 48 mg. Levorphanol, with its long duration of action and a lower incidence of GI side effects, would be a good oral agent to use for T.J. The levorphanol dose for T.J. would be 4 mg every 4 hours. A period of 4 to 6 hours of PCA overlapping dosing of oral opioids is recommended to allow equilibration of the oral medicines, but the PCA's continuous basal infusion should be stopped as soon as the oral dose is given.

Tapering of Opioid Analgesics

18. How should T.J.'s opioid analgesics be tapered?

Most patients gradually decrease their activation of a PCA pump as soon as their acute pain begins to subside. In instances in which patients have not decreased their PCA pump use, the dose may safely be reduced by 15% to 20% each day without precipitating symptoms of abstinence. For T.J., the oral levorphanol regimen should be changed to an as-needed schedule once the pain has stabilized. For most patients, a scheduled opioid taper is not essential unless the total daily requirement is in excess of 160 mg of oral morphine (or its equivalent) or if opioid use is prolonged. T.J. should be able to be converted to acetaminophen 325 mg with codeine 30 mg (or an equivalent opioid preparation) once her oral levorphanol has been completely discontinued.

Pain Management in the Opioid-Dependent Patient

19. If T.J. had a history of heroin and cocaine abuse, how would her pain treatment be modified?

Pain management in an IV drug abuser is not difficult as long as the clinician does not judge the patient's behavior or interject personal values into the decision-making process. As with any patient, the goal is to provide as much comfort as possible. Concerns over opiate abuse or addiction are not relevant when treating acute pain, although the clinician must recognize the potential for physical tolerance of opioids and adjust medication doses accordingly.

The first step in the treatment of a patient with a history of substance abuse is to try to determine the amount of illicit drugs the patient has been using, being alert to the possible abuse of multiple drugs in varying quantities.⁸⁵ Patients who have a history of opiate (heroin) and stimulant (cocaine) use are likely to demonstrate a much greater tolerance to opiates than a patient who has been using opiates alone. Some evidence indicates that cross-tolerance can occur between cocaine and some opiates, but not to methadone.⁸⁶

The primary goal is to control the patient's pain. A combination of methadone titrated to prevent withdrawal and to provide background analgesia plus a short-acting opioid analgesic dosed adequately to prevent breakthrough pain can be used. If T.J. had a history of substance abuse, she could start with methadone 20 to 40 mg/day in four equally divided doses depending on how much heroin had been used (see Chapter 83, Drug Abuse). The methadone would prevent heroin withdrawal and possibly provide additional analgesia. Because her actual pain requirements are unknown, she also would be placed on a PCA with an agent such as morphine or hydromorphone. It is always important to reassess the patient 1 to 2 hours after starting the analgesic regimen for signs of withdrawal, clinical response, and toxicity, and then titrate the doses of both the methadone and hydromorphone accordingly, although it is best to adjust one medication at a time.⁸⁷ The final amount required may be higher than doses typically used in opioid-naïve patients. Conversely, some patients may exaggerate their history of prior drug use and will be quite sensitive to the prescribed therapy. Long-term management should include offering the patient appropriate referrals to drug treatment centers, but the final responsibility should rest with the patient.

Use of Opioids in Recovering Addicts

20. Should opioid analgesics be prescribed to recovering opiate addicts?

Acute opioid use in the hospitalized setting is unlikely to cause opioid addiction; the rate of addiction from clinical opioid use is much less than 1%. Unless it is the patient's choice not to use opioids, no rational reason to avoid them exists. Often the patient's fear of addiction can be alleviated by thorough education. The clinician should have a therapeutic contract with the patient that includes pain management as well as opioid tapering on the resolution of the acute pain (see Chapter 83, Drug Abuse).

Use of Opioids in Renal Disease

21. What adjustments in analgesic dosing would be required if T.J. had an estimated creatinine clearance of 30 mL/minute?

Uremia can produce CNS changes, which can cause patients with renal disease to be more sensitive to the CNS depressant effects of opioids. As discussed in Question 6, some opioids have active metabolites that are renally excreted, and uremia or significant renal disease can lead to their accumulation. For example, the active metabolites of meperidine and morphine (normeperidine and morphine-6-glucuronide, respectively) are renally excreted. Both of these active metabolites can cause CNS excitation; in particular, normeperidine can precipitate tonic-clonic seizures. Therefore, meperidine should be avoided in uremic patients, but other opioids can be used as long as the clinician is aware of the potential toxicities, the patient is closely monitored, and the dosage is properly titrated. For T.J., hydromorphone PCA could still be a reasonable choice for the management of her acute pain; however, a continuous basal infusion would be unnecessary in a patient with significant renal dysfunction. As with all patients receiving opioid analgesics, close monitoring and follow-up care are essential.

Obstetric Pain: Special Considerations for Opioid Analgesia EPIDURALS

22. M.T., a 28-year-old woman who has been in labor for 10 hours, is experiencing strong, erratic contractions at 5- to 15-minute intervals. Her cervix is minimally dilated, suggesting that delivery is still several hours away. Her pain is severe and, if it continues, may compromise her ability to assist in the labor and delivery process. A single, 50 mcg epidural dose of fentanyl is ordered for M.T. by anesthesia. What guidelines are necessary for the safe use of epidural opioids?

Fentanyl and morphine are frequently administered epidurally during labor and during lower extremity surgical procedures (e.g., cesarean delivery, total joint replacements) because they have limited systemic effects and long durations of analgesic action.⁸⁸ Epidural analgesia has also been used in thoracic surgery.⁸⁹ A single dose of morphine 2 to 10 mg given epidurally may provide analgesia for >12 hours.⁹⁰ Respiratory depression can occur 1 to 3 hours after the administration of epidural morphine and can be readily reversed by naloxone. Facial or generalized pruritus also can occur hours after the administration of epidural morphine. If pruritus does occur, it can be controlled with low doses of IM or IV naloxone 0.02 to 0.08 mg without reversing the analgesic effect of the epidural morphine. Frequent monitoring of vital signs is essential after the administration of epidural opioids. Always be vigilant for delayed signs of toxicity, because their onset occurs up to several hours after the administration of the opioid.

Besides morphine, fentanyl (Sublimaze), sufentanil (Sufenta), and buprenorphine (Buprenex) also have been used epidurally. The duration of analgesia of epidurally administered opioids depends less on the serum half-life of the opioid than on the lipid solubility of the drug. The more lipophilic the opioid, the shorter its duration because these agents rapidly diffuse out of the epidural space. In contrast, the more hydrophilic opioids remain in the epidural space longer. For example, methadone, which is highly lipophilic, has a very short duration of activity when administered epidurally despite a long serum half-life of 24 hours.^{91,92} For M.T., fentanyl is a good choice because it has a fairly long duration of analgesia but will not produce significant systemic effects that would compromise the fetus through transplacental migration. Also, the duration of fentanyl is sufficiently short that it will not unnecessarily delay maternal postpartum recovery. A single 50 mcg dose of epidural fentanyl was given to M.T. through an epidural catheter and complete analgesia was achieved.

Spinal Analgesia in Opioid-Dependent Patients

23. Why would spinal opioid analgesia still be appropriate if M.T. is opioid dependent?

Previous opioid use has minimal influence on epidural doses. Opioid-dependent patients can achieve adequate analgesia from epidural opioids, but their physical opioid dependency will not be satisfied. In fact, despite adequate analgesia, an opioid-dependent patient may exhibit symptoms of opiate withdrawal. These include restlessness, insomnia, nervousness, irritability, sweating, and GI hypermotility (nausea, emesis, and diarrhea). If withdrawal symptoms occur, they can be treated effectively by systemic administration of morphine or other opioids. Without treatment, such symptoms may persist for a few days. The dose of the systemic opioids varies with the patient's previous level of opioid dependence, and doses need to be adjusted accordingly. It would be appropriate to start M.T. on a short-acting opioid, such as meperidine 10 mg IV every 15 to 20 minutes, until the symptoms of withdrawal subside. This may be somewhat hazardous because the incidence of respiratory depression in the first 24 hours may be increased when opioids are administered by simultaneous epidural and systemic routes.⁹³ Therefore, longer-acting opioids, such as methadone or levorphanol, should be avoided. The respiratory depression can be treated with the opioid antagonist naloxone, but the dose must be limited to 0.1 mg increments given IV to avoid precipitation of an acute withdrawal syndrome and reversal of analgesia. The naloxone dose can be repeated and the dose titrated to the desired clinical response.

Clonidine for Opioid Withdrawal Symptoms

24. If M.T. was opioid dependent, what are the alternatives for management of the symptoms of physical withdrawal while she is treated with epidural opioids?

Clonidine (Catapres) 0.2 to 1.2 mg/day can effectively suppress the signs and symptoms of opioid withdrawal without eliciting other opioid effects.^{94,95} The specific dose must be individualized for each patient to avoid hypotension, dry mouth, or drowsiness.^{96,97} Clonidine also can be given sublingually or transdermally in equivalent doses. Clonidine transdermal patches of 3.5, 7.0, and 10.5 cm² deliver 0.1, 0.2, and 0.3 mg of

clonidine, respectively, over a 24-hour period. Approximately 24 hours must elapse before steady-state plasma concentrations of clonidine are attained from the patches.^{98,99} Therefore, supplemental oral or sublingual⁹⁶ clonidine 0.1 mg every 6 to 12 hours must be administered during the first 24 hours of the application of the transdermal patches. Clonidine transdermal patches should be used to treat the signs of physical opioid withdrawal only when these symptoms are expected to be severe or prolonged. In addition, clonidine is available for epidural administration and has been used in combination with opioids alone or with opioids and local anesthetics for epidural analgesia. For M.T., who is in labor, clonidine should be avoided owing to the risk of hypotension and possible adverse effects on the fetus. A shorter-acting opioid should be used as in Question 23.

SYSTEMIC OPIOIDS DURING LABOR

25. Should M.T. be given a systemic analgesic rather than epidural analgesia?

If possible, CNS depressants should be avoided during labor because they can compromise fetal vital functions.^{100,101} Nevertheless, if an analgesic is deemed necessary, then an agent that meets the following criteria should be chosen: (a) provides adequate pain relief; (b) has little effect on the course or duration of labor; and (c) affects fetal vital signs minimally during labor, delivery, and postpartum phases. Meperidine and fentanyl meet most of these criteria and, therefore, are frequently preferred over other opioids in obstetrics when given in small, frequent parenteral injections or through a PCA.^{102,103} As with all opioid analgesic use, close monitoring of the patient for analgesia and untoward effects is essential.

Although meperidine and fentanyl seem to have only minimal residual effects on the neonate at analgesic doses, adverse effects, such as respiratory depression, can still occur.^{104,105} According to an early neonatal neurobehavioral scale, meperidine broadly depressed most measured neonatal activities on the first and second days of life.¹⁰⁶ Nevertheless, if the contractions are very strong, erratic, and prolonged early in the course of labor (as with M.T.), a short-acting analgesic (e.g., meperidine) could be useful to blunt the labor pain and calm the mother, so that she can regain control over her contractions and conserve her energy for the actual delivery.

Butorphanol (Stadol) also has minimal effects on fetal and neonatal function and is a reasonable alternative to meperidine or fentanyl in this situation.¹⁰⁷ All potent analgesics should be administered IM or subcutaneously because IV administration is associated with more neonatal and fetal depression because of the high peak serum concentration achieved by this route.^{108,109} Pentazocine has similar effects as butorphanol, but is seldom used because of local tissue reactions at the site of IM or subcutaneous injections. Pentazocine and butorphanol are mixed opiate-agonists/antagonists and can precipitate acute withdrawal reactions in some opiate-dependent individuals. As a result, these drugs need to be used cautiously, if at all, in the opiate-addicted population (see Question 27).

If neonatal respiratory difficulties are manifested as a result of opioid analgesics administered during labor, they can be reversed with naloxone (Narcan). For M.T., meperidine 50 mg IM was given with good clinical response. As with all opioid analgesics, the dose has to be adjusted after an evaluation of the

patient's history and clinical findings. Analgesic doses always should be individualized for the specific patient.

Variability in Intramuscular Meperidine Absorption

26. M.T. achieved excellent analgesia from the first dose of meperidine 50 mg IM, but she started to complain that subsequent doses produced variable pain relief, and she accused the nurse of giving her placebos. What are some of the explanations for this problem?

The most common cause of variable clinical response after an IM meperidine injection is erratic bioavailability after repetitive injections at the same site. The absorption of meperidine from an injection can vary by as much as 30% to 50% after repeated IM administrations. Other considerations include tachyphylaxis, progression of an underlying disease (e.g., in patients with cancer), and the possibility of opioid diversion by the patient or someone else through dilution or removal of active drug from its container.

Special Consideration for Using Partial Agonist and Antagonist Opioid Analgesics

27. What are precautions for using partial agonist and antagonist opioids for analgesia in M.T.?

Pentazocine, butorphanol, dezocine, and nalbuphine are partial agonist/antagonist opioid analgesics. Besides exhibiting agonist analgesic effects, they all possess opiate antagonist properties as well. Generally, they act as agonists at κ -opiate receptors and as antagonists at μ -opiate receptors, which explains their ability to simultaneously produce analgesia and precipitate withdrawal symptoms. Pentazocine has an opioid antagonist effect equal to 1/50 of nalorphine; 80 mg has been known to precipitate abstinence in patients who have been given opioids for chronic pain. If a partial opiate agonist is instituted in a patient previously taking a pure agonist, the dose should be increased gradually, and the patient should be observed closely for symptoms of abstinence. If possible, the pure agonist opioid should be withdrawn gradually. If the agonist dose is fairly low and the patient has not been on the drug for >10 days, then the patient can be changed over to pentazocine. In this situation, the patient may experience mild diaphoresis, but should not have significant withdrawal symptoms. A drug-free period of 2 days before the institution of pentazocine also has been suggested, but this is impractical for a patient in pain.

When partial agonist/antagonist opioid analgesics are being considered, the risk of unpleasant psychotomimetic side effects must be weighed against the benefits. For example, butorphanol-induced dysphoric responses are well documented.^{110,111} A 2-mg dose of butorphanol was associated with an 18% incidence of psychic disturbance, and a 4-mg dose with a 33% incidence. Pentazocine (Talwin) also is associated with a higher incidence of psychotomimetic reactions than traditional opiate agonist analgesics. Hallucinations occurred in 24 of 65 patients (37%) who received 40 to 50 mg of IM pentazocine. In another trial, psychic changes occurred in 1.7% of patients receiving morphine versus 11.4% of patients treated with pentazocine. In comparison, nalbuphine (Nubain) and other analgesics induce much less psychotomimetic effect than butorphanol or pentazocine.^{112,113} Therefore, a partial ag-

onist/antagonist opioid analgesic should be used in M.T. only if she cannot tolerate the available shorter-acting opioid agonist analgesics.

Tramadol

28. What is the purported advantage of tramadol (Ultram) over other opioid analgesics and NSAID?

Tramadol, a centrally acting analgesic with weak opioid agonist properties, activates monoaminergic spinal inhibition of pain. The *O*-demethylated metabolite of tramadol has a higher affinity for opioid receptors than the parent drug; however, after a single oral dose, the binding of tramadol to the μ -opioid receptor is overshadowed by its nonopioid analgesic effects.¹¹⁴ The tolerance and dependence potential of tramadol during treatment for up to 6 months appear to be low; however, the possibility of dependence with long-term use cannot be excluded entirely.¹¹⁵ Tramadol is indicated for the treatment of moderate to severe pain, but analgesia is not superior to other opiate analgesics.^{116,117} It, however, has a lower incidence of respiratory depression or significant GI dysmotility than most traditional opioids.

Tramadol is well tolerated in short-term use. Doses range from 50 to 100 mg orally every 4 to 6 hours and should not exceed 400 mg/day.¹¹⁸ As with other opiate agonists, the principal adverse effects are sedation, dizziness, nausea, vomiting, dry mouth, constipation, and sweating; however, the potential for respiratory depression is low. Seizures have occurred during therapy with recommended doses. Seizure risk increases with doses >500 mg/day and in patients taking concurrent selective serotonin-reuptake inhibitors (SSRI), tricyclic antidepressants (TCA), and other opiate agonists.^{119,120} Tramadol should be used cautiously in patients taking drugs known to lower the seizure threshold, such as monoamine-oxidase inhibitors or antipsychotic agents. In addition, patients with epilepsy, head trauma, metabolic disorders, alcohol or drug withdrawal, or CNS infections may be at increased risk for seizures with tramadol therapy.¹¹⁸ Tramadol also has SSRI-like properties that can initially overshadow the opiate effect in some patients. Therefore, instead of sedation, patients may experience excitation. For more on drug interactions with tramadol, see Question 69.

CHRONIC MALIGNANT PAIN

Goal of Malignant Pain Management

29. A.J., a 68-year-old man, was diagnosed with metastatic prostate cancer 6 months ago. Now he is admitted for excessive sedation and respiratory rate of eight breaths per minute. A.J.'s admitting diagnosis is possible opioid overdose. A.J. was started on a fentanyl patch 100 mcg/hour 24 hours ago by his physician because of spinal pain not adequately relieved by oral acetaminophen 325 mg and oxycodone 5 mg every 3 hours. The fentanyl patch was removed 86 hours ago, and A.J. is again complaining of his spinal pain radiating to his buttocks and left leg. A.J. is currently awake and alert and relates that his pain level is at 9 of 10 on the pain scale. What is the goal in managing A.J.'s pain?

The goal in treating pain of terminal illness is comfort and an acceptable (to the patient) level of consciousness. Opioids

should not be withheld for fear of addiction or that the dose may be too high. Instead, the dose should be titrated based on the patient's clinical response. Ideally, the patient should be comfortable and voice no complaints when questioned about his or her level of activity and alertness. Under these conditions, any dosage reductions or changes in therapy serve no purpose, even if the patient is receiving doses several times those typically used to treat acute pain. To emphasize, clinicians should focus attention on their patients' clinical response rather than on an arbitrary list of doses or ideal number of medications. The immediate goal for A.J. is to break the cycle of pain and to rapidly achieve the greatest degree of comfort possible.

Indications for Use of Fentanyl Patches

30. What special considerations are necessary for use of fentanyl transdermal patches in patients such as A.J.?

Transdermal fentanyl can be used to effectively manage chronic cancer pain. Because of the nature of the transdermal delivery system, the onset of analgesia may be delayed by 6 to 12 hours after placement of the patch.^{121,122} On removal of the patch, the fentanyl deposited in the subcutaneous tissue continues to release active drug for approximately another 8 to 12 hours. These delays in onset on application and in offset after removal of the transdermal patch discourage use of the patch except for patients who require a steady maintenance analgesic dose. The transdermal patches do not provide sufficient flexibility in dosing to manage rapidly changing analgesic needs. Even after stabilized on a given drug regimen, patients with cancer pain always should be given an immediate-onset opioid analgesic (e.g., morphine elixir or solution) to take as needed for management of breakthrough pain.¹²³ If the need for breakthrough drugs becomes frequent, the underlying dosage regimen should be reassessed and the doses increased as appropriate. Fentanyl absorption from the patches can be affected by body temperature, and unintentional overdoses can occur with hyperthermia.¹²⁴

A patient given fentanyl patches must be instructed to dispose of used patches appropriately to prevent inadvertent access by children or household animals. Fentanyl patches were thought to be safe from diversion and abuse, but the drug enclosure membrane can be removed and active drug accessed.¹²⁵

31. What other delivery system options are available for A.J. to manage his breakthrough pain?

Oral transmucosal delivery of fentanyl offers the advantage of controlling pain relatively quickly without being invasive. Oral transmucosal delivery systems deliver drug with a relatively rapid onset and increased bioavailability compared with GI absorption. Because this route delivers medication into the bloodstream so quickly, it is imperative that the relative potency of this agent is understood.^{126,127}

Morphine

Use of Oral Morphine

32. What oral dose of morphine should be selected for A.J.?

The usual initial dose for morphine is 30 mg orally every 3 hours (Table 8-5), but A.J. has been receiving acetaminophen

with oxycodone for an unknown length of time and likely has some degree of opioid tolerance. His response to morphine should be monitored carefully 1 to 2 hours after his initial dose and the dose adjusted appropriately. If A.J. experiences clinical signs of overdose (excessive sedation and somnolence, low respiratory rate), the dose should be decreased; however, if he is still uncomfortable after the 2 hours, an additional 30 mg should be given at once and subsequent doses increased by 10 mg to a total of 40 mg every 3 hours. A.J.'s response should be the primary criterion for determining the dose, and the pharmacokinetics of the drug should determine the dosing interval. Frequent reassessment of A.J.'s pain status and level of consciousness is essential.

When the pain has been relieved, the dose of morphine often can be decreased. Ideally, only one clinician should assume responsibility for coordinating frequent monitoring of the patient's level of awareness and pain control. Once the pain has been controlled, single-day dosage adjustment should be sufficient. If the dose is changed, then it should be reassessed within the first 2 hours to prevent unnecessary exposure to pain or adverse effects. Most oral opioids reach maximal analgesic effect within the first 2 hours after administration, but for longer-acting opioid analgesics such as methadone, the patient should be monitored for several days because of potential drug accumulation.

Tolerance, Dependence, and Addiction

33. Should tolerance, dependence, and addiction to morphine be an issue in A.J.?

Tolerance and physical dependence should be anticipated and discussed openly with patients who are receiving chronic opioid analgesia. Tolerance occurs when a given dose no longer produces the same effect over time. For patients with a malignant disease, it is difficult to differentiate between tolerance and increased pain from disease progression. A.J. should be instructed to inform his clinicians when his pain regimen becomes ineffective. Escalating doses of opioid analgesics should be expected and should not deter the clinician from continuing with analgesic therapy. The need for increasing doses, however, should serve as a warning that alternative analgesic or adjunct agents need to be considered.

Physical dependence should also be anticipated. It should be explained to A.J. that this is a natural adaptation process of the body that occurs with opiates. The signs and symptoms of dependence are seen when abrupt withdrawal or a marked decrease in opioid administration occurs. Therefore, it is important that A.J. receive an adequate supply of medication to prevent exacerbating withdrawal symptoms caused by difficulties in obtaining medication or missed doses. The potential for dependency to opioid analgesics should never prevent the clinical use of opioid analgesics in malignant disease.

Addiction is a compulsive behavior relating to drug procurement and use. Addiction from clinical opioid use for the treatment of pain is rare. Misunderstanding by clinicians and caregivers regarding the difference between tolerance, dependence, and addiction is common and often results in undertreatment of painful conditions.^{128,129} Addiction is not an issue in patients requiring opiates for the treatment of chronic malignant pain. Tolerance and dependence should be expected and should in no way be misconstrued as evidence of addiction.

Use of Sustained-Release Morphine

34. A.J.'s pain was controlled on 40 mg of morphine solution orally every 3 hours, but he is now complaining of the frequency of the morphine dose. He wishes to have the therapy changed to allow fewer daily doses so that he may have longer periods of rest. What can be done about A.J.'s request?

Several controlled release opioid formulations are available for this patient. Morphine is available in four different formulations: MS Contin, Oramorph SR, Kadian, and Avinza. Oxycodone is also available as extended release tablet (OxyContin). Pharmacokinetic profiles differ among formulations of which clinicians need to be aware. Avinza and Kadian provide 24-hour sustained release of morphine, which leads to less fluctuation in drug levels, and therefore less frequent dosing. Avinza is always dosed once daily, whereas Kadian can be given once or twice a day. MS Contin, Oramorph SR, and OxyContin are usually dosed twice daily, whereas some patient may require doses three times a day. Whenever converting patients from one sustained-release (SR) product to a short-acting opioid, it is important to remember that SR formulations (e.g., Kadian and Avinza) will deliver morphine up to 36 hours from the last dose. This warrants intensive monitoring, especially in patients who received high doses for long periods of time.

These opioid formulations have been a target of misuse and abuse. When altering its delivery system, daily drug supply can be released immediately, potentially causing overdose and death. It is important to remember that sustained release formulations should not be crushed and chewed. Kadian and Avinza capsules can be opened and sprinkled over applesauce; however, the integrity of the beads must not be altered.

A.J.'s daily morphine requirement of 320 mg can be provided by use of an SR dosage form given every 8 to 12 hours. However, direct conversion of doses from oral morphine solutions or other immediate-release dosage forms to SR tablets often leads to oversedation initially, particularly during the first hours of the dosing period. Therefore, the SR dose should be reduced by 25% to 240 mg/day ($320 \text{ mg} \times 75\%$) for A.J. This can be given as 90 mg every 8 hours or as 120 mg every 12 hours. SR morphine is available as 15-, 30-, 60-, 100-, and 200-mg tablets and 20-, 50-, and 100-mg capsules. When starting a patient on oral SR preparations, it often is desirable to try an every-8-hour regimen to prevent the initial sedation that often is associated with the larger individual doses of the 12-hour regimen. Likewise, when larger doses are needed, 8-hour dosing intervals usually cause less sedation than 12-hour intervals (i.e., during the first 2 hours of the dosing period). Some patients also may have more breakthrough pain at the end of the 12-hour dosing interval. Careful assessment of the patient's response and toxicity by the clinician is the most essential ingredient between success and failure with either product in managing the patient's pain.

Rectal Use of Morphine Suppositories and Sustained-Release Tablets

35. Several weeks later, A.J. is no longer able to swallow his medication because of worsening of an existing esophageal stricture. What are alternatives for giving A.J. his required daily analgesic?

In addition to the parenteral routes already presented, morphine can be administered as an oral solution or via a rectal suppository. The absorption of the rectal suppository is at least comparable to, or better than that of, the morphine

solution.^{130,131} If A.J. was stabilized on 240 mg/day of SR morphine, the initial morphine suppository dose also should be 240 mg/day. The duration of action of morphine suppositories is similar to that of morphine solution and therefore must be administered every 3 to 4 hours. For A.J., the starting dose is 30 mg rectally every 3 hours. Other agents, such as hydromorphone (Dilaudid) and codeine, are also available as suppositories. The equianalgesic doses of these agents for A.J. (Table 8-3) would be 6 and 10 mg, respectively. SR oral morphine tablets also can be used for rectal administration. The rectal absorption of SR tablets is comparable to the oral route of administration.^{132,133} There is no maximal dose for opioid analgesics for the management of pain of a terminal disease, but there is a limit to how many suppositories or tablets the patient can hold rectally.

Oral Infusion

36. Because A.J. was unable to swallow, he agreed to have a gastrostomy feeding tube placed by a general surgeon. He is now being fed through the tube at a rate of 50 mL/hour. Morphine sulfate solution is added to each feeding bag to deliver 10 mg/hour. He also is receiving amitriptyline (Elavil) 150 mg at bedtime, naproxen suspension 250 mg four times a day (QID), and lorazepam (Ativan) 4 mg three times a day (TID) via the feeding tube. A.J. is reasonably alert and is only slightly uncomfortable. Are there any problems associated with placing A.J.'s morphine in the feeding formula?

No reason exists why morphine cannot be given in this manner. The obvious questions about drug stability, solubility, and binding to proteins in the feeding formula do not appear to present a problem because A.J. has been receiving morphine in this manner for the past several days. The dose of morphine (240 mg/day) is apparently not causing undesirable effects, and A.J. is quite comfortable. Administering morphine as a continuous oral infusion at night while he is sleeping is perhaps the best method to ensure restful, pain-free sleep.

Tricyclic Antidepressants

37. What are the indications for amitriptyline in A.J.'s treatment regimen?

Tricyclic antidepressants have been used experimentally at low to moderate doses as an adjunct to analgesic pain control. These agents may alter psychological responses to pain, have intrinsic analgesic activity, and may potentiate opioid analgesics.¹³⁴ European investigations noted an 82% overall response rate to these agents.¹³⁵ Imipramine (Tofranil) relieved cancer and surgical pain in approximately 75% to 80% of patients, and doxepin (Sinequan) relieved pain completely in approximately half of 16 depressed patients with chronic pain.¹³⁶ Tension headaches also were improved with 25 to 100 mg of doxepin.¹²⁹ Imipramine 50 to 200 mg/day or amitriptyline 10 to 40 mg/day alone or in combination with fluphenazine (Prolixin) have also been investigated for neuropathic pain.¹³⁷ Neuroleptic agents have fallen out of general use, however, for chronic pain syndromes because of their potential for extrapyramidal syndromes (EPS) and other long-term effects. TCA and methadone combination also have been used successfully for the long-term management of chronic phantom limb pain (see Questions 49 and 51).¹³⁸ For A.J., the choice

of TCA is limited, because of his inability to swallow. A few TCA, however, are available as oral suspensions (doxepin and nortriptyline). Therefore, it would be reasonable to continue A.J.'s present TCA therapy.

Methadone

Guidelines

38. The decision has been made to use oral methadone to treat A.J.'s pain. What are guidelines for the safe use of methadone in treating cancer pain?

Clinical experience with the use of methadone for cancer pain is favorable.¹³⁹ The patient's physical and mental condition should be monitored closely, and clinicians should be aware of the long elimination half-life of methadone. Repeated dosing with methadone requires decreasing the dose when comfort is achieved to prevent drug accumulation and overdose. Methadone is 85% bound to serum proteins, and its average plasma half-life is approximately 23 hours, with a range of 13 to 47 hours. Therefore, the drug is tightly bound and only slowly released from its binding sites. Plasma levels of methadone can continue to rise for up to 10 days after an increase in dose.

The duration of analgesia, however, does not correlate to the serum half-life, and multiple doses must be given each day. The absolute amount of methadone in plasma, although it undoubtedly affects sedation and respiratory depression, is not a factor in the magnitude of analgesic response. Nevertheless, analgesic effects are obtained only while methadone plasma levels are above a certain individualized concentration. Most patients can be maintained on doses of methadone every 6 or 8 hours after pain control is achieved, but the drug often must be given every 4 hours or administered with another short-acting opioid analgesic during the first day or two of therapy to control pain.¹⁴⁰ Alternatively, methadone loading with larger doses for the first few doses can accomplish rapid analgesia at the onset of methadone administration. However, this carries a higher risk of rapid drug accumulation and excessive drowsiness. Thus, loading doses must be reduced after the first one to two doses.

The necessity for shorter dosing intervals during the initiation of methadone can cause clinicians who are unfamiliar with the long half-life of methadone to adjust doses too frequently or to maintain a patient at an inappropriately high dose after initial pain control is achieved. This can threaten the patient with dangerous drug accumulation. A scenario that often is repeated is one in which analgesia and patient comfort are achieved after 2 or 3 days of gradually increasing doses. On days 4 and 5, the patient becomes increasingly sedated and on day 6 alarmingly so. The drug is then discontinued, or the opioid antagonist naloxone (Narcan) is administered. Suddenly, the patient is no longer sedated, but the pain has reappeared. This sudden reversal of sedation may be short lived. Because the half-life of methadone is much longer than that of naloxone, the patient can still slip back into sedation once the naloxone is cleared from the plasma in 1 to 2 hours.¹⁴¹ Elderly and severely debilitated patients may require smaller doses of methadone for pain control; therefore, caution must be exercised when methadone is used in these patients.¹⁴²

Dosing

39. What dose of methadone should be prescribed to treat A.J.'s pain?

To convert A.J.'s dose of morphine to an equivalent dose of methadone, use Table 8-3 as a standard reference for comparison. A.J.'s 10-mg every hour oral morphine sulfate solution dose is estimated to be approximately equivalent to 10 mg every 3 hours of morphine IM. On a single-dose basis, IM doses of methadone and morphine are equally potent; however, with repeated doses on a chronic basis, the duration of methadone activity is approximately four times longer than that of morphine. Therefore, the total daily parenteral methadone dose will be only one-fourth that of parenteral morphine. In this case, A.J. would require 20 mg/day of IM methadone. Because oral methadone is only 75% as effective as methadone IM,¹⁴³ A.J. should receive approximately 7.5 mg of methadone orally every 6 hours. Approximately 5 to 10 days will elapse before the full methadone effect is realized, unless loading doses equal to twice that of the maintenance analgesic dose are used for the first two doses. These two larger doses accelerate the process of reaching the steady-state concentration. Breakthrough pain should be anticipated despite around-the-clock dosing of methadone, especially immediately after the conversion from other opioids. Because of long half-life and risk of accumulation, additional methadone doses should not be used as a breakthrough drug. Instead, morphine or oxycodone would be reasonable choices to treat A.J.'s breakthrough pain before methadone reaches its steady-state and maintenance dose can be safely increased.

Continuous Intravenous Morphine Infusion

40. Three months later, A.J. is again hospitalized because of a compression fracture of his spine. He is cachectic and weighs only 87 pounds. He has been receiving 20 mg of morphine IM every 3 hours since his admission. His pain is bothersome and his loss of muscle mass is not conducive to IM injections. What would be a reasonable IV analgesic program for A.J.?

Continuous IV infusions of morphine are superior to IM injections in maintaining a pain-free condition in cancer and surgical patients.^{144,145} In one study, six of eight children with cancer experienced complete pain control with 0.025 to 2.6 mg/kg/hour of morphine for 1 to 16 days.

A.J. has been receiving 160 mg of morphine daily, which is approximately 7 mg/hour. His initial IV infusion dose of morphine should be increased to 8 mg/hour because his pain is still bothersome. When 500 mg of morphine sulfate is added to 500 mL of 5% dextrose in water, the resulting 1-mg/mL solution can be infused IV at 8 mL/hour to deliver the 8-mg/hour dose. In addition, an order should be written for a 4-mg IV bolus of morphine every hour as needed for signs of pain or discomfort.

The supplemental bolus doses of IV morphine will facilitate subsequent adjustments of the continuous infusion rate. At the end of a predetermined period of time, the number of milligrams of drug that were administered by constant infusion is added to 1.5 times the number of milligrams of drug used in supplemental bolus doses. This amount of drug is then divided by the elapsed interval of time, thereby calculating the new infusion rate. For example, if at the end of 6 hours A.J. has received five supplemental doses of 4 mg each, then (6 hours at 8 mg/hour) plus (1.5 × 5 doses of 4 mg) = 78 mg per

6 hours. The new infusion rate should then be 13 mg/hour, and the new supplemental doses should be 6 mg (approximately equal to the amount of drug normally infused in 30 minutes) every hour as needed. Continual assessment of the patient and hourly adjustments of dose are probably superior to the method outlined previously, but the aforementioned method may be more practical for the busy clinician.

Pentazocine

41. Why should pentazocine (Talwin) not be used in treating cancer pain?

The use of agonist/antagonists also should be avoided because of poor oral efficacy and because of the particularly disturbing nature of the psychotomimetic side effects in patients who are already fearful and anxious. Furthermore, pentazocine is a “ceiling” drug; that is, doses cannot be greatly increased to treat increasing pain without greatly increasing the incidence or severity of side effects.

Hydroxyzine or Phenthiazine

42. Would coadministration of either hydroxyzine or phenthiazine be beneficial for A.J.’s pain?

The addition of hydroxyzine (Vistaril, Atarax) to an analgesic regimen is thought to potentiate the analgesia of the opioid analgesic.^{20,146,147} Whether this is a true analgesic effect or a consequence of its sedating properties is unclear. An additional benefit related to the antihistamine properties of hydroxyzine is prevention of opiate-induced nausea and itching.

Phenthiazines, as with antihistamines, often are administered concomitantly with opioids to “enhance” analgesia. Claims of enhanced analgesia are not supported by well-designed studies, however. Many of these studies lack double-blinding, cross-over of patients, placebo control, or appropriate instruments capable of evaluating pain. Another problem in the design of studies evaluating the combination of a phenthiazine or antihistamine with an opioid is the failure to differentiate between analgesia and sedation. Two excellent reviews summarize the studies that demonstrate analgesia with antihistamines and discuss the proposed mechanisms of action.^{148,149}

All phenthiazines, except for methotrimeprazine, initially demonstrated antianalgesic effects in experimental pain studies. Clinicians now realize that experimental pain is not a completely valid model to assess the response of a patient in pain. These studies could not assess the anxiolytic properties of the phenthiazines and the effect a reduction in anxiety has on pain perception. Furthermore, cancer and chronic pain cause anxiety, and anxiety worsens pain perception and, consequently, pain severity. This reinforcement cannot be overestimated and helps explain the apparent benefit many patients obtain from the combination of hydroxyzine with an opioid.

Adrenal Corticosteroids

43. Why might corticosteroids be useful for A.J.’s spinal pain?

Patients who have spinal metastatic disease often obtain pain relief with corticosteroids. This is thought to be because of a combination of direct anti-inflammatory effects and a reduction of pressure from edema around affected nerves. A short course of dexamethasone at a dose of 4 mg orally or IV four times daily with rapid tapering should be considered for A.J.¹⁵⁰

Corticosteroid response may decrease with repeated use, but a single short-course therapy often can produce a significantly prolonged effect. Dexamethasone is most often used because of its long duration of action and lack of mineralocorticoid effects. Other corticosteroids may be substituted for the dexamethasone, however, using a conversion table to calculate equivalent doses.

Nonsteroidal Anti-Inflammatory Drugs

44. Why should the use of an NSAID be considered for A.J.’s spinal pain?

Pain from tumor metastasis to bone is particularly distressing and difficult to treat. Although the most effective therapy for the relief of bone pain is radiation to the site of the pain,¹⁵¹ prostaglandin inhibitors may be another reasonable alternative to increased doses of opioids. Osseous metastases induce the production of prostaglandins that can cause osteolysis, sensitize free nerve endings, and augment pain perception. NSAIDs effectively decrease prostaglandin and endoperoxide production and may be useful in treating metastatic bone pain if administered on a scheduled basis. Usual analgesic doses of NSAIDs often are effective, but maximal therapeutic doses may be necessary. Some specialists in treating cancer pain advocate doses considerably larger than the manufacturers’ recommendations. Sometimes IV ketorolac is used for this purpose.¹⁵² In extremely painful cases, IV ketorolac has been used as a continuous infusion for managing metastatic bone pain.¹⁵² Beside an NSAID, strontium, and radiopharmaceuticals (e.g., phosphorus 32, strontium 89, samarium 153, rhenium 186, and tin 117m) have been used to treat metastatic bone pain, but occasionally with limited benefit. Nevertheless, they can be considered for severe bony metastatic pain unresponsive to corticosteroids or an NSAID.

CHRONIC NONMALIGNANT PAIN

Goal of Therapy

45. W.C., a 38-year-old man, has been disabled for the past 2 years because of an injury to his cervical spine sustained while operating a forklift at a warehouse. He is currently taking oral oxycodone 5 mg with acetaminophen 325 mg (Percocet) two tablets QID as needed for severe pain, codeine 30 mg with acetaminophen 325 mg (Tylenol #3) or hydrocodone 5 mg with acetaminophen 325 mg (Lorcet-5) two tablets QID as needed for less severe pain, and diazepam 10 mg TID for neck spasms. W.C. describes the pain as sharp and stabbing, and the spasms in his neck are his most troublesome problem. The spasms become severe if he stops taking the diazepam, and the pain starts to build 2 hours after taking the opioids. W.C. currently is seeing an internist and an orthopedic surgeon who prescribed his analgesics. W.C. also has

undergone several cervical discectomies and vertebral fusion with minimal pain relief. What are the treatment goals in W.C.?

Opioid use for chronic nonmalignant pain remains the most controversial issue facing clinical pain management. Not only is opioid efficacy subject to debate, but, in addition, the potential for opioid dependency creates considerable hesitation on the part of many prescribers.^{153,154} Although neuropathic pain may respond to opioids, high dosages are often needed.¹⁵⁵ Opioid analgesics should be considered only after the patient has received and failed adequate trials of an NSAID or other analgesic agents. In addition, patients should be evaluated for physical interventions, such as muscle strengthening or conditioning exercises that may improve their clinical situation, before becoming over-reliant on opioids for pain management. As with any chronic pain management, time-contingent dosing (fixed dose and interval) is superior to as-needed dosing. If an opioid is used to manage chronic pain, a longer-acting agent (e.g., SR morphine, methadone, levorphanol) should be used to minimize fluctuations in serum concentrations. Patients should be monitored closely for both efficacy and toxicity.

Shorter-acting opioid analgesics often can complicate chronic nonmalignant pain management by exacerbating the pain perception because of fluctuating serum concentrations and the production of opioid withdrawal hyperalgesia when serum concentrations are low. Analogous withdrawal effects can occur with sedative-hypnotics and antispasmodics as well, particularly those with relatively short half-lives.

Before any therapeutic modality is initiated, the primary caregiver and the patient must have a written agreement that includes provisions for a single prescriber; monitoring of serum drug concentrations; urine or blood substance abuse screening; as well as an agreement to inform all current and future health care providers regarding pain management, and termination of service. There should be only one prescriber for all of W.C.'s medications, and all of his health care providers must be informed of the therapeutic plans. The immediate goal of pain management for W.C. is to consolidate his analgesic regimen to a time-contingent, longer-acting opioid. Longer-term goals should include withdrawal of diazepam, consideration of opioid withdrawal, and institution of alternative analgesic adjuncts (antidepressants or membrane stabilizers). Psychological evaluation and support should supplement pharmacologic therapy. The overall therapeutic goal for W.C. is pain control and pain reduction, but not total pain elimination. He should be able to conduct activities of daily life with minimal discomfort, and ideally be able to return to gainful employment in some capacity, even if his work duties are modified.

Analgesic Consolidation

46. W.C. relates that he has been taking up to 18 tablets of various opioid analgesics daily. How should his pain be managed?

Chronic opiate use can lead to dependence as well as tolerance. The immediate need is to stabilize W.C.'s pain, but a longer-term goal should include analgesic tapering if tolerated. Evidence from pain studies in animal models, and in longitudinal studies of humans, indicate that chronic opioid use can lead to changes in the CNS that result in hyperalgesia. It is not known if this effect is drug- and time-dependent.^{156,157}

Tapering is not likely to be achieved quickly, however. W.C. should be started on an opiate tapering regimen after his pain is stabilized, and this process should occur within 24 hours after the analgesic dose has stabilized. The first step in opiate analgesic tapering is opiate consolidation. As in this case, the patient often is receiving several analgesics unnecessarily. A longer-acting opioid analgesic should be used for W.C. to minimize the pain and analgesia fluctuations. One method is to sum his total opioid use per day during the past several weeks and then convert to an equivalent dose of either methadone or SR morphine. Alternatively, an arbitrary dose, such as oral methadone 5 mg every 6 hours, could be started, and all of his current analgesics could be discontinued. If this dose is insufficient, a temporary dosage increase may be necessary. The long half-life of methadone will be beneficial when instituting opioid tapering.

Alternative analgesic adjuncts, such as antidepressants or anticonvulsants, should also be considered and introduced at this time. Opiate consolidation in W.C. would also serve to reduce his exposure to acetaminophen. He is currently taking three different acetaminophen-containing products. Although concern for opioid dosing emphasizes a balance between benefits and risks from the opioids, the risk of either short-term overdose or cumulative effects from acetaminophen (e.g., liver or renal toxicity) should not be overlooked. W.C. should be instructed not to exceed 4 to 5 g/day of acetaminophen from all sources, including analgesic and cold/sinus medications products he may be purchasing over the counter.

Opioid Tapering and Withdrawal

47. How rapidly can opiate analgesics be discontinued in a patient such as W.C. without precipitating withdrawal symptoms?

W.C. would benefit from long-term multidisciplinary pain management that includes behavioral therapy as well as medication adjustments. An acute pain opiate analgesic dose can be decreased in hospitalized patients by 20% daily without precipitating opiate withdrawal symptoms; but in a patient such as W.C., who has been taking opiate analgesics for an extended period of time, the decrease in analgesic dose will have to be much more gradual. In chronic opiate dependence, the opioid dose can be decreased by approximately 10% every 3 to 5 days without inducing withdrawal symptoms. The addition of clonidine can also improve the overall opioid tapering process, because it may impart analgesic effects while assisting in controlling abstinence symptoms.

Managing Opioid Overdose

48. W.C. accidentally received an excessive dose of methadone leading to a respiratory rate of 8 breaths/minute and excessive sedation. How should he be treated?

Methadone can accumulate when converting from short-acting opioids to this longer-acting opioid unless careful attention is paid to the differences in pharmacokinetic properties. Because methadone has a long half-life, steady-state plasma levels may not be achieved for 5 to 10 days. In W.C., the challenge is to treat the respiratory depression induced by methadone without interfering with the desired analgesic

effects and without precipitating narcotic withdrawal. Opioid toxicity is not life threatening if it is managed immediately. Naloxone reverses opioid-induced CNS sedation and respiratory depression after overdose of all opiates except buprenorphine. W.C. should be given naloxone 0.1 mg parenterally at 2- to 3-minute intervals until the desired effect (improved respiration rate and increased alertness) is achieved. Because methadone has a long half-life, the naloxone dose may need to be repeated every 15 to 20 minutes, sometimes for several hours, until the methadone toxicity dissipates. Overly aggressive dosing of naloxone can cause agitation and exaggerated responses to pain. The methadone dose will have to be adjusted accordingly if too much naloxone has been administered.

In the event of a massive overdose of opioid analgesics, naloxone can be given as a continuous infusion of 0.2 mg/hour to 0.4 mg/hour. In light of the low incidence of side effects from naloxone, it might be reasonable to start with a loading dose of 0.8 mg and a higher infusion dose such as 0.4 mg/hour, followed by subsequent dosage adjustments, depending on clinical response. The same approach may be utilized for the treatment of overdose with extended release formulations of opioids. As intermittent naloxone may reverse the immediate effect of opioids on receptors, extended release formulation would continue to deliver more drug and, therefore, further the effects of overdose. The required duration of naloxone infusion will vary, depending on the specific opioid and the amount involved.^{158,159}

A longer-acting opiate antagonist, nalmefene (Revex), may provide an alternative to naloxone. Approved for the use of conscious sedation reversal and management of opioid overdose, nalmefene may be most beneficial in overdoses of methadone or propoxyphene where repeated administration of antagonists is necessary because of their long elimination half-lives.¹⁶⁰ Nalmefene has a long half-life (8–11 hours) compared with naloxone (1–1.5 hours). Although fewer doses of nalmefene may be needed to reverse opioid intoxication, studies have not shown any difference in efficacy between nalmefene and naloxone.^{160,161}

NEUROPATHIC PAIN

49. R.L., a 40-year-old, generally healthy woman, suffered a superficial laceration of her left arm at work from a broken glass window. The initial laceration has since healed without complications, but now she is referred for evaluation of pain management because of persistent intolerable pain in her left arm and hand. Physical examination reveals allodynia (pain resulting from a non-noxious stimulus to normal skin) in her left hand and arm. What caused R.L.'s condition, and how would you manage her pain pharmacologically?

Hyperalgesia after a minor injury is well described, but the pathogenic basis of such pain is not understood. In these afflicted patients, the pain threshold is decreased and stimuli response in the affected region is increased. This persistent pain also can be associated with changes in regional cutaneous blood flow, osteoporosis, swelling, changes in regional temperature, and atrophic musculocutaneous changes in the affected region without demonstrable nerve injury. In the affected areas, pain is elicited by even the slightest mechanical or thermal stimuli. This painful hyperalgesic condition, known as, *reflex sympa-*

thetic dystrophy, or *chronic regional pain syndrome* (CRPS) has been attributed to sympathetic excess and has been called *sympathetically maintained pain* (SMP) by some. It also can be the result of other central or peripheral mechanisms that are independent of the sympathetic nervous system. SMP may partially respond to pharmacologic agents that interfere with the α -adrenergic function; therefore, it would be expected to respond to clonidine, prazosin, phenoxybenzamine, or guanethidine. Some symptoms of these syndromes may respond to other classes of pharmacologic agents, such as steroids and NSAIDs, TCAs, anticonvulsants, antiarrhythmics, or local anesthetics.

α_2 -Agonists

50. R.L.'s CRPS will be managed by a sympathoplegic agent. What doses of clonidine or prazosin will be required for pain management in R.L.?

The α_2 -agonists (e.g., clonidine) are useful in the management of SMP. They act by reversing the excessive sympathetic adrenergic response at central and peripheral receptors and by reversing local vasoconstriction with improvement in blood flow. Clonidine has analgesic effects when administered either systemically or locally at the spinal level. The α_1 -antagonist, prazosin, also has been used in the management of SMP. The dosages for clonidine and prazosin are 0.2 to 0.6 mg/day and 1 to 6 mg/day, respectively, in two to three equally divided doses. The major disadvantage of these agents is their side effects, especially hypotension and exacerbation of depression.¹⁶² In addition, rapid development of tachyphylaxis has been noted. Clonidine 0.1 mg orally four times daily would be a good starting dose for R.L., but the final dose must be titrated based on the patient's clinical response or side effects.

Tricyclic Antidepressants

51. What types of pain are most responsive to antidepressants? Is there any advantage of using one antidepressant over another for pain management in patients such as R.L.?

The analgesic properties of TCAs are independent of their antidepressant properties. Depression, however, often accompanies chronic pain, which in turn, often exacerbates a patient's response to pain and inability to cope with pain-induced lifestyle changes.^{163,164} Thus, the antidepressant may interrupt this cycle of events. TCAs produce analgesia directly through modulation of the descending inhibitory nerve pathway by either altering serotonin or norepinephrine neurotransmission. They are also believed to reduce pain through local anesthetic (sodium-channel blocking) effects. Another secondary benefit of some TCAs is their sedative effect, which can help the patient sleep and reduce feelings of anxiety.

Antidepressants have been most widely studied in patients with diabetic neuropathy and postherpetic neuralgia.^{165,166} They also have some value in deafferentation pain (central pain resulting from loss of spinal afferent nerve pathway), phantom limb pain, human immunodeficiency virus (HIV) neuropathy,¹⁶⁷ postsurgical pain,^{168,169} fibromyalgia, and chronic pain associated with depression. They also have limited usefulness in the management of lower back pain, radiation neuropathy, and direct malignant nerve infiltration.

Clinical data for the management of pain is most extensive for amitriptyline, but other TCAs also have been used for this purpose.^{160,170} Data on the use of SSRIs, such as fluoxetine, paroxetine, and sertraline, are limited.¹⁷¹ The major disadvantage associated with the use of TCAs is their side-effect profile, which includes sedation, anticholinergic effects, and cardiotoxicity (quinidinelike widening of QRS on electrocardiogram [ECG]). Sedation and anticholinergic effects are less severe with secondary amine TCAs (desipramine, nortriptyline) than with tertiary amine TCAs, such as amitriptyline and doxepin. Weight gain can be a limiting factor as well.^{172,173} In patients such as R.L., who have no histories of cardiac problems, a TCA can be helpful in pain management. Whether TCAs should be used to treat pain in the elderly population remains controversial because these agents also can produce cognitive impairment and hypotension.¹⁷⁴

52. L.K., a 46-year-old woman with diabetes mellitus, is admitted to the hospital with pain that involves both hands and feet and which is associated with symptoms of pain, burning sensation, numbness, and tingling. Physical examination reveals only that pinprick sensation in the hands and feet is lessened.

Another class of antidepressants, the serotonin-norepinephrine reuptake inhibitors, duloxetine hydrochloride and venlafaxine provide an alternative for patients whose use of a TCA may be limited because of side effects. These drugs act by providing dual reuptake inhibition of both serotonin and norepinephrine transporters with weak affinity for the dopamine transporter. The most frequently observed side effects with duloxetine are nausea, vomiting, constipation, somnolence, dry mouth, increased sweating, loss of appetite, and weakness. The immediate-release version of venlafaxine is associated with more CNS and somatic side effects, but the extended-release version of this medication is more tolerable with the main side effect being gastrointestinal disturbances. The optimal dose of duloxetine is 60 mg/day with 150 to 225 mg/day being an effective dose for venlafaxine.^{175,176}

Anticonvulsants and Antiarrhythmics

53. What other alternatives are there for the management of L.K.'s neuropathic pain?

Anticonvulsants have been used frequently in the management of neuropathic pain with varying success. In randomized-controlled studies, gabapentin and pregabalin have improved symptoms of diabetic neuropathy and postherpetic neuralgia.^{177,178} Doses of gabapentin up to 3,600 mg/day or greater may be required in some patients, whereas the range for pregabalin is from 150 to 600 mg/day. Additionally, higher doses of gabapentin are generally well tolerated compared with pregabalin. Gabapentin requires more individualization in patients because doses are slowly titrated to pain control. Pregabalin can be titrated more rapidly and has a short onset of action (<1 week), which may require less combination therapy in some patients. The most common side effects of gabapentin and pregabalin include dizziness, somnolence, peripheral edema, and dry mouth.^{176,179}

HEAD INJURY AND OPIOID ANALGESIA

54. M.C., a 24-year-old male hemophiliac, is admitted to the emergency department (ED) with several minor lacerations, contusions, and painful hemarthrosis secondary to a bicycle accident. Meperidine 50 mg IV was ordered and he was transferred to the medical ward for further evaluation. There, M.C. was given antihemophilic factor. He also was given meperidine 50 to 75 mg IV every 3 hours, as needed, for pain. What was the danger in administering an opioid to M.C. in the ED or shortly after he was admitted?

Opioid analgesics generally are avoided in patients with head injury for the following reasons: (a) opioid-induced pupillary changes, nausea, and general CNS clouding can mask or confuse the neurologic evaluation; (b) head injury potentiates the respiratory depressant effects of opioids; (c) opioids induce carbon dioxide retention, which in turn causes vasodilation of cerebral arteries and an increase in cerebrospinal fluid pressure that might already be elevated because of head injury^{180,181}; (d) opioids in excessive doses can mask internal organ injury; and (e) morphine and meperidine can produce further hypotension in patients who have blood loss caused by trauma. These potential complications, however, should not preclude the use of a short-acting opioid, such as fentanyl, for pain control in emergency situations, especially when the patient's clinical condition and analgesic responses are monitored closely. If fentanyl is to be used, small but frequent IV doses are preferred over single, large boluses (see Table 8-5 for starting doses). The final dose is based on the patient's analgesic and toxic responses. It would be reasonable to start M.C. on fentanyl 25 to 50 mcg IV every 30 to 60 minutes followed by analgesic titration.

MYOCARDIAL PAIN

55. C.P., a 65-year-old man with a history of angina pectoris, is brought to the ED with a suspected acute myocardial infarction (MI). Meperidine 25 mg IV is prescribed for pain control. Would another analgesic be preferred over pentazocine in C.P.?

This dose of meperidine might be effective for analgesia; however, meperidine has variable hemodynamic effects in patients with hemodynamic instability, whereas fentanyl and morphine's effects are more predictable. Butorphanol (Stadol) and pentazocine can increase pulmonary vascular resistance and pulmonary artery pressure.^{182,183} Furthermore, pentazocine can produce idiosyncratic hypotensive episodes, which could be disastrous in these patients. Therefore, these agents should be avoided after MI.

Morphine does not increase myocardial wall tension or oxygen consumption and does not affect cardiac dimensions. Morphine also can decrease heart rate and induces only minimal orthostatic changes in blood pressures. In postsurgical patients who are volume depleted, the orthostatic effect of morphine can be quite dramatic, however. Sedative and emetic effects of morphine are comparable to methadone, but may be greater than those of meperidine or hydromorphone. Methadone, hydromorphone, buprenorphine, and nalbuphine affect the cardiovascular system in a manner similar to that of morphine.¹⁸³

In summary, although all the aforementioned agents are effective analgesics, pentazocine and butorphanol cause greater

cardiovascular effects and can exacerbate an acute MI by increasing the cardiac workload and oxygen consumption. Therefore, morphine remains the preferred agent. (See Chapter 17, Myocardial Infarction, for further discussion.)

COLIC PAIN

Biliary Colic

56. B.C., a 42-year-old man, is admitted for severe, intermittent right upper quadrant pain accompanied by nausea, vomiting, and clay-colored stools. The differential diagnosis is biliary colic versus acute pancreatitis. Two doses of meperidine 100 mg IM 3 hours apart fail to ease the pain. What other potent analgesics are preferred in this situation?

Opioid analgesics can induce smooth-muscle spasms in the sphincter of Oddi and thereby increase intrabiliary pressure.^{184,185} The resulting intraductal back pressure can aggravate pain symptoms and increase the serum concentrations of amylase 5 to 10 times above the control value.¹⁸⁶ Although it often is claimed that meperidine is less likely than morphine to cause spasm of the sphincter of Oddi, no clear evidence indicates the superiority of one agent over the other.¹⁸⁷ Significant increases in intrabiliary pressures of patients receiving fentanyl (Sublimaze), morphine, meperidine, pentazocine (Talwin), butorphanol (Stadol), and oxycodone are documented.^{188,189}

In one study,¹⁹⁰ buprenorphine (Buprenex) did not increase biliary pressure, but further controlled investigations are needed to substantiate this finding. Generally, biliary pressure increases and spasm begins within 5 minutes of parenteral opioid administration. These effects peak within 20 to 60 minutes, and values gradually return to normal over 1 to 2 hours.^{191,192} Because the reported severity, intensity, and duration of biliary hypertension vary greatly, it is unlikely that any agent presently available has a clear advantage over another.¹⁸⁷

Opioid-induced biliary hypertension and sphincter of Oddi spasm can be reversed by parenteral glucagon or naloxone.^{191,193} It is still unclear whether orally administered naloxone will have similar effects, although orally administered naloxone prevented opioid-induced constipation in one study.¹⁹⁴ It is unclear whether B.C. is having more pain because of an adverse drug effect or primary failure of meperidine. Because no consistent way exists to measure intraductal pressure clinically, it is recommended that he be given a longer-acting opioid, such as methadone 5 mg IV every 8 hours for pain.

Renal Colic

57. M.J., a 36-year-old woman with a history of urolithiasis, comes to the ED because of severe flank pain along with microscopic hematuria. She is diagnosed with renal colic by the ED physician who wishes to treat her pain with meperidine 100 mg IM, but M.J. does not want to take opioids. What can M.J. be given for her severe pain from her renal colic?

Renal colic is extremely painful, and patients often require parenteral opioid analgesics. No significant clinical difference is seen between any of the opioids for this type of acute analgesic indication. Because M.J. does not want to receive opioids, the choice of analgesics is limited. The parenteral nonsteroidal

analgesic ketorolac is likely to be the best alternative.¹⁹⁵ It would be appropriate to start M.J. on ketorolac 15 mg IV every 6 hours as an alternative to the opioids for acute analgesia.

LIVER DISEASE AND ANALGESIA

58. A.A., a 54-year-old man with alcoholic cirrhosis, severe ascites, and mild jaundice, has been hospitalized with severe right upper quadrant abdominal pain. His stools are guaiac positive, and he occasionally has bright red blood present at the rectum secondary to hemorrhoids. He was placed on oral lactulose 30 g QID when the protein content of his diet was increased. Although he has a history of hepatic encephalopathy, he is currently alert and receiving only spironolactone 200 mg/day and prophylactic lactulose. What problems can arise when administering opioid analgesics to patients such as A.A.?

Morphine can induce electroencephalogram (EEG) changes similar to those associated with impending hepatic encephalopathy when administered to patients with hepatic cirrhosis.¹⁹⁶ These morphine-induced EEG changes cannot be correlated with alkalosis, hypokalemia, or increased blood ammonia levels, and the mechanism is unknown.

Because most opioid analgesics are significantly metabolized in the liver, their serum levels can accumulate if dosing intervals are not adjusted in patients with decreased hepatic function.^{197,198} The oral bioavailability of some of the opioids also can be increased because of a decreased hepatic first-pass effect.¹⁹⁹ The opioids with the greatest first-pass effect or a high extraction ratio have the greatest variability in bioavailability. For example, oral morphine and meperidine have a higher extraction ratio than methadone and, therefore, are more likely to be absorbed unpredictably in patients with severe liver disease. In these patients, methadone is most likely to be absorbed consistently when administered orally.

It would be reasonable to treat A.A.'s pain with a single, modest dose of parenteral morphine, but subsequent doses should await the reappearance of signs of pain to prevent the possible precipitation of hepatic encephalopathy. Careful monitoring of A.A. is essential to minimize risk while maximizing analgesia. The clinician should remember that any CNS depressant can trigger significant problems in a patient such as A.A. If an oral opioid is to be used, then methadone will be a good choice because of its more consistent bioavailability. Although methadone has a long half-life, it is still safer to use orally than morphine. All opioid analgesics should be given in small, frequent, on-demand doses in patients such as A.A. Time-contingent dosing of opioids should be avoided in patients with liver disease because of the risk of drug accumulation. A.A. can be given methadone 2.5 mg no more often than every 6 hours, as needed, accompanied by close monitoring.

RESPIRATORY DISEASE AND ANALGESIA

59. C.T., a 65-year-old man admitted to the hospital with a hip fracture, has a history of chronic obstructive pulmonary disease (COPD). On admission, C.T. has a nonpurulent productive cough and wheezing. His medical history includes several episodes of pneumonia. Morphine sulfate 6 to 10 mg IM every 3 hours is ordered for his severe hip pain. What risks are associated with

using morphine in C.T.? Are there better alternative potent analgesics?

Systemic opioids remain the first-line agents in managing pain in patients with COPD. Careful monitoring orders also should be written along with the opioid orders. Morphine and all other opioid analgesics can depress respiration when given in therapeutic doses and should be used cautiously in patients with advanced respiratory disease and decreased respiratory function. Respiratory rate, tidal volume, and sensitivity to hypercapnia or hypoxemia are all decreased by opioid analgesics.²⁰⁰ Although all opioids and agonists produce respiratory depression at therapeutic doses, there appears to be a ceiling effect to the respiratory depression caused by butorphanol (Stadol), nalbuphine (Nubain), and buprenorphine (Buprenex) at higher doses.^{201,202} Increased doses of these compounds do not further depress respiration and still provide increased analgesia. The antagonist naloxone reverses the respiratory difficulty (and analgesia) produced by nalbuphine and butorphanol. Although respiratory depression caused by buprenorphine is uncommon, naloxone does not reverse buprenorphine's effects predictably.²⁰³ Ventilatory support is the only treatment.

Because C.T. is in severe pain, a lower dosage of morphine should be used initially. Opioids do not always depress respiration when dosed correctly and, in some instances, they actually can improve respiratory function in patients who have recently had a thoracotomy. These patients often are afraid to breathe deeply because of the pain elicited by such activity. The analgesic phenothiazine, methotrimeprazine, nerve block, or epidural anesthetics also can be used with fewer respiratory effects than systemic morphine.^{204,205} Alternatively, morphine PCA should be considered for C.T., because PCA will allow him to self-administer small, frequent doses, thereby reducing the possibility of opioid-induced respiratory depression.

60. During his admission, C.T. mentions that he was recently diagnosed with sleep apnea. Would your approach to C.T.'s pain management change?

Patients with sleep apnea must be carefully monitored when receiving pain medications and sedation, especially via the parenteral route.

Sleep apnea generally can be described as prolonged apneic episodes during sleep that can be attributed to relative hypotonia of upper pharyngeal muscles. These muscles play an important role in patency of the airway.

During an apneic episode, arterial oxygen saturation falls and carbon dioxide concentration rises, which stimulates arousal by the autonomic nervous system alerting the patient to breathe. This can occur multiple times during sleep and often is unnoticed by a patient with sleep apnea. In severe disease, patients may experience cardiac dysrhythmias owing to repeated falls in oxygen saturation. Chronic and untreated sleep apnea can lead to pulmonary and systemic hypertension, cor pulmonale, and cardiopulmonary arrest.²⁰⁶ Clinicians must exercise caution when providing pain management to patients with sleep apnea. Opioid administration causes relaxation of upper respiratory tract muscles as well as a decrease in the sensitivity to rising CO₂. The ability to maintain an open airway is already compromised in a patient with sleep apnea. As a result,

patients with sleep apnea may experience respiratory failure, cardiac arrhythmias, and even death.²⁰⁶

Currently, there are no published guidelines on pain management of patients with sleep apnea. It is prudent that C.T. receive continuous cardiac and oxygen saturation monitoring while being treated with opioids. Continuous positive airway pressure (CPAP) may be used to prevent hypoxic episodes caused by opioids.²⁰⁷ Short acting opioids would be preferred if C.T.'s pain can be adequately controlled with these agents.

Use of buprenorphine, a partial opioid agonist, for severe pain in patients with sleep apnea has been postulated, but published clinical trials are lacking. Concomitant use of an NSAID and acetaminophen is recommended to reduce opioid requirements.²⁰⁶

OPIATES IN SPECIAL AGE GROUPS

Advanced Age

61. B.V., a 75-year-old woman, is seen in the office for a routine physical examination. She has a history of osteoarthritis in both knees, osteoporotic vertebral disease, and peptic ulcer disease. In addition to estrogen and calcium supplementation, B.V. takes acetaminophen 650 mg every 4 hours during the day for general discomfort and ibuprofen 400 mg every night to "help [her] sleep." What further information should be assessed before modifying B.V.'s drug therapy?

Chronic pain can have a significant impact on daily functioning and quality of life and should be recognized as a significant problem requiring prompt attention. Chronic pain is common in older adults and may easily go unrecognized and untreated. Painful conditions affecting bones and joints often develop as people age. These conditions provide a chronic source of pain and are often incurable. Approximately one of five older adults takes analgesic medications regularly and more than half of these patients have taken prescription analgesics for >6 months. Prevalence rates for chronic pain among community-dwelling older people have been estimated to be between 25% and 50%.²⁰⁸ Studies of nursing home residents have documented similar rates for chronic nonmalignant pain and also have shown a consistent trend toward undertreatment with analgesics.^{209,210}

Clinical practice guidelines have been developed for the management of chronic pain in older persons.²⁰⁸ All older patients should be assessed for evidence of chronic pain as well as for acute pain that may indicate a new illness or exacerbation of a chronic condition. Older patients may be reluctant to report pain because they may fear the consequences of a diagnostic workup. Older adults may also perceive pain to be synonymous with serious disease or death.²⁰⁸ When providing a history, they may not use the word "pain" to describe how they feel. Instead, they may describe their discomfort as "aching, soreness, burning, or tightness." Finally, patients with dementia or language deficits may not be able to communicate the presence of pain. In these individuals and others, grimacing or other unusual behavior may provide clues to the presence of pain.

B.V. should receive a comprehensive assessment that includes a complete medical history and physical examination to determine any new underlying causes of pain, sensory deficits,

or neurologic abnormalities. Physical function and pain associated with activities of daily living should be assessed as well as her psychosocial function to evaluate her for depression and to understand her social network and support system. A thorough evaluation of current pain should be performed to characterize her pain and to determine the patterns of her analgesic use and their effectiveness. The medication history should be reviewed for potential drug side effects and interactions. B.V.'s use of ibuprofen should be further evaluated, because older patients who use NSAID chronically have a higher frequency of GI bleeding, especially if they have a previous history of this condition.²⁰⁸

62. When asked, B.V. states that her current pain level is a 7 on a 10-point scale, and that it can vary from 4 to 8 during the day. It is usually better after rest and worsens later in the day, especially after physical exertion. Although she takes acetaminophen and ibuprofen regularly, they do not effectively reduce her pain. B.V. realizes that her current medical condition will probably not allow her to be completely pain free and states that a pain level of 3 would be acceptable. Would opiate analgesics be appropriate to control B.V.'s pain?

The use of opioid analgesic for chronic nonmalignant pain is controversial. The usefulness of this class of drugs should not be overlooked, however, and may provide fewer risks than long-term or high-dose NSAID therapy. The doses needed are often much smaller than those needed to treat chronic malignant pain. Older patients often experience greater pain relief from opioid analgesics than do younger patients, probably because both the extent and duration of analgesia are enhanced in this group.^{211,212} Older patients achieve higher-than-expected plasma opioid levels (compared with younger patients) after IM or IV administration. Physiologic changes associated with aging, such as decreases in lean body mass, renal function, plasma proteins, hepatic blood flow, and hepatic metabolism,^{213,214} may be responsible for the enhanced activity of opioids in older patients.²¹⁵

When initiating opioid or adjunct analgesics in older patients, it is important to remember the phrase “start low and go slow.” Because B.V. has underlying conditions that cause continuous pain, time-contingent dosing will be more beneficial. An appropriate initial regimen for B.V. using oxycodone HCl 2.5 mg and acetaminophen 325 mg would be one tablet orally every 6 hours, with one tablet every 4 hours as needed. This would provide continuous analgesic therapy throughout the day and allow B.V. flexibility to take an additional dose before activities that may exacerbate her pain. B.V. should be instructed to discontinue taking ibuprofen and to avoid other products containing acetaminophen. B.V. may also respond to tramadol 25 to 50 mg (i.e., 1/2–1 tablet) every 8 hours for her pain, because it has shown efficacy equivalent to NSAIDs in osteoarthritis pain. This agent can be considered as an alternative to a high-potency analgesic, but still presents a risk of dizziness and drowsiness.

B.V. should be monitored closely for sedation that could affect her concentration and ability to perform her activities of daily living. Because older patients are more sensitive to the constipating side effects of opioids, a bowel regimen consisting of a stimulant laxative and stool softener should be started at the beginning of therapy. Patients also should be encouraged to maintain good fluid intake and to include fruits and vegeta-

bles that are high in fiber in their diet. B.V.'s therapy should be adjusted based on careful monitoring for efficacy and side effects.

Neonates and Children

63. M.M., a 2-day-old, 3-kg girl, has just had bowel surgery for congenital bowel atresia. How should pain management be approached for M.M.?

Many misconceptions exist about the management of pain in the pediatric population. Historically, infants and children have been undertreated for pain and painful procedures. This is partly because of difficulty in communicating with, and evaluating pain, in children, particularly those who are nonverbal. It was also believed that children did not experience pain in the same way as adults do. Significant advances have been made in the understanding of children's pain perception, and assessment tools designed for different stages of development and communication abilities are available.^{216,217} Nevertheless, misconceptions still exist, ranging from the amount of pain a child should experience after a painful procedure to the fear of addiction. Inadequately treated pain can interfere with the healing process, increase heart and respiratory rates, reduce oxygen saturation, and induce hyperglycemia and metabolic acidosis. Increased morbidity and mortality associated with unrelieved pain has been documented in neonates undergoing cardiac surgery.²¹⁸ The reality is that infants and children experience pain just as adults do and should receive appropriate medication and doses to treat their pain.

64. What would be a rational pain management plan for M.M.?

Because M.M. has had significant GI surgery, severe pain should be anticipated and prevented. Therefore, use of opiates, such as morphine or fentanyl, would be appropriate in this situation. Children appear to mature very early with respect to morphine metabolism. Infants as young as 5 months of age show very similar pharmacokinetic parameters as adults; however, morphine concentrations in patients younger than 2.4 months are five times higher than in older patients because of slower metabolic clearance and a lower central compartment volume of distribution.²¹⁹ The dosing of morphine in children is similar to adults on a milligram-per-kilogram basis, but children <5 months of age may require less-frequent dosing. The use of opiates in infants and children does not lead to addiction. Critically ill children who are receiving opiates for long periods of time develop tolerance and physical dependence and exhibit signs and symptoms of withdrawal if opiates are weaned too quickly, which however, should not preclude pediatric patients from receiving opiates.

An appropriate initial dosing regimen for M.M. would be fentanyl 1 mcg/kg IV every 4 hours with 1 mcg/kg every 2 hours as needed for breakthrough pain. When using parenteral morphine preparations in infants, close attention should be given to the preparation used and the age of the infant. Parenteral morphine preparations are available with and without preservatives. Infants <3 months of age are more susceptible to respiratory depression caused by an allergic reaction to the sulfites or to CNS irritation induced by benzyl alcohol. Thus, neonates and infants <3 months of age should receive only preservative-free morphine. When choosing a route of administration,

attention should be given to the patient's clinical condition. Although oral routes are preferred, they may not be appropriate immediately following surgery. Opiates are frequently administered IM; however, IM administration offers no advantage over IV and causes much more pain and distress. Children receiving repeated IM injections often deny the presence of pain to avoid the injection.²¹⁷ Therefore, IV administration is the preferred parenteral route in pediatric patients.

Assessment of pain and relief in M.M. is more challenging because she is unable to verbalize specific information. Careful attention to behavioral responses, such as crying characteristics, crying duration, facial expressions, visual tracking, response to stimuli, and body movement, will be most useful in assessing pain and relief in M.M.^{216,217} Heart rate, respiratory rate, blood pressure, and presence of diaphoresis can provide useful clues to M.M.'s level of pain or comfort and can alert the clinician to potential side effects. Careful monitoring, together with adjustments to the dose and frequency of administration, provides optimal therapy.

MORPHINE-INDUCED NAUSEA AND VOMITING

65. J.J., a 48-year-old woman, has advanced inoperable cervical cancer. The physician has ordered 30 mg of oral morphine solution every 4 hours for pain, but she has vomited after each dose despite apparently adequate doses of prochlorperazine. What can be done to relieve pain in J.J. who vomits after oral morphine?

Morphine and its derivatives induce nausea and vomiting by stimulating the chemoreceptor trigger zone (CTZ). Although the CTZ is stimulated initially, subsequent doses of morphine generally suppress the vomiting center. Because the incidence of nausea (40%) and vomiting (15%) increases in ambulatory patients, a vestibular component also is likely to be involved. If the vomiting is vestibular in origin, instructing J.J. to lie quietly, with as little head motion as possible for an hour or two, often will help. The nausea usually persists for 48 to 72 hours.²²⁰

Levorphanol (Levo-Dromoran) may cause less nausea and vomiting than other potent opioid analgesics at equianalgesic doses and might be an alternative to morphine if the aforementioned recommendations are ineffective in modifying J.J.'s nausea and vomiting. An equipotent dose of levorphanol for J.J., according to Table 8-3, would be 4 mg. The reported duration of action of levorphanol is 6 hours, longer than that of morphine.²²¹

Adjunctive drugs such as droperidol, prochlorperazine, hydroxyzine, scopolamine, and diphenhydramine have been used successfully to control opioid-induced nausea and vomiting. Patients who are extremely sensitive to this opioid-induced effect have to be placed on concurrent or scheduled antiemetics; transdermal scopolamine can be used for this purpose. Although much more costly, agents such as ondansetron may also be useful in patients who have contraindications to the use of phenothiazines or butyrophenones.

USE OF CENTRAL NERVOUS SYSTEM STIMULANTS

66. D.H., a 34-year-old man, is diagnosed with acquired immunodeficiency syndrome (AIDS) and Kaposi's sarcoma. He was discharged from the hospital with a prescription for oral morphine solution, 30 mg every 3 hours. He has been relatively pain

free for about a month, but now returns to the clinic complaining of excessive morning sedation. He cannot reduce his morphine dose because the pain makes him too uncomfortable. What therapeutic intervention can be used to alleviate D.H.'s problem of excessive morning sedation?

Limited clinical data suggest that a morning dose of methylphenidate (Ritalin) or dextroamphetamine (Dexedrine) could both relieve opioid-induced drowsiness and potentiate analgesia.²²² Less sleepiness has been associated with these combinations than with opioid analgesics alone, and a 10-mg dose of amphetamine combined with the opioid analgesic improved pain tolerance more than the analgesic alone.^{223,224} Although these studies involved only single doses, these agents should cause sufficient CNS stimulation to obviate morning drowsiness. D.H. should try a morning dextroamphetamine dose of 5 to 20 mg. A somewhat smaller dose may be added around noon if he desires increased alertness in the late afternoon and early evening hours. Another alternative would be to switch D.H. to an opioid analgesic that is less sedating. Drugs such as hydromorphone, levorphanol, methadone, and fentanyl often produce the desired clinical response in a patient such as D.H.²²⁵

IMPORTANT DRUG INTERACTIONS

Phenytoin and Methadone

67. B.D., a 32-year-old man, has an 18-year history of chronic pain in the right hip as a result of a motor vehicle accident. He has a long problem list that includes grand mal seizures and gastric ulcer disease. In the past, he has been treated with a variety of opioid analgesics on an as needed schedule, which resulted in escalating drug requirements and a complex regimen of multiple-ingredient drugs (e.g., Percocet, Tylenol #3, Vicodin). B.D.'s attending physician prescribed methadone 10 mg every 6 hours several weeks ago. This switch was initially very successful, but B.D. now presents with symptoms suggestive of opioid withdrawal and poor pain control despite good compliance to his methadone regimen. A note in his chart indicates that B.D. saw a neurologist recently who started him on phenytoin therapy. What important drug-drug interactions might explain this rather complex case?

Phenytoin (Dilantin) induces cytochrome P450 (CYP) 3A4 isoenzymes that are responsible for the clearance of methadone, and can thereby decrease serum concentrations of methadone and precipitate symptoms of withdrawal.^{226,227} The methadone dose should be increased to 20 mg every 6 hours, and a note should be made in the chart that the doses will need to be reduced if the phenytoin is discontinued for any reason. After his dose has been increased, B.D. should be watched closely for the next several days for drug-induced drowsiness because the long half-life of methadone can produce accumulation.

Cimetidine and Methadone

68. One week later, B.D.'s wife calls and says that he is very drowsy and that his speech has started to slur. On further questioning, his wife notes that B.D. restarted oral cimetidine 400 mg TID for symptoms of gastritis. She confirms that B.D. has been taking oral methadone 20 mg every 6 hours. What may explain B.D.'s symptoms of apparent opioid toxicity?

Cimetidine (Tagamet) inhibits CYP3A4 isoenzymes, thereby decreasing the metabolism of methadone and potentially subjecting patients to toxic levels. B.D. also could be reaching serum methadone steady-state levels at this time. He should be instructed to withhold the methadone until his mental status returns to baseline; then, the dose of methadone needs to be decreased to 10 mg every 6 hours. When adding cimetidine to existing methadone therapy, methadone doses need to be decreased; the doses should be increased again if cimetidine is subsequently withdrawn.²²⁸

Similar precautions need to be instituted for other CYP3A4 inhibitors, such as antiretroviral agents, ketoconazole or fluconazole, erythromycin, and other agents.

Codeine Interactions With CYP2D6 Inhibitors

Tramadol and SSRI

69. T.R. is a 42-year-old man who suffered a right tibial fracture requiring pinning and external fixation. He is now able to ambulate with crutches. Before discharge from the hospital, four acetaminophen 500 mg with hydrocodone 5-mg tablets throughout the day provided good pain control. At the time of discharge, T.R.'s pain regimen was changed to acetaminophen 325 mg with codeine 60 mg, two tablets orally every 3 to 4 hours, owing to his pharmacy benefit limitations. T.R. calls your office because the acetaminophen with codeine is not controlling his pain even when he takes two tablets every 3 hours. T.R. also is taking oral paroxetine 20 mg every morning for his chronic depression. His physician is considering switching his medication to tramadol or acetaminophen with oxycodone. What changes in T.R.'s therapy can be recommended to provide better pain control?

Codeine is metabolized to morphine in the liver by CYP2D6 isoenzymes. Concurrent administration of codeine with agents that inhibit the CYP2D6 system, such as paroxetine, fluoxetine, amiodarone, and ritonavir, may reduce the conversion of codeine to morphine and influence drug response.²²⁹ In addition, this isoenzyme shows genetic polymorphism and individuals may demonstrate ultrarapid, extensive, or poor metabolism. Recognition of these potential drug interactions is important because concurrent administration of CYP2D6 inhibitors may make some patients appear to be poor metabolizers and less responsive to codeine, which, in fact, may not be true.

Oxycodone, hydrocodone, and tramadol are also substrates for the CYP2D6 isoenzyme. Although a potential interaction exists between oxycodone and paroxetine, little evidence at this time indicates that oxycodone requires conversion to an active metabolite via the 2D6 pathway to be an effective analgesic. However, tramadol is partially metabolized by CYP2D6 and has an active metabolite. Concurrent administration with a CYP2D6 inhibitor could potentially reduce analgesic activity.²²⁹

Coadministration of tramadol and paroxetine could potentially cause more serious problems in this patient. Tramadol has SSRI-like activity because it decreases the synaptic reuptake of norepinephrine and serotonin. Coadministration with SSRI agents, such as paroxetine, fluoxetine, fluvoxamine, and citalopram, can put the patient at risk for serotonin syndrome.²³⁰ Signs and symptoms associated with serotonin syndrome include diaphoresis, chest pain, tachycardia, hypertension, con-

fusion, psychosis, agitation, and tremor. Neurotoxicity can be severe and may progress to seizures or coma. Therefore, tramadol is not a good choice for this patient.

Similarly, tramadol can interact with the antimigraine agents known as "triptans," because their mode of action includes enhancing serotonin activity centrally. Therefore, combinations of tramadol, SSRI, or triptans are relatively contraindicated and require close and judicious monitoring.

It would be reasonable to consider either acetaminophen with oxycodone or hydrocodone for pain control in this patient, especially because he has experienced good pain control with the hydrocodone preparation in the past.

PRIMARY DYSMENORRHEA

70. P.O., a 27-year-old woman, is seen in the primary care clinic because of severe abdominal pain secondary to her menstrual periods. She reports having pain-free menstrual periods only once or twice yearly. She has been diagnosed as having primary dysmenorrhea with no other gynecologic pathology being found. How should P.O.'s menstrual pain be treated?

Primary dysmenorrhea is a common gynecologic disorder affecting 60% to 80% of women at some time in their life.²³¹ Pain usually occurs 2 to 12 hours before the commencement of menstrual flow, but it can occur simultaneously with, or a few hours after, the beginning of menstruation. It reaches maximal intensity at 2 to 24 hours, then decreases over the next few days.²³² Primary dysmenorrhea is associated with increases in endometrial and circulatory prostaglandins. Thus, NSAIDs, which alter the production of the prostaglandins, are frequently used to manage primary dysmenorrhea. The dosages required for the treatment of primary dysmenorrhea usually are higher than those used for analgesia, but frequently a single dose is sufficient to terminate the dysmenorrhea pain. On some occasions, frequent, high doses may be required.

The best time to initiate an NSAID remains controversial. Some clinicians recommend beginning drug therapy a few days before the start of menses; others argue that the prostaglandins are not stored and, therefore, prefer to initiate drug therapy only after the start of menses. Pretreatment with an NSAID carries the risk of fetal drug exposure during early pregnancy. Studies comparing pretreatment with dosing at the onset of menses show no difference in the analgesia between either of the regimens.^{233,234} (Also see Chapter 47, Treatment of Menstrual and Menstrual-Related Disorders.) P.O. should be instructed to take 600 to 800 mg of ibuprofen at the onset of menses or when discomfort begins. Repeat dosages of 400 to 600 mg may be taken every 4 to 6 hours as needed. If this regimen is ineffective, she can take the first dose 1 to 2 days before the first day of menses is expected.

HEADACHES

71. M.K., a 32-year-old man, is complaining of severe headaches that occur at least once every 2 weeks. He takes two Excedrin extra-strength tablets (acetaminophen 250 mg, aspirin 250 mg, and caffeine 65 mg) every 2 hours until the headache starts to ease and sometimes requires a cumulative dose of up to 16 tablets. Migraine and vascular headaches have been ruled out in M.K.

Would one of the nonsalicylate NSAIDs be more efficacious for M.K.? Are there any other considerations in managing M.K.'s headache? Is caffeine an effective analgesic for headaches?

Headaches are common, afflicting nearly everyone at some time during their life. The incidence of headache is higher in females and increases with age; 10% of headaches develop into chronic disabling conditions. For M.K., who self-medicates chronically with large doses of acetaminophen, the concern is toxicity from the analgesics. Chronic use of both NSAID analgesics and caffeine (either as single agents or in combination) can possibly precipitate withdrawal ("rebound") headaches on discontinuation. Although NSAIDs are not considered habituating, accumulating evidence indicates that chronic intake of peripheral-acting analgesics can perpetuate the underlying pain syndrome. In the case of M.K., it is important to consider the possibility of caffeine withdrawal headache as well, because he is taking a caffeine-containing combination product. Other dietary sources of caffeine ingestion from coffee, tea, and other foods should be determined as well.

Caffeine is used in analgesic combination products because it has both a CNS stimulant and a vasoconstrictive effect, which may reverse some of the headache symptoms. The value of caffeine, especially in the small quantities found in most pain relievers, has been controversial. A meta-analysis and subsequent study conclude, however, that caffeine does add to the analgesic effect of aspirin and acetaminophen.^{235,236}

Acute headache can be managed with parenteral ketorolac, but it is not a viable alternative for chronic headache management.²³⁷ M.K.'s headaches may resolve on gradual withdrawal of NSAID analgesics and caffeine, but this process is slow and requires the clinician's as well as the patient's determination to stay with the treatment plan. (Also see Chapter 53, Headache.)

PROCEDURAL PAIN

72. C.T., a 26-year-old woman, injured her left knee during a fall while skiing. After immobilizing her left knee and using ice

therapy, most of her swelling has subsided. She is now seen in the outpatient surgical center for an arthroscopic evaluation of her knee. She is very concerned that the lidocaine that is to be used to anesthetize her knee is going to produce pain, because she has had a bad experience with regional lidocaine injections. What can be recommended to reduce the pain associated with lidocaine infiltration?

Lidocaine injection is quite acidic and can produce local irritation and pain during the infiltration procedure before the anesthetic effect takes place. Because this is a common complaint, C.T.'s concerns should be taken seriously. A simple solution is to neutralize the lidocaine injection solution by adding 1 mL of 1 mEq/mL sodium bicarbonate to 9 mL of 1% to 2% lidocaine before injecting C.T.^{238,239} Because lidocaine is stable over a wide range of pH values, the bicarbonate will not reduce its efficacy of local anesthetic blockade. This technique should not be used with other local anesthetics, however, because they may be subject to rapid degradation by basic agents.

TOPICAL ANESTHETICS AND ANALGESICS

73. J.G., a 6-year-old boy, is being treated for osteomyelitis of his foot as a result of a skate boarding accident. Because of the need for long-term antibiotic therapy, he requires occasional IV access replacement. He is very fearful of the procedure because of the associated pain. What can be offered to J.G. to reduce his discomfort?

Insertion of a venous catheter often produces significant discomfort and pain, but there is no reason C.T. has to endure it. Topical lidocaine-prilocaine cream (EMLA) can provide good pain relief during catheter insertion for minor surgical procedures such as circumcision and skin grafts.^{240,241} The cream must be applied 30 to 60 minutes before the procedure with an occlusive dressing; the anesthetic effect lasts approximately 60 to 120 minutes.²⁴² A smaller-gauge catheter also may reduce the amount of pain associated with the venipuncture.²⁴³

ECONOMIC ISSUES 9-33

- Value-Based Anesthesia Care 9-33
- Total Costs of Surgical Stay 9-33
- Fast-Track Anesthesia 9-33

The operating room (OR) is one of the most medication-intensive settings in a hospital. During the perioperative period (broadly defined as the preoperative, intraoperative, and postoperative periods), a patient may receive many medications. Most of these medications are used primarily in the OR setting and have limited application elsewhere in the institution. For other medications, their use in the OR may differ from that

seen in other patient care areas. The OR is unique in that a significant number of the medications are administered as single doses by the anesthesia care provider (e.g., physician, nurse anesthetist). To ensure continuity of care of the surgical patient, health care providers from all settings (e.g., acute care, home health care, extended care) should have a basic understanding of perioperative drug therapy.

This chapter reviews seven major classes of medications used during the perioperative period: preoperative medications, intravenous (IV) anesthetic agents, volatile inhalation agents, neuromuscular blocking agents, local anesthetics, antiemetic agents, and analgesic agents. The clinical use of cardioplegia solution is also presented. The chapter concludes with a presentation of economic considerations associated with the use of anesthesia-related medications.

PREOPERATIVE MEDICATIONS

Administration of preoperative medications (premedicants) to patients can be thought of as the start of their operative course. Many different medications are used preoperatively and can be grouped into the following classes: benzodiazepines, opioids, anticholinergics, dissociative anesthetics, gastric motility stimulants, H₂-receptor antagonists, antacids, and α -2 agonists.

A key point concerning preoperative medication is that not all patients will require premedicants. A preoperative evaluation by the anesthesia provider ensures that the patient is medically prepared for surgery (e.g., pre-existing medical conditions such as diabetes, hypertension, or asthma are controlled or stabilized), allows the provider to discuss the most appropriate anesthetic and postoperative pain management options with the patient, and helps reassure and educate the patient. Preoperative assessment by an anesthesia provider is an important component of the patient's preparation for surgery. Patients should be assessed individually regarding their need for pharmacologic premedication. If required, premedicants should be selected based on patient-specific needs. Administration of a standard preoperative regimen to all patients should be avoided. Furthermore, the anesthesia provider and the surgeon must determine whether the patient should take his or her regularly scheduled medications the morning of surgery. These medications are often necessary to maintain the patient's physiological condition. The decision to continue or withhold chronic medications before surgery depends on the surgical procedure (e.g., major vs. minor), the patient's current medical condition, the pharmacological effect of the medication, and the potential for drug interactions with anesthetics. Medications that cause bleeding, excessive hemodynamic effects, or withdrawal symptoms are the most problematic. Antihypertensives, bronchodilators, tricyclic antidepressants, selective serotonin reuptake inhibitors, corticosteroids, thyroid preparations, anxiolytics, and anticonvulsants are generally continued up to, and including, the morning of surgery. Alternatively, medications that increase the risk for bleeding (e.g., aspirin, nonsteroidal anti-inflammatory drugs [NSAIDs], warfarin, clopidogrel) may need to be discontinued up to 7 days or more before surgery. Finally, patients with suppression of the pituitary-adrenal axis (e.g., patients currently or recently taking corticosteroids) may not be able to respond to surgical stress. Hydrocortisone can be administered intravenously before surgery, with subsequent doses dependent on the estimated amount of surgical stress and the need for suprphysiological steroid replacement in the postoperative period.

Goals of Premedication

A major goal of premedication is to decrease the patient's fear and anxiety about his or her upcoming surgery. In addition to

reducing anxiety, premedication is used for a variety of other reasons. Medications can be used before surgery to produce sedation, provide analgesia, produce amnesia, facilitate a smooth anesthetic induction, reduce anesthetic requirements, prevent autonomic responses resulting in intraoperative hemodynamic stability, decrease salivation and secretions, reduce gastric fluid volume, and/or increase gastric pH. Table 9-1 lists medications commonly used preoperatively and their major indications, routes of administration, and dosages.¹⁻⁵ Midazolam is by far the most commonly used premedicant.

Selection Criteria

Factors to consider when selecting a preoperative drug for a patient include his or her American Society of Anesthesiologists (ASA) physical status class, medical conditions, degree of anxiety, age, surgical procedure to be performed, length of procedure, postoperative admission status (e.g., inpatient vs. outpatient), drug allergies, previous experience with medications, and concurrent drug therapy. The ASA physical status classification system classifies patients as I through V. ASA-I patients are healthy with little medical risk, whereas ASA-V patients have little chance of survival. Severe systemic disorders (e.g., uncontrolled diabetes mellitus, coronary artery disease) are present in ASA-III through ASA-V patients. Selection of preoperative medications in this group of patients will be more difficult. These patients generally have limited physiological reserve; thus, administration of a cardiovascular depressant agent, for example, can be harmful. Furthermore, these patients will be taking a significant number of medications; hence, chances for drug interactions are increased. The patient's other medical conditions are important to consider to prevent the administration of contraindicated medications. For example, the benzodiazepines are contraindicated in pregnancy.³ A patient's age will play a role in the response seen with premedicant administration. The elderly are often more sensitive to preoperative opioids and benzodiazepines, as well as to the central nervous system (CNS) effects of anticholinergic agents.⁶

Familiarity with the surgery to be performed will aid in selecting appropriate premedicants. In surgical cases in which painful procedures (e.g., vascular cannulation, peripheral nerve block) will be performed on the patient, an analgesic premedicant may be warranted. The length and type of the procedure is important to consider when selecting premedicants. For example, a patient undergoing emergency surgery who has not fasted is often administered a nonparticulate antacid because he or she is at risk for aspiration of gastric contents.¹ Likewise, in short duration, outpatient surgery, agents with a long duration of action should be avoided because residual effects can prolong discharge time. Some drugs should not be administered to patients because of drug allergies; however, genuine allergies must be differentiated from adverse effects. For example, patients often state allergies to opioids after having experienced nausea and vomiting, which are common adverse effects of these drugs. A patient's previous experience with premedicants can assist in agent selection. If a medication has caused trouble in the past, it should be avoided. Finally, it is important to review the patient's current drug therapy before selecting an agent to prevent potentially harmful drug interactions.

Table 9-1 Indications, Routes of Administration, and Doses of Preoperative Agents^a

| <i>Agent</i> | <i>Indications</i> | <i>Routes of Administration</i> | <i>Doses^b</i> |
|---|---|---------------------------------|--|
| Benzodiazepines | | | |
| Diazepam (Valium) | Anxiolysis, amnesia, sedation | PO | Adults: 5–10 mg |
| Lorazepam (Ativan) | Anxiolysis, amnesia, sedation | PO IV | 0.025–0.05 mg/kg (range, 1–4 mg for adults) Adults: 0.025–0.04 mg/kg; <i>pediatrics</i> : 0.01–0.03 mg/kg (titrate dose; max: 2 mg) |
| Midazolam (Versed) | Anxiolysis, amnesia, sedation | PO IM IV IN | Adults: 20 mg; <i>pediatrics</i> : 0.5–0.75 mg/kg (max: 20 mg) Adults: 0.07–0.08 mg/kg (max: 10 mg); <i>pediatrics</i> : 0.1–0.15 mg/kg (max: 10 mg) Adults: 1–2.5 mg (titrate dose); <i>pediatrics</i> : 0.025–0.05 mg/kg (titrate dose) <i>Pediatrics</i> : 0.2 mg/kg (max: 15 mg) |
| Opioids | | | |
| Morphine | Analgesia, sedation | IM IV | Adults: 2–4 mg; <i>pediatrics</i> : 0.02–0.05 mg/kg Titrate dose |
| Fentanyl (Sublimaze) | Analgesia, sedation | IV | Adults: 25–100 mcg (titrate dose); <i>pediatrics</i> : 0.05–2 mcg/kg |
| Anticholinergics | | | |
| Atropine (A) | Antisialagogue (S > G > A), sedation (S > A > G) | IM/IV | Adults: 0.4–0.6 mg; <i>pediatrics</i> : 0.02 mg/kg IM, 0.01 mg/kg IV (max: 0.4 mg) |
| Scopolamine (S) | Sedation, amnesia, antisialagogue | IM/IV | Adults: 0.2–0.4 mg; <i>pediatrics</i> : 0.02 mg/kg IM, 0.01 mg/kg IV (max: 0.4 mg) |
| Glycopyrrolate (G) (Robinul) | Antisialagogue | IM/IV | Adults: 0.2–0.3 mg; <i>pediatrics</i> : 0.005–0.01 mg/kg (max: 0.3 mg) |
| Dissociative Anesthetics | | | |
| Ketamine (Ketalar) ^c | Sedation, amnesia, analgesia | PO IM IV | <i>Pediatrics</i> : 3–6 mg/kg Adults: 3–4 mg/kg; <i>pediatrics</i> : 2–4 mg/kg Adults: 0.5–1 mg/kg |
| Gastric Motility Stimulants | | | |

^aGeneral dosage guidelines; doses must be individualized based on patient-specific parameters.

^bDoses listed are for agents when used as sole premedicant; doses may need to be reduced if premedicants are administered in combination (e.g., opioids, benzodiazepines).

^cThe duration and depth of sedation from ketamine is determined by the dose and route of administration. Low dosages (0.025–0.075 mg/kg IV or 2–3 mg/kg IM) should produce light sedation for a short period. Higher dosages will produce deep sedation to the point of general anesthesia. In addition, airway reflexes are depressed, increasing the patient's risk for aspiration. An anesthesia care provider should be present, and resuscitative/suction equipment should be readily available.

IM, intramuscular; IN, intranasal; IV, intravenous; PO, oral.

Adapted from references 1–5.

Timing and Routes of Administration

The timing and route of administration is almost as important as the choice of the agent. For optimal results, the agent's peak effects should occur before the patient arrives in the OR suite. This will require the agent to be administered at varying times before surgery, depending on the route of administration. Preoperative agents are administered by several routes: IV, intramuscular (IM), oral (PO), and intranasal (IN). As a general rule, agents administered by the IV route produce the fastest onset of action and are often given after the patient arrives in the OR, whereas medications administered via the IM route are usually administered 30 to 60 minutes before the patient arrives in the OR. If possible, the IM route should be avoided because it is painful and undesirable for the patient. Onset of peak effect is the slowest with PO administration of agents, which should be administered 60 to 90 minutes before the patient's scheduled arrival in the OR.¹

Drug Interactions

Preoperative medications can interact with one another, as well as with drugs the patient is receiving currently or will receive in the OR. These drug interactions can be advantageous and intentionally produced, or they can be problematic. For example, patients must be closely monitored when they concurrently receive a benzodiazepine and an opioid for premedication due to synergistic respiratory and cardiovascular adverse effects.¹ The α -2 agonists, however, can reduce the requirements for inhalational anesthetics and opioids.⁴

Administration of a Premedicant

1. K.J., a 21-year-old man, is scheduled to undergo a laparoscopic hernia repair on an outpatient basis under general anesthesia. This is the first time K.J. has undergone surgery, and he is highly anxious in the preoperative area. Should K.J. receive premedication, and, if so, what medication(s) should be administered?

The administration of a preoperative sedative to a patient undergoing outpatient surgery was formerly controversial; however, with midazolam, the delayed recovery and discharge that had been associated with agents used in the past (e.g., lorazepam, triazolam, temazepam) is less of a concern. Midazolam should be titrated to the desired effect (in increments of 0.5–1 mg IV), with the average adult generally requiring 2 mg IV. Elderly patients who receive as little as 0.5 mg midazolam intravenously can experience decreased oxygen saturation in the preoperative period and longer recovery time in the postanesthesia care unit (PACU) following short duration surgery.⁷ Midazolam premedication produces sedation and provides anterograde amnesia and anxiolysis,^{7,8} which can be problematic if these effects continue into the postoperative period when outpatients are provided with discharge instructions. In children, premedication with oral midazolam can reduce both the child's and the parents' anxiety during the preoperative period,⁸ the likelihood of a child's distress at induction of anesthesia,⁹ and the manifestation of negative behavioral changes in the child during the first 7 postoperative days.¹⁰ The use of oral midazolam premedication in children who are

undergoing outpatient surgery, however, can delay discharge.⁹ Therefore, nonpharmacologic approaches to reduce anxiety must be optimized. If explanation of upcoming events and reassurance by the anesthesia provider has not sufficiently allayed K.J.'s anxiety, small titrated doses of IV midazolam can be administered.

Aspiration Pneumonitis Prophylaxis

Definition

Aspiration pneumonitis, although uncommon, is a potentially fatal condition that occurs as a result of regurgitation and aspiration of gastric contents. Aspiration of undigested or semidigested gastric contents into the respiratory tract can cause obstruction and an inflammatory response. Acute chemical pneumonitis and subsequent acute lung injury (aspiration pneumonitis) can result from aspiration of acidic gastric secretions.¹¹ Aspiration of gastric contents is also an important risk factor for the development of adult respiratory distress syndrome (ARDS).¹² Historically, a gastric pH of <2.5 and a gastric volume >25 mL (0.4 mL/kg) have been accepted as the cutoff values that place the patient at greater risk for severe pneumonitis should aspiration occur. However, in clinical practice, the values commonly used are a gastric pH <3.5 and gastric volume >50 mL, with pH appearing to be a greater determinant of morbidity than volume.¹³

Risk Factors

Patients at greatest risk for regurgitation and aspiration include those with increased gastric acid, elevated intragastric pressure, gastric or intestinal hypomotility, digestive structural disorders, neuromuscular incoordination, and depressed sensorium. These can include pregnant patients, obese patients, and trauma patients, as well as patients with a hiatal hernia, gastroesophageal reflux, esophageal motility disorders, or peptic ulcer disease.¹⁴ Diabetic patients with reflux symptoms or poor glucose control may also benefit from pharmacologic prophylaxis.¹⁵ In addition to having delayed gastric emptying, obese patients will often present with increased abdominal pressure and an abnormal airway; both factors predispose these individuals to aspiration. Hormonal changes in pregnant patients account for delayed gastric emptying and relaxation of the lower esophageal sphincter. An increase in intra-abdominal pressure is also seen in pregnant patients. Labor can increase gastrin levels, increasing gastric volume and acidity as well as delaying gastric emptying. Patients undergoing emergency surgery frequently have full stomachs because they have not had time to fast appropriately.

Rapid sequence induction, effective application of cricoid pressure, maintaining a patent upper airway, avoiding inflation of the stomach with anesthetic gases, inserting a large-bore gastric tube once the airway has been secured, as well as the use of regional anesthesia when possible, are probably the most important measures the anesthesia provider can take to reduce the patient's risk of aspiration.^{16,17} Administration of pharmacologic aspiration prophylaxis is not cost effective and does not reduce morbidity or mortality in healthy patients undergoing elective surgery. Administration of pharmacologic aspiration prophylaxis should, however, be considered to prevent morbidity (e.g., ARDS) in patients at risk for aspiration.

Medications

Many medications (e.g., antacids, gastric motility stimulants, H₂-receptor antagonists) can reduce the risk of pneumonitis if aspiration occurs. These drugs, with the possible exception of metoclopramide, are relatively free of adverse effects and have a favorable risk–benefit profile.

ANTACIDS

Antacids, effective in raising gastric pH to >3.5,¹ should be given as a single dose (30 mL) approximately 15 to 30 minutes before induction of anesthesia. Nonparticulate antacids (e.g., sodium citrate/citric acid [Bicitra]) are the agents of choice because the suspension particles in particulate antacids can act as foci for an inflammatory reaction if aspirated and increase the risk of pulmonary damage.¹⁸ Antacids have two major advantages when used for aspiration pneumonitis prophylaxis; there is no “lag time” for onset of activity, and antacids are effective on the fluid already in the stomach. Their major disadvantages are (a) a short-acting buffering effect that is not likely to last as long as the surgical procedure (sodium citrate must be administered no more than 1 hour before induction of anesthesia, with its duration possibly dependent on gastric emptying); (b) the potential for emesis (due to their lack of palatability); (c) the possibility of incomplete mixing in the stomach; and (d) their administration adds fluid volume to the stomach.^{19,20}

GASTRIC MOTILITY STIMULANTS

The gastric motility stimulant, metoclopramide (Reglan), has no effect on gastric pH or acid secretion. This agent reduces gastric volume in predisposed patients (e.g., parturients, obese patients) by promoting gastric emptying. Preoperative metoclopramide increases lower esophageal sphincter pressure and reduces gastric volume.^{3,21} Metoclopramide should be administered 60 minutes before induction of anesthesia when given orally. When given by the IV route, metoclopramide should be administered 15 to 30 minutes before induction of anesthesia. The effects of metoclopramide on gastric emptying have been variable, especially when used with other agents. For example, the concomitant administration of anticholinergics (e.g., glycopyrrolate, atropine), or prior administration of opioids, can reduce lower esophageal sphincter pressure, which can offset the effects of metoclopramide on the upper gastrointestinal (GI) tract.²²

H₂-RECEPTOR ANTAGONISTS

H₂-receptor antagonists reduce gastric acidity and volume by decreasing gastric acid secretion. Unlike antacids, the H₂-receptor antagonists do not produce immediate effects. Onset time for these agents when administered orally is 1 to 3 hours; good effects will be seen in 30 to 60 minutes when administered intravenously.³ Oral doses of the H₂-receptor antagonists should not be crushed and given via a nasogastric tube at the time of surgery. As already mentioned, onset of action is not immediate. Furthermore, administration of tablets introduces particulate matter into the stomach, which can be detrimental if aspirated. Duration of action of H₂-receptor antagonists is also important because the risk of aspiration pneumonitis extends through emergence from anesthesia. After IV administration, the cimetidine (Tagamet) dose should be repeated in 6 hours if necessary, whereas therapeutic concentrations of ranitidine (Zantac) and famotidine (Pepcid) persist for 8 and 12 hours,

respectively.³ Although cimetidine is associated with more adverse reactions than famotidine or ranitidine, this is probably not clinically significant because only one or two doses of the agent are given.¹

PROTON-PUMP INHIBITORS

Proton-pump inhibitors (PPIs) (omeprazole, rabeprazole, lansoprazole, esomeprazole, and pantoprazole) act at the final site of gastric acid secretion, making these agents very effective in suppressing acid secretion. When the effects of preoperative IV pantoprazole on gastric pH and volume were compared with IV ranitidine and placebo, both pantoprazole and ranitidine significantly reduced the volume and increased the pH of gastric contents when compared to placebo (saline). There was no difference, however, between the pantoprazole and ranitidine groups.²³ Therefore, there appears to be no need to use the more expensive PPIs in patients at risk for pulmonary aspiration.

Choice of Agent

2. D.W., a 5'4", 95-kg, 38-year-old woman, ASA-II, is scheduled to undergo a laparoscopic cholecystectomy under general anesthesia. D.W. has type 2 diabetes. Physical examination is normal except for an abnormal airway, which is anticipated to complicate intubation. Her medications include glipizide and an antacid for dyspepsia. The procedure is scheduled as a same-day surgery. What factors predispose D.W. to aspiration, and what premedication, if any, should D.W. receive for aspiration prophylaxis?

D.W. has several factors that place her at risk for aspiration. She is obese with an abnormal airway. She also has diabetes and reports symptoms of dyspepsia that are relieved by antacids. These conditions will predispose D.W. to increased abdominal pressure, delayed gastric emptying, and increased risk of regurgitation. Her abnormal airway may delay intubation, increasing the amount of time D.W. is susceptible to aspiration. Therefore, aspiration prophylaxis with medications that buffer gastric acid and reduce gastric volume is prudent for D.W. Because D.W.'s surgery is scheduled as a same-day surgery, D.W. will arrive at the hospital or surgical center approximately 90 minutes before the start of surgery. Although oral agents, in general, are less expensive than their parenteral counterparts, cimetidine 300 mg (Tagamet), famotidine 40 mg (Pepcid), or ranitidine 150 mg (Zantac) should be administered approximately 1 to 2 hours before induction of anesthesia to effectively decrease gastric acidity. Hence, due to time constraints, cimetidine 300 mg, famotidine 20 mg, or ranitidine 50 mg should be administered intravenously 30 to 60 minutes before induction of anesthesia in D.W. A nonparticulate antacid such as sodium citrate/citric acid solution (Bicitra) 30 mL PO can be administered to D.W. immediately before entering the OR rather than, or in addition to, an H₂-receptor antagonist.

3. C.T., a 28-year-old woman, ASA-I, is admitted for an emergency cesarean section under general anesthesia. She is otherwise healthy and currently taking no medications. Why is C.T. susceptible to aspiration pneumonitis, and what preoperative medications would be appropriate to help prevent this adverse event from occurring in her?

C.T. is at an increased risk for aspiration and the possible development of pneumonitis because she is pregnant and about

to undergo emergency surgery. In the obstetric patient, preoperative administration of the nonparticulate antacid, sodium citrate, or a H₂-receptor antagonist can effectively reduce gastric acidity. Furthermore, the administration of a nonparticulate antacid before C-section can reduce maternal complications. Metoclopramide, however, can reduce peripartum nausea and vomiting. Therefore, an appropriate regimen for C.T. would include both sodium citrate/citric acid solution (Bicitra) 30 mL PO and metoclopramide 10 mg IV. Famotidine (or another H₂-receptor antagonist) can be given instead of, or in addition to, the sodium citrate/citric acid solution. There is not sufficient time to administer famotidine and metoclopramide orally because of their slower onsets of action when administered by this route. Sodium citrate/citric acid solution provides immediate protection by raising gastric pH, metoclopramide will help reduce the increased gastric volume commonly seen in pregnant patients, and famotidine will provide sustained coverage throughout the surgery. These agents have not been shown to have detrimental effects on the fetus.²⁴

INTRAVENOUS ANESTHETIC AGENTS

General Anesthesia

General anesthesia is a state of drug-induced unconsciousness. Other components of general anesthesia include amnesia, analgesia, immobility, and attenuation of autonomic responses to noxious stimuli.²⁵ Drugs used to induce general anesthesia should produce unconsciousness rapidly and smoothly while minimizing any cardiovascular changes. Table 9-2 lists additional desirable, as well as undesirable, characteristics of an IV induction agent. Although currently available IV induction agents possess many of the desirable characteristics, no agent is free of the undesirable effects. An IV induction agent is commonly administered for initiation of general anesthesia. Drugs commonly used for IV induction include ultrashort-acting barbiturates (thiopental, methohexital), etomidate, and propofol. The synthetic opioids (fentanyl, sufentanil, alfentanil, and remifentanil), benzodiazepines (primarily midazolam), and ketamine are less frequently used. Propofol can also be used to maintain general anesthesia, as drugs that do not accumulate during repeat or continuous dosing are ideal choices for maintenance therapy. When used at dosages lower than those necessary for unconsciousness, some of the IV anes-

thetic agents can be used to produce sedation for monitored anesthesia care or regional anesthesia, as well as in the medical procedure units and intensive care units (ICUs). Table 9-3 lists common clinical uses for IV anesthetic agents.

Mechanisms of Action

Most IV anesthetic agents produce CNS depression by action on the γ -aminobutyric acid (GABA) benzodiazepine chloride ion channel receptor. GABA is the principal inhibitory neurotransmitter in the CNS. The barbiturates bind to a receptor site on the GABA-receptor complex, reducing the rate of dissociation of GABA from its receptor. This results in increased chloride conductance through the ion channel, nerve cell hyperpolarization, and inhibition of nerve impulse transmission. Barbiturates can directly activate the chloride channels by mimicking the action of GABA. Benzodiazepines also bind to this GABA-receptor complex and their subsequent potentiation of the inhibitory action of GABA is well described. At large doses, most of the benzodiazepine receptors will be occupied, and hypnosis (unconsciousness) will occur. The site of action of etomidate (Amidate) and propofol (Diprivan) is also at the GABA receptor, with etomidate augmenting GABA-gated chloride currents and propofol enhancing the activity of the GABA-activated chloride channel. Ketamine (Ketalar) acts at a different site than other induction agents. It produces dissociation between the cortex and the thalamus within the limbic system, resulting in a dissociative state; that is, the patient appears to be detached from his or her surroundings. Unlike anesthesia produced by other agents (e.g., propofol for induction followed by sevoflurane/nitrous oxide/oxygen for maintenance) where the patient's eyes are closed resembling normal sleep, a ketamine-anesthetized patient's eyes are often open and move from side to side. Ketamine also produces analgesia and amnesia in patients.²⁶

Pharmacokinetics

The onset and duration of effect are the most important pharmacokinetic properties of IV anesthetic agents when used for induction of anesthesia. In general, the commonly used IV induction agents have a rapid onset of action and short clinical duration, with the short clinical duration resulting from redistribution of the drug from the brain to other tissue sites (e.g., muscle, fat). Using the barbiturates as an example, thiopental

Table 9-4 Pharmacokinetic Comparison of Common Intravenous Anesthetic Agents

| Drug | Half-Life (hours) | Onset (seconds) | Clinical Duration (minutes) ^a | Hangover Effect ^b |
|-------------------------|-------------------|-----------------|--|------------------------------|

^dWhen midazolam is administered as the induction agent (e.g., 0.15 mg/kg IV).

Adapted from references 26–28.

and methohexital undergo maximal brain uptake within 30 seconds of injection as a result of their high lipophilicity and high rate of blood flow to the brain. This is followed by a decline over the next 5 minutes to half of the initial peak brain concentration, predominately through drug redistribution. As a result, patients awaken in <10 minutes after a single induction dose of thiopental, despite a half-life of approximately 11 hours. Because cumulative effects can be seen after repeat or continuous dosing of barbiturates due to fat deposition and storage, these drugs make poor choices for maintenance of general anesthesia. The degree to which metabolism plays a role in the clinical duration of IV induction agents is variable; rapid metabolism can be a significant factor in the relatively shorter duration to full recovery of propofol.²⁶ Table 9-4 compares the pharmacokinetic properties of IV anesthetic agents.^{26–28}

Adverse and Beneficial Effects

IV anesthetic agents can produce a variety of adverse and beneficial effects other than loss of consciousness (e.g., cardiovascular depression or stimulation, pain on injection, nausea and vomiting, respiratory depression or stimulation, CNS cerebroprotection or excitation, adrenocorticoid suppression). Table 9-5 compares the relative significance of these effects among available agents.^{26–28} The most troublesome are usually cardiovascular effects or CNS excitation reactions. Contribution

to postoperative nausea and vomiting (PONV) and “hangover” can be significant and may delay full recovery and patient discharge from the PACU. This is of particular concern in the ambulatory surgery setting because the patient will be discharged home. CNS effects can include hiccups, myoclonus, seizure activity, euphoria, hallucinations, and emergence delirium. The cerebroprotective effect produced by barbiturates, etomidate, and propofol results from a reduction in cerebral blood flow secondary to cerebral vasoconstriction. As a result, cerebral metabolic rate, cerebral blood flow, and intracranial pressure are reduced.^{26–28} This effect is useful if these drugs are available in therapeutic concentrations at a time of potential cerebral ischemia. Thiopental, for example, has been given during deep hypothermic circulatory arrest to minimize the possibility of ischemic events.

Agent Selection

The selection of an IV anesthetic agent should be determined based on patient characteristics, circumstances associated with surgery, and cost. Patient characteristics may include history of PONV, allergy profile, psychiatric history, or cardiovascular status. Circumstances associated with surgery that could influence the choice of IV anesthetic include the postoperative admission status (inpatient vs. outpatient), placement of an IV line, duration of surgery, and extubation status at the end of

Table 9-5 Adverse Effects and Costs of Intravenous Induction Agents

| Adverse Effect | Etomidate (Amidate) | Ketamine (Ketalar) | Methohexital (Brevital) | Midazolam (Versed) | Propofol (Diprivan) | Thiopental (Pentothal) |

Adapted from references 26–28.

the procedure. The cost of induction agents varies, with older agents (e.g., thiopental, methohexital) priced higher per single induction dose than newer agents (e.g., etomidate, propofol).

Propofol Use in Ambulatory Surgery: Antiemetic Effect and Full Recovery Characteristics

4. K.T., a 19-year-old girl, ASA-I, is admitted to the ambulatory surgery center for strabismus surgery to correct misalignment of her extraocular muscles. She is otherwise healthy, and all laboratory values obtained before surgery are within normal limits. The duration of K.T.'s surgery is anticipated to be approximately 90 minutes. Which IV induction agent should be used?

Propofol (Diprivan) is a good choice here for several reasons. Strabismus surgery is considered highly emetogenic because operative manipulation of extraocular muscles triggers the release of dopamine, serotonin, and acetylcholine (ACh) in the chemoreceptor trigger zone (CTZ) through the oculocardiac reflex.²⁹ Therefore, precautions should be taken to reduce the possibility of nausea and vomiting postoperatively. Propofol produces the lowest incidence of PONV when compared with other IV induction agents and the volatile inhalation agents; it has even been associated with a direct antiemetic effect.³⁰ This effect does not preclude the need for prophylactic antiemetic therapy, but may contribute to the avoidance of emesis in K.T. Furthermore, ambulatory surgery demands rapid, full recovery from general anesthesia. Propofol, etomidate, and methohexital produce less of a hangover than other IV induction agents. Propofol, in particular, is associated with a more rapid recovery of psychomotor function and a patient-perceived superior quality of recovery.²⁸ Propofol also offers advantages for maintenance of anesthesia in this case, and it does not accumulate when administered as a continuous infusion.

Etomidate Use in Cardiovascular Disease

5. L.M., a 73-year-old man, ASA-IV, is in need of repair of an abdominal aortic aneurysm. During a preoperative evaluation a few days before surgery, his blood pressure (BP) was 160/102 mmHg, and his medical records revealed hypertension that was poorly controlled by hydrochlorothiazide 25 mg daily and metoprolol XL (Toprol) 100 mg daily. He also has angina that occasionally requires treatment with SL nitroglycerin. An exercise stress test showed electrocardiogram changes at a moderate exercise load. Two days before the elective aneurysm repair was scheduled, L.M. presented to the emergency department (ED) with a 4-hour history of severe back pain. His surgeon believes that there is a high likelihood that the aneurysm is leaking or expanding and schedules surgery immediately. What is the best plan for L.M.'s anesthetic induction and maintenance?

L.M. has significant cardiovascular disease, and care should be taken to minimize any cardiovascular depression, tachycardia, or hypertension during induction and maintenance of anesthesia. Of the currently available induction agents, etomidate has the most stable cardiovascular profile²⁸ and is associated with minimal cardiovascular depression. Opioids generally produce minimal cardiovascular effects and could potentially be used for induction. Thiopental, propofol, and ketamine can

cause hemodynamic changes and are best avoided in L.M. Etomidate would be an excellent choice for induction, followed by isoflurane (with low-dose opioids) to maintain anesthesia. Although opioid-based anesthetics provide cardiovascular stability, the doses required to maintain anesthesia can prolong the duration of respiratory depression, which might necessitate postoperative mechanical ventilation.

Methohexital for Electroconvulsive Therapy

6. T.B., a 33-year-old woman, ASA-I, will undergo an electroconvulsive therapy (ECT) procedure for treatment of her severe, medication-resistant depression. T.B. is scheduled to go home within 1 to 2 hours after the procedure, which will be performed under general anesthesia. What IV induction agent should be used?

ECT procedures are an important method of treatment of severe and medication-resistant depression, mania, and other serious psychiatric conditions. During the ECT procedure, an electrical current is applied to the brain, resulting in an electroencephalographic (EEG) spike and wave activity, a generalized motor seizure, and acute cardiovascular response. For an optimal therapeutic (antidepressant) response, T.B.'s seizure activity should last from 25 to 50 seconds. General anesthesia is administered to ensure amnesia, prevent bodily injury from the seizure, and control the hemodynamic changes. When selecting an IV induction agent, its effect on EEG seizure activity, its ability to blunt the hemodynamic response to ECT, and its recovery profile (e.g., short time to discharge, nonemetogenic) are important considerations. Because most IV induction agents have anticonvulsant properties, small doses must be used to allow adequate seizure duration. Methohexital is considered the gold standard. Propofol, in smaller doses, can also be used. Combining a short-acting opioid such as remifentanyl with propofol will allow a small dose of propofol to be used and the seizure duration to be prolonged. Although etomidate does not adversely affect the seizure duration, the hemodynamic response to ECT is accentuated because etomidate is cardiovascularly stable and cannot blunt the cardiovascular response to ECT. In addition, it can cause nausea and vomiting, resulting in delayed recovery. Midazolam reduces seizure activity, and ketamine increases the risk of delayed recovery by producing nausea and ataxia.^{31,32} Therefore, methohexital, in a dose of 0.75 to 1 mg/kg IV, can be administered because it will not affect the seizure duration or prolong T.B.'s recovery time. Alternatively, a small dose of propofol (0.75 mg/kg) and remifentanyl (up to 1 mcg/kg) are also appropriate.

Ketamine Use in Pediatrics

7. R.L., a 4-year-old boy, ASA-II, is scheduled for a painful debridement and dressing change that is anticipated to take approximately 15 minutes. He is brought to the procedure room near the OR along with his parents and is in distress over parting from them. He currently has no IV line in place. How could sedation and analgesia be provided to R.L.?

Ideally, analgesia should be provided without the need to start an IV and, for children with a high level of separation

anxiety, in the presence of a parent. Although ketamine can be given intramuscularly, administration by this route is painful and not optimal. However, it might be preferable to starting an IV in R.L. for a short, painful procedure. At relatively low doses (3 or 4 mg/kg IM), ketamine produces analgesia and a compliant patient who is not heavily sedated. Intubation is unnecessary because ketamine causes little or no respiratory depression. Ketamine, however, can produce a dissociative stare and nystagmus, random movements of the head and extremities, and tonic/clonic movements. R.L.'s parents should be informed about these potential effects. An anticholinergic drug (e.g., glycopyrrolate) can be given along with ketamine to counteract its sialagogue effect. Ketamine use has expanded to EDs because of the quality of sedation and analgesia and the short duration of action (<30 minutes) associated with this drug. Appropriate guidelines for use of ketamine in this setting should be followed.³³

Delirium and hallucinations are unusual adverse effects of ketamine that occur in 10% to 30% of patients on awakening from anesthesia. Emergence reactions (e.g., dreaming, illusions, sense of floating out of body) vary in severity; occur within hours of awakening from anesthesia; and occur more often in adults, females, frequent dreamers, patients with personality disorders, and patients receiving high doses of ketamine (>2 mg/kg) by rapid IV administration. These reactions can be attenuated by prophylactic administration of benzodiazepines.^{28,33} R.L. is at very low risk for an emergence reaction based on age, gender, dose, and route of ketamine administration; therefore, benzodiazepines are not needed in R.L.

VOLATILE INHALATION AGENTS

Currently, four volatile inhalation agents are available for use in the United States: desflurane, sevoflurane, isoflurane, and enflurane, with the latter being less commonly used in clinical practice than the other three. The volatile inhalation agents are unique in that they can produce all components of the anesthetic state, to varying degrees (e.g., minimal, if any, analgesia). Immobility to surgical stimuli and amnesia is postulated to be the predominant effect produced by these agents. Unlike IV anesthetic agents, these drugs are administered into the lungs via an anesthesia machine, and as a result, it is easy to increase or decrease drug levels in the body. The anesthetist can estimate, with the use of technology, the anesthetic partial pressure at the site of action (brain); this helps the anesthetist maintain an optimal depth of anesthesia.³⁴

Although the volatile inhalation agents could, theoretically, be used to produce general anesthesia by themselves, it is much more common to use a combination of drugs intended to take advantage of smaller doses of each drug while avoiding the disadvantages of high doses of individual agents. This practice is referred to as *balanced anesthesia*. For example, midazolam is used routinely to produce sedation, anxiolysis, and amnesia, whereas the administration of a barbiturate (e.g., thiopental) or other IV anesthetic agent (e.g., propofol), followed by administration of a neuromuscular blocking agent (e.g., succinylcholine), can induce rapid loss of consciousness and muscle relaxation to facilitate endotracheal intubation. Volatile inhalation agents provide maintenance of general anesthesia, along with reflex suppression (e.g., lowering BP and heart rate) and

some muscle relaxation. Opioids (e.g., fentanyl) also can induce reflex suppression, thereby lowering total anesthetic requirements. Subsequent doses of a nondepolarizing neuromuscular blocking drug might be necessary to provide adequate relaxation for surgery.

Uses

The volatile inhalation agents are primarily used in clinical practice to maintain general anesthesia. Sevoflurane also can be used to induce general anesthesia via a face mask because of its low pungency. Desflurane and sevoflurane, because of their low blood solubility, are ideally suited for maintenance of general anesthesia in ambulatory surgery patients and for inpatients when rapid wake-up is desired (e.g., neurosurgery procedures).

Site/Mechanism of Action

The goal of inhalation anesthesia is to develop and maintain a satisfactory (anesthetizing) partial pressure of anesthetic in the brain, which is the site of anesthetic action.³⁴ Although the mechanism of action of the volatile inhalation agents is not fully understood, these agents are believed to disrupt neuronal transmission in discrete areas throughout the CNS by either blocking excitatory, or enhancing inhibitory, transmission through synapses. Ion channels (especially GABA receptors) are likely targets of volatile inhalation anesthetic agent action.²⁵

Anesthesia Machine and Circuit

A basic understanding of the anesthesia machine and circuit is helpful to understanding many of the concepts associated with the administration of volatile inhalation agents. Three parts of the anesthesia machine are critically important for the administration of volatile inhalation anesthetics. The *flow meters* regulate the amount of nitrous oxide (an anesthetic gas), air, and oxygen delivered to the patient. The *vaporizers* regulate the concentration of volatile inhalation agent administered to the patient, whereas the *carbon dioxide absorber*, which contains either soda lime or Baralyme, removes carbon dioxide from exhaled air. The first step in the administration of a volatile inhalation agent to a patient is to begin the flow of background gases. Flow is measured in liters per minute. A mixture of nitrous oxide and oxygen is commonly used. This gas mixture flows to one of the vaporizers, where a portion of it enters the vaporizer and “picks up” the anesthetic vapor of the volatile inhalation agent. The concentration of volatile inhalation agent delivered by the vaporizer is proportional to the amount of gas mixture passing through it, which is regulated by adjusting the vaporizer’s concentration dial. The gas and anesthetic vapor mixture exits the vaporizer and continues through the anesthetic circuit, where it is ultimately delivered to the patient via an endotracheal tube or face mask. The exhaled air from the patient, which contains the volatile inhalation agent and carbon dioxide, is returned to the circuit. If a semiclosed circle breathing system is being used, rebreathing of the exhaled volatile agent can occur if the fresh gas flow rate is low enough (e.g., ≤ 2 L/minute).³⁵

Table 9-6 Pharmacologic and Pharmacokinetic Properties of the Volatile Inhalation Agents

| Property/Effect | Desflurane | Sevoflurane | Isoflurane | Enflurane |
|---|------------|-------------|------------|-----------|
| MAC in O ₂ (adults) | 6.0 | 1.71 | 1.15 | 1.7 |
| Blood/gas partition coefficient ^a | 0.42 | 0.69 | 1.46 | 1.91 |
| Brain/blood partition coefficient ^b | 1.29 | 1.7 | 1.6 | 1.4 |
| Muscle/blood partition coefficient ^c | 2.02 | 3.13 | 2.9 | 1.7 |
| Fat/blood partition coefficient ^d | 27.2 | 47.5 | 45 | 36 |
| Metabolism | 0.02% | 3% | 0.2% | 2% |
| Molecular weight (g) | 168 | 201 | 184.5 | 184.5 |
| Liquid density ^e | 1.45 | 1.505 | 1.496 | 1.517 |

^aThe greater the blood/gas partition coefficient, the greater the blood solubility.

^bThe greater the brain/blood partition coefficient, the greater the brain solubility.

^cThe greater the muscle/blood partition coefficient, the greater the muscle solubility.

^dThe greater the fat/blood partition coefficient, the greater the fat solubility.

^eDensity determined at 25°C for desflurane, isoflurane, and enflurane and at 20°C for sevoflurane.

MAC, minimum alveolar concentration to prevent movement in 50% of subjects.

Adapted from reference 34.

Potency

Potency of the volatile inhalation agents is compared in terms of minimum alveolar concentration (MAC). MAC is the alveolar concentration of anesthetic at one atmosphere that prevents movement in 50% of subjects in response to a painful stimulus (e.g., surgical skin incision).³⁴ The lower an agent's MAC, the greater is the anesthetic potency. A value of 1.3 MAC is required to produce immobility in 95% of patients, whereas 1.5 MAC is required to block the adrenergic response to noxious stimuli.³⁴ Furthermore, the inhalation agents are additive in their effects on MAC; the addition of a second agent reduces the required concentration of the first agent. For example, when desflurane, isoflurane, and sevoflurane are administered with 60% to 70% nitrous oxide, their MAC values decrease from 6%, 1.15%, and 1.71% to 2.38%, 0.56%, and 0.66%, respectively.³⁴ Of the volatile inhalation agents routinely used, isoflurane has the lowest MAC and desflurane the highest (Table 9-6).³⁴

Chemical Stability

Desflurane and isoflurane are very stable compounds and are not broken down by the moist soda lime or Baralyme contained in the carbon dioxide absorber of the anesthesia machine. Sevoflurane degrades in the presence of carbon dioxide absorbent to multiple by-products, with compound A being most important. In rats, compound A has caused nephrotoxicity,³⁶ but no clinically significant changes in serum creatinine and blood urea nitrogen (BUN) have been demonstrated in human studies.³⁷⁻³⁹ The administration of sevoflurane at low flow rates is one of the major factors that increases compound A concentration. The U.S. Food and Drug Administration (FDA) requires that the sevoflurane package insert contain a warning that sevoflurane exposure should not exceed 2 MAC hours at flow rates of 1 to <2 L/minute, and flow rates <1 L/minute are not recommended. Nevertheless, even when low fresh gas flows are used for long periods of time and exposure to compound A was high, the levels of compound A are much less than what is believed to be a toxic level.⁴⁰

Unlike sevoflurane, desflurane, isoflurane, and enflurane can react with dry carbon dioxide absorbent to produce carbon monoxide.⁴¹ The water content of the absorbent is the major factor leading to the production of carbon monoxide.⁴² When these agents pass through dry absorbent, carbon monoxide is produced. This situation is most commonly encountered on a Monday morning in an anesthesia machine that has been idle during the weekend and has had a continuous flow of fresh gas through the absorbent. Carbon monoxide production can be prevented by ensuring that only fully hydrated absorbent is used.

The newer alkali hydroxide-free carbon dioxide absorbents containing calcium hydroxide (vs. sodium or potassium hydroxide) make the chemical stability of volatile inhalation agents in the absorbent not a clinical concern. In an in vitro study of one of these absorbents (Amsorb), compound A levels were no higher than those found in sevoflurane itself when it was passed through this absorbent at a low flow rate (1 L/minute). Likewise, carbon monoxide production was negligible when desflurane, isoflurane, or enflurane passed through an anhydrous form of this absorbent.⁴³

Pharmacokinetics

A series of anesthetic partial pressure gradients beginning at the anesthesia machine serve to drive the volatile inhalation agent across barriers to the brain. These gradients are as follows: anesthesia machine > delivered > inspired > alveolar > arterial > brain. The alveolar partial pressure provides an indirect measurement of the anesthetic partial pressure in the brain because the alveolar, arterial, and brain partial pressures rapidly equilibrate.³⁴

Factors that influence the uptake and distribution of a volatile inhalation agent include the inspired concentration of the agent, alveolar ventilation, solubility of the agent in the blood (blood/gas partition coefficient), blood flow through the lungs, distribution of blood to individual organs (levels rise most rapidly in highly perfused organs—brain, kidney, heart, liver), solubility of the agent in tissue (tissue/blood partition coefficient), and mass of tissue.³⁴ If all other factors are equal,

agents with low solubilities will equilibrate quickly and, as a result, have a faster wash-in (onset). Solubility is also a factor in the elimination of volatile inhalation agents, in addition to metabolism and extent of tissue equilibration. Low-solubility agents are more rapidly washed out (eliminated) because more of the agent is removed from the blood in one passage through the lungs.³⁴ As can be seen in Table 9-6, desflurane has the lowest solubility of any of the volatile inhalation agents, with sevoflurane's solubility being lower than isoflurane's for blood and muscle. As a result of their low solubility, quicker responses to intraoperative concentration changes are seen with desflurane and sevoflurane as well as a faster emergence and awakening from anesthesia and a more rapid return to normal motor function and judgment when compared with isoflurane.⁴⁴⁻⁴⁶

As seen in Table 9-6, the metabolism of the volatile inhalation agents varies (e.g., desflurane is metabolized least). An important point is that metabolism does not alter the rate of induction or maintenance of anesthesia because the amount of anesthetic administered to the patient greatly exceeds its uptake.³⁴ Metabolism of sevoflurane has resulted in peak inorganic fluoride levels $>100 \mu\text{mol/L}$.³⁸ Historically, a fluoride level of $50 \mu\text{mol/L}$ has been used as a cut-off for potential nephrotoxicity based on reports of methoxyflurane-associated nephrotoxicity at levels $>50 \mu\text{mol/L}$.⁴⁷ Despite this, sevoflurane has not been demonstrated to produce nephrotoxicity. Potential reasons for this include the fact that sevoflurane's low blood gas solubility may limit the degree of its metabolism once the anesthetic is discontinued and that sevoflurane, unlike methoxyflurane, undergoes minimal renal defluorination.⁴⁸ In clinical studies examining the preanesthetic and postanesthetic serum creatinine and BUN values in patients receiving sevoflurane anesthesia, clinically significant renal damage in patients with normal renal function has not been reported, nor has renal function worsened in patients with stable renal insufficiency or in those undergoing hemodialysis.⁴⁹⁻⁵¹

Pharmacologic Properties

All volatile inhalation agents depress ventilation (with an elevation of PaCO_2) and dilate constricted bronchial musculature in a dose-dependent manner. As mentioned previously, sevoflurane can be used for mask induction of general anesthesia because it is not as pungent as desflurane, isoflurane, or enflurane. Administration of a pungent agent by mask for induction can cause coughing, breath-holding, laryngospasm, and salivation in the patient. All volatile inhalation agents depress myocardial contractility and decrease arterial BP in a dose-dependent manner. Isoflurane can increase heart rate, so cardiac output is usually maintained. Sevoflurane produces little increase in heart rate, so cardiac output may not be as well maintained as with isoflurane. Although enflurane can increase heart rate, cardiac output is usually decreased. Desflurane can produce sympathetic nervous system activation, resulting in a transient increase in BP and heart rate, when concentrations are rapidly increased.⁵² The sympathetic nervous system activation may be due to stimulation of medullary centers via receptors in the upper airway and lungs.⁵³ Enflurane can sensitize the myocardium to the arrhythmogenic effects of epinephrine. The volatile inhalation agents decrease cerebral metabolic rate and produce cerebral vasodilation, resulting in increased cere-

bral blood flow and volume. Enflurane can cause epileptiform activity that can result in clinical tonic-clonic seizures. All volatile inhalation agents produce muscle relaxation and potentiate the actions of the neuromuscular blocking agents. The volatile inhalation agents relax uterine smooth muscle, which can contribute to perinatal blood loss. All volatile inhalation agents have been implicated as triggers of malignant hyperthermia (MH) and are contraindicated in MH-susceptible patients. Finally, all volatile inhalation agents are associated with postoperative nausea, vomiting, and shivering.^{34,47}

Drug Interactions

Opioids, benzodiazepines, α -2 agonists, and neuromuscular blocking agents potentiate the effects of the volatile inhalation agents. Thus, their administration permits use of lower dosages of the volatile inhalants, thereby reducing their potential for adverse effects.

Economic Considerations

The following items must be considered when examining the costs associated with the administration of volatile inhalation agents from an institutional perspective: cost of the volatile inhalation agent (including waste), cost of the equipment necessary to administer the volatile inhalation agent, cost of adjuvants used to treat adverse effects of the volatile agent, and time spent in the OR and PACU.

The cost of a volatile agent depends on (a) the cost per milliliter of the liquid anesthetic, (b) the amount of vapor generated per milliliter, (c) the amount of volatile agent that must be delivered from the anesthesia machine to sustain the desired alveolar concentration, and (d) the flow rate of the background gases.⁵⁴ Items a and b are, for the most part, constant, with price increases or decreases occurring periodically. Because desflurane and sevoflurane are less soluble in blood and tissue than isoflurane, lower amounts of these agents will need to be delivered to the alveoli to attain the desired anesthetic depth.⁵⁴ The flow rate of background gases is a major determinant of the cost; as flow rate increases, the amount of anesthetic consumed per time increases.⁵⁵ The following formula is frequently used to calculate the cost of volatile inhalation agent used:

$$\text{Cost used} = (\text{PFTMC}) / (2412d)$$

where P is vaporizer concentration (%), F is fresh gas flow (L/minute), T is time (minute), M is molecular weight of the agent, C is the cost of the agent (\$/mL), and d is the density of the agent.⁵⁶ The use of low flow rates can result in substantial reductions in the volatile anesthetic drug cost per case. An important point to keep in mind when comparing only the cost of the volatile inhalation agents themselves (e.g., excluding any benefits in terms of cost reduction that may be realized by a quicker discharge from the recovery room) is that the low-solubility volatile agents have to be administered at low flow rates to prevent their cost from being substantially higher than that of the more traditional agents (e.g., isoflurane) when administered at rates of 2 to 3 L/minute.

The cost of purchasing new vaporizers and upgrading or replacing agent analyzers that are used to administer and monitor volatile inhalation agents, respectively, can be significant. These costs become a concern when a new product is introduced onto the market.

Medications used to treat adverse effects associated with the volatile inhalation agents include β -blockers, opioids, benzodiazepines, vasopressors, and antiemetic agents. Antiemetic agents are routinely used to prevent and/or treat the PONV seen with the volatile inhalation agents. Intraoperative use of volatile inhalation agents is a leading cause of early (within the first 2 hours following surgery) postoperative vomiting.⁵⁷ Although the administration of an antiemetic agent adds costs,⁵⁸ it is significantly less than the cost of an unanticipated admission to the hospital secondary to PONV.

The use of low-solubility volatile inhalation agents can significantly reduce the overall net cost of the surgical procedure by reducing the time patients spend in the OR and PACU. This concept is discussed at the end of this chapter.

Desflurane Use for Maintenance of General Anesthesia

Sympathetic Nervous System Activation

8. C.K., a 26-year-old man, ASA-I, is scheduled to undergo a laparoscopic hernia repair on an outpatient basis. During his preoperative evaluation on the morning of surgery, his BP was 115/75 mmHg, and his heart rate was 70 beats/minute. The surgery is expected to last <2 hours, so a propofol induction is planned followed by maintenance of general anesthesia with desflurane without nitrous oxide. After induction of anesthesia, the desflurane concentration on the vaporizer was rapidly increased to 8%. Within 1 minute of the concentration increase, C.K.'s BP increased to 148/110 mmHg, and his heart rate increased to 112 beats/minute. What could be causing C.K.'s increased BP and heart rate, and how could it have been prevented?

Desflurane can produce sympathetic nervous system activation with a resultant increase in BP and heart rate under certain circumstances. One of these is the rapid increase of desflurane concentration to 1.1 MAC as seen with C.K.⁵⁹ This hemodynamic response can be attenuated by the IV administration of fentanyl approximately 5 minutes before the increase in desflurane concentration.⁶⁰ Fentanyl is a good choice because it effectively blunts the increase in heart rate and BP, while having minimal cardiovascular depressant and postoperative sedative effects. Alternatively, nitrous oxide can be administered with desflurane, thereby allowing the desflurane concentration to be maintained at <1 MAC (6%).

Emergence Agitation in Children

9. P.F., a 3-year-old child, ASA-I, is undergoing a tonsillectomy. General anesthesia will be induced and maintained with sevoflurane and nitrous oxide. His surgery was uneventful, with a duration of 30 minutes. He was awakened from anesthesia and transferred to the postanesthesia care unit to recover. Shortly after he arrived, P.F. became extremely restless and began crying. The nurse and his mom were unable to console him. Could this reaction be attributed to sevoflurane, and, if so, can it be prevented?

Emergence agitation following the administration of the short-acting inhaled anesthetics, desflurane and sevoflurane, is fairly common, with a reported incidence as high as 80%.⁶¹

Emergence agitation is more common in young children, and its cause is not clear. Children become restless, cry, and exhibit involuntary physical activity that can result in self-injury. Caring for a child experiencing emergence agitation is difficult and very upsetting to the caregiver and the parents of the child. Premedication with oral midazolam⁶² and administering analgesics to minimize postoperative pain⁶³ may reduce the incidence. A small dose of dexmedetomidine (0.3 mcg/kg IV), an α -2 agonist with sedative and analgesic properties, after induction of anesthesia reduces the incidence of emergence agitation, without prolonging recovery in children undergoing sevoflurane anesthesia.⁶⁴ Although desflurane cannot be used to induce general anesthesia, switching to desflurane for maintenance of anesthesia following sevoflurane induction effectively reduces the severity of emergence agitation when it occurs.⁶⁵

NEUROMUSCULAR BLOCKING AGENTS

Uses

Neuromuscular blocking agents are one of the most commonly used classes of drugs in the OR. They are used primarily as an adjunct to general anesthesia to facilitate endotracheal intubation and to relax skeletal muscle during surgery under general anesthesia.⁶⁶ Skeletal muscle relaxation optimizes the surgical field for the surgeon and prevents patient movement as a reflex response to surgical stimulation. Neuromuscular blocking agents are also used in the ICU to paralyze mechanically ventilated patients.⁶⁷ An important point to remember is that neuromuscular blocking agents have no known effect on consciousness or pain threshold. Consequently, adequate sedation and analgesia must be ensured when neuromuscular blocking agents are administered to ICU patients.

Mechanism of Action

When two molecules of Ach bind to the Ach subunits of the nicotinic cholinergic receptors located on the motor nerve end plate, the Ach receptor undergoes a conformational change that allows the influx of sodium and potassium into the muscle cell, the membrane depolarizes, and the muscle contracts. Neuromuscular blocking agents bind to these subunits and effectively block normal neuromuscular transmission. Two classes of neuromuscular blocking agents exist based on their mechanism of action: depolarizing and nondepolarizing. Succinylcholine, the only depolarizing neuromuscular blocking agent in clinical use today, acts like Ach to depolarize the membrane. Because succinylcholine is not metabolized as quickly as Ach at the neuromuscular junction, its action at the nicotinic receptor persists longer than Ach. Succinylcholine causes a persistent depolarization of the motor end plate because the sodium channels cannot reopen until the motor end plate repolarizes. As a result, sustained skeletal muscle paralysis occurs. The paralysis produced by depolarizing agents is preceded initially by fasciculations (transient twitching of skeletal muscle). The nondepolarizing neuromuscular blocking agents act as competitive antagonists to Ach at the Ach subunits of the nicotinic cholinergic receptors, thereby preventing Ach from binding and causing depolarization of the muscle membrane and muscle contraction.^{66,68}

Table 9-7 Classification of Neuromuscular Blocking Agents

| Agent | Type of Block | Clinical Duration of Action ^a | Structure |
|--------------------------------------|---------------|--|----------------------|
| Atracurium (Tracrium) | – | Intermediate | Benzylisoquinolinium |
| Cisatracurium (Nimbex) | – | Intermediate | Benzylisoquinolinium |
| Pancuronium (Pavulon) | – | Long | Steroidal |
| Rocuronium (Zemuron) | – | Intermediate | Steroidal |
| Succinylcholine (Anectine, Quelicin) | + | Ultrashort | Acetylcholine-like |
| Vecuronium (Norcuron) | – | Intermediate | Steroidal |

^aTime from injection of agent to return to twitch height to 25% of control (time at which another dose of agent will need to be administered to maintain paralysis); in general, clinical duration of a standard intubating dose of ultrashort agents ranges from 3 to 5 minutes, intermediate agents from 30 to 40 minutes, and long agents from 60 to 120 minutes.

+, depolarizing; –, nondepolarizing.

Adapted from reference 69.

Monitoring Neuromuscular Blockade

In addition to clinical assessment (e.g., lack of movement) by the anesthesia provider and the surgeon, the degree of neuromuscular blockade produced by neuromuscular blocking agents is monitored by nerve stimulation with a peripheral nerve stimulator. Most commonly, the ulnar nerve is electrically stimulated, and the response of the innervated muscle, the adductor pollicis in the thumb, is visually assessed. Adequate neuromuscular blockade is present when the train-of-four (four electrical stimulations of 2 Hz delivered every 0.5 seconds) count is 1/4 or 2/4 (one or two visible muscle twitches out of a possible four twitches).⁶⁷

Classification

Neuromuscular blocking agents are commonly classified by the type of blockade produced (depolarizing vs. nondepolarizing), chemical structure (steroidal compound, Ach-like, benzylisoquinolinium compound), or duration of action (ultrashort, intermediate, long), as listed in Table 9-7.⁶⁹

Adverse Effects

The underlying mechanisms for the cardiovascular adverse effects of neuromuscular blocking agents are listed in Table 9-8 and include blockade of autonomic ganglia (hypotension), blockade of muscarinic receptors (tachycardia), and/or release of histamine from circulating mast cells (hypotension).^{68–70} In general, the steroidal compounds exhibit varying degrees

of vagolytic effect, whereas the benzylisoquinolinium compounds are associated with varying degrees of histamine release. Although not reported as a problem when used short term in the OR, the use of neuromuscular blocking agents in ICU patients for extended periods can result in prolonged neuromuscular blockade or acute quadriplegic myopathy syndrome, albeit infrequently.⁶⁸ Of the currently available neuromuscular blocking agents, cisatracurium (Nimbex) and vecuronium (Norcuron) are devoid of clinically significant cardiovascular effects and are the agents of choice for patients with unstable cardiovascular profiles.^{66,68,69} Succinylcholine (Anectine, Quelicin) is associated with a significant number of adverse effects, including hyperkalemia; arrhythmias; fasciculations; muscle pain; myoglobinuria; trismus; phase II block; and increased intraocular, intragastric, and intracranial pressures.^{69,70} Succinylcholine, like inhalational anesthetics, can trigger MH.⁶⁸ Of these adverse effects, bradycardia, hyperkalemia (which can trigger arrhythmias and cardiac arrest in patients at risk), and MH crisis are severe and potentially life-threatening reactions. Nevertheless, succinylcholine is still used today because of its rapid onset and ultrashort duration of action as well as its ability to be administered intramuscularly in children in an emergent situation when IV access has not been established.

Drug Interactions

Several drugs interact with neuromuscular blocking agents. The volatile inhalation agents potentiate the neuromuscular

Table 9-8 Causes of Cardiovascular Adverse Effects of Neuromuscular Blocking Agents

| Agent | Histamine Release ^a | Autonomic Ganglia | Vagolytic Activity | Sympathetic Stimulation |
|--------------------------------------|--------------------------------|-------------------|--------------------|-------------------------|
| Atracurium ^a (Tracrium) | ++ | – | – | – |
| Cisatracurium (Nimbex) | – | – | – | – |
| Pancuronium (Pavulon) | – | Weak block | ++ | ++ |
| Rocuronium ^b (Zemuron) | – | – | + | – |
| Succinylcholine (Anectine, Quelicin) | + | Stimulates | – | – |
| Vecuronium (Norcuron) | – | – | – | – |

^aHistamine release is dose and rate related; cardiovascular changes can be lessened by minimizing dose and injecting agent slowly.

^bProduces an increase in heart rate of approximately 18% with intubating dose of 0.6 mg/kg; effect usually transient and resolves spontaneously.

+ – ++, likelihood of developing the cardiovascular adverse effect relative to the other agents; –, no effect.

Adapted from references 68–70.

blockade produced by nondepolarizing agents, thereby allowing a lower dose of the latter to be used when administered concomitantly. Other agents reported to potentiate the effects of neuromuscular blocking agents include the aminoglycosides, clindamycin, magnesium sulfate, quinidine, furosemide, lidocaine, amphotericin B, and dantrolene. Carbamazepine, phenytoin, corticosteroids (chronic administration), and theophylline antagonize the effects of neuromuscular blocking agents.^{68,69} By appropriately monitoring the patient and dosing the neuromuscular blocking agent to effect, significant problems from drug interactions can be minimized.

Reversal of Neuromuscular Blockade

The action of neuromuscular blocking agents ceases spontaneously as plasma concentrations decline or when anticholinesterases (e.g., neostigmine, edrophonium, pyridostigmine) are administered. Anticholinesterases inhibit the enzyme acetylcholinesterase, which degrades Ach, and are used to reverse paralysis produced by nondepolarizing agents. Anticholinergic agents are coadministered (in same syringe) with the anticholinesterases to minimize other cholinergic effects (e.g., bradycardia, bronchoconstriction, salivation, increased peristalsis, nausea, vomiting) caused by the increase in Ach concentration. Atropine is routinely administered with edrophonium, and glycopyrrolate with neostigmine or pyridostigmine, to take advantage of similar onset times and durations of action.^{66,67,69} Reversal of neuromuscular blockade, as a general rule, is not attempted until spontaneous recovery is well established. Before extubation, adequacy of reversal is assessed with the use of a peripheral nerve stimulator and by clinical assessment of the patient (e.g., ability to sustain head lift for 5 seconds).^{69,70}

A new reversal agent, sugammadex, is currently under development that may eliminate some of the issues currently seen with the anticholinesterases. Sugammadex, a modified cyclodextrin, encapsulates steroidal (e.g., rocuronium) neuromuscular blocking agents, thereby preventing them from acting at the neuromuscular junction. It produces a rapid recovery from neuromuscular blockade, even when administered during

profound blockade, and does not appear to have any serious adverse effects.⁷¹

Pharmacokinetics and Pharmacodynamics

Rapid Sequence Induction

10. R.D., a 36-year-old man, ASA-I, is admitted through the ED for an emergency appendectomy. R.D. is otherwise healthy, has no drug allergies, and is currently taking no medications. All laboratory values are normal. Admission notes reveal that R.D. ate dinner approximately 2 hours earlier. Because of this, the anesthesia provider plans to perform a rapid sequence induction using the Sellick maneuver. Which neuromuscular blocking agent would be most appropriate for R.D.?

Rapid sequence induction is indicated for patients at risk for aspiration of gastric contents should regurgitation occur. Patients who have recently eaten (with a full stomach), morbidly obese patients, or patients with a history of gastroesophageal reflux are at risk for aspiration, as is the case for R.D. The goal of rapid sequence induction is to minimize the time during which the airway is unprotected by intubating the patient as fast as possible (e.g., within 60 seconds). In this technique, the patient is preoxygenated, after which an IV induction agent is administered, followed immediately by a neuromuscular blocking agent. Manual ventilation of the patient is not attempted after administration of these agents. Apnea occurs as the neuromuscular blocking agent takes effect; therefore, a neuromuscular blocking agent with as rapid an onset as possible is required to produce adequate intubating conditions as quickly as possible. The Sellick maneuver is often used during rapid sequence induction. It is performed by placing downward pressure on the cricoid cartilage, which compresses and occludes the esophagus and helps prevent passive regurgitation of gastric contents into the trachea. Intubation is then performed within 60 seconds.

Table 9-9 lists the onset times of normal intubating doses and other information pertaining to the use of neuromuscular blocking agents.⁶⁷⁻⁷⁰ Succinylcholine has the fastest onset time, which makes it an appropriate agent to use in rapid sequence induction.⁷²

Table 9-9 Pharmacokinetic and Pharmacodynamic Parameters of Action of Neuromuscular Blocking Agents

| Agent | Cl (mL/kg/min) | V _d ^{ss} (L/kg) | Half-Life (minutes) | ED ₉₅ (mg/kg) | Intubating Dose ^{a,b} (mg/kg) | Onset ^c (minutes) | Clinical Duration of Action of Initial Dose (minutes) |
|---|-------------------|--|------------------------|-----------------------------|---|---------------------------------|---|
| Atracurium ^d (Tracrium) | 5–7 | 0.2 | 20 | 0.2–0.25 | 0.4–0.5 | 2–3 | 25–30 |
| Cisatracurium (Nimbex) | 4.6 | 0.15 | 22 | 0.05 | 0.15–0.2 | 2–2.5 | 50–60 |
| Pancuronium (Pavulon) | 1–2 | 0.3 | 80–120 | 0.07 | 0.04–0.1 | 3–5 | 80–100 |
| Rocuronium ^d (Zemuron) | 4.0 | 0.3 | 60–70 | 0.3 | 0.6–1.2 | 1–1.5 | 30–60 |
| Succinylcholine ^d (Anectine, Quelicin) | 37 | 0.04 | 0.65 | 0.25 | 1.5 | 1 | 5–10 |
| Vecuronium ^d (Norcuron) | 4.5 | 0.4 | 50–70 | 0.05–0.06 | 0.1 | 2–3 | 25–30 |

^aDose when nitrous oxide-opioid technique is used.

^bIntermittent maintenance doses to maintain paralysis, as a general rule, will be approximately 20% to 25% of the initial dose.

^cTime to intubation.

^dAlso can be administered as a continuous infusion to maintain paralysis. Suggested infusion ranges under balanced anesthesia are atracurium, 4–12 mcg/kg/min; cisatracurium, 1–2 mcg/kg/min; rocuronium, 6–14 mcg/kg/min; succinylcholine, 50–100 mcg/kg/min; vecuronium, 0.8–2 mcg/kg/min.

Cl, clearance; ED₉₅, effective dose causing 95% muscle paralysis; V_d^{ss}, steady-state volume of distribution.

Adapted from references 67–70.

Because R.D. is an otherwise healthy man with no contraindications to the use of succinylcholine, this agent should be used.

Depolarizing Agent Contraindications

11. What would be your choice of a neuromuscular blocking agent if R.D. presents with a history of susceptibility to MH, and why?

Succinylcholine is contraindicated in patients with skeletal muscle myopathies; after the acute phase of injury (i.e., 5–70 days after injury) following major burns, multiple trauma, extensive denervation of skeletal muscle, or upper motor neuron injury; in children and adolescents (except when used for emergency tracheal intubation or when the immediate securing of the airway is necessary); and in patients with a hypersensitivity to the drug.^{66,69} Succinylcholine can also trigger MH and is absolutely contraindicated in MH-susceptible patients.⁷³

The nondepolarizing neuromuscular blocking agents are safe to use in MH-susceptible patients.⁷⁴ Rocuronium (Zemuron) has the fastest onset time of the nondepolarizing agents, although it is slightly slower than succinylcholine.⁷⁰ The onsets of the remaining intermediate and long duration agents can be shortened by increasing the dose, which not only results in a faster onset of action but also prolongs the duration of action. Rocuronium's time to maximum blockade, for example, can be reduced to 60 seconds with an initial dose of 1.2 mg/kg (vs. a normal initial dose of 0.6 mg/kg). Increasing the dose from 0.6 mg/kg to 1.2 mg/kg, however, will prolong the clinical duration from approximately 30 minutes to at least 60 minutes.⁷⁵ Rocuronium, with its rapid onset of action, would be a suitable alternative to succinylcholine in R.D.'s case. Its longer clinical duration of action could be a concern if the airway cannot be secured immediately or if the procedure is shorter than the duration of an intubating dose of rocuronium. Because this procedure will last longer than the duration of muscle relaxation provided by the intubating dose of rocuronium, this is not a concern.

Routes of Elimination

12. M.M., a 70-year-old woman, ASA-IV, is scheduled to undergo a 2-hour GI procedure. Pertinent laboratory findings are aspartate aminotransferase (AST), 272 U/L (normal, 5–45 U/L); alanine aminotransferase (ALT), 150 U/L (normal, 5–37 U/L); BUN, 40 mg/dL (normal, 8–21 mg/dL); serum creatinine (SrCr),

1.8 mg/dL (normal, 0.5–1.1 mg/dL); albumin, 2.6 g/dL (normal, 3.5–5.0 g/dL); and bilirubin, 0.74 mg/dL (normal, 2–18 mg/dL). Which neuromuscular blocking agent would you recommend for M.M.?

[SI units: AST, 4.5 μ kat/L; ALT, 2.5 μ kat/L; BUN, 14.28 mmol/L; SrCr, 159 μ mol/L; albumin, 26 g/L; bilirubin, 12.7 mol/L]

When selecting a neuromuscular blocking agent, one of the factors that must be considered is the patient's renal and hepatic function. Neuromuscular blocking agents often depend on the kidneys and liver for varying amounts of their metabolism and excretion (Table 9-10).^{66,67,70} Some agents, however, are primarily metabolized by plasma cholinesterase (pseudocholinesterase), Hofmann elimination (a nonbiological process that does not require renal, hepatic, or enzymatic function), and/or nonspecific esterases.

Hofmann elimination is a pH- and temperature-dependent process unique to atracurium (Tracrium) and cisatracurium (Nimbex). One of the products produced by Hofmann elimination is laudanosine, a CNS stimulant in high concentrations. Laudanosine undergoes renal and hepatic elimination. Due to the short-term use of atracurium and cisatracurium in the OR, accumulation of laudanosine with resultant seizure activity is not a concern, even in patients with end-stage renal failure.⁷⁶ Because plasma cholinesterase levels may be decreased in patients with renal or hepatic dysfunction, the duration of action of succinylcholine could be prolonged. The increased duration of action of succinylcholine in patients with low levels of normal plasma cholinesterase is not clinically significant. Atypical plasma cholinesterase can increase the duration of action of succinylcholine significantly.⁷⁷

Unchanged neuromuscular blocking agents and their metabolites are excreted by the renal or biliary routes. The duration of action of the renally eliminated agent, pancuronium, will be increased in patients with renal failure. Vecuronium's duration of action can be increased in patients with liver disease, particularly when larger doses (0.2 mg/kg) are administered, reflecting impaired metabolism or excretion rather than termination of effect by redistribution.⁷⁸ Although the main route of elimination of rocuronium is hepatobiliary, the duration of action of rocuronium can be significantly prolonged in chronic renal failure.⁷⁹

Because M.M. has evidence of both significant renal and hepatic impairment, cisatracurium or atracurium would be appropriate choices for a neuromuscular blocking agent because their properties are not altered significantly by renal and hepatic failure. Furthermore, because these agents have an

Table 9-10 Elimination of Neuromuscular Blocking Agents

| Agent | Renal | Hepatic | Biliary | Plasma |
|--------------------------------------|---------|---------|---------|---------------------------------------|
| Atracurium (Tracrium) | 10% | | NS | Hofmann elimination, ester hydrolysis |
| Cisatracurium (Nimbex) | NS | | NS | Hofmann elimination |
| Pancuronium (Pavulon) | 80% | 10% | 5%–10% | |
| Rocuronium (Zemuron) | 10%–25% | 10%–20% | 50%–70% | |
| Succinylcholine (Anectine, Quelicin) | | | | Plasma cholinesterase |
| Vecuronium (Norcuron) | 15%–25% | 20%–30% | 40%–75% | |

NS, not significant.

Adapted from references 66, 67, and 70.

intermediate duration of action, they can easily be used in a 2-hour procedure. The availability of generic atracurium makes this agent a more economic choice; however, the greater propensity of atracurium to cause histamine release with resultant hypotension makes cisatracurium the most appropriate choice in this 70-year-old, ASA-IV patient.

LOCAL ANESTHETICS

Local and Regional Anesthesia

Some surgical procedures can be performed under regional anesthesia (anesthesia selective for part of the body, such as the area near the surgical site) rather than general anesthesia (total body anesthesia with the patient rendered unconscious). Epidural, spinal (intrathecal), IV regional, peripheral nerve block, topical, or local infiltration anesthesia can be chosen, depending on the location of the surgical site, extent of the surgery, patient health and physical characteristics, coagulation status, duration of surgery, and the desires and cooperativeness of the patient. For epidural anesthesia, the local anesthetic is administered into the epidural space, which is located between the dura and the ligament covering the spinal vertebral bodies and disks. To provide spinal anesthesia, the local anesthetic is injected into the cerebrospinal fluid within the subarachnoid (intrathecal) space. By injecting a local anesthetic in the tissue near a specific nerve or nerve plexus, anesthesia can be provided for a carotid endarterectomy (cervical plexus), upper extremity surgery (brachial plexus), or hand surgery (ulnar, median and/or radial nerve). Regional anesthesia can be selected to reduce or avoid the likelihood of complications such as postoperative pain, nausea, vomiting, and laryngeal irritation, or dental complications, all of which are associated with general anesthesia. Peripheral nerve block may be selected over general, spinal, or epidural anesthesia because it is not associated with bowel obstruction or urinary retention, and it provides postoperative analgesia (particularly when long-acting local anesthetics are used).⁸⁰ Potential advantages of spinal or epidural anesthesia include reduction of the stress response to surgery, improvement in cardiac function in patients with ischemic heart disease, fewer postoperative pulmonary com-

plications, potentially favorable effects on coagulation (lower risk of venous thrombosis), and the ability to continue epidural analgesia into the postoperative period.⁸¹ Disadvantages of spinal, epidural, or peripheral nerve block include the additional time and manipulations required to perform it, possible complications or pain from invasive catheter placements or injections, slow onset of effect, possible failure of technique, and toxicity from absorption of the drugs administered. Local infiltration anesthesia can be used to provide localized anesthesia to allow a minor procedure (e.g., a deep laceration repair) to be performed.

Uses of Local Anesthetic Agents

Local anesthetics are a mainstay of analgesia because they prevent the initiation or propagation of the electrical impulses required for peripheral and spinal nerve conduction. These agents can be administered by all routes previously discussed, depending on the drug chosen. Table 9-11 lists the common uses of currently available local anesthetics.^{82,83} Local anesthetics are often given in combination with other agents, such as sodium bicarbonate (to increase the speed of onset and reduce pain on local infiltration), epinephrine (to prolong the duration of action and to delay vascular absorption of the local anesthetic, thereby minimizing plasma concentration and systemic toxicity), or opioids (to provide analgesia by a different mechanism of action).

Mechanism of Action

The two structural classes of local anesthetics are characterized by the linkage between the molecule's lipophilic aromatic group and hydrophilic amine group: amides and esters. Both amide and ester classes provide anesthesia and analgesia by reversibly binding to and blocking the sodium channels in nerve membranes, thereby decreasing the rate of rise of the action potential such that threshold potential is not reached. As a result, propagation of the electrical impulses required for nerve conduction is prevented. The axonal membrane blockade that results is selective depending on the drug, the concentration and volume administered, and the depth of nerve penetration.

Table 9-11 Clinical Uses of Local Anesthetic Agents

| <i>Agent</i> | <i>Primary Clinical Use</i> |
|-------------------------------------|--|
| Esters | |
| Chloroprocaine (Nesacaine) | Epidural |
| Cocaine | Topical |
| Procaine (Novocain) | Local infiltration, spinal |
| Tetracaine (Pontocaine) | Topical, spinal |
| Amides | |
| Bupivacaine (Marcaine, Sensorcaine) | Local infiltration, nerve block, epidural, spinal |
| Etidocaine (Duranest) | Local infiltration, nerve block, epidural |
| Levobupivacaine (Chirocaine) | Local infiltration, nerve block, epidural |
| Lidocaine (Xylocaine) | Local infiltration, nerve block, spinal, epidural, topical, intravenous regional |
| Mepivacaine (Carbocaine, Polocaine) | Local infiltration, nerve block, epidural |
| Ropivacaine (Naropin) | Local infiltration, nerve block, epidural |

Adapted from references 82 and 83.

C fibers (pain transmission and autonomic activity) appear to be the most easily blocked, followed by fibers responsible for touch and pressure sensation (A- α , A- β , and A- Δ), and finally, those responsible for motor function (A- α and A- β). At the most commonly used doses and concentrations, some non-pain-transmitting nerve fibers are also blocked. The blockade of sensory, motor, or autonomic (sympathetic, parasympathetic) fibers may result in adverse effects such as paresthesia, numbness and inability to move extremities, hypotension, and urinary retention. Systemic effects (e.g., seizures or cardiac arrhythmias) are related to the inherent cardiac and CNS safety margins of these drugs.^{82,83}

Ropivacaine, like bupivacaine, has a long duration of action. Higher plasma concentrations of ropivacaine are required to produce mild CNS toxicity (lightheadedness, tinnitus, numbness of the tongue) in volunteers, when compared with bupivacaine. In animal studies, ropivacaine was found to be less cardiotoxic than bupivacaine. In addition, ropivacaine may produce less motor blockade than bupivacaine.⁸⁴ As a result, some anesthesia providers believe ropivacaine is safer than bupivacaine. However, inadvertent intravascular administration of ropivacaine can produce significant CNS toxicity (seizures), emphasizing the importance of ensuring appropriate placement of the local anesthetic solution by the anesthesia provider.

Allergic Reaction

Most adverse effects to local anesthetics are manifestations of excessive plasma concentration (systemic toxicity) of the local anesthetic. Localized hypersensitivity reactions (e.g., local erythema, edema, dermatitis) to local anesthetics are rare. Ester-type local anesthetic agents (benzocaine, procaine, tetracaine) produce most of the allergic reactions, which is probably caused by their metabolite, para-aminobenzoic acid (PABA). True (systemic) allergy to amide-type local anesthetics is extremely rare and may be due to the preservative (methylparaben or other substances that are structurally similar to PABA) or to accidental intravascular injection of an epinephrine-containing local anesthetic. Because amide-type local anesthetics do not undergo metabolism to a PABA metabolite, a patient with a known allergy to an ester-type local anesthetic can safely receive an amide-type agent.^{82,83,85} It is best to administer a preservative-free, epinephrine-free preparation to a patient with a known allergy to a local anesthetic.

Toxicity

Factors that influence the toxicity of local anesthetics include the total amount of drug administered, presence or absence of epinephrine, vascularity of the injection site, type of local anesthetic used, rate of destruction of the drug, age and physical status of the patient, and interactions with other drugs. Systemic absorption of the local anesthetic is positively correlated with the vascularity of the injection site (IV > epidural > brachial plexus > subcutaneous). End-stage pregnancy, older age (e.g., the elderly), significant hepatic/renal dysfunction, and advanced heart failure can result in either higher peak levels or accumulation of local anesthetic with continued or repeat dosing. In general, local anesthetic doses should be reduced in patients with these conditions.⁸⁶

Toxic levels of local anesthetics are most often achieved by unintentional intravascular injection, which result in excessive plasma concentrations. Systemic toxicity of local anesthetics involves the CNS and cardiovascular system. Patients may initially complain of tinnitus, lightheadedness, metallic taste in their mouth, tingling, numbness, and dizziness. Hypotension may occur. These symptoms can quickly be followed by tremors, seizures, arrhythmias, unconsciousness, and cardiac/respiratory arrest as plasma levels rise.^{82,87}

Physicochemical Properties Affecting Action

The potency of a local anesthetic is primarily determined by the degree of lipid solubility. Local anesthetics such as bupivacaine are highly lipid soluble and can be given in concentrations of 0.25% to 0.5%. Less lipid-soluble agents, such as lidocaine, require concentrations of 1% to 2% for many anesthetic techniques.

Amide-type local anesthetics are metabolized primarily by microsomal enzymes in the liver. The cytochrome P450 enzyme system is involved in the metabolism of lidocaine (CYP3A4), levobupivacaine (CYP3A4, CYP1A2), and ropivacaine (CYP3A2, CYP3A4, and CYP1A2). Agents that induce or inhibit these enzymes could affect the metabolism, and therefore the plasma concentration, of these drugs. Ester-type local anesthetics are hydrolyzed by plasma cholinesterase and, to a lesser extent, cholinesterase in the liver.^{82,83}

Differences in the clinical activity of local anesthetics are explained by other physicochemical properties such as protein binding and pK_a (the pH at which 50% of the drug is present in the unionized form and 50% in the ionized form). Agents that are highly protein bound typically have a longer duration of action. Agents with a lower pK_a typically have a faster onset of action.⁸³

Choice of local anesthetic is based on the duration of the surgical procedure (e.g., the duration of analgesia required). Usually, a local anesthetic that will, at least minimally, outlast the duration of surgery with a single injection is chosen; a continuous infusion can also be administered for titration of effect with shorter-acting agents. Important physicochemical and pharmacokinetic properties of local anesthetics are shown in Table 9-12.^{82,83}

Regional Anesthesia in High-Risk Patients

13. M.S., a 52-year-old, 5'9", 105-kg black man, is undergoing an emergent minor hand repair procedure after a fall-related injury. His medical history is positive for type 1 diabetes mellitus for 41 years, angina, and hypertension. On OR admission, laboratory values of note are plasma glucose, 240 mg/dL, and BP, 145/92 mmHg. His sister tells the anesthesia provider that he has been having increasing difficulty walking up stairs and, of late, is often short of breath. The anesthesia provider chooses to provide regional anesthesia via an axillary block; the anticipated duration of surgery is 2 hours. M.S. agrees with this plan. Why is this a good plan for M.S., and which local anesthetic should be chosen?

[SI unit: glucose, 13.3 mmol/L]

With his medical conditions of diabetes, angina, and hypertension, M.S. is at risk for complications from general

Table 9-12 Physicochemical and Pharmacokinetic Properties of Local Anesthetic Agents

| Agent | pK_a | Potency | Toxicity | Onset | Duration ^a | Maximum Recommended Dose ^b | |
|-------------------------------------|--------|----------|----------|-----------|-----------------------|---------------------------------------|-----------------------|
| | | | | | | Plain (mg) | With Epinephrine (mg) |
| Esters | | | | | | | |
| Cocaine ^c | – | – | – | – | – | 1.5 mg/kg | – |
| Chloroprocaine (Nesacaine) | 9.1 | Low | Very low | Very fast | Short | 800 | 1,000 |
| Procaine (Novocain) | 8.9 | Low | Low | Fast | Short | 400 | 600 |
| Tetracaine (Pontocaine) | 8.4 | High | Moderate | Slow | Very long | 100 (topical) | 200 |
| Amides | | | | | | | |
| Bupivacaine (Marcaine, Sensorcaine) | 8.1 | High | High | Slow | Long | 175 | 225 |
| Etidocaine (Duranest) | 7.9 | High | Moderate | Fast | Very long | 300 | 400 |
| Levobupivacaine (Chirocaine) | 8.1 | High | Moderate | Slow | Long | 150 | – |
| Lidocaine (Xylocaine) | 7.8 | Moderate | Moderate | Fast | Moderate | 300 | 500 |
| Mepivacaine (Carbocaine, Polocaine) | 7.7 | Moderate | Moderate | Moderate | Moderate | 300 | 500 |
| Ropivacaine (Naropin) | 8.1 | High | Moderate | Slow | Long | 300 | – |

^aDepends on factors such as injection site, dose, and addition of epinephrine. In general, a short duration is <1 hour, a moderate duration is 1–3 hours, and a long/very long duration of action is 3–12 hours when the local anesthetic is administered without epinephrine.

^bMaximum recommended single dose for infiltration or peripheral nerve block in 70-kg adults.

^cTopical use only; concentrations >4% are not recommended due to increased risk for systemic adverse effects.

Adapted from references 82 and 83.

anesthesia. General anesthesia is not absolutely necessary in this localized surgery. Regional anesthesia would be beneficial in M.S. because it does not disrupt autonomic function. In addition, his diabetes and obesity, and possibly full stomach (emergency surgery, diabetic gastroparesis), place him at significant risk for aspiration during induction or emergence from general anesthesia. An axillary block with a local anesthetic could provide M.S. with adequate anesthesia and analgesia during and after his procedure.

The local anesthetic of choice is one with a duration at least that of the anticipated surgery and with a good safety profile should systemic absorption inadvertently occur. A local anesthetic containing epinephrine would increase the agent's duration of action and reduce the systemic absorption; however, such an agent is not indicated in M.S. because of his diabetes (peripheral vascular effects) and hypertension (added effect from catecholamine administration). Lidocaine as a single injection without epinephrine has a duration of action that may be too short for M.S.'s procedure. Mepivacaine, an intermediate-acting local anesthetic, or bupivacaine, a long-acting agent, would be appropriate choices to use in M.S.

Alkalinization of Local Anesthetics

15. T.F., a 22-year-old man, is scheduled for a hernia repair. He has never undergone surgery and is very anxious. In the preoperative area, the nurse chooses to locally infiltrate 1% lidocaine to reduce the pain and discomfort from IV catheter placement. She injects a small amount of lidocaine under the skin. T.F. flinches and complains of pain from the injection. Can anything be done to speed the onset and reduce the pain from injection of lidocaine?

The onset of action of local anesthetics depends on their pK_a . Drugs with pK_a s closest to body pH (7.4) will have the fastest onset because a high percentage of the local anesthetic molecules will be unionized and therefore able to cross the

nerve membranes to their intracellular site of action. Local anesthetics are formulated in solutions with acidic pHs to optimize their shelf-lives. When sodium bicarbonate is added to local anesthetic solutions, the pH is increased, the percentage of unionized drug is increased, and the onset of local anesthetic action can be shortened considerably. The amount of bicarbonate added to the solution depends on the pH of the local anesthetic agent. Because too much sodium bicarbonate will precipitate the local anesthetic, a dose of 0.1 mEq (0.1 mL of a 1 mEq/mL concentration) of sodium bicarbonate is added to 10 mL of bupivacaine, whereas 1 mEq (1 mL of a 1 mEq/mL concentration) is added to 10 mL of lidocaine. Furthermore, alkalized lidocaine can be significantly less painful for subcutaneous injection before IV catheter placement when compared with lidocaine at pH 5 (its pH in the commercially available vial).⁸⁸

CARDIOPLEGIA SOLUTION

Use in Cardiac Surgery

Hypothermic, hyperkalemic cardioplegia solution was first used in open heart surgery in the 1970s and enjoys widespread clinical use today. Cardioplegia solution is infused into the coronary vasculature to produce an elective diastolic cardiac arrest. Inducing cardiac arrest, or cardioplegia, helps protect the myocardium while providing the surgeon with a still, bloodless operative field and a flaccid heart on which to work. Cardioplegia solution is administered via the cardiopulmonary bypass pump (a heart-lung machine) through specialized circuits.

During open heart surgery, the heart is excluded from normal circulation by diverting venous blood away from the right atrium via gravity drainage and by clamping the aorta. Systemic circulation of blood is maintained through the use of the cardiopulmonary bypass pump; a cannula is placed in the aorta distal to the clamp and carries oxygenated blood from

the pump to the patient. The blood circulates through the body and is returned to the cardiopulmonary bypass pump through cannulas inserted into the superior and inferior venae cava.

Delivery Methods

Cardioplegia solution is delivered to the coronary circulation by three approaches: antegrade, retrograde, or combination antegrade/retrograde. With antegrade administration, the solution is administered via a cannula placed in the aortic root, whereas with retrograde administration, the cannula is placed in the coronary sinus.⁸⁹ The commonly used combination approach eliminates problems such as the nonhomogeneous distribution of cardioplegia solution, which can occur with the antegrade approach, while still ensuring a rapid arrest (arrest produced by retrograde administration is not as fast as antegrade).^{90,91} This approach has significantly reduced patient morbidity when compared with antegrade administration, especially in high-risk patients requiring reoperation.⁹⁰

Phases of Cardioplegia

Cardioplegia can be divided into three phases: induction of arrest, maintenance of arrest, and reperfusion (immediately before aortic unclamping). Cardioplegia solution is used routinely during the induction and maintenance phases, and reperfusion solution is used at the end of surgery before aortic unclamping. The solutions used in each phase may differ in composition and characteristics.

Goal of Treatment

Cardioplegia solution is used to prevent myocardial ischemic damage that can occur during the induction and maintenance of arrest, whereas reperfusion solution is used to help prevent and minimize the destructive phenomena that can occur during reperfusion. Myocardial ischemia can result in a number of

detrimental changes to the heart, including rapid cellular conversion from aerobic to anaerobic metabolism, high-energy phosphate (e.g., adenosine triphosphate [ATP]) depletion, intracellular acidosis, calcium influx, and myocardial cell membrane disruption. Destructive changes that can occur during reperfusion include intracellular calcium accumulation, explosive cell swelling, and inability to use delivered oxygen.⁹² Chemical components are added to cardioplegia solution to counteract the specific cellular effects of ischemia and the cellular events that can occur during reperfusion.

Cardioplegia Solution Vehicles

The chemical composition of a cardioplegia solution depends on the vehicle used: blood or crystalloid. Each has advantages and disadvantages, as can be seen in Table 9-13.^{89,90,93} Blood, because of its many advantages, is the vehicle most commonly used. Blood cardioplegia provides oxygen while the heart is arrested, proteins in blood maintain osmotic pressures closer to normal and are capable of serving as buffers, and endogenous oxygen-free radical scavengers are beneficial during reperfusion.⁹³ The disadvantages listed for blood have not been shown to occur during clinical use of blood-based cardioplegia solution. The patient's own hemodiluted blood from the extracorporeal circuit is used. Blood-based cardioplegia solution delivery systems include commercially available microprocessor-controlled pumps that are capable of directly injecting an additive into the blood as well as more conventional systems that deliver a fixed ratio of blood with a premixed crystalloid cardioplegia solution. Ratios of blood to crystalloid composition range from 1:1 to 16:1. The concentration of additives in the crystalloid solution must be tailored to the specific delivery ratio used to prevent accidental overdose or underdose. A commonly used ratio in clinical practice today is 4:1; in other words, the blood-based cardioplegia solution being delivered to the patient contains four parts blood to one part crystalloid solution. Therefore, the concentration

Table 9-13 Advantages and Disadvantages of Cardioplegia Solution Vehicles

| <i>Vehicle</i> | <i>Advantages</i> | <i>Disadvantages</i> |
|----------------|---|---|
| Blood | <ul style="list-style-type: none"> Oxygen-carrying capacity Active resuscitation Reduction in systemic hemodilution Minimize reperfusion damage Provision of inherent buffering, oncotic, and rheologic effects Provision of physiological calcium concentration Presence of endogenous oxygen-free radical scavengers | <ul style="list-style-type: none"> Possible sludging at low temperatures Possible unfavorable shift in oxyhemoglobin association curve Potential for poor distribution of solution beyond coronary stenoses Possible red blood cell crenation Impaired visualization |
| Crystalloid | <ul style="list-style-type: none"> History of effectiveness Ease of solution preparation Low cost Minimal potential for capillary obstruction | <ul style="list-style-type: none"> Minimal oxygen-carrying capacity Possible damage of coronary endothelium Reduced efficacy (compared with blood) in preserving left ventricular function postoperatively Systemic hemodilution Possible role in production of late myocardial fibrosis |

Adapted from references 89, 90, and 93.

of additives contained in the crystalloid solution is five times greater than that actually delivered to the patient due to the dilution of this solution with blood before it reaches the patient. Furthermore, with blood-based cardioplegia solution, there is a reduced need to place additives in the crystalloid component of the solution. For example, calcium and magnesium need not be added to the crystalloid component because sufficient quantities are contained in blood.

Common Characteristics

Most cardioplegia solutions have certain basic characteristics in common. Crystalloid cardioplegia solutions are made hyperosmolar to help minimize myocardial edema associated with cardiac arrest and are usually made slightly basic to compensate for the metabolic acidosis that accompanies myocardial ischemia. Cardioplegia solutions are traditionally chilled to a temperature of 4°C to 8°C before being infused into the coronary circulation. Hypothermia decelerates the metabolic activity of the heart, reduces myocardial oxygen demand and the detrimental effects seen with myocardial ischemia, and helps maintain cardiac arrest.^{94,95} However, hypothermia can also produce deleterious effects on the heart, including impaired mitochondrial energy generation and substrate utilization, membrane destabilization, and the need for a longer period of reperfusion to rewarm the heart, which can increase the chances of reperfusion injury. In an effort to minimize the adverse consequences of hypothermia, the use of normothermic cardioplegia solution for induction of arrest (with cardioplegia maintained with a hypothermic solution) and the administration of a normothermic reperfusion solution before aortic cross-clamp removal was demonstrated to improve myocardial metabolic and functional recovery in energy-depleted hearts.⁹³ The benefits seen with this technique prompted investigators to study the use of intermittent, normothermic (37°C) cardioplegia. Positive results were reported with this technique and included a decreased incidence of perioperative myocardial infarction (MI) and need for intra-aortic balloon pump (IABP) support, as well as a lower incidence of postoperative low cardiac output syndrome.^{96,97} However, studies examining the use of normothermic cardioplegia solution have not consistently demonstrated a decrease in mortality or perioperative MI when compared with hypothermic cardioplegia solution. With normothermic cardioplegia, a major concern is that not as much protection from ischemia is provided during the time that cardioplegia solution is not being infused as that provided with the use of hypothermic solution. Furthermore, when compared with hypothermic cardioplegia solution, warm cardioplegia is associated with a greater use of crystalloid and α -agonists to maintain perfusion pressure, higher total volumes of cardioplegia, increased use of high-potassium cardioplegia to stop periodic episodes of electrical activity, a higher incidence of systemic hyperkalemia, and lower systemic vascular resistance.⁹⁸ In an attempt to reduce problems seen with normothermic cardioplegia, the use of tepid (29°C) cardioplegia solution has been advocated. When compared with hypothermic techniques, tepid cardioplegia resulted in greater left and right ventricular stroke work indices (slightly less than normothermic cardioplegia) and a much faster recovery of myocardial function.^{99,100} Currently, a combination normothermic/hypothermic technique is still used

more frequently in practice. Additional work is needed in this area.

Additives

Table 9-14 presents additives commonly used in cardioplegia and/or reperfusion solutions, the reason for their addition, and frequently used concentrations.^{89,90} In addition to these additives, several other classes of agents continue to be examined for their usefulness in cardioplegia and/or reperfusion solutions.

Oxygen-free Radical Scavengers

Oxygen-free radicals (e.g., superoxide anion, hydrogen peroxide, free hydroxyl radical) are released during the sudden reintroduction of oxygen to ischemic tissue during reperfusion. They have been implicated in myocyte death, reperfusion-induced arrhythmias, and prolonged left ventricular dysfunction after reperfusion.⁹² The addition to reperfusion solution of drugs that inhibit oxygen-free radical production or degrade free radicals (e.g., mannitol, deferoxamine, allopurinol) has been demonstrated to reduce post-reperfusion myocardial injury and other free radical-induced surgical complications.¹⁰¹⁻¹⁰³ An advantage of using blood-based cardioplegia solution is that blood contains endogenous oxygen-free radical scavengers (e.g., catalase, superoxide dismutase, glutathione).¹⁰⁴

Adenosine

Adenosine is an endogenous nucleoside that is released from the ischemic myocardium during the catabolism of ATP. It protects the heart from ischemic and reperfusion injury and may have a role in ischemic preconditioning. Adenosine produces the majority of its effects through interaction at the adenosine A1, A2, and A3 receptors. Stimulation of A1 receptors causes activation of the ATP-sensitive potassium channel (K-ATP), ultimately resulting in positive chronotropic and dromotropic effects, antiadrenergic effects, stimulation of glycogenolysis, and stimulation of neutrophil adherence. Stimulation of A2 receptors results in vasodilation, renin release, inhibition of neutrophil adherence to endothelium, and inhibition of superoxide generation. The physiological effects of stimulation of A3 receptors include inhibition of neutrophil adherence to endothelium.¹⁰⁵ The cardioprotective effects during preconditioning are believed to be the result of K-ATP channel activation. Preliminary results of a phase II trial found that adenosine may improve postoperative hemodynamic function and possibly reduce morbidity and mortality when patients receive IV adenosine immediately before and after aortic cross-clamping in addition to cold blood cardioplegia containing 2 mM adenosine.¹⁰⁶ However, further multicenter studies are needed to identify patients who will benefit the most from adenosine and whether adenosine will definitively reduce the incidence of MI or death following open heart surgery.

L-Arginine

Ischemia results in decreased formation of nitric oxide; nitric oxide helps prevent neutrophils from adhering to the vascular endothelial cells. Neutrophil adhesion to the coronary endothelium is a prerequisite for neutrophil activation and accumulation in the myocardium. Activated neutrophils may be a

Table 9-14 Commonly Used Cardioplegia Solution Additives

| Additive | Frequently Used Concentration ^a | Function |
|---|--|---|
| Amino acid substrates (glutamate/aspartate ^b) | 11–12 mL/L ^c | Improves myocardial metabolism; improves metabolic and functional recovery in energy-depleted hearts |
| Calcium | At least trace amounts (0.1 mEq/L) | Maintains integrity of myocardial cell membrane; prevents “calcium paradox” ^d |
| Chloride | 90–110 mEq/L | Establishes a solution similar in composition to extracellular fluid |
| CPD solution | 12 mL/L ^e 45 mL/L ^c | Chelates calcium in blood-based cardioplegia solution to produce safe levels of hypocalcemia for rapid diastolic arrest; limits postischemic calcium accumulation and improves postischemic performance |
| Glucose | 5–10 g/L safely used | Helps achieve desired osmolarity of solution; serves as a metabolic substrate for the heart |
| Magnesium | 32 mEq/L | Reduces magnesium loss during ischemia; reduces calcium influx and potassium efflux during ischemia; has a weak arresting action on heart |
| Potassium | 15–30 mEq/L ^f | Induces rapid diastolic arrest |
| Sodium | 120–140 mEq/L | Necessary for protective action of potassium; establishes a solution similar in composition to extracellular fluid |
| Sodium bicarbonate or THAM | Variable; added until desired pH is obtained | Provides buffering capacity; helps maintain physiologically normal pH range; counters acidosis produced by ischemia |

^aConcentration delivered to patient; concentration dependent on other cardioplegia solution additives (concentration of any one additive may be changed by inclusion of other additives).

^bNot commercially available in parenteral formulation; each milliliter of solution contains 178.4 mg monosodium L-glutamate and 163.4 mg monosodium L-aspartate (for preparation directions, see reference 89).

^cWarm, blood-based induction and reperfusion solutions.

^dCalcium paradox is a condition that results in rapid consumption of high-energy phosphates, extensive ultrastructural damage of myocardial cells, and myocardial contracture; it results from an influx of calcium into the myocardial cells, resulting from the introduction of a calcium-containing perfusate (i.e., blood) into the system during reperfusion after the use of a cardioplegia solution completely lacking in calcium.

^eCold, blood-based induction and maintenance solutions.

^fLower concentrations (5–10 mEq/L) used during maintenance phase.

CPD, citrate-phosphate-dextrose; THAM, trishydroxymethylaminomethane.

Adapted from references 89 and 90.

major source of oxygen-free radical production. They enhance degranulation and the release of proteases, which cause cellular damage, and they adhere to microvascular endothelium or embolize in the microcirculation. Nitric oxide-dependent vasodilation and inhibition of neutrophil activity are believed to play important roles in preventing reperfusion damage after ischemia.

L-arginine is a nitric oxide donor and may have a role as a supplement to cardioplegia and/or reperfusion solutions. Animal studies have demonstrated benefits (reduction in oxygen-free radical formation, restoration of endothelial function) from the addition of L-arginine to cardioplegia solutions.^{107–109} Limited trials in patients undergoing coronary artery bypass grafting have demonstrated that the addition of L-arginine (7.5 g/500 mL) to blood cardioplegia reduced the release of cardiac troponin T, a marker of myocardial ischemia.¹¹⁰

Potassium

16. W.D., a 64-year-old man, ASA-III, is scheduled to undergo a coronary artery bypass graft. W.D.’s serum potassium concentration is 4 mEq/L. A blood-based cardioplegia solution is ordered for the patient with the concentration of potassium in the crystalloid component to be 76 mEq/1,000 mL. Cold induction (e.g., chilled cardioplegia solution) using a delivery system of four parts blood to one part cardioplegia solution will be used. On administration of the solution to W.D., cardiac arrest was not achieved. A STAT chemical analysis of the crystalloid solution revealed that it

contained no potassium. Why is this consistent with the findings in W.D.?

Failure to see immediate arrest within 1 to 2 minutes after the administration of cardioplegia solution can be due to several factors, including incomplete aortic clamping, aortic insufficiency, and failure to have a potassium concentration sufficient to produce arrest. Because W.D.’s cardioplegia solution contained no potassium, a direct cause-and-effect relationship can be made to the inability to achieve an arrest.

The major role of potassium in cardioplegia solution is to induce a rapid diastolic arrest by blocking the inward sodium current and initial phases of cellular depolarization. This results in cessation of electromechanical activity and helps preserve ATP and creatine phosphate stores for postischemic work. A delivered potassium concentration in the range of 15 to 20 mEq/L is used most commonly. This concentration has consistently produced asystole while minimizing adverse effects (e.g., tissue damage, systemic hyperkalemia). Potassium concentrations >40 mEq/L alter myocardial cell membranes, allow extracellular calcium to enter the cell, and raise energy demands.¹¹¹ In laboratory studies, high concentrations of potassium (>100 mEq/L) increase myocardial contracture and wall tension, a condition referred to as *stone heart syndrome*.¹¹² Varying concentrations of potassium are used in the cardioplegia solution, depending on the phase of cardioplegia. As previously discussed, a high concentration of potassium is required to induce arrest, whereas lower concentrations (e.g., 5–10 mEq/L) are sufficient to maintain arrest.¹¹³ On first glance, the

concentration of potassium ordered in W.D.'s blood-based cardioplegia solution appears excessive. However, the concentration delivered to the coronary circulation is slightly <20 mEq/L if one considers that the potassium contribution from the blood component of this blood-based cardioplegia solution is approximately 4 mEq/L and that from the crystalloid component is approximately 15 mEq/L ($76 \text{ mEq/L} \div 5$). This highlights the importance of knowing the delivery ratio being used for the administration of blood-based cardioplegia solution.

Amino Acids: Normothermic, Blood-Based Cardioplegia Solution

17. T.E., a 55-year-old man, ASA-IV, is admitted to the hospital with an MI. He is currently in the coronary care unit and is scheduled for myocardial revascularization surgery. He has poor left ventricular function (cardiac output, 2.2 L/minute [normal, 4–6 L/minute]; pulmonary capillary wedge pressure, 25 mmHg [normal, 5–12 mmHg]; left ventricular ejection fraction, 25% [normal, $>60\%$]), and is on an IABP for circulatory support. In addition to being on the IABP, he is receiving dopamine and milrinone. A diagnosis of cardiogenic shock is made. What type of cardioplegia solution should T.E. receive during his revascularization surgery?

Normothermic (37°C), blood-based cardioplegia and reperfusion solutions containing the amino acids glutamate and aspartate have been advocated for the induction and reperfusion phases of cardioplegia in patients with ischemic hearts (e.g., extending MI, cardiogenic shock, hemodynamic instability) or those with advanced left or right ventricular hypertrophy or dysfunction.^{114–116} Glutamate and aspartate, Krebs' cycle precursors, are added to cardioplegia solution to counteract the depletion of Krebs' cycle intermediates during myocardial ischemia and to enhance energy production during reperfusion.^{114,116,117} These agents enhance oxidative metabolism optimally at normothermia (37°C).¹¹⁷

With this technique, cardioplegia induction is accomplished with an infusion of the normothermic, blood-based cardioplegia solution over 5 minutes. Normothermia optimizes the rate of cellular repair, whereas glutamate and aspartate improve oxygen utilization capacity.¹⁰³ The normothermic solution is immediately followed by a 5-minute infusion of hypothermic, blood-based cardioplegia solution. Cardioplegia is maintained with hypothermic, blood-based solution. Normothermic reperfusion solution is administered for 3 to 5 minutes immediately before aortic unclamping (reperfusion). The administration of normothermic solution at the conclusion of surgery is referred to by some as a *hot shot*. It is believed to result in early resumption of temperature-dependent mitochondrial enzymatic function and to allow energy supplies to be channeled into cellular recovery rather than electromechanical work. This results in improved hemodynamic and myocardial metabolic recovery.^{117,118}

T.E., with his poor myocardial function, is a suitable candidate to receive amino acid-enriched, normothermic, blood-based cardioplegia solution and reperfusion solution during the induction and reperfusion phases of cardioplegia, respectively.

ANTIEMETIC AGENTS AND POSTOPERATIVE NAUSEA AND VOMITING

Impact of Postoperative Nausea and Vomiting

PONV is a relatively common (overall incidence, 25%–30%) yet highly undesirable anesthetic and surgical outcome. Patients who develop PONV are greatly dissatisfied with their surgical experience and require additional resources such as nursing time and medical/surgical supplies. PONV typically lasts <24 hours; however, symptom distress can continue at home, thereby preventing the patient from resuming normal activities or returning to work.¹¹⁹ It is important to remember that nausea is a separate subjective sensation and is not always followed by vomiting. Nausea can be as or more distressing to patients as vomiting.

Mechanisms of and Factors Affecting Postoperative Nausea and Vomiting

The vomiting center is reflex activated through the chemoreceptor trigger zone (CTZ). Input from other sources can also stimulate the vomiting center. Afferent impulses from the periphery (e.g., manipulation of the oropharynx or GI tract), the cerebral cortex (e.g., unpleasant tastes, sights, smells, emotions, hypotension, pain), and the endocrine environment (e.g., female gender) can also stimulate the vomiting center. In addition, disturbances in vestibular function (e.g., movement after surgery, middle ear surgery) can stimulate the vomiting center via direct central pathways and the CTZ. Neurotransmitter receptors that play an important role in impulse transmission to the vomiting center include dopamine type 2 (D_2), serotonin ($5HT_3$), muscarinic cholinergic (M_1), histamine type 1 (H_1), and neurokinin type 1 (NK_1) (Fig. 9-1).^{119–125} The vestibular apparatus is rich in M_1 and H_1 receptors. Opioid analgesics can activate the CTZ, as well as the vestibular apparatus, to produce nausea and vomiting.^{119–122}

PONV is probably not caused by a single event, entity, or mechanism; instead, the cause is likely to be multifactorial. Factors that place a patient at risk for developing PONV in adults include female gender, history of PONV and/or motion sickness, nonsmoking status, use of opioids, type of surgery, duration of surgery, and general anesthesia with inhalation anesthetic agents and/or nitrous oxide.¹²⁶ For children, risk factors for postoperative vomiting include duration of surgery ≥ 30 minutes, age ≥ 3 years, strabismus surgery, and a history of postoperative vomiting in the child or PONV in the mother, father, or siblings.¹²⁵ Unlike adults, nausea is not easily measured in children and hence not routinely assessed.

18. J.E., a 34-year-old, 55-kg woman, is scheduled to undergo a gynecologic laparoscopy under general anesthesia on an outpatient basis. She has had one previous surgery, has no known medication allergies, and is a nonsmoker. On questioning, she reports that she developed PONV following her first surgery. Her physical examination is unremarkable. Is J.E. a candidate for prophylactic antiemetic therapy?

J.E. has several risk factors that make her susceptible to developing PONV. Adult women are two to three times more likely than adult men to develop PONV. Previous PONV also

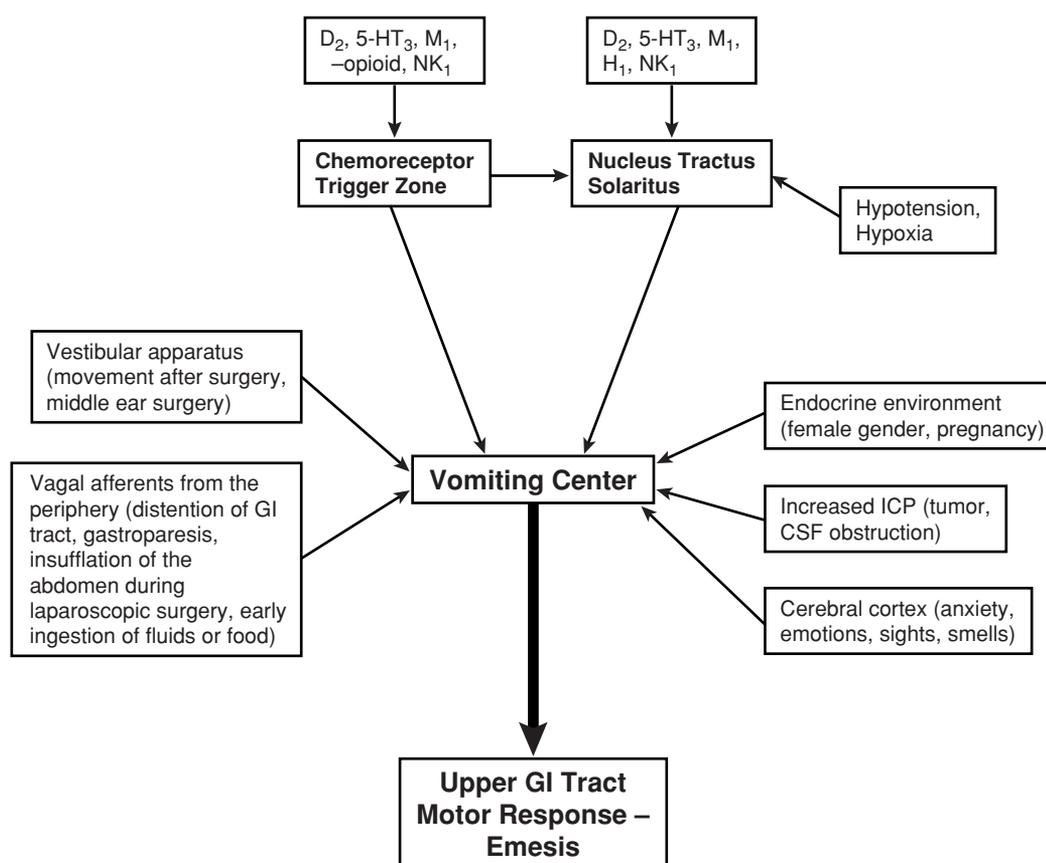

FIGURE 9-1 Mechanisms and neurotransmitters of postoperative nausea and vomiting. The chemoreceptor trigger zone (CTZ) is located in the area postrema of the midbrain. The vomiting center is also located in the midbrain, close to the nucleus tractus solaritus (NTS) and the area postrema. The CTZ, NTS, and area postrema are rich in 5-HT₃, H₁, M₁, D₂, and μ -opioid receptors. Antiemetic agents used to manage postoperative nausea and vomiting block one or more of these receptors. D₂, dopamine type 2 receptor; 5-HT₃, serotonin type 3 receptor; M₁, muscarinic cholinergic type 1 receptor; NK₁, neurokinin type 1 receptor; H₁, histamine type 1 receptor; GI, gastrointestinal; ICP, intracranial pressure; CSF, cerebral spinal fluid. Source: Adapted from references 119–125.

increases the likelihood of developing PONV threefold. In addition, a nonsmoking status increases the risk of developing PONV. The type of procedure J.E. is undergoing (gynecologic laparoscopy) places her at a higher risk for developing PONV. Finally, J.E. is scheduled for general anesthesia, which is also associated with a greater risk of PONV when compared with regional anesthesia. Because of the presence of many risk factors, J.E. is at high risk and should be administered at least two prophylactic antiemetic agents. Patients undergoing surgery view PONV as a highly undesirable consequence, thereby reducing their overall level of satisfaction.

Prevention of Postoperative Nausea and Vomiting: Choice of Agent

19. Which antiemetic drugs would be most appropriate for J.E., and when should they be administered?

Antiemetic drugs can be classified as antimuscarinics (scopolamine, promethazine, diphenhydramine), serotonin antagonists (ondansetron, dolasetron, granisetron), benzamides

(metoclopramide), butyrophenones (droperidol), phenothiazines (prochlorperazine), and the NK₁ antagonist, aprepitant. These drugs exert their antiemetic effects primarily by blocking one central neurotransmitter receptor. Dopamine antagonists include the benzamides, butyrophenones, and phenothiazines. Ondansetron, granisetron, and dolasetron block 5HT₃ receptors of vagal afferent nerves in the GI tract and in the CTZ. Antimuscarinics likely exert their antiemetic effect by blocking Ach in the vestibular apparatus, vomiting center, and CTZ. The proposed site of action, usual adult dose, and select adverse effects of the commonly used antiemetic drugs for prevention and treatment of PONV are summarized in Table 9-15.^{3, 119, 121, 125–127}

Butyrophenones

Droperidol possesses significant antiemetic activity, with IV doses of 0.625 to 1.25 mg effectively preventing PONV. Droperidol is more effective for nausea than vomiting, even at a dose as low as 0.3 mg. Droperidol has an onset of action of 3 to 10 minutes, with peak effects seen at 30 minutes. Doses of 0.625 or 1.25 mg often prevent PONV for up to 24 hours.

Table 9-15 Classification, Proposed Site(s) of Action, Usual Dose, and Adverse Effects of Select Antiemetic Drugs

| Antiemetic Drug | Proposed Receptor Site of Action | Usual Dose ^a | Duration of Action | Adverse Effects | Comments |
|-----------------------------------|--|--|------------------------------|--|--|
| Butyrophenones | | | | | |
| Droperidol (Inapsine) | D ₂ | <i>Adult:</i> 0.625–1.25 mg IV <i>Pediatric:</i> 20–50 μg/kg IV for prevention; 10–20 mcg/kg IV for treatment | ≤12–24 hr | Sedation, dizziness, anxiety, hypotension (especially in hypovolemic patients), EPS | Monitor ECG for QT prolongation/torsades de pointes |
| Phenothiazines | | | | | |
| Prochlorperazine (Compazine) | D ₂ | <i>Adult:</i> 5–10 mg IM or IV; 25 mg PR <i>Pediatric:</i> ^b 0.1–0.15 mg/kg IM, 0.1–0.13 mg/kg PO, 2.5 mg PR | 4–6 hr (12 hr when given PR) | Sedation, hypotension (especially in hypovolemic patients), EPS | |
| Antimuscarinics | | | | | |
| Promethazine (Phenergan) | D ₂ , H ₁ , M ₁ | <i>Adult:</i> 6.25–25 mg IM, IV, or PR ^c | 4–6 hr | Sedation, hypotension (especially in hypovolemic patients), EPS, serious tissue injury from inadvertent arterial injection or IV extravasation | Limit concentration to 25 mg/mL; dilute in 10–20 mL saline, inject through a running line, and advise patient to report IV site discomfort |
| Diphenhydramine (Benadryl) | H ₁ , M ₁ | <i>Adult:</i> 12.5–50 mg IM or IV <i>Pediatric:</i> 1 mg/kg IV, PO (max: 25 mg for children younger than 12 years) | 4–6 hr | Sedation, dry mouth, blurred vision, urinary retention | |
| Scopolamine (Transderm Scop) | M ₁ | <i>Adult:</i> 1.5 mg transdermal patch | 72 hr ^d | Sedation, dry mouth, visual disturbances, dysphoria, confusion, disorientation, hallucinations | Apply at least 4 hr before end of surgery; wash hands after handling patch; not appropriate for children, elderly, or patients with renal/hepatic impairment |
| Benzamides | | | | | |
| Metoclopramide (Reglan) | D ₂ | <i>Adult:</i> 10–20 mg IV <i>Pediatric:</i> 0.25 mg/kg IV | ≤6 hr | Sedation, hypotension, EPS | Consider for rescue if N/V is believed to be due to gastric stasis; reduce dose to 5 mg in renal impairment; give slow IV push |
| Serotonin Antagonists | | | | | |
| Ondansetron (Zofran) | 5-HT ₃ | <i>Adult:</i> 4 mg IV <i>Pediatric:</i> 0.05–0.1 mg/kg IV | Up to 24 hr | Headache, lightheadedness, QT prolongation | |
| Dolasetron (Anzemet) | 5-HT ₃ | <i>Adult:</i> 12.5 mg IV <i>Pediatric:</i> 0.35 mg/kg IV | Up to 24 hr | Headache, lightheadedness, QT prolongation | |
| Granisetron (Kytril) | 5-HT ₃ | <i>Adult:</i> 0.35 mg–1 mg IV <i>Pediatric:</i> Not known | Up to 24 hr | Headache, lightheadedness, QT prolongation | |
| Palonosetron (Aloxi) | | <i>Adult:</i> 0.075 mg IV | Up to 24 hr | Bradycardia, headache, QT prolongation | |
| NK₁ Antagonists | | | | | |
| Aprepitant (Emend) | NK ₁ | <i>Adult:</i> 40 mg PO up to 3 hr before surgery | Up to 24 hr | Headache | |

Table 9-15 Classification, Proposed Site(s) of Action, Usual Dose, and Adverse Effects of Select Antiemetic Drugs (Continued)

| Antiemetic Drug | Proposed Receptor Site of Action | Usual Dose ^a | Duration of Action | Adverse Effects | Comments |
|---|----------------------------------|---|--------------------|---|----------|
| Other Dexamethasone (Decadron) | None | Adult: 4–8 mg IV Pediatric: 0.15 mg/kg IV | Up to 24 hr | Genital itching, flushing, hyperglycemia | |

^aUnless otherwise indicated, pediatric doses should not exceed adult doses.
^bChildren >10 kg or older than 2 years only. Change from IM to PO as soon as possible. When administering PR, the dosing interval varies from 8 to 24 hours, depending on the child's weight.
^cMaximum of 12.5 mg in children younger than 12 years.
^dRemove after 24 hours. Instruct patient to thoroughly wash the patch site and their hands.
5-HT₃, serotonin type 3 receptor; D₂, dopamine type 2 receptor; ECG, electrocardiogram; EPS, extrapyramidal symptoms (e.g., motor restlessness or acute dystonia); H₁, histamine type 1 receptor; IV, intravenous; IM, intramuscular; M₁, muscarinic cholinergic type 1; N/A, not applicable; N/V, nausea and/or vomiting; PO, orally (by mouth); PR, per rectum.
Adapted from references 3, 119, 121, and 125–127.

The duration of action of a 0.3-mg dose, however, is short lived, with repeated doses often necessary. Droperidol is most effective when administered near the end of surgery. Adverse effects include sedation (especially at doses ≥ 2.5 mg), anxiety, hypotension, and, rarely, restlessness or other extrapyramidal (EP) reactions.¹²⁸ Because of its effectiveness and cost, droperidol has historically been used extensively as a first-line agent. However, in December 2001, the FDA strengthened warnings regarding adverse cardiac events following droperidol administration. With the new warning to perform continuous 12-lead electrocardiographic monitoring before and for 2 to 3 hours following administration of droperidol, it became an issue, from both expense and logistical viewpoints, to administer droperidol to an outpatient, patient in the PACU (recovery room), or patient in an unmonitored bed. Because low-dose droperidol has been used for >30 years to prevent PONV, many anesthesia providers challenged the decision of the FDA to issue this “black box” warning.¹²⁹ Nuttall et al.¹³⁰ retrospectively examined whether low-dose droperidol administration increased the incidence of torsades de pointes (TdP) in patients undergoing general surgery. Of the 16,791 patients exposed to droperidol, no patient experienced TdP. The authors concluded that the FDA’s black box warning for low-dose droperidol is excessive and unnecessary.

Benzamides

Metoclopramide, in doses of 10 to 20 mg, has been used in the prevention and treatment of PONV. However, variable results have been seen with this agent.¹³¹ For maximum benefit, metoclopramide must be administered near the end of surgery (secondary to its rapid redistribution after IV administration); 10 mg IV administered at the beginning of surgery is not effective. Adverse effects of metoclopramide include drowsiness and EP reactions, such as anxiety and restlessness. Metoclopramide should be administered by slow intravenous injection over at least 2 minutes to minimize the risk of EP reactions and cardiovascular effects such as hypotension, bradycardia, and supraventricular tachycardia.

Serotonin Antagonists

Ondansetron (4 mg IV) was the first 5HT₃ antagonist to receive an indication for PONV. Dolasetron (12.5 mg IV) and

granisetron (1 mg IV) are also approved for preventing and treating PONV. Palonosetron (0.075 mg IV) is approved for the prevention of PONV for up to 24 hours following surgery. As a general rule, serotonin antagonists are consistently more effective in reducing vomiting rather than nausea.¹³² Ondansetron and dolasetron are equally efficacious in preventing PONV.¹³³ A single dose of ondansetron, dolasetron, or granisetron provides acute relief and can protect against nausea and vomiting for up to 24 hours after administration. For optimal efficacy, serotonin antagonists should be administered near the end of surgery. Adverse effects are minimal and include headache, constipation, and elevated liver enzymes. Because of their good efficacy and adverse effect profile, serotonin antagonists are recommended as first-line therapy.¹²⁵

Dexamethasone

Dexamethasone is frequently used as an antiemetic in patients undergoing highly emetogenic chemotherapy. Its mechanism of action as an antiemetic is not well understood, particularly in the surgical setting. When compared to placebo, a prophylactic dose of dexamethasone is antiemetic in high-risk patients. It is most effective in preventing late PONV (up to 24 hours). Adverse effects in otherwise healthy patients are minimal and include headache, dizziness, drowsiness, constipation, and muscle pain.¹³⁴ Because of its good efficacy and adverse effect profile (from a single dose), dexamethasone is also recommended as first-line therapy.¹²⁵ Unlike droperidol and the serotonin antagonists, dexamethasone is most effective when administered at the beginning of surgery (immediately before induction).¹³⁵

Phenothiazines

Prochlorperazine has been used successfully to prevent PONV. Prochlorperazine (10 mg IM) was found to have superior efficacy (less nausea and vomiting, as well as less need for rescue antiemetics) when compared with ondansetron for preventing PONV.¹³⁶ Prochlorperazine may cause sedation, EP reactions, and cardiovascular effects. Because it has a short duration of action, multiple doses may be necessary.

Antimuscarinics

Scopolamine blocks afferent impulses at the vomiting center and blocks Ach in the vestibular apparatus and CTZ.

Transdermal scopolamine is useful for prevention of nausea, vomiting, and motion sickness. Compared with placebo, transdermal scopolamine effectively reduces the incidence of emetic symptoms.¹³⁷ Common side effects include dry mouth and visual disturbances. Patients can also have trouble correctly applying the patch. It is important to apply the patch before surgery because its onset of effect is 4 hours. Patients should also be instructed to wash their hands after applying the patch and to dispose of the patch properly.

Neurokinin-1 Antagonists

Aprepitant is the first NK₁ antagonist to be approved for prevention of PONV. Aprepitant has a long half-life and is administered orally prior to surgery. For prevention of PONV in patients undergoing abdominal surgery, aprepitant was similar in efficacy (defined as no vomiting and no use of rescue antiemetics in the first 24 hours following surgery) to ondansetron. Aprepitant, however, was significantly more effective than ondansetron in preventing vomiting at 24 and 48 hours after surgery. Aprepitant was well tolerated, with adverse effects similar to ondansetron.¹³⁸

Combination of Agents

As discussed, droperidol, serotonin antagonists, dexamethasone, and transdermal scopolamine effectively prevent PONV. However, these agents fail to prevent PONV in approximately 20% to 30% of patients. Most of the agents effectively block one receptor believed to be involved in the activation of the vomiting center. However, because the cause of PONV is likely multifactorial, a combination of antiemetic agents (from different classes) is more efficacious for preventing PONV in a high-risk patient. In a factorial trial of six interventions for prevention of PONV in more than 5,000 high-risk patients undergoing surgery, patients were randomly assigned to 1 of 64 possible combinations of six different prophylactic interventions: 4 mg IV ondansetron or no ondansetron; 4 mg IV dexamethasone or no dexamethasone; 1.25 mg IV droperidol or no droperidol; propofol or a volatile inhalation anesthetic agent; nitrous oxide or nitrogen (i.e., no nitrous oxide); and remifentanyl (an ultrashort-acting opioid) or fentanyl (a short-acting opioid).¹³⁹ Each antiemetic agent intervention (ondansetron, dexamethasone, droperidol) had similar efficacy and reduced the risk of PONV by about 26%. The risk was further reduced when a combination of any two antiemetics was administered, with no difference between the various combinations of agents. The risk was the lowest when all three antiemetic agents were administered.

For prophylaxis of PONV, J.E. should receive at least two antiemetic agents because she is at high risk for developing PONV. Dexamethasone 4 mg IV can be administered at the beginning of surgery (just after induction of anesthesia) and 4 mg IV ondansetron should be administered approximately 30 minutes before the end of surgery. If an alternative agent (to ondansetron and dexamethasone) or third agent is warranted, a transdermal scopolamine patch can be placed within 2 hours before the induction of general anesthesia. The addition of transdermal scopolamine to ondansetron for prevention of PONV significantly reduces PONV, as well as supplemental antiemetic requirements.¹⁴⁰

Treatment of Postoperative Nausea and Vomiting

20. J.E. is taken to surgery. Anesthesia is induced with propofol and maintained with sevoflurane. Fentanyl is administered intraoperatively for analgesia. A prophylactic dose of dexamethasone is administered at the beginning of surgery, and ondansetron is administered near the end of surgery. Neuromuscular blockade produced by vecuronium is reversed with neostigmine and glycopyrrolate. In the recovery room, J.D. becomes nauseated and has several emetic episodes. What do you recommend?

Although dexamethasone and ondansetron are effective for both prevention and treatment of PONV, a rescue antiemetic is more efficacious if it works by a different mechanism of action.¹⁴¹ Prophylactic dexamethasone and/or ondansetron can be effective for up to 24 hours. If nausea and emetic episodes occur in the recovery room, the prophylactic antiemetic agents were ineffective. Phenothiazines (prochlorperazine) and benzamides (metoclopramide) block dopaminergic stimulation of the CTZ, making these agents appropriate for J.E. Prochlorperazine may be preferred because metoclopramide's primary effect is in the GI tract rather than the CTZ. Diphenhydramine or promethazine, which blocks Ach receptors in the vestibular apparatus, as well as histamine receptors that activate the CTZ, would also be appropriate choices for rescue for J.E. Because excessive sedation could delay J.E.'s discharge from the ambulatory surgery center, doses should not exceed 25 mg IV for promethazine and 50 mg IV for diphenhydramine. In addition, it is important to assess J.E. for postoperative factors that could increase the likelihood of PONV. If postural hypotension is present, IV fluids and ephedrine would be appropriate therapy. Postoperative pain must also be assessed because PONV is directly related to the degree of postoperative pain; a threefold higher frequency of PONV has been reported in ambulatory surgery patients with postoperative pain.¹⁴²

Anesthetic Agents With a Low Incidence of Postoperative Nausea and Vomiting

21. How could J.E.'s anesthetic regimen have been modified to reduce the likelihood of PONV?

Several changes could be made in the anesthetic regimen to reduce the likelihood of PONV. When propofol is used for both induction and maintenance of anesthesia, it reduces the risk of PONV similar to the administration of a single antiemetic.¹³⁹ Because perioperative administration of opioids is associated with PONV, the use of NSAIDs (oral agents preoperatively and postoperatively, parenteral ketorolac intraoperatively and postoperatively), when appropriate, can reduce the need for postoperative opioids. In addition, surgical wound infiltration with a long-acting local anesthetic, such as bupivacaine, should also be used, as needed, to reduce postoperative incisional pain.

ANALGESIC AGENTS AND POSTOPERATIVE PAIN MANAGEMENT

Acute Pain

Surgery causes injury to the body, resulting in acute pain. Specifically, the tissue trauma from surgery directly stimulates

nociceptors (receptors in the periphery that detect damaging or unpleasant stimuli, inflammation, pressure, and/or temperature). In addition, tissue injury causes the release of inflammatory mediators (e.g., prostaglandins, substance P) that sensitize and activate nociceptors. Sensitized nociceptors amplify the pain impulse by generating nerve impulses more readily and more often; this is called “peripheral sensitization.” The pain impulse then travels from the periphery to the dorsal horn of the spinal cord. From here, the pain impulse ascends to higher centers in the brain, which results in the patient “feeling” the pain. Because both cortical and limbic systems are involved and social and environmental influences are present, the same surgery can result in significant individual differences in pain perception. Persistent bombardment of the dorsal horn with pain impulses from the periphery results in central sensitization (“wind-up”), where there is increased firing of dorsal horn neurons. Clinically, when these two processes occur, the patient will experience a lower pain threshold, both at the site of injury and in the surrounding tissue. When this occurs, pain may be prolonged beyond the usual expected duration following surgery. If central sensitization is prolonged, permanent changes in the CNS can occur. Clinically, this can result in postoperative pain that is hard to manage.^{143,144}

The degree of pain usually depends on the magnitude of the surgery¹⁴⁵ and the patient’s level of fear and anxiety. Patients vary in their response to pain (and interventions) and in their personal preferences toward pain management. Acute pain usually resolves when the injury heals (hours to days). Unrelieved acute postoperative pain has detrimental physiological and psychological effects, including impaired pulmonary function (leading to pulmonary complications); thromboembolism; tachycardia; hypertension and increased cardiac work; impairment of the immune system; nausea, vomiting, and ileus; chronic pain; and anxiety, fatigue, and fear.¹⁴⁶

Adequate pain assessment and management are essential components of perioperative care. Education of patients and families about their roles, as well as the limitations and side effects of pain treatments, is critical to managing postoperative pain. Pain management must be planned for and integrated into the perioperative care of patients. Proactive planning includes obtaining a pain history based on the patient’s own experiences with pain; determining the patient’s pain goal; and anticipating preoperative, intraoperative, and postoperative pain therapies. The intensity and quality of pain, as well as the patient’s response to treatment and the degree to which pain interferes with normal activities, should be monitored. Ideally, pain should be prevented by treating it adequately because once established, severe pain can be difficult to control.

Management Options

Effective postoperative pain management should provide subjective pain relief while minimizing analgesic-related adverse effects, allow early return to normal daily activities, and minimize the detrimental effects from unrelieved pain. The following techniques can be used to manage postoperative pain: (a) systemic administration of opioids, NSAIDs, and acetaminophen; (b) on-demand administration of IV opioids, also known as *patient-controlled analgesia* (PCA); (c) epidural analgesia (continuous and on-demand, usually with an opioid/

local anesthetic mixture); (d) local nerve blockade such as local infiltration or peripheral nerve block; and (e) application of heat or cold, guided imagery, music, relaxation, or other nonpharmacologic intervention. Local anesthetics, opioids, acetaminophen, and NSAIDs can be used alone or in combination to create the optimal analgesic regimen for each patient based on factors such as efficacy of the agent to reduce pain to an acceptable level, type of surgery, underlying disease, adverse effects, and cost of therapy. For patients experiencing mild to moderate postoperative pain, local anesthetic wound infiltration or peripheral nerve blockade, or administration of a nonopioid analgesic such as an NSAID or acetaminophen are appropriate approaches to analgesia. For moderate postoperative pain, a less potent oral opioid, such as hydrocodone or codeine, is added. For moderate to severe pain following more invasive surgery, an IV opioid (e.g., morphine, hydromorphone), an epidural containing a local anesthetic and opioid, or a peripheral nerve block with local anesthetic is necessary. (For more information about general pain management, see Chapter 8.) Analgesia for acute pain in the perioperative setting is best achieved by using a multimodal (balanced) approach with a combination of two or more analgesic agents that have different mechanisms of action or that are administered by different techniques.¹⁴⁶

Patient-Controlled Analgesia

ADVANTAGES

22. J.A., a 50-year-old, 5’4”, 50-kg woman, is immediately postoperative from a total abdominal hysterectomy for a neoplasm. Her laboratory values are remarkable for a SrCr of 1.3 mg/dL (normal, 0.6–1.0 mg/dL). She is allergic to penicillin. She will be admitted to the postsurgical floor for a planned stay of 2 to 3 days. What mode of pain management should be chosen for J.A.?

PCA is a popular method of administering analgesics and offers several advantages over traditional IM or IV opioid dosing. Patients treated with intermittent IM or IV dosing of opioids “as needed” can experience severe pain because the serum opioid concentration is allowed to fall to less than the minimum effective analgesic concentration (the concentration that provides approximately 90% pain relief). In addition, high peak plasma opioid concentrations can be seen with this administration method, often resulting in excessive nausea, vomiting, or sedation, as well as respiratory depression. Small, frequent opioid doses, as seen in PCA, minimize the peaks and valleys in serum concentrations seen with relatively larger intermittent IM or IV doses. This is helpful in avoiding adverse effects associated with high peak serum concentrations and inadequate pain relief caused by subtherapeutic serum concentrations. Small, frequent, patient-controlled dosing of opioids is efficacious because opioids have a steep sigmoidal dose–response curve for analgesia, resulting in the ability of a small opioid dose to move the plasma concentration from being subtherapeutic to above the minimum effective plasma concentration that will provide effective pain relief.^{147,148} In terms of safety, analgesia occurs at lower opioid dosages than sedation, and sedation generally precedes respiratory depression.¹⁴⁹ Therefore, if a patient becomes sedated, self-administration of additional patient-controlled bolus doses will stop, allowing the serum opioid concentration to fall to a safe level.

Therapy can be individualized by using small doses of opioids at preset intervals (e.g., 1 mg morphine every 8 minutes), with the patient in control of his or her analgesic administration. An infusion pump, with a programmed on-demand dose (the dose the patient can self-administer) and number of minutes between allowable doses (lock-out interval), is equipped with a button that the patient presses to receive a dose. IV bolus is the most common PCA route, with opioids being the drugs of choice to provide postoperative analgesia. The epidural route can also be used in select patients.

If the patient is educated to use PCA properly, it can be used to alleviate anticipated pain before movement or physical therapy in a pre-emptive fashion. J.A. has undergone a procedure for which moderate-to-severe pain is expected in the immediate postoperative period. J.A.'s pain requirement in the immediate postoperative period could be met with PCA opioid administration after first administering a bolus dose of opioid, which is titrated to achieve the appropriate level of analgesia. When her opioid requirements decline or when she can tolerate oral intake, she can then be switched to oral analgesics.

PATIENT SELECTION

23. J.A.'s surgeon decides to prescribe PCA for postoperative pain management. How should J.A. be evaluated for her ability to appropriately participate in her analgesic administration?

Patients receiving PCA therapy must be able to understand the concept behind PCA and to operate the drug administration button. J.A. must be alert and oriented before being put in control of her own pain management. She must be able to comprehend verbal and/or written instructions regarding the function and safety features of the infusion pump and how to titrate drug as needed for satisfactory analgesia. PCA has been used successfully in children, generally after ages 8 or 9 (adjusting doses appropriately) and in elderly patients. PCA is not indicated in patients who are expected to require parenteral opioids for analgesia for <24 hours because these patients will generally be able to tolerate oral analgesics shortly after surgery.

PATIENT INSTRUCTIONS

24. J.A. is nervous about giving herself an overdose while using PCA. What instructions should be provided to her?

Patients often worry about the safety of PCA, which can lead to reluctance to provide themselves with adequate pain relief. J.A. should be informed that if she administers too large of an amount of the prescribed opioid analgesic, she should fall asleep. Because she is asleep, she will not press the button. When this adverse effect of the opioid has worn off, she will wake up (plasma opioid level has fallen back into or below the therapeutic range). This is an important safety feature of PCA and is the reason family members must not push the button for the patient. However, J.A. should also know that she may have to press the button several times (after the lock-out interval has passed) before her pain is relieved. She must also be informed that she may require a larger PCA dose, so it is important for J.A. to assess her pain relief from the "usual" dose most patients are initially started on following surgery. Accurate pain assessment following her prescribed dose is critical for ensuring that her dose is sufficient to provide the desired level of analgesia.

She should also understand the possible adverse effects of her PCA medication and what can be done to prevent and treat these effects, as well as the advantages of providing herself with adequate analgesia (e.g., early ambulation). Finally, she should be told of the negligible risk of "narcotic" addiction from short-term PCA use and be given ample opportunity to ask questions.

CHOICE OF AGENT

25. Meperidine is ordered for J.A.'s PCA. Is this a reasonable drug choice for her?

Ideally, opioids for PCA administration have a rapid onset and intermediate duration of action (30–60 minutes), with no accumulation, ceiling effect, or adverse effects. The physicians, nurses, and pharmacists involved with the care of the patient should be familiar with the drug selected for PCA. Morphine is by far the most common choice for PCA, although other opioids such as fentanyl and hydromorphone can be used. Drug choice is based on past patient experiences, allergies, adverse effects, and special considerations, such as renal function. Meperidine has a metabolite, normeperidine, which is renally excreted; has a long half-life; and can cause cerebral irritation and excitation. Symptoms of CNS toxicity from normeperidine include agitation, shaky feelings, delirium, twitching, tremors, and myoclonus/tonic-clonic seizures. These symptoms can be seen when meperidine is administered in higher doses and/or for a prolonged period.^{150,151} The presence of renal insufficiency increases the risk of accumulation of normeperidine.¹⁵⁰ Meperidine also inhibits serotonin reuptake and has a fairly high serotonergic potential. The risk of a patient developing the serotonin syndrome is greater when meperidine is coadministered with another drug that has moderate or high serotonergic potential (e.g., fluoxetine, fluvoxamine, paroxetine, venlafaxine).¹⁵² For these reasons, meperidine is a poor choice for analgesia, particularly for J.A. who has diminished renal function. Morphine is conjugated with glucuronide in hepatic and extrahepatic sites (particularly the kidney) to its two major metabolites, morphine-3-glucuronide and morphine-6-glucuronide; both metabolites are excreted primarily in the urine. Morphine-6-glucuronide is an active metabolite that can accumulate in patients with renal failure, resulting in prolonged analgesia, sedation, and respiratory depression.¹⁵³ Because of J.A.'s diminished renal function, morphine should probably be avoided because other options exist. Hydromorphone is not metabolized to an active 6-glucuronide metabolite, and fentanyl is metabolized to inactive metabolites. Either hydromorphone or fentanyl is an appropriate analgesic choice for J.A. Hydromorphone is chosen. Table 9-16 lists common doses and lock-out intervals for drugs administered by PCA.^{154–156}

DOSING

26. J.A. was not receiving an opioid prior to surgery (e.g., she is opioid naive). What dose of hydromorphone and what lock-out interval should be used for her initial PCA pump settings?

If J.A. is experiencing pain before PCA has been initiated, she should receive a loading dose of IV hydromorphone titrated to achieve baseline pain relief (usually up to 1 mg). Once adequate analgesia is achieved, demand doses of 0.2 mg with a lock-out interval of 8 minutes would be a good choice to

Table 9-16 Adult Analgesic Dosing Recommendations for Intravenous Patient-Controlled Analgesia^a

| Drug | Usual Concentration | Demand Dose (mg) | | Lock-Out Interval (min) |
|--|---------------------|------------------|-----------|-------------------------|
| | | Usual | Range | |
| Fentanyl (as citrate) (Sublimaze) | 10 µg/mL | 0.01–0.02 | 0.01–0.05 | 4–8 |
| Hydromorphone hydrochloride (Dilaudid) | 0.2 mg/mL | 0.2–0.3 | 0.1–0.5 | 5–10 |
| Morphine sulfate | 1 mg/mL | 1–2 | 0.5–3 | 5–10 |

^aAnalgesic doses are based on those required by a healthy 55- to 70-kg, opioid-naive adult. Analgesic requirements vary widely between patients. Doses may need to be adjusted because of age, condition of the patient, and prior opioid use.

Adapted from references 154–156.

maintain analgesia for this opioid-naive patient. If J.A.'s pain is not relieved after two to three demand doses within 1 hour, the demand dose can be increased to 0.3 mg.

USE OF A BASAL INFUSION

27. After the first postoperative evening, J.A. tells you that she had a terrible time sleeping. She describes waking up in pain frequently, despite pressing her PCA button many times. She rates her pain as moderate to severe in intensity and fairly constant. A review of the history on her PCA device reveals successful delivery of 9 mg of hydromorphone (30 demand doses, 0.3 mg each) over the past 12 hours. J.A. is not sedated and reports no adverse effects from hydromorphone. How can J.A.'s pain management be improved?

Many PCA infusion pumps offer a continuous infusion setting for a basal infusion during intermittent dosing. Use of a basal (continuous) infusion has not been shown to improve analgesia and likely increases the risk of adverse effects (due to the potential of an opioid overdose in some patients). Therefore, routine basal (continuous) infusion of opioids cannot be recommended for acute pain management. In an opioid-naïve patient such as J.A., however, continuing to increase the demand dose increases the risk of excessive sedation and respiratory depression (due to high peak levels). Also, J.A. describes her pain as moderate to severe in intensity and fairly constant in nature when she does not regularly push the demand button. For J.A., a continuous infusion would be beneficial. As a rule of thumb, an opioid-naïve patient experiencing acute pain (that can change quickly) should only receive about one-third of her average hourly usage as a continuous infusion or 1 mg/hour of morphine (or its equivalent, which would be 0.2 mg/hour for hydromorphone). For J.A., begin a continuous infusion of 0.2 mg/hour hydromorphone in addition to her demand dose of 0.3 mg every 8 minutes. Because the onset of action of hydromorphone is about 5 minutes, shortening the lock-out interval is not a good idea because J.A. could access the next dose of hydromorphone before the effects of the initial dose can be appreciated. That could lead to significant adverse effects, such as excessive sedation and respiratory depression.

ADVERSE EFFECTS

28. The next day, J.A. requested only a few demand doses and reports adequate pain relief with her PCA, but now complains of feeling slightly groggy and nauseated. Bowel sounds are noted on physical examination, and J.A. plans to try to take clear liquids

later that morning. What are the adverse effects of PCA opioids, and how can J.A.'s complaints be addressed?

Opioids given by PCA can produce adverse effects similar to those given by other parenteral routes. Sedation, confusion, euphoria, nausea and vomiting, constipation, urinary retention, and pruritus can be experienced, and these can be managed by dose adjustments or pharmacologic intervention. Respiratory depression is very rare with PCA opioid administration.¹⁵⁵ However, elderly patients, patients with severe underlying systemic disease or pre-existing respiratory compromise, and those who are receiving other sedative-hypnotics concomitantly are predisposed to respiratory depression.¹⁴⁸ Technical problems must also be ruled out. The PCA pump should be checked to ensure that it is delivering the correct drug and dose, programming should be checked for accuracy (e.g., drug concentration, dosing interval), and the opioid reversal agent naloxone must be readily available. Monitoring for efficacy and adverse effects of PCA therapy should include pain intensity and quality, response to treatment, number of on-demand requests, analgesic consumption, BP, heart rate, respiratory rate, and level of sedation, as well as the presence of other adverse effects of opioids such as nausea and itching.

J.A.'s PCA hydromorphone dose could be reduced to manage her sedation and nausea. However, her pain control must be carefully reassessed to ensure efficacy of the newly lowered dose. An order for an antiemetic could also be provided. NSAIDs (ketorolac IM/IV or other NSAID orally) are not sedating; thus, they could be added to the analgesic regimen to provide analgesia and allow a reduction in her opioid dose. However, because of J.A.'s compromised renal function, NSAIDs should be administered with caution and in lower doses (e.g., 15 mg IM/IV ketorolac). Before administering ketorolac, J.A.'s hydration status should be evaluated to ensure that she is not hypovolemic.¹⁵⁷ If J.A. is able to take fluids orally, PCA should be discontinued and oral analgesics administered as needed. As healing occurs, her pain intensity should lessen, and oral opioid/acetaminophen products should manage her pain adequately.

Epidural Analgesia

29. T.M., a 69-year-old man, enters the surgical ICU after surgery for colorectal cancer (lower anterior resection, urethral stents, ileorectal pull-through). His pain is managed through a lumbar epidural catheter. What are the benefits and risks of epidural analgesia, and why was this approach to postoperative analgesia chosen for T.M.?

ADVANTAGES AND DISADVANTAGES

Epidural analgesia can offer superior pain relief over traditional parenteral (IM and IV PCA) analgesia.¹⁵⁸ Continuous epidural infusions offer an advantage over intermittent epidural injections because peak and trough concentrations of drugs are avoided. Epidural catheter placement is an invasive procedure that can result in unintentional dural puncture, causing postdural puncture headache, insertion site inflammation or infection, and, rarely, catheter migration during therapy and epidural hematoma.¹⁵⁵

PATIENT SELECTION

Epidural analgesia should be chosen based on the need for good postoperative pain relief and reduced perioperative physiological responses. Postoperative pain should be localized at an appropriate level for catheter placement in the lumbar or thoracic location of the epidural space. Patients undergoing abdominal, gynecologic, obstetric, colorectal, urologic, lower limb (e.g., major vascular), or thoracic surgery are excellent candidates for epidural pain management. Absolute contraindications to epidural analgesia include severe systemic infection or infection in the area of catheter insertion, known coagulopathy, significant thrombocytopenia, recent or anticipated thrombolytic therapy, full (therapeutic) anticoagulation, uncorrected hypovolemia, patient refusal, and anatomical abnormalities that make epidural catheter placement difficult or impossible.¹⁵⁹ T.M. is a good candidate for epidural analgesia based on the severity of pain associated with his surgery and the surgical procedure.

CHOICE OF AGENT AND MECHANISMS OF ACTION

30. What drug or drug combination can be used for T.M.'s epidural infusion? What are the mechanisms of action of the analgesics commonly administered in the epidural space?

Opioids and local anesthetics are administered alone or in combination in epidural infusions. Opioids in the epidural space are transported by passive diffusion and the vasculature to the spinal cord, where they act at opioid receptors in the dorsal horn. After epidural administration, opioids can reach

brainstem sites by cephalad movement in the cerebrospinal fluid. In addition, lipophilic opioids (fentanyl, sufentanil) have substantial systemic absorption from the epidural space.^{153,160} Opioids selectively block pain transmission and have no effect on nerve transmission responsible for motor, sensory, or autonomic function.¹⁶¹ Local anesthetics, however, act on axonal nerve membranes crossing through the epidural space to produce analgesia by blocking nerve transmission. Depending on the drug, concentration, and depth of nerve penetration, local anesthetics also produce sensory, motor, or autonomic blockade (see Local Anesthetics section). Table 9-17 describes the spinal actions, efficacy, and adverse effects of opioids and local anesthetics administered by the epidural route.^{154,159,160,162}

Most often, opioids and local anesthetics are combined in the same solution because these two classes of drugs act synergistically at two different sites to produce analgesia, allowing the administration of lower doses of each drug to reduce the risk of adverse effects while providing effective analgesia. Table 9-18 lists the drugs, concentrations, and typical infusion rates for epidural administration.^{155,156,160,161,163} Bupivacaine is commonly chosen as the local anesthetic agent because it can preferentially block sensory fibers (producing analgesia) without significantly blocking motor fibers.¹⁵⁵ The choice of opioid is based on pharmacokinetic differences among the available agents. Onset, duration, spread of agent in the spinal fluid (dermatomal spread), and systemic absorption are affected by the lipophilicity of the drug.¹⁶² Highly lipophilic opioids such as fentanyl and sufentanil have a faster onset of action, a shorter duration of action (from a single dose), less dermatomal spread, and much greater systemic absorption. Morphine, which is relatively hydrophilic, has a slower onset of action, longer duration of action, greater dermatomal spread and migration to the brain, and less systemic absorption.^{160,162} However, after several hours of epidural infusion, the dermatomal (regional) effect of fentanyl is lost, and analgesia is achieved because of a therapeutic plasma concentration. Morphine, however, retains its spinal mechanism of action.¹⁶⁰ The lipophilicity of hydromorphone is intermediate between fentanyl and morphine. Clinically, hydromorphone has a faster onset and shorter duration than morphine. Its site of action is likely spinal.¹⁶⁴ A

Table 9-17 A Comparison of the Spinal Actions, Efficacy, and Adverse Effects of Opioids and Local Anesthetics^a

| | Opioids | Local Anesthetics |
|--------------------|--|--|
| Actions | | |
| Site of action | Substantia gelatinosa of dorsal horn of spinal cord ^b | Spinal nerve roots |
| Modalities blocked | “Selective” block of pain conduction | Blockade of sympathetic pain fibers; can cause loss of sensation and motor function |
| Efficacy | | |
| Surgical pain | Partial relief | Complete relief possible |
| Labor pain | Partial relief | Complete relief |
| Postoperative pain | Fair/good relief | Complete relief |
| Adverse effects | Nausea, vomiting, sedation, confusion, pruritus, constipation/ileus, urinary retention, respiratory depression | Hypotension, urinary retention, loss of sensation, loss of motor function resulting in inability to ambulate |

^aEpidurally administered morphine and local anesthetics exert their effects mainly by a spinal mechanism of action; lipophilic opioids such as fentanyl and sufentanil achieve therapeutic plasma concentrations when administered epidurally.

comparison of the pharmacokinetic properties important to epidural opioids is found in Table 9-19.^{155,158,162,163} T.M. should receive a combination of opioid and local anesthetic, such as fentanyl and bupivacaine, as an epidural infusion for postoperative pain management.

31. Fentanyl/bupivacaine is chosen for T.M. How should this be prepared, and what infusion rate should be chosen?

Fentanyl and bupivacaine are commonly admixed in 0.9% sodium chloride (usual concentration ranges are found in Table 9-18). Concentrations are often institution specific and depend on the rate of administration. Preservative-free preparations of each drug should be used because neurologic effects are possible with inadvertent subdural administration of large amounts of benzyl alcohol or other preservatives. Strict aseptic technique should be used when admixing and administering an epidural solution.

The rate of administration is chosen empirically based on the anticipated analgesic response, the concentration of opioid in the admixture, and the potential for adverse effects. Usually, a rate of 4 to 10 mL/hour is adequate; the epidural space can safely handle up to approximately 20 mL/hour of fluid. An initial infusion rate of 5 to 8 mL/hour would be reasonable for T.M., with titration based on efficacy and adverse effects.

ADVERSE EFFECTS

32. Two hours after initiation of his fentanyl/bupivacaine epidural infusion, T.M. experiences discomfort in the form of an itchy

feeling on his nose, torso, and limbs. Is this related to his epidural infusion?

Pruritus has been associated with almost all opioids, with a significantly greater frequency when the opioid is administered as an epidural infusion rather than by IV administration.¹⁶⁵ This effect is usually seen within 2 hours and is probably dose related. It generally subsides as the opioid effect wears off and can be more of a problem with continuous epidural administration of opioids or when opioids are administered via PCA. Although pruritus from opioids is probably μ -receptor mediated and not histamine mediated,¹⁶⁶ antihistamines (e.g., diphenhydramine) can provide symptomatic relief. Alternatively, very small doses of opioid antagonists (e.g., naloxone 0.04 mg) can be used to effectively reverse opioid adverse effects, such as pruritus, but not analgesia. Due to naloxone's short duration of action, repeat doses or a continuous infusion may be necessary.

Other adverse effects possible with epidural opioids include nausea, vomiting, sedation, confusion, constipation, ileus, urinary retention, and respiratory depression. Although rare, respiratory depression from epidural opioids is the most dangerous adverse effect. Respiratory depression can occur as long as 12 to 24 hours after a single bolus of morphine^{160,162} or within hours to 6 days after beginning a continuous infusion of fentanyl/bupivacaine.¹⁶⁷ Typically, regular assessments of sedation level and rate and depth of respirations safely detect respiratory depression from opioids.^{148,160} As with parenteral opioid administration, risk factors for opioid-related respiratory depression include severe underlying systemic

Table 9-19 Pharmacokinetic Comparison of Common Epidural Opioid Analgesics

| Agent | Partition Coefficient ^a | Onset of Action of Bolus (minutes) | Duration of Action of Bolus (hours) | Dermatome Spread |
|------------------------------|------------------------------------|------------------------------------|-------------------------------------|------------------|
| Fentanyl (Sublimaze) | 955 | 5 | 3–6 | Narrow |
| Hydromorphone (Dilaudid) | 525 | 15 | 6–17 | Intermediate |
| Morphine Sulfate (Duramorph) | 1 | 30 | 12–24 | Wide |
| Sufentanil (Sufenta) | 1,737 | 5 | 4–7 | Narrow |

Adapted from references 155, 158, 162, and 163.

disease or pre-existing respiratory compromise, concomitant use of other sedative-hypnotics (e.g., benzodiazepines, opioids administered by another route), and older age. As a result, reduced doses should be used in patients with these risk factors. Adverse effects of epidural local anesthetics include hypotension, urinary retention, lower limb paresthesias or numbness, and lower limb motor block. Depending on the degree of numbness and motor block, the patient may have difficulty ambulating. Monitoring for efficacy and adverse effects of epidural analgesia should include pain intensity and quality, response to treatment, number of on-demand requests (if PCA is being used), analgesic consumption, BP, heart rate, respiratory depth and rate, level of sedation, urinary output, presence of numbness/tingling, inability to raise legs or flex knees/ankles (lumbar epidural placement), and temperature.

ADJUNCTIVE KETOROLAC USE

33. On the second postoperative day, T.M. is able to rest comfortably when undisturbed, while receiving treatment with a lumbar epidural infusion of fentanyl 3 $\mu\text{g}/\text{mL}$ and bupivacaine 1.25 mg/mL at a rate of 8 mL/hour . However, when he is moved at the change of each nursing shift, he complains of significant pain. Increasing the rate of his epidural infusion was tried, but caused unacceptable pruritus and sedation. How can T.M.'s intermittent pain needs be addressed?

The use of additional analgesics for breakthrough pain may be necessary in patients receiving continuous epidural infusion. T.M.'s intermittent pain could be managed by patient-controlled epidural analgesia. Like IV PCA, patient-activated epidural boluses can be administered to control pain during movement. Alternatively, ketorolac, an injectable NSAID, may be considered for T.M.; it does not contribute to respiratory depression, sedation, or pruritus and effectively treats moderate-to-severe pain. The analgesic effects of NSAIDs are additive with the opioids and can lower postoperative pain scores. Patient selection for ketorolac therapy should consider renal function, plasma volume and electrolyte status, GI disease, risk of bleeding, and concomitant drugs and therapies such as epidural analgesia.

ADJUNCTIVE ANTICOAGULANT ADMINISTRATION

34. The surgeon has determined that T.M. is at risk for developing postoperative venous thromboembolism. Enoxaparin 40 mg SC QD has been ordered postoperatively. What are the risks of enoxaparin in this situation? What are reasonable precautions?

Prolonged therapeutic anticoagulation appears to increase the risk of epidural and spinal hematoma formation, which can lead to long-term or permanent paralysis. Administration of antiplatelet or anticoagulant drugs in combination with low-molecular-weight heparin (LMWH) results in an even greater risk of perioperative hemorrhagic complications, including spinal hematoma. These findings have led to concern for the safety of spinal and epidural anesthesia and analgesia in patients receiving LMWH. Important considerations for managing a patient being administered LMWH and receiving continuous epidural analgesia are (a) the time of catheter placement and removal relative to the timing (and peak effect) of LMWH administration, (b) total daily dose of LMWH, and (c) the dosing schedule of LMWH.¹⁶⁸ For T.M., the epidural catheter is

already in place and the LMWH is started postoperatively as a single daily dose. It is safe to leave the epidural catheter in place as long as the first dose of LMWH is administered 6 to 8 hours postoperatively. The second dose should be administered no sooner than 24 hours after the first dose. The timing of the catheter removal is of the utmost importance; it should be delayed for at least 10 to 12 hr after the last dose of LMWH, with subsequent dosing occurring a minimum of 2 hours after the catheter has been removed. There may be a greater risk of spinal hematoma when LMWH is administered twice a day. For that reason, if Q 12 hr enoxaparin is required, the catheter should be removed, and the first dose of LMWH administered at least 2 hours after catheter removal.¹⁶⁸ Because T.M. is receiving prophylactic daily enoxaparin, his catheter should be removed no earlier than 10 hours after his last dose of enoxaparin, with his next dose administered no earlier than 2 hours after catheter removal.

MULTIMODAL PAIN MANAGEMENT

35. W.W., a 36-year-old male, arrives at the ambulatory surgery center for an inguinal hernia repair. This procedure will be performed under local anesthesia, with sedation as needed, and is expected to be completed within 30 minutes. His medical and surgical histories are unremarkable. He is not currently taking any medication and reports no drug allergies. Following discharge from the ambulatory surgery center, how should W.W.'s postoperative pain be managed?

In general, one would expect that the greater the magnitude of the surgical trauma, the greater the patient's postoperative pain.¹⁴⁵ For minor surgical procedures (e.g., inguinal hernia repair, breast biopsy), there is minimal surgical trauma, and the patient goes home shortly after surgery. For intermediate surgical procedures (e.g., total abdominal hysterectomy, laparoscopic cholecystectomy), short-term hospitalization is often necessary to observe the patient's recovery and manage his or her pain. Patients undergoing major surgery (e.g., bowel resection, thoracotomy) experience a significant surgical stress response that can significantly increase postoperative morbidity. Effective pain management is essential.

If pain is mild in intensity, a nonopioid analgesic such as acetaminophen or an NSAID is appropriate. If pain is moderate in intensity or not controlled with acetaminophen or an NSAID, a low-potency opioid combination (e.g., acetaminophen with hydrocodone or codeine) is used. When pain is moderate to severe in intensity, a more potent opioid (e.g., morphine, oxycodone) is necessary. If a fixed combination of opioid and nonopioid is used, the total daily dose administered to the patient is limited by the maximum allowable daily dose of the nonopioid (e.g., acetaminophen, ibuprofen).

Multimodal or "balanced" analgesia is often used to provide postoperative analgesia. It is difficult to optimize postoperative pain relief, to the point of achieving normal function, by using one drug or route of administration. By using two or more drugs that work at different points in the pain pathway, additive or synergistic analgesia can be achieved and adverse effects reduced because doses are lower and side effect profiles are different. Opioids are a mainstay of analgesic therapy for moderate-to-severe pain. However, opioids are often associated with intolerable adverse effects (e.g., nausea, vomiting,

Table 9-20 Commonly Used Analgesic Drugs and Nonpharmacologic Techniques for Postoperative Pain Management

| Type of Agent | Examples | Potential Adverse Effects |
|---------------------|--|--|
| Local anesthetics | Peripheral nerve block, tissue infiltration, wound instillation | Tingling, numbness, residual motor weakness, hypotension, CNS and cardiac effects from systemic absorption |
| NSAIDs | Ketorolac (IV, IM, oral), ibuprofen (oral), naproxen (oral), celecoxib (oral) | GI upset, edema, hypertension, dizziness, drowsiness, GI bleeding, operative site bleeding (not celecoxib) |
| Other nonopioids | Acetaminophen (oral, rectal) | GI upset, hepatotoxicity |
| Nonpharmacologic | Transcutaneous electrical nerve stimulation, acupuncture Ice or cold therapy Distraction, music, deep breathing for relaxation | Skin irritation, discomfort Excessive vasoconstriction, skin irritation |
| Less potent opioids | Hydrocodone + acetaminophen, codeine or oxycodone + acetaminophen | Nausea, vomiting, constipation, rash, sedation, mental confusion, hallucinations, respiratory depression |
| More potent opioids | Morphine (IV, epidural), hydromorphone (IV, epidural), fentanyl (IV, epidural), oxycodone (oral) | Nausea, vomiting, pruritus, constipation, rash, sedation, mental confusion, hallucinations, respiratory depression |

CNS, central nervous system; NSAIDs, nonsteroidal anti-inflammatory drugs; IV, intravenous; IM, intramuscular; GI, gastrointestinal.

Adapted from references 145, 146, and 169–172.

constipation, itching, sedation). Maximizing the use of nonopioid analgesics generally results in less need for opioids and improved analgesia (Table 9-20).^{145,146,169–172} When compared to morphine alone, the addition of an NSAID following major surgery reduces pain intensity and 24-hour morphine consumption. As a result, the incidence of morphine-related adverse effects of nausea, vomiting, and sedation is also reduced. Although the risk of surgical bleeding from nonselective NSAIDs is low, the risk can be increased in certain settings (e.g., after tonsillectomy).¹⁶⁹

For W.W., the anticipated surgical trauma is minor, and he will recover at home. The surgeon will inject a long-acting local anesthetic (e.g., bupivacaine) into the tissues surrounding the surgical field. This will provide intraoperative anesthesia at the surgical site and postoperative analgesia until the effects of bupivacaine wear off. Then, W.W. will likely require a less potent opioid (e.g., hydrocodone, codeine) combined with acetaminophen for pain control. If his pain is not controlled or his pain is mild in intensity, W.W. may take an NSAID (e.g., ibuprofen 200 or 400 mg Q 4–6 hr PRN or naproxen 220 mg Q 12 hr PRN).

ECONOMIC ISSUES

It is still common to find several anesthesia-related medications (e.g., sevoflurane, rocuronium) on an institution's top 25 expenditure list. Because of this, these medications are often targeted for cost-containment activities (e.g., appropriate flow rate for sevoflurane, use of vecuronium in place of rocuronium when appropriate).^{173–177} Although many anesthetic agents do not appear to be excessively expensive when looking at individual patient use, large dollar savings can be realized because of the thousands of patients that are anesthetized per year in a hospital.

Value-Based Anesthesia Care

When trying to reduce costs in the perioperative setting, one should not focus solely on using the least expensive technology, piece of equipment, or drug. This strategy can lead to unacceptable patient outcomes and higher total costs. The importance of

looking at the “big picture” has been recognized by the anesthesiology profession since the early 1990s when they put forth the concept of value-based anesthesia care, which seeks the best patient outcomes at the most reasonable costs. The advantages and disadvantages of the technique or drug are balanced against all costs associated with the surgical experience.¹⁷⁸

Total Costs of Surgical Stay

In one study, anesthesia costs, including medication use, accounted for 6% of the total costs for inpatient surgery, with approximately 50% being variable. Hence, modifying medication selection can impact, at most, 3% of the total costs associated with surgery. However, OR costs, including the costs of the PACU, accounted for 37% of the total costs of surgery, with approximately 44% being variable. Therefore, modifying practices that influence these costs can impact total cost by up to 16%.¹⁷⁹ In another study, labor costs were estimated to be two orders of magnitude greater than anesthesia maintenance costs for a 60-minute outpatient procedure; therefore, a major component of cost-containment efforts should be directed at the reduction of labor costs by streamlining OR time and shortening PACU discharge time.¹⁸⁰ Methods to reduce a patient's PACU stay may allow personnel reductions and/or reassignment of staff during slow periods. These studies highlight the opportunity for cost reduction in the perioperative setting by focusing on nonmedication costs and support the concept of fast-track anesthesia.

Fast-Track Anesthesia

Throughput is a major issue in most hospitals today. The perioperative setting is often targeted as needing improvement. Fast-track anesthesia, if successfully implemented, can help with throughput issues. The goal of fast tracking is to accelerate the movement of the patient through the perioperative experience (OR, PACU, and/or ICU). It has been promoted to improve patient satisfaction, to improve OR and PACU efficiency, and to lower the costs of the surgical experience. Several developments have facilitated the fast-track process and include the wide-scale use of less invasive surgical procedures

(e.g., laparoscopy), the incorporation of new monitoring techniques to allow better titration of anesthesia (e.g., “consciousness” monitors),¹⁸¹ and the use of short-acting, fast-emergence anesthetic agents to reduce wake-up times and drug hangovers. Although medication costs may be higher with fast-track anesthesia, fast tracking can improve clinical and financial outcomes in both inpatient and outpatient settings. Fast tracking cardiac surgery patients has resulted in quicker extubation, reduced length of stay, reduced ICU readmission rate, and a 25% cost reduction.^{182,183} Furthermore, fast-track cardiac surgery patients have a decreased health care resource usage for at least 1 year following discharge.¹⁸⁴ In a landmark outpatient study, fast tracking was implemented in five surgical centers and resulted in annual net savings from \$50,000 to \$160,000, with no significant differences in patient outcomes.^{185,186} In this study, outpatients meeting a well-defined set of criteria were allowed to skip phase I recovery and proceed directly to phase II

from the OR. Phase I recovery can be considered an ICU-type environment. Patients are taken here from the OR to recover hemodynamically and fully regain consciousness; this requires intensive nursing care (usually one nurse to two patients). Once patients are awake, hemodynamically stable, and able to sit upright, they are moved to phase II recovery to finish the recovery process. In this setting, the nurse—patient ratio is 1:3, or greater if nurse assistants are employed. The low-solubility, volatile inhalation agents (desflurane, sevoflurane) are ideally suited for fast tracking in the outpatient setting.^{181,187}

Thus, the goal for the cost-effective use of medications in the perioperative setting is a net reduction in the cost of surgical procedures (either the result of a lower overall medication cost or process modifications such as fast tracking) by taking advantage of the medications’ properties and keeping in mind that patients’ outcomes should not be negatively impacted and, ideally, should be improved.

- Causes 10-13

Understanding the etiology of a clinically important acid-base disturbance is important because therapy generally should be directed at the underlying cause of the disturbance rather than merely the change in pH. Severe acid-base disorders can affect multiple organ systems: cardiovascular (e.g., impaired contractility, arrhythmias), pulmonary (e.g., impaired oxygen delivery, respiratory muscle fatigue, dyspnea), renal (e.g., hypokalemia, nephrolithiasis), or neurologic (e.g., decreased cerebral blood flow, seizures, coma).

ACID-BASE PHYSIOLOGY

To protect body proteins, acid-base balance must be tightly controlled in an attempt to maintain a normal extracellular pH of 7.35 to 7.45 and an intracellular pH of approximately 7.0 to 7.3.¹ This narrow range is maintained by complex buffer systems, ventilation to expel CO₂, and renal elimination of acids and reabsorption of HCO₃⁻². At rest, about 200 mL of CO₂, and even more during exercise, is transported from the tissues and excreted in the lungs.³ Whereas HCO₃⁻ is only responsible for about 36% of intracellular buffering, it provides about 86% of the buffering activity in extracellular fluid (ECF).¹ Extracellular fluid contains approximately 350 mEq HCO₃⁻, which buffers generated H⁺.

Hydrogen ion (H⁺) combines with HCO₃⁻ and shifts the equilibrium of Equation 10-1 to the right. In the proximal renal tubule lumen, carbonic anhydrase catalyzes the dehydration of H₂CO₃ to CO₂ and H₂O, which are absorbed into the tubule

cell, as illustrated in Equation 10-2 and Figure 10-1. Within the tubule cell, H₂O dissociates into H⁺ and OH⁻. The H⁺ is then secreted into the lumen by a Na⁺-H⁺ exchanger. Carbonic anhydrase then catalyzes the combination of OH⁻ and CO₂ to HCO₃⁻, which is carried into the circulation by a Na⁺HCO₃⁻ cotransporter.⁴

To maintain acid-base balance, the kidney must reclaim and regenerate all the filtered HCO₃⁻. The daily amount that must be reabsorbed can be calculated by the product of the glomerular filtration rate (GFR) and the HCO₃⁻ concentration in ECF (180 L/d GFR × 24 mEq/L HCO₃⁻ = 4,320 mEq/day).¹ The proximal tubule reabsorbs about 85% of the filtered HCO₃⁻. The loop of Henle and the distal tubule reabsorb about 10%.⁵ Acid salts, such as HPO₄⁻ (pK_a of 6.8), which have a pK_a greater than the pH of the urine (titratable acids) can accept a proton and be excreted as the acid, thus regenerating an HCO₃⁻ anion.⁵ Sulfuric acid and other acids with a pK_a <4.5 are not titratable. Protons from these acids must be combined with another buffer to be secreted. Glutamine deamination in proximal tubular cells forms NH₃ that accepts these protons. In the collecting tubule, the NH₄⁺ produced is lipid insoluble, trapping it in the lumen and causing its excretion, eliminating the proton, and allowing for regeneration of HCO₃⁻.⁴⁻⁶ Figure 10-2 is a simplified illustration of the buffering of these acids.

The daily metabolism of carbohydrates and fats generates about 15,000 mmol of CO₂. Although CO₂ is not an acid, it reversibly combines with H₂O to form carbonic acid (i.e., H₂CO₃). Respiration prevents the accumulation of volatile acid

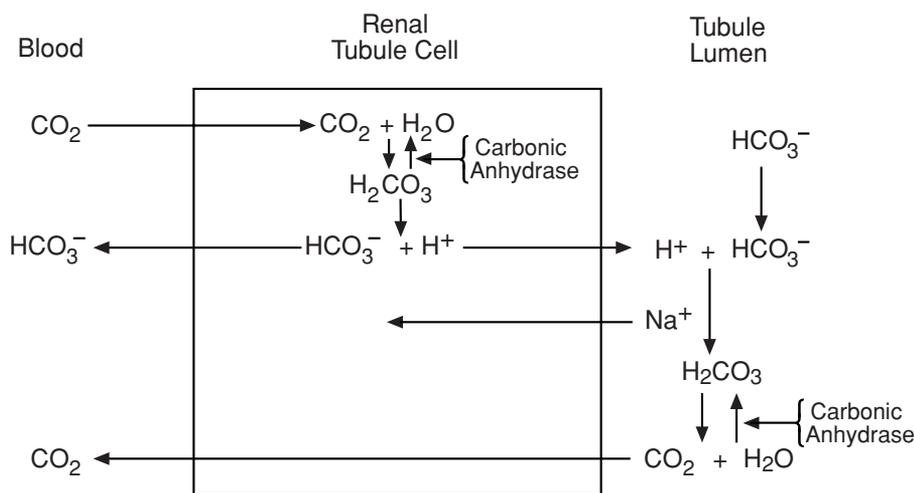

FIGURE 10-1 Renal tubular bicarbonate reabsorption.

through the exhalation of CO_2 . Metabolism of proteins and fats results in several fixed acids and bases. Amino acids such as lysine and arginine have a net positive charge and serve as acids. Compounds, such as glutamate, aspartate, and citrate, have a negative charge. In general, animal proteins contain more sulfur and phosphates, producing an acidic diet. Vegetarian diets consist of more organic anions, resulting in a more alkaline diet.⁷ Normally, fatty acids are metabolized to HCO_3^- ; however, during starvation or diabetic ketoacidosis, they may be incompletely oxidized to acetoacetate and β -hydroxybutyric acid.⁶ The typical diet generates a net nonvolatile acid load of about 70 to 100 mEq of H^+ (1.0–1.5 mEq/Kg) per day.^{1,8} Renal excretion of 70 mEq in 2 L of urine each day would require a pH of 1.5. Because the kidney cannot produce a pH less than 4.5, most of this fixed acid load must be buffered. The primary buffers for renal net acid excretion are $\text{NH}_3^-/\text{NH}_4^+$ and titratable buffers, such as $\text{HPO}_4^-/\text{H}_2\text{PO}_4^{2-}$, as mentioned above.⁷ The correct assessment of acid-base disorders begins with an evaluation of appropriate laboratory data and an understanding of the physiologic mechanisms responsible for maintaining a normal pH.

Laboratory Assessment

Laboratory data used to evaluate acid-base status are arterial pH, arterial carbon dioxide tension (PaCO_2), and serum bicarbonate (HCO_3^-).^{9–11} These values are obtained routinely with an arterial blood gas (ABG) determination. Acid-base abnormalities occur when the concentration of PaCO_2 (an acid) or HCO_3^- (a base) is altered. ABG measurements also include the arterial oxygen tension (PaO_2); however, this value does not directly influence decisions regarding acid-base abnormalities. Normal ABG values are listed in Table 10-1. When arterial pH is <7.35 , the patient is considered acidemic, and the process that caused acid-base imbalance is called *acidosis*. Conversely, when the arterial pH is >7.45 , the patient is considered alkalemic, and the causative process is *alkalosis*. The process is further defined as respiratory in cases of an inappropriate elevation or depression of PaCO_2 or metabolic with an inappropriate rise or fall in serum HCO_3^- .

Acid-base balance is normally maintained by the primary extracellular buffer system of $\text{HCO}_3^-/\text{CO}_2$. Components of this buffer system are measured routinely to assess acid-base

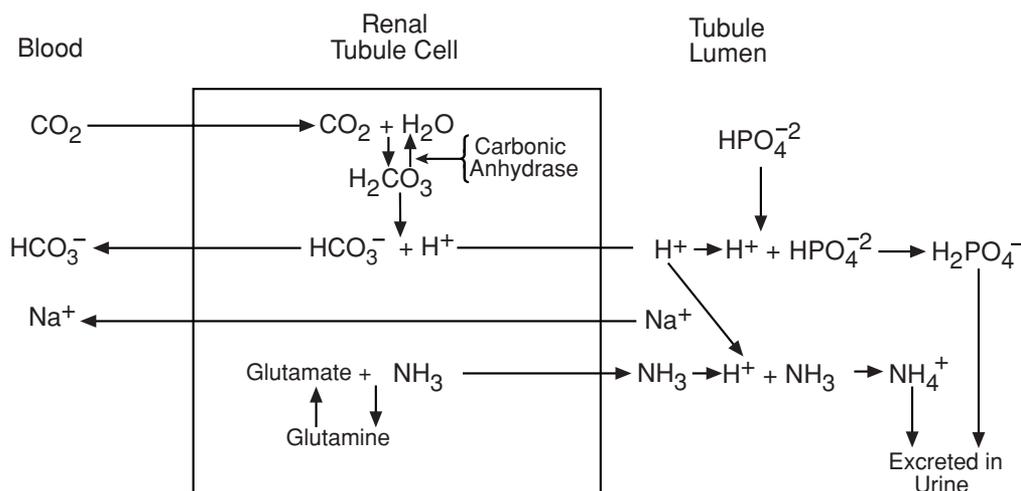

FIGURE 10-2 Renal tubular hydrogen ion excretion.

Table 10-1 Normal Arterial Blood Gas (ABG) Values

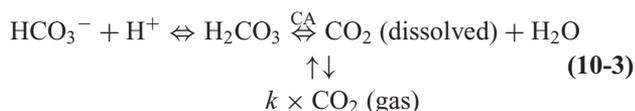

| ABGs | Normal Range |
|-------------------------------|--------------|
| pH | 7.36–7.44 |
| Pao ₂ | 90–100 mmHg |
| Paco ₂ | 35–45 mmHg |
| HCO ₃ [−] | 22–26 mEq/L |

status. Other extracellular buffers (e.g., serum proteins, inorganic phosphates) and intracellular buffers (e.g., hemoglobin, proteins, phosphates), however, also contribute significant buffering activity.^{1,7–10} Serum electrolytes are obtained to calculate the anion gap, an estimate of the unmeasured cations and anions in serum. The anion gap helps determine the probable cause of a metabolic acidosis.^{6,10,12–29} Urine pH, electrolytes, and osmolality help to further differentiate among the possible causes of metabolic acidosis.^{10,30–34}

Acid-Base Balance, Carbon Dioxide Tension, and Respiratory Regulation

In aqueous solution, carbonic acid (i.e., H₂CO₃ formed through the reaction described in Equation 10-1) reversibly dehydrates to form carbon dioxide (CO₂) and water (H₂O) as shown in Equation 10-2.

The enzyme carbonic anhydrase (CA), present in red blood cells, renal tubular cells, and other tissues, catalyzes the interconversion of carbonic acid and carbon dioxide. Some of the carbon dioxide produced by dehydration of carbonic acid remains dissolved in plasma, but most exists as a volatile gas:

In Equation 10-3, *k* is a solubility constant that has a value of approximately 0.03 in plasma at body temperature.^{2,34} Virtually all the carbonic acid in body fluids is in the form of carbon dioxide. Therefore, the Paco₂, a measure of carbon dioxide gas, is directly proportional to the amount of carbonic acid in the HCO₃[−]/H₂CO₃ buffer system. The normal range for Paco₂ is 35 to 45 mmHg.

The lungs can rapidly exhale large quantities of carbon dioxide and thereby contribute significantly to the maintenance of a normal pH. Carbon dioxide formed through the reaction described in Equation 10-3 diffuses easily from tissues to capillary blood and from pulmonary capillary blood into the alveoli where it is exhaled from the body.³ Pulmonary ventilation is regulated by peripheral chemoreceptors (located in the carotid arteries and the aorta) and central chemoreceptors (located in the medulla). The peripheral chemoreceptors are activated by arterial acidosis, hypercarbia (elevated Paco₂), and hypoxemia (decreased Pao₂). Central chemoreceptors are activated by cerebrospinal fluid (CSF) acidosis and by elevated carbon dioxide tension in the CSF.³ Activation of these chemoreceptors stimulates the respiratory control center in the medulla to increase the rate and depth of ventilation, which results in increased exhalation of carbon dioxide.

Bicarbonate and Renal Control

As described in the acid-base physiology section above, the kidneys are responsible for regulating the serum bicarbonate concentration. This is accomplished through two important and interrelated functions. First, they must reabsorb the bicarbonate that undergoes glomerular filtration and is present in the renal tubular fluid. Second, the kidneys must excrete hydrogen ions released from nonvolatile acids. Both functions are important in preventing systemic acidosis.

One mechanism of bicarbonate reabsorption in the proximal renal tubule is illustrated in Figure 10-1. Carbonic anhydrase catalyzes intracellular formation of carbonic acid (H₂CO₃) from carbon dioxide (CO₂) and water in the renal tubular cell. The carbonic acid then dissociates to form H⁺ and HCO₃[−]. The H⁺ ion is secreted into the lumen of the tubule in exchange for a sodium ion (Na⁺), and the bicarbonate from the renal tubule cell is reabsorbed into the capillary blood. Inside the lumen, carbonic acid is reformed from secreted H⁺ and filtered HCO₃[−]. Carbonic anhydrase present inside the lumen (on the brush border membrane of the cell) catalyzes conversion of carbonic acid to carbon dioxide that can readily diffuse back into the blood. Thus, the net result is reabsorption of sodium and bicarbonate. Although a hydrogen ion is secreted into the lumen in this process, no net excretion of acid occurs because of the reabsorption of carbon dioxide.^{4–6} Figure 10-2 illustrates H⁺ excretion by the kidney. This process was discussed in the physiology section above.

In clinical practice, the serum bicarbonate concentration usually is estimated from the total carbon dioxide content when the serum concentration of electrolytes are ordered on an electrolyte panel or calculated from the pH and Paco₂ on an ABG determination. These estimations of the serum bicarbonate concentration are more convenient than directly measuring serum bicarbonate. The total carbon dioxide content that is reported on serum electrolyte panels is determined by acidifying serum to convert all the bicarbonate to carbon dioxide and measuring the partial pressure of CO₂ gas. Approximately 95% of the total carbon dioxide content is bicarbonate. The serum bicarbonate concentration reported on ABG results is calculated from the patient's pH and Paco₂ using the Henderson-Hasselbalch equation (Equation 10-4). This calculated bicarbonate concentration should be within 2 mEq/L of the measured total carbon dioxide. The normal range of serum bicarbonate using these methods is 22 to 26 mEq/L.¹⁰

Bicarbonate:Carbonic Acid Ratio

The relationship between the pH and the concentrations of the acid-base pairs in buffer systems is described by the Henderson-Hasselbalch equation:

$$\text{pH} = \text{pK} + \log \frac{[\text{base}]}{[\text{acid}]} \quad (10-4)$$

The pK_a is the negative logarithm of the equilibrium constant for the buffer reaction. The pK for the carbonic acid–bicarbonate buffer system is 6.1. Because most of the carbonic acid in plasma is in the form of carbon dioxide gas, the concentration of acid [acid], can be estimated as Paco₂ multiplied by 0.03 (the solubility constant, *k*, in Equation 10-3). The concentration of base [base] is equal to the serum bicarbonate concentration. Using these values, Equation 10-4 can be rewritten

as follows:

$$pH = 6.1 + \log \frac{(HCO_3^-)}{(0.03)(Paco_2)} \quad (10-5)$$

As shown by Equation 10-5, the arterial pH will be 7.40 when the ratio of $HCO_3^-:H_2CO_3$ is approximately 20:1. Note that it is the *ratio* of bicarbonate to the carbon dioxide tension and not the absolute concentration of these factors that determines the arterial pH. Therefore, if the serum bicarbonate concentration and the carbon dioxide tension are increased or decreased proportionately, the ratio remains fixed and the pH is not affected.^{33–36}

EVALUATION OF ACID-BASE DISORDERS

Acid-base disorders should be evaluated using a stepwise approach.^{32,33}

1. Obtain a detailed patient history and clinical assessment.
2. Check the arterial blood gas, sodium, chloride, and HCO_3^- . Identify all abnormalities in pH, $Paco_2$, and HCO_3^- .
3. Determine which abnormalities are primary and which are compensatory based on pH.
 - a. If the pH is <7.40, then a respiratory or metabolic acidosis is primary.
 - b. If the pH is >7.40, then a respiratory or metabolic alkalosis is primary.
 - c. If the pH is normal (7.40) and there are abnormalities in $Paco_2$ and HCO_3^- , a mixed disorder is probably present because metabolic and respiratory compensations rarely return the pH to normal.
4. Always calculate the anion gap. If ≥ 20 , a clinically important metabolic acidosis is usually present even if the pH is within a normal range.³⁷
5. If the anion gap is increased, calculate the excess anion gap (anion gap – 10). Add this value to the HCO_3^- to obtain corrected value.³⁸
 - a. If corrected value >26, a metabolic alkalosis is also present.
 - b. If corrected value is <22, a nonanion gap metabolic acidosis is also present.
6. Consider other laboratory tests to further differentiate the cause of the disorder.
 - a. If the anion gap is normal, consider calculating the urine anion gap.
 - b. If the anion gap is high and a toxic ingestion is expected, calculate an osmolal gap.
 - c. If the anion gap is high, measure serum ketones and lactate.
7. Compare the identified disorders to the patient history and begin patient-specific therapy.

METABOLIC ACIDOSIS

Metabolic acidosis is characterized by loss of bicarbonate from the body, decreased acid excretion by the kidney, or increased endogenous acid production. Two categories of simple metabolic acidosis (i.e., normal anion gap and increased anion gap) are listed in Table 10-2. The anion gap (AG) represents the concentration of unmeasured negatively charged substances (anions) in excess of the concentration of unmeasured posi-

Table 10-2 Common Causes of Metabolic Acidosis

| <i>Normal AG</i> | <i>Elevated AG</i> |
|--------------------------------|---------------------------|
| <i>Hypokalemic</i> | <i>Renal Failure</i> |
| Diarrhea | <i>Lactic Acidosis</i> |
| Fistulous disease | (see Table 10-5) |
| Ureteral diversions | <i>Ketoacidosis</i> |
| Type 1 RTA | Starvation |
| Type 2 RTA | Ethanol |
| Carbonic anhydrase inhibitors | Diabetes mellitus |
| <i>Hyperkalemic</i> | <i>Drug Intoxications</i> |
| Hypoaldosteronism | Ethylene glycol |
| Hydrochloric acid or precursor | Methanol |
| Type 4 RTA | Salicylates |
| Potassium-sparing diuretics | |
| Amiloride | |
| Spironolactone | |
| Triamterene | |

AG, anion gap; RTA, renal tubular acidosis.

tively charged substances (cations) in the extracellular fluid. The concentrations of total anions and cations in the body are equal because the body must remain electrically neutral. Most clinical laboratories, however, measure only a portion of these ions (i.e., sodium, chloride [Cl^-], and bicarbonate). The concentrations of other negatively and positively charged substances, such as potassium (K^+), magnesium (Mg^{2+}), calcium (Ca^{2+}), phosphates, and albumin, are measured less often. The concentration of unmeasured anions normally exceeds the concentration of unmeasured cations by 6 to 12 mEq/L and the anion gap can be calculated as follows:

$$\text{Anion gap} = Na^+ - (Cl^- + HCO_3^-) \quad (10-6)$$

Of the unmeasured anions, albumin is perhaps the most important. In critically ill patients with hypoalbuminemia, the calculated AG should be adjusted using the following formula: adjusted AG = AG + 2.5 × (normal albumin – measured albumin in g/dL), where a normal albumin concentration is assumed to be 4.4 g/dL.^{19–22} For example, a hypoalbuminemic patient (serum albumin, 2.4 g/dL) with early sepsis and lactic acidosis might have a calculated AG of 11 mEq/L; however, after the calculation is corrected for the effect of the abnormal serum albumin concentration, the presence of elevated AG acidosis is more prominent (the calculated AG is adjusted: $AG_{(adjusted)} = 11 \text{ mEq/L} + 2.5 \times [\text{normal albumin} - \text{measured albumin}] = 16 \text{ mEq/L}$).

Metabolic acidosis with a normal AG (e.g., hyperchloremic metabolic acidosis) usually is caused by loss of bicarbonate and can be further characterized as hypokalemic or hyperkalemic.^{5,31,34,39–50} Diarrhea can result in severe bicarbonate loss and a hyperchloremic metabolic acidosis. Elevated AG metabolic acidosis usually is associated with overproduction of organic acids or with decreased renal elimination of nonvolatile acids.^{34,51–53} Increased production of organic acids (e.g., formic, lactic acids) is buffered by extracellular bicarbonate with resultant consumption of bicarbonate and appearance of an unmeasured anion (e.g., formate, lactate).^{32,51,52} The decrement in serum bicarbonate approximates the increment in the AG, the latter being a good estimate of the circulating anion level. Prolonged hypoxia results in lactic acidosis.

Uncontrolled diabetes mellitus or excessive alcohol intake with starvation can cause ketoacidosis. In the case of renal failure, the capacity for H^+ secretion diminishes, resulting in metabolic acidosis.³⁹ The accompanying increased AG results from decreased excretion of unmeasured anions such as sulfate and phosphate.²⁶

Normal Anion Gap (Hyperchloremic) Metabolic Acidosis

Evaluation

1. A.B., a 27-year-old, 60-kg woman, is hospitalized for evaluation of weakness. She has a history of bipolar affective disorder and reports recent ingestion of paint from the walls of her house. A.B.'s only current medication is lithium carbonate 300 mg TID. On admission, she appears weak and apathetic and complains of anorexia. Laboratory tests reveal the following: serum Na, 143 mEq/L (normal, 135–145 mEq/L); K, 3.0 mEq/L (normal, 3.5–5.0 mEq/L); Cl, 121 mEq/L (normal, 95–105 mEq/L); albumin, 4.4 g/dL (normal, 3.6–5.0 g/dL); pH, 7.28 (normal, 7.35–7.45); $Paco_2$, 26 mmHg (normal, 35–45 mmHg); HCO_3^- , 12 mEq/L (normal, 22–26 mEq/L); and urine pH, 5.5. A.B.'s urine pH following an ammonium chloride (NH_4Cl) 0.1 g/kg IV load is <5.1. A bicarbonate load of 1 mEq/kg infused IV over 1 hour induces bicarbonaturia (urinary pH, 7.0) and lowers the serum potassium to 2.0 mEq/L. Her blood pH only increased to 7.31. Assess A.B.'s acid-base status.

[SI units: Na, 143 mmol/L (normal, 135–145); K, 3.0 and 2.0 mmol/L, respectively (normal, 3.5–5.0); Cl, 121 mmol/L (normal, 95–105); albumin, 44 g/L (normal, 36–50); $Paco_2$, 3.5 kPa (normal, 4.7–6.0); HCO_3^- , 12 mmol/L (normal, 22–26)]

Using a stepwise approach, we see that A.B.'s history gives a clue to the cause for her acidosis. The low pH is consistent with a metabolic acidosis because her CO_2 and HCO_3^- are both reduced (Table 10-2). Alterations in pH resulting from a primary change in serum bicarbonate are metabolic acid-base disorders. Specifically, metabolic acidosis is associated with a decrease in serum HCO_3^- and decreased pH, whereas metabolic alkalosis is associated with an increase in serum HCO_3^- and increased pH. In respiratory disorders, the primary change occurs in the $Paco_2$. If A.B. had a decrease in pH and increase in $Paco_2$, a respiratory acidosis would be present. Because A.B. has a low $Paco_2$ and decreased serum HCO_3^- , she has a metabolic acidosis. In most cases of metabolic acidosis or alkalosis, the lungs compensate for the primary change in serum HCO_3^- concentration by increasing or decreasing ventilation. Most stepwise approaches would next suggest the evaluation of whether the decrease in $Paco_2$ of 14 mmHg for A.B. is consistent with respiratory compensation (Table 10-3). A primary decrease in the serum bicarbonate to 12 mEq/L should result in a compensatory decrease in the $Paco_2$ by 12 to 17 mmHg (Table 10-3). A.B.'s $Paco_2$ has fallen by 14 mmHg (normal, 40 mmHg; current, 26 mmHg), confirming that normal respiratory compensation has occurred. When values for $Paco_2$ or serum HCO_3^- fall outside of normal compensatory ranges, either a mixed acid-base disorder, inadequate extent of compensation, or inadequate time for compensation should be suspected.

Nomograms, especially ones that are different for acute and chronic disorders, are inherently difficult to memorize, how-

Table 10-3 Normal Compensation in Simple Acid-Base Disorders

| Disorder | Compensation ^a |
|-----------------------|--|
| Metabolic acidosis | $\downarrow Paco_2$ (mmHg) = $1.0 - 1.2 \times HCO_3^-$ (mEq/L) |
| Metabolic alkalosis | $\uparrow Paco_2$ (mmHg) = $0.5 - 0.7 \times \uparrow HCO_3^-$ (mEq/L) |
| Respiratory acidosis | |

^aBased on change from normal $HCO_3^- = 24$ mEq/L and $Paco_2 = 40$ mmHg.

ever, and are often not available to the clinician at the point of care. Following the stepwise approach advocated above will enable clinicians to identify most clinically important disorders without needing to depend on tables or formulas.

Causes

2. What are potential causes of metabolic acidosis in A.B.?

Steps 4 to 7 of the stepwise approach in the evaluation of acid base disorders (see above) are used to further determine the cause of the acid-base disorder. In patients with metabolic acidosis, calculation of the AG serves as a first step in classifying the metabolic acidosis and provides additional information about conditions that might be responsible for the acid-base disorder. A.B.'s calculated AG is 10 mEq/L (Equation 10-6). Thus, A.B. has hyperchloremic metabolic acidosis with a normal AG.

The common causes of metabolic acidosis are presented in Table 10-2.^{5,10,51} Normal AG metabolic acidosis usually is caused by gastrointestinal loss of bicarbonate (diarrhea, fistulous disease, ureteral diversions); exogenous sources of chloride (normal saline infusions); or altered excretion of hydrogen ions (renal tubular acidosis). A.B. reports a history of both paint ingestion (perhaps lead-based paint) and chronic use of lithium. Both lead and lithium have been associated with the development of renal tubular acidosis.^{31,54}

RENAL TUBULAR ACIDOSIS

3. How do the results of NH_4Cl and sodium bicarbonate ($NaHCO_3$) loading help identify the type of renal tubular acidosis in A.B.?

Renal tubular acidosis (RTA) is characterized by defective secretion of hydrogen ion in the renal tubule with essentially normal GFR. Many medical conditions and chemical substances have been associated with RTA (Table 10-4).^{31,34} The recognized forms are type 1 (distal), type 2 (proximal), and type 4 (distal, hypoaldosterone). Type 1 RTA is caused by a defect in the distal tubule's ability to acidify the urine; type 2 by altered urinary bicarbonate reabsorption in the proximal tubule; and type 4 by hypoaldosteronism and impaired ammoniogenesis.^{31,48}

Evaluation of bicarbonate reabsorption during bicarbonate loading and of response to acid loading by infusion of ammonium chloride is useful in distinguishing between the various

Table 10-4 Common Causes of Lactic Acidosis

| Type A | Type B |
|---------------------------|-------------------|
| Anemia | Diabetes mellitus |
| Carbon monoxide poisoning | Liver failure |
| Congestive heart failure | Renal failure |
| Shock | Seizure disorder |
| Sepsis | Leukemia |
| | Drugs |
| | Didanosine |
| | Ethanol |
| | Isoniazid |
| | Metformin |
| | Methanol |
| | Salicylates |
| | Zidovudine |

types of RTA. In healthy subjects, approximately 10% to 15% of the filtered bicarbonate escapes reabsorption in the proximal tubule but is reabsorbed in more distal segments of the nephron. Therefore, urine bicarbonate excretion is negligibly small, and urine pH is maintained between 5.5 and 6.5.

Type 2 (proximal) RTA is associated with a decrease in proximal tubular bicarbonate reabsorption. The distal tubular cells partially compensate for this defect by increasing bicarbonate reabsorption, but urinary bicarbonate excretion still is increased. As occurred with A.B., serum HCO_3^- concentration in patients with type 2 RTA may acutely fall below a threshold of 15 but then stabilize around 15 mEq/L.^{10,31} At this point, distal bicarbonate delivery no longer is excessive, allowing the distal nephron to acidify the urine appropriately and excrete acid in the form of titratable ammonia and phosphate.

In type 1 (distal) RTA, a defect in net hydrogen ion secretion, results from a back-diffusion of H^+ from the tubule lumen to the tubule cell. Patients with type 1 RTA cannot reduce their urine pH below 5.5 even when systemic acidosis is severe.⁴⁸

A.B.'s response to the acid (NH_4Cl) load demonstrates an ability to acidify the urine (i.e., pH <5.1), which helps rule out type 1 RTA. During bicarbonate loading in patients with type 2 RTA, serum bicarbonate concentration is increased and abnormally large amounts of bicarbonate are again delivered to the distal tubule. Its hydrogen secretory processes are overwhelmed, resulting in bicarbonaturia. Administration of bicarbonate to A.B. produced bicarbonaturia and an elevation in urine pH (7.0), with low blood pH (7.31). These findings indicate that the reabsorption of bicarbonate in the proximal tubule is impaired, which is characteristic of type 2 RTA. Type 4 (hypoaldosterone) RTA is unlikely given her initial serum potassium of 3.0 mEq/L.

LEAD-INDUCED

4. What is the cause of A.B.'s proximal RTA?

The most likely cause of A.B.'s proximal RTA is her exposure to presumably lead-based paint (Table 10-4). The pathogenesis of lead-induced type 2 RTA is unclear. Some studies suggest that carbonic anhydrase deficiency in the proximal tubule is the major factor, but these data are inconclusive.

5. Why is A.B. hypokalemic?

Bicarbonate wasting in proximal RTA is associated with sodium loss, extracellular fluid reduction, and activation of the renin-angiotensin-aldosterone axis. Aldosterone increases distal tubular sodium reabsorption and greatly augments potassium and hydrogen ion secretion. This results in potassium wasting, which explains A.B.'s hypokalemia.⁵⁵ When plasma bicarbonate achieves steady-state, less bicarbonate reaches the distal tubule, and the stimulus for aldosterone release is removed. Therefore, A.B. experiences only a mild depletion of potassium body stores. When A.B. is exposed to bicarbonate loading, the renin-angiotensin-aldosterone axis is reactivated, and hypokalemia worsens. In addition, raising the concentration of bicarbonate in the blood drives potassium intercellularly, and contributes to her hypokalemia.

Treatment

6. What treatment is indicated for A.B.?

Although it is rare for patients with type 2 RTA to develop severe acidosis and potassium depletion chronically, it is not uncommon in an acute situation such as this. A.B. has a bicarbonate deficit; thus, she should be treated with alkali replacement, and the offending agent, if confirmed to be lead, should be removed concurrently. Her serum potassium is also dangerously low and bicarbonate correction could further decrease it. A.B. needs potassium supplementation. The clinician should obtain hourly blood samples for electrolytes until her potassium is >3.5 mEq/L. In adults such as A.B., chronic treatment often is not needed because acidosis is self-limited. A.B., however, should be treated with sodium bicarbonate until proximal RTA resolves. Very large doses of bicarbonate (6–10 mEq/kg/day) would be required to increase serum bicarbonate to the normal range.¹⁰ In adults with proximal RTA, however, the goal is to increase serum bicarbonate to no more than 18 mEq/L.³¹ Bicarbonate can be provided as sodium bicarbonate tablets (8 mEq/600-mg tablet) or Shohl's solution. Shohl's solution, USP, contains 334 mg citric acid and 500 mg sodium citrate per 5 mL. Sodium citrate is metabolized to sodium bicarbonate in the liver. Shohl's solution provides 1 mEq of sodium and 1 mEq of bicarbonate per milliliter of solution. Therapy for A.B. should be initiated with 1 mEq/kg/day. The clinician should monitor A.B.'s lithium levels while she is receiving alkali therapy. Sodium ingestion might increase renal lithium excretion and exacerbate her bipolar disorder. Because of severe hypokalemia resulting from alkali administration, supplemental potassium as chloride, bicarbonate, acetate, or citrate salts also should be administered.

Metabolic Acidosis With Elevated Anion Gap

Evaluation and Osmolal Gap

7. G.D., a 34-year-old, 60-kg man, is brought to the emergency department (ED) by the police in a semicomatose state. He was found lying on the floor of his hotel room 30 minutes ago. G.D. has a long history of alcohol abuse. In the ED, supine blood pressure (BP) is 120/60 mmHg, pulse is 100 beats/minute, and respiratory rate is 40 breaths/minute. G.D.'s pupils are reactive, and mild papilledema is noted. Laboratory tests reveal the following: serum Na, 140 mEq/L (normal, 135–145 mEq/L); K, 5.8 mEq/L (normal,

3.5–5.0 mEq/L); Cl, 103 mEq/L (normal, 95–105 mEq/L); blood urea nitrogen (BUN), 25 mg/dL (normal, 10–26 mg/dL); creatinine, 1.4 mg/dL (normal, 0.7–1.4 mg/dL); and fasting glucose, 150 mg/dL (normal, 70–105 mg/dL). ABG include pH, 7.16 (normal, 7.35–7.45); PaCO₂, 23 mmHg (normal, 35–45); HCO₃⁻, 8 mEq/L (normal, 22–26). His toxicology screen is negative for alcohol and his serum osmolality is 332 mOsm/kg (normal, 280–295).

What acid-base disturbance is present in G.D., and what are possible causes of the disorder?

[SI units: Na, 140 mmol/L; K, 5.8 mmol/L; Cl, 103 mmol/L; BUN, 8.9 mmol/L (normal, 3.57–9.28); creatinine, 124 mmol/L (normal, 62–124); fasting glucose, 8.3 mmol/L (normal, 2.8–5.8); PaCO₂, 3.1 kPa; HCO₃⁻, 8 mmol/L; osmolality, 332 mmol/kg (normal, 280–295)]

G.D. has an acidosis (pH, 7.16; HCO₃⁻, 8 mEq/L) with a large AG (29 mEq/L). Subtracting 10 from the anion gap of 29 and adding this value to his serum bicarbonate concentration (see Step 5 in above section on evaluation of acid base disorders) yields a value of 27, suggesting no other metabolic abnormality is present.

An elevated AG metabolic acidosis often indicates lactic acidosis resulting from intoxications (e.g., salicylates, acetaminophen, methanol, ethylene glycol, paraldehyde, metformin) or ketoacidosis induced by diabetes mellitus, starvation, or alcohol.^{14,29,33,39,52,56–61} The sixth step in the stepwise approach leads to the consideration of additional laboratory tests that may be helpful in the differential diagnosis of an elevated AG. These include serum ketones, glucose, lactate, BUN, creatinine, and plasma osmolal gap.³³ Osmolal gap is defined as the difference between measured serum osmolality (SO) and calculated SO using Equation 10-7.

$$\text{Calculated SO (mOsm/Kg)} = 2 \times \text{Na}^+ (\text{mEq/L}) + \frac{\text{Glucose (mg/dL)}}{18} + \frac{\text{BUN (mg/dL)}}{2.8} \quad (10-7)$$

When the difference between measured and calculated SO is >10 mOsm/kg, the presence of an unmeasured osmotically active substance, such as ethanol, methanol, or ethylene glycol, should be considered.^{33,61,62} G.D.'s calculated SO is 297 mOsm/kg, compared with the measured value of 332; therefore, his osmolal gap is 35 mOsm/kg. An increase in the anion gap and osmolal gap, without diabetic ketoacidosis or chronic renal failure, suggests the possibility of metabolic acidosis resulting from a toxic ingestion.³³ On the basis of G.D.'s presentation (papilledema, history of alcohol abuse, increased osmolal gap, increased AG metabolic acidosis), methanol intoxication should be considered.

Causes

METHANOL-INDUCED

8. How would G.D.'s methanol intake induce metabolic acidosis with an elevated anion AG?

Methanol intoxication results in the formation of two organic acids, formic and lactic acid, which consume bicarbonate with production of an AG metabolic acidosis. Alcohol dehydrogenase in the liver metabolizes methanol to formaldehyde and then to formic acid. The formic acid contributes to the metabolic acidosis and also is responsible for the retinal edema and blindness associated with methanol intoxication.^{33,34,61}

Table 10-5 Classification of Metabolic Alkalosis

| Saline-Responsive | Saline-Resistant |
|----------------------------------|---------------------|
| Diuretic therapy | Normotensive |
| Extracellular volume contraction | Potassium depletion |
| Gastric acid loss | Hypercalcemia |
| Vomiting | Hypertensive |
| Nasogastric suction | Mineralocorticoids |
| Exogenous alkali administration | Hyperaldosteronism |
| Blood transfusions | Hyperreninism |
| | Licorice |

Serum lactic acid concentrations also are increased in patients with methanol intoxication.³³ Lactic acidosis classically has been divided into type A, which is associated with inadequate delivery of oxygen to the tissue, and type B, which is associated with defective oxygen utilization at the mitochondrial level (Table 10-5). Although these distinctions often are not clear, the lactic acidosis caused by methanol intoxication is most consistent with the type B variety.⁶³

Treatment

9. How should G.D.'s methanol intoxication be managed acutely?

ANTIDOTES

In addition to expert management of G.D.'s airway, breathing, and circulation, therapy should be directed toward treatment of the underlying cause and may include additional supportive management. Ethanol and fomepizole (Antizol) compete with methanol for alcohol dehydrogenase binding sites.^{34,61–65} Because ethanol and fomepizole have much greater affinity for alcohol dehydrogenase than methanol, these agents may reduce the conversion of methanol to its toxic metabolite, formic acid. The unmetabolized methanol then is excreted by the lungs and kidneys. Fomepizole can be given intravenously (IV) as a 15 mg/kg loading dose over 30 minutes, followed by bolus doses of 10 mg/kg Q 12 hr. Because of induction of metabolism of fomepizole, doses should be increased to 15 mg/kg every 12 hours if therapy is required beyond 2 days.⁶¹ Fomepizole is usually continued until the serum methanol concentration is <20 mg/dL (6.2 mmol/L). Adverse effects of fomepizole are relatively mild, consisting of headache, nausea, dizziness, agitation, metallic taste, abnormal smell, and rash. Because of its high cost and infrequent use, some hospitals might not have fomepizole readily available. In such cases, ethanol is an alternative. Administration of IV ethanol as an antidote can be technically difficult and may produce central nervous system (CNS) depression.^{61,64} For patients with methanol toxicity, an IV loading dose of 0.6 gm/kg ethanol solution can be administered over 30 minutes, followed by a continuous infusion of about 150 mg/kg/hour for drinkers and 70 mg/kg/hour for nondrinkers. Serum ethanol concentration should be maintained >100 mg/dL.^{34,63} Charcoal may be considered to bind other agents that may be co-ingested.^{34,66}

When other low-molecular-weight toxins, such as ethanol or ethylene glycol, are not present, the serum methanol level can be estimated by multiplying the patient's osmolal gap by a standardized conversion factor of 2.6. G.D.'s osmolal gap of

35 mOsm/L, therefore, may reflect a methanol level of ~ 91 mg/dL ($35 \text{ mOsm/L} \times 2.6$). When methanol blood levels are higher than 50 mg/dL, hemodialysis is indicated to rapidly reduce concentrations of methanol and its toxic metabolite. The dosage of fomepizole or ethanol should be increased in patients receiving hemodialysis to account for the increased elimination of these antidotes.^{34,63} Ethylene glycol poisoning can also be treated by using fomepizole or ethanol.

BICARBONATE

Severe acidosis causes reduced myocardial contractility, impaired response to catecholamines, and impaired oxygen delivery to tissues as a result of 2,3-diphosphoglycerate depletion. For this reason, some clinicians have judiciously administered IV sodium bicarbonate to patients with metabolic acidosis in an attempt to raise the arterial pH to about 7.20.^{67–69} If IV sodium bicarbonate is given, the amount required to correct serum HCO_3^- and arterial pH can be estimated using Equation 10-8 as follows:

$$\text{Bicarbonate dose (mEq)} = 0.5 \text{ (L/kg)} \times \text{Body Weight (kg)} \times \text{Desired increase in serum } \text{HCO}_3^- \text{ (mEq/L)} \quad (10-8)$$

Bicarbonate distributes to approximately 50% of total body weight (thus, the factor of 0.5 L/kg in Equation 10-8). To prevent overtreatment, bicarbonate doses should only attempt to increase the bicarbonate concentration by 4 to 8 mEq/L (see Question 10).⁶⁸ For G.D., the dose required to raise serum bicarbonate from 8 to 12 mEq/L amounts to 120 mEq of bicarbonate ($0.5 \text{ L/kg} \times 60 \text{ kg} \times 4 \text{ mEq/L}$; Equation 10-8). Clinical assessment of the effect of bicarbonate can be determined about 30 minutes after administration.⁶⁸ Arterial pH and serum bicarbonate concentrations should be obtained before any additional therapy.

Risks of Bicarbonate Therapy

10. What are the risks of G.D.'s bicarbonate therapy?

Concerns about the risks of bicarbonate administration and the failure of studies to demonstrate significant short-term benefits have raised questions about the appropriateness of bicarbonate therapy in metabolic acidosis, particularly in ketoacidosis and lactic acidosis caused by cardiac arrest or other hypoxic events.^{69–76} Bicarbonate administration can result in overalkalinization and a paradoxical transient intracellular acidosis. Whereas arterial pH can increase rapidly following bicarbonate administration, intracellular pH increases more slowly because of slow penetration of the negatively charged bicarbonate ion across cell membranes. The bicarbonate in plasma, however, is converted rapidly to carbonic acid, and the carbon dioxide tension increases as a result (Equation 10-2). Because CO_2 diffuses into cells more rapidly than HCO_3^- , the intracellular $\text{HCO}_3^-:\text{CO}_2$ ratio decreases, resulting in a decrease in intracellular pH. This intracellular acidosis will persist as long as bicarbonate administration exceeds the CO_2 excretion; therefore, adequate tissue perfusion and ventilation must be provided in patients with diminished CO_2 excretion (e.g., cardiac or pulmonary failure).⁷¹

Overalkalinization also will cause a shift to the left in the oxygen-hemoglobin dissociation curve. This shift increases hemoglobin affinity for oxygen, decreases oxygen delivery to

tissues, and potentially increases lactic acid production and accumulation.³⁴ Sodium bicarbonate administration also can cause hypernatremia, hyperosmolality, and volume overload; however, the excessive sodium and water retention usually can be avoided by the administration of loop diuretics.^{34,62} Hypokalemia is another potential adverse effect of bicarbonate therapy. Acidosis stimulates movement of potassium from intracellular to extracellular fluid in exchange for hydrogen ions. When acidosis is corrected, potassium ions move intracellularly, and hypokalemia can occur. This translocation of potassium tends to reduce serum potassium levels by ~ 0.4 to 0.6 mEq/L for each 0.1 unit increase in pH, although wide interpatient variability in this relationship exists.^{5,8} In G.D. and other patients with organic acid intoxications, raising extracellular pH helps to provide a gradient to shift the toxin from the CNS and “trap” it into the blood and urine, enhancing elimination. To prevent the risks of bicarbonate therapy, G.D.'s mental status, serum sodium and potassium levels, and ABG should be monitored.

ALTERNATIVE ALKALINIZING THERAPY

Although sodium bicarbonate is the most commonly used agent to raise arterial pH, alternative therapies are available. Sodium lactate and acetate have been used in select patients; however, these agents, which require metabolic conversion to bicarbonate, are associated with many of the same risks as sodium bicarbonate (i.e., sodium and fluid overload, overalkalinization, carbon dioxide production).³⁹

Tromethamine acetate (THAM), a sodium-free organic amine with a pH of 8.6, is available commercially as a 0.3 M (36 mg/mL) solution for IV administration. THAM can combine with hydrogen ions from carbonic acid and lactic, pyruvic, or other metabolic acids; however, its role in the management of metabolic acidosis needs clarification. THAM may produce hyperkalemia in patients with renal impairment and is contraindicated in anuric or uremic patients. Administration of THAM also has been associated with other serious side effects, including respiratory depression, increased coagulation times, and hypoglycemia.^{77–80} Carbicarb and dichloroacetate have been used investigatively in the treatment of metabolic acidosis.^{39,63,81} Carbicarb and THAM are better than bicarbonate at improving extracellular pH and bicarbonate and intracellular pH, while not increasing CO_2 ; however, neither has yet resulted in better patient outcomes.^{5,24,71} Hemofiltration and “continuous renal replacement” therapies have been advocated for patients with lactic acidosis, especially in Europe; however, their roles need further study.

METABOLIC ALKALOSIS

Metabolic alkalosis is associated with an increase in serum bicarbonate concentration and a compensatory increase in PaCO_2 (caused by hypoventilation). The two general classifications of metabolic alkalosis, saline-responsive and saline-resistant (Table 10-6), are usually distinguishable based on an assessment of the patient's volume status, BP, and urinary chloride concentration.

Saline-responsive metabolic alkalosis is associated with disorders that result in the loss of chloride-rich, bicarbonate-poor fluid from the body (e.g., vomiting, nasogastric suction, diuretic therapy, cystic fibrosis). Physical examination

Table 10-6 Common Causes of Respiratory Acidosis

| | |
|----------------------------|---------------------------------|
| Airway Obstruction | Cardiopulmonary |
| Foreign body aspiration | Cardiac arrest |
| Asthma | Pulmonary edema or infiltration |
| COPD | Pulmonary embolism |
| Adrenergic blockers | Pulmonary fibrosis |
| CNS Disturbances | Neuromuscular |
| Cerebral vascular accident | Amyotrophic lateral sclerosis |
| Sleep apnea | Guillain-Barré syndrome |
| Tumor | Myasthenia gravis |
| CNS depressant drugs | Hypokalemia |
| Barbiturates | Hypophosphatemia |

| Opioids | Aminoglycosides |
| | Antiarrhythmics |
| | Lithium |
| | Phenytoin |

CNS, central nervous system; COPD, chronic obstructive pulmonary disease.

may reveal volume depletion (e.g., orthostatic hypotension, tachycardia, poor skin turgor), and the urinary chloride concentration often will be <10 to 20 mEq/L (although urine chloride levels may be >20 mEq/L in patients with recent diuretic use).^{10,35,82}

Severe hypokalemia or excessive mineralocorticoid activity can result in a saline-resistant metabolic alkalosis, but this disorder is rare in comparison with saline-responsive metabolic alkalosis. Saline-resistant metabolic alkalosis should be suspected in alkalemic patients with evidence of increased ECF volume, hypertension, or high urinary chloride values (>20 mEq/L) without recent diuretic use.^{10,82}

Evaluation

11. K.E., a 60-year-old, 50-kg woman, was admitted to the hospital 4 days ago with peripheral edema and pulmonary congestion consistent with a congestive heart failure exacerbation. Since admission, she has been treated aggressively with furosemide 80 to 120 mg IV daily, which has generated approximately 3 L of urine output each day. Her chest radiograph findings and peripheral edema now show considerable improvement with diuresis; however, she now complains of dizziness when she gets out of bed to go to the bathroom. Physical examination reveals a tachycardic (heart rate [HR], 100 beats/minute), a thin elderly woman with poor skin turgor and slight muscle weakness. K.E.'s electrocardiogram shows flattened T waves and U waves. Laboratory tests reveal the following: serum Na, 138 mEq/L; K, 2.5 mEq/L; Cl, 92 mEq/L; creatinine, 0.9 mg/dL; BUN, 28 mg/dL; pH, 7.49; PaCO₂, 46 mmHg; and HCO₃⁻, 34 mEq/L. Urine Cl concentration is 60 mEq/L.

What acid-base disorder is present in K.E.?

[SI units: Na, 138 mmol/L; K, 2.5 mmol/L; Cl, 92 mmol/L; creatinine, 79.6 mmol/L; BUN, 10 mmol/L; PaCO₂, 6.1 kPa; HCO₃⁻, 34 mmol/L; urine Cl, 60 mmol/L]

Using the stepwise approach to the evaluation of acid-base disorders as previously described, K.E.'s elevated pH is consistent with alkalosis. Furosemide-induced diuresis may be a clue to her acid-base disorder. The increased serum HCO₃⁻

and increased PaCO₂ suggest primary metabolic alkalosis with respiratory compensation. K.E.'s anion gap is 12, suggesting no additional metabolic acid-base abnormalities are present. A PaCO₂ of 46 mmHg suggests normal respiratory compensation for metabolic alkalosis. Appropriate treatment of the metabolic alkalosis should return her PaCO₂ to normal if there is no underlying pulmonary disease.

Causes

Diuretic-Induced

12. What is the most likely cause of K.E.'s acid-base imbalance?

Common causes of metabolic alkalosis are listed in Table 10-6. The hypokalemic, hypochloremic, metabolic alkalosis in K.E. most likely is the result of diuretic-induced volume contraction. The incidence of this adverse effect is influenced by the type, dose, and dosing frequency of the diuretic.

Diuretics cause metabolic alkalosis (sometimes referred to as a "contraction alkalosis") by the following mechanisms. First, they enhance excretion of sodium chloride and water, resulting in extracellular volume contraction. Volume contraction alone will cause only a modest increase in plasma bicarbonate; however, volume contraction also stimulates aldosterone release. Aldosterone increases distal tubular sodium reabsorption and induces hydrogen ion and potassium secretion, resulting in alkalosis and hypokalemia. In addition, hypokalemia induced by diuretics will stimulate intracellular movement of hydrogen ions to replace cellular potassium, producing extracellular alkalosis. Hypochloremia also is important in sustaining metabolic alkalosis. In a hypochloremic state, sodium will be reabsorbed, accompanied by bicarbonate generated by secreted hydrogen (Fig. 10-1).⁸²⁻⁸⁴

Treatment

13. How should K.E.'s acid-base imbalance be corrected and monitored?

Treatment of metabolic alkalosis depends on removal of the cause. K.E.'s diuretic therapy should be temporarily discontinued until her volume status and electrolytes can be restored. The initial goal is to correct fluid deficits and replace chloride and potassium by infusing sodium and potassium chloride. As long as hypochloremia exists, renal bicarbonate excretion will not occur and the alkalosis will not be corrected.⁸³ The severity of alkalosis dictates how rapidly fluid and electrolytes should be administered. In patients with hepatic or renal failure or congestive heart failure, infusion of large volumes of sodium and potassium salts can produce fluid overload or hyperkalemia. Thus, fluid and electrolyte replacement should proceed cautiously and these patients should be monitored closely for these complications.

Potassium chloride should be administered to correct K.E.'s hypokalemia. The amount of potassium required to replace total body stores is difficult to determine accurately because 98% of the potassium in the body is intracellular. Although wide variation exists, for each 1 mEq/L decrease in K⁺ from an ECF concentration of 4 mEq/L, the total body K⁺ deficit is about 4 to 5 mEq/kg.¹⁰ K.E.'s serum potassium is 2.5 mEq/L, which correlates with a decrease of about 350 mEq in total body potassium stores. K.E. should be treated with the chloride

salt to ensure potassium retention and correction of alkalosis. Potassium replacement can be achieved over several days with supplements of 100 to 150 mEq/day given either orally in divided doses or as a constant IV infusion. K.E.'s laboratory tests for BUN, creatinine, chloride, sodium, and potassium should be monitored during sodium and potassium chloride therapy. As noted above, hypercapnia should disappear after correction of the alkalemia, which can be confirmed with an ABG, if clinically indicated.

14. What other agents are available to treat K.E.'s alkalosis if fluid and electrolyte replacement does not correct the arterial pH?

Patients unresponsive to sodium and potassium chloride therapy or those at risk for complications with these agents can be treated with acetazolamide, hydrochloric acid (HCl), or a hydrochloric acid precursor. The most commonly used agent is acetazolamide, a carbonic anhydrase inhibitor that blocks hydrogen ion secretion in the renal tubule, resulting in increased excretion of sodium and bicarbonate. Although the serum bicarbonate concentration often improves with acetazolamide, metabolic alkalosis may not completely resolve. Other concerns with the use of acetazolamide include its ability to promote kaliuresis and its relative lack of effect in patients with renal dysfunction.^{82,85,86}

A solution of 0.1 N HCl may be administered to patients who require rapid correction of alkalemia. The dose of HCl is based on the bicarbonate excess using Equation 10-9, where the factor $0.5 \times$ body weight (kg), represents the estimated bicarbonate space.^{10,82,83,85}

$$\text{Dose of HCl (mEq)} = 0.5 \times \text{Body Weight (kg)} \\ \times (\text{plasma bicarbonate} - 24) \quad (10-9)$$

Parenteral hydrochloric acid is prepared extemporaneously by adding the appropriate amount of 1 N HCl through a 0.22-micron filter into a glass bottle containing 5% dextrose or normal saline. The dilute solution should be administered via central venous catheter in the superior vena cava to reduce the risk of extravasation and tissue damage. The infusion rate should not exceed 0.2 mEq/kg/hour.⁸⁵ ABG should be monitored at least every 4 hours during the infusion. HCl should not be added to total nutrient solutions.⁸⁶

Precursors of hydrochloric acid, such as ammonium and arginine hydrochloride, are not recommended.⁸² The adverse effect profile of these agents has significantly limited their role.⁸⁵ Ammonium hydrochloride is metabolized to HCl and NH_3 in the liver. Severe ammonia intoxication with CNS depression can occur during rapid infusion of ammonium hydrochloride or in patients with liver disease.⁸² Arginine can cause rapid shifts in potassium from the intracellular to extracellular space, resulting in dangerous hyperkalemia.⁸²

RESPIRATORY ACIDOSIS

Respiratory acidosis occurs as a result of inadequate ventilation by the lungs. When the lungs do not excrete CO_2 effectively, the PaCO_2 rises. This elevation in PaCO_2 (a functional acid) causes a fall in pH (Equations 10-3 and 10-5). Common causes of respiratory acidosis are listed in Table 10-7. They generally can be categorized into conditions of airway obstruction, reduced stimulus for respiration from the CNS, failure of the heart

Table 10-7 Common Causes of Respiratory Alkalosis

or lungs, and disorders of the peripheral nerves or skeletal muscles required for ventilation.⁸⁷

Evaluation

15. B.B., a 56-year-old man, is admitted to the hospital for treatment of an exacerbation of chronic obstructive pulmonary disease (COPD). He complains of worsening shortness of breath and increased production of sputum for the past 3 days. He has also noted a mild headache, a flushed feeling, and drowsiness within the past 24 hours. He has a history of COPD, hypertension, coronary artery disease, and low back pain. Current medications are ipratropium (Atrovent) inhaler two puffs QID, salmeterol (Serevent) dry powder inhaler one inhalation BID, hydrochlorothiazide 25 mg daily, diltiazem (Cardizem LA) 240 mg daily, and diazepam (Valium) 5 mg TID PRN for back pain.

Vital signs include respiratory rate of 16 breaths/minute and HR of 90 beats/minute. Diffuse wheezes and rhonchi are heard on chest auscultation. Laboratory tests reveal the following: Na, 140 mEq/L; K, 4.0 mEq/L; Cl, 100 mEq/L; pH, 7.32; PaCO_2 , 58 mmHg; PaO_2 , 58 mmHg; and HCO_3^- , 29 mEq/L. B.B.'s baseline ABG at the physician's office last month was pH, 7.35; PaCO_2 , 51 mmHg; PaO_2 , 62 mmHg; and HCO_3^- , 28 mEq/L.

Which of B.B.'s signs and symptoms are consistent with the diagnosis of respiratory acidosis?

[SI units: Na, 138 mmol/L; K, 2.5 mmol/L; Cl, 92 mmol/L; PaCO_2 , 7.7 and 6.8 kPa; PaO_2 , 7.7 and 8.3 kPa; HCO_3^- , 29 and 28 mmol/L]

A stepwise evaluation reveals a respiratory acidosis. A history of COPD and physical findings of dyspnea, headache, drowsiness, and flushing support the ABG evaluation. Respiratory acidosis also can cause more severe symptoms, including CNS effects, such as disorientation, confusion, delirium, hallucinations, and coma. These CNS abnormalities probably are partly caused by the direct effects of carbon dioxide. Hypoxemia (decreased PaO_2), which commonly accompanies respiratory acidosis, also contributes to these symptoms. Elevated PaCO_2 causes cerebral vascular dilation, resulting in headache caused by increased blood flow and increased intracranial

pressure. Cardiovascular effects typically include tachycardia, arrhythmias, and peripheral vasodilation.⁸⁸

16. Is the respiratory acidosis present in B.B. consistent with an acute or a chronic disorder?

Following the stepwise approach, it is determined that B.B. has a respiratory acidosis. He has a normal AG. Comparing his current to previous values (e.g., pH, PaCO₂, HCO₃⁻), it appears B.B. has an acute on chronic respiratory acidosis since his baseline PaCO₂ was 51 mmHg with an acute worsening to 58 mmHg. In respiratory acidosis, increased renal reabsorption of bicarbonate compensates for the increase in PaCO₂; however, at least 48 to 72 hours are needed for this compensatory mechanism to become fully established.¹⁰ Patients with COPD commonly present with an “acute-on-chronic” respiratory acidosis similar to B.B.

Causes

17. What potential causes of respiratory acidosis are present in B.B.?

Respiratory acidosis often is caused by airway obstruction, as shown in Table 10-7.^{87,88} Chronic obstructive airway disease is a common cause of both acute and chronic respiratory acidosis. Upper respiratory tract infections, such as acute bronchitis, can worsen airway obstruction and produce acute respiratory acidosis.

Drug-Induced

B.B.’s drug therapy also may be contributing to respiratory insufficiency. Many drugs (Table 10-7) decrease ventilation, but usually these drugs only significantly affect patients who are predisposed to respiratory problems because of underlying diseases. Because B.B. has COPD, he may be more sensitive to drugs affecting respiration. The benzodiazepines, barbiturates, and opioids minimally decrease respiration in normal subjects and in most patients with COPD when given usual therapeutic doses. These drugs, however, can cause significant respiratory insufficiency when administered either in large doses or in combination with other respiratory depressant drugs.⁸⁸ B.B.’s diazepam may be contributing to hypoventilation and respiratory acidosis and should be withdrawn from his regimen. Nonselective adrenergic blocking drugs should not be used in patients with COPD.

Treatment

18. How should B.B.’s respiratory acidosis be treated?

As with most cases of respiratory acidosis, treatment primarily involves correction of the underlying cause of res-

piratory insufficiency. In this case, treatment of acute bronchospasm with ipratropium or an α -adrenergic agent, such as inhaled albuterol, is warranted. Corticosteroids, such as methylprednisolone (60–125 mg Q 6–12 hr initially) are commonly used in hospitalized patients with acute exacerbations of COPD.⁸⁹ Antibiotic therapy with a β -lactam or β -lactamase inhibitor should be considered in hospitalized patients producing purulent, large-volume secretions.⁹⁰ B.B.’s respiratory status should be monitored closely during his hospitalization. If the acidosis, hypercarbia, or associated hypoxemia worsen, noninvasive positive pressure ventilation or intubation with mechanical ventilation may be required.⁶⁸

Treatment with IV sodium bicarbonate is not recommended in most cases of acute respiratory acidosis because of the risks associated with bicarbonate therapy (see Question 10) and because an absolute deficiency of bicarbonate is not present. When the excess CO₂ is excreted, arterial pH should return to normal. Hypercapnia should not be overcorrected, because hypocapnia results in decreased lung compliance, increases dysfunctional surfactant production, and shifts the oxyhemoglobin dissociation curve to the left, restricting the release of oxygen to tissues.^{75,76,91}

RESPIRATORY ALKALOSIS

Respiratory alkalosis usually is not a severe disorder. Excessive rate or depth of respiration results in increased excretion of carbon dioxide, a fall in PaCO₂, and a rise in arterial pH. Common causes of respiratory alkalosis are presented in Table 10-8. Many conditions can cause respiratory alkalosis by stimulating respiratory drive in the CNS. In addition, pulmonary diseases can stimulate receptors in the lung to increase ventilation, and conditions that decrease oxygen delivery to tissues also can stimulate ventilation, causing respiratory alkalosis.^{92,93}

Evaluation

19. S.P., a 35-year-old, 60-kg woman, is admitted for treatment of presumed bacterial pneumonia. She was in good health until 24 hours before presentation when she noted a fever; increased a productive cough with thick, yellowish sputum; and chest pain on deep inspiration. She has taken aspirin 650 mg Q 4 hr since the onset of fever, with mild relief. Since arriving in the ED, she has become anxious and lightheaded and has developed tingling in her hands, feet, and lips. Vital signs include the following: temperature, 38°C; respiratory rate, 24 breaths/minute; HR, 110 beats/minute; and BP, 135/70 mmHg. Physical examination reveals dullness to percussion, rales, and decreased breath sounds over the left lower lung field.

Laboratory findings include the following: serum Na, 135 mEq/L; Cl, 105 mEq/L; pH, 7.49; PaCO₂, 30 mmHg; PaO₂,

Table 10-8 Laboratory Values in Simple Acid-Base Disorders

| Disorder | Arterial pH | Primary Change | Compensatory Change |
|-----------------------|-------------|--------------------------------|--------------------------------|
| Metabolic acidosis | ↓ | ↓HCO ₃ ⁻ | ↓PaCO ₂ |
| Respiratory acidosis | ↓ | ↑PaCO ₂ | ↑HCO ₃ ⁻ |
| Metabolic alkalosis | ↑ | ↑HCO ₃ ⁻ | ↑PaCO ₂ |
| Respiratory alkalosis | ↑ | ↓PaCO ₂ | ↓HCO ₃ ⁻ |

90 mmHg; and HCO_3^- , 22 mEq/L. Gram stain of sputum reveals 25 white blood cells (WBC) per high-power field and many gram-positive diplococci. WBC count is 15,400 cells/mm³ (normal, 3,500–10,500 cells/mm³) with a left shift. A left lower lobe infiltrate is seen on chest radiograph.

What acid-base disorder is present in S.P.?

[SI units: PaCO_2 , 4.0 kPa; PaO_2 , 12.0 kPa; HCO_3^- , 22 mmol/L; other SI units are: Na, 135 mmol/L; Cl, 105 mmol/L]

Steps 1 to 3 in the evaluation of the ABG values, as described previously, indicate a respiratory alkalosis (increased pH, decreased PaCO_2). The history and physical findings of deep, rapid breathing and tingling sensations are clues to the etiology. This disorder is most likely acute because her HCO_3^- concentration is normal. She does not have an AG. If a large AG was present, it would suggest she has a coexisting metabolic acidosis, possibly caused by salicylate intoxication (see below).

20. Which of S.P.'s signs and symptoms are consistent with the diagnosis of acute respiratory alkalosis?

Respiratory alkalosis typically produces paresthesias of the extremities and perioral region, lightheadedness, confusion, decreased mental acuity, and tachycardia.^{5,6,10} Increased rate and depth of respiration may be evident. Simple respiratory alkalosis rarely produces life-threatening abnormalities.

Causes

21. What is the cause of the acid-base disorder in S.P.?

Common causes of respiratory alkalosis are listed in Table 10-8.^{5,6,10,92–94} Based on physical examination, laboratory findings, and chest radiograph, S.P. appears to have an acute bacterial pneumonia. Pneumonia and other pulmonary diseases can result in stimulation of ventilation and respiratory alkalosis, even with a normal PaO_2 , as in this case. The anxiety S.P. is experiencing also may be contributing to respiratory alkalosis by producing the familiar anxiety-hyperventilation syndrome. Although salicylate intoxication is a potential cause of respiratory alkalosis because of the direct respiratory stimulant effect of salicylate,⁹⁴ S.P. displays few other symptoms of salicylate intoxication (e.g., nausea, vomiting, tinnitus, altered mental status, elevated AG metabolic acidosis). The total aspirin dose reportedly ingested (65 mg/kg over 24 hours) is not large enough to be associated with significant risk for toxicity.

Treatment

22. What is the appropriate treatment for S.P.'s respiratory alkalosis?

Similar to respiratory acidosis, treatment of respiratory alkalosis usually involves correcting the underlying disorder. Initiation of appropriate antibiotic therapy is indicated in this case. Simple respiratory alkalosis is unlikely to cause life-threatening symptoms, although mortality rates for critically ill patients with this disorder can be high.⁸⁸ The well-known remedy of rebreathing expired air from a paper bag for treatment of hyperventilation associated with anxiety appears to

be effective for this cause of respiratory alkalosis and may be helpful for S.P.

MIXED ACID-BASE DISORDERS

Evaluation

23. B.L., a 58-year-old man, transferred from a nursing home 2 days previously, is disorientated and lethargic. He was doing well until 1 week before admission, when the staff noted that he was somnolent. He progressively became more lethargic and could no longer remember the names of other persons. B.L. has a history of alcoholic cirrhosis, non-insulin-dependent diabetes mellitus, and hypertension. Medications before admission were nadolol 80 mg QD, isosorbide mononitrate 20 mg BID, glyburide 10 mg QD, and spironolactone 50 mg BID. On admission, B.L. was disoriented to person, place, and time and was difficult to arouse. Vital signs include the following: temperature, 37°C; respirations, 16 breaths/minute; HR, 70 beats/minute; and BP, 154/92 mmHg. Physical examination revealed asterixis and mild ascites. Laboratory studies included the following: Na, 133 mEq/L; K, 4.3 mEq/L; Cl, 106 mEq/L; BUN, 5 mg/dL; creatinine, 0.7 mg/dL; fasting glucose, 150 mg/dL; albumin, 3.2 g/dL (normal, 3.6–5.0 g/dL); and ammonia, 120 $\mu\text{mol/L}$ (normal, 19–43 $\mu\text{mol/L}$); ABG: pH, 7.43; PaCO_2 , 30 mmHg; PaO_2 , 90 mmHg; and HCO_3^- , 19 mEq/L.

On admission, spironolactone was increased to 75 mg BID and lactulose 60 mL PO QID was started for treatment of hepatic encephalopathy. Within the first 24 hours of lactulose therapy, B.L. produced four loose, watery stools; however, his mental status worsened to the point of being unresponsive, his BP dropped to 100/60 mmHg, and his breathing became labored and eventually required mechanical ventilation. At the time of intubation, his laboratory values were Na, 136 mEq/L; K, 4.5 mEq/L; Cl, 105 mEq/L; BUN, 10 mg/dL; creatinine, 1.2 mg/dL; arterial pH, 7.06; PaCO_2 , 48 mmHg; PaO_2 , 58 mmHg; and HCO_3^- , 13 mEq/L. Gram stain of peritoneal fluid revealed many WBC and gram-negative rods; the diagnosis of spontaneous bacterial peritonitis with possible septicemia is made.

Describe B.L.'s acid-base status on admission and at the current time.

[SI units: Na, 133 and 136 mmol/L; K, 4.3 and 4.5 mmol/L; Cl, 106 and 105 mmol/L; BUN, 1.8 and 3.6 mmol/L; creatinine, 62 and 106 mmol/L; fasting glucose, 8.3 mmol/L; albumin, 32 g/L; PaCO_2 , 4.0 and 6.4 kPa; PaO_2 , 12.0 and 7.7 kPa; HCO_3^- , 19 and 13 mmol/L]

An evaluation of B.L.'s ABG using steps 1 and 2 (in the section on evaluation of acid-base disorders) reveals abnormal PaCO_2 and serum bicarbonate values, suggesting the existence of an underlying acid-base abnormality. The direction of change in his PaCO_2 and serum HCO_3^- along with a pH of 7.43 suggests a respiratory alkalosis is a primary disorder. His calculated AG of 8 is not increased. Examination of the ranges of expected compensation in Table 10-3 reveals that these values are indeed consistent with chronic respiratory alkalosis (serum HCO_3^- decreased by 0.5 mEq/L for each 1-mmHg drop in PaCO_2). B.L.'s history of alcohol-induced liver disease is consistent with the diagnosis of chronic respiratory alkalosis (Table 10-8).^{8,10}

The second set of ABG reveals severe acidosis. B.L.'s serum bicarbonate has fallen from 19 to 13 mEq/L, and his PaCO_2

has increased acutely from 30 to 48 mmHg. Because these values have changed in opposite directions, a mixed acid-base abnormality should be suspected.

The diagnosis of a mixed, metabolic and respiratory acidosis can be confirmed by applying the stepwise approach outlined previously. If the acidosis was purely metabolic in nature, a serum HCO_3^- of 13 mEq/L should result in hyperventilation and a low PaCO_2 . B.L.'s PaCO_2 of 48 mmHg is high, which would be consistent with coexistent respiratory acidosis. The anion gap is 18, indicating an AG metabolic acidosis is present. The excess AG ($\text{AG} - 10 = 8$) added to B.L.'s gap of 18 yields a corrected HCO_3^- of 26 which is normal. This suggests no additional metabolic disturbances are present.

Causes

24. What are possible causes for the mixed acidosis in B.L.?

The AG should be calculated in all patients with a metabolic acidosis. B.L.'s calculated AG has increased from 8 to 18 mEq/L (11 and 21 mEq/L, respectively, after adjusting for hypoalbuminemia), suggesting that an elevated AG acidosis is now present. Septicemia from bacterial peritonitis can produce profound hypotension, which leads to tissue hypoperfusion, generation of lactic acid, and a subsequent elevation in the AG. Other causes of elevated AG metabolic acidosis can be excluded with additional laboratory data (e.g., serum ketones, glucose, osmolal gap).

Although diarrhea and spironolactone should be considered in the differential diagnosis, these are usually associated with hyperchloremic, normal AG metabolic acidosis (Table 10-2).⁹⁵ The coexisting respiratory acidosis is most likely the result of B.L.'s altered mental status and his diminished respiratory drive.

25. Over the next 6 hours, B.L.'s hepatic encephalopathy, peritonitis, and acid-base disorders are aggressively treated with lactulose, antibiotics, fluids, and mechanical ventilation. His most recent ABG reveals the following: pH, 7.45; PaCO_2 , 24 mmHg; PaO_2 , 90 mmHg; and HCO_3^- , 16 mEq/L. Ventilator settings are assist-control mode at 16 breaths/minute, tidal volume 700 mL, and inspired oxygen concentration 40%. B.L. is noted to be more awake, anxious, and initiating 25 to 30 breaths/minute. Describe the current acid-base status and probable cause.

[SI units: PaCO_2 , 3.2 kPa; PaO_2 , 12.0 kPa; HCO_3^- , 16 mmol/L]

Evaluation of the ABG reveals a pH at the upper limit of normal with significant decreases in both PaCO_2 and serum HCO_3^- concentration. This clinical scenario is most consistent with a mixed, acute respiratory alkalosis and ongoing metabolic acidosis. The time frame in which B.L.'s PaCO_2 decreased from 48 to 24 mmHg is consistent with acute respiratory alkalosis. B.L.'s low serum HCO_3^- suggests ongoing metabolic acidosis as a result of his septicemia. The metabolic acidosis should improve with time, given adequate antibiotic therapy and supportive measures that maintain BP and increase oxygen delivery to the tissues.

The acute respiratory alkalosis in this case is most likely caused by the mechanical ventilator, B.L.'s anxiety, or sepsis. In the assist-control mode, any inspiratory effort by B.L. results in delivery of a full assisted breath by the ventilator.⁹⁶ B.L.'s anxiety and resultant tachypnea are stimulating the ventilator to hyperventilate him, producing excessive CO_2 excretion and respiratory alkalosis. Appropriate changes in therapy may include use of an anxiolytic, analgesic if needed to treat pain, changing the ventilator mode, or probably a combination of these strategies.

BASIC PRINCIPLES

Body Water Compartments and Electrolyte Composition

In newborns, approximately 75% to 85% of the body weight is water. After puberty, the percentage of water per kilogram of weight decreases as the amount of adipose tissue increases with age.^{1,2} Body water constitutes 50% to 60% of the lean body weight (LBW) in adult men but only 45% to 55% in women because of their greater proportion of adipose tissue. The water content per kilogram of body weight further decreases with advanced age.

Two-thirds of the total body water resides in the cells (intracellular water). The extracellular water can be divided into different compartments: the interstitial fluid (12% LBW) and the plasma (5% LBW) are the two major compartments. Other compartments of the extracellular fluid include the connective tissues and bone water, the transcellular fluids (e.g., glandular

secretions), and other fluids in sequestered spaces, such as the cerebrospinal fluid.¹

The electrolyte composition differs between the intracellular and extracellular compartments. Potassium (K), magnesium (Mg), and phosphate (PO₄) are the major ions in the intracellular compartment, whereas sodium (Na), chloride (Cl), and bicarbonate (HCO₃) are predominant in the extracellular space.² Water travels freely across the cell membranes of most parts of the body. The cell membrane, however, is only selectively permeable to solutes. The impermeable solutes are osmotically active and can exert an osmotic pressure that dictates the distribution of water between fluid compartments. Water moves across the cell membrane from a region of low osmolality to one of high osmolality. Net water movement ceases when osmotic equilibrium occurs. Each fluid compartment contains a major osmotically active solute: potassium in the intracellular space and sodium in the extracellular fluid. The volumes of the

two compartments reflect the asymmetrically larger number of solute particles or osmoles inside the cells.^{2,3}

The capillary wall separates the interstitial fluid from plasma. Because sodium moves freely across the capillary wall, its concentration is identical across both sides of the wall. Therefore, no osmotic gradient is generated, and water distribution between these two spaces is not affected. Plasma proteins, which are confined in the vascular space, are the primary osmoles that affect water distribution between the interstitium and the plasma.² In contrast, urea, which traverses both the capillary walls and most cell membranes, is osmotically inactive.^{2,3}

Plasma Osmolality

Osmolality is defined as the number of particles per kilogram of water (mOsm/kg). It is determined by the number of particles in solution and not by particle size or valence. Nondissociable solutes, such as glucose and albumin, generate 1 mOsm/mmol of particles; and dissociable salts, such as sodium chloride liberate two ions in solution to produce 2 mOsm/mmol of salt. The osmolality of body fluid is maintained between 280 and 295 mOsm/kg. Because all body fluid compartments are iso-osmotic, plasma osmolality reflects the osmolality of total body water. Plasma osmolality can be measured by the freezing point depression method, or estimated by the following equation, which takes into account the osmotic effect of sodium, glucose, and urea^{2,3}:

$$P_{OSM} = 2(\text{Na})(\text{mmol/L}) + \frac{\text{Glucose (mg/dL)}}{18} + \frac{\text{BUN (mg/dL)}}{2.8} \quad 11-1$$

This equation predicts the measured plasma osmolality within 5 to 10 mOsm/kg. Although urea contributes to the measured osmolality, it is an ineffective osmole because it readily traverses cell membranes and, therefore, does not cause significant fluid shift within the body. Hence, the effective plasma osmolality (synonymous with tonicity, the portion of total osmolality that has the potential to induce transmembrane water movement) can be estimated by the following equation:

$$P_{OSM} = 2(\text{Na})(\text{mmol/L}) + \frac{\text{Glucose (mg/dL)}}{18} \quad 11-2$$

An osmolal gap exists when the measured and calculated values differ by >10 mOsm/kg⁴; it signifies the presence of unidentified particles. When the individual solute has been identified, its contribution to the measured osmolality can be estimated by dividing its concentration (mg/dL) by one-tenth of its molecular weight. Calculating the osmolal gap is used to detect the presence of substances, such as ethanol, methanol, and ethylene glycol, which have high osmolality. Occasionally, the osmolal gap can also result from an artificial decrease in the serum sodium secondary to severe hyperlipidemia or hyperproteinemia.

1. J.F., a 31-year-old man, is admitted to the inpatient medicine service for methanol (molecular weight, 32) intoxication. Routine laboratory analysis reveals the following: Na, 145 mEq/L (normal, 134–146); K, 3.4 mEq/L (normal, 3.5–5.1); Cl, 105 mEq/L (normal, 92–109); carbon dioxide (CO₂), 20 mEq/L (normal,

22–32); blood urea nitrogen (BUN), 10 mg/dL (normal, 8–25); creatinine, 1.1 mg/dL (normal, 0.5–1.5); and glucose, 90 mg/dL (normal, 60–110). The blood methanol concentration was 108 mg/dL, and the measured plasma osmolality was 333 mOsm/kg. What is J.F.'s calculated osmolality? Are other unidentified osmoles present?

[SI units: Na, 135 mmol/L; K, 3.4 mmol/L; Cl, 105 mmol/L; CO₂, 20 mmol/L; BUN, 3.57 mmol/L; creatinine, 97.4 μmol/L; glucose, 5.0 mmol/L; methanol, 33.7 mmol/L]

Using Equation 11-1, J.F.'s total calculated osmolality is as follows:

$$P_{OSM} = 2(145 \text{ mEq/L}) + \frac{90 \text{ mg/dL}}{18} + \frac{10 \text{ mg/dL}}{2.8} \quad 11-A$$

$$= 290 + 5 + 3.6$$

$$= 299 \text{ mOsm/kg}$$

$$\text{Osmolal gap} = 333 \text{ mOsm/kg} - 299 \text{ mOsm/kg} \quad 11-B$$

$$= 34 \text{ mOsm/kg}$$

In J.F., the entire osmolal gap can be accounted for by the presence of the methanol (because 108 mg/dL of methanol will provide $108/3.2 = 33.7$ mOsm/kg). It is unlikely, therefore, that other unmeasured osmoles are present (e.g., ethylene glycol, isopropanol, and ethanol). The laboratory determination of osmolality measures the total number of osmotically active particles but not their permeability across the cell membrane. Methanol increases plasma osmolality but not tonicity because the cell membrane is permeable to methanol. Therefore, no net water shift occurs between the intracellular and extracellular compartments. Conversely, mannitol, which is confined to the extracellular space, contributes to both plasma osmolality and tonicity.

Tubular Function of Nephron

The kidney plays an important role in maintaining a constant extracellular environment by regulating the excretion of water and various electrolytes. The volume and composition of fluid filtered across the glomerulus are modified as the fluid passes through the tubules of the nephron.

The renal tubule is composed of a series of segments with heterogeneous structures and functions: the proximal tubule, the medullary and cortical thick ascending limb of Henle's loop, the distal convoluted tubule, and the cortical and medullary collecting duct² (Fig. 11-1). The mechanism for sodium reabsorption is different for each nephron segment, but is generally mediated by carrier proteins or channels located on the luminal membrane of the tubule cell.² Na⁺-K⁺-ATPase (adenosine triphosphatase) actively pumps sodium out of the renal tubule cell in exchange for potassium in a 3:2 ratio. Hence, the intracellular sodium concentration is kept at a low level. The potassium that is pumped into the cell leaks back out through potassium channels in the membrane, rendering the cell interior electronegative. The low intracellular sodium concentration and a negative intracellular potential produce a favorable gradient for passive sodium entry into the cell.³ The Na⁺-K⁺-ATPase also indirectly provides the energy for active sodium transport and the reabsorption and secretion of other solutes across the luminal membrane of the renal tubule.

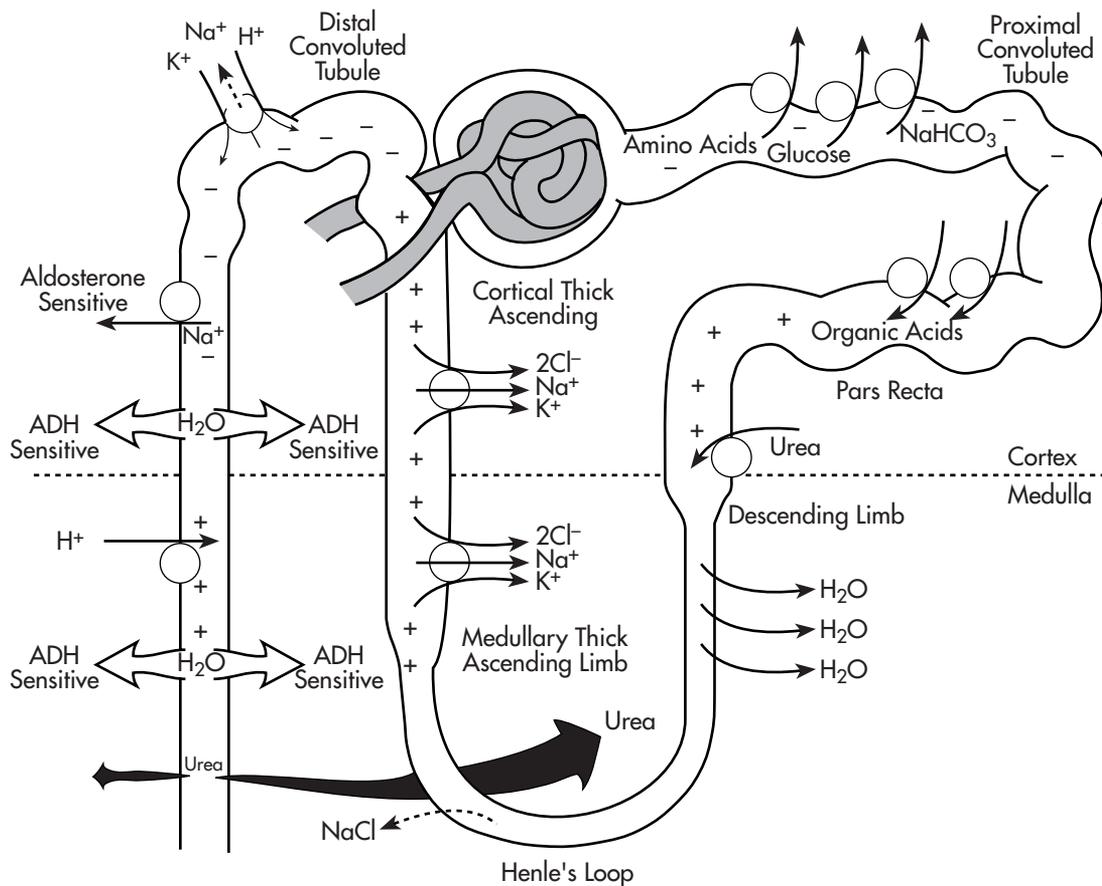

FIGURE 11-1 Sites of tubule salt and water absorption. Sodium is reabsorbed with inorganic anions, amino acids, and glucose in the proximal tubule against an electrical gradient that is lumen negative. In the late part of the proximal tubule (pars recta), sodium and water are reabsorbed to a lesser extent and organic acids (hippurate, urate) and urea are secreted into the urine. The electrical potential is lumen positive in the pars recta. Water, but not salt, is removed from tubule fluid in the thin descending limb of Henle's loop, but in the ascending portion salt is reabsorbed without water, rendering the tubule fluid hyposmotic with respect to the interstitium. Sodium, chloride, and potassium are reabsorbed by the medullary and cortical portions of the ascending limb; the lumen potential is positive. Sodium is reabsorbed and potassium and hydrogen ions are secreted in the distal tubule and collecting ducts. Water absorption in these segments is regulated by antidiuretic hormone (ADH). The electrical potential is lumen negative in the cortical sections and positive in the medullary segments. Urea is concentrated in the interstitium of the medulla and assists in the generation of maximally concentrated urine. (From reference 23, with permission.)

The distal segments are mainly involved in the reabsorption of sodium and chloride ions and the secretion of hydrogen and potassium ions.²

Iso-osmotic reabsorption of the glomerular filtrate occurs in the proximal tubule such that two-thirds of the filtered sodium and water and 90% of the filtered bicarbonate are reabsorbed. The Na⁺-H⁺ antiporter (exchanger) in the luminal membrane is instrumental in the reabsorption of sodium chloride, sodium bicarbonate, and water. The reabsorption of most nonelectrolyte solutes, such as glucose, amino acids, and phosphates, are coupled to sodium transport.^{2,5}

Both the thick ascending limb of Henle's loop and the distal convoluted tubule serve as the diluting segments of the nephron because they are impermeable to water. Sodium chloride is extracted from the filtrate without water. Sodium transport in both of these segments is flow dependent and varies with the amount of sodium ions delivered from the proximal segments of the nephron. Decreased sodium ions in the tubular fluid will

limit sodium transport in the thick ascending limb of Henle's loop and the distal convoluted tubule.^{2,6}

Reabsorption of sodium in the thick ascending limb of Henle's loop accounts for approximately 25% of the total sodium reabsorption. Sodium, chloride, and potassium are reabsorbed by the medullary and cortical portions of the ascending limb, but the leakage of reabsorbed potassium ions back into the tubular lumen, via potassium channels, makes the tubular lumen electropositive. This electrical gradient promotes the passive reabsorption of cations, such as sodium, calcium, and magnesium, in the distal convoluted tubules. Because the thick ascending limb of Henle's loop is impermeable to water, it contributes to the interstitial osmolality in the medulla. This high osmolality is key to the reabsorption of water by the medullary portion of the collecting duct under the influence of antidiuretic hormone (ADH, vasopressin). Therefore, the thick ascending limb of Henle's loop is important for both urinary concentration and dilution.⁶

Because, as noted previously, the distal convoluted tubule also is impermeable to water, the osmolality of the filtrate continues to decline as sodium is being reabsorbed. In the distal convoluted tubule and collecting duct, sodium is reabsorbed in exchange for hydrogen ions and potassium. When sodium ions are reabsorbed, the tubule lumen becomes electronegative, which promotes potassium secretion in the lumen via potassium channels. Aldosterone enhances sodium reabsorption in the collecting duct by increasing the number of opened sodium channels.^{2,7}

The collecting duct is usually impermeable to water. Under the influence of ADH, however, water permeability is increased through an increase in the number of water channels along the luminal membrane. The amount of water reabsorbed depends on the tonicity of the medullary interstitium, which is determined by the sodium reabsorbed in the thick ascending limb of Henle's loop and urea.^{2,7,8}

Osmoregulation

An increase in the effective plasma osmolality often reduces intracellular volume; conversely, decreased effective plasma osmolality is associated with cellular hydration. Water homeostasis is important in the regulation of plasma osmolality, and plasma tonicity is maintained within normal limits through a delicate balance between the rates of water intake and excretion. The amount of daily water intake includes the volume of water ingested (sensible intake), the water content of ingested food, and the metabolic production of water (insensible intake).² To maintain homeostasis, these should be equal to the amount of water excreted by the kidney and the gastrointestinal (GI) tract (sensible loss) plus water lost from the skin and respiratory tract (insensible loss).^{2,3}

Changes in plasma tonicity are detected by osmoreceptors in the hypothalamus, which also houses the thirst center and is the site for ADH synthesis.^{9,10} When the plasma tonicity falls below 280 mOsm/kg as a result of water ingestion, ADH release is inhibited,² water is no longer reabsorbed in the collecting duct, and a large volume of dilute urine is excreted. Conversely, when the osmoreceptors in the hypothalamus sense an increased plasma osmolality, ADH is released to increase water reabsorption. A small volume of concentrated urine is then excreted. The threshold for ADH release is 280 mOsm/kg, and maximal ADH secretion occurs when the plasma osmolality is 295 mOsm/kg.⁹ Thus, urine osmolality varies from 50 mOsm/kg in the absence of ADH to 1,200 mOsm/kg during maximal ADH release. The volume of urine produced depends on the solute load to be excreted, as well as the urine osmolality^{2,3,9,10}:

$$\text{Urine volume (L)} = \left(\frac{\text{Solute load (mOsm)}}{\text{Urine osmolality (mOsm/kg)}} \right) \left(\frac{1}{\text{Density of water (kg/L)}} \right) \quad 11-3$$

Therefore, for a typical daily solute load of 600 mOsm:

$$= \left(\frac{600 \text{ mOsm}}{50 \text{ mOsm/kg}} \right) \left(\frac{1}{1 \text{ kg/L}} \right) = 12 \text{ L} \quad 11-C$$

$$= \left(\frac{600 \text{ mOsm}}{1,200 \text{ mOsm/kg}} \right) \left(\frac{1}{1 \text{ kg/L}} \right) = 0.5 \text{ L} \quad 11-D$$

Although the kidney has a remarkable ability to excrete free water, it is not as efficient in conserving water. ADH minimizes further water loss, but it cannot correct water deficits. Therefore, optimal osmoregulation requires increased water intake stimulated by thirst. Both ADH and thirst can be stimulated by nonosmotic stimuli. For example, volume depletion is such a strong nonosmotic stimulus for ADH release that it can override the response to changes in plasma osmolality. Nausea, pain, and hypoxia are also potent stimuli for ADH secretion.¹¹

Volume Regulation

Sodium resides almost exclusively in the extracellular fluid; the amount of total body sodium, therefore, determines the extracellular volume.^{2,11} Because daily sodium intake varies from 100 to 250 mEq, the body must rely on adjustments in urinary sodium excretion to maintain the extracellular volume and tissue perfusion.^{2,11} The ability of the kidney to retain sodium is so remarkable that a person can survive with a daily sodium intake as low as 20 to 30 mEq.

The afferent sensors for the changes in the effective circulating volume are the intrathoracic volume receptors, the baroreceptors in the carotid sinus and aortic arch, and the afferent arteriole in the glomerulus.¹¹ When the effective circulating volume is decreased, both the renin-angiotensin and the sympathetic nervous systems are activated.^{2,11} Angiotensin II and norepinephrine enhance sodium reabsorption at the proximal convoluted tubule. In addition, aldosterone stimulates sodium reabsorption at the collecting tubule. The decrease in effective arterial volume also stimulates ADH release, which enhances water reabsorption at the collecting duct. Conversely, after a salt load, the increases in atrial pressure and renal perfusion pressure suppress the production of renin and, subsequently, angiotensin II and aldosterone. The release of atrial natriuretic peptide secondary to increased atrial filling pressure and intrarenal production of urodilation increase urinary excretion of the excess sodium.^{12,13}

Although the kidney can excrete a 20-mL/kg water load in 4 hours, only 50% of the excess sodium is excreted in the first day.³ Sodium excretion continues to increase until a new steady state is reached after 3 to 4 days, when intake equals output.^{3,12} It is important to recognize that osmoregulation and volume regulation occur independently of each other.^{2,3} The two homeostatic systems regulate different parameters and possess different sensors and effectors. Both systems can be activated simultaneously, however.

DISORDERS IN VOLUME REGULATION

Sodium Depletion

2. A.B., a 17-year-old girl, presented to the emergency department (ED) with complaints of anorexia, nausea, vomiting, and generalized weakness for the past 3 days. She denied other medical problems and had not used any medications. On examination, her supine blood pressure (BP) was 105/70 mm Hg, with a pulse of 80 beats/min. Her standing BP was 85/60 mm Hg with a pulse of 100 beats/min, and she complained of feeling dizzy when she stood up. Her mucous membranes were dry but her skin turgor was normal. The jugular vein was flat, and peripheral or sacral edema was not present. Laboratory blood tests showed serum Na,

134 mEq/L (normal, 134–146); K, 3.5 mEq/L (normal, 3.5–5.1); Cl, 95 mEq/L (normal, 92–109); total CO₂ content, 35 mEq/L (normal, 22–32); BUN, 18 mg/dL (normal, 8–25); creatinine, 0.8 mg/dL (normal, 0.5–1.5); and glucose, 70 mg/dL (normal, 60–110). Random urinary Na was 40 mEq/L, K was 40 mEq/L, and Cl was <15 mEq/L. The hemoglobin (Hgb) was 14 g/dL (normal, 12–16), and white cell and platelet counts were normal. Why were the clinical and laboratory data in A.B. consistent with an assessment of volume depletion?

[SI units: serum Na, 134 mmol/L; K, 3.5 mmol/L; Cl, 95 mmol/L; CO₂, 35 mmol/L; BUN, 5.7 mmol/L; creatinine, 70.72 μmol/L; glucose, 3.9 mmol/L; urine Na, 40 mmol/L; K, 40 mmol/L; Cl, <15 mmol/L; Hgb, 140 g/L]

The signs and symptoms in A.B. were consistent with volume depletion. The loss of gastric fluid owing to vomiting and decreased oral intake secondary to anorexia had led to moderate to severe volume depletion. There were orthostatic changes in both her BP (a drop in systolic BP of 20 mm Hg) and pulse (an increase of 20 beats/minute). The dry mucous membranes, the flat jugular vein, and the absence of edema support volume depletion as well, and dizziness on standing indicates extracellular volume depletion.¹⁴ Her hypochloremic metabolic alkalosis was probably initiated by loss of acidic gastric contents through vomiting. Her volume depletion increased renal bicarbonate reabsorption, which perpetuated the metabolic alkalosis. The decreased renal perfusion brought about by volume depletion enhanced proximal tubular reabsorption of urea, resulting in an increased BUN:creatinine ratio (prerenal azotemia). When renal perfusion is decreased and the renin-angiotensin-aldosterone system is activated, the proximal reabsorption of sodium and chloride is increased. A.B.'s urinary sodium is therefore <10 mEq/L.¹⁵ Excretion of the poorly permeable bicarbonate ions, however, results in obligatory urinary sodium loss to maintain luminal electroneutrality. A.B.'s urinary sodium was therefore elevated (40 mEq/L). In this situation, the urinary chloride remained low, and this is a better index of volume status.¹⁵ Both urinary sodium and chloride are elevated, however, in patients using diuretics, in those undergoing osmotic diuresis, and in those with underlying renal disease or hypoaldosteronism, even in the face of volume depletion. Physical examination should therefore be conducted as part of the volume status assessment. A.B.'s volume depletion increased the concentration of red blood cells, which could explain her slightly elevated Hgb concentration of 14 g/dL.

3. How should A.B.'s volume depletion be managed?

The etiology of A.B.'s vomiting should be sought and the cause removed. Because the patient is neither hypernatremic nor hyponatremic, normal saline should be administered intravenously to replenish the extracellular volume and improve tissue perfusion.^{2,14} If the patient is hypernatremic (having a greater deficit of water than solute), half-isotonic saline (1/2NS) or dextrose solution, which contains more free water, should be administered. In contrast, hyponatremic hypovolemic patients have a greater deficit of solute than water; isotonic or hypertonic saline should then be given. The amount of volume deficit is often difficult to ascertain. Because A.B. was severely orthostatic, 1 or 2 L of fluid can be given over 2 to 4 hours. The subsequent rate of infusion will depend on A.B.'s response and the prevailing symptoms. The clinician should

monitor her body weight, skin turgor, supine and upright BP, jugular venous pressure, urine output, and urine chloride concentration to assess the adequacy of volume repletion. Because the treatment goal is to achieve a positive fluid balance, the infusion rate should be 50 or 100 mL/hour in excess of the sum of urine output, insensible losses, and other losses, such as emesis and diarrhea.²

Sodium Excess

4. L.J., a 45-year-old man, presented to the clinic with complaints of swollen legs and puffy eyelids. He also noticed that his urine had been foamy recently. On examination, his BP was 180/100 mm Hg and his pulse was 80 beats/minute. Bilateral periorbital edema and 2+ bilateral pitting edema up to the thigh were noted. On auscultation, his heart was normal and his lungs had bilateral crackles. His jugular venous pressure was elevated at 10 cm H₂O. Laboratory tests revealed serum Na, 132 mEq/L (normal, 134–146); K, 3.8 mEq/L (normal, 3.5–5.1); Cl, 100 mEq/L (normal, 92–109); bicarbonate, 26 mEq/L (normal, 22–32); BUN, 40 mg/dL (normal, 8–25); creatinine, 2.5 mg/dL (normal, 0.5–1.5); glucose, 120 mg/dL (normal, 60–110); and albumin, 2 g/dL (normal, 3.4–5.4). The serum transaminases, alkaline phosphatase, and bilirubin were within normal limits. The serum cholesterol level was 280 mg/dL (normal, <200), and the triglyceride level was 300 mg/dL (normal, 30–200). Urinalysis showed specific gravity of 1.015 (normal, 1.002–1.030), pH 7.0 (normal, 4.6–7.9), protein >300 mg/dL, oval fat bodies, and fatty casts. The 24-hour urinary protein excretion was 6 g and the measured creatinine clearance (Cl_{Cr}) was 40 mL/minute. L.J. was taking no medications and he denied illicit drug use. Hepatitis B serology and human immunodeficiency virus (HIV) antibody were negative. The impression was anasarca (total body edema) secondary to nephrotic syndrome. What is nephrotic syndrome? What could be the cause of L.J.'s sodium excess state?

[SI units: Na, 132 mmol/L; K, 3.8 mmol/L; Cl, 100 mmol/L; bicarbonate, 26 mmol/L; BUN, 14.3 mmol/L; serum creatine (SrCr), 221 μmol/L; glucose, 6.7 mmol/L; albumin, 20 g/L; cholesterol, 7.24 mmol/L; triglyceride, 3.4 mmol/L; protein, 3 g/L; Cl_{Cr}, 0.67 mL/second]

Nephrotic syndrome is characterized by hypoalbuminemia, urine protein excretion >3.5 g/day, hyperlipidemia, lipiduria, and edema.^{16,17} The heavy proteinuria is a result of damage to the selective barrier of the glomerulus. The causes of nephrotic syndrome are multiple and diverse.¹⁶ The cause of nephrotic syndrome can be idiopathic (primary glomerular disease) or secondary to chronic systemic diseases (e.g., diabetes mellitus, amyloidosis, sickle cell anemia,¹⁸ lupus), cancer (e.g., multiple myeloma, Hodgkin's disease), infections (e.g., HIV,¹⁹ hepatitis B, syphilis, malaria), intravenous (IV) drug abuse, and medications (e.g., gold, penicillamine, captopril, nonsteroidal anti-inflammatory drugs [NSAID])²⁰.

A heavy urinary protein loss results in various extrarenal complications.^{16,17} Hypoalbuminemia reduces plasma oncotic pressure and contributes to the increased hepatic synthesis of both albumin and lipoproteins. This, coupled with the decreased catabolism of lipoproteins, resulted in L.J.'s hyperlipidemia.^{16,21} Loss of inhibitors of coagulation in the urine predispose these patients to thromboembolism.¹⁶ Specific therapy of nephrotic syndrome ranges from simple

removal of the offending medication and treatment of the underlying infection, to the use of immunosuppressive agents in specific glomerular diseases.

The edematous state (L.J.'s anasarca) results from changes in both capillary hemodynamics and renal sodium and water retention.²² The hypoalbuminemia (2 g/dL) and proteinuria (>300 mg/dL) produced an imbalance in the Starling forces across the capillary wall, namely the hydrostatic and oncotic pressures in the capillary and interstitial compartments. The reduced capillary oncotic pressure favors movement of fluid from the vascular space into the interstitium.²³ This leads to contraction of the effective arterial blood volume, which in turn activates humoral, neural, and hemodynamic mechanisms that signal the kidney to retain sodium and water.^{24,25} This *underfill hypothesis* has been challenged by data suggesting that hypoalbuminemia plays a minor role in nephrotic edema^{26,27} and the observation that patients with nephrotic syndrome can have increased, normal, or decreased plasma volumes.²³

A defect in the intrarenal sodium handling mechanism that causes inappropriate sodium retention also contributes to nephrotic edema.^{23,26} According to this *overflow hypothesis*, proteinuric renal disease leads to increased sodium reabsorption in the distal nephron. The mechanism is not well defined but may be related to cellular resistance to atrial natriuretic peptide.²³ Thus, a sodium excess state occurs and edema results. It is likely that the interaction between the “underfill” and “overflow” mechanisms results in the production of nephrotic edema.²⁸ Patients with severe hypoalbuminemia (i.e., serum albumin level <1.5 g/dL) who have a severe reduction in plasma oncotic pressure are most likely to exhibit evidence of the underfill phenomenon.²²

5. How should L.J.'s sodium excess state be managed?

The etiology of L.J.'s nephrotic syndrome should be identified for specific treatment. Although L.J.'s serum sodium concentration of 132 mEq/L is low, it reflects dilution secondary to fluid excess. Salt restriction is therefore important to control L.J.'s generalized edema.²³ For most nephrotic patients, modest dietary sodium restriction to approximately 50 mEq/day may be sufficient to maintain neutral sodium balance.^{22,23} For nephrotic patients who are very sodium avid (urine sodium concentration <10 mEq/L), sufficient restriction is difficult to achieve. Thus, slowing the rate of edema formation rather than hastening its resolution should be the goal of therapy for these patients.²³ Bedrest reduces orthostatic stimulation of the renin-angiotensin-aldosterone and sympathetic systems, thereby favoring the movement of interstitial fluid into the vascular space.²³ The central blood volume is thus increased and natriuresis and diuresis are facilitated. Prolonged bedrest might, however, predispose these hypercoagulable patients to thromboembolism.¹⁶ Similarly, use of support stockings may reduce the stimulation for sodium retention by redistributing blood volume to the central circulation.^{23,29}

Diuretics

Usually, loop diuretics are the mainstay of therapy in the management of nephrotic edema.^{2,23} In most of these patients, the edema can be removed safely with rapid diuresis without compromising the systemic circulation, probably because of the rapid refilling of the plasma volume by interstitial fluid.²³ Nevertheless, as the edema resolves, the rate of fluid removal and

weight loss should be decreased to avoid compromising the effective circulating volume. The patient should be monitored for the development of orthostatic hypotension.

Infusions of albumin can expand the plasma volume; however, it is expensive, the relief is temporary, and it should therefore be used only for resistant edema.³⁰ In patients who are resistant to the aforementioned measures, extracorporeal fluid removal, namely ultrafiltration, may be necessary.^{23,31}

L.J. was initially treated with IV furosemide 60 mg twice daily and placed on a low-sodium (50 mEq), low-fat, high-complex-carbohydrate diet that consisted of 0.8 g/kg protein of high biologic value with additional protein to match gram-per-gram of urinary protein loss. Fluid was restricted to 1,000 mL/day.³² He had 5 L of diuresis in 2 days, with resolution of respiratory symptoms and a reduction in the anasarca. Parenteral furosemide was discontinued on the fifth day of hospitalization and oral furosemide 120 mg twice daily was started. After a total weight loss of 12 kg, he was then discharged with instructions to maintain the diet and oral furosemide.

DISORDERS IN OSMOREGULATION

Hyponatremia

Serum sodium concentration reflects the ratio of total body sodium to total body water and is not an accurate indicator of total body sodium. Both hyponatremia and hypernatremia can occur in the presence of a low, normal, or high total body sodium.^{33,34} Because the kidney can excrete >12 to 16 L of free water daily, hyponatremia does not occur unless the water intake overwhelms the kidney's ability to excrete free water (e.g., psychogenic polydipsia),^{35,36} or free water excretion is impaired.^{2,37}

Free water formation requires a normal glomerular filtration rate (GFR), the reabsorption of sodium chloride without water in the thick ascending limb of Henle's loop and the distal convoluting tubule, and the excretion of a dilute urine in the absence of ADH³⁷ (Fig. 11-1). Therefore, hyponatremia can occur when the kidney's diluting ability is exceeded or impaired owing to volume depletion and nonosmotic stimulation of ADH release or inappropriate stimulation of ADH production.^{2,37}

Although plasma sodium is the primary determinant of plasma tonicity, hyponatremia does not always represent hypotonicity.^{2,37} In patients with severe hyperlipidemia or hyperproteinemia (e.g., multiple myeloma), pseudohyponatremia can occur because the increased amounts of lipids and proteins displace plasma water, which sodium ions dissolve in, resulting in a lower concentration of sodium per unit volume of plasma.^{34,37,38} Normally, water accounts for 93% of the plasma volume, and lipids and proteins make up the rest.³⁷ The increase in plasma lipid and protein contents expands plasma volume, displaces water, and increases the percentage of solids in plasma.^{34,37} Because sodium is distributed only in the aqueous phase, the sodium content per liter of the newly recomposed plasma is thus decreased and the plasma sodium concentration is reduced.^{34,37,38} The sodium concentration in plasma water remains the same, however. Because osmolality depends on the solute concentration in plasma water, serum osmolality remains unchanged.³⁴ Indeed, the measured osmolality is normal. Another example of isotonic hyponatremia can be

found when a large volume of isotonic mannitol irrigant is used during prostate surgery.^{34,37} Absorption of the irrigation solution can result in severe hyponatremia but normal osmolality. In contrast, use of large amounts of isotonic sorbitol and isotonic, or slightly hypotonic, glycine solutions during urologic surgery can cause the hypotonicity as a late complication.^{34,37} Similar to mannitol, sorbitol and isotonic glycine initially distribute

only in the extracellular space, resulting in hyponatremia without a change in osmolality.³⁷ Unlike mannitol, both sorbitol and glycine are later metabolized, leaving water behind to result in hypotonicity. The severe hypotonic hyponatremia, in conjunction with the neurotoxic effects of glycine and its metabolites, puts the patient at significant risk for severe neurologic symptoms (Table 11-1).^{37,39}

Table 11-1 Clinical Presentation and Treatment of Hyponatremia

| <i>Na⁺ and H₂O Status</i> | <i>Clinical Presentation/Cause</i> | <i>Treatment</i> |
|---|--|---|
| Edematous, Fluid Overload (Hypervolemic, Hypotonic) | | |
| ↑ Total Body Na ⁺ -↑↑ Total Body H ₂ O | <i>Cirrhosis/CHF/nephrotic syndrome:</i> A ↓ in renal blood flow activates renin angiotensin system. ↑ aldosterone leads to ↑ Na ⁺ , and ↑ ADH leads to free H ₂ O retention. Urine Na ⁺ is low (0–20 mEq/L) and urine osmolality ↓. Diuretics can induce paradoxical effects on urine Na ⁺ and osmolality. This form also can occur in patients with renal failure who drink excessive amounts of water. Patients have symptoms of fluid overload (ascites, distended neck veins, edema). | Fluid and Na ⁺ restriction. Correct underlying disorder (e.g., paracentesis for ascites). Diurese cautiously; avoid ↓ ECF and accompanying ↓ tissue perfusion. ↑ BUN may indicate overly rapid diuresis. |
| Nonedematous Hypovolemic (Hypotonic with ECF Depletion) | | |
| ↓↓ Total Body Na ⁺ ↓ Total Body H ₂ O | Occurs in: <i>GI fluid loss (e.g., diarrhea) with hypotonic electrolyte-poor fluid replacement, overdiuresis, "third spacing," Addison's disease, renal tubular acidosis, osmotic diuresis.</i> Replacement of fluid losses with solute-free fluid predisposes these patients to hyponatremia. Kidneys concentrate urine to conserve fluid (urine Na ⁺ <10 mEq/L). Symptoms: nonedematous; ECF depletion (collapsed neck veins, dehydration, orthostasis). Neurologic symptoms: (See Hyponatremia: Symptoms in text). | Discontinue diuretics. Replace fluid and electrolyte (especially K ⁺) losses. 0.9% saline preferred unless Na ⁺ deficit severe, then use 3%–5% saline. See footnote <i>a</i> for method of estimating Na ⁺ deficit. |
| Nonedematous, Normovolemic (Normovolemic, Hypotonic) | | |
| ↓ Total Body Sodium ↑ Total Body H ₂ O | <i>SIADH^a:</i> Hyponatremia, hypo-osmolality, renal Na ⁺ wasting (>40 mEq/L), absence of fluid depletion, U _{osm} > P _{osm} , normal renal and adrenal function. Free H ₂ O retained while Na ⁺ lost. <i>Causes:</i> (a) ADH production (infectious disease, vascular disease, cerebral neoplasm, cancer of lung, pancreas, duodenum); (b) exogenous ADH administration; (c) drugs; (d) psychogenic polydipsia. | <i>Conivaptan:</i> Loading dose of 20 mg IV over 30 minutes, followed by 20 mg IV as continuous infusion over 24 hours for an additional 1 to 3 days; may titrate up to maximal dose of 40 mg/day; maximal duration is 4 days after the loading dose. Dedicated IV line recommended and site of peripheral IV lines should be changed every 24 hours. <i>Chronic treatment:</i> Restrict fluids to less than urine loss. <i>Demeclocycline</i> (300–600 mg BID) induces reversible diabetes insipidus. <i>Emergency treatment</i> for unresponsive patients includes <i>furosemide</i> diuresis to achieve negative H ₂ O balance with careful replacement of Na ⁺ and K ⁺ using hypertonic saline solutions. ^b See footnote <i>b</i> for method of calculating TBW excess and type of solutions to use. |

^aEstimate Na deficit: (mEq) = (0.5 L/kg × wt in kg) (Na desired - Na observed), where 0.5 L/kg is volume of distribution (Vd) of Na in the body. Rate of Na and fluid repletion used depends on severity. Mild: replace with NS. First one-third over 6 to 12 hours at a rate of <0.5 mEq/L/hr, remaining two-thirds over 24 to 48 hours. Severe (e.g., seizures): Use 3% to 5% saline, rate gauged by patient's ability to tolerate Na and volume load. Monitor CNS function, skin turgor, BP, urine Na, signs of Na/H₂O overload, especially in patients with cardiovascular, renal, and pulmonary disease.

^bTotal body water (TBW) = 0.5 L/kg × wt in kg. TBW excess = TBW - TBW (observed serum Na)/(desired serum Na)

ADH, antidiuretic hormone; BID, twice daily; BUN, blood urea nitrogen; CHF, congestive heart failure; ECF, extracellular fluid; GI, gastrointestinal; IV, intravenous; NS, normal saline (0.9% Na); SIADH, syndrome of inappropriate ADH.

Remove estimated excess free water with IV furosemide (1 mg/kg). Repeat as necessary. Because furosemide generates a urine that resembles 0.5% NaCl, urine losses of Na and K must be carefully measured and replaced hourly with hypertonic salt solutions. *Correction rate:* 1 to 2 mEq Na/hr in symptomatic patients; 0.5 mEq/hr in asymptomatic patients.

6. T.T., a 23-year-old man with end-stage renal disease caused by diabetic nephropathy, is receiving chronic ambulatory peritoneal dialysis. Because of dietary and fluid noncompliance, T.T. complained of shortness of breath (SOB) and his dialysis prescription was adjusted to include six cycles of 2.5% peritoneal dialysis solutions. Today, his laboratory values are Na, 128 mEq/L (normal, 134–146); K, 4 mEq/L (normal, 3.5–5.1); Cl, 98 mEq/L (normal, 92–109); total CO₂, 24 mmol/L (normal, 22–32); BUN, 50 mg/dL (normal, 8–25); creatinine, 6 mg/dL (normal, 0.5–1.5); and glucose, 600 mg/dL (normal, 60–110). Evaluate T.T.'s plasma osmolality. What is the etiology of T.T.'s hyponatremia?

[SI units: Na, 128 mmol/L; K, 4 mmol/L; Cl, 98 mmol/L; CO₂, 24 mmol/L; BUN, 17.85 mmol/L; creatinine, 530.4 μmol/L; glucose, 33.3 mmol/L]

T.T.'s effective plasma osmolality is calculated to be 289 mOsm/L, of which 33 mOsm/L is contributed by the hyperglycemia. The slow utilization of glucose, because of the lack of insulin, causes water to move from the intracellular compartment into the plasma space because of the increased tonicity, thereby lowering the plasma sodium concentration.^{34,37} Despite the lowered plasma sodium concentration, the plasma osmolality is normal because of hyperglycemia. Hence, no symptoms attributable to hypo-osmolality are observed. Indeed, when serum glucose is normalized with insulin and hydration, the serum sodium level will increase to approximately 136 mEq/L. For each 100-mg/dL increment in serum glucose, serum sodium decreases by 1.3 to 1.6 mEq/L.^{34,37} Use of hypertonic mannitol or glycine solutions in patients with cerebral edema also results in a hyperosmolar hyponatremia.³⁴

Hypotonic Hyponatremia With Decreased Extracellular Fluid

7. Q.B., a 30-year-old male athlete who has had multiple bouts of diarrhea over the last several days, has been drinking Gatorade to keep himself from getting dehydrated. His vital signs are supine BP, 145/80 mm Hg, and pulse, 70 beats/minute; standing BP, 128/68 mm Hg, and pulse, 90 beats/minute. Respiratory rate (RR) was 12 breaths/minute, and he was afebrile. His skin turgor was mildly decreased and laboratory data were Na, 128 mEq/L (normal, 134–146); K, 3.0 mEq/L (normal, 3.5–5.1); Cl, 100 mEq/L (normal, 92–109); bicarbonate, 17 mEq/L (normal, 24–31); BUN, 27 mg/dL (normal, 8–25); and creatinine, 1.2 mg/dL (normal, 0.5–1.5). Urinary Na and Cl were both <10 mEq/L. Assess Q.B.'s electrolyte and fluid status. What is the etiology of Q.B.'s hyponatremia?

[SI units: plasma Na, 128 mmol/L; K, 3 mmol/L; Cl, 100 mmol/L; bicarbonate, 17 mmol/L; BUN, 7.14 mmol/L; creatinine, 106.1 μmol/L; urinary Na, <10 mmol/L; Cl, <10 mmol/L]

Q.B. has true hypotonic hyponatremia with extracellular fluid depletion, suggesting that his total body sodium deficit is greater than that of total body water.³⁴ His poor skin turgor, orthostasis, prerenal azotemia, and low urinary sodium are consistent with volume depletion. The urinary sodium concentration helps distinguish between renal and nonrenal losses that result in the sodium and water deficits.^{15,34,40} When the plasma volume is depleted, the urinary sodium concentration is <10 mEq/L, suggesting appropriate renal sodium conservation.¹⁵

This is usually seen in patients such as Q.B. with GI fluid loss as in vomiting, diarrhea, or profuse sweating.^{34,37,40} Other causes of hypotonic hyponatremia are less likely in Q.B. They include surreptitious cathartic abuse and “third spacing,” or accumulation of extracellular fluid in the abdominal cavity during acute pancreatitis, ileus, or pseudomembranous colitis.^{37,40} If the urinary sodium is >20 mEq/L in the face of volume depletion, renal salt wastage should be considered.^{15,37,40} The potential causes of this latter problem include diuretic use,^{41–44} adrenal insufficiency,⁴⁴ and salt-wasting nephropathy³⁵ (e.g., chronic interstitial nephritis, medullary cystic disease, polycystic kidney disease, obstructive uropathy, and cisplatin toxicity^{44,45}). In patients with renal insufficiency, neither the urinary sodium nor chloride concentration is a reliable index of volume status.¹⁵

Volume depletion leads to increased reabsorption of sodium and water in the proximal tubule and, thus, decreased sodium delivery to the diluting segments for free water formation.^{34,37,40} Decreased effective arterial volume is also a potent nonosmotic stimulus for ADH release.^{9,10} These factors combine to dampen the ability of the kidney to form dilute urine and result in high urine osmolality despite a low serum sodium concentration.^{34,37,40} Although the fluid lost in diarrhea is hypotonic, it is the replacement of fluid loss with an even more hypotonic fluid such as Gatorade or tap water that causes hyponatremia in patients such as Q.B.^{37,40}

Q.B.'s diarrhea probably caused loss of potassium and bicarbonate through the GI tract, resulting in hypokalemia and hyperchloremic metabolic acidosis. The potassium depletion can sensitize ADH secretion in response to hypovolemic stimuli, and the hypokalemia also can lead to hyponatremia.³⁷ The cellular efflux of potassium causes cellular uptake of sodium, further reducing the serum sodium concentration.

8. How should Q.B.'s hyponatremia be treated?

The treatment of hypovolemic hyponatremia involves sodium replacement to correct the deficit. The sodium deficit can be estimated by the following formula:

$$\begin{aligned} \text{Na Deficit} &= \text{Vd of Na} \times \text{Patient Weight (Desired} & \mathbf{11-4} \\ & \quad - \text{Current Na concentration)} \\ &= (0.5 \text{ L/kg})(70 \text{ kg})(140 - 125 \text{ mEq/L}) & \mathbf{11-E} \\ &= 525 \text{ mEq} \end{aligned}$$

Approximately one-third of the deficit can be replaced over the first 12 hours at a rate of <0.5 mEq/L/hour. The remaining amounts can be administered over the next several days.

The use of isotonic sodium chloride solution is ideal for the treatment of volume-depleted hyponatremia. As renal perfusion is restored, free water will be excreted with appropriate retention of sodium.⁴⁰ Because Q.B. has only mild volume depletion, oral replacement fluids can be given. Oral solutions containing both electrolyte and glucose⁴⁶ or rice-based solutions⁴⁷ are ideal for the management of persistent fluid loss. Glucose not only provides calories but also promotes the intestinal absorption of ingested sodium.⁴⁸ Because the rice-based solution provides more glucose and amino acids, both of which can promote intestinal sodium absorption, it is more effective than glucose alone.^{2,48}

In patients with renal salt wasting, the ongoing daily sodium loss also should be taken into consideration when estimating the amount of replacement. Potassium should be given to correct hypokalemia, thereby reducing the hyponatremia as well. The serum sodium concentration may rise faster than expected because as tissue perfusion is restored, sodium delivery to the distal tubules will increase and ADH secretion will be suppressed appropriately.^{34,37,40} In the absence of ADH, increased free water excretion will improve the serum sodium concentration faster than initially estimated.

Hypervolemic Hypotonic Hyponatremia

9. T.W., a 55-year-old man with a longstanding history of alcoholic liver cirrhosis, is admitted to the hospital for worsening SOB. His medical history includes portal hypertension, esophageal varices, and noncompliance with dietary restriction and medications. His BP is 120/60 mm Hg; pulse, 100 beats/minute; RR, 20 breaths/minute. He is afebrile. Physical examination reveals a jaundiced man in respiratory distress. His jugular vein is flat and lung examination reveals bilateral basal rales. Abdominal examination shows tense ascites with hepatomegaly and spider angiomas (telangiectasias resembling a spider). He has 1+ pedal edema bilaterally. Laboratory data on admission are Na, 127 mEq/L (normal, 134–146); K, 3.4 mEq/L (normal, 3.5–5.1); Cl, 95 mEq/L (normal, 92–109); total CO₂ content, 24 mEq/L (normal, 22–32); BUN, 10 mg/dL (normal, 8–25); SrCr, 1.2 mg/dL (normal, 0.5–1.5); and albumin, 2.5 g/dL (normal, 3.5–5.4). Urine Na was <10 mEq/L, and osmolality was 380 mOsm/L (normal, 250–1,000). Identify the possible causes of hyponatremia in T.W. and discuss its pathophysiology. How should he be treated?

[SI units: serum Na, 127 mmol/L; K, 3.4 mmol/L; Cl, 95 mmol/L; CO₂, 24 mmol/L; BUN, 3.57 mmol/L; SrCr, 106.1 μmol/L; albumin, 25 g/L; urine, Na <10 mmol/L]

T.W. had no history of vomiting or diarrhea and had stopped using diuretics before admission. The physical findings of ascites and bilateral edema are not consistent with volume depletion but indicate a sodium-excess state. Both sodium and water retention take place, but the disproportionate accumulation of ingested water relative to sodium leads to hyponatremia.^{34,37,40}

Cirrhotic patients who are susceptible to develop hyponatremia have a decreased effective arterial blood volume.^{24,37,46,47} The low urinary sodium concentration suggests that the effective arterial blood volume was decreased.¹⁵ The high urinary osmolality in the face of hypotonic hyponatremia suggests, however, that the release of ADH has been stimulated, impairing free water excretion. Peripheral vasodilation causes decreases in systemic arterial BP despite a normal to high cardiac output. This, along with splanchnic venous pooling and decreased oncotic pressure secondary to hypoalbuminemia, decreases renal perfusion in patients such as T.W. with cirrhosis.^{22,28,46} Decreased renal perfusion activates the renin-angiotensin-aldosterone system, the sympathetic nervous system, and the release of ADH. Reabsorption of sodium and water in the proximal tubules is enhanced, diminishing sodium and water delivery to the distal segments of the nephron. The diluting capacity of the kidney is thus impaired. Increased secretion of antidiuretic hormone also promotes free water reabsorption

at the collecting tubule and contributes to the hyperosmolality of urine and hyponatremia. The hypervolemic hyponatremia also is seen in patients with congestive heart failure (CHF) and nephrotic syndrome^{24–28} and in patients with chronic renal disease who drink excessive amounts of water.^{37,40} (See Chapter 18, Heart Failure.) As the GFR decreases, distal delivery of sodium is reduced and the ability to generate free water is impaired. In addition, the capacity to conserve sodium is impaired in these patients.¹⁵

Most patients who are edematous and hyponatremic are asymptomatic, but the degree of hyponatremia probably reflects the severity of the underlying disease.^{46,47,49} Unless an acute decrease in serum sodium occurs, rapid therapeutic correction is not warranted.^{37,40,46,47,50} Water restriction, the mainstay of therapy, is determined by the degree of hyponatremia and the severity of symptoms. Sodium restriction and judicious use of diuretics may help reduce the edematous state, but the patient must be monitored closely to avoid prerenal azotemia, which suggests overaggressive diuresis. Furthermore, diuretics can induce or worsen hyponatremia and volume depletion by impairing the diluting capacity of the kidney.^{43–47}

T.W. had abdominal paracentesis to relieve respiratory discomfort with no sequelae. He was then prescribed a 1,000-mg sodium diet, and water was restricted to 500 mL/day. Diuretic therapy was resumed.

Normovolemic Hypotonic Hyponatremia

10. C.C., a 50-year-old man who was diagnosed recently with small-cell lung carcinoma, was brought to the ED by his family because he had become progressively lethargic and stuporous over the past week. Laboratory data revealed the following: serum Na, 110 mEq/L (normal, 134–146); K, 3.6 mEq/L (normal, 3.5–5.1); Cl, 78 mEq/L (normal, 92–109); bicarbonate, 22 mEq/L (normal, 24–31); BUN, 10 mg/dL (normal, 8–25); SrCr, 0.9 mg/dL (normal, 0.5–1.5); glucose, 90 mg/dL (normal, 60–110); serum osmolality, 230 mOsm/kg (normal, 274–296); urine osmolality, 616 mOsm/kg (normal, 250–1,000); and urine Na, 60 mEq/L. Arterial blood gas (ABG) examination at room air showed pH, 7.38 (normal, 7.35–7.42); PCO₂, 38 mm Hg (normal, 35–45); and PO₂, 80 mm Hg (normal, 80–100). On physical examination, C.C. was normotensive, appeared to be euvolemic, and had no edema detected. Review of his medical records showed normal adrenal and thyroid function. C.C. was currently not using any medications. On admission to the ward, C.C. weighed 60 kg and was given 1 L of normal saline, after which his serum sodium concentration was 108 mEq/L. Identify the cause of hyponatremia in C.C. and describe its pathophysiology.

[SI units: serum Na, 110 mmol/L; K, 3.6 mmol/L; Cl, 78 mmol/L; bicarbonate, 22 mmol/L; BUN, 3.57 mmol/L; SrCr, 79.6 μmol/L; glucose, 5.0 mmol/L; serum osmolality, 230 mmol/kg; urine osmolality, 616 mmol/kg; urine Na, 60 mmol/L; PCO₂, 5.1 kPa; PO₂, 853.1 mmol/L; serum Na, 108 mmol/L]

In a patient with hypo-osmolar hyponatremia with a volume status that is apparently normal, the differential diagnosis⁴⁰ includes hypothyroidism,⁵¹ cortisol deficiency,⁵² a reset osmostat,⁵³ psychogenic polydipsia,^{36,38} and the syndrome of inappropriate antidiuretic hormone secretion (SIADH),^{54–56} which is a diagnosis of exclusion. C.C.'s normal thyroid and

adrenal function tests exclude hypothyroidism and cortisol insufficiency as causes of his hyponatremia. The inappropriately elevated urine osmolality (>100 mOsm/kg) is inconsistent with psychogenic polydipsia or a reset osmostat, because free water excretion is usually not impaired in these disorders. These findings, in addition to a urine sodium concentration >40 mEq/L and a normal acid–base and potassium balance, are consistent with SIADH.^{37,55,56}

In SIADH, the ADH secretion is considered inappropriate because of its persistence in the absence of appropriate osmotic and hemodynamic stimuli. Water ingestion is essential to the development of hyponatremia in SIADH because persistent ADH activity impairs water excretion, resulting in expansion of body fluids and hypo-osmolar hyponatremia. Edema rarely is apparent because only one-third of the retained water resides in the extracellular space and the sodium homeostatic mechanisms are intact.^{34,40} The extracellular fluid expansion activates volume receptors and results in natriuresis. At steady state, urinary sodium excretion reflects sodium intake and is usually >40 mEq/L, as in C.C.'s case. Nonetheless, if sodium intake is reduced severely, the urinary sodium concentration may become <40 mEq/L.³⁷

The causes of SIADH are diverse and are shown in Table 11-1. Four different patterns of inappropriate ADH release have been identified.³⁷ No correlation has been found between these patterns and the underlying causes of SIADH, however. Mechanisms for drug-induced SIADH include ADH-like action on the collecting tubule, central stimulation of ADH release, and potentiation of the ADH effect.^{37,57} Small-cell lung carcinoma is the most likely cause of C.C.'s SIADH.

11. Why was C.C.'s serum sodium concentration lower after the saline infusion?

Isotonic sodium chloride solution (154 mEq/L each of Na and Cl ions, or 308 mOsm/L) initially will increase the plasma sodium concentration because its osmolality is higher than C.C.'s.⁵⁸ C.C., however, has a relatively fixed urine osmolality of 616 mOsm/kg owing to persistent ADH activity; thus, he must excrete an osmolar load of 616 mOsm in a volume of 1,000 mL of urine at steady state. Because a total of 1 L of fluid containing 308 mOsm was administered, all the solutes were excreted in 500 mL of urine output, and 500 mL of free water was retained to cause a further dilution of sodium and a reduction in serum sodium concentration.^{37,58}

Neurologic Manifestations

12. Why are C.C.'s neurologic manifestations characteristic of hyponatremia?

As the plasma osmolality declines, the osmotic gradient created across the blood–brain barrier favors the movement of water into the brain and other cells.^{37,40} Water movement from the cerebrospinal fluid into the cerebral interstitium results in cerebral edema. Brain swelling is limited by the meninges and cranium, however, giving rise to increased intracranial pressure and neurologic symptoms. The degree of cerebral overhydration and the rapidity of its development appear to correlate with the severity of symptoms.^{37,40}

When hyponatremia develops in <2 to 3 days or the rate of decline in serum sodium >0.5 mEq/L/hour, the situation

is regarded as acute.^{37,59,60} The patient often becomes symptomatic when serum sodium concentration falls to 125 mEq/L; early complaints include nausea, vomiting, and malaise.^{37,61} Severe symptoms occur more commonly when the serum sodium falls to <120 mEq/L and the rate of decline >0.5 mEq/L/hour. The patient may present with headache, tremors, incoordination, delirium, lethargy, and obtundation. As the serum sodium drops below 110 to 115 mEq/L, seizure and coma may result.^{37,61} On occasion, severe brain edema leads to transtentorial herniation and eventually death. Women, especially those who are premenopausal, apparently are more susceptible to the development of severe neurologic symptoms and irreversible neurologic damage than are men.^{62,63}

In contrast to acute hyponatremia, patients who are chronically hyponatremic are usually asymptomatic.^{37,59} If present, symptoms are usually vague and nonspecific and tend to occur at lower serum sodium concentrations than those associated with symptomatic acute hyponatremia.^{37,59,61} The patient may experience anorexia, nausea, vomiting, muscle weakness, and cramps. Irritability, hostility, confusion, and personality changes also may be seen. At extremely low sodium levels, stupor and, rarely, seizures have been reported.

Brain Adaptation to Hyponatremia

The difference in symptoms between acute and chronic hyponatremia is related to cerebral adaptation to hypotonicity. Two adaptive mechanisms are important in minimizing cerebral edema.^{37,40,64,65} First, *cerebral overhydration* increases the hydrostatic pressure in the cerebral interstitium, which results in the movement of fluid from the cerebral interstitial space to the cerebrospinal fluid. Second, the *extrusion of intracellular solutes* reduces cellular osmolality, which in turn enhances water movement out of the cells. Sodium and potassium ions are the initial solutes extruded, followed over a period of hours to days by osmolytes such as inositol, glutamine, glutamate, and taurine.⁶⁴ Therefore, when the serum sodium concentration falls faster than the onset of brain osmotic adaptation processes, serious and permanent neurologic damage can occur.^{37,40,64,65} On the other hand, when hyponatremia develops over 2 to 3 days, symptoms are not usually seen unless the serum sodium concentration is reduced markedly.

It is often difficult to determine the acuity and chronicity of hyponatremia. Unless an obvious cause for acute hyponatremia is found, assume that the condition is chronic.^{37,59,60,65} A rapid decline in serum sodium concentration usually suggests that hypotonic fluid was administered to a patient with a condition that overwhelms or impairs renal water excretion. These conditions include psychogenic polydipsia^{35,36}; postoperative hyponatremia^{62,63,66,67}; postprostatectomy syndrome³⁹; and administration of thiazide diuretics,^{41,42} parenteral cyclophosphamide,⁶⁸ oxytocin,⁶⁹ and arginine vasopressin or its analogs.⁵⁷ C.C.'s symptoms appear to have developed over 7 days and are consistent with chronic hyponatremia.

Rate of Correction of Hyponatremia

13. How should C.C.'s hyponatremia be managed?

C.C.'s water excess should be calculated to estimate the amount of water that should be removed to achieve the desired

sodium concentration.

$$\text{Water excess} = \text{TBW} - \text{TBW} \left(\frac{\text{Observed serum Na}}{\text{Desired serum Na}} \right) \quad 11-5$$

$$= 30 \text{ L} - 30 \text{ L} \left(\frac{110 \text{ mEq/L}}{120 \text{ mEq/L}} \right) \quad 11-F$$

$$= 2.4 \text{ L}$$

$$\text{where TBW} = (0.5 \text{ L/kg})(60 \text{ kg}) = 30 \text{ L} \quad 11-G$$

The treatment of hyponatremia has been controversial. Severe hyponatremia is associated with high rates of morbidity and mortality, but its treatment can also result in morbidity. The rate of correction has been implicated as the main cause of complications.^{59-61,65,70-72}

It takes time for the brain to lose osmolytes to reduce cerebral swelling during hyponatremia; conversely, the rate of reaccumulation of these osmolytes must keep pace with the rise in serum sodium concentration to avoid brain dehydration and damage. Indeed, rapid correction of hyponatremia can cause a constellation of neurologic findings known as *osmotic demyelination syndrome* (ODS).^{71,72} Clinical manifestations usually are delayed and occur 1 to several days after the treatment has been started. Neurologic findings include transient behavioral changes, seizures, akinetic mutism in mild cases, and features of a pontine disorder in severe cases (pseudobulbar palsy, quadriparesis, and coma). In some patients, the damage is irreversible, and central pontine myelinolysis can be documented in fatal cases. Patients at greatest risk for osmotic demyelination are those with severe hyponatremia lasting >2 days and those in whom the rate of correction of hyponatremia is >12 mEq/L in any 24-hour period.^{65,71,72} Hypokalemia, which was found in about 90% of patients with ODS associated with rapid hyponatremia correction, has been suspected as a predisposing factor in the development of ODS.⁷² Because the etiology of this complication is unclear, it may be beneficial to correct the hypokalemia before correcting the severe hyponatremia.⁷²

Retrospective reviews suggest that acute hyponatremia can be treated safely at a rate of 1 mEq/L/hour initially, until the serum sodium concentration reaches 120 mEq/L. Thereafter, the rate of correction should be reduced to ≤0.5 mEq/L/hour, such that an increment in sodium concentration does not exceed 12 mEq/L in the first 24 hours.^{59,73} Slow correction is indicated for severe chronic hyponatremia. No neurologic complications were seen in patients with severe hyponatremia when the average rate of correction to serum sodium was <0.55 mEq/L/hour or when the increase in serum sodium was <12 mEq/L in 24 hours or <18 mEq/L in 48 hours.⁷³

In C.C., the serum sodium concentration should be raised to approximately 120 mEq/L at a correction rate of approximately 0.5 mEq/L/hour, using hypertonic saline and furosemide. Serum sodium concentrations should be monitored closely because the equation for calculating water excess does not take into account insensible loss, which can increase the rate of sodium correction.

The use of normal saline is not useful in C.C. because he excretes salt normally (urine Na, 60 mEq/L). C.C.'s sodium deficit is as follows:

$$(0.5 \text{ L/kg})(60 \text{ kg})(120 - 110 \text{ mEq/L}) = 300 \text{ mEq} \quad 11-H$$

Because 1 L of 3% sodium chloride solution contains 513 mEq of sodium, approximately 600 mL of 3% saline solution, which contains 308 mEq of sodium, will be required to correct the sodium deficit. The recommended serum sodium concentration correction rate is 0.5 mEq/L/hour; therefore, a minimum of 20 hours will be needed to raise the serum sodium concentration by 10 mEq/L (from 110–120 mEq/L). The amount of sodium replacement to safely increase the serum sodium concentration can be determined by the product of the rate of replacement (0.5 mEq/L/hour) and total body weight (TBW) (30 L, Equation 11-G)—that is, 15 mEq/hour. The maximal rate of infusion of 3% saline, which contains 0.513 mEq/mL of sodium, is therefore 29.2 mL/hour [15 mEq/hour]/[0.513 mEq/mL]. A rate of 25 mL/hour, therefore, is appropriate to safely replace C.C.'s sodium deficit.

Because calculations for water excess and sodium deficits are only approximations, the patient's serum osmolality, serum sodium, and clinical response must be monitored closely. Urinary losses can be replaced with 3% sodium chloride solution and appropriate amounts of potassium.

Chronic Management of the Syndrome of Inappropriate Antidiuretic Hormone Secretion

The SIADH is usually transient if the underlying cause can be removed. Chronic SIADH can occur, however, as illustrated by C.C. Water restriction sufficient to create a negative water balance is the primary therapy and should be attempted first.^{37,40} In general, all fluids, not just water, should be included in the restriction. Salt intake, however, should not be reduced or solute depletion can occur. The extent of fluid restriction depends on urine output, the amount of insensible water loss, and urine osmolality. For a given amount of solute excretion, patients with a high urine osmolality require a smaller volume of urine (i.e., more water retained) than those with a lower urine osmolality (i.e., less water retained). Hence, more stringent water restriction is required in patients with a high urine osmolality. Commonly, several days of restriction are needed before a significant increase in plasma osmolality is observed.

When fluid restriction fails to reverse the hypo-osmolar state or when the patient is unwilling or unable to comply with the severe fluid restriction, drugs that antagonize the effect of ADH can be used.^{37,40} These include loop diuretics,^{74,75} demeclocycline,⁷⁶ and lithium.⁷⁷ Furosemide, 20 to 40 mg/day, reduces urine osmolality by blocking the concentrating ability of the kidney.⁷⁴ Demeclocycline and lithium directly impair the response to ADH at the collecting tubule, inducing nephrogenic diabetes insipidus.^{76,77} Demeclocycline (300–600 mg twice daily) is usually better tolerated than lithium. Its effect on water excretion is delayed for a few days and it dissipates over a similar period of time after the drug is stopped. Nephrotoxicity has been reported with its use in patients with cirrhosis.⁷⁸ Limited data suggest that phenytoin may inhibit ADH secretion, but its effectiveness is questionable.⁸² Urea can correct hypo-osmolality by increasing solute-free water excretion and reducing urinary sodium excretion.⁸³ It has been used effectively, at 30 to 60 g/day, both short and long term, to reduce the need for fluid restriction.⁸⁴ An IV formulation of urea is available commercially; however, for oral administration, 30 g of urea crystals can be dissolved in 10 mL of aluminum-magnesium

antacid (Maalox) and 100 mL of water. Alternatively, orange juice or other strongly flavored liquids can be used to improve palatability.

Vasopressin Receptor Antagonists

Vasopressin receptor antagonists (VRA), also known as the “vaptans” or “aquaretic agents,” comprise a new class of agents used for the treatment of hyponatremia. Arginine vasopressin (AVP), a neuropeptide hormone, plays an important role in maintaining serum osmolality, as well as circulatory and sodium homeostasis.⁸⁵ AVP exerts its physiologic effects by acting on V_{1A} , V_2 , and V_{1B} receptors, causing effects such as vasoconstriction,^{86,87} water excretion,⁸⁸ and corticotropin release,⁸⁹ respectively. V_2 receptors are located in the renal collecting tubules and they mediate the antidiuretic effects of AVP. Antagonism of the V_2 receptors results in aquaresis, a unique solute-free and electrolyte-sparing (sodium and potassium) water excretion by the kidneys. Because circulating levels of AVP is elevated in SIADH, cirrhosis, and heart failure, VRA would be beneficial in the management of hyponatremia associated with these conditions.

Currently, conivaptan, a mixed V_{1A} and V_2 receptor antagonist, is the only VRA approved by the FDA for the treatment of euvolemic and hypervolemic hyponatremia in hospitalized patients.⁸⁵ Randomized, double-blind, placebo-controlled trials have demonstrated its efficacy in increasing serum sodium concentrations in patients with euvolemic and hypervolemic hyponatremia associated with SIADH and heart failure, respectively.^{90,91} Its use is restricted to a short-term (4 days) inpatient use only and it is administered as an IV infusion. Close monitoring of serum sodium concentration is necessary to prevent overly rapid correction of hyponatremia and central pontine myelinolysis that may ensue. Because conivaptan is a potent inhibitor of the CYP3A4 enzyme, drug interaction with medications that undergo CYP3A4-mediated metabolism is possible.⁸⁵ In addition, infusion-site reactions with conivaptan are common caused by the organic solvent, polypropylene glycol.

Tolvaptan, lixivaptan, and satavaptan are three other VRA that are selective for the V_2 receptor. Being orally active, they are useful in patients who require chronic therapy or when oral therapy is preferred. Because of their selectivity for the V_2 receptor, these agents should have less effect on lowering blood pressure and may be more suitable for use in patients with low to normal blood pressure, such as those with heart failure or cirrhosis. Tolvaptan has been shown to increase serum sodium concentration significantly and correct hyponatremia in patients with SIADH, chronic heart failure, or cirrhosis.⁹² It has also been studied most extensively in chronic heart failure where reduction of edema and weight, as well as normalization of serum sodium concentrations, were shown.^{93,94} To date, the use of tolvaptan in heart failure does not, however, appear to result in any overall mortality benefit.⁹⁵ Lixivaptan has been studied in patients with hyponatremia from heart failure and cirrhosis where the results showed significant increase in aquaresis and serum sodium concentrations.⁹⁶⁻⁹⁸ When satavaptan was administered to patients with hyponatremia caused by SIADH, normalization of serum sodium concentrations or an increase by ≥ 5 mEq/L was observed.⁹⁹ Adverse effects of these agents include thirst, dry mouth, polyuria, and blood pressure reduc-

tion. Additionally, all three agents are inhibitors of the CYP3A4 enzyme.

The VRA should be used in hyponatremic patients with mild to moderately severe neurologic symptoms. Not only have they been shown to maintain normal serum sodium concentrations both short- and long-term, their aquaretic effect could also reduce or eliminate the need for fluid restriction normally required of the patients.^{100,101} The effectiveness of VRA to correct euvolemic and hypervolemic hyponatremia has now been shown. Their long-term safety with chronic use and their potential benefits on morbidity and mortality, however, need to be assessed.

Hypernatremia

Hypernatremia can occur under the following conditions: (a) normal total body sodium with pure water loss, (b) low total body sodium with hypotonic fluid loss, and (c) high total body sodium as a result of pure salt gain.¹⁰² Therefore, as in hyponatremia, it is important to assess the volume status of the extracellular fluid when evaluating hypernatremia.

Pure water loss can result from the inability of the kidney to conserve water (diabetes insipidus) or from extrarenal water loss through the respiratory tract or the skin.¹⁰³ Usually, pure water loss does not cause hypernatremia unless the thirst center is damaged or access to free water is limited.¹⁰²

Hypotonic fluid loss can occur renally as a result of osmotic diuresis, use of loop diuretics, postobstruction diuresis, or intrinsic renal disease. Extrarenally, hypotonic fluid loss can result from diarrhea, vomiting, burns, and excessive sweating.

Pure salt gain can result from the use of hypertonic saline during abortion, sodium bicarbonate administration during cardiopulmonary resuscitation, hypertonic feedings in infants, and, rarely, mineralocorticoid excess.

The management of hypernatremia includes correcting the underlying cause of the hypertonic state, replacing the water deficits, and administering adequate water to match ongoing losses.¹⁰² The pure water deficit can be estimated as follows:

$$\text{Water deficit} = \text{Normal TBW} - \text{Present TBW} \quad \mathbf{11-6}$$

$$= 0.6 (\text{LBW}) - \left(\frac{\text{Normal Na concentration}}{\text{Present Na concentration}} \right) 0.6 (\text{LBW}) \quad \mathbf{11-I}$$

$$= 0.6 (\text{LBW}) \left[1 - \left(\frac{\text{Normal Na concentration}}{\text{Present Na concentration}} \right) \right]$$

The rate at which hypernatremia should be corrected depends on the severity of symptoms and degree of hypertonicity. Too rapid correction can precipitate cerebral edema, seizures, and irreversible neurologic damage, and it can be fatal. For asymptomatic patients, the rate of correction probably should not exceed changes of 0.5 mEq/L/hour in plasma sodium. A rule of thumb is to replace half the calculated deficit with hypotonic solutions over 12 to 24 hours. Any ongoing water loss, including insensible loss, also should be replenished while carefully monitoring the patient's neurologic status. The remaining deficit can then be replaced over the ensuing 24 to 48 hours. Concomitant solute deficits and ongoing solute losses should also be replaced as appropriate. If hypernatremia is caused only by pure water loss, free water can be administered as 5% dextrose in water. Half-normal or quarter-normal saline is used if

a sodium deficit is also present. In patients with hypotension or shock, the effective arterial blood volume should be restored with normal saline or colloids before the plasma tonicity is corrected.

CLINICAL USE OF DIURETICS

Diuretics reduce sodium chloride reabsorption in the kidney tubules, thereby increasing urine volume. Enhanced solute and fluid excretion can be initiated through osmotic diuresis or inhibition of transport in the kidney tubules. Diuretics are categorized according to the sites within the kidney tubules where they inhibit sodium reabsorption. (See Chapter 13, Essential Hypertension, and Chapter 31, Chronic Renal Failure.)

Loop Diuretics

The loop diuretics, furosemide, bumetanide, torsemide, and ethacrynic acid, are the most potent diuretics available. They are also known as *high-ceiling diuretics* because they can inhibit the reabsorption of up to 20% to 25% of the filtered sodium load. The loop diuretics act in the medullary and cortical portion of the thick ascending limb of Henle's loop. Sodium and chloride transport through the $\text{Na}^+ - \text{K}^+ - 2\text{Cl}^-$ carrier in the luminal membrane is inhibited. Reabsorption of calcium and magnesium is reduced secondary to the reduction in sodium chloride transport. The loop diuretics also possess a vasodilatory effect that can contribute to their diuretic activity.

Thiazide Diuretics

The thiazide diuretics are a group of structurally similar compounds that share a common mechanism of action. Several other sulfonamide diuretics that differ chemically, such as chlorthalidone, indapamide, and metolazone, also have diuretic effects similar to the thiazides. The primary site of action of these diuretics is at the proximal portion of the distal tubule. Sodium reabsorption via the $\text{Na}^+ - \text{Cl}^-$ cotransporter is blocked through competition with the Cl^- site of the transporter. Some of these agents, such as chlorothiazide, may also reduce sodium transport in the proximal tubule. The contribution of this effect toward net diuresis is negligible, however, because the sodium ions that are not reabsorbed in the proximal tubule will subsequently be reabsorbed in Henle's loop. Thiazide diuretics can enhance the reabsorption of calcium ion through a direct action on the early distal tubule. Therefore, these agents are useful to reduce calciuria in patients with kidney stones. In contrast, magnesium excretion is increased by the thiazides, which may result in hypomagnesemia.

Potassium-Sparing Diuretics

Spironolactone, Triamterene, and Amiloride

Spironolactone, triamterene, and amiloride are potassium-sparing diuretics that inhibit sodium reabsorption in the cortical collecting tubules through different mechanisms. Spironolactone (Aldactone) is a competitive receptor-site antagonist of aldosterone in the distal segment of the renal tubule and is indicated especially for patients with hyperaldosteronism secondary to decreased renal perfusion. Patients with hyperaldosteronism can be identified by urinary electrolyte screening,

which shows high urine potassium excretion with concomitant diminished or absent urine sodium excretion. By serving as an aldosterone antagonist, spironolactone inhibits sodium reabsorption and decreases the excretion of potassium and hydrogen ions. Dosages as high as 200 to 400 mg/day may be needed to induce natriuresis in patients with hyperaldosteronism.

In contrast to spironolactone, triamterene and amiloride reduce the passage of sodium ions through the luminal membrane, independent of aldosterone activity, by directly acting on sodium and potassium transport processes in the distal renal tubular cells. Triamterene and amiloride offer the advantage of a more rapid onset of action than spironolactone.

The initial effects of spironolactone are usually delayed for 2 or 3 days, and several additional days are needed to attain maximal diuretic effect. This delay is caused partly by the formation of an active metabolite, canrenone, which accounts for approximately 70% of the antimineralocorticoid activity of spironolactone. The elimination half-life of canrenone is 13.5 to 24 hours in normal subjects and is prolonged in patients with chronic liver disease (59 hours [range, 32–105 hours]) or CHF (37 hours [range, 19–48 hours]).¹⁰⁴ Although the elimination half-life of canrenone is prolonged in these patients, plasma canrenone concentrations do not differ significantly from those in normal subjects because assay methods for canrenone are nonspecific and include measurement of both active and inactive metabolites.^{105,106}

Triamterene (Dyrenium) is absorbed incompletely from the GI tract. The drug has a short half-life of 1.5 to 2.5 hours. The total body clearance is high because of rapid and extensive metabolism by the liver. Both the parent compound and the metabolite undergo biliary and renal excretion. As with spironolactone, the hepatic metabolism of triamterene can be altered in patients with cirrhosis.¹⁰⁷ The diuretic effect of triamterene begins within 2 to 3 hours of administration, with a maximal duration of 12 to 16 hours.

Amiloride (Midamor) does not undergo hepatic metabolism; approximately 50% of amiloride is excreted in the urine unchanged and the remainder is recovered in the stool as unabsorbed drug or through biliary excretion. Serum amiloride concentrations peak 3 hours after oral ingestion, and the half-life is 6 hours. Although commonly administered doses are in the range of 2.5 to 10 mg, diuresis increases over a much greater range. The onset of action is 2 hours, with maximal effects at 4 to 6 hours. Duration of action is dose dependent and ranges from 10 to 24 hours. Amiloride does not undergo hepatic metabolism, and the drug can accumulate in patients with renal insufficiency.

The maximal amount of filtered sodium that can be excreted through the action of potassium-sparing diuretics is approximately 1% to 2%. Their natriuretic activity, therefore, is relatively limited compared with the thiazide and loop diuretics. These agents are often used concurrently with thiazide and loop diuretics to reduce potassium loss. Spironolactone is especially useful in patients with liver cirrhosis and ascites, who are likely to have high levels of aldosterone.

Acetazolamide

Acetazolamide inhibits carbonic anhydrase, an enzyme that mediates the excretion of sodium, bicarbonate, and chloride

ions in the proximal tubule. Use of the drug will increase urine pH owing to the increased excretion of bicarbonate ion. The net diuretic and natriuretic effects are limited, similar to those of the potassium-sparing diuretics. Because of the drug's proximal site of action, the sodium ions that are not reabsorbed will subsequently be reclaimed in Henle's loop and the distal tubule. In addition, metabolic acidosis associated with the use of acetazolamide diminishes its diuretic effect.

Osmotic Diuretics

Osmotic diuretics are nonreabsorbable solutes in the kidney tubule. They act primarily in the proximal tubule, where the osmotic pressure they generate impedes the reabsorption of water and solutes. Unlike other diuretics, the amount of water loss exceeds the concurrent loss of sodium and potassium. Mannitol has been used in the early treatment of oliguric postischemic acute renal failure to increase urine output. Urea, another osmotic diuretic, and mannitol are used to reduce intracranial pressure through cellular dehydration.

Complications of Diuretic Therapy

Disturbances in fluid, electrolyte, and acid–base balance are common side effects associated with diuretic therapy. These side effects, including hypokalemia, are discussed in detail in Chapter 13, Essential Hypertension; Chapter 18, Heart Failure; and Chapter 42, Gout and Hyperuricemia. Two complications, hyponatremia and metabolic alkalosis and acidosis, are, however, discussed in the following section because of their specific relevance to fluid balance.

Hyponatremia

Thiazides induce diuresis by inhibiting sodium and water reabsorption in the kidney tubule. Because both sodium and water are lost, overdiuresis *per se* is not expected to cause hyponatremia. Instead, hyponatremia represents a dilution of plasma sodium by excess free water caused by volume depletion-induced ADH activity. The enhanced ADH secretion increases free water reabsorption, resulting in hyponatremia. Large doses of diuretic, excessive water drinking, and severe sodium intake restriction all will accentuate the hyponatremia. Elderly patients are susceptible to this diuretic-induced complication.

Metabolic Alkalosis and Acidosis

Metabolic alkalosis often occurs in conjunction with potassium depletion secondary to diuretic use. The diuretic-induced contraction of extracellular fluid volume stimulates the secretion of aldosterone, which promotes the absorption of sodium and the retention of hydrogen ions in the kidney tubule. The net urinary loss of hydrogen ions into the urine results in metabolic alkalosis. Generally, reducing the dose of the diuretic will restore the acid–base balance.

Acetazolamide causes metabolic acidosis by inhibiting carbonic anhydrase, which results in urinary excretion of sodium bicarbonate. Spironolactone, amiloride, and triamterene can cause hyperchloremic metabolic acidosis because of their ability to decrease potassium and hydrogen ion tubular secretion. Patients with renal dysfunction or those taking potassium supplements or angiotensin-converting enzyme inhibitors, which

reduce aldosterone secretion, are at increased risk for developing hyperkalemia and metabolic acidosis.

POTASSIUM

Homeostasis

The total amount of potassium stored in the body is approximately 45 to 55 mEq/kg and varies with age, gender, and muscle mass. Lower total body potassium is found in older adults, females, and individuals with a low lean body mass-to-fat ratio. Potassium is distributed unevenly between the intracellular and extracellular compartments: 98% of the total body potassium resides in the intracellular compartment, predominantly the muscle, and only 2% is found in the extracellular space.^{34,99,109} The disproportionate intracellular distribution of potassium is maintained by the $\text{Na}^+ - \text{K}^+$ -ATPase pump, which transports sodium out of the cell in exchange for potassium.^{108–111} The cell membrane resting potential is determined by the ratio of intracellular-to-extracellular potassium concentrations. As this ratio increases, hyperpolarization of the cell membrane occurs. Conversely, cellular depolarization results when the ratio decreases. In both situations, generation of the action potential is impaired.

The plasma potassium concentration is maintained within a narrow range: 3.5 to 5.0 mEq/L. Although the plasma potassium concentration can be affected by the total body potassium store, total body potassium excess or deficit cannot be estimated accurately based solely on the plasma concentration. In fact, a normal plasma potassium concentration does not imply normal total body potassium because multiple factors affect the plasma potassium concentration independent of total body potassium.¹⁰⁸

Potassium homeostasis is maintained by both renal and extrarenal processes. The renal process regulates total body potassium by matching potassium excretion to dietary intake (external balance),¹¹² whereas the extrarenal process regulates potassium distribution across cell membrane (internal potassium balance).^{108,110}

The normal daily intake of potassium ranges between 50 and 100 mEq. Approximately 90% of the ingested potassium is eliminated by the kidneys and approximately 10% is eliminated via the GI tract.¹¹² Potassium is filtered freely through the glomerulus and then reabsorbed. By the time the filtrate reaches the distal convoluted tubule, >90% of filtered potassium has already been reabsorbed. The amount of potassium excreted is determined by distal tubular potassium secretion in the principal cells of the cortical collecting duct, which is under the influence of aldosterone. Hyperkalemia, increased potassium load, and angiotensin II can all stimulate aldosterone secretion.¹⁰⁸

Factors that affect renal potassium excretion include tubular flow, sodium delivery to the distal segments of the nephron, the presence of poorly absorbable anions that increase luminal electronegativity, acid–base status, and aldosterone activity.⁹⁶ Potassium excretion increases during hyperkalemia and decreases during potassium depletion. Excretion of an acute potassium load is a slow process, with only half the potassium load excreted in the first 4 to 6 hours. Lethal hyperkalemia would ensue were it not for the extrarenal process that regulates intracellular–extracellular potassium distribution.¹⁰⁸

The Na⁺-K⁺-ATPase pump, which extrudes sodium from the cell in exchange for potassium, is pivotal in maintaining internal potassium balance.¹¹¹ Different hormonal factors regulate the activity of the Na⁺-K⁺-ATPase pump, namely insulin, catecholamines, and aldosterone. Insulin, the most important regulator, enhances potassium uptake by muscle, liver, and adipose tissue by stimulating Na⁺-K⁺-ATPase.¹¹⁴ Indeed, basal insulin secretion is essential for potassium homeostasis.¹⁰⁸ Whereas β₂-adrenergic agonists activate the Na⁺-K⁺-ATPase pump via cyclic adenosine monophosphate (cAMP) and cause hypokalemia, α-adrenergic stimulation promotes hepatic potassium release and causes hyperkalemia.¹¹⁵ Epinephrine, an α- and β-agonist, causes a transient increase in plasma potassium (α-agonism) followed by a more sustained decrease in plasma potassium (β-agonism).^{115,116} Besides its kaliuretic effect and enhanced potassium secretion in the colon, aldosterone also stimulates Na⁺-K⁺-ATPase.

Other factors that affect the transcellular distribution of potassium include systemic pH, plasma tonicity, and exercise.^{108,111} The effect of *acid-base balance* on potassium distribution is not readily predictable and depends on both the nature and the direction of the underlying disorder. The concomitant effect of the acid-base disorder on renal potassium excretion further complicates the relationship between plasma potassium concentration and pH.^{108,117} In acute inorganic acidosis, plasma potassium concentration increases by 0.2 to 1.7 mEq/L per 0.1-U decrease in pH. Chronic inorganic metabolic acidosis usually is associated, however, with hypokalemia because of urinary potassium loss associated with both proximal (type II) and distal (type I) renal tubular acidosis.^{108,117} In contrast, organic acidosis commonly has no effect on potassium distribution.¹¹⁸ Other associated factors in the organic acidosis may, however, affect cellular potassium distribution.¹¹⁷ For example, hyperglycemia in diabetic ketoacidosis may increase the serum potassium concentration because of the hypertonic effect of glucose.¹¹⁹ Hypertonicity causes cell shrinkage and increases the intracellular to extracellular fluid potassium gradient, favoring potassium egress. Acute metabolic alkalosis only modestly decreases the plasma potassium concentration: 0.3 mEq/L for each 0.1-U pH increment.^{108,117} As with chronic metabolic acidosis, chronic metabolic alkalosis causes profound renal potassium wasting and is associated with hypokalemia. Respiratory acid-base disorders usually are associated with less significant changes in plasma potassium concentration than are metabolic acid-base disorders.¹¹⁷ Exercise often causes an increase in the serum potassium concentration to a degree that varies with the intensity of the exercise.¹²⁰

Hypokalemia

Etiology

14. J.P., a 60-year-old woman, presents to the ED with complaints of malaise, generalized weakness, nausea, and vomiting for 3 days. Her medical history includes hypertension for 20 years. J.P.'s current medications include hydrochlorothiazide 25 mg/day and nifedipine XL 30 mg/day. She has not been able to take her medications in the past few days, however, because of vomiting. J.P. denies recent diarrhea or use of laxatives. Her BP is 130/70 mm Hg with a pulse of 80 beats/minute while sitting, and 120/70

mm Hg with a pulse of 95 beats/minute on standing. Physical examination reveals a thin, older woman with poor skin turgor, dry mucous membranes, and a flat jugular vein. T-wave flattening is noted on the electrocardiogram (ECG). Laboratory tests show serum Na, 138 mEq/L (normal, 134–146); K, 2.1 mEq/L (normal, 3.5–5.1); Cl, 100 mEq/L (normal, 92–109); bicarbonate, 32 mEq/L (normal, 24–31); BUN, 30 mg/dL (normal, 18–25); creatinine, 1.2 mg/dL (normal, 0.5–1.5); and glucose, 100 mg/dL (normal, 60–110). ABG shows pH 7.50 (normal, 7.35–7.45); Pco₂, 45 mm Hg (normal, 35–45); and Po₂, 70 mm Hg (normal, 80–100) at room air. Urine electrolytes are Na, 30 mEq/L; K, 60 mEq/L; and Cl, <15 mEq/L. The patient's presentation is consistent with gastroenteritis. What are the causes of J.P.'s hypokalemia?

[SI units: serum Na, 138 mmol/L; K, 2.1 mmol/L; Cl, 100 mmol/L; bicarbonate, 32 mmol/L; BUN, 10.7 mmol/L; creatinine, 106.1 μmol/L; glucose, 5.55 mmol/L; Pco₂, 6.0 kPa; Po₂, 9.33 kPa; urine Na, 30 mmol/L; K, 60 mmol/L; Cl, <15 mmol/L]

When evaluating hypokalemia, the clinician should determine whether the hypokalemia is a result of low intake, increased cellular uptake of potassium, or excessive loss of potassium via the kidneys, GI tract, or skin.^{34,121} History and physical evidence of potassium depletion; medication history (including use of over-the-counter medicines); and assessment of the patient's BP, extracellular volume, and concurrent acid-base status can provide clues to the causes of hypokalemia.^{34,121}

Because J.P. has been unable to eat for the past few days, decreased oral intake may have contributed to her hypokalemia. Because most foods are rich in potassium, however, inadequate intake rarely is the sole cause of potassium depletion unless inappropriate and continued renal or extrarenal losses occur, or potassium intake is severely restricted to <10 to 15 mEq/day.¹²¹ Alkalosis,¹¹⁷ insulin administration,¹⁰⁸ hypertonic solution administration, periodic paralysis,¹²² β₂-agonists,¹²³ barium poisoning,¹²⁴ and treatment of megaloblastic anemia with vitamin B₁₂¹²⁵ all have been associated with increased cellular potassium uptake (Table 11-2). Although the relationship between the degree of hypokalemia and increase in blood pH varies widely,¹¹⁷ J.P.'s metabolic alkalosis probably enhances the cellular uptake of potassium. The transcellular shift of potassium should not result in total body potassium depletion, however.

The GI tract is an important site of potassium loss, particularly through vomiting and diarrhea. Because the potassium content of gastric secretion (5–10 mEq/L) is much less than that of the intestinal secretion (up to 90 mEq/L),¹²¹ loss of a large volume of gastric secretion is needed to produce substantial potassium depletion. Potassium deficit induced by vomiting, however, is commonly secondary to renal potassium loss, especially within the initial 24 to 48 hours.¹²⁶ The loss of hydrogen ion in gastric juice results in an elevated plasma bicarbonate concentration. The increased amount of bicarbonate ion, as a nonreabsorbable anion, increases water delivery to the distal nephron and enhances sodium reabsorption and potassium secretion, resulting in hypokalemia. The potassium wasting is often transient, because increased proximal reabsorption of sodium and bicarbonate will result in diminished bicarbonate delivery to the distal site. Reduced potassium excretion will ensue, commonly within 48 to 72 hours. Subsequent potassium

Table 11-2 Drugs That Most Commonly Induce Hypokalemia

| <i>Drug</i> | <i>Mechanism</i> | <i>Predisposing Factors</i> |
|---|--|---|
| Acetazolamide | Marked ↑ in renal K ⁺ loss | Most profound with short-term therapy |
| Amphotericin | Renal K ⁺ loss (renal tubular acidosis) | Concurrent piperacillin, ticarcillin |
| β ₂ -agonists | Intracellular shift of K ⁺ | |
| Cisplatin | Renal K ⁺ loss secondary to renal tubular damage | May be dose related but can occur after a single 50-mg/m ² dose |
| Corticosteroids | Renal K ⁺ loss. Enhanced Na ⁺ reabsorption at distal tubule and collecting ducts in exchange for K ⁺ and H ⁺ | Supraphysiologic doses of agents with moderate to strong mineralocorticoid activity (e.g., prednisone, hydrocortisone) |
| Insulin with glucose | Intracellular shift of K ⁺ | Predictable effect when insulin administered to patients with diabetic ketoacidosis' combination used to treat hyperkalemia |
| Penicillins (piperacillin, ticarcillin) | High Na ⁺ load and nonreabsorbable anions can ↑ K ⁺ loss | Was more common with carbenicillin when it was available; newer penicillins are used in lower doses; less likely to produce hypokalemia |
| Thiazide and loop diuretics | Renal K ⁺ loss. ↑ Na ⁺ delivery to the late distal tubule, resulting in Na ⁺ resorption in exchange for K ⁺ | Patients with hyperaldosteronism (e.g., cirrhosis, CHF) predisposed; may be dose related |

CHF, Congestive heart failure.

loss will then be primarily consequent to gastric secretion removal.

The absence of diarrhea in J.P. excludes the GI tract as the source of potassium loss. Potassium loss through the skin also is unlikely in J.P. because the potassium concentration of sweat is <10 mEq/L. Therefore, profuse sweating, such as that induced by vigorous exercise in a hot, humid environment, or severe burns are needed to cause substantial loss.

J.P.'s inappropriately high urinary potassium concentration indicates that the kidney is the source of the potassium loss.^{34,121} The urinary potassium concentration is a good marker for differentiating various hypokalemic syndromes. A urinary potassium excretion of <20 mEq/day suggests extrarenal potassium loss. Renal potassium wastage cannot be excluded, however, unless the low urinary potassium excretion is accompanied by a sodium intake of at least 100 mEq/day, because a low-sodium diet can reduce renal potassium excretion.³⁴ In J.P., the metabolic alkalosis and hypovolemia promote renal potassium wastage.^{34,121} The distal delivery of a large sodium bicarbonate load and increased aldosterone activity (from hypovolemia) enhance potassium secretion and severely impair the kidney's ability to conserve potassium. The hydrochlorothiazide, which J.P. had been taking until 3 days before admission, could also have induced hypokalemia through volume depletion, hypochloremic metabolic alkalosis, and renal potassium wastage. The diuretic is unlikely, however, to be the cause for J.P.'s hypokalemia because she has stopped taking the medication, and this is reflected by the low urinary chloride concentration.¹⁵ Bartter's syndrome, which presents as normotension, hypokalemia, hypochloremic metabolic alkalosis, and renal potassium wastage, is characterized by impaired renal sodium and chloride reabsorption. The low urinary chloride concentration in J.P. can rule out Bartter's syndrome. Other causes of hypokalemia are listed in Table 11-2.

In an asymptomatic hypokalemic patient with no apparent causes for potassium depletion or transcellular redistribution, pseudohypokalemia should be excluded before pursuing an intensive evaluation.¹⁰⁴ Spurious hypokalemia can occur in leukemic patients whose leukocyte count ranges from 100,000

to 250,000 cells/μL.¹²⁷ The potassium in serum is taken up by the large number of leukemic cells when the blood specimen is allowed to stand at room temperature.

Clinical Manifestations

15. What clinical manifestations of hypokalemia are evident in J.P.?

The clinical presentation of hypokalemia, which depends on the severity of potassium depletion, is a result of changes in cell membrane polarization.¹²¹ Patients are usually asymptomatic when the plasma potassium level is 3.0 to 3.5 mEq/L, but they may complain of malaise, weakness, fatigue, and myalgia. J.P.'s muscle weakness and ECG changes reflect the muscular and cardiac manifestations of hypokalemia, respectively.^{128,129}

Potassium depletion can lead to hyperpolarization of myocardial cells and a prolonged refractory period. When serum potassium concentrations fall below 3 mEq/L, T-wave flattening, straight tubule segment depression, and prominent U waves are seen on the ECG.¹²⁹ Mild hypokalemia (potassium concentration of 3.0–3.5 mEq/L) is potentially arrhythmogenic in patients with underlying coronary artery disease. The incidence of ventricular arrhythmia increases with the degree of hypokalemia. Patients without underlying heart disease may be susceptible to these myocardial effects during exercise, especially if the patient's pre-exercise potassium concentration is <3.5 mEq/L, because the potassium concentration may drop below 3.0 mEq/L as a result of β₂-adrenergic receptor-mediated cellular potassium uptake.¹²¹ Potassium depletion may also increase the BP,¹²² which can be lowered with potassium supplementation.¹³⁰

When the serum potassium concentration is <2.5 to 3.0 mEq/L, muscle weakness, cramps, general malaise, fatigue, restless leg syndrome, and paresthesia can occur, probably because potassium is necessary for vasodilation in skeletal muscle. In addition, severe potassium depletion (<2.5 mEq/L) can result in elevation of serum creatine phosphokinase, aldolase, and aspartate aminotransferase levels. Rhabdomyolysis can

ensue when the serum potassium concentration falls below 2.0 mEq/L.^{121,128}

Chronic potassium depletion can alter renal function and structure, which can manifest as decreased GFR and renal blood flow, disturbance in tubular sodium handling, impaired urinary concentrating ability with polydipsia, and ADH-resistant nephrogenic diabetes insipidus.^{104,114} Reversible pathologic changes include renal hypertrophy and epithelial vacuolization of the proximal convoluted tubule. Interstitial scarring and tubular atrophy have been reported with prolonged potassium depletion.¹²¹

Other effects of hypokalemia and potassium depletion include decreased insulin secretion resulting in carbohydrate intolerance,¹³¹ metabolic alkalosis, and increased renal ammoniogenesis, which may play a role in the development of hepatic encephalopathy.¹³²

Treatment

16. How should J.P.'s hypokalemia be treated?

J.P.'s protracted vomiting should be corrected, and fluids and electrolytes (sodium, potassium, and chloride) should be replaced to correct the volume deficit, hypokalemia, and hypochloremic metabolic alkalosis. Hydrochlorothiazide should continue to be withheld.

The amount of potassium deficit and the rate of continued potassium loss should be determined to guide replacement therapy. It has been estimated that a 1-mEq/L fall in serum potassium from 4 to 3 mEq/L represents a total body deficit of approximately 200 mEq. When the serum potassium falls below 3 mEq/L, the total body deficit increases by 200 to 400 mEq for each 1-mEq/L reduction in serum concentration. Other data suggest that even greater degrees of potassium loss can occur: a deficit of 100 mEq per 0.27-mEq/L fall in the serum potassium concentration.¹⁰⁹ Transcellular redistribution of potassium may, however, significantly alter the relationship between serum concentration and total body deficit.¹²¹ Therefore, potassium repletion should be guided by close monitoring of serum concentrations and analysis of J.P.'s urine for potassium content to help assess the need for additional replacement.

The route of potassium administration depends on the acuity and severity of hypokalemia,¹³³ but oral supplementation is usually preferred. The parenteral route is indicated for patients who cannot tolerate high dosages of oral potassium supplements and for those with severe or symptomatic hypokalemia. J.P.'s potassium deficit is estimated to be 300 to 500 mEq, but because she is only moderately symptomatic, aggressive therapy is not indicated. Potassium chloride can be added to her IV fluid in a concentration of 40 mEq/L and infused at a rate that does not exceed 10 mEq/hour. For patients with life-threatening, hypokalemia-induced arrhythmias or those with a serum potassium level <2.0 mEq/L, a more concentrated potassium solution (60 mEq/L) can be infused at a rate not exceeding 40 mEq/hour. A solution that is too concentrated or a rate of infusion that is too rapid would likely cause phlebitis in the peripheral veins and could cause arrhythmias, especially when administered through a central line. The potassium concentration should be monitored every 4 hours, more frequently in patients with severe potassium depletion or when a rapid infusion is given.¹³⁴ ECG monitoring is mandatory to identify life-threatening hyperkalemia.

Parenteral potassium can be given as chloride, acetate, or phosphate. The chloride salt is preferred in J.P., who has concurrent hypochloremic metabolic alkalosis. The acetate preparation is useful in cases of concomitant metabolic acidosis. Potassium phosphate is in order if hypophosphatemia coexists. In the latter condition, the serum calcium concentration should also be monitored because hypocalcemia may ensue. Glucose solution should be avoided as the vehicle because glucose-induced insulin secretion will promote intracellular potassium uptake.¹³⁶

Once J.P.'s potassium levels are replenished and she can take medicine by mouth, oral potassium chloride can be started (see Chapters 13, Essential Hypertension, and 18, Heart Failure).

Hyperkalemia

Etiology

17. A.B., a 25-year-old woman with type 1 diabetes and hypertension, returns to the clinic for follow-up. Her BP is 170/90 mm Hg with a pulse of 80 beats/minute, and her physical examination is remarkable for 2+ pedal edema. Laboratory tests show plasma Na, 135 mEq/L (normal, 134–146); K, 5.8 mEq/L (normal, 3.5–5.1); Cl, 108 mEq/L (normal, 92–109); total CO₂, 20 mEq/L (normal, 22–32); BUN, 28 mg/dL (normal, 8–25); creatinine, 2 mg/dL (normal, 0.5–1.5); and glucose, 200 mg/dL (normal, 60–110). Current medications include oral captopril 25 mg three times daily (TID), Dyazide one capsule daily, human isophane (NPH) insulin 30 units subcutaneously (SC) every morning, and ibuprofen 200 mg as needed (PRN) for menstrual cramps. She uses a salt substitute occasionally. What is the etiology of her hyperkalemia?

[SI units: Na, 135 mmol/L; K, 5.8 mmol/L; Cl, 108 mmol/L; total CO₂, 20 mmol/L; BUN, 10 mmol/L; creatinine, 176.8 μmol/L; glucose, 11.1 mmol/L]

Before conducting any extensive evaluation to identify the etiology of hyperkalemia, the serum potassium concentration ought to be repeated to confirm the presence of hyperkalemia. Also to be ruled out are the different causes of spurious hyperkalemia, which can result from severe leukocytosis (>500,000/mm³),¹³⁶ thrombocytosis (>750,000/mm³),¹³⁷ or hemolysis within the blood collection tube.¹³⁸ *Pseudohyperkalemia* is a test-tube phenomenon that occurs when potassium is released from leukocytes, platelets, or erythrocytes during blood coagulation. These disorders can be confirmed easily by comparing serum (clotted) and plasma (unclotted) potassium concentrations from the same blood sample. The two values should agree within 0.2 to 0.3 mEq/L. Improper tourniquet technique, causing strangulation of the patient's arm before blood sampling, may also result in spurious hyperkalemia.¹³⁹

Identifying the etiology of hyperkalemia can be approached systematically by considering possible disturbances in internal and external potassium balance. The former involves transcellular flux of potassium from the intracellular to the extracellular space, whereas the latter involves either increased intake, including increased endogenous potassium load (e.g., rhabdomyolysis,¹⁴⁰ tumor lysis syndrome¹⁴¹), or decreased elimination. A thorough medication history is important to identify drugs associated with hyperkalemia.^{142–144} (Also see Chapter 31, Chronic Renal Failure, for additional information on hyperkalemia.)

A dietary history should ascertain whether A.B.'s consumption of potassium-rich foods, salt substitutes, or potassium

supplements has increased. Dietary intake alone will *not* induce hyperkalemia unless renal excretion is impaired. Usually, the GFR must be <10 to 15 mL/minute, unless there is concurrent hypoaldosteronism or distal tubular potassium secretory defects.¹ A.B.'s renal insufficiency is mild, with an estimated Cl_{Cr} of 40 mL/minute.

Conditions associated with low renin and aldosterone, which usually present as hyperkalemia and hyperchloremic metabolic acidosis, decrease potassium excretion by the kidneys. These include diabetes (present in A.B.),¹⁴⁵ obstructive uropathy, sickle cell disease, lupus nephritis, and various tubulointerstitial diseases (e.g., gouty nephropathy, analgesic nephropathy). Adrenal insufficiency presents commonly with hyperkalemia because of mineralocorticoid deficiency.¹⁴⁶ A.B.'s poorly controlled hyperglycemia may cause movement of potassium-rich fluid from the intracellular space to the extracellular space because of the increased tonicity. Elevating the plasma tonicity by 15 to 20 mOsm/kg will increase the plasma potassium concentration by 0.8 mEq/L.¹⁴⁷ Patients with diabetes, mineralocorticoid deficiency, or end-stage renal failure, which commonly results in hyporeninemic hypoaldosteronism, are particularly susceptible.

A.B. is also taking several medications that may impair her ability to excrete potassium. Captopril indirectly decreases aldosterone secretion by decreasing the formation of angiotensin II.¹⁴⁸ Ibuprofen inhibits prostaglandin production as well as renin and aldosterone secretion.¹⁴⁹ Other drugs that cause hyperkalemia by impairing renin and aldosterone production include angiotensin II receptor antagonists,¹⁵⁰ β -adrenergic blockers,¹⁵¹ lithium,¹⁵² heparin,^{153–155} and pentamidine.¹⁴⁰ Triamterene, the diuretic in Dyazide, inhibits tubular potassium secretion, as do amiloride, spironolactone, high-dose trimethoprim,^{156,157} cyclosporine,¹⁵⁸ tacrolimus,¹⁵⁹ and digitalis preparations.¹⁶⁰ By inhibiting $Na^+K^+ATPase$, digitalis decreases tubular potassium secretion and reduces cellular potassium uptake. Arginine,¹⁶¹ succinylcholine,¹⁶² β -adrenergic blockers, α -adrenergic agonists, and hypertonic solutions also cause hyperkalemia by impairing transcellular potassium distribution into the intracellular space.

Clinical Manifestations

18. V.C., a 44-year-old woman with chronic renal failure, returns to the outpatient unit for routine hemodialysis with complaints of severe muscle weakness. Her vital signs are BP, 120/80 mm Hg; pulse, 90 beats/minute; RR, 20 breaths/minute; and temperature, 98°F. Laboratory data are serum K, 8.9 mEq/L (normal, 3.5–5.1); total CO_2 , 15 mmol/L (normal, 22–32); BUN, 60 mg/dL (normal, 8–25); creatinine, 9 mg/dL (normal, 0.5–1.5); and glucose, 100 mg/dL (normal, 60–110). The ECG reveals an increased PR interval and a widened QRS complex. What clinical manifestations of hyperkalemia are evident in V.C.?

[SI units: K, 8.9 mmol/L; total CO_2 , 15 mmol/L; BUN, 21.42 mmol/L; creatinine, 795.6 μ mol/L; glucose, 5.55 mmol/L]

Hyperkalemia decreases the intracellular-to-extracellular potassium ratio. Hence, the resting membrane potential becomes less negative and moves closer to the threshold excitation potential. Muscle weakness and flaccid paralysis result when the resting membrane potential approaches the threshold potential, rendering the excitable cells unable to sustain an action potential.

The cardiac toxicity of hyperkalemia is a major cause of morbidity and mortality, with ECG findings paralleling the degree of hyperkalemia. When plasma potassium >5.5 to 6.0 mEq/L, narrow, peaked T waves and a shortened QT interval are seen. As the plasma potassium concentration increases further, the QRS complex widens and the P-wave amplitude decreases. As the level reaches 8 mEq/L, the P-wave disappears and the QRS complex continues to widen and merge with the T wave to form a sine wave pattern. If these ECG changes are not recognized and no treatment is initiated, ventricular fibrillation and asystole will ensue. Hyponatremia, hypocalcemia, and hypomagnesemia all reduce the threshold potential, thereby increasing the patient's susceptibility to the cardiac effects of hyperkalemia.¹⁴⁰ V.C.'s muscle weakness, ECG, chronic renal failure, and serum potassium concentration all are consistent with severe hyperkalemia.

Treatment

19. How should V.C.'s hyperkalemia be treated?

Hyperkalemia with ECG changes requires urgent treatment. Three therapeutic modalities are available: (a) agents that antagonize the cardiac effects of hyperkalemia, (b) agents that shift potassium from the extracellular into the intracellular space, and (c) agents that enhance potassium elimination. Considering V.C.'s severe ECG changes, calcium should be administered at a dose of 10 to 20 mL of 10% calcium gluconate IV over 1 to 3 minutes. Calcium counteracts the depolarizing effect of hyperkalemia by increasing the threshold potential, thus making it less negative and moving it away from the resting potential. The onset of action occurs in a few minutes, but the effect is short-lived, lasting approximately 15 to 60 minutes. The dose can be repeated in 5 minutes if ECG changes do not resolve and as needed afterward for recurrence. With no response after the second dose, additional attempts, however, are not beneficial. When the hyperkalemia presents with a digitalis overdose, calcium should be used cautiously because it can worsen the cardiotoxic effects of digoxin.^{140,163}

Because the serum potassium concentration is not affected by calcium administration, maneuvers should be employed to shift potassium from plasma into the cells. Three modalities are available: insulin and glucose, β_2 -agonists, and sodium bicarbonate.

Insulin rapidly shifts potassium into the cell in a dose-dependent fashion. The maximal effect occurs at insulin concentrations >20 to 40 times the basal levels. Therefore, endogenous insulin secreted in response to dextrose administration is insufficient, and exogenous insulin must be administered.¹⁰⁸ Although high concentrations of dextrose may worsen hyperkalemia, particularly in diabetic patients because intracellular potassium may be shifted to the extracellular space owing to the elevated plasma tonicity,¹⁶⁴ it is always administered with insulin to prevent hypoglycemia. Regular insulin (5–10 units) can be given with 50 mL of 50% dextrose as IV boluses, followed by a continuous infusion of 10% dextrose at 50 mL/hour to prevent late hypoglycemia.¹⁰⁹ In dialysis patients susceptible to developing fasting hyperkalemia, 20 units of insulin can be added to 1 L of 10% dextrose and administered at a rate of 50 mL/hour to prevent the hyperkalemia.¹⁶⁵ The insulin–dextrose combination lowers serum potassium by direct stimulation of cellular potassium uptake and potentiates the potassium-lowering effect of β -adrenergic stimulation.¹⁶⁵ The reduction in potassium

is apparent 15 to 30 minutes after the start of the therapy and persists for 4 to 6 hours.¹⁴⁰ In a diabetic patient who is both hyperkalemic and hyperglycemic, insulin alone may be insufficient. If the patient has end-stage renal disease, the insulin–glucose combination is more predictable in lowering plasma potassium concentrations than sodium bicarbonate.^{109,163,165}

β_2 -Agonists, by binding with the β_2 -adrenoreceptor to activate adenylyl cyclase, have an additive effect with the insulin–dextrose combination in decreasing serum potassium. When albuterol nebulization is used alone, the hypokalemic effect may be inconsistent.¹⁶⁶ Although side effects of albuterol nebulization are minimal, these agents can cause tachycardia and should be used cautiously in patients with underlying coronary artery disease.¹⁶⁷ Although not commercially available, IV albuterol has a faster onset of action (30 vs. 90 minutes).¹⁶⁸ In contrast, nebulization is easier to set up and is less likely to be associated with tachycardia, but multiple doses are often necessary to attain an adequate response. In conjunction with the insulin–dextrose combination, albuterol (20 mg dissolved in 4 mL of saline) can be administered by nebulization and inhaled over 10 minutes to further decrease serum potassium if necessary.¹⁶⁹

Although sodium bicarbonate has long been recommended for the acute treatment of hyperkalemia, its efficacy in this setting has been questioned.^{109,163} The usual dose, 44 to 50 mEq, is infused slowly over 5 minutes and repeated in 30 minutes when necessary. Alternatively, it can be added to dextrose and saline solution to form an isotonic sodium bicarbonate infusion.¹⁷⁰ The hypokalemic effect is variable and may be delayed up to 4 hours, and it is reportedly ineffective in patients on maintenance hemodialysis. Although bicarbonate therapy is not a reliable option in the acute management of hyperkalemia, it may be beneficial in patients with severe metabolic acidosis

(pH <7.20).¹⁰⁹ Potential complications of sodium bicarbonate therapy are volume overload and metabolic alkalosis.

The definitive treatment of hyperkalemia is removal of potassium from the body. Sodium polystyrene sulfonate (SPS) with sorbitol is an ion-exchange resin that binds potassium in the bowel and enhances its excretion in the stools.¹⁷¹ Each gram of SPS exchanges 0.5 to 1.0 mmol of potassium for an equal amount of sodium. SPS can be administered orally or rectally; the latter route is preferred in the symptomatic hyperkalemic patient because intestinal potassium exchange occurs mainly in the ileum and colon. A dose of 50 g of SPS in sorbitol can be given as an enema, retained for at least 30 to 60 minutes, at 4- to 6-hour intervals. For nonemergent removal of body potassium, 15 to 60 g of SPS with sorbitol suspension can be given orally, which can be repeated as needed. The onset of action is approximately 1 to 2 hours after administration. The major side effects are GI intolerance, including diarrhea and sodium overload, and, rarely, intestinal necrosis.¹⁷²

Hemodialysis is the most efficient way to remove potassium; potassium clearance by peritoneal dialysis is lower than for hemodialysis.¹⁷³ The hypokalemic effect is immediate and lasts for the duration of dialysis¹⁶³; however, the amount of potassium removed is variable.¹⁷⁴ Dialysis with a glucose-free dialysate will remove 30% more potassium than one containing 200 mg/dL of glucose.¹⁷⁵

Table 11-3 summarizes the treatment alternatives for hyperkalemia.

Although V.C. is receiving chronic maintenance hemodialysis, the severe cardiac effects of hyperkalemia she experienced warrant immediate institution of the aforementioned measures while awaiting preparation for dialysis. Loop diuretics, which enhance kaliuresis, are rarely useful in managing severe hyperkalemia, especially in patients with renal dysfunction.

Table 11-3 Treatment of Hyperkalemia

| Drug | Mechanism | Dose | Comment |
|---------------------------------------|--|---|---|
| Ca gluconate | Reverse cardiotoxicity caused by K^+ | 10 to 20 mL 10% Ca gluconate IV over 1 to 3 min; may repeat once. | <i>Onset:</i> 1 to 3 min <i>Duration:</i> 30 to 60 min. $[K^+]$ remains unchanged |
| Insulin and glucose | Redistribution of K^+ intracellularly | 5 to 10 units regular insulin with 50 mL 50% dextrose, then D ₁₀ W infused at 50 mL/hr ^a | <i>Onset:</i> 15 to 30 min <i>Duration:</i> several hours Watch for hypoglycemia and hypokalemia. Does not ↓ total body K^+ |
| β_2 -agonists (e.g., albuterol) | Redistribution of K^+ intracellularly | Oral: 2 or 4 mg TID-QID Inhalation: 20 mg in 4 mL saline via nebulizer | <i>Onset:</i> 30 to 60 min <i>Duration:</i> 2 hrs |
| Sodium polystyrene sulfonate (SPS) | Cationic binding resin. 1 g of resin binds 0.5 to 1 mEq K^+ in exchange for Na^+ | <i>Oral:</i> 15 to 20 g with 20 to 100 mL 70% sorbitol Q 4 to 6 hr; PRN preferred <i>Retention enema:</i> 50 g in 50 mL (70% sorbitol and 150 mL H ₂ O) Retain 30 min and follow with nonsaline irrigation | <i>Onset:</i> Slow; 50 g will lower $[K^+]$ by 0.5 to 1 mEq/L over 4 to 6 hrs; watch for Na^+ overload (100 mg Na^+ /1 g SPS) |
| NaHCO ₃ | Redistribution of K^+ intracellularly | 50 mEq IV over 5 min Repeat PRN | <i>Onset:</i> variable, ≈30 min May work best in acidosis Watch for Na^+ overload and hyperosmolar state No change in total body K^+ |
| Dialysis | Removal of K^+ | | Use as last resort |

^aGlucose unnecessary in patients with high glucose concentrations.

BID, twice daily; IV intravenous; PRN, as needed; QID, four times daily.

After V.C.'s condition stabilized, she admitted to eating a lot of fruits in the past few days. Because noncompliance with dietary potassium restriction is the most common cause for acute and chronic hyperkalemia in a dialysis patient, V.C. should be counseled to consume potassium-rich foods in moderation. Medications that impair V.C.'s extrarenal potassium handling should be avoided. If V.C. remains chronically hyperkalemic, SPS will then be needed, probably three or four times weekly. If hyperkalemia is associated with metabolic acidosis, however, an alkalinizing agent should be added to maintain a serum bicarbonate concentration of about 24 mEq/L.

CALCIUM

Homeostasis

Healthy adults have approximately 1,400 g of calcium in the body, of which >99% is stored in bone. Nonetheless, the 0.1% of the total body calcium that is in the plasma and extravascular fluid plays a critical role in many physiologic and metabolic processes. Calcium is important in maintaining nerve tissue excitability and muscle contractility. It regulates the secretory activities of exocrine and endocrine glands and serves as a cofactor for enzyme systems and the coagulation cascade. It also is an essential component of bone metabolism.

Plasma calcium concentration is normally maintained within a relatively narrow range: 8.5 to 10.5 mg/dL. This is accomplished through a complex interaction between parathyroid hormone (PTH), vitamin D, and calcitonin, as well as the effect of these hormones on calcium metabolism in bone, the GI tract, and the kidneys.

Normally, about 40% of the plasma calcium is protein bound, primarily to albumin, and is nondiffusible.¹²⁵ Of the 60% that is diffusible, about 13% is complexed to various small ligands: phosphate, citrate, and sulfate. The remaining 47% is ionized, free, and physiologically active. Changes in serum protein concentration will alter the concentrations of both protein-bound and total calcium. Therefore, the serum albumin concentration needs to be monitored to adequately interpret the total serum calcium concentration. Each 1-g/dL increase in serum albumin concentration is expected to increase the protein-bound calcium by 0.8 mg/dL, thus increasing the total serum calcium concentration by the same amount. The total serum calcium therefore can be corrected by the following equation:

$$\text{Correct Ca} = \text{Observed Ca} + 0.8 (\text{Normal albumin} - \text{Observed albumin}) \quad 11-7$$

Calcium is also bound to plasma globulins: 0.16 mg of calcium for each gram of globulin. When the total globulin concentration exceeds 6 g/dL (normal, 2.3–3.5 g/dL), moderate hypercalcemia may be seen. Changes in pH have an effect on calcium protein binding: acidosis decreases calcium binding, resulting in an increase in free calcium fraction, whereas an increase in pH reduces the amount of ionized calcium. Changes in serum phosphate and sulfate concentrations are expected to alter the fraction of ionized calcium because of the formation of calcium complexes with these anions. The presence of abnormal plasma proteins with a high affinity for calcium binding, as in patients with multiple myeloma, also affects the preceding equation for serum calcium concentration correction.¹⁷⁶

Serum calcium concentration is regulated by the combined effect of GI absorption and secretion, renal reabsorption, and turnover of the skeletal calcium pool. Several hormones, such as PTH, 1,25-dihydroxyvitamin D₃, and calcitonin, have significant effects on these processes. Balanced diets generally contain 600 to 1,000 mg of calcium, although the minimum daily requirement is 400 to 500 mg. Calcium is primarily absorbed in the duodenum and jejunum via saturable and non-saturable processes.¹⁷⁷ The nonsaturable process is diffusive in nature and varies with luminal calcium concentration. The saturable carrier-mediated component is stimulated by 1,25-dihydroxyvitamin D₃. Absorption of calcium is enhanced when the calcium intake is low and also when the demand is increased, such as in pregnancy and when total body calcium is depleted. Conversely, protein deficiency can reduce intestinal calcium absorption, presumably because of the reduced amount of specific calcium-binding protein.¹⁷⁸ Calcium also is secreted into the bowel lumen, which may account for the presence of a negative calcium balance when there is no oral calcium intake.¹⁷⁹

The portion of plasma calcium that is not bound to protein is filtered by the glomerulus. Approximately 97% to 99.5% of the filtered calcium is reabsorbed: 60% in the proximal tubule, 20% in the ascending limb, 10% in the distal tubule, and 3% to 10% in the collecting duct. Approximately 20% of the calcium in the kidney tubule is ionized, whereas the remainder is bound to cations such as citrate, sulfate, phosphate, and gluconate. The extent of calcium resorption depends on the presence of specific cations and also on the urine pH, which affects the fraction of calcium bound to cations. Passive reabsorption at the proximal convoluted tubule is linked closely to sodium transport and is increased by extracellular fluid contraction and decreased by volume expansion. At the proximal straight tubule, the transport process is active and dissociable from sodium and water transport. PTH increases the calcium reabsorption at the distal tubule and also at the collecting duct independent of sodium reabsorption. Acidosis can also increase renal calcium excretion by inhibiting tubule reabsorption and by increasing the ultrafiltrable calcium through reduced binding of calcium to plasma proteins. Conversely, alkalosis promotes calcium protein binding, thus reducing the amount of ultrafiltrable calcium. It also induces hypocalcemia independent of PTH. Phosphorus administration reduces renal calcium excretion, whereas phosphorus depletion increases urinary calcium elimination. Normally, approximately 50 to 300 mg of calcium is excreted by the kidneys daily, but this can be increased to 600 mg/day.¹⁸⁰

The other important factor regulating plasma calcium concentration is bone metabolism. The rate of bone turnover and calcium resorption is influenced by PTH, 1,25-dihydroxyvitamin D₃, and calcitonin.

Hypercalcemia

Etiology

20. A.C., a 62-year-old woman, is brought to the hospital by family members because she has become more lethargic and unresponsive over the past several days. Approximately 4 years ago, she underwent a radical mastectomy and node dissection followed by radiation and chemotherapy for breast carcinoma. Despite several courses of chemotherapy, she developed metastasis to the bone.

About 1 week before this admission, A.C. complained of fatigue, muscle weakness, and anorexia. Since then, she has spent most of her time in bed and has had very limited oral intake. Medications taken before admission included hydrochlorothiazide, oral morphine sulfate, and tamoxifen. Physical examination reveals a dehydrated, cachectic woman responsive only to painful stimuli. Vital signs include BP, 100/60 mm Hg, and RR, 16 breaths/minute. Pertinent laboratory values are Na, 138 mEq/L (normal, 134–146); K, 4.5 mEq/L (normal, 3.5–5.1); Cl, 99 mEq/L (normal, 92–109); CO₂, 33 mEq/L (normal, 22–32); BUN, 40 mg/dL (normal, 8–25); creatinine, 1.2 mg/dL (normal, 0.5–1.5); Ca, 19 mg/dL (normal, 8.0–10.4); P, 4.5 mg/dL (normal, 2.6–4.6); and albumin, 3.0 g/dL (normal, 3.5–5.4). The ECG revealed a shortened QT interval. What are the common causes of hypercalcemia? Which of these might be responsible for the hypercalcemia seen in A.C.?

[SI units: Na, 138 mmol/L; K, 4.5 mmol/L; Cl, 99 mmol/L; CO₂, 33 mmol/L; BUN, 14.3 mmol/L; creatinine, 106.1 μmol/L; Ca, 4.75 mmol/L; P, 1.45 mmol/L; albumin, 30 g/L]

MALIGNANCY

Malignancy and primary hyperparathyroidism are the most common causes for hypercalcemia. Hematologic malignancies, such as multiple myeloma, tend to be responsible for more hypercalcemia than solid tumors. Cancer of the breast, lung, head, and neck and renal cell carcinoma, are solid tumors commonly associated with hypercalcemia. Malignancy can cause paraneoplastic hypercalcemia secondary to bone metastasis, which results in increased bone resorption. Alternatively, patients may develop hypercalcemia in the absence of bone metastasis owing to the production of osteolytic humoral factors by the tumor. The mediators secreted may be PTH, PTH-like substances, prostaglandins, cytokines, transforming growth factor- α , and tumor necrosis factor.¹⁸¹

HYPERPARATHYROIDISM

Hyperparathyroidism is the other common cause of hypercalcemia. Although the etiology of primary hyperparathyroidism is unclear, women tend to develop the condition more frequently, especially in the fourth to sixth decades of life. Approximately 75% of patients have a single adenoma, whereas much smaller percentages of patients have multiglandular disease, hyperplasia, or carcinoma.¹⁸⁰ Other conditions that can result in hypercalcemia include postkidney transplantation, immobilization, vitamin A intoxication, hyperthyroidism, Addison's disease, and pheochromocytoma. Hypercalcemia can also occur secondary to increased intestinal calcium absorption because of vitamin D intoxication, sarcoidosis, and other granulomatous diseases. Use of thiazide diuretics, lithium, estrogens, and tamoxifen, as well as excessive calcium ingestion together with alkali (milk-alkali syndrome), may result in hypercalcemia.

A.C.'s breast cancer bone metastasis, volume contraction, and use of hydrochlorothiazide and tamoxifen may all contribute to her hypercalcemia.

Clinical Manifestations

21. How is hypercalcemia manifested in A.C.?

The clinical presentations of hypercalcemia vary substantially among patients, but the severity of the symptoms correlates well with free calcium concentrations.¹⁸² The specific

presentation depends on the rate of serum calcium concentration elevation, the presence of malignancy, the PTH concentration, and the patient's age. Concurrent electrolyte and metabolic abnormalities and underlying diseases also will have an effect. Because calcium is an important regulator of many cellular functions, hypercalcemia can produce abnormalities in the neurologic, cardiovascular, pulmonary, renal, GI, and musculoskeletal systems. As seen in A.C., the signs and symptoms can be nonspecific: fatigue, muscle weakness, anorexia, thirst, polyuria, dehydration, and a shortened QT interval on the ECG.

The effect of hypercalcemia on the central nervous system includes lethargy, somnolence, confusion, headache, seizures, cerebellar ataxia, altered personality, acute psychosis, depression, and memory impairment. The neuromuscular manifestations include weakness, myalgia, hyporeflexia or areflexia, and arthralgia.

Symptoms of impaired renal function include polyuria, nocturia, and polydipsia. These may reflect a defective concentrating ability, possibly because of resistance to the effects of ADH.¹⁸³ The GFR may be decreased because of afferent arteriolar vasoconstriction, and if hypercalcemia is prolonged, nephrolithiasis, nephrocalcinosis, chronic interstitial nephritis, and renal tubular acidosis may be present. Hypermagnesuria and metabolic alkalosis may also be observed.¹⁸⁰

Calcium has a positive inotropic effect and reduces heart rate, similar to cardiac glycosides. ECG changes indicative of slow conduction, with prolonged PR and QRS intervals and shortened QT intervals, are commonly seen. In severe hypercalcemia, increased QT intervals, widened T waves, and arrhythmia may be present.^{180, 184}

The GI symptoms of hypercalcemia are related primarily to the depressive action of calcium on smooth muscle and nerve conduction. Constipation, anorexia, nausea, and vomiting result from reduced GI motility and delayed gastric emptying. Duodenal ulcer can occur because of increased acid and gastrin secretion. Pancreatitis can occur during acute hypercalcemia owing to the blockade of the pancreatic ducts caused by intraductal calcium deposits.¹⁸⁰ Proteolytic enzymes may also be activated by calcium to cause tissue damage. Both ulcer disease and pancreatitis are more common in hypercalcemia associated with primary hyperparathyroidism; they are less likely to be seen in patients with malignancy-induced hypercalcemia.¹⁸⁴

Treatment

22. After vigorous fluid resuscitation with IV saline, combined saline and furosemide diuresis was instituted in A.C. Her serum calcium concentration declined very slowly, prompting the use of calcitonin. Despite initial success, the serum calcium concentration rose to pretreatment values within 24 hours. Higher dosages of calcitonin could have been attempted at this point; however, plicamycin was used instead. Her serum calcium concentration finally stabilized at 8 mg/dL (normal, 8.0–10.4) after several days of therapy. What was the rationale for each of these regimens? What other agents are available for hypercalcemia treatment?

Several therapeutic approaches are used to lower serum calcium concentration: increasing urinary calcium excretion, inhibiting release of calcium from bone, reducing intestinal calcium absorption, and enhancing calcium complex formation with chelating agents. The underlying disease that causes the hypercalcemia should also be treated if possible. The specific

Table 11-4 Treatment of Hypercalcemia

| <i>Intervention</i> | <i>Dose</i> | <i>Comment</i> |
|--|---|--|
| Saline and furosemide | 1 to 2 L NS; then furosemide 80 to 100 mg Q 2 to 4 hr Establish and maintain normovolemia Other electrolytes as needed. | Saline diuresis and volume expansion depresses Ca^{++} reabsorption in tubules. Lowers $[\text{Ca}^{++}]$ within 24 hrs. Treatment of choice in patients without CHF or renal failure. |
| Calcitonin | 4 IU/kg SC or IM Q 12 hr ↑ Dose or use another therapy if unresponsive after 24 hrs (<i>Max</i> : 8 IU/kg Q 6 hr) | Inhibits osteoclast resorption and renal reabsorption of calcium. Preferred second-line agent because it has a rapid onset (6 hrs) and is nontoxic. It can be used safely in CHF and renal failure. Nausea is the major adverse effect. Tolerance occurs in 24 to 72 hrs. Concomitant plicamycin can lead to hypocalcemia. Only the salmon-derived product is available. |
| Plicamycin | 25 mg/kg/day IV over 4 to 6 hrs; repeat PRN in 48 hrs <i>Renal failure</i> : 12.5 mg/kg | Inhibits osteoclast bone resorption. Onset 24 to 48 hrs; duration 3 to 14 days. Common side effects: N/V, minimized by slow IV. Because the dose is 10% of an antineoplastic dose, cytotoxic effects less severe. Obtain baseline renal and hepatic function, platelet counts. |
| Gallium nitrate | 100 to 200 mg/m ² /day infused IV over 24 hrs for 5 days (depending on severity of hypercalcemia) If calcium levels return to normal before 5 days, therapy may be discontinued | Inhibits bone resorption. Patients should be well hydrated during therapy. A urine output of ~2 L/day should be maintained owing to risk for nephrotoxicity (10%). |
| Biphosphonates (etidronate, pamidronate) | Etidronate: 7.5 mg/kg IV QD × 3 days over at least 2 hrs Maintenance: 20 mg/kg/day PO Pamidronate: 60 to 90 mg IV over 4 hrs × 1 Repeat in 7 days PRN | Inhibits osteoclast reabsorption in malignancy state. Efficacy 75% to 100%. Onset 48 hrs. Duration, days. Concomitant hydration is imperative. Do not use in renal failure. Adverse effects: ↑ P, ↑ SrCr, N/V (oral). |
| Zoledronic acid | Doses: 4 mg IV administration over 15 min | Potent effect on bone resorption. Preferred biphosphonate for hypercalcemia of malignancy. May have promising effects on skeletal complications secondary to bone metastasis. |
| Phosphate | IV PO_4^- not recommended PO PO_4^- gradually titrate to 30 to 60 mmol/day (1–3 g/day in divided doses) | Inhibits bone resorption; soft tissue calcification. IV onset 24 hrs, but not drug of choice. Oral agents used for chronic therapy. Contraindicated in renal failure. |
| Corticosteroids | Prednisone 60 to 80 mg/day Hydrocortisone 5 mg/kg/day IV × 2–3 days | Impair GI absorption and bone resorption. Onset several days. Best in patients with multiple myeloma, vitamin D intoxication, granulomatous conditions. Can be used in CHF, renal failure. |
| Indomethacin | 75 to 150 mg/day | Reports of efficacy are mixed. |

CHF, congestive heart failure; GI, gastrointestinal; IM, intramuscular; IV, intravenous; NS, normal saline; N/V, nausea and vomiting; PO, oral; PRN, as needed; QD, every day; SC, subcutaneously; SrCr, serum creatinine.

treatment used depends on the serum ionized calcium concentration, the presenting signs and symptoms, and the severity and duration of hypercalcemia. Immediate therapy was needed for A.C., who had symptoms consistent with severe hypercalcemia.

Specific interventions are described in the following paragraphs, but as an overview, hydration and diuresis with furosemide generally are the first steps in the acute treatment of hypercalcemia. If these measures fail to reduce the serum calcium concentration adequately, several other agents can be added. Calcitonin provides a rapid onset of hypocalcemic effect, but its duration of action is relatively short. Thus, one of the bisphosphonates could be used to elicit a longer hypocalcemic response. Gallium nitrate is an alternative to plicamycin without such toxic effects. Other agents, such as inorganic phosphates, glucocorticoids, and prostaglandin inhibitors, also

have been used to treat hypercalcemia with varying success (Table 11-4).

HYDRATION AND DIURESIS

As noted, the first-line emergency treatment for hypercalcemia is hydration and volume expansion. Most patients with hypercalcemia are volume depleted because of the accompanying polyuria, nausea, and vomiting. Normal saline 1 to 2 L is commonly given to correct the fluid deficit and to expand extracellular volume, which will increase urinary calcium excretion by increasing the GFR and inhibiting calcium reabsorption in the proximal tubule. Because both sodium and calcium are reabsorbed at the same site in the proximal tubule, saline hydration will reduce the reabsorption of both cations simultaneously. A.C. was hypotensive and appeared dehydrated; therefore, saline hydration was used initially to treat the

hypercalcemia. In patients who have renal failure or CHF, saline hydration and forced diuresis should be avoided.

After adequate volume repletion has been established, IV furosemide can be administered to augment calciuresis. Furosemide blocks the reabsorption of sodium, chloride, and calcium at the thick ascending limb of Henle's loop. Doses of 80 to 100 mg every 2 to 4 hours can be used until a sufficient decline of the serum calcium concentration is attained.¹⁸⁵ Smaller doses (20–40 mg) commonly are given to avoid the significant loss of fluid and electrolytes caused by the more aggressive regimen. Adequate amounts of sodium, potassium, magnesium, and fluid should be used to replace any therapy-induced electrolyte abnormalities. Fluid balance as well as serum and urine concentrations of these electrolytes must be monitored closely. Urine flow must be maintained and the renal loss of sodium chloride must be replaced to preserve the calciuric effect of furosemide.¹⁸⁶ In A.C., the decline of serum calcium concentration was slow, possibly because of inadequate restoration of plasma volume, replacement of renal sodium loss, or both. More aggressive hydration with adequate sodium replacement will ensure that the efficacy of furosemide is not compromised.

CALCITONIN

Calcitonin can be used when saline hydration and furosemide diuresis fail to lower serum calcium concentration adequately or when their use is contraindicated. Calcitonin reduces serum calcium concentration by inhibiting osteoclastic bone resorption. It may also increase the renal excretion of calcium and phosphorus. Only the salmon-derived calcitonin product is available in the United States.

The serum calcium concentration is often reduced several hours after calcitonin is administered, and the response may last approximately 6 to 8 hours. If used with plicamycin, the effect is additive and can lead to hypocalcemia. The drug is relatively nontoxic compared with agents such as plicamycin and organic phosphates and may be used in patients with dehydration, CHF, or renal failure.¹⁸⁶ Nausea, vomiting, diarrhea, and facial flushing are the more common side effects; soreness and inflammation at the injection site may also be seen.¹⁸¹ Because of the potential for developing a hypersensitivity reaction to salmon calcitonin, the manufacturer recommends skin testing with 1 IU of the salmon calcitonin before the first dose. As seen in A.C., tolerance to the hypocalcemic effect of calcitonin can develop after 24 to 72 hours of therapy. This "escape phenomenon" may be secondary to the altered responsiveness of the hormone receptors and might be prevented by concurrent use of corticosteroids.¹⁸⁷ After long-term therapy, antibodies may develop as well.¹⁷³

The dosage of salmon calcitonin is 4 IU/kg given SC or intramuscularly (IM) every 12 hours; the maximal dosage is 8 IU/kg every 6 hours. The hypocalcemic response is often limited, and serum calcium concentration seldom drops to the normal range.¹⁸⁸

PLICAMYCIN

Plicamycin (Mithramycin) is an antibiotic resembling actinomycin D, which was used to treat refractory testicular cancer. With the advent of cisplatin-based regimens, plicamycin is now used primarily to treat hypercalcemia. It inhibits RNA synthesis, which suppresses osteoclast-mediated calcium resorption from bone. The drug is effective for hypercalcemia associated

with breast cancer, myelomas, lung, renal cell, or parathyroid carcinoma, and hypervitaminosis D.

The recommended dosage of plicamycin is 25 mcg/kg infused over 4 to 6 hours. Generally, a response is seen within 24 to 48 hours, and most patients attain normocalcemia after a single dose.¹⁷⁴ The response lasts 3 to 14 days or longer in some patients. If an adequate response is not obtained, the dose can be repeated 48 hours later.

Many serious adverse effects are associated with plicamycin therapy. The drug is usually well tolerated at the lower doses used for hypercalcemia treatment, which is only one-tenth the antineoplastic dose.¹⁸⁸ Nausea and vomiting are common side effects that can be minimized by infusing the drug slowly and by using an antiemetic such as prochlorperazine. The drug is a vesicant and should be administered as a dilute solution to minimize the injury associated with extravasation. Other toxicities include impaired platelet function, proteinuria, azotemia, bone marrow suppression, and elevated hepatic transaminases.¹⁸⁹ Plicamycin can also cause hepatic toxicity, nephrotoxicity, and dose-related acute hemorrhagic syndrome. Because the drug is excreted primarily through the kidneys, impaired renal function may increase the risk for adverse effects.¹⁸⁰ Renal and hepatic function and platelet count should be assessed before and during therapy.

Plicamycin's side effect profile may potentiate the toxic effects of chemotherapeutic agents used to treat patients with malignancy-induced hypercalcemia. Thus, its use is limited to patients unresponsive to other antiresorptive agents. It also is used intermittently to take advantage of its relatively long duration of action. In addition, the drug should not be used in patients with severe hepatic or renal dysfunction, thrombocytopenia, or coagulopathies or those who are dehydrated or receiving myelosuppressive chemotherapy.¹⁸⁶

BISPHOSPHONATES

Bisphosphonates are synthetic analogs of pyrophosphate that form stable bonds that are resistant to phosphatase degradation during osteoclast-mediated bone mineralization and resorption. The compounds adsorb to the hydroxyapatite crystals of the bone, inhibiting their growth and dissolution. In addition, the compounds may have a direct effect on the osteoclasts.

The two distinct pharmacologic classes of bisphosphonates that exist have different mechanisms of action. Etidronate, which does not contain any nitrogen atom, is metabolized to cytotoxic, nonhydrolyzable adenosine triphosphate (ATP) analogs. In contrast, nitrogen-containing bisphosphonates, such as pamidronate and zoledronic acid, inhibit the prenylation of proteins and have potent inhibitory effects on osteoclast-mediated bone resorption.¹⁹⁰ In addition, they induce apoptosis of osteoclasts as well as certain tumor cells. Further antitumor activities may be mediated through their inhibitory effect on angiogenesis, stimulation of the γ -T-cell fraction in blood, and reduction of cancer cells' adherence to bone matrix. At present, etidronate, pamidronate, and zoledronic acid are approved in the United States for the treatment of hypercalcemia secondary to malignancy.

Etidronate

Etidronate is administered in doses of 7.5 mg/kg for 3 consecutive days by IV infusion over 2 to 4 hours. Response may be seen after 1 to 2 days, and normocalcemia is expected to

be attained in most patients, with response sustained for >10 days.¹⁹¹ Because of the inconvenient dosing schedule as well as variability in its duration of action, other bisphosphonates are now preferred for the treatment of hypercalcemia of malignancy. In addition, etidronate may inhibit bone mineralization, a property not shared by other bisphosphonates.

Pamidronate

Pamidronate is more potent than etidronate as an inhibitor of bone resorption, but it has negligible effect on bone mineralization. For moderate hypercalcemia (albumin-corrected serum calcium concentration of 12.0–13.5 mg/dL), a single dose of 60 to 90 mg of pamidronate is commonly infused over 3 to 4 hours. For severe hypercalcemia (albumin-corrected serum calcium concentration >13.5 mg/dL), the dose is 90 mg. The advantages of pamidronate are that it requires only a single dose and produces a superior response compared with three doses of etidronate.¹⁹²

If the hypercalcemia recurs, the etidronate or the pamidronate regimen may be repeated after an interval of ≥ 7 days. Etidronate (20 mg/kg/day by mouth) may be given to prolong the normocalcemic duration, but nausea and vomiting are common with the oral therapy. Long-term treatment may result in osteomalacia; however, the limited life expectancy of most patients may diminish the significance of this adverse effect.

Etidronate use has resulted in renal failure,¹⁹³ which probably is caused by the formation of bisphosphonate–calcium complexes in the serum.¹⁹⁴ Because pamidronate requires a lower molar concentration to produce a comparable hypocalcemic effect, it is less likely to impair renal function. In fact, pamidronate has been given to a limited number of patients with end-stage renal disease without adverse consequence.¹⁹⁴

Zoledronic Acid

Among the bisphosphonates approved for the treatment of hypercalcemia of malignancy, zoledronic acid has the most potent effect on bone resorption. It is superior to pamidronate with respect to the number of complete responses, time needed to attain calcium normalization, and duration of effect.¹⁹⁶ Because 8-mg doses were not superior to 4-mg, 4-mg doses are administered IV over 15 minutes.¹⁹⁷ The drug is well tolerated at 4-mg doses. Zoledronic acid's superior efficacy and convenience of administration make it the preferred bisphosphonate for hypercalcemia of malignancy. Emerging studies show that zoledronic acid also may have promising effects in reducing skeletal complications secondary to bone metastasis associated with breast cancer, prostate cancer, non–small-cell lung cancer, and multiple myeloma.¹⁹⁷

GALLIUM NITRATE

Gallium is a naturally occurring group IIIa heavy metal. In addition to its antitumor activity and potential for use as a chemotherapeutic agent, it has been shown to be effective in the treatment of moderate to severe hypercalcemia of malignancy. Hypocalcemia is induced primarily via the inhibition of bone resorption and reduction in urinary calcium excretion.¹⁹⁸ Several clinical studies have shown the effectiveness of gallium nitrate in the treatment of cancer-related hypercalcemia when compared with agents such as calcitonin and bisphosphonates.^{198–202} The recommended dose is 100 to

200 mg/m²/day as a continuous infusion for 5 days. Vigorous hydration is necessary to prevent nephrotoxicity. In general, its clinical use is limited by the inconvenient method of administration, significant risk of nephrotoxicity, and cost.

PHOSPHATE

Inorganic phosphates lower the serum calcium concentration by inhibiting bone resorption. They also promote the deposition of calcium salts (CaHPO₄) in the bone and soft tissue. If given orally, phosphate reduces intestinal calcium absorption by forming a poorly soluble complex in the bowel lumen and also by decreasing the formation of active vitamin D through enzyme inhibition.²⁰³

When given IV, phosphate is very effective, but renal failure and extensive extraskeletal calcifications are a concern. For these reasons, IV phosphate is not the agent of choice for acute treatment of hypercalcemia.

Oral phosphate (1–3 g/day in divided doses) may be used for long-term maintenance therapy, with the optimal dose determined by serum calcium concentrations. Nausea, vomiting, and diarrhea are common problems, especially when the daily dose exceeds 2 g. Soft tissue calcification is also a concern, and hyperphosphatemia and hypocalcemia can occur if the dose is not titrated appropriately. Phosphate therapy should not be given to patients with hyperphosphatemia or renal failure because it can cause further deterioration of renal function. Accumulation of the potassium and sodium salts in phosphate preparations may also present a therapeutic problem in certain patients.

CORTICOSTEROIDS

Several possible mechanisms exist that may explain the hypocalcemic effect of corticosteroids. Vitamin D₃-mediated intestinal calcium absorption may be impaired²⁰⁴ and the action of osteoclast-activating factor, which mediates bone resorption in malignancy, may be inhibited. Corticosteroids also may have a direct cytolytic effect on tumor cells and inhibit the synthesis of prostaglandins (see Prostaglandin Inhibitors). Prednisone (60–80 mg/day) is given initially, with subsequent dosage reduction based on the calcemic response. Alternatively, hydrocortisone (5 mg/kg/day for 2–3 days) may be given. The hypocalcemic effect will not be apparent for at least 1 to 2 days. Patients with hematologic malignancies and lymphomas tend to have a better response than those with solid tumors. Corticosteroids are also effective in treating hypercalcemia associated with vitamin D intoxication,²⁰⁵ sarcoidosis,²⁰⁶ and other granulomatous conditions. They are not generally used for long-term therapy because of their potential for serious adverse reactions.

PROSTAGLANDIN INHIBITORS

Because prostaglandins of the E series, especially PGE₂, may be responsible for hypercalcemia associated with some malignancies, NSAID may be useful for a select group of patients with hypercalcemia. For example, indomethacin is effective in lowering the serum calcium concentration in patients with renal cell carcinoma, but not in patients with other types of malignancy.¹⁹² Indomethacin, 75 to 150 mg/day, can be tried in patients unresponsive to other therapy, especially when it is used as part of palliative treatment for cancer pain.

PHOSPHORUS

Homeostasis

Phosphorus is found primarily in bone (85%) and soft tissue (14%); <1% of the total body store resides in the extracellular fluid. Virtually all of the “free” or active phosphorus exists as phosphates in the plasma. Most clinical laboratories, however, measure and express the concentrations of elemental phosphorus contained in the phosphate molecules. One millimole of phosphate contains 1 mmol of phosphorus, but 1 mmol of phosphate is three times the weight of 1 mmol of phosphorus. Therefore, it is incorrect to equate a certain milligram weight of phosphorus as the same milligram weight of phosphate. Of the total plasma phosphorus, 70% exists as the organic form and 30% as the inorganic form. Organic phosphorus, primarily phospholipids and small amounts of esters, is bound to proteins. About 85% of inorganic phosphorus, or orthophosphate, is unbound or “free.” The relative amounts of the two orthophosphate components, H_2PO_4^- and HPO_4^{2-} , vary with the pH. At pH 7.40, the ratio of the two species is 1:4, giving rise to a composite valence of 1.8 for the orthophosphate. Serum phosphate concentrations reported by clinical laboratories reflect only the inorganic portion of the total plasma phosphate. To avoid confusion related to the pH effect on valence, phosphate concentrations are reported as mg/dL or mmol/dL rather than mEq/volume.

The normal range of serum phosphate concentration in healthy adults is 2.7 to 4.7 mg/dL. The value is higher in children, possibly because of the increased amount of growth hormone and the reduced amount of gonadal hormones.²⁰⁸ In postmenopausal women, the range is slightly higher; however, it is lower in older men. The serum phosphate concentration is also affected by dietary intake. Phosphate-rich foods can transiently increase the serum phosphate concentration. In contrast, glucose decreases the serum phosphate concentration because of the flux of sugar and phosphate into cells and because of the phosphorylation of glucose. Similarly, administration of insulin and epinephrine decreases the serum phosphate concentration because of their effects on glucose. The serum concentration of phosphate is reduced in alkalosis and increased in acidosis.²⁰⁹

A balanced diet contains 800 to 1,500 mg/day of phosphorus. Both the organic and inorganic forms of phosphorus are present in food substances. Most of the phosphorus in milk is the organic form, whereas the phosphorus in meat, vegetable, and other nondairy sources represents organic forms bound to proteins, lipids, and sugars, which usually are hydrolyzed before absorption.²¹⁰ In general, 60% to 65% of the phosphorus ingested is absorbed, mostly in the duodenum and jejunum through an energy-dependent, saturable, active process.²¹¹ Phosphorus absorption is linearly related to the dietary intake when the intake is 4 to 30 mg/kg/day.¹⁵⁶ The amount of phosphorus ingested probably is the most important factor in determining net absorption. Phosphorus absorption is also stimulated during periods of increased demand, such as active growth and pregnancy.²¹² Increased intake of calcium and magnesium and concurrent use of aluminum hydroxide antacids may reduce phosphorus absorption owing to formation of a nonabsorbable complex.²¹³ In addition, absorption is also affected by vitamin D, PTH, and calcitonin.²⁰⁸

Renal phosphorus excretion depends on the dietary phosphorus intake. Normally, >85% of the filtered phosphate load

is reabsorbed; however, the fractional urinary excretion can vary from 0.2% to 20%.¹⁵⁹ Renal phosphate excretion is also affected by acid–base balance, extracellular fluid volume, and calcium and glucose concentrations.²⁰⁸ In addition, PTH, thyroid hormone, thyrocalcitonin, vitamin D, insulin, glucocorticoid, and glucagon can also alter renal phosphate excretion.²⁰⁸

Hypophosphatemia

Etiology

23. M.R., a 72-year-old woman, was admitted to the hospital with a 1-week history of increasing malaise, confusion, and decreased activity. M.R. has a history of CHF, hypertension, type 2 diabetes, and peptic ulcer disease. She was receiving hydrochlorothiazide, Maalox, sucralfate, and insulin. She is febrile and in significant respiratory distress. ABG results at admission were pH 7.5 (normal, 7.36–7.44); PO_2 , 42 mm Hg (normal, 80–90); and PCO_2 , 20 mm Hg (normal, 34–46). Respiratory function continued to deteriorate, requiring intubation and mechanical ventilation. Serum electrolytes are Na, 128 mEq/L (normal, 134–146); K, 3.6 mEq/L (normal, 3.5–5.1); Cl, 96 mEq/L (normal, 92–109); CO_2 , 23 mEq/L (normal, 22–32); glucose, 320 mg/dL (normal, 60–110); and phosphorus (P), 0.9 mg/dL (normal, 2.4–4.6). What may have contributed to the low serum phosphorus concentration in M.R.?

[SI units: Na, 128 mmol/L; K, 3.6 mmol/L; Cl, 96 mmol/L; CO_2 , 23 mmol/L; glucose, 17.8 mmol/L; P, 0.29 mmol/L]

Hypophosphatemia can develop as the result of a phosphorus deficiency or secondary to a net flux of phosphorus out of the plasma compartment without a total body deficit. Moderate hypophosphatemia is defined as a serum phosphorus concentration of 1.0 to 2.5 mg/dL. A concentration of <1.0 mg/dL, as in M.R., is considered severe.²¹⁴ The extent of hypophosphatemia may not be assessed accurately by a single plasma phosphorus concentration determination because of diurnal variation.²¹⁵ Patients receiving large doses of mannitol may have pseudohypophosphatemia owing to the binding of mannitol with molybdate, which is used in the calorimetric assay for phosphorus.²¹⁶

Hypophosphatemia is commonly caused by conditions that impair intestinal absorption, increase renal elimination, or shift phosphorus from the extracellular to the intracellular compartments. Hypophosphatemia secondary to low dietary phosphorus is exceedingly rare because phosphorus is ubiquitous.²⁰⁸ In addition, renal phosphorus excretion is reduced and intestinal phosphorus absorption is increased to prevent a deficiency state.^{159,217} Starvation in itself does not result in severe hypophosphatemia because the phosphorus content in plasma and muscles is often normal. Hypophosphatemia, however, can develop during refeeding with a high-calorie diet low in phosphorus. Therefore, hyperalimentation without phosphorus supplementation is likely to cause severe hypophosphatemia.²¹⁸

Impaired phosphorus absorption secondary to malabsorptive conditions, prolonged nasogastric suction, and protracted vomiting can also result in hypophosphatemia. In M.R., the use of aluminum- and magnesium-containing antacids may further reduce phosphorus absorption. The antacids bind with endogenous and exogenous phosphorus in the GI tract and cause severe hypophosphatemia in patients with or without

renal failure.²¹⁹ In addition, M.R. was taking sucralfate, which can bind phosphorus in the GI tract.²²⁰ Similarly, iron preparations can bind phosphorus.²²¹

Hyperglycemia-induced osmotic diuresis and diuretic use may have increased the renal loss of phosphorus in M.R. Other conditions associated with renal phosphorus wasting include renal tubular acidosis, hyperparathyroidism, hypokalemia, hypomagnesemia, and extracellular volume expansion.²⁰⁸ None of these situations, however, was evident in M.R. Shifting of phosphorus into the intracellular compartment by glucose or insulin and profound respiratory alkalosis, especially during alcoholic withdrawal, may also have contributed to M.R.'s hypophosphatemic state.^{222,223}

24. What other conditions are commonly associated with hypophosphatemia?

Diabetic ketoacidosis, chronic alcoholism, chronic obstructive airway disease, and extensive thermal burns are other conditions commonly associated with hypophosphatemia.^{224,225} They are characterized by a combination of factors that result in phosphate loss and intracellular phosphate use. In patients with diabetic ketoacidosis, metabolic acidosis enhances the movement of phosphate from the intracellular compartment to plasma, whereas the concurrent osmotic diuresis secondary to hyperglycemia increases the renal elimination of extracellular phosphate.²²⁶ The net result is a depletion of total body stores. Correction of the acidosis and administration of insulin then promotes the rapid uptake of phosphorus by tissues, and volume repletion dilutes the extracellular concentration. This sequence of events can ultimately lead to severe hypophosphatemia. The hypophosphatemia associated with chronic alcoholism and acute alcohol intoxication is also thought to be related to several factors, including reduced intestinal phosphorus absorption caused by vomiting, diarrhea, and antacid use; repeated acidosis that results in increased urinary phosphate excretion; and a shift of phosphorus into cells because of respiratory alkalosis. Renal phosphorus wasting can also result from hypomagnesemia or as a direct effect of alcohol.²²⁷

Clinical Manifestations

25. What are the signs and symptoms associated with hypophosphatemia?

The clinical effects associated with chronic phosphorus depletion are often insidious and gradual in onset. In contrast, a rapid decline in plasma phosphorus concentrations results in sudden and serious organ dysfunction. Most of the effects can be attributed to impaired cellular energy stores and tissue hypoxia secondary to depletion of ATP or erythrocyte 2,3-diphosphoglycerate (2,3-DPG).²²⁸ Severe hypophosphatemia can result in generalized muscle weakness, confusion, paresthesias, seizures, and coma. In addition, reduced cardiac contractility, hypotension, respiratory failure, and rhabdomyolysis have been observed with acute severe hypophosphatemia.²⁰⁸ Chronic phosphorus depletion has been associated with decreased mentation; muscle weakness; osteomalacia; rickets; anorexia; dysphagia; cardiomyopathy; tachypnea; reduced sensitivity to insulin; and dysfunction of red blood cells, white blood cells, and platelets. Renal function is altered, as manifested by hypophosphaturia, hypercalciuria, hypermagnesuria, bicarbonaturia, and glycosuria. M.R.'s decreased mentation,

weakness, and respiratory failure are consistent with severe hypophosphatemia.

Treatment

26. How can phosphate depletion be assessed? Outline a treatment regimen that would effectively and safely correct the phosphorus deficit in M.R. How should her therapy be monitored?

Phosphorus resides primarily in the intracellular space; the amount in the extracellular fluid is only a small percentage of the total body store. Because the patient's pH, blood glucose concentration, and insulin availability may affect phosphorus distribution, it is difficult to determine the magnitude of the phosphorus deficit based on the serum concentration alone. As discussed, a patient may have hypophosphatemia secondary to a rapid shift of phosphorus into the intracellular space without a total body deficit. The duration of the hypophosphatemia is often limited because it may be corrected by renal phosphorus conservation and oral intake of phosphorus-containing foods. Aside from serum phosphorus concentrations, urinary phosphorus excretion may be used to further assess the phosphorus deficit. Typically, renal phosphorus excretion is severely limited in patients with significant deficits. A phosphorus excretion of <100 mg/day (fractional phosphorus excretion <10%) confirms appropriate renal phosphorus conservation when the serum phosphorus is <2 mg/dL. It also suggests a nonrenal etiology (e.g., impaired GI absorption) or some type of internal redistribution (e.g., respiratory alkalosis).²²⁹

Prophylactic supplementation should be used in situations that predictably increase the risk for developing hypophosphatemia. These include patients who are receiving total parenteral nutrition or large doses of antacids for an extended period, alcoholic patients, and those with diabetic ketoacidosis.

The specific treatment of hypophosphatemia depends on the presence of signs and symptoms, as well as the anticipated duration and severity of hypophosphatemia. In an asymptomatic patient with mild hypophosphatemia (1.5–2.5 mg/dL) who has no evidence of phosphorus depletion, phosphorus supplementation is generally not necessary because the condition is usually self-limited.²⁰⁸ In other patients with mild and moderate hypophosphatemia who have evidence of phosphorus deficit, oral supplementation is the safest and preferred mode of replacement. Skim or low-fat milk is a convenient source of phosphorus and calcium. Whole milk, because of its high fat content, can cause diarrhea if a large amount is consumed. Several oral phosphorus preparations can be used in patients who cannot tolerate milk products.

When hypophosphatemia is severe, as in M.R., or when the patient is vomiting or unable to take oral medication, parenteral phosphorus replacement is needed. Several empiric regimens have been evaluated. IV administration of 0.08 to 0.5 mmol/kg body weight of phosphorus over 4 to 12 hours is safe and effective in restoring the serum phosphorus concentration.^{230,231} More aggressive regimens, such as infusion over 30 minutes to 2 hours, have also been suggested for critically ill and surgical patients.^{232,233} Parenteral phosphorus replacement should be stopped once the serum phosphorus concentration reaches 2.0 mg/dL and also when oral supplementation is started. In general, no more than 32 mmol (1 g) of phosphorus should be administered IV in a 24-hour period. Regardless of the regimen used, serum phosphorus, calcium, and magnesium concentrations should be monitored closely because IV phosphorus

administration can induce hyperphosphatemia quite rapidly, as well as hypocalcemia and hypomagnesemia. Monitoring of urine phosphorus concentration also helps determine the adequacy of therapy. Metastatic soft tissue calcification, hypotension, and, depending on the preparation used, potassium, sodium, or volume overload may occur. This could be significant in patients such as M.R. who have a history of CHF and hypertension. Therefore, renal function and volume status should be monitored during therapy. Diarrhea, a common dose-related side effect of oral phosphorus replacement, can be minimized by diluting the supplement and slowly titrating the dose. Large doses can also result in metabolic acidosis.²³⁰

Phosphorus can be administered orally in doses of 30 to 60 mmol/day, usually given in two to four divided doses to minimize GI adverse events, using any commercially available oral supplement (e.g., Fleet or Neutra-Phos). Fleet Phospho-Soda (5 mL twice daily) delivers 40 mmol/day of phosphorus. Skim milk, the preferred agent for diluting the supplement, contains approximately 7 mmol of phosphorus/cup and provides calcium and potassium as well.

In M.R., oral supplementation was not feasible because she had intermittent diarrhea and vomiting. Potassium phosphate 15 mmol (providing 22 mEq of potassium) was therefore infused IV in 250 mL of 0.45% saline over 12 hours. The regimen was repeated once until the serum phosphorus concentration reached 2 mg/dL. Oral supplementation with Fleet Phospho-Soda then was begun by adding one teaspoonful twice daily to her enteral tube feeding.

Hyperphosphatemia

Refer to the section on “Secondary hyperparathyroidism and renal osteodystrophy” in Chapter 31 “Chronic Renal Failure.”

MAGNESIUM

Homeostasis

Magnesium is an intracellular cation found primarily in bone (65%) and muscle (20%). Only 2% of the total body store of 21 to 28 g (1,750–2,400 mEq) is located in the extracellular compartment. Serum magnesium concentrations, therefore, do not reflect the total magnesium body store accurately. In healthy adults, the serum magnesium concentration is 1.80 to 2.40 mEq/L, with approximately 20% of the serum magnesium bound to proteins.

Magnesium plays an important role in different metabolic processes, particularly in energy transfer, storage, and utilization. Cation deficiency can impair many ATP-mediated energy-dependent cellular processes as well as the action of phosphatases.²³⁴ Magnesium is necessary for many enzymes involved in the metabolism of carbohydrate, fat, and protein, as well as RNA aggregation, DNA transcription, and degradation. The normal operation of many sodium, proton, and calcium pumps and the regulation of potassium and calcium channels are all dependent on the availability of intracellular magnesium.^{235,236} In addition, adequate magnesium stores are needed to maintain normal neuronal control, neuromuscular transmission, and cardiovascular tone.

The average diet in North America contains about 20 to 30 mEq of magnesium.²³⁷ The daily requirement is approximately 18 to 33 mEq for young persons and 15 to 28 mEq

for women.²³⁸ Normally, 30% to 40% of the elemental magnesium is absorbed, primarily in the jejunum and ileum. However, absorption may be increased to 80% in deficiency states and reduced to 25% during high magnesium intake. In patients with uremia, GI absorption of magnesium is decreased; however, absorption in the jejunum can be normalized by physiologic doses of $1\alpha,25$ -dihydroxyvitamin D_3 .²³⁹ In addition, PTH also modulates magnesium absorption.²⁴⁰

Magnesium is eliminated primarily by the kidneys; only 1% to 2% of the endogenous magnesium is eliminated by the fecal route.¹⁷⁹ The magnitude of renal removal is determined by GFR and tubular reabsorption. Approximately 20% to 30% of the tubular reabsorption takes place in the proximal tubule, whereas Henle’s loop, primarily the thick ascending limb, is responsible for up to 65% of the total reabsorption.²⁴¹ Only about 5% to 6% of the filtered magnesium is generally eliminated in the urine. The extent of magnesium reabsorption changes in parallel with sodium reabsorption, which is affected by the extracellular fluid volume. The renal threshold for urinary magnesium excretion is 1.3 to 1.7 mEq/L, which is similar to the normal plasma magnesium concentration. Slight changes in plasma magnesium concentration, therefore, may substantially alter the amount of magnesium excreted in the urine.²⁴²

Urinary magnesium reabsorption is affected by many factors, including sodium balance; extracellular fluid volume; serum concentrations of magnesium, calcium, and phosphate; and metabolic acidosis and alkalosis.²⁴³ Concurrent use of loop and osmotic diuretics will also modulate the reabsorption.^{144,245} Hormones, such as PTH, and possibly calcitonin, glucagon, and mineralocorticoids may affect the routine maintenance of magnesium balance as well.^{246–248}

Hypomagnesemia

Etiology

27. R.J., a 61-year-old man, is admitted to the hospital because of trauma to his forehead after falling at home. He has a long history of conditions related to his alcohol abuse: liver disease, ascites, seizures, pancreatitis, and malabsorption. R.J. complained of abdominal pain, nausea, vomiting, and diarrhea for the past several days. At admission, R.J. was confused, apprehensive, and combative, and he had marked tremors. He also had delirium, as evidenced by hallucinations, screaming, and delusions, and he was having multiple tonic-clonic seizures. The medical record revealed that R.J. had been taking furosemide for the last 2 months. Pertinent laboratory test results obtained at admission were K, 2.5 mEq/L (normal, 3.5–5.1); Mg, 0.8 mEq/L (normal, 1.6–2.8); and creatinine, 0.8 mg/dL (normal, 0.5–1.5). Phenytoin was administered for seizure control and R.J. was placed on nasogastric suction. Fluid restriction was instituted and furosemide therapy was continued to control his ascites. What are the circumstances that have contributed to R.J.’s hypomagnesemia?

[SI units: K, 2.5 mmol/L; Mg, 0.4 mmol/L; creatinine, 70.72 μ mol/L]

Magnesium body stores are difficult to assess because magnesium is primarily an intracellular ion, and serum magnesium concentrations do not provide an accurate indication of the total body load. In fact, cellular magnesium depletion may be present with low, normal, or even high serum magnesium concentrations.^{249,250} Conversely, hypomagnesemia may be seen without a net loss of body magnesium. Refeeding after

starvation will result in increased trapping of magnesium by newly formed tissue, resulting in hypomagnesemia. Similarly, acute pancreatitis and parathyroidectomy can cause hypomagnesemia without a net loss of the cation.^{251,252}

The prevalence of hypomagnesemia in ambulatory and hospitalized patients was found to be approximately 6% to 12%.²⁵³ The incidence increased to 42% in patients who were hypokalemic²⁵⁴ and to 60% to 65% in those under intensive care.²⁵⁵ Multiple risk factors and clinical conditions can contribute to the high rate of hypomagnesemia in critically ill patients.

Magnesium depletion and hypomagnesemia can develop owing to GI, renal, and endocrinologic causes. Depletion can occur in patients whose dietary magnesium intake is severely restricted²⁵⁶ and in those who have protein calorie malnutrition.²⁵⁷ Also at risk are patients who receive prolonged parenteral nutrition²⁵⁸ and those who undergo prolonged nasogastric suction.²⁵⁹ Hypomagnesemia may be present in patients who have increased magnesium requirements, such as pregnant women and infants.²⁶⁰ Conditions associated with steatorrhea, such as nontropical sprue and short-bowel syndrome, can result in reduced GI magnesium absorption. Insoluble magnesium soaps may be formed in the GI tract because of the presence of unabsorbed fat.²⁶¹ Hypomagnesemia can also occur in patients with a bowel resection²⁶² and severe diarrhea.²⁶³ A rare genetic disorder has also been reported in patients with defective GI magnesium absorption.²⁶⁴ An impaired carrier-mediated magnesium transport system is believed to be responsible for the symptomatic deficiency, which requires high oral magnesium intake to overcome the defect.

Renal magnesium wasting can be caused by a primary defect or be secondary to systemic factors. A rare form of renal magnesium wasting is congenital.²⁶⁵ Various drugs can induce hypomagnesemia through increased renal loss: cisplatin,²⁶⁶ aminoglycosides,²⁶⁷ cyclosporine,²⁶⁸ and amphotericin B.²⁶⁹ Use of loop and thiazide diuretics can also result in hypomagnesemia, which can be reversed with the concurrent use of amiloride or triamterene. Magnesium depletion can be associated with phosphate depletion,²⁷⁰ calcium infusion,²⁷¹ and ketoacidosis.²⁷² Acute and chronic ingestion of alcohol will result in increased renal magnesium loss.^{204,273} Various endocrinologic disorders, such as SIADH,²⁷⁴ hyperthyroidism,²⁷⁵ hyperaldosteronism,²⁴⁸ and postparathyroidectomy,²⁷⁶ are also associated with hypomagnesemia.

R.J. could be hypomagnesemic for many reasons. His long history of alcohol use, malnutrition, and malabsorption may all have contributed to his magnesium deficit. The vomiting and diarrhea that he experienced could have reduced GI magnesium absorption. Use of furosemide and nasogastric suction while in the hospital could also have exacerbated his magnesium depletion through renal and GI losses, respectively.

Clinical Manifestations

28. What are the clinical manifestations of hypomagnesemia in R.J.?

Magnesium depletion can result in abnormal function of the neurologic, neuromuscular, and cardiovascular systems. Hypomagnesemia lowers the threshold for nerve stimulation, resulting in increased irritability. Typical findings include Chvostek's and Trousseau's signs, muscle fasciculation, tremors, muscle spasticity, generalized convulsions, and possibly tetany. The

patient may experience weakness, anorexia, nausea, and vomiting, as seen in R.J. Hypokalemia, hypocalcemia, and alkalosis may be present as well. In patients who are moderately depleted, changes in the ECG include widening of the QRS complex and a peaking T wave.²⁷⁷ In severe depletion, a prolonged PR interval and a diminished T-wave may be seen. Ventricular arrhythmias also have been reported in some patients.²⁷⁸

Treatment

29. Outline a regimen to replenish the body stores of magnesium for R.J., and develop a monitoring plan to assess efficacy and potential adverse effects.

The specific regimen for magnesium replenishment depends on the clinical presentation of the patient. Symptomatic patients require more aggressive parenteral therapy, whereas oral replacement may suffice for asymptomatic hypomagnesemia. Patients with life-threatening symptoms, such as seizures and arrhythmias, need immediate magnesium infusion. Because serum magnesium concentrations do not reflect total body stores, symptoms are more important determinants of the urgency and aggressiveness of therapy.

The body stores of magnesium must be replenished slowly. Serum magnesium concentrations may return to the normal range within the first 24 hours, but total replenishment of body stores may take several days. Furthermore, approximately 50% of the administered IV dose of magnesium will be excreted in the urine.²⁷⁹ Because the threshold for urinary magnesium excretion is low, the abrupt increase in serum magnesium after an IV dose will result in increased urinary magnesium excretion despite a total body magnesium deficit. Conversely, in patients with renal insufficiency, decreased excretion of magnesium will place the patient at risk for hypermagnesemia. A reduced rate of magnesium administration and frequent monitoring of serum magnesium concentrations are therefore necessary in patients with renal dysfunction.

Oral replacement of magnesium is indicated for asymptomatic patients with mild depletion. Magnesium-containing antacids, Milk of Magnesia, and magnesium oxide are effective choices for replacement. Sustained-release preparations, such as Slow Mag (containing magnesium chloride) and Mag-Tab SR (containing magnesium lactate), are preferred, however. With 5 to 7 mEq (2.5–3.5 mmol or 60–84 mg) of magnesium per tablet, six to eight tablets should be given daily in divided doses for severe magnesium depletion. For mild and asymptomatic disease, two to four tablets per day may be sufficient.²⁸⁰ A diet high in magnesium (cereals, nuts, meat, fruits, fish, legumes, and vegetables) also will help replenish body stores and prevent depletion.²⁸¹

For patients with symptomatic hypomagnesemia, such as R.J., parenteral magnesium replacement is indicated. The magnesium deficit in patients with chronic alcoholism is estimated to be 1 to 2 mEq/kg.²⁸² Because up to half of the IV magnesium dose will be excreted in the urine during replacement, approximately 2 to 4 mEq/kg will be needed to replenish R.J.'s body store.²⁷⁹ One milliequivalent per kilogram of magnesium, as magnesium sulfate 10% solution, should be administered IV in the first 24 hours. Half of this amount is given in the first 3 hours, and the remaining half is infused over the rest of the day. This dose may be repeated to keep the serum magnesium concentration >1.0 mg/dL.²⁸⁰ Later on, 0.5 mEq/kg of

magnesium may be replenished daily for up to 4 additional days.^{279,283} Magnesium can be given IM as 50% solution, but the injections are painful and potentially sclerosing, and multiple administrations are needed. Therefore, the IV route is the preferred mode of parenteral administration. For patients with symptomatic hypomagnesemia who are unstable, such as those experiencing seizures or life-threatening arrhythmias, 16 mEq of magnesium sulfate may be administered as a short IV infusion over 2 minutes, followed by 16 mEq over 20 minutes, then 16 to 24 mEq over 2 to 4 hours.^{279,284}

After IV magnesium administration, the patient should remain in a supine position to avoid hypotension. He should be monitored carefully for marked suppression of deep tendon reflexes (Mg, 4–7 mEq/L); ECG, BP, and respiration changes; and high serum magnesium levels. Facial flushing, a sensation of warmth, and sweatiness may result from vasodilation secondary to a rapid magnesium infusion.²⁷⁹ Particular caution is warranted in patients with renal impairment, in whom the rate of magnesium should be reduced. These patients should be monitored frequently to avoid toxicities related to hypermagnesemia. IV magnesium should also be administered cautiously in patients with severe atrioventricular heart block or bifascicular blocks because magnesium possesses pharmacologic properties similar to calcium channel blockers.^{279,284}

In patients who develop hypomagnesemia secondary to a thiazide or loop diuretic, amiloride may be added to reduce renal magnesium loss by increasing reabsorption in the cortical collecting tubule.²⁸⁰

30. Over the initial 2 days of hospitalization, R.J. received 3 mEq/kg of IV magnesium sulfate. However, his serum magnesium concentration remained <1.5 mEq/L (normal, 1.5–2.6). What might have contributed to the lack of favorable response to the magnesium therapy?

The total amount of magnesium administered to R.J. over the past 2 days was higher than the usual recommended rate (4–5 days) of magnesium replenishment, leading to renal excretion of a large portion of the dose.²⁸⁶ Furthermore, the use of nasogastric suction and furosemide have increased the magnesium loss during the replacement period, and hypokalemia may have reduced the effectiveness of magnesium replacement. In a patient whose serum magnesium concentration does not increase after appropriate magnesium therapy, a 24-hour urine collection to assess magnesium renal excretion can be helpful. A low urinary magnesium concentration is consistent with magnesium depletion, whereas high urinary magnesium excretion in the presence of hypomagnesemia suggests renal magnesium wasting.

Hypermagnesemia

Etiology

31. J.O., a 63-year-old man with renal insufficiency, was admitted to the hospital because of increasing weakness over the past several days. J.O. began taking a magnesium–aluminum hydroxide antacid several times daily 2 weeks ago when he developed stomach upset. Physical examination reveals hypotension and depressed deep tendon reflexes. The ECG reveals prolonged PR and QRS intervals. The serum magnesium concentration is

6.5 mEq/dL (normal, 1.6–2.8). What is the most likely cause of hypermagnesemia in J.O.?

[SI unit: Mg, 3.25 mmol/L]

Because the kidney is the primary route of magnesium elimination, renal impairment is a virtual requisite for hypermagnesemia (see Chapter 31, Chronic Renal Failure). A common cause of hypermagnesemia is the use of magnesium-containing medications, such as antacids and laxatives, by patients with impaired renal function, including older adults. When a patient with renal failure, such as J.O., takes magnesium-containing medications, the serum magnesium concentration can increase substantially, resulting in toxicities. Hypermagnesemia may be seen when the creatinine clearance drops below 30 mL/minute; an inverse relationship is observed between the serum magnesium concentrations and the creatinine clearances.²⁸⁷ Hypermagnesemia is also seen in patients with acute renal failure during the oliguric phase, but not the diuretic phase.²⁸⁸ Other potential causes of hypermagnesemia include adrenal insufficiency,²³⁴ hypothyroidism,²⁸⁹ lithium,²⁸⁹ magnesium citrate used as a cathartic for drug overdose,²⁹⁰ and parenteral magnesium given for pre-eclampsia.²⁹¹

Clinical Manifestations

32. Describe the usual clinical presentation of a patient with hypermagnesemia.

An elevated magnesium serum concentration alters the normal function of the neurologic, neuromuscular, and cardiovascular systems. When the serum magnesium concentration is >4 mEq/L, deep tendon reflexes are depressed; they are usually lost at >6 mEq/L. Flaccid quadriplegia can develop when the concentration is >8 to 10 mEq/L. Respiratory paralysis, hypotension, and difficulty in talking and swallowing may also be present.²⁹³ Changes in the ECG may include a prolonged PR interval and widening of the QRS complex. Complete heart block may be seen at concentrations of approximately 15 mEq/L. In mild hypomagnesemia, the patient may experience nausea and vomiting.

Drowsiness, lethargy, diaphoresis, and altered consciousness may be present at higher serum magnesium concentrations. J.O.'s increasing weakness, hypotension, depressed deep tendon reflexes, and ECG findings are consistent with hypermagnesemia.

Treatment

33. How should J.O.'s hypermagnesemia be treated?

If magnesium-containing medications are discontinued in patients with hypermagnesemia, the serum magnesium concentration will usually return to the normal range through renal elimination. When potentially life-threatening complications are present, as in J.O., 5 to 10 mEq of IV calcium should be administered to antagonize the respiratory and cardiac manifestations of magnesium.^{291,292} The dose of the calcium can be repeated as necessary because its effect is short lived. In patients with good renal function without life-threatening complications, IV furosemide, plus 0.45% sodium chloride to replace lost urine volume, will enhance urinary magnesium excretion while preventing volume depletion. Hemodialysis or peritoneal dialysis is indicated for patients with significant renal function impairment and possibly for those with severe hypermagnesemia.

Dyslipidemias (one or more abnormalities of blood lipids) produce atherosclerosis, which in turn produces coronary heart disease (CHD) and coronary artery disease (CAD). Successful management of dyslipidemias alters the natural course of atherosclerosis and prevents CHD as well as other forms of atherosclerosis. This is the simple but profound notion behind the modern approach to reducing the incidence of the nation's number-one killer. The challenge for the clinician is to know how to assess the patient's CHD risk, to understand lipid-modulating therapies, to match the intensity of treatment with the patient's risk, and to implement treatments that meet and maintain treatment goals. The principal focus of this chapter is on providing the information required to meet this challenge.

Lipid Metabolism and Drug Effects

The journey begins with acquiring an understanding of how lipids are formed, transported, and utilized; how these processes can go awry; and how our therapies alter these aberrant processes. At the center of these processes are cholesterol, triglycerides (TG), and phospholipids. Of these three, cholesterol plays the central role in the pathogenesis of atherosclerosis. Cholesterol is a naturally occurring sterol that is essential for life. It is the precursor molecule for the formation of bile acids (which are required for absorption of nutrients), the synthesis of steroid hormones (which provide important modulating effects in the body), and the formation of cell membranes. TG are an important source of stored energy in adipose tissue. TG are synthesized from three molecules of fatty acids esterified to glycerol. Phospholipids are a class of lipids formed from fatty acids, a negatively charged phosphate group, nitrogen containing alcohol, and a glycerol backbone. Phospholipids are essential for cellular function and the transport of lipids in the circulation by forming a membrane bilayer of lipoproteins (discussed below).

In Vivo Cholesterol Synthesis

Cells derive cholesterol in two ways: by intracellular synthesis or by uptake from the systemic circulation. Within each cell, cholesterol is synthesized through a series of biochemical steps, many of which are catalyzed by enzymes (Fig. 12-1). One important and early step in its synthesis is the conversion of hydroxymethylglutaryl-coenzyme A (HMG-CoA) to mevalonic acid. The enzyme HMG-CoA reductase catalyzes this step. One of the most effective therapies developed to date for managing dyslipidemias (i.e., HMG-CoA reductase inhibitors or statins) interferes with this enzyme and thereby reduces the cellular synthesis of cholesterol. Other catalytic enzymes involved in the biosynthesis of cholesterol, including HMG-CoA synthase and squalene synthase, have been targets in the search for therapies to reduce cholesterol synthesis. Drugs modifying these enzymes, however, caused more, not less, atherosclerotic disease. For example, a drug released for cholesterol lowering in the 1950s, MER 29, interfered with a late step in cholesterol biosynthesis and effectively reduced cellular cholesterol production, but caused a toxic accumulation of desmosterol and other cholesterol precursors that resulted in the development of cataracts and myocardial ischemia.

Intracellular cholesterol is stored in an esterified form. Free cholesterol is converted to this ester form through the action of the enzyme acetyl CoA acetyl transferase (ACAT). Two forms

of ACAT have been identified. ACAT1 is present in many tissues, including inflammatory cells, whereas ACAT2 is present in intestinal mucosa cells and hepatocytes. ACAT2 is required for the esterification and absorption of dietary cholesterol from the gut. In theory, inhibition of this enzyme should reduce the absorption of dietary cholesterol, the secretion of cholesterol by the liver, and even the uptake and storage of circulating cholesterol in inflammatory cells in the arterial wall. Several inhibitors of ACAT have been developed. These inhibitors do not appear to reduce atherosclerosis, however.¹

Lipoproteins

The second way cells obtain cholesterol is by extracting it from the systemic circulation. The source of this cholesterol is the liver, where it is synthesized and secreted into the systemic circulation. Because cholesterol and other fatty substances are insoluble in water, they are formed into complexes (particles) in the hepatocyte and gut before being secreted into the aqueous medium of the blood. These particles contain an oily inner lipid core made up of cholesterol esters and TG and an outer hydrophilic coat made up of phospholipids and unesterified cholesterol (Fig. 12-2). The outer coat also contains at least one protein, which provides the ligand for interaction with receptors on cell surfaces. The presence of a central lipid core and an outer protein gives rise to the name of these particles, *lipoproteins*.

The three major lipoproteins found in the blood of fasting (10–12 hours) patients are very-low-density lipoprotein (VLDL), low-density lipoprotein (LDL), and high-density lipoprotein (HDL).² These particles vary in size, composition, and accompanying proteins (Table 12-1).

VERY-LOW-DENSITY LIPOPROTEINS

Very-low density lipoprotein particles are formed in the liver (Fig. 12-2). They normally contain 15% to 20% of the total blood cholesterol concentration and most of the total blood TG concentration. The concentration of cholesterol in these particles is approximately one fifth of the total TG concentration; thus, if the total TG concentration is known, the VLDL-cholesterol (VLDL-C) level can be estimated by dividing total TG by 5. VLDL particles are large and appear to play only a small role in the pathogenesis of atherosclerosis.

VLDL REMNANTS

As VLDL particles flow through capillaries, some of their TG content is removed through the action of the enzyme lipoprotein lipase. Drugs that enhance the activity of lipoprotein lipase (i.e., fibrates) increase the delipidization process and lower blood TG levels. The removed TG is converted to fatty acids and stored as an energy source in adipose tissue. As TG are removed, the VLDL particle becomes progressively smaller and relatively more cholesterol rich. The particles formed through this process include small VLDL particles (called remnant VLDL), intermediate-density lipoproteins (IDL), and LDL (Fig. 12-2). Approximately 50% of the remnant VLDL and IDL particles are removed from the systemic circulation by receptors on the surface of the liver (receptors called LDL or B-E receptors); the other 50% are converted into LDL particles.

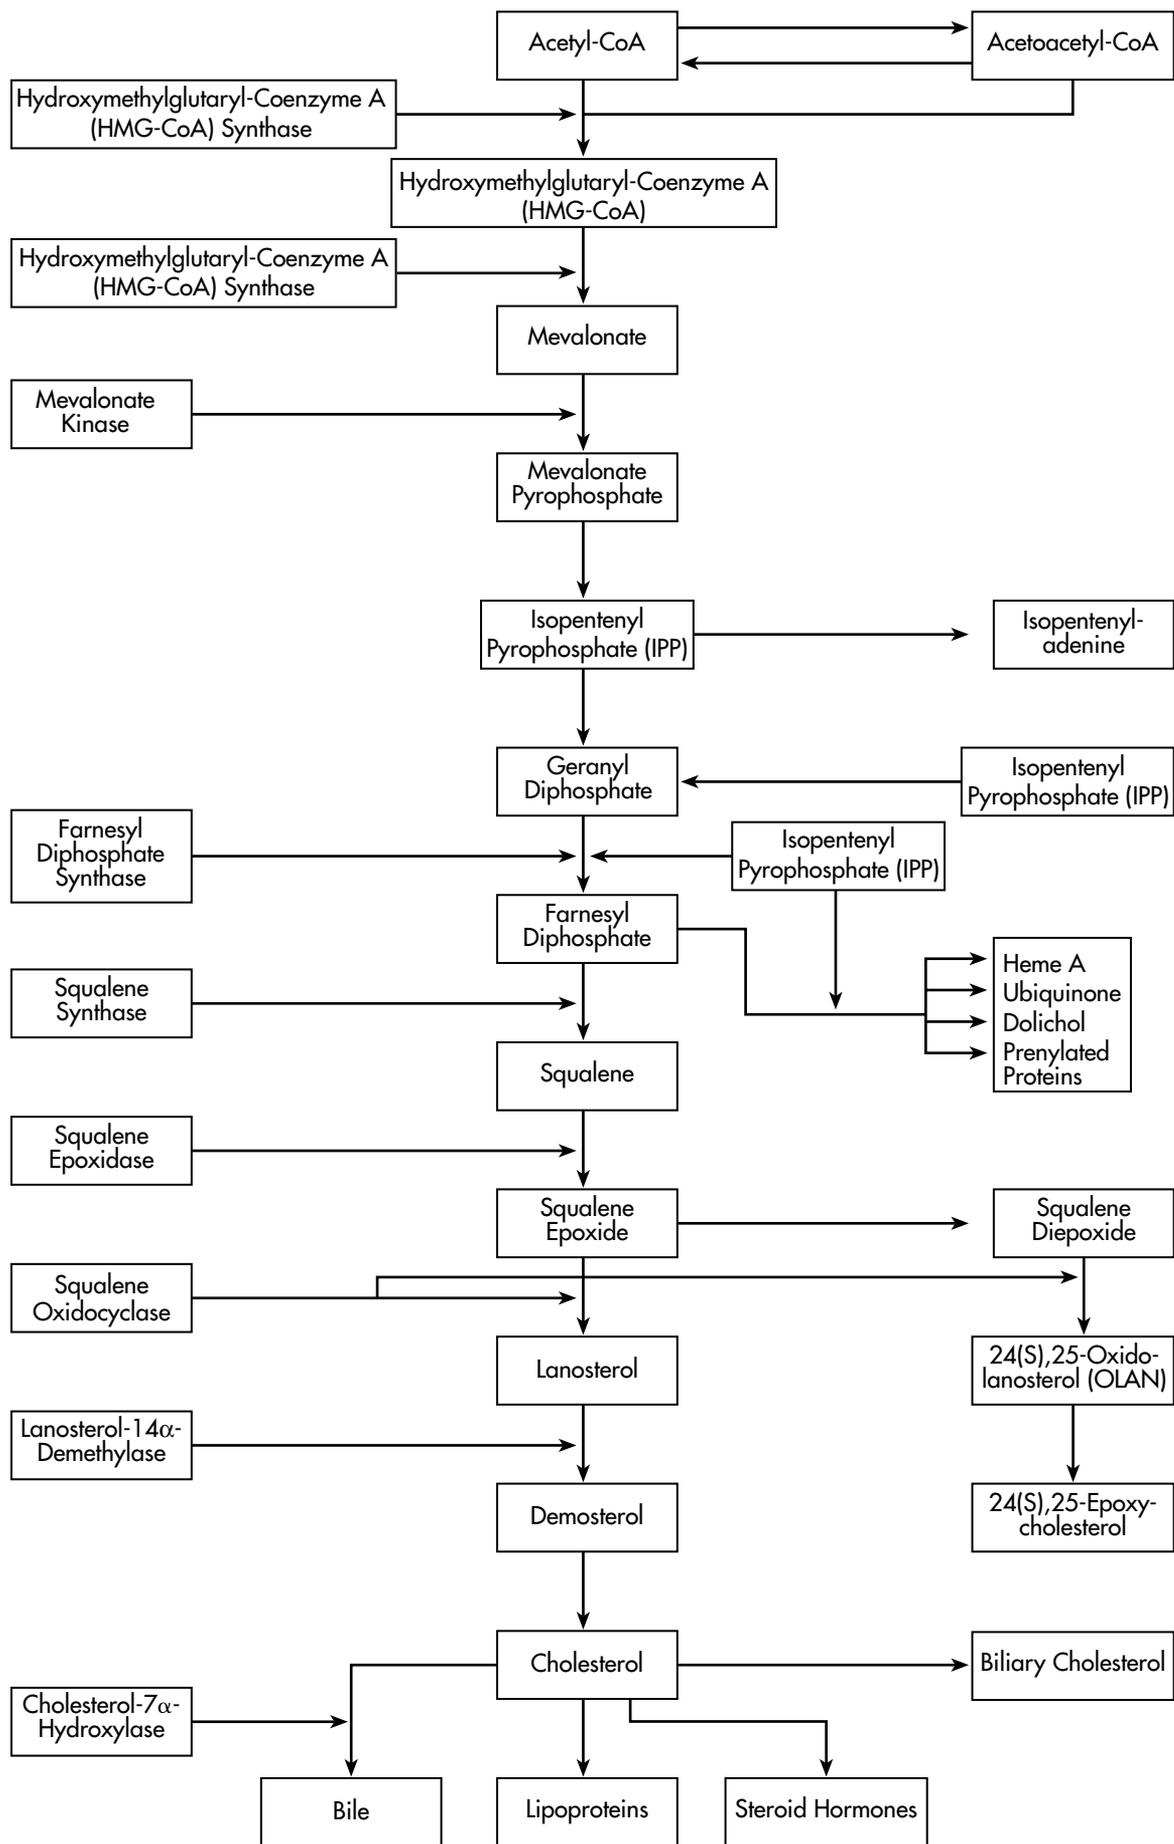

FIGURE 12-1 Biosynthetic pathway of cholesterol.

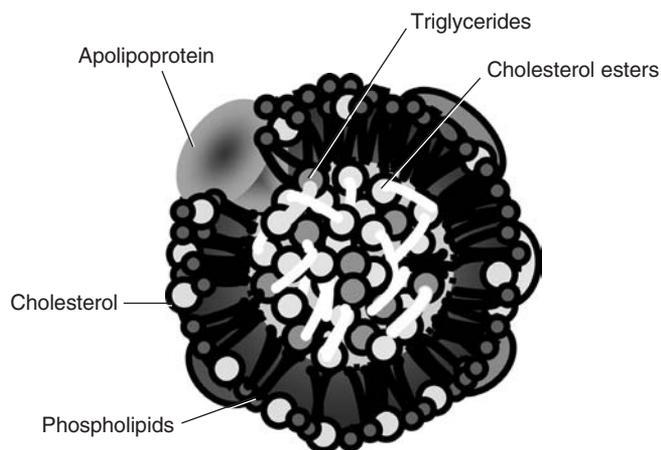

FIGURE 12-2 Basic structure of a lipoprotein. (From Harper C, Jacobsen T. New perspectives on the management of low levels of high-density lipoprotein cholesterol. *Arch Intern Med* 1999;159:1049, with permission.)

LOW-DENSITY LIPOPROTEINS

Low-density lipoprotein particles carry 60% to 70% of the total blood cholesterol and make the greatest contribution to the development of atherosclerosis. This is why LDL-C is the primary target of cholesterol-lowering therapy. Approximately half of the LDL particles are removed from the systemic circulation by the liver; the other half may be taken up by peripheral cells or deposited in the intimal space of coronary, carotid, and other peripheral arteries, where atherosclerosis can develop. The probability that atherosclerosis will develop is directly related to the concentration of LDL-C in the systemic circulation and the length of time this level of exposure persists (the cumulative risk of CHD in men and women increases with age).

HIGH-DENSITY LIPOPROTEINS

High-density lipoprotein particles transport cholesterol from peripheral cells back to the liver, a process called *reverse cholesterol transport*.³⁻⁵ In contrast to LDL, high HDL-C con-

centrations are desirable because cholesterol is being removed from vascular tissue and is not available to contribute to atherogenesis. In peripheral cells, the adenosine triphosphate binding cassette transporter A-1 (ABCA-1 transporter) and adenosine triphosphate binding cassette transporter G-1 (ABCG-1) facilitates the efflux of both cholesterol and phospholipids. Through mechanisms that have not been defined fully, HDL particles acquire this cholesterol and either transport it directly to the liver through interaction with an HDL receptor on the hepatocyte (the scavenger receptor, SR-B1) or transfer it to circulating remnant VLDL and LDL particles through the action of cholesterol ester transfer protein (CETP) in exchange for TG making the HDL particle less cholesterol rich. If the latter occurs, the cholesterol can be returned to the liver for clearance from the circulation or delivered back to peripheral cells (Fig. 12-3). Patients have been described who have a deficiency of CETP; they often have a high plasma concentration of HDL-C and a low incidence of CHD. Drugs are being developed and tested that inhibit this protein. Recent trials, however, have not looked promising for this class of drugs.⁶

High-density lipoprotein particles are further subfractionated. The smaller HDL₃ particle is converted to the larger HDL₂ particle as it acquires TG and cholesterol from peripheral cells and circulating lipoproteins. Conversely, HDL₂ particles are converted to HDL₃ particles by lipolysis of TG through the action of hepatic lipase. Cholesterol acquired from peripheral cells by HDL particles is converted into an esterified form through the action of the enzyme lecithin-cholesterol acyl transferase (LCAT).

NON-HDL CHOLESTEROL

Non-HDL cholesterol (non-HDL-C) refers to the combined amount of cholesterol carried by VLDL and LDL particles (the cholesterol carried by IDL particles is reported as part of LDL cholesterol). As indicated, most often an elevated LDL-C is encountered, but in about 30% of cases, VLDL-C is also elevated. In these cases, it is helpful to know how much cholesterol is being carried by all of these particles. Non-HDL-C is determined by subtracting the HDL-cholesterol (HDL-C) level from the total cholesterol level.

Table 12-1 Classification and Properties of Plasma Lipoproteins

| | <i>Chylomicron</i> | <i>VLDL</i> | <i>LDL</i> | <i>HDL</i> |
|--------------------------|--------------------------------------|--------------------------------|----------------------------------|----------------------------------|
| Density (g/mL) | <0.94 | 0.94–1.006 | 1.006–1.063 | 1.063–1.210 |
| Composition (%) | | | | |
| Protein | 1–2 | 6–10 | 18–22 | 45–55 |
| Triglyceride | 85–95 | 50–65 | 4–8 | 2–7 |
| Cholesterol | 3–7 | 20–30 | 51–58 | 18–25 |
| Phospholipid | 3–6 | 15–20 | 18–24 | 26–32 |
| Physiologic origin | Intestine | Intestine and liver | Product of VLDL catabolism | Liver and intestine |
| Physiologic function | Transport dietary CH and TG to liver | Transport endogenous TG and CH | Transport endogenous CH to cells | Transport CH from cells to liver |
| Plasma appearance | Cream layer | Turbid | Clear | Clear |
| Electrophoretic mobility | Origin | Pre-beta | Beta | Alpha |
| Apolipoproteins | A-IV, B-48, C-IC-II, C-III | B-100, C-IC-III, C-III, E | B-100, (a) | A-I, A-II, A-IV |

CH, cholesterol; HDL, high-density lipoprotein; LDL, low-density lipoprotein; TG, triglyceride; VLDL, very-low-density lipoprotein.

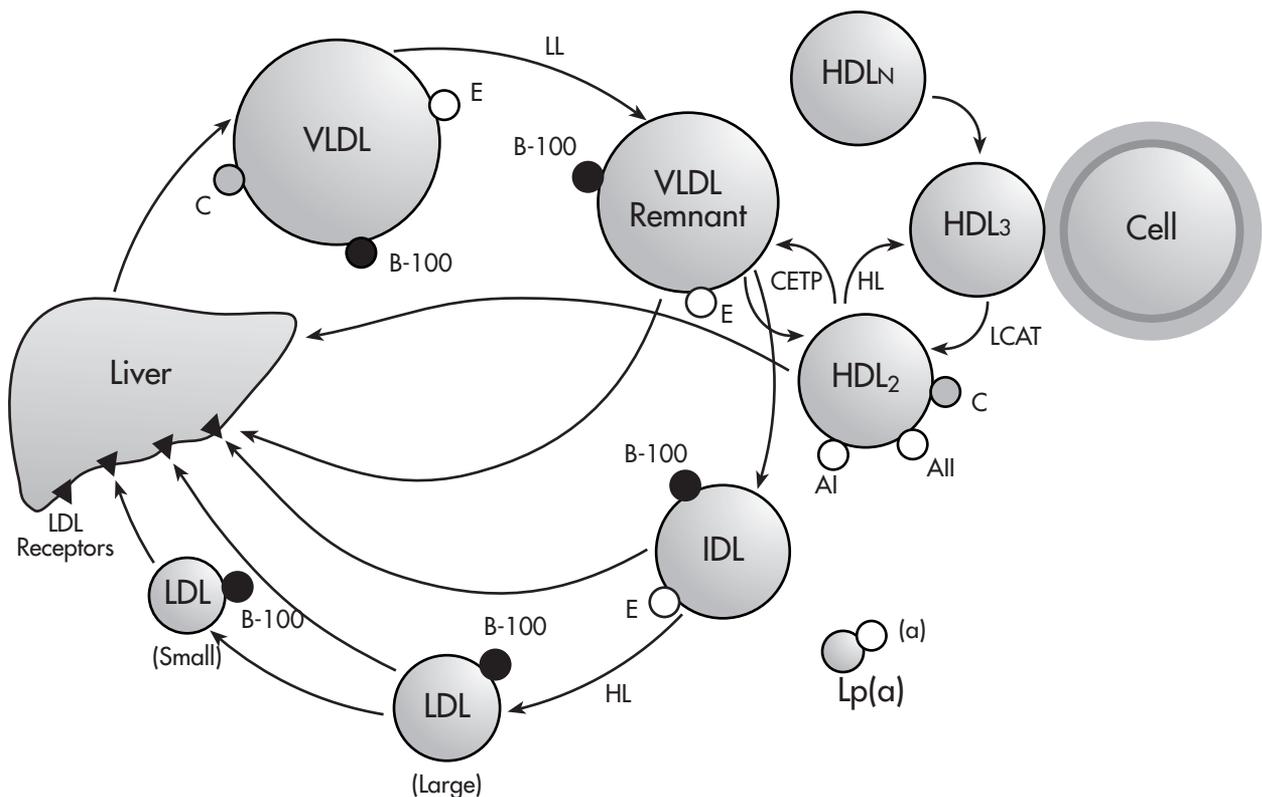

FIGURE 12-3 The lipoproteins, apolipoproteins, and enzymes involved in the transport of cholesterol and triglycerides. HDL, high-density lipoprotein; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; VLDL, very-low-density lipoprotein.

CHYLOMICRONS

Unlike the lipoproteins that transport cholesterol from the liver to peripheral cells and back (endogenous system), chylomicrons transport fatty acids and cholesterol derived from the diet or synthesized in the intestines from the gut to the liver (exogenous system) (Fig. 12-3 and Table 12-1). Chylomicrons are large, TG-rich lipoproteins. As they pass through capillary beds on the way to the liver, some of the TG content is removed through the action of lipoprotein lipase in a manner similar to that described for TG removal from VLDL particles. In the rare individual who has a lipoprotein lipase deficiency, this removal process is faulty and TG levels in the blood become very high (e.g., 1,000 to 5,000 mg/dL).

Following a fatty meal, the number of chylomicron particles (and therefore the concentration of TG) is high. If the patient fasts for 10 to 12 hours, however, chylomicrons will have time to be removed from the blood. TG concentrations obtained during fasting reflect TG that is produced by the liver and carried in VLDL and other remnant particles (unless the patient has a rare chylomicron clearance disorder). This is why patients are asked to fast before a lipoprotein profile is obtained. A blood sample that is rich in chylomicrons (and to a lesser extent VLDL particles) appears turbid; the higher the TG level, the more turbid the sample. If the sample from a patient with hyperchylomicronemia is refrigerated, chylomicrons will float to the top and form a frothy white layer, whereas smaller VLDL stay suspended below.

Apolipoproteins

Each lipoprotein particle contains proteins on its outer surface called *apolipoproteins* (Fig. 12-3 and Table 12-1). These proteins have three functions: (a) provide structure to the lipoprotein, (b) activate enzyme systems, and (c) bind with cell receptors.² Abnormal metabolism of apolipoproteins, even in the face of seemingly normal blood cholesterol levels, can result in faulty enzyme activity or cholesterol transport and an increased risk of atherosclerosis. Because of this, lipid specialists often assess blood levels of apolipoproteins to evaluate dyslipidemic patients fully, especially those who have a family history of premature CHD. The five most clinically relevant apolipoproteins are A-I, A-II, B-100, C, and E.

Very-high-density lipoprotein particles contain apolipoproteins B-100, E, and C (Fig. 12-3). The B and E proteins are ligands for LDL receptors (also called *B-E receptors*) on the surface of hepatocytes and peripheral cells. Linkage allows the transfer of cholesterol from the circulating lipoprotein into the cell through absorptive endocytosis and cellular uptake of the particle. Defects in these proteins reduce their ability to bind with receptor proteins. This results in defective clearance of lipoproteins from the systemic circulation and increased levels of circulating cholesterol.

Apolipoprotein C-II (Apo C-II) is a cofactor for lipoprotein lipase (LPL). By activating LDL, Apo C-II stimulates the hydrolysis of TG from lipoprotein particles in the capillary beds. Deficiencies of C-II apolipoproteins result in

faulty TG metabolism and ultimately in hypertriglyceridemia. Apolipoprotein C-III has become a marker of atherogenic dyslipidemia (described below) and for an increased risk of atherosclerosis. Apolipoprotein C-III downregulates lipoprotein lipase activity and interferes with the hepatic uptake of VLDL remnant particles. This leads to increased concentrations of small VLDL remnant particles, which are able to penetrate into the arterial wall and contribute to atherogenesis. In addition, prolonged residence of VLDL and LDL particles in the systemic circulation results in the formation of small, highly atherogenic LDL particles (see below).⁷ With further research, apolipoprotein C-III may emerge as an important marker of atherosclerosis and provide a way for clinicians to identify patients requiring aggressive treatment.

Remnant VLDL particles retain apolipoproteins B-100 and E during the delipidization process; LDL particles contain only apolipoprotein B-100 (Fig. 12-3). Each VLDL and LDL particle contains one apolipoprotein B-100. Thus, the blood concentration of apolipoprotein B-100 is an indication of the total number of VLDL and LDL particles in the circulation. An increased number of lipoprotein particles (i.e., an increased apolipoprotein B-100 concentration) is a strong predictor of CHD risk. The ratio of non-HDL-C (total cholesterol-HDL-C) to apolipoprotein B-100 gives an estimate of the cholesterol contained in each VLDL and LDL particle. Some patients have high levels of apolipoprotein B-100 (suggesting an increased number of VLDL and LDL particles in the circulation), even though their cholesterol level is in the desirable range. These patients have an increased risk of atherosclerosis. A apolipoprotein B-100:LDL-C ratio greater than 1 is also an indicator of the presence of small, dense LDL—particles that convey a higher CHD risk than larger LDL particles.

High-density lipoprotein particles contain apolipoproteins A-I, A-II, and C. A-I protein activates LCAT, which catalyzes the esterification of free cholesterol in HDL particles. Levels of apolipoprotein A-I have a stronger inverse correlation with CHD risk than apolipoprotein A-II levels. HDL particles that contain only A-I apolipoproteins (LpA-I) are associated with a lower CHD risk than are HDL particles containing both A-I and A-II (LpA-I, A-II).⁸

LDL Receptor

The uptake of cholesterol into peripheral and hepatic cells is accomplished by the binding of apolipoproteins B-100 and E on circulating lipoproteins to cell-surface LDL receptors. The synthesis of LDL receptors is stimulated by a low intracellular cholesterol concentration.⁸ Within the cell, the receptor protein travels from the mitochondria (where it is synthesized) to the cell surface (where it migrates to an area called the *coated pits*). Once in this position, it is capable of binding with lipoproteins that contain apolipoprotein E or B-100, including VLDL, remnant VLDL, IDL, and LDL. Because remnant VLDL and IDL particles contain both B-100 and E proteins, they may have a higher affinity for LDL receptors than do LDL particles, which contain only the B protein. Furthermore, drugs that increase the synthesis of LDL receptors (e.g., statins) can increase the clearance of both VLDL remnant particles and LDL particles from the circulation. This would account for their ability to reduce serum TG levels as well as cholesterol levels. After these proteins are bound, the lipoproteins undergo endocytosis and are taken up by lysosomes, where

they are broken into elemental substances for use by the cell. The cholesterol is transferred into the intracellular cholesterol pool. The receptor protein may be returned to the cell surface, where it can bind with another circulating apolipoprotein E- or B-containing lipoprotein. Drugs that reduce the intracellular cholesterol concentration (e.g., bile acid resins, ezetimibe, and statins) cause the upregulation of LDL receptors and thereby increase the removal of cholesterol-carrying lipoproteins from the systemic circulation.

Abnormalities in Lipid Metabolism

As can be imagined from the above description of lipid synthesis and transport, literally hundreds of possible steps could malfunction and cause a lipid disorder. Only a few relatively common and important lipid disorders are seen, however. The first two described below, polygenic hypercholesterolemia and atherogenic dyslipidemia, are largely the result of an interaction between genes and lifestyle choices; following these are several prominent, but rarer familial lipid disorders. Table 12-2 summarizes the characteristics of the most common lipid disorders.

Polygenic Hypercholesterolemia

Polygenic hypercholesterolemia, the most prevalent form of dyslipidemia, which is found in more than 25% of the U.S. population, is caused by a combination of environmental (e.g., poor nutrition, sedentary lifestyle) and genetic factors (thus, the term “polygenic”). Saturated fatty acids in the diet of these patients can reduce LDL receptor activity, thus reducing the clearance of LDL particles from the systemic circulation. As a result, patients with polygenic hypercholesterolemia have mild to moderate LDL-C elevations (usually in the range of 130 to 250 mg/dL), but no unique physical findings are seen. Family history of premature CHD is present in approximately 20% of cases. These patients are effectively managed with dietary restriction in saturated fats and cholesterol and by drugs that lower LDL-C levels (i.e., statins, bile acid sequestrants, niacin, and ezetimibe).

Atherogenic Dyslipidemia

Atherogenic dyslipidemia is found in about 25% of patients who have a lipid disorder. It is characterized by a moderate TG elevation (150 to 500 mg/dL; indicative of the increased presence of VLDL remnant particles), a low HDL-C level (<40 mg/dL); and a moderately high LDL-C level (including increased concentrations of small-dense LDL particles). Most commonly, these patients are either overweight or obese with increased waist circumference, hypertensive, and insulin resistant with or without diabetes and are said to have the *metabolic syndrome*.

Patients who are obese or have diabetes have an increased mobilization of fatty acids from adipose cells to the systemic circulation, which leads to increased TG synthesis and secretion of VLDL particles by the liver. Often these particles contain apolipoprotein C-III, which interferes with the action of lipoprotein lipase, thus retarding lipolysis of TG from VLDL particles. This results in the formation of TG-rich VLDL remnant particles. TG from these particles is exchanged with cholesterol esters from HDL under the influence of CETP, which means the VLDL remnant particles become enriched

Table 12-2 Characteristics of Common Lipid Disorders

| Disorder | Metabolic Defect | Lipid Effect | Main Lipid Parameter | Diagnostic Features |
|---|--|---|--|--|
| Polygenic hypercholesterolemia | ↓LDL clearance | ↑LDL-C | LDL-C: 130–250 mg/dL TG: 150–500 mg/dL | None distinctive |
| Atherogenic dyslipidemia | ↑VLDL secretion, ↑C-III synthesis ↓LPL activity ↓VLDL removal | ↑TG ↑Remnant VLDL ↓HDL ↑Small, dense LDL | HDL-C: <40 mg/dL | Frequently accompanied by central obesity or diabetes |
| Familial hypercholesterolemia (heterozygous) | Dysfunctional or absent LDL receptors | ↑LDL-C | LDL-C: 250–450 mg/dL | Family history of CHD, tendon xanthomas |
| Familial defective apoB-100 | Defective ApoB on LDL and VLDL | ↑LDL-C | LDL-C: 250–450 mg/dL | Family history of CHD, tendon xanthomas |
| Dysbetalipoproteinemia (type III hyperlipidemia) | ApoE2:E2 phenotype, ↓VLDL remnant clearance | ↑Remnant VLDL, ↑IDL | LDL-C: 300–600 mg/dL TGs: 400–800 mg/dL | Palmar xanthomas, tuberoeruptive xanthomas |
| Familial combined hyperlipidemia | ↑ApoB and VLDL production | ↑CH, TG, or both | LDL-C: 250–350 mg/dL TGs: 200–800 mg/dL | Family history, CHD Family history, Hyperlipidemia |
| Familial hyperapobetalipoproteinemia | ↑ApoB production | ↑ApoB | ApoB: >125 mg/dL | None distinctive |
| Hypoalphalipoproteinemia | ↑HDL catabolism | ↓HDL-C | HDL-C: <40 mg/dL | None distinctive |

ApoB, apolipoprotein B; ApoE, apolipoprotein E; CH, cholesterol; CHD, coronary heart disease; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; LDL-C, low-density lipoprotein cholesterol; TGs, triglycerides; VLDL, very-low-density lipoprotein.

with cholesterol whereas HDL particles lose cholesterol (and gain TG) (Fig. 12-3). TG is also exchanged from VLDL remnant particles with cholesterol esters from LDL particles. Thus, VLDL remnants become even more cholesterol enriched and LDL becomes TG enriched. The cholesterol-enriched, small VLDL remnant particle is atherogenic. TG-rich LDL and HDL particles undergo lipolysis catalyzed by hepatic lipase to remove TG, leaving small, cholesterol ester-deficient LDL particles (called *small dense LDL*) that are highly atherogenic and a reduction in HDL-C from the loss of apolipoprotein A-I by the kidneys.⁹

Patients with atherogenic dyslipidemia can often be effectively managed with weight reduction and increased physical activity. If needed, drugs that enhance the removal of remnant VLDL and small dense LDL particles (i.e., statins) and that lower TG levels (i.e., niacin or fibrates) are effective in the management of these cases.

Familial Hypercholesterolemia

Familial hypercholesterolemia (FH) is the classic lipid disorder of defective clearance. This autosomal dominant disorder is strongly associated with premature CHD.^{10,11} Heterozygotes (1 of 500 people in the United States) of this disorder inherit one defective LDL receptor gene. Consequently, these persons possess approximately half the number of functioning LDL receptors and double the LDL-C level of unaffected patients (i.e., LDL-C of 250 to 450 mg/dL).^{12,13} Clinically, heterozygous FH patients may deposit cholesterol in the iris, leading to arcus senilis. Cholesterol also deposits in tendons, particularly the Achilles' tendon and extensor tendons of the hands, leading to tendon xanthomas. The clinical diagnosis of FH is established by documenting a very high LDL-C level, a strong family history of premature CHD events, and the presence of tendon xanthomas. Untreated heterozygous FH patients have approximately a 5% chance of a myocardial infarction (MI) by

age 30, a 50% chance by age 50, and an 85% chance by age 60. The mean age of death in untreated male heterozygotes is in the mid 50s; for untreated female heterozygotes, it is in the mid 60s.¹⁴

Homozygotes (1 of 1,000,000 people in the United States) for this disorder inherit a defective LDL receptor gene from both parents and generally have LDL-C levels >500 mg/dL. This rare disorder results in CHD by age 10 to 20 years. Because these individuals have lost the ability to clear cholesterol-carrying lipoproteins from the circulation, apheresis (analogous to dialysis for the kidney patient) is required to help remove these atherogenic particles.

Familial defective apolipoprotein B-100 (FDB) is a genetic disorder clinically indistinguishable from heterozygous FH. These patients have normally functioning LDL receptors, but a defective apolipoprotein B-100, which results in reduced binding to LDL receptors and reduced clearance of LDL particles from the systemic circulation.^{15,16} As with FH, LDL-C levels are 250 to 450 mg/dL.^{15,17,18} Presumably, the apolipoprotein E and half of the apolipoprotein B in heterozygous FDB patients function normally, providing mechanisms for removal of these lipoproteins from the systemic circulation. Clinical diagnosis of FDB, as FH, is based on a very high LDL-C level, a family history of premature CHD, and tendon xanthomas. The definitive diagnosis requires molecular screening techniques.

Familial Dysbetalipoproteinemia

Familial dysbetalipoproteinemia (also called *type III hyperlipidemia* and *remnant disease*) is caused by poor clearance of VLDL and chylomicron particles from the systemic circulation.¹⁹ Apolipoprotein E is necessary for the normal clearance of these particles. It is inherited as an E2, E3, or E4 isoform from each parent. The E2 isoform has a low binding affinity for the LDL receptor. Thus, individuals with an apolipoprotein E2:E2 phenotype have delayed clearance of

VLDL remnant (and possibly chylomicron) particles from the circulation and a reduced conversion of IDL to LDL particles. A lipid disorder, however, usually does not result unless triggered by other metabolic problems (e.g., diabetes, hypothyroidism, or obesity). Clinically, these patients have high cholesterol (owing to an enrichment of cholesterol esters in VLDL remnant particles), high TG (usually in the range of 400 to 800 mg/dL), and a VLDL-C:TG ratio >0.3 .²⁰ Some patients have palmar xanthomas (yellow-orange discoloration in the creases of the palms and fingers) and tuberoeruptive xanthomas (small, raised lesions in areas of pressure, particularly the elbows and knees). A personal and family history of premature atherosclerotic vascular disease often is present. As noted above, these patients often have diabetes mellitus, hypertension, obesity, and hyperuricemia.

Familial Combined Hyperlipidemia

Familial combined hyperlipidemia (FCHL) is the classic example of a dyslipidemia caused by increased production of lipoproteins. For reasons that are not clear, patients with FCHL overproduce apolipoprotein B-containing particles, VLDL, and LDL.^{21–23} Many patients have an elevated apolipoprotein B-100 level.²⁴ As the name implies, patients with this disorder may have hypercholesterolemia (usually in the range of 250 to 350 mg/dL), or hypertriglyceridemia (usually between 200 and 800 mg/dL) or a combination of both (usually with a low HDL-C level). First-degree relatives of these individuals frequently have a lipid disorder. A family history of premature CHD is often present as well. Patients with FCHL commonly are overweight and hypertensive and also may have diabetes or hyperuricemia. A diagnosis of FCHL is presumed in patients who have increased cholesterol or TG levels, a strong family history of premature CHD, and a family history of dyslipidemia.

Familial Hyperapobetalipoproteinemia

Familial hyperapobetalipoproteinemia is a variant of FCHL. This disorder is characterized by increased hepatic production of apolipoprotein B in the absence of other lipid abnormalities.²⁵ These patients have acceptable LDL-C and TG levels and a family history of CHD. Their apolipoprotein B-100 concentration is usually >125 mg/dL, indicating an increase in the number of cholesterol-carrying lipoprotein particles. It is likely that FCHL and hyperapobetalipoproteinemia are related disorders, both resulting from excessive secretion of apolipoprotein B-100 containing lipoproteins.²⁶

Hypoalphalipoproteinemia

Low HDL-C (<40 mg/dL; hypoalphalipoproteinemia) without an increase in TG level is fairly uncommon, but is associated with increased CHD risk.^{27,28} Little, however, is known about the precise molecular defect causing this problem, although genetic influences undoubtedly are involved.²⁹ Recently, Tangier disease, which is characterized by low HDL-C, orange tonsils, and hepatosplenomegaly, has been linked to a defect in the ABCA-1 transporter responsible for the efflux of cholesterol from peripheral cells. The inherited tendency to have low HDL-C is accentuated by lifestyle factors such as obesity, smoking, and lack of exercise. Despite strong epidemiologic evidence showing an inverse relationship between HDL-C and CHD, clinical trials demonstrating a benefit of raising isolated low

HDL-C with drugs are lacking. What has been shown is that lowering LDL-C in patients with low HDL-C reduces CHD risk.³⁰ It is anticipated that therapies to raise HDL-C will become available and can be tested to see if they reduce CHD risk also.

Rationale for Treating Dyslipidemia

Scientific data from animal studies, genetic studies, epidemiologic studies, and clinical trials support the link between cholesterol, atherosclerosis, and CHD. This collective body of knowledge resoundingly supports a critical role for cholesterol in the pathogenesis of atherosclerosis. Even more important, in clinical trials the lowering of blood cholesterol levels has been consistently associated with reduced CHD, whether the blood cholesterol was reduced by drug, diet, or surgical means. Even the most vigorous cholesterol-lowering approach does not result in the complete amelioration of CHD, however, suggesting that other causes are in play. Some of the significant literature on the pathogenesis of atherosclerosis and clinical trials establishing the link between blood cholesterol and CHD is summarized below.

Pathogenesis of Atherosclerosis

Circulating cholesterol has a central role in the pathogenesis of atherosclerosis. Even the name *atherosclerosis* depicts this (from the Latin *athero* [“porridge-like”] and *sclerosis* [“fibrous-like”]). Atherosclerotic lesions begin with the accumulation of cholesterol from LDL and VLDL remnant particles in the intimal space (Fig. 12-4). The reason this occurs is unknown, but in some way it appears directly related to the level of circulating cholesterol and the provocation by risk factors such as hypertension, smoking, diabetes, stress, and genetic predisposition. An important finding is that native LDL *per se* does not contribute to the development of atherosclerosis;

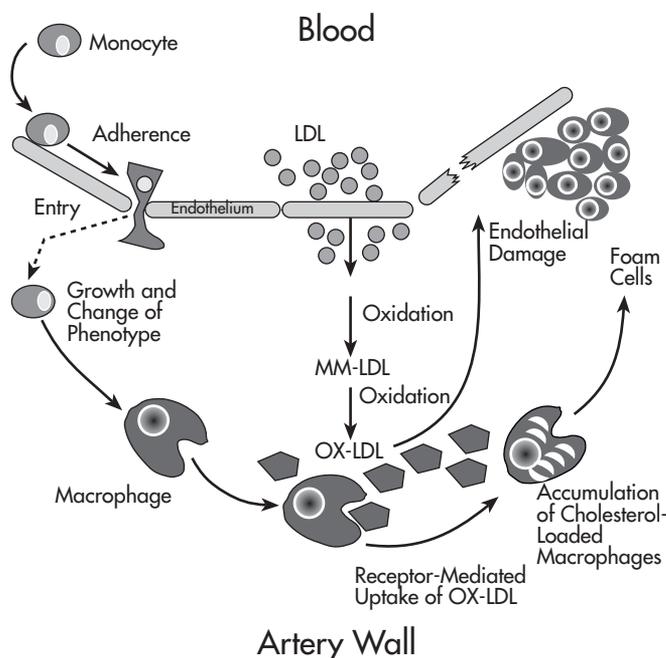

FIGURE 12-4 Some of the steps involved in the development of the fatty streak. LDL, low-density lipoprotein.

instead, LDL must be modified (e.g., oxidized) before it becomes a factor in causing atherosclerosis.

Soon after taking up residence in the subendothelial space, LDL is modified primarily by oxidation. Simultaneously, monocyte adhesion molecules are released from endothelial cells on the surface of the lumen.^{31,32} They cause circulating monocytes to attach to the intact endothelial surface, and then chemoattractants cause these monocytes to squeeze between endothelial cells into the intima (Fig. 12-4).³³

Once recruited, the monocytes are converted to activated macrophage cells, which begin to ingest modified LDL and remnant VLDL particles. These modified particles are taken up by special scavenger or acetyl-LDL receptors on the surface of macrophage cells.³⁴ Modified LDL serves as another chemoattractant for circulating monocytes, thus causing more monocytes from the systemic circulation to take up residence in the intima. It also inhibits the mobility of resident macrophage cells (blocking the egress of these cells from the intima); macrophage cells become a cytotoxic agent (causing damage to the endothelium).³¹ As the uptake of modified LDL into macrophage cells continues, the cells become laden with lipid, grow in size, and eventually become *foam cells* (Fig. 12-4 and Fig. 12-5).

Early in the process, the monocellular layer surrounding the lumen (the endothelium) becomes dysfunctional. Notably, the release of nitric oxide from these cells is impaired, which results in vasoconstriction and ischemic symptoms. Regulation of blood cholesterol levels and management of other risk fac-

tors restore endothelial function, nitrous oxide release, and the vasodilatory response.

The accumulation of foam cells in the intimal space below the endothelium eventually results in a raised lesion, the *fatty streak*, which is widely recognized as the precursor to atherosclerosis. Fatty streaks transform the once smooth endothelial surface of the artery into a lumpy, uneven surface. As this process continues, an atherosclerotic plaque is formed. In the initial stages, this plaque is characterized by a large lipid core made up of macrophage (foam) cells filled with cholesterol along the surface and at the shoulders of the lesion (Fig. 12-5).

During plaque growth, a number of cells (including macrophages, endothelial cells, platelets, and smooth muscle cells) secrete chemoattractant and growth factors, which cause smooth muscle cells from the media to migrate upward and proliferate near the luminal surface.³⁵ Collagen synthesis is increased. This leads to conversion of atherosclerotic lesions that initially are weak and unstable (because they contain a large lipid core surrounded by a thin fibrous cap) to become strong and hard (because they contain a small inner lipid core and much collagen, and matrix). At any given time, atherosclerosis at various stages of development can be found all along the arterial tree in susceptible patients (Fig. 12-4).

As atherosclerotic lesions grow, the coronary artery remodels. Lesions initially grow away from the lumen toward the media, thus preserving the luminal opening and ensuring normal blood flow. Late in the growth of the lesion, however, the

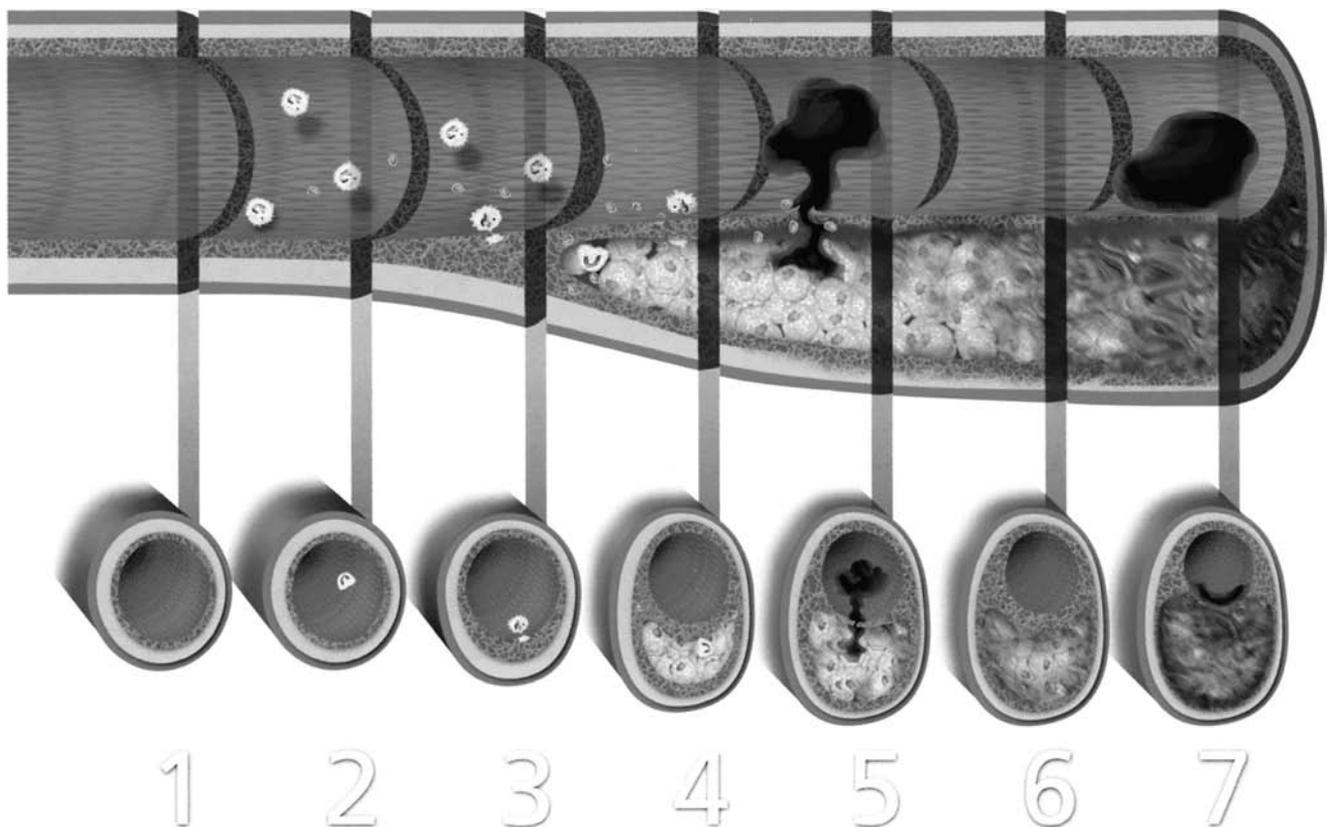

FIGURE 12-5 Initiation, progression, and complication of human coronary atherosclerotic plaque.

luminal space is invaded and becomes progressively narrowed as the atherosclerotic lesion grows.

Similar to the stages of development, atherosclerotic lesions exist along a continuum from vulnerable lesions that can rupture and cause a thrombosis to older, rigid lesions that will not rupture. The younger lesions occupy only the intimal space, whereas the older lesions may protrude into the luminal space. In examining the coronary angiogram of a patient, evidence of stenosis (narrowing of the lumen) indicates the presence of older, more advanced lesions. When these lesions are seen, other lesions distal to the narrowing are likely to be present. They are younger and more susceptible to erosion or rupture, which can cause a thrombosis. In fact, the culprit lesion that results in an MI is usually not at the site of the greatest stenosis, but distal to it.³⁶

A number of processes cause younger lesions to become unstable; most of these are a part of an active inflammatory process. The uptake of cholesterol by activated macrophage cells is one of these processes. Chemoattractants, such as monocyte chemoattractant protein-1 (MCP-1), adhesion molecules, and a family of T-cell substances, participate in the migration of monocytes into the intima. Macrophage colony-stimulating factor (M-CSF) contributes to the differentiation of blood monocytes into macrophage cells. T cells elaborate inflammatory cytokines that stimulate macrophages, endothelial cells, and smooth muscle cells. Activated macrophage cells produce proteolytic enzymes that degrade collagen and weaken the fibrous cap.³⁷ The release of metalloproteinase enzymes causes the destruction of connective tissue and renders the atherosclerotic lesion vulnerable to rupture. Apoptosis (cell death) of smooth muscle cells in the shoulders of the atherosclerotic cap further weakens the lesion.^{38–43} These processes increase the chance that the atherosclerotic lesion will rupture or erode, especially at the shoulders of the lesion, and expose the underlying tissue to circulating blood elements.⁴⁴ With this exposure, platelets may adhere and microthrombi may form. The resultant clot can occlude blood flow entirely, causing an MI. More commonly, only partial occlusion of blood flow occurs, causing transient ischemic symptoms and unstable angina. The clot creates a barrier between the underlying tissue and circulating blood and allows healing to take place. Subsequently, as the atherosclerotic plaque grows further and again ruptures, a new clot can form to mend the lesion. This process of fissuring and rehealing appears to lead to the more complicated lesions of atherosclerosis.

In summary, the atherosclerotic lesions that result in sudden death or a nonfatal MI are not the large lesions that have formed over months and years and that appear prominently on a patient's coronary angiogram. Rather, they are the smaller, less stable lesions that have a large lipid core and a thin fibrous cap.⁴⁵ When shear forces, elevated blood pressure, or other toxic processes in the artery cause these plaques to fissure, erode, or rupture, a thrombosis can develop, leading to the occlusion of the affected vessel and a clinical event.

Epidemiologic Studies

Over the past three decades, epidemiologic studies have established a direct relationship between blood cholesterol concentrations in a population and the incidence of CHD events.^{46–48} For every 1% increase in blood cholesterol levels, a 1% to 2%

increase exists in the incidence of CHD. HDL-C has an inverse relationship with CHD. For every 1% decrease in HDL-C levels, a 1% to 2% increase in the risk of CHD events occurs.⁴⁹

Other epidemiologic trials have demonstrated the influence of environmental versus genetic factors on cholesterol levels and CHD incidence. One of the most revealing studies comes from the Honolulu Heart Study, which reported that Japanese individuals who had very low cholesterol levels and a low CHD death rate experienced a rise in cholesterol levels as well as the incidence of CHD when they migrated to Hawaii and subsequently to the west coast of the United States.⁵⁰ Similarly, Mexicans who live close to the U.S. border have cholesterol levels and a CHD incidence that is similar to those of U.S. residents, whereas those living in the southern part of Mexico have a lower cholesterol level and a lower incidence of CHD.

Gender differences have been the focus of other epidemiologic studies. Before menopause, the incidence of CHD in women is low,^{51,52} but after menopause the rate of CHD in women parallels that of men. In fact, the prevalence of CHD in women is ultimately similar to that in men; it is just displaced by about 10 years.^{48,53} Whereas men begin to experience CHD events in their 50s and 60s, women experience it in their 60s and 70s. Eventually, CHD causes nearly as many deaths in women as it does in men.⁵⁴ In fact, CHD is the cause of more deaths in women than all forms of cancer combined, including cancer of the breast, ovary, and cervix. Furthermore, the presence of diabetes in a woman with dyslipidemia negates whatever protection she may have had before menopause and is associated with a very high incidence of CHD events.^{55,56} Conversely, a high HDL-C level may offer women more protection from CHD than a similar level offers a man.⁴⁹

Finally, epidemiologic trials have taught us lessons about the influence of age on blood cholesterol levels and CHD. A direct relationship exists between blood cholesterol and CHD at all ages, to at least the mid 80s.⁵⁷ Because CHD risk increases with age, most CHD events occur among the elderly. In fact, CHD is the most common cause of death among the elderly.⁵⁸ Intravascular ultrasound studies that examine the inner walls of coronary arteries demonstrate that practically all patients older than 70 years have advanced and prevalent atherosclerotic disease. The relative risk of CHD is nearly twofold greater in elderly patients with elevated cholesterol levels compared with those with normal levels, but this risk level is less than that found in younger populations with similar cholesterol levels. The absolute rate of CHD deaths attributable to high blood cholesterol, however, increases in the elderly compared with younger patients.^{58,59} An elevated blood cholesterol level contributes to more cases of CHD in the older patient population than in the younger, which is partly because of the sheer number of elderly people affected by the disease. Some authorities see age as a marker for plaque burden, suggesting that one way to identify patients with a high CHD risk is to use age as a surrogate for the presence of coronary artery plaque. Because CHD is so prevalent in the elderly, it has been estimated that a mere 1% decline in mortality rates from CHD in the elderly would translate into 4,300 fewer deaths per year in the United States.⁶⁰ As demonstrated below, cholesterol-lowering treatments that target this population result in a substantial reduction in CHD, underscoring the importance of age in forecasting a high risk of future CHD events.

Clinical Trials

ANGIOGRAPHIC REGRESSION TRIALS

Based on animal, epidemiologic, and genetic studies, the direct relationship between blood cholesterol levels and CHD events was established. The critical hypothesis that remained to be proven before cholesterol-lowering therapies could be widely recommended was that lowering blood cholesterol levels would reduce CHD risk. The proof for this hypothesis was ultimately demonstrated in clinical trials. The initial test of this hypothesis involved angiographic trials that sought to demonstrate that by lowering blood cholesterol levels, coronary stenosis visualized on coronary angiography would regress.^{61–78} Much to the surprise of investigators, this did not occur. In fact, more commonly, cholesterol lowering seemed only to slow lesion progression.

Despite these disappointing results, angiographic trials taught many important lessons. They demonstrated that aggressive lipid lowering caused lesions to progress at a slower rate regardless of the vascular bed under study, including coronary,^{62–70,73,74,76–78} carotid,^{71,72,75} and femoral arteries.^{67,75} They established that this effect was achieved regardless of the lipid-lowering therapy deployed: diet and other lifestyle modification,⁶⁴ lipid-lowering drugs,^{7,30,38–43,62,63,66,69–77} or ileal bypass surgery.⁶¹ They also suggested that the more aggressive the lipid lowering, especially if it resulted in >60% reduction in LDL-C, the greater the chance of plaque regression.^{79,80}

The reason early angiographic studies failed to demonstrate lesion regression was not because this process did not occur, but because the methodology could not detect it. Angiograms outline the lesion from the outside of the coronary artery. Because atherosclerotic lesions initially remodel outward away from the lumen, as explained above, the lumen would appear normal until the late stage of atherosclerosis plaque development. Thus, lesions that were visible on a coronary angiogram were the older, more rigid lesions that were less likely to change with lipid-lowering therapy. Younger lesions, which were not visualized in a coronary angiogram, may well have regressed, however. Recent investigations of the contour of the inner lining of the lumen using intravascular ultrasound report that lipid lowering does cause widespread plaque regression without any change in lumen size.⁸¹

Angiographic studies were the first to suggest that lipid-modifying therapy could alter the composition of plaque. As summarized earlier, plaques are initially characterized by a large lipid core and a thin fibrous cap; these lesions are more susceptible to rupture.^{32,44} Additionally, these lesions are small, usually <50% the size of the lumen diameter. Angiographic studies revealed that the lesions that caused MI were not the large ones that caused substantial stenosis, but the smaller lesions. Subsequently, pathology studies performed during autopsies on patients who had died following MI showed that these smaller lesions were lipid laden and had thin fibrous caps.

Although angiographic trials were primarily designed to study coronary angiograms, they reported fewer CHD events in treated patients. Most of these observations did not reach statistical significance because of the small numbers of patients in the study and the relatively short (1 to 3 years) duration of observation. When these studies were combined, the message

was clear, however: cholesterol lowering was associated with fewer CHD events.⁴⁵ These results set the stage for the larger clinical trials.

CHOLESTEROL-LOWERING CLINICAL TRIALS

Proof of whether LDL-C lowering reduces CHD events has been demonstrated by well-designed, large, placebo-controlled clinical trials. Since the early 1990s, the results of a dozen or more major clinical trials have conclusively demonstrated the value of lipid-modifying therapy to prevent CHD events (Table 12-3).

The first of these, the Lipid Research Clinics Coronary Primary Prevention Trial,⁸² showed that a relatively modest 10% reduction in cholesterol levels with the bile acid sequestrant cholestyramine compared with placebo over a 5-year period reduced CHD deaths and nonfatal MI by an impressive 19%. The results of this study launched the modern era of cholesterol management to reduce CHD risk.

Secondary Prevention

Beginning in the mid 1990s, the results of clinical trials with the more potent cholesterol-lowering statins were reported. Five of these (4S,⁸³ CARE,⁸⁴ LIPID,⁹⁰ TNT,⁸⁵ and IDEAL⁸⁶) were secondary prevention trials (i.e., they were conducted in patients with known CHD). In 4S, CARE, and LIPID, CHD death and nonfatal MI occurred in 13% to 22% of placebo-treated patients over 5 years, compared with event rates of 10% to 14% with statin therapy. Total mortality was reduced significantly in two of these trials. Fewer revascularization procedures were required in patients receiving statin therapy; also 31% fewer strokes occurred.⁸⁷ This important and unexpected finding suggests that the same mechanisms by which statins affect coronary atherosclerosis may be operable in extracranial carotid atherosclerosis. It also demonstrates that patients who have atherosclerosis in one vascular bed (e.g., the coronary vessels) are likely to have atherosclerosis in other vascular beds, and that cholesterol-lowering treatment can have beneficial effects throughout the vascular tree. Finally, these studies demonstrate that LDL-C-lowering therapy not only improves the quality of life (by preventing MI, strokes, and revascularization procedures), but can also prolong life (by delaying deaths from any cause). Most recently, the TNT and IDEAL trials demonstrated additional cardiovascular benefit for lowering LDL-C substantially <100 mg/dL in patients with stable CHD. These two trials randomized patients to either high-dose (atorvastatin 80 mg) statin therapy or moderate-dose (atorvastatin 10 mg or simvastatin 20 mg) statin therapy with an approximate follow-up period of 5 years. In both trials, more intensive lowering of LDL-C significantly <100 mg/dL was associated with a reduction in CHD. The results of these two trials allowed the Writing Group for the cholesterol guidelines (see below) to lower the target goal of LDL-C in patients with CHD to <70 mg/dL.^{88,89}

Likewise, the Heart Protection Study (HPS)⁹¹ extended the results of the earlier statin trials (4S,⁸³ CARE,⁸⁴ LIPID⁹⁰). The HPS included 20,536 patients with a history of CHD or cerebrovascular disease (stroke or transient ischemic attacks), peripheral vascular disease, or diabetes not considered by their general practitioner to have a clear indication for statin therapy because of relatively low baseline cholesterol levels (mean

Table 12-3 Randomized Endpoint Trials With Cholesterol-Lowering Therapies

^cEstimated 5-year CHD risk reduction.
^dAcute coronary events.

LDL-C was 131 mg/dL). Of note, with the exception of the patients with a history of CHD, this grouping of patients is designated by the National Cholesterol Education Program's Adult Treatment Panel III (NCEP ATP-III) as being a "CHD equivalent population" because their risk of a CHD event is >20% in a 10-year period.⁹² Treatment with simvastatin therapy for 5 years reduced LDL-C to 89 mg/dL and lowered the future risk of a CHD event in each of these populations by about 24% compared with placebo. By coincidence, the results of the HPS support the NCEP ATP-III recommendation for aggressive management of cholesterol in patients at high-risk for CHD events without established CHD. The CHD event reduction was achieved equally in men and women; in all age groups, including those ages 75 to 85 years; and regardless of the baseline LDL-C, including those with initial levels <100 mg/dL.

Trials carried out in patients with acute coronary syndromes have also demonstrated CHD risk reduction (Table 12-3). The MIRACL study randomized patients presenting to the hospital with unstable angina or non-Q-wave MI to statin therapy or placebo for 4 months. This resulted in a 24% reduction in symptomatic ischemia requiring emergency hospitalization and a 60% reduction in nonfatal strokes in those receiving the statin.^{93,94} The AVERT study evaluated statin-based medical management versus revascularization and usual medical care

in patients who had stable CAD and were candidates for a revascularization procedure. After 18 months of therapy, the statin-treated group had 36% fewer cases of ischemia requiring hospitalization compared with placebo-treated patients.⁹⁵ These studies show that intervention with a statin in patients with acute coronary syndromes can have important effects on ischemic symptoms in a relatively brief time after beginning therapy. The CHD risk reductions reported in the 5-year clinical trial were evident within the first 1 to 2 years of statin therapy and were significantly different from placebo after 5 years of treatment. More recently, PROVE-IT⁹⁶ was designed to determine if intensive LDL-C lowering with atorvastatin (80 mg) would reduce major coronary events to a greater extent compared with less-intensive LDL-C lowering with pravastatin (40 mg) in patients who had been hospitalized for an acute coronary syndrome. Following 2 years of treatment, mean LDL-C in patients randomized to atorvastatin (80 mg) and pravastatin (40 mg) were 62 mg/dL and 95 mg/dL, respectively. The composite cardiovascular endpoint (death from any cause, MI, documented unstable angina requiring rehospitalization, revascularization, and stroke) was significantly reduced by 16% with atorvastatin compared with pravastatin. Both treatments were well tolerated; however, elevations in alanine aminotransferase were threefold higher in patients treated with atorvastatin compared with pravastatin.

Primary Prevention

Five trials with statin therapy have been reported in patients without evident CHD (i.e., primary prevention) but with multiple CHD risk factors. WOSCOPS, which included men who had two or more CHD risk factors, found that CHD events and revascularization procedures were reduced by 31% and 37%, respectively, in those receiving statin therapy for 5 years; total mortality was reduced 22% ($P < 0.051$).⁹⁷ The ASCOT trial, which included men and women with hypertension and an average of 3.7 other CHD risk factors, reported that CHD events were reduced by 36% and strokes by 27% after only 3.3 years of statin treatment.⁹⁸ Similarly, the ALLHAT trial enrolled 10,355 hypertensive patients with moderately elevated hypercholesterolemia with at least one additional CHD risk factor and randomized them to nonblinded treatment with pravastatin or usual care for 4.8 years.⁹⁹ The results, however, were in contrast to those found in the ASCOT trial, likely because of the high use of nonstudy statin in the usual-care group (30%) and only a 77% adherence to pravastatin in the treatment group. This likely resulted in the total cholesterol difference between the two groups of only 9.6% and a nonsignificant reduction in CHD deaths and nonfatal MI of 9%. The TexCAPS/AFCAPS trial was important because it included the lowest risk population, with an estimated 10-year CHD risk of only 6%. Despite this relatively low CHD risk, the composite endpoint (i.e., fatal and nonfatal MI, sudden cardiac death, and unstable angina) was reduced by 37%, fatal and nonfatal MI were reduced by 40%, and unstable angina was reduced by 32%, with 5 years of statin treatment.¹⁰⁰ Significant reductions in CHD events were seen in women, older patients, and diabetic patients, emphasizing the value of treatment in these populations.

Lowering LDL-C by other means also reduces CHD events.⁶¹ For example, LDL-C lowering with ileal bypass surgery in the POSCH study resulted in a 40% reduction of CHD events compared with the groups not having this surgery.⁶¹ These studies suggest that effective LDL-C lowering by any means can reduce CHD risk.

Taken together, the results of these trials demonstrate that LDL-C lowering reduces the risk of a CHD event in patients at practically any level of risk. In the aggregate, common CHD events, including sudden CHD deaths and nonfatal MI, were reduced by 25% to 40%. Revascularization procedures were reduced by 25% to 50%. Strokes were reduced by an average of 15% in primary prevention patients and 32% in secondary prevention patients.⁸⁷ In fact, essentially all known adverse consequence of atherosclerosis has been reduced with lipid-lowering therapy. In some of these studies, especially those in patients at very high risk for CHD, total mortality was significantly reduced. These trials show that aggressive lipid lowering improves the quality as well as the length of life. In addition, in patients with stable CHD and those having had an acute coronary event, aggressive lowering of LDL-C to < 70 mg/dL provides further protection from CHD events. The protective effects are illustrated by a plot of the relative risk of CHD and LDL-C levels, which shows a log-linear relationship (Fig. 12-6)⁸⁹ which suggest the optimal level of LDL-C is far below 70 mg/dL (the relative risk is set at 1.0 for LDL-C = 40 mg/dL). This log-linear relationship is consistent with epidemiologic data, clinical trials, and population data.¹⁰¹ Evidence from hunter-gatherer populations who still follow their indigenous lifestyles show no evidence for atherosclero-

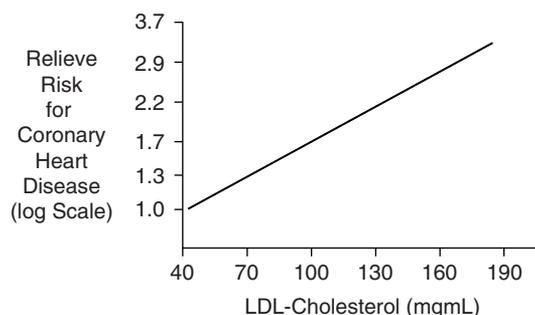

FIGURE 12-6 Log-linear relationship between LDL-C levels and relative risk for CHD. (Adapted from Grundy SM, et al. Coordinating Committee of the National Cholesterol Education Program. Implications of recent clinical trials for the National Cholesterol Education Program Adult Treatment Panel III guidelines. *Arterioscler Thromb Vasc Biol* 2004;24:e149–61, with permission.)

sis into the seventh and eighth decades of life and their estimated LDL-C are approximately 50 to 75 mg/dL. The above cumulative evidence has led the NCEP ATP III to define the “optimal” LDL-C level as < 100 mg/dL and a reasonable goal of < 70 mg/dL for all patients with CHD.^{88,89}

Patients with Diabetes

Diabetic patients have a very high risk of macrovascular disease (i.e., CHD) as well as microvascular disease (e.g., retinopathy). Investigations have shown that diabetic patients with no history of CHD have the same risk of a future CHD event as do nondiabetic patients who have experienced an MI (approximately 20% risk in 7 years).¹⁰² Close management of blood glucose levels appears to reduce microvascular disease, but not CHD.^{103,104} Because of this, NCEP ATP III and the American Diabetic Association (ADA) considered patients with diabetes to be a CHD risk equivalent ($> 20\%$ 10-year CHD risk) and recommended that these patients be treated with aggressive lipid-modifying therapy to an LDL-C goal of < 100 mg/dL.⁹² Findings from the above clinical trials demonstrate that a reduction in CHD events with lipid-modifying therapy is of a similar or greater magnitude in diabetic patients compared with nondiabetic patients.^{90,105} This supports the NCEP ATP III recommendation for aggressive management of diabetic patients.⁹²

Global CHD Risk Identification

The large number of clinical trials available illustrates the continuum of risk in patients with CHD (secondary prevention) and those without (primary prevention). In fact, the CHD risk in these two populations overlaps considerably. In secondary prevention patients, atherosclerosis is known to be present and the risk of a subsequent event is great. In primary prevention patients with multiple risk factors, atherosclerosis is likely present and that this increases the risk of a future CHD event. In fact, some primary prevention patients have so many risk factors that they reach the level of a “CHD risk equivalent” as defined by the NCEP ATP III guidelines, denoting a $> 20\%$ CHD risk in 10 years.⁹² Others have only a few or no accompanying CHD risk factors and have a low to moderate future risk of a CHD event. Thus, the decision of how aggressively to treat patients begins with an assessment of their global CHD risk.

Table 12-4 NCEP ATP III Major Risk Factors That Modify LDL-C Goals**Positive Risk Factors (↑Risk)**

Age: Male ≥ 45 yr
 Female: ≥ 55 yr
 Family history of a premature CHD (definite MI or sudden death before 55 yr in father or other male first-degree relative or before 65 yr in mother or other female first-degree relative)
 Current cigarette smoking
 Hypertension ($\geq 140/90$ mm Hg or on antihypertensive drugs)
 Low HDL-C (< 40 mg/dL)

Negative Risk Factor (↓Risk, protective)

High HDL-C (≥ 60 mg/dL)

Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults, 2001.⁹²

Note: Presence of diabetes mellitus is considered a CHD risk equivalent (see Table 12-7). It is not included in counting the number of risk factors because its presence automatically qualifies the patient for aggressive treatment whether or not true CHD is manifest.

CHD, coronary heart disease; HDL-C, high-density lipoprotein cholesterol; MI, myocardial infarction.

The first step is to identify patients who have two or more risk factors and no CHD and CHD risk equivalent history (Table 12-4). The next step is to assess their global CHD risk with an instrument such as that illustrated in Figure 12-7 from the Framingham Heart Study.⁹² (It is not necessary to conduct a global risk assessment of CHD patients, as their risk is known to be $> 20\%$ in 10 years.) Patients with a very high risk of a future CHD event (e.g., diabetic patients and those with a global risk of $> 20\%$ in 10 years) can be considered a CHD equivalent and given aggressive LDL-C-lowering treatment with the same LDL-C goal as applied to patients who have experienced a CHD event (i.e., an LDL-C treatment goal of < 100 mg/dL).¹⁰⁶ Those with $< 20\%$ risk of a CHD event in 10 years can be given lifestyle modification and drug therapy, if needed, to reach an intermediate LDL-C goal (< 130 mg/dL).

This approach of assessing a patient's CHD risk and matching the intensity of treatment is illustrated in the cases that follow.

TG-LOWERING CLINICAL TRIALS

Five clinical trials have tested TG-lowering therapies (fibrates and niacin) in randomized endpoint trials involving patients who generally had baseline TG levels of 150 to 500 mg/dL and HDL-C < 40 mg/dL (Table 12-5). The Helsinki Heart Study studied 4,081 men without CHD and found a 34% reduction in CHD death and nonfatal MI after 5 years of gemfibrozil therapy compared with placebo.¹⁰⁷ *Post hoc* analysis of this study showed that the group of patients with TG > 200 mg/dL and an LDL:HDL ratio > 5.0 (generally with LDL-C > 194 mg/dL and HDL-C < 40 mg/dL) accounted for 71% of the CHD reduction achieved in the entire study, although the group represented only 10% of the total study population¹⁰⁸ (Table 12-5). The VA-HIT (HDL Intervention Trial) studied 2,531 men with a history of CHD and low HDL-C levels (mean HDL-C level, 32 mg/dL) and reported a 22% reduction in CHD events with gemfibrozil therapy. The authors reported that approximately 25% of this risk reduction resulted from the 6% increase in HDL-C.¹⁰⁹ The Bezafibrate Infarction Prevention (BIP) trial studied CHD patients with a lipid profile similar to the patients in the Tex/AFCAPS trial (high LDL-C, low HDL-C, normal TG) and reported an insignificant 9% reduction in CHD events associated with an 18% increase in HDL-C and a 21% reduction in TG.¹¹⁰ A post hoc analysis of this trial found that patients who had TG levels of > 175 and 200 mg/dL had significant CHD event reductions of 22% and 40%, respectively. The FIELD study investigated the effects of fenofibrate versus placebo with an average follow-up of 5 years on CHD events in patients with type 2 diabetes with a mean baseline LDL-C, HDL-C, and triglyceride level of 119 mg/dL, 42 mg/dL, and 153 mg/dL, respectively.¹¹¹ Similar to the BIP trial, this trial failed to demonstrate a significant reduction in major coronary events (11% reduction in risk; $P = 0.16$) in patients randomized to fenofibrate. Because this trial allowed changes in therapy at the discretion of the patient's primary care physician, significantly more patients receiving placebo

Table 12-5 Randomized Endpoint Trials With Triglyceride-Lowering Therapies

| Trial | Intervention | Lipids: Initial (On Rx) | Lipid Changes (%) | Placebo CHD Rate (%) | CHD Event Reduction (%) |
|-----------------------|--------------|---|-------------------|----------------------|-------------------------|
| HHS ¹⁰⁷ | Gemfibrozil | LDL-C: 189 (170) TG: 178 (116) HDL-C: 47 (52) | ↓10 ↓35 ↑11 | 4 | ↓34 |

| CDP ¹¹² | Niacin | TC: 250 (235) TG: 480 (354) | ↓10 ↓26 | 30 | ↓13 |

CHD, coronary heart disease; HDL, high-density lipoprotein cholesterol; LDL-C, low-density lipoprotein cholesterol; Rx, drug therapy; TG, triglyceride.

(17%) compared with fenofibrate (8%) were taking nonstudy lipid-lowering agents. This may have partially accounted for the study results.

The current outcome evidence for fenofibrate and gemfibrozil (bezafibrate is not available in the United States) reasonably supports their use as second-line agents in type 2 diabetes and secondary prevention with low HDL-C, respectively. In addition, post hoc analyses suggest that patients with atherogenic dyslipidemia obtain CHD risk reduction with fibrate therapy. The risk reduction may be similar to that achieved with statins, although no head-to-head trials exist to refute or affirm this. This presents a dilemma for the clinician: When presented with a patient who has atherogenic dyslipidemia, which is the drug of choice, a statin or fibrate? Some guidance to this question will be provided during the case discussions that follow.

Only one placebo-controlled endpoint study is available for niacin (Table 12-5). The study was completed in men who had had a prior MI and mixed hyperlipidemia. After 5 years of niacin therapy, the CHD event rate was reduced by 13%.¹¹² Fifteen years after the start of the study, and 9 years after the study was terminated, the investigators reported that total mortality was 11% lower in the men in the niacin arm, suggesting that any period of lipid-modifying treatment may translate into a long-term benefit.¹¹² Combination therapy with niacin plus a statin has been studied in patients with CHD with low HDL-C and normal LDL-C.¹¹³ Compared with a mean 3.9% progression in coronary stenosis with placebo, niacin–simvastatin therapy was associated with a mean regression of 0.4% ($P < 0.001$). The authors posited that event reduction with this combination should be equivalent to the sum of the LDL-C reduction and the HDL-C increase. In the study, LDL-C was reduced by 42% and HDL-C was increased by 26%, and the composite endpoint of death from coronary causes, MI, stroke, or revascularization for worsening ischemia was reduced 60% with the niacin–statin combination ($P = 0.02$).

Niacin has long been an intriguing drug to lipid specialists. It is one of the few drugs that positively affects each component of the lipid profile (LDL-C, TG, and HDL-C). It is the best therapy available to raise HDL-C and one of the best at lowering TG. It is logical to expect that these effects would translate into substantial CHD risk reduction. It is especially interesting to speculate on how these effects may combine to offer better risk reduction, especially when combined with one of the statins. This hypothesis is being evaluated in the ongoing AIM HIGH study.

Mechanisms of CHD Risk Reduction

Given the consistent relationship between lowering blood cholesterol and reducing CHD events, the question arises, “what is the mechanism of this protection?” Scientists are offering many new and exciting answers to this question. At present, it appears that the reduction in CHD with lipid-altering therapy is mediated through, or at least tracked by, a reduction in cholesterol levels. In addition to lowering blood cholesterol levels, statins and other lipid-altering therapies produce other, so-called pleiotropic, effects that may partly explain their CHD-reducing capability.¹¹⁴

One way in which cholesterol lowering may reduce CHD is by changing atherosclerotic plaque from “high risk” lesions with a large lipid core, thin fibrous cap, and many cholesterol-

filled macrophage cells along the shoulders of the lesion to “lower risk” lesions with a small lipid core and much connective tissue and smooth muscle matrix throughout. The lesion does not appear to change much in size, or at least not in ways that can be visualized on an arteriogram. The harder lesion created with lipid lowering is much less likely to rupture or erode, however, thus reducing the risk of forming an occluding clot and producing CHD events.

Lipid lowering may also affect endothelial function. Evidence indicates that high LDL-C levels cause “endothelial dysfunction,” as evidenced by a lowered ability of coronary arteries to dilate. Cholesterol lowering by practically any means restores endothelial function. Many studies have demonstrated improvement in brachial artery reactivity and coronary artery dilation when cholesterol levels are reduced.^{115–120} Positron emission tomography (PET) scans demonstrate improved blood flow and reduced areas of ischemia throughout the myocardium in patients receiving lipid-altering therapy.^{117,118} These effects may have important clinical benefits. In patients with CAD, cholesterol lowering reduces the number of ST-segment depressions recorded during a 48-hour electrocardiogram (ECG) Holter monitor study.^{121,122} Therapy with a statin can also reduce ischemic events requiring acute management, a potential effect of restored endothelial function.⁹⁵

Cholesterol lowering might also combat the inflammation that accompanies atherogenesis. Early in the development of plaques, monocyte-derived macrophages are recruited to engulf modified LDL particles, and in every stage of the disease, specific subtypes of T lymphocytes are present.^{36,42} At various stages, cytokines, chemokines, and growth factors are released. Inflammatory processes may be especially active just before or after the plaque ruptures. Several investigators have attempted to identify markers of inflammation that may signal an increased risk of a CHD event. One promising marker is high-sensitivity C-reactive protein (hs-CRP). An elevated hs-CRP level predicts a high risk of future CHD events and appears to add to the risk predicted by LDL-C alone.¹²³ A subanalysis of the CARE trial reported that high levels of hs-CRP forecast CHD risk in patients on placebo, but this was attenuated and nonsignificant in patients assigned to pravastatin, suggesting that statin treatment has an anti-inflammatory effect.¹²⁴ The American Heart Association (AHA) has recently recommended that measurement of the hs-CRP level be considered in a patient with two or more risk factors as a way to further characterize the patient’s future CHD risk.¹²⁵

Cost-Effectiveness

Several cost-effectiveness analyses of lipid-lowering therapies have been conducted.^{126–129} One variable used in these analyses is the cost per years of life saved (YOLS). Analyses of other prophylactic measures to reduce CHD risk, such as the use of aspirin in patients after MI and the treatment of mild hypertension with antihypertensive drugs, indicate that it costs up to \$50,000 per YOLS to treat these patients. Our society has accepted this level of expenditure as cost-effective. Analyses of cholesterol-lowering treatment in clinical trials have found that drug treatment of high-risk patients for secondary prevention costs approximately \$12,000 per YOLS, whereas treatment of high-risk patients for primary prevention costs approximately \$25,000 per YOLS. In the 4S study, the cost saved in reduced

hospital days by treatment was so great that simvastatin was estimated to cost only \$0.28 per day (an 88% savings).¹³⁰ In another analysis of the cost of treating patients to their NCEP goal in an office setting, atorvastatin was found to cost the least, approximately \$1,064 per year, in combined expenses for drugs, office visits, and laboratory monitoring.¹³¹ These analyses support aggressive (i.e., drug and lifestyle) treatment of CHD and high-risk patients with lipid-lowering therapy.

HYPERCHOLESTEROLEMIA

Evaluation of the Lipoprotein Profile

1. T.A., a 43-year-old premenopausal woman, is screened with a lipid profile during an annual medical evaluation. She has never taken cholesterol-lowering medication and currently takes only a multivitamin daily. She has had no symptoms of coronary, carotid, or peripheral vascular disease. She has a 20-pack/year history of smoking and exercises four times a week, without physical limitations. T.A. states that she follows a low-fat, low-cholesterol diet. Her father is alive and well at age 71, with a normal cholesterol level. Her mother had an MI at age 47 and died at age 57 from a second event. Her grandfather died of an MI at age 52; a sister has hypercholesterolemia and is taking simvastatin. Pertinent physical findings are weight, 125 lb; height, 63 in; blood pressure (BP), 120/82 mm Hg; pulse, 66 beats/min and regular; carotid pulses symmetric bilaterally without bruits; no neck masses; no abdominal bruit; and no evidence of tendon xanthomas. Pertinent laboratory findings, obtained after a 12-hour fast, show total cholesterol, 290 mg/dL; TG, 55 mg/dL; HDL-C, 55 mg/dL; LDL-C, 224 mg/dL; non-HDL-C, 235; plasma glucose, 96 mg/dL (normal, 60 to 115); thyroid-stimulating hormone (TSH), 0.92 IU/mL (normal, 0.4 to 6.2); alanine aminotransferase (ALT), 11 U/L (normal, 6 to 34); aspartate aminotransferase (AST), 8 U/L (normal, 9 to 34); blood urea nitrogen (BUN), 12 mg/dL (normal, 4 to 24); creatinine, 1.0 mg/dL (normal, 0.4 to 1.1); and a negative urinalysis. What is your assessment T.A.'s lipid panel results?

[SI units: total cholesterol, 7.5 mmol/L; TG, 0.62 mmol/L; HDL-C, 1.42 mmol/L; LDL-C, 5.79 mmol/L; glucose, 5.33 mmol/L; TSH, <100 units; ALT, 0.18 μ kat/L; AST, 0.13 μ kat/L; BUN, 4.28 mmol/L urea; creatinine, 88.4 μ mol/L]

T.A.'s LDL-C is considered "very high" (>190 mg/dl); NCEP defines the optimal LDL-C as <100 mg/dL.⁹² Her HDL-C is right at the average HDL-C for a woman and her TG is normal (<150 mg/dL) (Table 12-6). In most cases, it is wise to repeat the lipid profile to be sure the first results are not atypical. However, T.A.'s LDL-C is so high a repeat test is not likely to change the assessment. Thus, in this case, a second test is optional.

While it is possible to measure LDL-C directly, it is common for many laboratories to calculate LDL-C. Total cholesterol, HDL-C, and TG are measured directly and then the following formula (Friedwald equation) is applied to calculate LDL-C:

$$\text{LDL-C} = \text{Total Cholesterol} - (\text{HDL-C} + \text{VLDL-C})$$

Because the ratio of cholesterol to TG in LDL is 1:5, VLDL-C is estimated by dividing the total TG level by 5. Thus, the formula is rewritten as:

$$\text{LDL-C} = \text{Total Cholesterol} - (\text{HDL-C} + \text{TG}/5)$$

Table 12-6 NCEP ATP III Classifications of Blood Lipids⁹²

| | |
|-------------------|-------------------------------|
| LDL-Cholesterol | |
| <100 mg/dL | Optimal |
| 100–129 mg/dL | Near optimal or above optimal |
| 130–159 mg/dL | Borderline high |
| 160–189 mg/dL | High |
| ≥190 mg/dL | Very high |
| Total Cholesterol | |
| <200 mg/dL | Desirable |
| 200–239 mg/dL | Borderline high |
| ≥240 mg/dL | High |
| HDL-Cholesterol | |
| <40 mg/dL | Low |
| ≥60 mg/dL | High |
| Triglycerides | |
| <150 mg/dL | Normal |
| 150–199 mg/dL | Borderline high |
| 200–499 mg/dL | High |
| >500 mg/dL | Very high |

HDL, high-density lipoprotein; LDL, low-density lipoprotein.

Applying the formula to T.A.'s lipid profile, the calculated LDL-C is 224 mg/dL.

$$\begin{aligned} \text{LDL-C} &= \text{Total Cholesterol} - (\text{HDL-C} + \text{TG}/5) \\ &= 290 - (55 + 55/5) \\ &= 224 \text{ mg/dL} \end{aligned}$$

If the TG level is >400 mg/dL, the formula for estimating VLDL-C is not accurate and, therefore, LDL-C cannot be calculated. An accurate LDL-C measurement also requires that the patient fast for 10 to 12 hours. This provides sufficient time for exogenous TG, carried by chylomicrons, to be cleared from the systemic circulation (provided the patient does not have hyperchylomicronemia). Most laboratories can measure LDL-C directly and should be asked to do so when the TG is >400 mg/dL or the patient has not fasted.

Non-HDL-C is calculated by the following formula:

$$\text{Non-HDL-C} = \text{Total Cholesterol} - \text{HDL-C}$$

For T.A.:

$$\begin{aligned} \text{Non-HDL-C} &= 290 \text{ mg/dL} - 55 \text{ mg/dL} \\ &= 235 \text{ mg/dL} \end{aligned}$$

Secondary Causes of High Blood Cholesterol

2. Is there any evidence that T.A.'s elevated LDL-C is secondary to other conditions or concurrent drug therapy?

As a routine, every new patient with hypercholesterolemia should be evaluated for four things in the following order: (1) secondary causes of the high cholesterol level, (2) familial disorders, (3) presence of CHD and CHD equivalents, and (4) CHD risk factors.

Conditions that can produce lipid abnormalities (i.e., secondary causes) include diabetes mellitus, hypothyroidism, nephrotic syndrome, and obstructive liver disease. Selected drugs can also produce lipid abnormalities (Table 12-7). When

Table 12-7 Drug-Induced Hyperlipidemia

| | <i>Effect on Plasma Lipids</i> | | | <i>Comments</i> |
|---|--------------------------------|--------------------------|------------------|--|
| | <i>Cholesterol (%)</i> | <i>Triglycerides (%)</i> | <i>HDL-C (%)</i> | |
| Diuretics | | | | |
| Thiazides | ↑5–7% initially ↑0–3% later | ↑30–50 | ↑1 | Effects transient; monitor for long-term effects |
| Loop | No change | No change | ↓ to 15 | |
| Indapamide | No change | No change | No change | |
| Metolazone | No change | No change | No change | |
| Potassium-sparing | No change | No change | No change | |
| β-blockers | | | | |
| Nonselective | No change | ↑20–50 | ↓10–15 | Selective β-blockers have greater effects than nonselective; β-blockers with ISA or α-blocking effects are lipid neutral |
| Selective | No change | ↑15–30 | ↓5–10 | |
| α-Blocking | No change or ↓ | No change | No change | |
| α-Agonists and antagonists (e.g., prazosin and clonidine) | ↓0–10% | ↓ 0–20 | ↑0–15 | In general, drugs that affect α-receptors ↓cholesterol and ↑HDL-C |

| Glucocorticoids | ↑5–10 | ↑15–20 | | |
| Ethanol | No change | ↑up to 50 | ↑ | Marked elevations can occur in patients who are hypertriglyceridemic |
| Isotretinoin | ↑5–20 | ↑50–60 | ↓10–15 | Changes may reverse 8 wk after stopping drug |
| Cyclosporine | ↑15–20 | No change | No change | |

ACE, angiotensin-converting enzyme; HDL-C, high-density lipoprotein cholesterol; ISA, intrinsic sympathomimetic activity.

one of these secondary causes is identified, it should be managed first, as this may resolve the lipid abnormality.

In T.A.'s case, no secondary causes are evident. Her blood glucose level does not indicate the presence of diabetes; her TSH level does not indicate hypothyroidism; her ALT and AST levels are within acceptable levels, suggesting normal liver function; and her BUN, creatinine, and urinalysis are acceptable, signifying normal renal function. She is not taking any drugs that could have contributed to her cholesterol elevation.

Familial Forms of Hypercholesterolemia

3. Could T.A. have an inherited form of hyperlipidemia?

T.A.'s history is consistent with polygenic hypercholesterolemia, the form of hypercholesterolemia that affects 98% of patients with hypercholesterolemia. As described previously, polygenic hypercholesterolemia is suspected when the patient's LDL-C is 130 to 250 mg/dL and no evidence seen of tendon xanthomas (Table 12-2). A family history of CHD is present in approximately 18% of these patients and is a strong finding in T.A.'s case. Polygenic hypercholesterolemia is caused by a combination of nutritional and genetic factors that reduce the clearance of LDL particles from the plasma. It is impossible to determine which of these factors are causing hypercholesterolemia in a given patient by simply examining the lipopro-

tein profile. If the patient's blood lipids normalize with a low-fat diet, however, one can assume that the diet is a major etiologic factor for that person. Conversely, if little or no change is seen in blood cholesterol levels after dietary modification, genetics likely significantly influences the patient's elevated cholesterol. In most cases, a relatively equal contribution is made by genetic factors and environment on cholesterol elevations.

CHD and CHD Risk Equivalents

4. Does T.A. have evidence of CHD or a CHD risk equivalent?

A search for CHD starts with a good medical history of symptomatic coronary artery disease, but is quickly followed with a broader search for atherosclerotic disease in other artery beds, including the arteries of the limbs and carotid arteries⁹² (Table 12-8). If detected in one site, atherosclerosis is likely to be present in all or most vessels, and it is associated with a five- to sevenfold higher risk of a major coronary event.^{132–134}

The patient should be asked about a history of myocardial ischemia (exercise-induced angina), prior MI (i.e., severe angina with elevated cardiac creatine phosphokinase [CPK] or characteristic ECG changes), history of revascularizations (i.e., coronary artery bypass surgery, angioplasty with percutaneous transluminal coronary angioplasty or stent placement), or history of hospitalization due to unstable angina

Table 12-8 NCEP APT III Definitions of CHD and CHD Risk Equivalents⁹²

| |
|---|
| Clinical CHD |
| Myocardial ischemia (angina) |
| Myocardial infarction |
| Coronary angioplasty and/or stent placement |
| Coronary bypass graft |
| Prior unstable angina |
| Carotid artery disease |
| Stroke history |
| Transient ischemic attack history |
| Carotid stenosis >50% |
| Peripheral arterial disease |
| Claudication |
| ABI >0.9 |
| Abdominal aortic aneurysm |
| Diabetes mellitus |

Estimated global CHD risk >20% in 10 years for any of the factors above.
ABI, ankle:brachial blood pressure index; CHD, coronary heart disease.

(see Table 12-8). The presence of any of these findings is associated with a very high (>20%) risk of a CHD death or nonfatal MI in the next 10 years; the risk approaches 40% if unstable angina and stroke are also considered. None of these signs are present in T.A.

The evaluation can stop here, but some would advocate continuing the search with noninvasive procedures, even if the patient has not experienced symptoms (Table 12-9). The case for pursuing these evaluations is more convincing in patients who have a high probability of atherosclerosis because of the presence of multiple risk factors or a strong family history of premature CHD events. One noninvasive evaluation is exercise testing with either ECG monitoring for signs of ischemia or pharmacologic perfusion imaging (e.g., exercise thallium). Because these tests are expensive and not widely available, they

Table 12-9 Emerging CHD Risk Factors⁹²

| <i>Noninvasive Evaluations for Subclinical Atherosclerosis</i> | <i>Blood Tests</i> |
|--|---|
| Exercise ECG | Lipoprotein(a) |
| Myocardial perfusion imaging | Small, dense LDL |
| Stress echocardiography | Apolipoprotein B (particle concentration) |
| Carotid intimal-medial thickness (IMT) | High-sensitivity CRP (and other inflammatory markers) |
| Electron beam computed tomography (EBCT) | Homocysteine |
| | HDL subspecies |
| | Apolipoprotein A-I |
| | Apolipoprotein B:C-III |
| | Thrombogenic factors (e.g. fibrinogen, PAI-1, t-PA) |

CRP, C-reactive protein; ECG, electrocardiogram; HDL, high-density lipoprotein cholesterol; LDL-C, low-density lipoprotein cholesterol; t-PA, tissue plasminogen activator.

are reserved for selected use. Even if the results are found to be normal, atherosclerosis is not ruled out because both tests are designed to detect flow-limiting disease, and atherosclerosis can be present without causing obstructions in luminal blood flow.⁹²

In recent years, electron beam computed tomography and spiral computed tomography have been used to detect calcium in coronary vessels. The presence of coronary calcium suggests the presence of old atherosclerotic plaque. If old disease is present, then it is likely that younger, more vulnerable plaques are also present. This test is simple, quick, and noninvasive, but it is relatively expensive and not widely available. High coronary calcium volume scores can add to the prediction of future coronary events based on traditional risk factor assessment.⁹² Use of these tests is particularly helpful in modifying the assessment of risk in patients with multiple risk factors. In T.A.'s case, her strong family history could support obtaining an electron beam computed tomography evaluation. If she has a significantly positive calcium volume score, more aggressive medical therapy could be considered.

A good history should also probe for evidence of atherosclerotic vascular disease in peripheral vessels. Patients with flow-limiting atherosclerosis in peripheral vessels often describe claudication (pain and weakness in the limb muscles) after walking a distance (Chapter 14, Peripheral Vascular Disorders). NCEP recommends that patients >50 years of age be evaluated with an ankle:brachial index (ABI). This index is determined by measuring the systolic blood pressure of the brachial, posterior tibia, and dorsalis pedis arteries using a handheld Doppler device and dividing the higher of the two ankle systolic blood pressures by the higher of two systolic brachial pressures.⁹² An ABI of <0.9 constitutes the diagnosis of peripheral vascular disease (PVD; also called peripheral arterial disease or PAD). Finding atherosclerosis in peripheral vessels probably means it is present in coronary arteries as well. In fact, most patients with PVD die of a CHD event. Further, most patients with PVD have a very high (>20%) risk of a CHD event in the next 10 years, and so are said to have a CHD risk equivalent.

The clinician should also evaluate the patient for atherosclerosis in the carotid vessels by asking about signs and symptoms of transient ischemic attacks (TIA) and strokes (see Chapter 15, Peripheral Vascular Disorders). On the physical examination, the carotid vessels should be evaluated for the presence of a bruit (indicative of a space-occupying lesion in the carotid vessel). If a bruit is present, further evaluation with carotid duplex imaging is indicated to detect stenotic lesions. Some authorities recommend performing carotid sonography to measure the intimal-medial thickness. This test is safe and simple but relatively expensive and not widely available. Intimal-medial thickness results correlate with the severity of coronary atherosclerosis. Patients who have experienced a stroke or TIA have a >20% 10-year risk of experiencing a CHD event and so are also considered a CHD risk equivalent. Patients found to have a stenosis of >50% in their carotid vessel, even if asymptomatic, have a >20% 10-year CHD risk and again can be considered a CHD risk equivalent. Patients found to have an increased intimal-medial thickness, suggesting the presence of subclinical atherosclerosis, may also have a high

CHD risk and, therefore, are candidates for more aggressive medical therapy.⁹²

Other conditions that confer a >20% risk of a CHD event in the next 10 years, and thus are considered by NCEP to be CHD risk equivalents, include abdominal aortic aneurysm and the diagnosis of diabetes. More will be said about diabetes below. T.A. does not have evidence of CHD or a CHD risk equivalent.

CHD Risk Factors

5. Does T.A. have CHD risk factors, and what is her global CHD risk?

Patients who are found to have CHD or CHD risk equivalent do not need a risk factor assessment to establish their LDL-C treatment goal; the presence of CHD or a CHD risk equivalent satisfies that. These patients, however, should have an appraisal of risk factors so that risk factor modification can be incorporated in the overall treatment plan. For patients who do not have CHD or a CHD risk equivalent, risk factor counting and global risk assessment is important to establish treatment goals and approaches.

Begin this process by counting the number of risk factors present (Table 12-4). Patients with either zero or one risk factor most likely have a low risk of a CHD event in the next 10 years and are assigned an LDL-C goal of <160 mg/dL. Patients with two or more risk factors have a moderate to high risk, depending on the number and type of risk factors present. NCEP recommends that patients who have two or more risk factors be further evaluated using the Framingham-based global risk assessment tool (Fig. 12-7) to define the 10-year risk. Patients with two or more risk factors have an LDL-C goal of <130 mg/dL. The clinician, however, has the option to treat these patients to reach <100 mg/dL depending on clinical judgment of the patient's absolute risk and potential benefit if that patient's Framingham calculated 10-year CHD risk is between 10% and 20%. The presence of modifiable risk factors should become the target of any risk-reduction treatment program.

T.A. has two CHD risk factors: current cigarette smoking and a family history of premature CHD. She thus has an LDL-C treatment goal of <130 mg/dL (Table 12-10). T.A. is found to have a 5% 10-year CHD risk, which is several times greater than the average risk for women her age but below the threshold where aggressive drug treatment is indicated (i.e., >10% CHD risk in 10 years). If she were not a smoker, her 10-year CHD risk estimate would be 1%, illustrating the prominent influence that smoking has on her future risk of a CHD event.

Based on this assessment and assuming that the noninvasive assessments performed on her, if any, were negative, T.A. should be counseled on diet and exercise and strongly advised to stop smoking. Because of its strong effect on her risk, smoking cessation should be a primary focus of her risk-reduction program. If these measures fail to bring her LDL-C to her treatment goal of <130 mg/dL and her LDL-C remains \geq 160 mg/dL, drug therapy should be considered (Table 12-10). If she stopped smoking, however, she would have only one risk factor (family history), and her new LDL-C goal would be <160 mg/dL. In this case, drug therapy would be considered only if the LDL-C remains \geq 190 mg/dL.

Therapy for Lowering Cholesterol Levels

Diet Therapy

6. What dietary changes should be recommended to T.A.?

The centerpiece of treatment for high blood cholesterol is a diet low in saturated fat and cholesterol. The therapeutic lifestyle change (TLC) diet recommended by NCEP restricts total fat intake to 25% to 35% of calories, saturated fats to <7% of calories, and dietary cholesterol to 200 mg/day (Table 12-11).⁹² The TLC diet is aggressive and requires instruction by a dietitian, nurse, or other health professional well versed in nutrition counseling. The TLC diet is also flexible and allows for modification of carbohydrate and monounsaturated fat intake according to the individual patient's needs. The goals presented by the TLC diet are minimal goals, and some patients will want to exceed them, even to the point of following a "vegetarian" diet. This is permissible, as long as the diet is nutritionally balanced.

When saturated fat is removed from the diet, it is important to understand what should be given in replacement. In the overweight or obese patient, it may be appropriate to do nothing, because a reduction in saturated fat is a good way to lower calories and encourage weight loss.

In individuals who are close to their ideal weight, such as T.A., replacing saturated fats with carbohydrates may not be the best choice. Increased intake of sugar and highly refined starches, as found in the many low-fat, high-calorie snack foods, may actually increase weight and reduce HDL-C as well as LDL-C.¹³⁵ More importantly, a low-fat, high-carbohydrate diet has not been shown to reduce the risk of CHD. Consumption of complex carbohydrates is recommended, however, and could be a replacement for saturated fat calories in a TLC diet.

Replacing saturated fat with unsaturated fats, especially monounsaturated fats (e.g., canola, olive oil products) and omega-3 polyunsaturated fats (e.g., fish oil sources), is highly desirable.¹³⁶ This is the diet of the Mediterranean people, who have a low incidence of CHD, and has the advantage of lowering LDL-C without affecting HDL-C. In fact, in a major randomized clinical trial in which it was compared with a "prudent Western-type diet," the Mediterranean diet was associated with a >70% reduction in cardiovascular endpoints and total mortality, a result that exceeds that achieved by our best lipid-lowering drug trials.¹³⁷ This study alone illustrates how important it is to initiate a good diet in hyperlipidemic patients, even with the availability of very potent, highly efficacious, and safe drugs to lower serum cholesterol levels.

In western society, diets high in protein and saturated fats and low in carbohydrates (e.g., Atkins Diet) promise quick weight loss and other health effects. Although these diets can reduce lipid levels and cause weight loss, they are not nutritionally sound and may even be unhealthy. Patients should be advised to avoid them.

T.A. is likely to need help in translating the dietary recommendations of a TLC diet into practical terms and concepts that she can easily implement in her everyday life. Two approaches can be used to achieve this: (a) teach her to count calories or (b) provide general guidance in the selection of low-fat foods.

The more sophisticated patient may want to count calories or grams of total and saturated fat per day. The first step in

FIGURE 12-7 A: Estimate of 10-year risk for men. B: Estimate of 10-year risk for women.

Table 12-10 NCEP ATP III and AHA/ACC LDL-C Goals and Cutpoints for Therapeutic Lifestyle Changes (TLC) and Drug Therapy^{88,89,92}

| Risk Category | LDL-C Goal | LDL-C at which to Initiate TLC | LDL-C at which to Consider Drug Therapy ^a |
|---|--|--------------------------------|--|
| CHD or CHD risk equivalents (10-year risk >20%) | <100 mg/dL (Reasonable goal <70 mg/dL) ^c | >100 mg/dL | >100 mg/dL (<100 mg/dL, consider drug options) ^b |
| 2+ risk factors (10-year risk 10% to 20%) | <130 mg/dL (Optional goal <100 mg/dL) | >130 mg/dL | >130 mg/dL (100–129 mg/dL; consider drug options) ^d |
| 2+ risk factors (10-year risk <10%) | <130 mg/dL | >130 mg/dL | >160 mg/dL |
| <2 risk factors ^e | <160 mg/dL | >160 mg/dL | 190 mg/dL (160–189 mg/dL, LDL-C lowering drug therapy is optional) |

^aFor all patients without CHD: LDL-C lowering medications should be initiated at a dose that is consistent with at least a 30% to 40% reduction in LDL-C levels. The use of lower doses just to barely attain the LDL-C goal would not be a prudent use of medications.

^bThe clinician may select niacin or fibrate therapy if patient has high triglycerides and/or low HDL-C. The decision to lower LDL-C with drug therapy is optional based on available clinical trial evidence.

^cAll patients with CHD: When LDL-C <70 mg/dL is not achievable because high baseline LDL-C levels, it generally is possible to achieve reductions of >50% by either statins or LDL-C lowering drug combinations.

^dThe decision to lower LDL-C with drug therapy to achieve an LDL-C <100 mg/dL is optional based on available clinical trial evidence.

^ePatients with <two risk factors usually have a 10-year risk of <10%, and therefore do not need a 10-year risk assessment.

CHD, coronary heart disease; LDL-C, low-density lipoprotein cholesterol.

teaching a patient to do this is to determine his or her daily caloric requirements, adjusted for his or her level of activity. The average caloric requirement for women is 1,800 calories/day; for men it is 2,500 calories/day. Based on this, T.A. should be instructed to keep her total fat intake to 450 to 630 calories/day (25% to 35% of calories) and saturated fat to <126 calories/day (<7% of total calories). Converting fat calories to grams (i.e., dividing calories by 9 calories/g), T.A. should be instructed to restrict her total fat intake to <50 to 70 g/day and saturated fat to <14 g/day.

Once these calculations have been made, the next step is to teach T.A. how to determine the grams of saturated and unsaturated fat contained in the foods she eats by reading food labels and referring to reference charts or books that list the nutritional content of foods. A good source for this nutrition information is the National Institutes of Health website on Therapeutic Lifestyle Change (<http://www.nhlbi.nih.gov>) under the Health Information icon). This site contains information on the TLC diet, a 10-year risk calculator, recipes, a virtual grocery store, a cyberkitchen, a fitness room, and a resource library. The AHA sites (www.americanheart.org and www.deliciousdecisions.org) provide equally good information on risk assessment, a cholesterol tracker, low-fat recipes, and guidance for eating in restaurants, cooking, and fitness.

For patients who are not able or willing to count calories or grams, general instruction on how to select low-fat foods and control portion sizes of higher-fat foods would provide an alternative approach. Principles to teach include the following:

- Eat less high-fat food (especially food high in saturated fats).
- Replace saturated fats with monounsaturated fats and fish oils whenever possible.
- Eat less high-cholesterol food.
- Choose foods high in complex carbohydrates (starch and fiber).
- Attain and maintain an acceptable weight.

T.A. should be counseled to recognize and minimize the three main sources of saturated fats in her diet: meat products, dairy products, and oils used in processed foods and cooking.

All meat products, including beef, pork, and poultry, contain fat. Much of the fat is visible and should be trimmed off before consumption. The remaining fat is contained within the meat and can be limited by (a) selecting the leanest meat (e.g., lean beef, skinless chicken, fish), (b) limiting portion size to about the size of a deck of playing cards (no more than 6 oz/day), and (c) cooking the meat in a manner that allows the fat to drip away from the meat (i.e., broiling, grilling).

High-fat dairy products are made with whole milk (~4% fat); low-fat alternatives are made with skim or 1% milk (which contain all of the nutrient value of whole milk products). T.A. should be taught to substitute low-fat alternatives for high-fat products—for example, by choosing soft margarine (or no fatty spread at all) instead of stick butter (note that unsaturated fats exist normally in liquid form and saturated fats in solid form); nonfat creams rather than whole milk creams; low-fat or nonfat soft cheese (e.g., cottage cheese) rather than natural or processed hard cheese (including cream cheese); skim milk rather than whole milk; light or nonfat sour cream rather than regular sour cream; and nonfat frozen yogurt rather than ice cream. She also should avoid or limit cream sauces on meats and vegetables and creamy soups.

Products prepared with coconut, palm, or palm kernel oils, as well as lard and bacon fat contain a high concentration of saturated fats, and intake should be restricted. In their

Table 12-11 NCEP ATP III Therapeutic Lifestyle Change Diet⁹²

| Nutrient | Recommended Intake |
|---------------------|-------------------------------|
| Total fat | 25–35% of total calories |
| Saturated fat | <7% of total calories |
| Polyunsaturated fat | Up to 10% of total calories |
| Monounsaturated fat | Up to 20% of total calories |
| Carbohydrate | 50–60% of total calories |
| Fiber | 20–30 g/day |
| Cholesterol | <200 mg/d |
| Protein | Approx. 15% of total calories |

place, products made with monounsaturated fats (e.g., olive oil, canola oils) or polyunsaturated fats (especially oils that contain omega-3 fatty acids) may be substituted. Monounsaturated fats have little or no effect on blood lipids, and polyunsaturated fats actually may help reduce total cholesterol. Although unsaturated fats do not elevate cholesterol levels, they are sources of dense calories and, therefore, may contribute to the development of obesity and hypertriglyceridemia. Also, when the “good” (unsaturated) oils are partially hydrogenated (i.e., saturated to make them solid, as in some margarine products), they take on the character of saturated oils and may raise cholesterol levels. These are called *trans fatty acids*. Major sources of saturated and trans fatty acids include cakes, pies, cookies, chips, and crackers. T.A. should be advised to avoid or limit not only saturated fats, but also trans fatty acids by reading food labels.

It is best not to give the patient a list of foods to avoid; this aversive approach is likely to fail. Rather, good instruction about a low-fat diet should teach the patient how to make good selections. Any food, even a high-fat food, is not prohibited as long as portion size and frequency of use are controlled.

Another dietary approach to lowering blood cholesterol is to use dietary adjuncts. For example, adding 5 to 10 g of viscous fiber (e.g., guar, pectin, oat gum, psyllium) or other dietary sources of fiber (e.g., vegetables, legumes, whole grains, fruits) to the diet daily will aid in lowering blood cholesterol levels about 5% on average. Also, plant stanol and sterol esters have been made available in margarine and salad dressing products (Benecol and Total Control) and can lower LDL-C 5% to 15% when the equivalent of one tablespoonful is ingested one to three times a day. They act by reducing the absorption of cholesterol in the intestine. The estimated cumulative percent reduction in LDL-C achievable through therapeutic lifestyle changes is between 20% and 30%.

T.A. will need to follow a low-fat diet indefinitely to sustain its benefit. For this reason, it might be necessary to have T.A. work with a registered dietitian or other professional who understands low-fat, low-cholesterol diets and who can give her personalized instruction. Particularly important is instruction on how to shop for and prepare low-fat foods and how to select low-fat foods in restaurants.

EFFECT ON LDL-C

7. What changes in T.A.’s LDL-C can be expected if she follows a TLC diet?

Serum cholesterol is reported to be reduced by an average of 3% to 14% in males who restrict saturated fat to <10% of calories; a slightly smaller response is attained in women, perhaps because their intake of saturated fats is generally lower than that of men.^{138–140} Patients who can restrict saturated fat intake to <7% of daily calories should experience an additional 3% to 7% average reduction. Most patients can attain at least a 5% reduction in cholesterol levels with a TLC diet, some patients much more. If dietary adjuncts are added, LDL-C may be lowered by an additional 5% to 15%.

Patients’ response to a low-fat diet is variable. In some patients, blood cholesterol levels fall substantially, whereas in others practically no change occurs. Response to a low-fat diet depends on many factors, including the patient’s dietary habits before implementing the low-fat diet, the patient’s adherence

with the diet, the degree to which the patient restricts fats and cholesterol, and the influence of genetic factors. The patient should not be discouraged if LDL-C levels do not change much or at all despite close adherence to the diet. The Mediterranean diet, for example, which is high in monounsaturated fats and fiber, has no appreciable effect on blood lipids, but can still reduce cardiovascular disease and mortality by 70%.¹³⁷ Patients who adhere to a low-fat diet might also respond to lower doses of lipid-lowering drugs.

Because T.A. is a woman and was following a low-fat diet before her diagnosis, a TLC diet is not likely to have a substantial effect on her blood cholesterol levels. It would be prudent to have her maintain a 3-day diary of everything she eats to allow a more objective view of her eating habits. If there are ways for her to improve her diet, this approach will reveal them.

Other Lifestyle Changes

8. What other modifications in behavior are prescribed in the TLC program?

Weight reduction in the overweight patient can reduce LDL-C and is a key component to the TLC plan. A 5- to 10-lb weight loss, for example, can up to double the LDL-C reduction achieved with a low saturated fat diet alone.¹³⁸ The predominant effect of weight loss is a reduction in serum TG and a small increase in HDL-C, however.¹⁴¹ In addition, weight reduction may offset the risk of developing hypertension and diabetes. The initial goal of a weight loss program is to reduce body weight by approximately 10% within about 6 months.¹⁴² This is best achieved by restricting total daily energy consumption through a reduction in saturated and trans fatty acid intake and by increasing physical exercise. A normal weight is defined as a body mass index (BMI) between 18.5 and 24.9, and a desirable waist circumference is <40 inches for male patients and <35 inches for female patients.¹⁴² Because T.A. has an acceptable weight, these considerations do not apply.

Smoking cessation substantially reduces the risk of CHD, pulmonary disease, and cancer and is a central component of a TLC program. This is an important consideration in T.A. The CHD risk she has from smoking is greater than the risk she has from her LDL-C elevation. By stopping smoking, T.A. will not only reduce her blood cholesterol levels slightly, but will also substantially alter her risk profile. Because most patients gain weight when they stop smoking and because weight gain may worsen lipid levels, plans need to be made to alter her diet and increase physical activity to counter these effects.

Increasing physical activity should be a component of the treatment of any patient with high blood cholesterol. Regular physical exercise may reduce TG and VLDL-C levels, raise HDL-C levels slightly, promote weight loss or maintenance of desired weight, lower BP, and cause favorable changes in coronary blood flow.¹⁴³ Regular aerobic exercise (e.g., brisk walking, jogging, swimming, bicycling, and tennis) should be prescribed in terms of amount (e.g., walking 4 miles), intensity (e.g., walking 4 mph), and frequency (walking each day if possible, but at least three times a week). T.A. states that she is already physically active. The level of her activity should be documented and enhancements recommended if needed.

Goal of Therapy

9. A lipid profile obtained 12 weeks after T.A. initiated a TLC diet and exercise program and had stopped smoking revealed an LDL-C level of 195 mg/dL; HDL-C and TG did not differ from baseline values. What is your assessment of the need for additional lipid-modifying treatment?

[SI units: LDL-C, 5.40, 5.43, and 5.17 mmol/L, respectively]

Based on her initial assessment, T.A.'s LDL-C goal is <130 mg/dL; drug therapy can be considered if her LDL-C is >160 mg/dL (Table 12-10). She has stopped smoking, however, and now has a global CHD risk of 1% in the next 10 years. Thus, her LDL-C goal today is <160 mg/dL. While she is not currently smoking, it may take a year or more for the associated risk to fully dissipate. NCEP recommends that drugs be considered in patients with fewer than two risk factors if their LDL-C remains \geq 160 mg/dL after implementing a TLC plan. Realistically, this is a therapeutic gray area where clinical judgment must be exercised. T.A. has a relatively low risk of CHD despite her current LDL-C level, supporting a decision to maximize TLC and withhold lipid-lowering drug therapy until her CHD risk rises to a high level. Her strong family history suggests, however, there is more to the story than LDL-C alone.

Emerging Risk Factors

10. To help determine whether to initiate lipid-lowering drug therapy in T.A., is there value in ordering additional laboratory tests to identify possible emerging risk factors?

As mentioned in question 4, noninvasive tests, such as ABI, carotid intimal-medial thickness, and electron beam computed tomography, can uncover evidence of subclinical atherosclerotic disease and help the clinician decide whether to pursue more aggressive therapy with lipid-lowering drugs. In addition, the clinician can measure several specialized laboratory tests of emerging risk factors to help with these decisions (Table 12-9). In T.A.'s case, a global risk assessment indicating about a 1% risk of a CHD event in 10 years and her strong family history for premature CHD events present conflicting information. Measuring one or more of the emerging risk factors may help focus the treatment decision in one direction or another.

Lp(a) (pronounced "el, pea, little a") appears to be an independent risk factor for CHD, although this is not a universal finding.¹⁴⁴ This very small cholesterol-containing lipoprotein particle contains the apolipoprotein(a). Its structure suggests that it could be an important source of cholesterol for the formation of atherosclerosis as well as a stimulus for thrombogenic mechanisms. High Lp(a) levels suggest a high CHD risk and support a more aggressive approach to lowering LDL-C. Evidence has shown that lowering LDL-C aggressively can overcome the increased CHD risk predicted by an elevated Lp(a) level. The only drug that can lower Lp(a) is niacin, but no studies have shown that giving niacin to these patients reduces CHD risk.

Apolipoprotein B is a marker for the number of atherogenic lipoproteins (VLDL and LDL) in the circulation. It is a strong predictor of CHD risk, at least as strong as LDL-C. It is a surrogate for LDL-C, but provides different information.¹⁴⁵ Some specialists prefer to use apolipoprotein B levels rather than, or in addition to, LDL-C in treating patients. Apolipoprotein

B levels are usually disproportionately high in patients with high TG, although they may also parallel LDL-C levels. There is a genetic dyslipidemia that is characterized by increased apolipoprotein B levels (increased particle number) and normal LDL-C levels. Based on this information, it appears reasonable to measure apolipoprotein B to gain additional information.

Severe elevations in homocysteine are positively correlated with CHD risk, especially in patients with inherited forms of hyperhomocysteinemia.¹⁴⁶ Several clinical trials are underway to determine whether treating moderate hyperhomocysteinemia will lower CHD events. High levels of homocysteine are easily treated with folic acid; the recent fortification of foods with folic acid is predicted to substantially reduce homocysteine levels. NCEP ATP III does not recommend homocysteine measurements in risk assessment to modify LDL-C goals because panel members were uncertain of the relationship between homocysteine levels and CHD risk.⁹² It may be useful in patients such as T.A. when searching for causes of a strong family history of CHD.

Increasingly, it is recognized that atherosclerosis is a chronic inflammatory disease. Thus, markers of inflammation have been sought to measure arterial inflammation. The marker that has emerged from this search is hs-CRP. Many observational studies have found that hs-CRP predicts a two- to fourfold increase in CHD risk over what is predicted by LDL-C alone.¹²³ Recently, the AHA has recommended that hs-CRP levels between 3 and 10 be considered suggestive evidence of a chronic inflammatory disease.¹²⁵ Levels >10 suggest the presence of an acute inflammation caused by infection, trauma, connective tissue disease, or other causes; in this case, the hs-CRP measurement should be repeated after 6 weeks.

T.A. was found to have a slightly elevated apolipoprotein B level (135 mg/dL) (which is consistent with her elevated LDL-C level), normal Lp(a) and homocysteine levels, and an hs-CRP of 4.7 mg/dL. An hs-CRP >3.0 is consistent with the presence of a chronic inflammatory disease, possibly atherosclerosis. Some clinicians believe that these findings would support more aggressive LDL-C lowering therapy in T.A.

Drug Therapy

11. L.W. is a 53-year-old man with a LDL-C of 200 mg/dL. He states that he follows a low saturated fat diet and jogs 2 miles three times a week. He does not smoke and has no family history of premature CHD. His high BP is under marginal control with enalapril 10 mg/day (BP, 134/88 mm Hg). His glucose level is 80 mg/dL (normal). He does not have hypothyroidism. His total cholesterol is 261 mg/dL, HDL-C is 45 mg/dL (normal average for a man), LDL-C is 200 mg/dL, and TG level is 80 mg/dL. No secondary or familial causes of his hypercholesterolemia are evident, and his physical examination findings are normal. Is L.W. a candidate for cholesterol-lowering drug therapy?

[SI unit: LDL-C, 5.17 mmol/L]

According to NCEP guidelines, L.W. has two CHD risk factors: male >45 years and a diagnosis of hypertension; this makes his LDL-C goal <130 mg/dL (Tables 12-4 and 12-6). Because he has two risk factors, his global risk was assessed (Fig. 12-7). L.W. was found to have a 12% risk of a CHD event in the next 10 years and has an optional LDL-C treatment goal of <100 mg/dL. With two risk factors and an estimated

10-year risk assessment between 10% and 20%, he is a candidate for cholesterol-lowering drug therapy in addition to therapeutic lifestyle change (Table 12-10).

BILE ACID RESINS AND CHOLESTEROL ABSORPTION INHIBITORS

12. The NCEP recognizes four drug categories for lowering LDL-C: bile acid resins, cholesterol absorption inhibitors, niacin, and the statins.⁹² Which of these is preferred to treat L.W. (Table 12-12)?

Bile acid resins have appeal in the management of hypercholesterolemia because they have a strong safety record established from years of use, effectively lower LDL-C, and demonstrated the ability to reduce CHD events in the Coronary Primary Prevention Trial.^{82,147} Resins are not absorbed from the gastrointestinal (GI) tract and thus lack systemic toxicity. They are available in powder and tablet forms. They reduce total and LDL cholesterol in a dose-dependent manner (Table 12-13). LDL-C is reduced approximately 15% with 5 g (1 packet) daily of colestipol (Colestid) powder (equivalent to 4 g of cholestyramine [Questran]), 23% with 10 g/day, and 27% with 15 g/day.¹⁴⁷ Therapy should be initiated with one packet, scoop, or tablet of resin daily (Table 12-14). The reduction achieved is inversely proportional to the baseline, untreated LDL-C level.¹⁴⁸ Thus, patients with a moderate cholesterol elevation (such as L.W.) will have a greater relative reduction than if the LDL-C were higher.

The older resins are not well tolerated, however, because of numerous GI side effects and the unpleasant granular texture of the powder. A new bile acid resin, colesevelam (WelChol), is available in 0.625-g tablets; the daily dose is six tablets (3.8 g) administered in one or two divided doses daily. Although the tablets are large and difficult for some patients to swallow, the product is much easier to administer and, owing in part to a smaller total daily dose, less susceptible to cause GI side effects than the older products. The standard daily dose reduces LDL-C by 15% to 18%.

Mechanism of Action

The resins are anion exchange agents that bind bile acids in the intestinal lumen and cause them to be eliminated in the stool.¹⁴⁹ By disrupting the normal enterohepatic recirculation of bile acids from the intestinal lumen to the liver, the liver is stimulated to convert hepatocellular cholesterol into bile acids. This in turn causes a reduction in the concentration of cholesterol in the hepatocyte, prompting the upregulation

of LDL receptor synthesis. Finally, circulating LDL-C levels are lowered by binding to the newly formed LDL receptors on the liver surface. This mechanism has appeal not only because it effectively lowers LDL-C but also because it is additive with

^aNumbers following drugs are references.

Table 12-14 Dosages of Selected Lipid-Modulating Drugs

| Drug | Initial Dosage | Usual Dosage | Maximal Dosage | Comment |
|--------------------------|--|--|--|--|
| Cholestyramine | 4 g before main meal | 4 g BID before heaviest meals | 8 g BID before heaviest meals | May prescribe 24 g/day, but few patients can tolerate. |
| Colestipol | 5 g powder or 2 g tabs QD before main meal | 5 g of powder or 4 g of tabs BID before heaviest meals | 10 g powder or 8 g of tabs BID before heaviest meals | May prescribe 30 g of powder per day, but few patients can tolerate. |
| Colesevelam | 6–0.63-g tablets per day | Same | 7 × 0.63-g tablets/day | Less bulk is associated with less gastrointestinal intolerance. |
| Niacin | 100–125 BID with food | 750–1,000 mg BID | 1,500 mg BID | Dosages up to 6 g/day have been used, but few can tolerate. Dosages may be increased 200–250 mg/day every 3–7 days until desired dosage has been obtained. |
| Niaspan | 500 mg q HS | 1,000–2,000 mg q HS | 2,000 mg q HS | Increase dose by 500 mg daily Q 4 wks. |
| Atorvastatin | 10–40 mg QD | 10–40 mg QD | 80 mg QD | Administer any time of day. |
| Fluvastatin | 20–40 mg QHS | 20–40 mg QHS | 40 mg BID 80 mg XL QD | Modified-release form (XL) has similar efficacy but has less bioavailability (and less risk of adverse effects). |
| Lovastatin | 20 mg with dinner | 20–40 mg with dinner | 40 mg BID | Administration with food increases bioavailability. BID dosing provides greater LDL-C lowering efficacy than QD. |
| Pravastatin | 10–40 mg QD | 10–40 mg QD | 80 mg QD | Administer with food to reduce dyspepsia. |
| Rosuvastatin | 10–20 mg QD | 10–20 mg QD | 40 mg QD | Administer any time of the day. |
| Simvastatin | 20–40 mg Q pm | 20–40 mg Q pm | 80 mg Q pm | Administer with food to reduce dyspepsia. |
| Gemfibrozil | 600 mg BID | Same | Same | |
| Fenofibrate ^a | 67–201 mg QD | Same | 201 mg QD | |

^aMultiple formulations are available and doses do vary.

other therapies to lower cholesterol. For example, combining a drug that reduces hepatocellular cholesterol biosynthesis (e.g., statins) with a resin that interferes with bile acid recycling can cause a substantial upregulation of LDL receptors and enhance removal of cholesterol from the blood.¹⁰

Adverse Effects

The disadvantage of the older resins (i.e., colestipol or cholestyramine) is their side effects. These resins often cause GI symptoms, including constipation, bloating, epigastric fullness, nausea, and flatulence¹⁴⁷ (Table 12-15). Colesevelam is associated with less GI intolerance. If one of the older resins is prescribed, the patient should be instructed to mix the resin powder in noncarbonated, apple juice or pulpy juices such as orange juice¹⁵⁰; to swallow it without engulfing air (administering it through a straw may help avoid air entrapment); and to maintain an adequate intake of fluids and fiber in the diet.

The older resins also can raise TG levels by 3% to 10% or more, especially in patients with high TG levels; this appears to be less of a problem with colesevelam. Reduction in the absorption of fat-soluble vitamins and folic acid has been reported with high dosages of resins, but this is rarely a problem in otherwise healthy patients consuming a nutritionally balanced diet. The older resins also can reduce the absorption of digoxin (but not digoxin), warfarin, thyroxine, thiazide diuretics, beta-blockers, and presumably other anionic drugs. This interaction can be minimized by administering other drugs 1 hour before or 4 hours after the resin dose. Colesevelam appears to have a high specificity for binding with bile acids and not with

other anionic drugs, including warfarin; thus, it may be safely administered with other drugs.

Based on this summary, no contraindications exist to the use of resin therapy in L.W. Colesevelam, which can safely be taken along with his BP medication and is less likely to cause intolerable symptoms, would be the preferred choice. Colesevelam therapy, however, is unlikely to achieve the desired 30% to 40% reduction in LDL-C levels needed by L.W. As shown in Table 12-11, it lowers LDL-C only about 20% on average, which is not sufficient to reduce L.W.'s LDL-C from 200 mg/dL to <130 mg/dL (or <100 mg/dL as an optional goal).

EZETIMIBE

Ezetimibe represents a class of lipid-altering drugs called cholesterol absorption inhibitors. One advantage of this compound is its ability to reduce LDL-C by an action in the gut, with minimal systemic exposure. This suggests that the drug may be very safe, much like the resins. It is administered once a day as a 10-mg tablet.

Ezetimibe reduces LDL-C by 18% to 22%, but has little effect on TG or HDL-C.¹⁵¹ In combination with a statin, it demonstrates an additive effect, enhancing LDL-C lowering by an additional 10% to 20%. In fact, when added to a low dose of a statin, the net LDL-C reduction can be similar to the lowering achieved with the maximal dose of the statin.¹⁵² When added to the maximal dose of a statin, it causes further LDL-C reduction, an effect important in patients with very high LDL-C levels requiring substantial reduction to achieve treatment goals.

Table 12-15 Monitoring Parameters, Adverse Effects, and Drug Interactions with Major Cholesterol-Lowering Drugs

| Drug | Adverse Effects | Drug Interactions | Monitoring Parameters |
|---------|---|--|--|
| Resin | Indigestion, bloating, nausea, constipation, abdominal pain, flatulence | GI binding and reduced absorption of anionic drugs (warfarin, β -blockers, digitoxin, thyroxine, thiazide diuretics); administer drugs 12 hr before or 4 hr after resin | Lipid profile Q 4–8 wk until stable dose; then Q 6–12 mo long term. Check TG level after stable dose achieved, then as needed. |
| Niacin | Flushing, itching, tingling, headache, nausea, gas, heart-burn, fatigue, rash, worsening of peptic ulcer, elevation in serum glucose and uric acid, hepatitis, and elevation in hepatic transaminase levels | Hypotension with BP-lowering drugs such as α -blockers possible; diabetics taking insulin or oral agents may require dosage adjustment because of increase in serum glucose levels | Lipid profile after 1,000–1,500 mg/day and then after stable dosage achieved; then Q 6–12 mo long term. LFT at baseline and Q 6–8 wk during dose titration; then as needed for symptoms. Uric acid and glucose at baseline and again after stable dose reached (or symptoms produced), more frequently in diabetic patients. |
| Statins | Headache, dyspepsia, myositis (myalgia, CPK >10 times normal), elevation in hepatic transaminase levels | Increased myositis risk with concurrent use of drugs that inhibit or compete for P450 3A4 system (e.g., cyclosporine, erythromycin, calcium blockers, fibrates, nefazodone, niacin, ketoconazole); risk greater with lovastatin and simvastatin; caution with concurrent fibrate or niacin use; lovastatin increases the pro-time with concurrent warfarin | Lipid profile 4–8 wk after dose change, then Q 6–12 mo long term. LFT at baseline, in 3 months, and periodically thereafter. CPK at baseline and if the patient has symptoms of myalgia. |

BP, blood pressure; CPK, creatinine phosphokinase; GI, gastrointestinal; LFT, liver function tests; TC, total cholesterol; TG, triglyceride.

Mechanism of Action

Cholesterol that is ingested in the diet and circulated through the bile from the liver is actively reabsorbed in the intestines. Once transported across the intestinal lumen into the enterocyte, it is combined with TG and apolipoprotein B48 to form chylomicron particles that transport the lipids through the lymphatic system to the hepatocyte. The TG and cholesterol can then be packaged into VLDL particles and secreted into the systemic circulation.

Ezetimibe interferes with the active absorption of cholesterol from the intestinal lumen into the enterocyte by binding to the Niemann-Pick C1 Like 1 (NPC1L1) transporter, which is a cholesterol transporter responsible for the uptake of dietary and biliary cholesterol into the small intestine. By interfering with the absorption of cholesterol, about 50% less cholesterol is transported from the intestines to the liver by the chylomicrons. This causes an upregulation in hepatic cholesterol synthesis, which is diverted to the intestines via the bile to replenish the cholesterol available for absorption processes. It also causes an upregulation of hepatic LDL receptors and increased clearance of circulating VLDL and LDL particles. The net effect of the inhibition of cholesterol absorption in the gut is approximately a 70% increase in GI sterol excretion, a 50% reduction in hepatic cholesterol concentration, a 90% increase in hepatic cholesterol synthesis, and approximately a 20% increase in LDL-C taken up from the systemic circulation via upregulated LDL receptors.¹⁵³

Ezetimibe also inhibits the absorption of sitosterol, a plant sterol, from the gut, resulting in about a 40% reduction in blood sitosterol levels. The occurrence of sitosterolemia is rare, but patients who have it have a high CHD risk. Ezetimibe provides one of the first effective treatments for this rare disorder.

Adverse Effects

Ezetimibe's side effects include diarrhea, arthralgias, cough, and fatigue. These occur no more frequently with ezetimibe than they do with placebo. Whether used alone or together with a statin, no increases in liver function abnormalities have been reported nor any cases of myopathy or rhabdomyolysis. As with resin therapy, ezetimibe can safely reduce the LDL-C by about 20%, which is not likely to be sufficient to reduce L.W.'s LDL-C to his goal of <130 mg/dL (or <100 mg/dL as an optional goal).

NIACIN

Clinical Use

Niacin (or nicotinic acid) is a water-soluble B vitamin that can improve the levels of all serum lipids. Favorable attributes are low cost, a long history of use, and clinical trial evidence that it can reduce CHD events.^{112,113,154} Crystalline (immediate-release) niacin lowers LDL-C levels by 15% to 25% and TG 30% to 60% and raises HDL-C levels 20% to 35%.^{154–156} (Tables 12-13 and 12-16). Reduction in LDL-C follows a linear relationship to dose: Doses need to be increased to 2 to 3 g/day to reduce LDL-C levels by 20% to 25%. Conversely, the increase in HDL-C and reduction in TG follows a curvilinear relationship with dose: Low to moderate doses (i.e., 1 to 2 g/day) can increase HDL-C by 25% and lower TG by 30% to 40%.¹⁵⁵ (Table 12-13, Fig. 12-8). Crystalline niacin should be started at a low level (e.g., 250 mg in two or three divided doses daily) and slowly titrated as tolerated (e.g., daily doses increased by 250 mg every 3 to 7 days) to a maximum of 3,000 mg/day (Table 12-14). Higher doses have been used but are associated with unpleasant side effects. Niacin is also the only drug that lowers Lp(a), with reductions being as great as 30%.¹⁵⁷ Its metabolite, nicotinamide, has no effect on

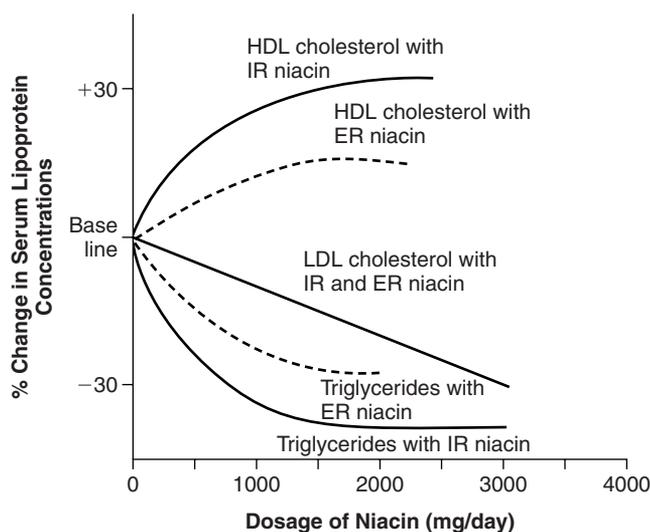

FIGURE 12-8 Dose-related effects of niacin on lipoproteins. (From Knopp RH. Drug treatment of lipid disorders. *N Engl J Med* 1999;341:498, with permission.)

cholesterol and should not be used as a substitute to lower side effects.

Sustained-release (timed-release) dosage forms of niacin were developed to reduce the flushing side effects associated with crystalline niacin. These products are sold as a dietary supplement ostensibly for treating niacin deficiency, but are mistakenly purchased by patients to treat high blood cholesterol. These products may have slightly greater LDL-C-lowering efficacy at each dose level and slightly less HDL-C and TG effects compared with crystalline niacin, but they cannot be recommended because of a substantially increased risk of liver toxicity at higher dosages (see Adverse Effects).

An extended-release dosage form of niacin, Niaspan, is available by prescription to treat elevated cholesterol and TG levels and appears to be better tolerated than either the crystalline or sustained-release forms. Niaspan releases niacin over an 8- to 12-hour period, a feature that turns out to be important in improving its side effect profile, and it has the efficacy pattern of crystalline niacin. It lowers LDL-C by 10% to 15% and TG by 20% to 30%, and it raises HDL-C by 15% to 25% with daily doses between 1,000 and 2,000 mg. Daily doses of Niaspan should not exceed 2,000 mg/day to reduce the risk of liver side effects.

Mechanism of Action

Niacin inhibits the mobilization of free fatty acids from peripheral adipose tissue to the liver, which, either alone or together with other hepatic effects, results in reduced synthesis and secretion of VLDL particles by the liver.¹⁵⁸ This explains its effectiveness in lowering TG levels. Because LDL is a VLDL degradation product, reducing the secretion of VLDL particles secondarily lowers the LDL-C level. Niacin reduces the amount of apolipoprotein A-I extracted and catabolized from HDL during the hepatic uptake of cholesterol, thus preserving the structural and functional integrity of HDL particles.¹⁵⁹ As a result, cholesterol-deficient apolipoprotein A-I-containing

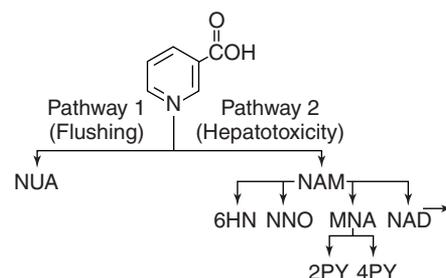

FIGURE 12-9 Niacin metabolism. NAM, nicotinamide; NUA, nicotinuric acid. (From Piepho RW. The pharmacokinetics and pharmacodynamics of agents proven to raise high-density lipoprotein cholesterol. *Am J Cardiol* 2000;86(Suppl):35L, with permission.)

HDL particles are recirculated from the liver to the peripheral cells, maintaining HDL levels and enhancing reverse cholesterol transport.¹⁶⁰

Adverse Effects

The differences in release characteristics among various niacin products are important because they determine how the drug is metabolized, in turn influencing the side effect profile of the product. Niacin is metabolized through two separate metabolic pathways (Fig. 12-9).¹⁶¹ The nicotinamide (NAM) pathway is a high-affinity, low-capacity pathway. Crystalline niacin quickly saturates this pathway and is predominantly metabolized through the high-capacity conjugation pathway. The flushing effect with crystalline niacin results from prostaglandin-mediated vasodilation associated with the formation of nicotinuric acid (NUA) by the conjugation pathway. In contrast, sustained-release niacin is slowly absorbed and preferentially metabolized via the NAM pathway. Because of this, sustained-release niacin rarely causes flushing, but it can cause serious, dose-related hepatotoxicity because of the formation of toxic metabolites of the NAM pathway. Niaspan, with its intermediate absorption rate, has a more balanced metabolism between the two pathways. The result is less flushing and less risk of hepatotoxicity, at least with daily doses of >2 g.

The main drawbacks to crystalline niacin therapy are frequent, bothersome vasodilation-related side effects: flushing, itching, and headache.^{155,156,162} (Table 12-15). Practically every patient will experience these side effects, at least transiently.¹⁶³ These symptoms can be reduced by having patients take doses with food and by taking 325 mg of aspirin 30 minutes before the morning dose of niacin (to inhibit prostaglandin synthesis, which is thought to mediate these side effects).¹⁶⁴ Use of Niaspan can further reduce these symptoms, and administering it once daily at bedtime can diminish the patient's awareness of flushing symptoms. Niacin also can cause fatigue and a variety of GI symptoms, including nausea, dyspepsia, and activation of peptic ulcer. As with flushing, GI side effects are minimized by taking the drug with food. Other less common, though potentially troublesome, side effects of niacin are hyperuricemia, gout, and transient worsening of glucose tolerance in some diabetic patients (Table 12-15).

The most worrisome side effect associated with niacin is hepatotoxicity, which is associated almost exclusively with the

sustained-release forms of niacin.^{155,165} Hepatotoxicity is detected by an increase in liver transaminase enzymes exceeding three times the upper limit of normal; in severe cases, this can be accompanied by symptoms such as fatigue, anorexia, malaise, and nausea. This side effect occurs when daily doses of sustained-release niacin exceed 1,500 mg. Hepatotoxicity has been reported to occur in up to half of the patients titrated to daily doses of 3,000 mg of sustained-release niacin; many of these patients had symptoms, as well as laboratory findings, consistent with toxicity.¹⁵⁵ Conversely, <1% of patients titrated up to 2,000 mg/day of Niaspan have elevated liver function tests. Rare cases of fulminant hepatitis have been reported with sustained-release niacin. Niacin-induced hepatotoxicity appears to be completely reversible when the drug is discontinued.

Because of the hepatotoxic effects of sustained-release niacin and the flushing side effects of crystalline niacin, Niaspan is the preferred form of niacin for general use. It can be safely used in a daily dose up to 2,000 mg. An estimated 30% of patients experience flushing symptoms that will cause them to discontinue therapy.

No apparent contraindications are seen to the use of niacin in L.W. Niacin, however, would not be expected to lower his LDL-C by the 35% to 50% required to reach his treatment goal of <130 mg/dL or <100 mg/dL (optional goal), respectively.

STATINS

Clinical Use

The group of drugs with the most potent cholesterol-lowering potential is composed of the statins. They lower LDL-C by approximately 20% to 40% with initial doses and 35% to 60% with maximal doses^{166,167} (Table 12-13). Statins also reduce TG levels by 15% to 45% and increase HDL-C modestly (5% to 8%) (Table 12-16). The LDL-C lowering achieved is dose dependent and log linear. Low dosages produce substantial LDL-C-lowering effects, and with each doubling of the daily dose, LDL-C is lowered an additional 6% to 7% on average (Table 12-13).

The currently available statins are atorvastatin (Lipitor), fluvastatin (Lescol), lovastatin (Mevacor), pravastatin (Pravachol), rosuvastatin (Crestor), and simvastatin (Zocor). Rosuvastatin provides the most substantial LDL-C lowering, followed by atorvastatin, simvastatin, lovastatin, pravastatin, and fluvastatin in descending order. With clinical trial evidence that lower LDL-C levels are associated with less CHD, higher initial doses of these statins are being advocated, thus blurring these

LDL-C differences. The efficacy of many statins is greater if administered in the evening to coincide with the nighttime upturn in endogenous cholesterol biosynthesis; atorvastatin, and rosuvastatin with a longer half-life and more potent LDL-C lowering, may be administered without regard to time of day. The LDL-C-lowering efficacy of twice-daily administration of statins is slightly greater (by 2% to 4%) than once-daily evening doses, but this difference is rarely sufficient to make a clinical difference. The bioavailability of lovastatin is improved by administration with food; thus, it is recommended for dosing with the evening meal. This, too, may not make much difference in the clinical setting.

The major statin trials described earlier in this chapter demonstrate that statins can significantly reduce CHD death and nonfatal MI, revascularization procedures, strokes, and total mortality. The mechanism for these beneficial outcomes is not fully known, but is at least partially associated with LDL-C reduction.¹¹⁴ Most authorities believe that the CHD event reduction with statins is a class effect and can be accomplished with any of the available statins. This, coupled with their favorable safety profile and their potency in lowering LDL-C, supports the NCEP ATP III recommendation that statins are the drugs of first choice to lower cholesterol and reduce CHD risk.^{92,168}

Mechanism of Action

Statins competitively inhibit the enzyme responsible for converting HMG-CoA to mevalonate in an early, rate-limiting step in the biosynthetic pathway of cholesterol (Fig. 12-1).¹⁰ Reduction in hepatocellular cholesterol prompts an upregulation of LDL receptor proteins and thus increases the clearance of circulating LDL particles from the blood. The TG-lowering effects appear to be produced in two ways: by an increase in the clearance of VLDL and VLDL remnant particles from the systemic circulation (by the upregulation of LDL receptors) and by a reduced secretion of VLDL particles from the liver.^{169–171} All statins have the ability to lower TG levels. Their TG-lowering efficacy is related, however, to their LDL-C-lowering effectiveness (thus, statins with greater LDL-C-lowering efficacy will have greater TG-lowering efficacy) and to the patient's baseline TG level (the higher the TG level, the greater the percentage of reduction produced by the statin).

Adverse Effects of Statins

13. L.W.'s physician decides to start therapy with 20 mg/day of simvastatin. Several days after starting the drug, he played tennis for the first time in several years. The next morning he experiences new leg and arm pain. He had been warned that statins can cause muscle damage. He does not complain of any other side effects since starting the drug. Could this be a side effect of simvastatin? Should he discontinue the therapy?

Statins are well tolerated by most patients. Headache; myalgias (without CPK changes); and GI symptoms, including dyspepsia, flatus, constipation, and abdominal pain, occasionally are experienced^{166,172,173} (Table 12-15). These symptoms are usually mild and disappear with continued therapy. The statin side effects receiving the most attention include increases in liver function tests and myopathy. These two problems are described in detail below.

Table 12-16 Average Effects of Selected Drugs on Lipoprotein Cholesterol and Triglycerides

| Drug | LDL (%) | HDL (%) | TG (%) |
|-----------|---------|---------|--------|
| Resin | -15–30 | ±3 | +3–10 |
| Ezetimibe | -18–22 | +0–2 | -0–5 |
| Niacin | -15–30 | +20–35 | -30–60 |
| Statin | -25–60 | +5–15 | -10–45 |
| Fibrates | ±10–25 | +10–30 | -30–60 |

HDL, high-density lipoprotein; LDL, low-density lipoprotein; TG, triglycerides.

Statins can cause an elevation in transaminase enzyme levels of more than three times the upper limit of normal in 1% to 1.5% of patients in a dose-dependent manner. The transaminase level can return to normal spontaneously even with continued statin therapy. Similarly, elevations in transaminase will return to normal if the statin is discontinued. Rechallenge with the same or a different statin after enzymes have returned to normal limits is acceptable. If the drug is tolerated on rechallenge, it can be continued; recurrence of transaminase elevation warrants further evaluation of other potential causes. No cases of hepatic failure or liver transplant associated with statin therapy have been reported, leading many to conclude that transaminase elevations are relatively unimportant and not associated with worrisome adverse consequences.

The potential for muscle toxicity is a different matter. Myositis, defined as the presence of muscle symptoms, including aches, soreness, or weakness (i.e., myalgia), and an increase in serum CPK >10 times the upper limit of normal, occurs in approximately 0.1% to 1% of patients in a dose-dependent manner. Routine monitoring of CPK levels is unnecessary; rather, unexplained symptoms of muscle aches, weakness, or soreness should prompt a CPK evaluation. If myositis is present, a careful history is necessary to rule out usual causes (i.e., trauma, increased physical activity). If no explanation is present for the findings and the CPK is elevated, the statin should be withdrawn until CPK levels return to normal. Occasionally, symptoms of myalgia are bothersome to the patient, even with a normal CPK, resulting in discontinuation of the statin. Once symptoms subside, statin therapy can be restarted, preferably with a different statin. Myositis is more likely to occur with high systemic concentrations of the statin and when there is a provocation for the event (e.g., hypothyroidism, trauma, or flulike syndromes). Myositis has also been reported more often when a statin is combined with gemfibrozil or when a drug is given concurrently that can increase blood levels of the statin, such as a macrolide antibiotic (e.g., erythromycin). Cases of rhabdomyolysis, myoglobinuria, and acute tubular necrosis have been reported in patients receiving statin therapy. Most of these cases have occurred with high doses, in patients with impaired renal or hepatic function, in older individuals, or when statins are used in combination with interacting drugs.

Drug interactions with statins that result in higher blood levels of the statin or an active metabolite can increase the risk of myositis. Statins that depend on the P450 3A4 enzyme system to be metabolized are most vulnerable to this interaction (i.e., lovastatin, simvastatin, and to a lesser extent atorvastatin). Fluvastatin is metabolized by the P450 2C9 system and, therefore, is more vulnerable to interactions with drugs that directly inhibit 2C9 or act as competitive inhibitors (substrates) for this alternate system. Rosuvastatin is metabolized minimally (i.e., about 10%) by 2C9 to less active metabolites. Pravastatin undergoes isomerization in the gut to a relatively inactive metabolite. Variability of gastric metabolism has been shown to be associated with the LDL-C-lowering effects of pravastatin.¹⁷⁴ Some of the more commonly encountered drugs that inhibit the 3A4 enzyme system are azole antifungals (itraconazole, ketoconazole, and miconazole), certain calcium channel blockers (diltiazem and verapamil), macrolide antibiotics (clarithromycin and erythromycin), protease in-

hibitors (ritonavir), and antidepressants (nefazodone). Drugs that are substrates for the 3A4 system include certain benzodiazepines (alprazolam, midazolam, triazolam), calcium channel blockers (especially diltiazem), carbamazepine, cisapride, cyclosporine, estradiol, felodipine, loratadine, quinidine, and terfenadine. When these substrate drugs are used together with simvastatin or lovastatin (and to a lesser extent atorvastatin), systemic blood levels of the statin may be increased because of competitive inhibition of the 3A4 enzymes, and this may increase the risk for myositis. Inhibitors of 2C9 isoenzymes include alprenolol, diclofenac, hexobarbital, tolbutamide, and warfarin.

It is preferable to avoid the combined use of interacting drugs with statins. If the patient requires a short course of therapy with a potentially interacting drug (e.g., erythromycin), the statin should be discontinued during this period and restarted when the course has been completed. If an interacting drug must be used long term (e.g., cyclosporine) with a statin, the lowest effective dose of the statin should be selected, with careful monitoring of muscle symptoms. If myositis occurs, it is quickly reversible when the statin is discontinued.

Caution should also be exercised when adding gemfibrozil with a statin to treat patients with high blood cholesterol and TG. Gemfibrozil interferes with the glucuronidation of statins, thereby interfering with their renal clearance. This interaction results in two- to fourfold increases in systemic statin levels and has been demonstrated with all statins except fluvastatin. Because the interaction has not been reported to occur with fenofibrate, it is the preferred fibrate to add to a statin when treating patients with a mixed lipid disorder.

Hospitalizations and deaths caused by rhabdomyolysis led to the withdrawal of one statin, cerivastatin, from the market, punctuating the importance of this potential side effect. Cerivastatin at its top dosage of 0.8 mg daily caused a significantly higher incidence of myotoxicity than other currently marketed statins. Additionally, when interacting drugs or gemfibrozil were added to this dose of cerivastatin, many cases of severe muscle toxicity and rhabdomyolysis occurred. The U.S. Food and Drug Administration (FDA) subsequently observed that factors that appeared to raise the risk of severe muscle toxicity and rhabdomyolysis with cerivastatin included older individuals (especially women), small body frame, reduced renal function, multiple organ diseases, and use of multiple concurrent medications, particularly those known to interact with statins. Whenever these factors are present in a patient receiving a statin, it is advisable to use the lowest effective statin dose, to avoid or use with caution interacting drugs, and to monitor the patient carefully. It is also advisable not to unduly frighten the patient with dire warnings about the potential for this side effect; it occurs only rarely, especially when these drugs are used responsibly in the manner described.

Lovastatin and rosuvastatin may prolong the prothrombin time in patients receiving coumarin anticoagulants concurrently; this effect is not caused by pravastatin. Statins should not be used in patients with active liver disease or those who are (or hope to become) pregnant because of potential hazards to the fetus.

Based on this information, it is unlikely that simvastatin is causing any serious side effects. His muscle pain is most likely the result of heavy exercise that is not part of his usual pattern

of exercise. If the muscle soreness persists for more than the expected 2 to 3 days or worsens, he should report it to his doctor to determine if measuring a CPK level is necessary.

14. Was simvastatin a good choice for L.W.? Was the dose appropriate?

A statin is the preferred drug for L.W. He is not receiving a potentially interacting drug and has no apparent contraindication to its use. Further, it is more likely than a resin, ezetimibe, or niacin to help him reach his LDL-C goal. In selecting the specific statin for the patient, it is assumed, for reasons previously stated, that all statins are equally safe and have a similar potential to reduce CHD events. The characteristic that differentiates the statins is their ability to lower LDL-C (Tables 12-13 and 12-16). Given the minimum of a 35% reduction required to achieve L.W.'s LDL-C goal, it would be preferable to select the statin with the greatest LDL-C-lowering potency, such as simvastatin, atorvastatin, or rosuvastatin. At 20 mg/day of simvastatin, 10 mg/day of atorvastatin, or 10 mg/day of rosuvastatin, LDL-C is reduced by an average of 39%, indicating that 50% of patients will experience at least this level of LDL-C reduction. Starting therapy with even higher doses (i.e., rosuvastatin 20 mg, simvastatin 40 mg or atorvastatin 20 mg) will increase the chance of reaching L.W.'s minimal treatment goal of <130 mg/dL. For now the 20 mg starting dose of simvastatin given to L.W. is reasonable. He should be assessed for success in achieving his lipid goal in about 6 weeks.

Fiber

15. What role can supplemental fiber play in the treatment of L.W.?

Increasing fiber intake in the diet or adding supplemental fiber in the form of psyllium (Metamucil), oat bran, gums, or other products might temporarily aid in LDL-C reduction. When given to a patient who is following a low-fat diet, the LDL-C reduction is modest (usually about 5%). A dietary supplement of fiber would make little overall contribution to L.W.'s treatment, although appropriate fiber intake in the form of fresh fruits, beans, and vegetables is highly advisable. Overuse of fiber is associated with bothersome GI symptoms, including flatulence and bloating.

Fish Oils

16. Is there a role for fish oil supplements in L.W.'s treatment?

Fish oils predominantly contain polyunsaturated (omega-3) fatty acids, which lower TG levels significantly (30% to 60%) but have variable effects on cholesterol levels. They serve little value in achieving LDL-C reduction, as is needed by L.W. As noted, however, under the discussion of diet, consumption of foods rich in omega-3 fatty acids (e.g., fish) several times a week has been associated with a reduced risk of heart disease, and they are recommended as part of a low-fat diet. Supplements of fish oils demonstrated a reduction in CHD events in several large clinical trials.¹⁷⁵ Commercial sources of fish oils vary in their content. The fish oil supplements used in the GISSI study, which demonstrated a CHD risk

reduction, contained 850 mg of eicosapentaenoic acid (EPA) and docosahexanoic acid (DHA). Fish oils are most useful in the treatment of patients who have hypertriglyceridemia and who cannot achieve adequate control with conventional TG-lowering drugs (niacin and a fibrate) alone. The CHD risk reduction with fish oils appears to be caused by an antiarrhythmic effect and not a change in atherosclerosis, because sudden CHD deaths are the outcome primarily affected by fish oil therapy.

Postmenopausal Drug Therapy

17. C.M. is a 57-year-old woman whose last menses occurred 2 years ago. She follows a TLC diet and participates in an aerobic exercise program three times a week. She has a strong family history of CHD (her father died suddenly at age 59 and her 43-year-old brother has had a heart attack). Her mother is alive at age 78, but lives in a nursing home because of a hip fracture last year. C.M. does not have diabetes or hypertension; she smokes half a pack of cigarettes per day. Her mean BP for the last two visits is 142/88. She does not have hypothyroidism. Her lipid profile is total cholesterol, 260 mg/dL; LDL-C, 186 mg/dL; HDL-C, 58 mg/dL; and TG, 78 mg/dL. C.M. has no evidence of secondary or familial dyslipidemia or atherosclerotic vascular disease on her physical examination. She has not had a hysterectomy. She complains of frequent daily hot flashes and night sweats. Does C.M. need cholesterol-lowering drug therapy, and if so, with which drug? Is she a candidate for estrogen replacement therapy?

[SI units: LDL-C, 5.17 mmol/L; HDL-C, 1.5 mmol/L; and TG, 0.88 mmol/L]

Being postmenopausal, whether natural, surgical, or premature, is associated with an increased CHD risk. C.M. has three risk factors: postmenopausal status, smoking, and family history of premature CHD (Table 12-4). Because she has two or more risk factors, her LDL-C goal is <130 mg/dL. An assessment of her global risk (Fig. 12-6B) indicates that she has an 11% risk of a CHD event in the next 10 years. Because her global risk is between 10% and 20%, the option is to treat her LDL-C to <100 mg/dL. Because her mean LDL-C after diet is still 186 mg/dL, she will require a 46% reduction to achieve her goal. Until recently, C.M. would have been a candidate for estrogen therapy before (or instead of) other cholesterol-lowering drugs. Estrogen is known to improve lipid and lipoprotein profiles and was thought to provide cardioprotective effects as well as minimizing osteoporosis and menopausal symptoms. Today, with new data in hand, this approach has changed.

Estrogen Replacement Therapy

CONSIDERATIONS FOR USE IN HYPERCHOLESTEROLEMIA

18. What are the considerations for using estrogen therapy in C.M. to reduce her CHD risk?

Epidemiologic studies report up to 50% lower CHD rates in women who use estrogens compared with those who do not.¹⁷⁶⁻¹⁷⁹ A meta-analysis of 31 case-control, cross-sectional, and cohort studies found an overall relative risk of 0.56 (i.e., a 44% lower rate of CHD in estrogen users compared with nonusers).¹⁸⁰ The difference in CHD rates between estrogen users and nonusers is even greater in women who have developed CHD.^{178,181} Despite calls for caution,¹⁸² the

epidemiologic evidence of lower CHD risk was so impressive and consistent that many authorities supported the use of estrogen therapy as a first-line treatment to reduce CHD risk in dyslipidemic, postmenopausal women, especially if they were experiencing menopausal symptoms or were at risk from osteoporosis.

Following the reports of the Heart and Estrogen/Progestin Replacement Study (HERS) and the Women's Health Initiative (WHI), this position has changed. HERS evaluated 2,763 women with known CHD.¹⁸³ The active treatment group received conjugated equine estrogen (0.625) and medroxyprogesterone (2.5) mg/day (Prempro) for 5 years. Compared with placebo, the hormone replacement therapy (HRT) regimen lowered LDL-C by 11% and increased HDL-C by 10%. At the conclusion of the study, no difference was seen between the groups with regard to CHD death and nonfatal MI (the primary study outcome measure) or total mortality. Of greatest concern was a 52% increase in CHD events during the first year of the study. By the fourth and fifth years of the study, HRT-treated women had 33% fewer CHD events, but this difference was not sufficiently great to counter the first-year results. Venous thromboembolic events occurred in 0.6% of treated women compared with 0.2% in placebo-treated women; the incidence of gallbladder disease was 38% greater in HRT-treated than in placebo-treated patients. No significant differences were found between the groups with respect to breast cancer, endometrial cancer, or fracture. Study investigators searched for explanations of these surprising results, but ultimately concluded that in this well-controlled study of estrogen therapy in CHD women, estrogen provided no benefit and may have caused harm.

Subsequently, the WHI reported the results of a 5.2-year, randomized, placebo-controlled study of the same estrogen/progestin product in 16,608 postmenopausal women who had no prior evidence of CHD.¹⁸⁴ The study was stopped before its planned 8.5-year duration because the rate of invasive breast cancer exceeded the stopping boundary. Investigators reported the following negative outcomes: a 29% increase in CHD events (nonfatal MI or CHD death), a 26% increase in breast cancer, a 41% increase in stroke, and a twofold increase in pulmonary embolism. Positive outcomes included a 37% reduction in colorectal cancer, a 17% reduction in endometrial cancer, a 34% reduction in hip fracture, and an 8% reduction in death from non-CHD causes. These relative changes in risk camouflage a low overall absolute risk of harmful study events. That said, however, the absolute excess risk of adverse events during the study was 19 per 10,000 person-years, supporting an overall conclusion that the risks of estrogen/progestin (Prempro) therapy exceeded the benefits among healthy postmenopausal women. Because the whole purpose of healthy women taking a therapy is to preserve health and prevent disease, this study provides further strong evidence that women should not receive combination estrogen/progestin therapy for long-term use to prevent CHD. It should be noted that the WHI study arm with postmenopausal women taking estrogen alone was not stopped prematurely, suggesting that the adversities reported above were caused by the progestin component of the combination and not to the estrogen. Nonetheless, until further data are available, long-term use of estrogen for lipid management is not recommended. Short-term (1 to 2 years) use for relief of C.M.'s menopausal symptoms is acceptable.

Alternative Lipid Therapy for Postmenopausal Women

19. If C.M. should not be started on estrogen/progestin therapy, what should she be given?

C.M.'s risk of dying of CHD is as great as it is for a male patient. Further, her risk rises after menopause in a logarithmic manner parallel to men (although behind men by about 10 years). The Heart Protection Study and a meta-analysis of most of the major statin trials has shown strong evidence that postmenopausal women benefit from lipid-lowering treatment just as much as men^{91,185} (Table 12-3). For all of these reasons, C.M. is a candidate for lipid-modifying therapy. Because she requires a 46% reduction to achieve her LDL-C goal of <100 mg/dL, a statin with sufficient LDL-C-lowering potency to achieve this target (i.e., simvastatin, atorvastatin, or rosuvastatin) would be the drug of choice or a statin combined with another drug (see below). Even if the decision is made by her and her gynecologist to initiate short-term HRT to reduce vasomotor symptoms, a statin will still be needed to reduce her LDL-C to the goal level and to reduce her CHD risk.

Familial Hypercholesterolemia

20. D.E. is a 45-year-old man with no evidence of CHD. His father and grandfather both died suddenly from apparent heart attacks in their early 50s, but D.E. has no other CHD risk factors. He has no evidence of secondary causes of dyslipidemia. On physical examination, he is noted to have bilateral corneal arcus and bilateral Achilles' tendon xanthomas; the rest of his examination findings are normal. Likewise, his laboratory test results are within normal limits, except for the following lipid profile: total cholesterol, 440 mg/dL; TG, 55 mg/dL; HDL-C, 55 mg/dL; and LDL-C, 374 mg/dL. What form of hypercholesterolemia does D.E. most likely have? Is he a candidate for drug therapy at this time?

[SI units: total cholesterol, 11.38 mmol/L; TGs, 0.62 mmol/L; HDL-C, 1.42 mmol/L; LDL-C, 9.67 mmol/L]

The combination of a very high LDL-C, tendon xanthomas, corneal arcus, and a strong family history of premature CHD is consistent with a diagnosis of familial hypercholesterolemia (FH) (Table 12-2). The risk of a CHD event in the next 10 years associated with FH is very high, well in excess of 20%. Thus, it is not necessary to conduct a global risk assessment, because the diagnosis of the genetic disorder defines his risk. Although D.E. has bilateral tendon xanthomas, this finding would not necessarily be detected in all 45-year-old patients because it takes time for xanthomas to develop. With a strong family history and a very high LDL-C level independent of the presence or absence of xanthomas, however, it is still presumed that the person has either FH or severe polygenic hypercholesterolemia. Thus, he deserves aggressive lipid management to reduce his high CHD risk. D.E. should be given therapy to lower his LDL-C to 130 mg/dL, lower if possible. To achieve this goal, D.E. will require a 65% LDL-C reduction, which almost assuredly will require combination drug therapy in addition to a low-fat diet. Because this is a genetically induced lipid abnormality, a low-fat diet alone will not correct the problem; in fact, diet may have little effect on his LDL-C.

Combination Drug Therapy

21. What cholesterol-lowering drugs should be combined to manage D.E.'s lipid disorder?

As stated previously, four drugs effectively reduce LDL-C: a statin, a resin, ezetimibe, and niacin (Table 12-12). When two or more of these are combined, an additive LDL-C-lowering effect is achieved. Combinations of niacin and resin result in LDL-C reductions of 32% to 43%;⁶² a statin and a resin lower LDL-C by 45% to 55%,⁶³ and ezetimibe plus a statin reduces LDL-C by 46% to 70%.^{152,186} LDL-C reductions of 50% to 60% are possible when the three-drug regimen of a statin plus resin plus niacin is used.^{187,188}

The major limiting factor in combining drugs is side effects. Niacin and the older resins both cause bothersome side effects to the extent that 25% to 50% of patients cannot tolerate them. The use of Niaspan rather than crystalline niacin may reduce the vasodilatory side effects, however, and the use of colesevelam rather than one of the older resins should reduce GI intolerance.¹⁸⁹ The combination of a statin and niacin is said to be associated with an increased risk of myositis, although this risk appears to be very low.¹⁹⁰ The combination of a statin and ezetimibe is the one best tolerated and offers the most convenient once-a-day dosing of the possible combinations. This is the combination that was selected for D.E.

INITIATING THERAPY

22. How should combined therapy with a statin and ezetimibe be initiated in D.E.?

Given the amount of LDL-C lowering needed to reach D.E.'s LDL-C goal, it is reasonable to select one of the more potent LDL-C-lowering statins (e.g., simvastatin, atorvastatin, or rosuvastatin) and to start with a high daily dose (40 mg/day). Before therapy is initiated, baseline liver function tests and CPK levels should be obtained (Table 12-15). Renal function should be assessed because impaired renal clearance of the statin or its active metabolite could result in increased systemic levels, which might increase the risk of myotoxicity. LDL-C levels should be evaluated in about 6 weeks, when the maximal effect of the statin is anticipated. If the LDL-C is within 6% of D.E.'s goal, the dosage of the statin may be advanced to 80 mg as this should be sufficient to achieve the goal. If the LDL-C is >6% below goal, however, ezetimibe (10 mg) daily should be added to the regimen. This should add an additional 10% to 20% LDL-C-lowering effect.¹⁸⁶ D.E. should be seen in another 6 weeks for further LDL-C evaluation. Alternatively, the patient can be started on a fixed combination product of simvastatin and ezetimibe (Table 12-14).

If D.E. does not achieve his goal with this two-drug combination, the addition of a third drug should be considered. Choices are to add a bile acid resin, such as colesevelam, or niacin. Presently, no study has described the efficacy of an ezetimibe, resin, and statin combination. Theoretically, the combination should be effective, but a limit may exist to how much hepatic LDL receptors can be upregulated. Niacin has been successfully added as a third drug in a regimen and provides a 10% to 15% additional LDL-C-lowering effect when titrated to about 2,000 mg/day.

ADDING A THIRD LIPID-LOWERING DRUG TO THE REGIMEN

23. How should niacin be initiated in D.E., and what monitoring is required?

Before niacin therapy is started (and after its maximal dosage is reached), liver function tests should be evaluated (Table 12-15). Patients with an active peptic ulcer or liver disease should not receive niacin. Niacin can increase glucose levels by 10% to 20% in some diabetic patients or patients with impaired fasting glucose levels, necessitating careful monitoring of glucose control. None of these issues is a factor in D.E.

The addition of niacin to D.E.'s statin and ezetimibe regimen should be initiated with low doses that are slowly titrated upward to allow tolerance to develop at each dosage level (Table 12-14). D.E. should be given as much control over niacin administration as possible. Crystalline niacin can be started at 250 to 300 mg/day, administered in two or three divided doses. Thereafter, daily dosages can be increased every 3 to 7 days in the following sequence: 500, 1,000, 1,500, 2,000, and 3,000 mg. Niaspan is initiated at 500 mg at bedtime and increased every 7 days to 1,000 mg, 1,500 mg, and 2,000 mg daily as tolerated by the patient. The over-the-counter sustained-release niacin dosage form is not recommended because of its increased risk of causing hepatotoxicity.

D.E. should be warned about the vasodilatory symptoms associated with niacin use (facial flushing, itching, rash) and reassured that these symptoms are not dangerous and that tolerance should develop after several weeks of therapy. He should be advised to take 325 mg of aspirin or another prostaglandin-inhibiting drug 30 minutes before the morning dose of crystalline niacin or the bedtime dose of Niaspan to decrease these symptoms. Taking each dose with food will help to reduce flushing and GI symptoms. Instruction can also be provided to reduce doses if necessary to manage bothersome symptoms. He should be encouraged to call his clinician whenever troublesome symptoms occur.

Several weeks after the 1,500-mg/day dosage is reached (Table 12-14), the patient should be evaluated for achievement of the LDL-C goal and side effects. If the LDL-C goal is not achieved with 1,500 mg/day, further increments can be made up to the maximal tolerated dose or a ceiling dose of 3,000 mg of crystalline niacin or 2,000 mg of Niaspan. In addition to a fasting lipid profile, laboratory tests of liver function, glucose, and uric acid may be indicated.

MIXED HYPERLIPIDEMIA

Assessing the Patient With Mixed Hyperlipidemia

24. B.C., a 56-year-old man, experienced acute chest pain 3 months ago and was admitted to the local hospital with a diagnosis of unstable angina. His only known medical problem was hypertension treated with enalapril 10 mg QD. His lipid profile on admission was total cholesterol, 235 mg/dL; HDL-C, 30 mg/dL; LDL-C, 165 mg/dL; and TG, 300 mg/dL. He underwent a cardiac catheterization, which revealed a 90% stenotic lesion in his left anterior ascending artery. A drug-coated stent was placed without difficulty. He was subsequently discharged on simvastatin 40 mg QHS, ezetimibe 10 mg QD, ASA 325 mg QD, propranolol 40 mg BID, and enalapril 10 mg QD.

Today, he weighs 220 lb, is 6 feet tall (ideal body weight [IBW], 140 to 185 lb), and has a waist circumference of 42 inches. He has lost 10 lb since his MI by following a low-fat diet and an exercise program. He swims 1 mile three times a week without symptoms of cardiac ischemia, and he drinks two glasses of wine each evening with dinner. His father died at age 58 of an MI (lipids unknown). He has never smoked. Pertinent physical findings include BP 148/90 mm Hg; heart rate 60 regular; arcus senilis; carotid pulses equal without bruits; and chest clear to auscultation without cardiomegaly. Laboratory tests disclose normal thyroid-stimulating hormone levels, normal renal and liver function, and a fasting glucose level of 120 mg/dL. His urinalysis was normal. The lipid profile while taking the above regimen is total cholesterol, 143 mg/dL; TG, 210 mg/dL; HDL-C, 33 mg/dL; and LDL-C, 68 mg/dL.

What is your assessment of B.C.'s lipids and lipoprotein cholesterol concentrations?

[SI units: glucose, 6.66 mmol/L; total cholesterol, 3.7 mmol/L; TG, 2.37 mmol/L; HDL-C, 0.85 mmol/L; LDL-C, 1.76 mmol/L]

According to NCEP guidelines, B.C. has reached the “reasonable” LDL-C treatment goal (<70 mg/dL) for a patient with a history of CHD.^{88,89} (Table 12-10). The LDL-C should be confirmed with a second lipid profile (because of biologic and analytical variability). According to NCEP guidelines, his TG level remains high (200 to 500 mg/dL) and his HDL-C is low (<40 mg/dL) (Table 12-6). The lipid profile obtained during his hospitalization can be interpreted in a normal manner, because it was drawn within 24 hours of his acute coronary event. Profiles drawn after 24 hours are generally lower, however, than pre-event levels and remain so for several weeks.

Based on his recent CHD event, B.C. has a >20% chance of a recurrent CHD event in the next 10 years. He is therefore considered to be a high-risk, CHD risk equivalent patient. Additionally, B.C. has several risk factors for CHD that add to his risk: family history, male >45 years, high BP, and low HDL-C. His fasting blood sugar is defined as impaired fasting glucose (i.e., a fasting value 110 to 126 mg/dL). Some clinicians would consider him to be diabetic, given how close he is to the definition of diabetes (fasting blood sugar >126 mg/dL). Evaluation of HgA1c and a glucose tolerance test are indicated to further define B.C.'s diabetes state.

B.C. was appropriately treated with a statin (as well as antiplatelet, angiotensin-converting enzyme [ACE] inhibitor, and beta-blocker therapy) and a TLC diet and exercise program to achieve an LDL-C <70 mg/dL. In such a high-risk patient, therapeutic interventions should not be delayed. Not only will the initiation of drug treatment in the hospital setting provide risk-reducing benefit, but the patient is more likely to relate this therapy to his acute event and adhere to it.¹⁸⁹

Although B.C. has reached his LDL-C goal, the job of reducing his CHD risk is not complete. The next step is to evaluate the CHD risk associated with the high TG level and, if indicated, develop a plan to address it (Table 12-17).

Relation of Triglycerides to Coronary Heart Disease

25. Does the increased TG level in B.C. indicate an increased CHD risk?

The exact role that TG play in the pathogenesis of CHD is under intense investigation. Most epidemiologic studies have found that a high TG level is an independent risk factor for CHD when evaluated with univariate analysis. When other lipid abnormalities, such as increased LDL-C or low HDL-C, are included in a multivariate analysis, TG often lose their independent predictive power.¹⁹¹ Part of the reason for this is the close interrelationship between lipids. Patients with high TG levels almost always have a low HDL-C, which also predicts CHD risk.^{192,193} In addition, elevated TG levels are associated with increased levels of TG-rich lipoproteins (i.e., remnant VLDL particles) and small, dense LDL particles.^{9,194} These particles are atherogenic and mediate a higher CHD risk than associated with an elevated LDL-C alone.^{195–198} When epidemiologic studies were combined, a meta-analysis found that TG independently predicted CHD risk, even after adjustment for other lipid risk factors.¹⁹⁹ High TG levels are also found in certain familial disorders, including dysbetalipoproteinemia and familial combined hyperlipidemia, which carry increased CHD risk.^{19,200} Additionally, hypertriglyceridemia is associated with a procoagulant state, which promotes coronary thrombosis.¹⁹⁴

Paradoxically, very high TG levels (>500 mg/dL) are not commonly associated with an increased CHD risk, but do cause an increased risk of pancreatitis, especially when levels exceed 1,000 mg/dL. Often, a genetic defect in lipoprotein lipase is present in these cases that impairs the removal of TG from TG-rich particles (VLDL and chylomicrons). These particles do not become enriched with cholesterol and, therefore, are not often atherogenic.^{200,201} If the blood sample is stored in the refrigerator overnight, a thick creamy layer often appears on the surface, indicating the presence of chylomicrons. Although most patients with very high TG remain free of CHD throughout their lives, some develop it.¹⁹¹

On the other hand, patients such as B.C., with TG in the borderline to high range (150 to 500 mg/dL), have an increased CHD risk because they likely have atherogenic TG-rich lipoproteins (Table 12-6). Characteristically, B.C. has a high TG level and a low HDL-C and is likely to also have elevated remnant VLDL-C and small dense LDL levels. This is the profile of atherogenic dyslipidemia described earlier in this chapter and is linked to a high CHD risk. This is exemplified by the placebo groups in the HIT and BIP trials, two studies that included patients with mixed hyperlipidemia. Untreated subjects had CHD event rates of 15% to 22% in 5 to 6 years, respectively.^{110,111}

Atherogenic Dyslipidemia

26. Why does atherogenic dyslipidemia occur? How should the clinician assess and treat atherogenic dyslipidemia?

Patients such as B.C. with borderline high or high TG levels (Table 12-6) secrete large numbers of TG-enriched VLDL particles from the liver. One reason for this is increased levels of nonesterified fatty acids in the systemic circulation that come from adipose cells (especially in patients with central obesity). The liver clears these fatty acids and is stimulated to increase the synthesis of triglycerides.²⁰²

A second reason for the increased secretion of VLDL particles is an upregulation of the gene expression for microsomal

Table 12-17 Treatment Targets for Patients Who Have Achieved Their LDL-C Goal and Have a Triglyceride Level >200 mg/dL and Meet Criteria for the Metabolic Syndrome

| Patient Category | LDL-C Treatment Target | Non-HDL-C Treatment Target | Apolipoprotein B Treatment Target |
|---|------------------------|----------------------------|-----------------------------------|
| CHD or CHD risk equivalent | <100 mg/dL | <130 mg/dL | <90 mg/dL |
| (Reasonable target for patients with CHD) | <70 mg/dL | <100 mg/dL | <70 mg/dL |
| No CHD, >2 risk factors | <130 mg/dL | <160 mg/dL | <110 mg/dL |
| No CHD, <2 risk factors | <160 mg/dL | <190 mg/dL | <130 mg/dL |

CHD, coronary heart disease; HDL, high-density lipoprotein cholesterol; LDL-C, low-density lipoprotein cholesterol.

triglyceride transfer protein (MTP) that is caused by the elevated insulin levels in these patients.²⁰³ MTP is responsible for assembling VLDL particles in the hepatocyte. It brings together TG, cholesterol, and apolipoproteins to form the VLDL particle. This mechanism suggests a molecular basis for the link between insulin resistance and increased VLDL secretion. One way of telling that there are increased numbers of lipoprotein particles in the systemic circulation is to measure apolipoprotein B. One apolipoprotein B is attached to each VLDL and LDL particle. An increased apolipoprotein B level indicates an increased number of particles. Patients with a high apolipoprotein B level have a high risk of CHD.

With the increase in VLDL particles, plasma levels of apolipoprotein C-III also increase. Apolipoprotein C-III has two detrimental effects. It interferes with the normal removal of TG from VLDL by reducing the action of lipoprotein lipase. This reduces lipolysis and increases the concentration of TG in the VLDL particle. The second negative effect of apolipoprotein C-III is an interference with the normal removal of VLDL particles from the circulation via LDL receptors on the hepatocytes.²⁰²

TG-rich VLDL particles interact with other circulating lipoproteins through the action of cholesterol ester transfer protein. Through this protein, a molecule of cholesterol ester is exchanged from circulating HDL and LDL particles for a molecule of TG from VLDL particles. With time, the HDL particles give up >50% of their cholesterol content and become enriched with TG. This results in low HDL-C levels. VLDL becomes more enriched with cholesterol and simultaneously smaller in size, close to the size of LDL, and thus more atherogenic (both because of its smaller size and its higher cholesterol content). LDL particles take on more TG than normal. Subsequently, under the influence of hepatic lipase, TG is removed from LDL particles, leaving a very small particle that is deficient in cholesterol and TG, but is present in great numbers. Because of their small size and concentration, small, dense LDL particles are very atherogenic.

The net result of the above mechanisms is a high VLDL-C, low HDL-C, and increased small, dense LDL, a lipid triad termed *atherogenic dyslipidemia*. How does the clinician measure this in the clinical setting? VLDL-C and VLDL-TG levels are not available from most clinical laboratories, however. Several companies provide measurements of particle size, but these are not widely available and do not yet relate to a reference standard; particle size measurements are best reserved for research purposes at present. The clinician can measure apolipoprotein B as an indicator of the number of atherogenic particles; these levels are available from most clinical laboratories. A much easier, more accessible measure is non-HDL-C.

Non-HDL-C is the product of VLDL-C and LDL-C and is determined by subtracting HDL-C from total cholesterol. NCEP recommends that non-HDL-C be determined in patients who have a TG >200 mg/dL after attaining their LDL-C goal.⁹² Once the patient is at his or her LDL-C goal, any elevation in non-HDL-C will result from an increase in VLDL-C. Because VLDL-C levels are normally <30 mg/dL, non-HDL-C treatment goals are set 30 mg/dL above LDL-C treatment goals (Table 12-17). Included in the same table are alternative apolipoprotein B treatment goals that have been recommended by authorities.²⁰⁴ Note that non-HDL-C levels can be determined from a nonfasting sample measuring only total cholesterol and HDL-C, thus making it very convenient for the clinician to make these measurements any time of the day without regard to food intake.

Secondary Causes of Hypertriglyceridemia

27. In addition to an assessment of B.C.'s lipid profile, what other evaluations should be made?

One of the questions that should be answered routinely when evaluating patients with lipid disorders: Is there a secondary cause of the patient's lipid disorder? Secondary causes of hypertriglyceridemia include chronic renal failure; diabetes mellitus; alcohol use and abuse; a sedentary lifestyle; obesity; and the use of TG-raising drugs, including β -blockers, estrogens, and glucocorticoids (Table 12-7). B.C. has a normal TSH level, normal liver and renal function test results, and a normal urinalysis. His blood glucose is elevated into the impaired fasting glucose range, which can be associated with impaired TG metabolism, as described earlier. In addition, he is overweight, with much of the weight distributed around his waist (i.e., a waist circumference >40 inches). Patients who have truncal obesity often overproduce TG and oversecrete VLDL particles, thereby raising their TG level. The HDL-C is inversely reduced. This would appear to be an important factor affecting TG levels in B.C. A reduction in weight through an exercise program and a low-calorie, low saturated fat, and low-carbohydrate diet would be one of the most effective ways to improve B.C.'s glucose level, raise his HDL-C, and lower his TG level.

Light to moderate alcohol intake, defined as up to two drinks per day (1 drink = 5 oz wine, 12 oz beer, or 1.5 oz 80-proof liquor), as is practiced by B.C., has been associated with lower CHD rates. The observed reduction in CHD among light to moderate alcohol drinkers is consistently on the order of 40% to 60% in epidemiologic trials.^{205,206} Available epidemiologic evidence supports arguments of causality.^{207,208} It is problematic, however, to recommend alcohol consumption for CHD

prevention. From a public health point of view, the adverse consequences of alcohol consumption are great and may outweigh the benefits gained. One known adverse consequence of alcohol consumption is hypertriglyceridemia, especially when alcohol is abused, but it may be seen with only moderate intake as well. Even though B.C.'s alcohol intake appears moderate, it may be contributing to his hypertriglyceridemia, so a period of abstinence is warranted to determine whether this is the case.

Use of a β -blocker could also raise TG levels (Table 12-7) and might be a contributing factor in B.C.'s lipid profile. He already had a high TG level on admission to the hospital before starting propranolol therapy, however. In this case, the beta-blocker is providing an important health benefit that probably outweighs the small risk posed by its effect of TG levels. More probably, B.C.'s weight and impaired glucose are the key factors contributing to his increased TG level and are the logical places to start when attempting to correct secondary causes of elevated TG levels.

Metabolic Syndrome

28. B.C. has a combination of obesity, impaired fasting glucose, and hypertension in addition to atherogenic dyslipidemia. What is the significance of this constellation of findings?

Not only does B.C. have CHD and a combination of lipid abnormalities that substantially raise his risk of CHD, but he also has a number of nonlipid risk factors that raise it as well.²⁰⁹ These factors include obesity, impaired fasting glucose, and hypertension. Most of B.C.'s excess weight is concentrated around his waist. This central distribution of fat may reflect an excess of intra-abdominal fat, which in turn may influence the development of atherogenic dyslipidemia, as already described.²¹⁰ An increased outflow of fatty acids from intra-abdominal TG stores may provide the substrate for increased hepatic TG synthesis and VLDL secretion. This could explain B.C.'s elevated TG level.

Abdominal obesity also is strongly associated with insulin resistance.^{202,211} Insulin resistance leads to mild hyperglycemia, and the pancreas responds by increasing insulin secretion; hyperinsulinemia results.^{212,213} Some genetically predisposed patients are not able to secrete sufficient insulin to overcome this resistance and they develop impaired glucose metabolism or diabetes. The presence of a fasting blood sugar between 110 and 126 mg/dL in B.C. suggests impaired glucose metabolism and probably insulin resistance (with hyperinsulinemia).²¹⁴

B.C. has hypertension. The beta-blocker and ACE inhibitor he is receiving to reduce his CHD risk also help lower his blood pressure. According to the most recent guidelines, B.C. still has stage I hypertension (systolic BP 140 to 159 mm Hg); his untreated BP may be higher.²¹⁵ Before concluding inadequate BP control, however, BP readings should be obtained on at least two other occasions and adherence to therapy documented. Abdominal obesity and insulin resistance also are commonly associated with high BP and could be a factor in B.C.^{216,217} The exact mechanisms for this remain speculative.

What emerges from the preceding discussion is the strong possibility that B.C.'s risk factors are not independent, but rather represent a constellation of medical problems that have a common pathway. This pathway may be related to insulin resistance.^{216,218} NCEP called this constellation the *metabolic*

Table 12-18 Clinical Identification of the Metabolic Syndrome

Presence of any three of the following:

| | |
|--|--|
| • Waist Circumference | |
| • Men | ≥40 inches (>35 inches for Asian-Americans) |
| • Women | ≥35 inches (>31 inches for Asian-Americans) |
| • Triglycerides | ≥150 mg/dL (or on drug treatment for elevated triglycerides) |
| • High-density lipoprotein cholesterol (HDL-C) | |
| • Men | <40 mg/dL (or on drug treatment for reduced HDL-C) |
| • Women | <50 mg/dL (or on drug treatment for reduced HDL-C) |
| • Blood pressure (systolic/diastolic) | ≥130/≥85 (or on drug treatment for hypertension) |
| • Fasting glucose | >110 mg/dL (or on drug treatment for elevated glucose) |

syndrome.⁹² Other names given the same problem in the literature are *syndrome X*, *the deadly quadrangle*, *insulin resistance syndrome*, and *Reaven's syndrome*.^{197,198,207,213,216,218} Metabolic syndrome is diagnosed when any three of the factors listed in Table 12-18 are present. The syndrome is associated with a substantial increase in CHD risk; the exact level of risk should be determined by using the risk-scoring charts in Figure 12-7. B.C. has the metabolic syndrome by having met all five criteria in Table 12-18. Weight loss, especially loss of visceral abdominal adiposity, will be the centerpiece of his nondrug treatment program. The goal is for weight reduction to correct, or at least substantially improve, his blood glucose, TG, and HDL-C levels and BP.

Hypertension Management With Atherogenic Dyslipidemia

29. If B.C.'s BP elevation persists after lifestyle changes are made, how should he be treated?

Consideration of antihypertensive therapy in a patient with dyslipidemia should take into account how BP-modifying drugs affect blood lipids. As noted above, the propranolol B.C. is receiving can elevate TG levels, but the benefit in post-MI prophylaxis warrants its continued use.²¹⁵ Substitution of a β -blocker with intrinsic sympathomimetic activity (e.g., pindolol) or a mixed alpha-beta-blocker (e.g., labetalol) may have less adverse effect on lipids (Table 12-7), but their benefits for post-MI prophylaxis are unproved.

The ACE inhibitor B.C. currently is receiving for his hypertension has a neutral effect on serum lipids. His BP is not under good control, however, so an adjustment to his antihypertensive regimen is in order. One of the best drugs to reduce BP in patients receiving an ACE inhibitor is a thiazide diuretic.²¹⁵ Although thiazides can increase blood cholesterol levels (Table 12-7), these effects usually are small, especially with long-term use. The thiazide dose should be kept low (i.e., 12.5 mg/day) to minimize the effect on his blood lipids. Calcium channel blockers (e.g., ACE inhibitors) are lipid neutral and are possible alternatives to a thiazide.

Treatment of the Metabolic Syndrome CHOLESTEROL-LOWERING AND WEIGHT-LOSS DIET

30. What nondrug therapies should be implemented to help B.C. achieve his treatment goals?

B.C. needs to lose weight in addition to lowering his LDL-C and non-HDL-C levels. Effective weight loss and subsequent weight maintenance could substantially or fully correct his atherogenic dyslipidemia, lower his BP, reduce his waist circumference, and correct his blood glucose. He has already shown progress, having lost 10 pounds since his MI 3 months ago. He appears to be following a low-fat diet, which undoubtedly has helped him lose weight. He needs to lose more weight and needs to modify his lipids further, however. A more rigorous restriction of saturated fats might help him accomplish these goals. This will also substantially reduce total daily calories, because fats contain 9 calories/g. Restriction of saturated fat calories will encourage weight loss and will reduce TG levels; however, it may also reduce HDL-C levels. If saturated fat calories are replaced with polyunsaturated fats, HDL-C usually does not change and may increase. An increase in carbohydrate intake will increase TG and may cause weight gain. Therefore, in a weight-loss diet for the metabolic syndrome, saturated fats and carbohydrates should generally both be restricted. This level of complexity supports the involvement of a registered dietician who can provide expert advice and practical meal planning.

DRUG THERAPY FOR THE METABOLIC SYNDROME

31. If weight loss and an exercise program are insufficient to fully correct B.C.'s lipid disorder, it is appropriate to consider drug therapy. What lipid-modulating drugs should be considered?

In patients with the metabolic syndrome and not at their non-HDL-C goal, four drugs are used: statins, statins combined with ezetimibe, niacin, or a fibrate. The statin combined with ezetimibe given to B.C. has achieved his primary treatment goal, an LDL-C <70 mg/dL. It has also reduced his TG level about 30% and raised his HDL-C level modestly, both typical effects of statins. His non-HDL-C is 110 mg/dL (goal <100 mg/dL). The reduction in non-HDL-C with each dose doubling of a statin is about 6%. Thus, an increase in the daily dose of simvastatin from 40 mg to 80 mg per day would be expected to reduce B.C.'s non-HDL-C level from 110 mg/dL to approximately 103 mg/dL, not likely sufficient to achieve his non-HDL-C goal of <100 mg/dL (Table 12-17). A more potent statin, such as atorvastatin or rosuvastatin, lowers LDL-C, non-HDL-C, and TG more than simvastatin and may achieve B.C.'s treatment goal with daily doses of 40 to 80 mg or 10 to 20 mg, respectively.

An alternative is to add a third drug (niacin, bile acid resin, or fibrate) to his simvastatin and ezetimibe to achieve the non-HDL-C treatment goal. Adding another drug, however, can increase side effects while adding complexity to, and increasing cost of, the regimen.

The bile acid resins will add 10% to 20% additional LDL-C lowering when added to a statin; non-HDL-C will be lowered nearly as much. Much of the reduction in non-HDL-C will be from a reduction in LDL-C, however. VLDL-C and TG levels may not change or may even increase with a bile acid resin.

This effect of resins is most pronounced in patients such as B.C. with hypertriglyceridemia.

Niacin generally enhances VLDL-C and TG lowering (up to double the amount) and substantially increases HDL-C levels when added to a statin.²¹⁹ The effects on VLDL-C, TG, and HDL-C with niacin follow a curvilinear pattern such that substantial changes in these parameters can be achieved with modest daily doses of niacin (1 to 1.5 g/day) (Fig. 12-8). Thus, when niacin is added to a statin, it need not be titrated to maximal doses, which might in turn increase patient tolerance of niacin. In one study, the addition of 750 mg/day of niacin to simvastatin extended the reduction in TG from 26% to 31% and in VLDL-C from 28% to 44%, while increasing HDL-C from 13% to 31%.²²⁰ The principal concern with niacin in patients with the metabolic syndrome is its potential to worsen glucose metabolism. Several recent studies in subjects with and without diabetes have shown that niacin causes transient increases in fasting glucose and glycosylated hemoglobin levels in about a third of patients. These increases return to baseline levels in about 6 weeks, presumably because of adjustments made to the subject's diabetic therapy.^{204,221} Investigators with the Coronary Drug Project reported that fasting and 1-hour postprandial blood glucose levels were increased in patients assigned to niacin, but this metabolic change did not adversely affect CHD risk reduction. In fact, nonfatal MI after 6 years of therapy and all-cause death after 15 years of therapy was reduced by 11% and 9%, respectively, among study patients with a 1-hour postprandial glucose of <140 mg/dL compared with reductions of 21% and 14% among patients with a 1-hour postprandial glucose of >220 mg/dL.²²² Nonetheless, it is important to use appropriate doses of insulin or oral hypoglycemics in patient with inadequately controlled diabetes.

FIBRIC ACID DERIVATIVES

32. What are the characteristics of gemfibrozil and fenofibrate that would qualify either drug for use in B.C.?

Clinical Use

Gemfibrozil (Lopid) and fenofibrate (TriCor) (and the other fibric acid derivative available in the United States, clofibrate [Atromid S]) lower TG levels by 20% to 50% and in patients with hypertriglyceridemia, raise HDL-C by 10% to 15%.^{223–227} (Table 12-16). Gemfibrozil generally lowers LDL-C by 10% to 15%, but in patients with both hypercholesterolemia and hypertriglyceridemia it may have no effect on (or may actually increase) LDL-C levels. Fenofibrate lowers LDL-C by 15% to 25%.²²⁸ This effect is blunted in patients with combined hypercholesterolemia and hypertriglyceridemia, but an LDL-C reduction of 10% to 15% is still expected.^{223,224,228,229}

Gemfibrozil and fenofibrate are both indicated for the reduction of TG levels in patients with hypertriglyceridemia.²¹⁹ In patients who have TG levels >1,000 mg/dL and are at risk for developing pancreatitis, fibrates, along with niacin, are the drugs of choice. Similarly, in patients with familial dysbetalipoproteinemia, fibric acid derivatives are highly effective and are considered the drugs of choice. Fibrates also have a place in the management of combined or mixed hyperlipidemia. Support for this comes primarily from the results of the Helsinki Heart Study and the HIT trials, in which gemfibrozil combined with diet therapy was associated with a reduction in CHD

deaths and nonfatal MI.^{107,109} These positive outcomes are attributed to significant reductions in serum TG (and, therefore, a reduction in TG-rich VLDL remnants and in small, dense LDL) and an increase in HDL-C. Persons most likely to benefit are those with diabetes or the lipid triad found in patients with the metabolic syndrome.^{230,231}

Mechanism of Action

Fibrates activate peroxisome proliferator-activated receptors alpha (PPAR α), which explains most of their effects on blood lipids.²³² PPAR α receptors are located in the nucleus of cells and are ligand-dependent transcription factors that regulate target gene expression. Stimulation of PPAR α suppresses the gene responsible for synthesis of apolipoprotein C-III and stimulates the gene responsible for LDL receptor synthesis.^{232,233} As a result, lipolysis of TG from VLDL particles and the removal of these particles via hepatic LDL receptors is enhanced. Stimulation of PPAR α also increases fatty acid oxidation, which reduces the synthesis of TG in the liver, and this in turn reduces the TG content of secreted VLDL particles.²³³ Stimulation of PPAR α may increase the synthesis of apolipoprotein A-1, the critical building block of nascent HDL, thereby enhancing reverse cholesterol transport. Research also suggests that fibrates stimulate the expression of ABC₁ transporters in macrophage cells, which are responsible for bringing cholesterol from within the cell to the cell surface, where it can be taken up by nascent HDL particles and removed from these cells.²³²

Adverse Effects

33. Gemfibrozil and fenofibrate appear to have a similar mechanism of action. What factors might lead to choice of one agent over the other?

Gemfibrozil and fenofibrate are usually well tolerated. Gemfibrozil causes mild GI symptoms (nausea, dyspepsia, abdominal pain) in about one third of patients. Fenofibrate causes a rash in 2% to 4% of patients. Fibrate therapy can also cause muscle side effects, including myositis and rhabdomyolysis.²³⁴ Most cases of muscle toxicity have been reported with gemfibrozil, especially when it is used in combination with a statin. Recent studies reveal that the area under the blood-concentration curve of most statins is increased two- to fourfold when given concurrently with gemfibrozil. These effects are not seen with fenofibrate. The mechanism causing this interaction appears to be related to an interference by gemfibrozil with the glucuronidation of statins and thereby a reduction in statin renal clearance from the systemic circulation.^{235,236} This supports the preferential use of fenofibrate over gemfibrozil when a combination with a statin is indicated in managing cases such as B.C. with a mixed hyperlipidemia. Patients who receive gemfibrozil or fenofibrate therapy alone or in combination with a statin should be monitored for symptoms of muscle soreness and pain. If these symptoms emerge, a CPK level should be obtained. A CPK level >10 times the upper limit of normal, along with muscle symptoms, supports a diagnosis of myositis. The presence of myositis is an indication to withdraw fibrate therapy, provided other possible causes are not apparent, such as increased physical exercise or a recent trauma or fall.

Gemfibrozil increases biliary secretion of cholesterol, which increases the lithogenicity of bile and results in the devel-

opment of cholesterol gallstones. Presumably, the same effect occurs with all fibrates.

The results of three major primary prevention trials have raised questions about the safety of fibrates. In the World Health Organization trial, clofibrate reduced nonfatal MI by 25%, but caused an increase in total mortality.^{237,238} As a result, its use has declined markedly in the United States. Some of these deaths may have been related to gallstone disease.²³⁷ In the Helsinki Heart Study, gemfibrozil reduced fatal and nonfatal MI by 37%, but was associated with a slight increase in non-CHD mortality such that there was no net reduction in total mortality.¹⁰⁸ In a 3.5-year follow-up to this study, total mortality in patients given gemfibrozil was increased because of an increase in non-CHD mortality. Follow-up evaluations of nongemfibrozil therapies were associated with continued event reduction.¹¹² In the HIT trial, death from CHD was significantly reduced by 22% with gemfibrozil, but total mortality was not.¹⁰⁹ In the FIELD study, fenofibrate did not significantly reduce CHD deaths and nonfatal MI compared with placebo. In addition, more patients receiving fenofibrate had pancreatitis or a pulmonary embolism compared with those given placebo.¹¹¹ Fenofibrate was also evaluated against placebo in 418 patients with diabetes and at least one visible lesion on angiographic evaluation in the DAIS trial.²³⁹ The trial was not powered to examine clinical endpoints, but fewer events, including deaths, occurred in the fenofibrate group. Taken together, the clinical trial evidence for the fibric acid derivatives is not as robust as with the statins. The data supporting the use of gemfibrozil in the primary and secondary prevention setting has been established. In contrast, clear improvements in CHD-related outcomes is still lacking for fenofibrate. Thus, these data support the use of fibric acid derivatives as second-line agents, with the exception in patients with hypertriglyceridemia.

DRUG SELECTION FOR MANAGING ATHEROGENIC DYSLIPIDEMIA

34. Given these considerations, what drugs are indicated for B.C.?

One approach would be to replace simvastatin with atorvastatin or rosuvastatin, as mentioned previously. This should attain both the LDL-C and non-HDL-C goals. Alternatively, consideration could be given to adding a TG-lowering (i.e., non-HDL-C lowering) drug such as niacin or fenofibrate. Gemfibrozil should be avoided, given its documented pharmacodynamic drug interaction with statins and the increased risk of muscle toxicity. Both niacin and fenofibrate effectively lower TG by 30% to 50%; more importantly, they reduce VLDL-C and small dense LDL and raise HDL-C (Table 12-16). Both alter the mechanisms responsible for atherogenic dyslipidemia, although the effect of PPAR α agonism has a broader and more fundamental effect on these mechanisms. Fibrate therapy is not likely to worsen B.C.'s impaired fasting glucose, whereas niacin might do so. Fenofibrate is certainly more tolerable than niacin: About 30% of niacin-treated patients cannot tolerate its vasodilatory side effects. Niacin is less expensive and has demonstrated CHD risk reduction alone or together with a statin in major clinical trials. Given these considerations, it is obvious that there is no one correct choice; the choice will be based on individual preferences.

INITIATING COMBINATION DRUG THERAPY FOR ATHEROGENIC DYSLIPIDEMIA

35. How should combined therapy with a statin and fenofibrate be initiated in B.C.? What monitoring is required?

Fenofibrate can be added as a 200-mg/day capsule and the lipid profile rechecked in 6 to 8 weeks. A lower daily dose of 67 mg should be selected for patients with impaired renal function and in patients >65 years, because creatine clearance declines with older age. As with all lipid-altering therapies, patients should be instructed on the purpose of the medication and its expected effects on blood lipids and on CHD risk reduction. They should be encouraged to remain adherent with the regimen to sustain its effects on serum lipids and, thereby, attain its CHD risk-reducing benefit. Withdrawal, even after a long period of consistent cholesterol control, will likely result in a return of blood lipids to pretreatment levels. Patients should be counseled to call a health professional if they experience any untoward symptoms, especially muscle soreness or discomfort or a rash. A CPK level should be obtained whenever a patient experiences symptoms of myositis (muscle soreness and aches).

LOW HDL-C

36. J.M. is a 59-year-old man who has no history of CHD or a CHD risk equivalent. He has no known medical problems. He does not smoke. His mother had an ischemic episode at age 70 and subsequently had coronary artery bypass surgery. There is no other family history of CHD. J.M. eats a diet low in saturated fat and is sedentary. His physical examination is unremarkable: BP, 122/82 mm Hg, heart rate, 66 regular. He weighs 206 lb and is 6 feet tall (BMI 28). His laboratory values are fasting blood glucose, 80 mg/dL; total cholesterol, 137 mg/dL; LDL-C, 84 mg/dL; TG, 120 mg/dL; HDL-C, 29 mg/dL. Should J.M. be treated for his low HDL-C?

J.M. has two CHD risk factors (age and low HDL) and a LDL-C goal of <130 mg/dL. His NCEP CHD risk is 6% in 10 years, mostly because of his age. His LDL-C is well within his treatment goal. His TG are in the normal range. Epidemiologic studies clearly link low HDL-C with increased CHD events, especially in those over age 50. These studies show that a 1% decrease in HDL-C is associated with a 1% to 2% increase in CHD risk. Most commonly, low HDL-C is secondary to a number of lifestyle and medical conditions (Table 12-19). Of these conditions, overweight, physical inactivity, and a diet very low in fat may play a part in J.M.'s low HDL-C. Patients who substantially restrict saturated fats have lower HDL-C levels as well as LDL-C. A careful dietary history would be important to determine whether this is occurring with J.M. Vegetarians who have a low LDL-C and low BP have a low CHD risk despite having a low HDL-C. Increasing intake of monounsaturated fats and lowering carbohydrate intake is one maneuver to raise HDL-C. An obvious approach to improving J.M.'s HDL-C is to encourage him to increase his physical activity.

In addition to secondary causes, there are rare primary (genetic) causes of low HDL-C. Some are associated with increased CHD risk, whereas others are not. Tangier disease is associated with a reduction in the ABC₁ transporter that moves cholesterol out of peripheral cells. Patients with Tangier disease have characteristic orange tonsils as well as splenomegaly

Table 12-19 Factors Causing Low HDL-C

Secondary Causes

- Hypertriglyceridemia
- Obesity (visceral fat)
- Physical inactivity
- Type 2 diabetes
- Smoking
- Very-low-fat diet
- Drugs
 - β -blockers
 - Androgenic steroids
 - Androgenic progestins

Primary (Genetic) Causes

- Apo A-1
 - Apo A-1 mutations (e.g., ApoA-1_{Milano})
- LCAT
 - Complete LCAT deficiency
 - Partial LCAT deficiency (fish-eye disease)
- ABC A-1
 - Tangier disease
 - Familial hypoalphalipoproteinemia (some families)
- Unknown genetic etiology
 - Familial hypoalphalipoproteinemia (most families)
 - Familial combined hyperlipidemia with low HDL-C
 - Metabolic syndrome

ABC A-1, adenosine triphosphate binding cassette A-1; Apo A, apolipoproteins; HDL-C, High-density lipoprotein cholesterol; LCAT, lecithin-cholesterol acyl transferase.

and neuropathy. Fish-eye disease is characterized by corneal opacification and an HDL deficiency. About a third of patients with fish-eye develop CHD. Patients with apolipoprotein A-1_{Milano} have very low HDL-C levels, but live well into their ninetieth decade, apparently because their reverse cholesterol transport is very efficient. J.M. does not appear to have any of these disorders. Importantly, he also does not have a family history of premature CHD. This suggests that his low HDL-C is not caused by a genetic abnormality associated with an increased CHD risk.

What makes cases of patients such as J.M. difficult to manage is that little clinical trial evidence indicates that raising low levels of HDL-C with diet or drugs will reduce CHD risk. Part of the problem is that no effective drugs substantially and specifically increase HDL-C. Niacin has the most substantial raising effect (mean increases of 25% to 35%). Fibrates also raise HDL-C by 10% to 20%, but they may also raise LDL-C in patients with hypertriglyceridemia. The available evidence indicates that aggressive LDL-C lowering is the most powerful way to reduce CHD risk in patients with low HDL-C. In fact, the lower the HDL-C level, the greater the CHD risk reduction with statin therapy.²⁴⁰ Based on this evidence, NCEP recommended aggressive LDL-C lowering with a statin in patients with a low HDL-C.⁹² In cases of isolated low HDL-C (without hypertriglyceridemia), NCEP recommended lifestyle modification with weight reduction and increased physical activity and the empiric use of HDL-C-raising drugs (niacin or a fibrate), if indicated, to reduce CHD risk.⁹²

It would be prudent to encourage J.M. to lose weight and especially to adopt a more physically active lifestyle. This will help his overall well-being. Because he lacks a family history

Table 12-20 Randomized Clinical Trials of Vitamin E Supplementation and CHD Events

| Investigator/Reference | Number of Subjects | Vitamin E Dose (U) | Population | Follow-Up (yrs) | Relative Risk |
|-------------------------|--------------------|---|------------------------------|-----------------|---------------|
| Rapola ²⁴⁷ | 29,133 | 50 | Males, no CHD | 4.7 | 0.9 (NS) |
| Stephens ²⁴⁸ | 2,002 | 400 and 800 | Males and females, with CHD | 1.4 | 0.53 |
| Vitamo | 27,271 | 50 | Males, no CHD | 6.1 | 0.98 (NS) |
| GISSI ¹⁷⁵ | 2,830 | 300 | Males and females, with CHD | 3.5 | 0.95 (NS) |
| HOPE ²⁴⁹ | 9,541 | 400 | Males and females, high risk | 4.5 | 1.05 (NS) |
| HPS ⁹¹ | 20,536 | 600 (+ vitamin C and β -carotene) | Males and females, with CHD | 5.0 | 1.02 (NS) |

CHD, coronary heart disease; NS, not significant.

of premature CHD or associated CHD risk factors, his CHD risk would appear to be low and not supportive of an aggressive effort to raise his low HDL-C. If he did have a family history of premature CHD, a more aggressive approach, particularly with increased physical activity and possibly niacin therapy, would be advisable.

ANTIOXIDANT THERAPY

37. Should antioxidants, such as vitamin E or beta-carotene, be considered in the management of hyperlipidemic patients, especially patients who have developed CHD?

Only oxidized (or otherwise modified) LDL is taken up by macrophage cells in the initial phase of atherogenesis. This observation has led to the supposition that drugs that have antioxidant properties might reduce or block the development of atherosclerosis. Vitamins E, C, and beta-carotene (the precursor of vitamin A) have antioxidant properties and have been variably recommended to prevent CHD.²⁴¹

Studies in hypercholesterolemic animals have demonstrated that antioxidants, such as probucol, can reduce the development of atherosclerosis.^{241,242} In humans, oxidized LDL-C has been detected in atheromatous lesions, and circulating antibodies to oxidized LDL have also been detected.^{243,244} In epidemiologic studies, people who frequently used beta-carotene and vitamin E had 35% to 50% fewer CHD events.^{245,246} When the hypothesis that antioxidant therapy will prevent CHD events was tested in well-controlled, randomized clinical trials, however, no benefit was observed. For example, vitamin E, whether administered in low, moderate, and high daily doses, either as monotherapy or combined with other antioxidants, failed to demonstrate a CHD risk-reducing effect during clinical trials involving close to 100,000 patients (Table 12-20).^{91,175,247–249}

The latest, and one of the largest of these trials, the Heart Protection Study, prescribed vitamin E (600 U) plus beta-carotene or placebo daily for 5 years to 20,536 high-risk individuals. No demonstrable benefit was shown, whether measured as CHD death, nonfatal MI, stroke, or revascularization procedures and whether or not the study population had a history of CHD, stroke, peripheral vascular disease, or diabetes. Further, no change was seen in the incidence of cancer, another claim of potential benefit for antioxidant therapy. These results effectively close the door on the use of antioxidant therapy for the prevention of CHD events. Future randomized clinical trials will have to demonstrate a benefit before these products can be recommended.

HYPERCHYLOMICRONEMIA

38. M.B., an asymptomatic woman, is screened with a lipoprotein profile during an annual physical evaluation by her primary care provider. She has non-insulin-dependent diabetes, which is treated with 60 U/day of NPH insulin. M.B. is approximately 20% overweight. Her fasting lipoprotein profile is total cholesterol, 234 mg/dL; TG, 2,300 mg/dL; HDL-C, 24 mg/dL; and LDL-C (direct measured), 160 mg/dL. Fasting blood glucose is 290 mg/dL.

What is the assessment of M.B.'s CHD risk, and what treatment, if any, should she be given?

[SI units: total cholesterol, 6.05 mmol/L; TG, 25.97 mmol/L; and HDL-C, 0.62 mmol/L]

Patients with fasting TG >500 mg/dL have an increase in TG-rich chylomicron and VLDL particles. TG elevations of this magnitude typically increase the risk of pancreatitis, but usually not atherosclerosis and CHD. On the other hand, patients with type II diabetes have a high CHD risk. Thus, it is possible that M.B. has two lipid disorders, one causing hyperchylomicronemia and a second causing the typical pattern of atherogenic dyslipidemia. There is no way of knowing whether M.B. has atherogenic dyslipidemia until her TG levels are lowered. Because of the life-threatening nature of TG levels of this magnitude, the priority in treating this patient is to first lower her TG to as close to normal as possible, then assess her LDL.

Most likely, she has an inherited deficiency of lipoprotein lipase, which is the most common cause of very high TG levels. TG levels this high can also be triggered by uncontrolled diabetes mellitus, alcohol abuse, obesity, or drugs, including estrogens, beta-blockers, and steroids. Treatment of these patients should be aggressive. One of the first steps is to improve her diabetes control, because this alone may normalize lipid levels. A TG-lowering diet (severe carbohydrate restriction), fish oil supplementation, and drug therapy (gemfibrozil or fenofibrate or niacin) should be initiated. If the patient has symptoms of pancreatitis, she should be treated in the hospital. In the absence of symptoms, outpatient management is possible, but frequent follow-up and aggressive therapy are indicated. Once the TG level is reduced to <400 mg/dL, a calculated LDL-C can be determined; if it is >100 mg/dL, therapy with a statin or other suitable lipid-modifying agent should be initiated to achieve a LDL-C level <100 mg/dL.
