It is worthwhile to look at the business aspects of the illicit drug trade to gain some perspective on the accuracy of historical information provided by the patient. The supply of drugs to the illicit marketplace is subject to the demand for such commodities and obeys laws of economics just as other businesses. Nevertheless, some notable differences exist. There is no quality control at illicit drug laboratories such as that mandated by the US Food and Drug Administration (FDA) for legally sanctioned pharmaceutical manufacturers. Premarketing research for efficacy and safety is not of concern to illicit drug laboratories. The chemicals that the underground chemist must use to synthesize the desired products are to some degree controlled and monitored by the "narcs" (law enforcement officers, specifically plainclothes narcotics officers). As a particular drug synthesis process becomes known to law enforcement authorities, the sale of the required chemicals becomes restricted, and the illicit drug chemists will use alternate methods of synthesis, sometimes with unpredictable results. The dealer (drug seller) is generally attempting to maximize profits and may dilute the relatively expensive drug with cheaper sugars, local anesthetics, and other substances. Frequently, a cheaper or more readily available chemical is substituted for the one desired by the customer (e.g., ephedrine sold as amphetamine). Generally, substituted drugs are in the same pharmacologic class; otherwise, the customer would not obtain the desired psychic effect and would not purchase more drug from that dealer. Nor will a dealer wish to put any acutely toxic chemical in the drugs sold because such an action discourages further purchases.

Despite a trend toward drugs of higher purity in the illicit marketplace, clinicians should be aware that the patients often do not really know which drug they have taken. Any history obtained from users concerning drug use should be substantiated by looking for the expected physical symptoms and obtaining appropriate laboratory studies. Any paraphernalia, such as syringes or drug samples, brought to the clinician may provide valuable evidence to explain a pathologic state. Needles should be considered infectious and should never be handled; they should be promptly discarded into appropriate needle disposal boxes.

URINE SCREENING

1. J.R., who is applying for a new job, has been told that his pre-employment physical will include a urine drug screen. He is worried because for the past 6 months he has been smoking one joint (i.e., cigarette) of marijuana per day, using cocaine twice per week, and drinking a half-pint of brandy to sleep on the days when he has been using cocaine. He last used these drugs 1 week

ago. Now he wants to know if he can cleanse his urine of drugs in 2 days by drinking lots of water and exercising heavily. What is a reasonable answer to his question?

Drug users try several methods to avoid detection of illicit drugs in their urine. In addition to exercise and hydration, attempts at enhancing excretion include taking diuretics (attempted forced diuresis), drinking vinegar or cranberry juice; taking vitamin C (attempted pH manipulation for ion trapping of drugs in the urine and enhancing excretion); taking saunas (attempted hastening of drug elimination from fat stores); buying clean urine from a drug-free individual (assumes that the urine collection is unobserved so the switching of samples can be accomplished); and adding bleach, isopropanol, or salt (NaCl) to the urine sample (inactivates the enzymes used by the popular immunoassay "urine drug screen" systems). Commercial products specifically created for the purpose of adulterating urine samples ("Urinaid," "Urine Luck," "Klear") are widely available in head shops (commercial establishments that sell drug paraphernalia) and on the internet. These products either destroy the drug or interfere with the assay. Most of these methods are derived from research literature describing the immunoassay techniques. Although each of the above techniques may decrease the urinary concentration of a drug to some small degree, none of these methods will enhance the total body clearance of drug. Dehydration (e.g., from diuretics) may actually increase the effective drug concentration in the urine, allowing easier detection. Forced fluid administration, resulting in a greatly increased output of dilute urine, or adding water to the specimen in an effort to lower the drug concentration below the cutoff level of the assay may result in a false-negative result, but this technique is often detected by the laboratory by measuring the creatine concentration and the specific gravity of the urine.³

The immunoassay techniques used for drug detection are not 100% accurate. Several medications (over-the-counter and prescription), foods, and workplace chemicals are cross-reactive and may produce false-positive results for certain intoxicating drugs. For example, diphenhydramine and quetiapine in the urine can cause a false-positive result for methadone, cloxacillin may test positive for benzodiazepines, fluoroquinolones may cross-react with assays for opiates, efavirenz may cause a false-positive result for marijuana, ephedrine may cause a false-positive test result for amphetamines, and tramadol and venlafaxine have caused false-positive test findings for phencyclidine.³⁻⁸ Current product information should be studied for specific test systems, which are constantly being altered to minimize spurious results.

Many factors influence the length of time a drug can be detected in body fluids (e.g., individual metabolism and excretion rates); therefore, drug detection periods are rough estimates. Urine tests for most drugs of abuse are usually negative within a week of the last use. Heavy, chronic use of marijuana or phencyclidine may, however, produce positive urine results for up to several weeks.⁹ Drug testing does not pick up sporadic use that falls outside of these ranges, nor does it indicate chronicity of use. A positive test obtained by random screening is as likely to represent first-time use as it is chronic use.¹⁰ Drug test results should be interpreted only by persons familiar with the laboratory technology and the pharmacokinetics of the drugs being tested.

Hair, saliva, and sweat testing for abused drugs is gaining popularity. Abused drugs can be detected for a longer time in hair. A question of racial bias in hair testing has been raised because the coarse hair of some blacks may absorb proportionately more cocaine than the hair of whites.¹⁰ Commercial products to clean the hair and saliva have also become available to beat these drug tests.¹¹

Passive exposure to drugs resulting in a positive urine test is possible but highly improbable. It would take exposure to the smoke from 30 marijuana joints in a small, unventilated space to produce a positive urine drug screen.³ Passive exposure to drugs may be problematic, however, with the hair testing method.¹⁰

Therefore, J.R.'s urine is likely to be positive only for marijuana when he is tested, assuming he uses no drugs in the meantime. Forced fluids and exercise will not affect his urinary drug tests.

OPIOIDS

Abuse of opioids includes illicit drugs, such as heroin, and the nonmedical use of prescription pain relievers. According to the Drug Enforcement Administration (DEA), prescription pain relievers appear to be increasingly diverted from legitimate and illegitimate sources of supply via the internet.¹² In the 2006 National Survey on Drug Use and Health, the rate of past month and past year use among persons aged 12 years or older reporting nonmedical use of pain relievers was second only to marijuana and far surpassed those of cocaine and heroin. The survey reported 5.2 million Americans had used prescription pain relievers nonmedically in the past month.¹³ Diverted oxycodone is generally sold as 20- or 40-mg tablets at \$1 per milligram.¹⁴

Heroin

2. D.J., age 28, has been “fixing” (injecting) two “quarter bags” (\$25 worth) of “junk” (heroin sold on the street) daily for about a month. This “run” (daily use) began when he met a new “connection” (drug supplier) at a party. D.J. describes a steady supply of “Mexican tar.” He explains he began smoking the heroin but has now progressed to injecting. What is “Mexican tar”?

Over the past 2 decades, a dramatic shift occurred in the heroin market in the United States. Southeast Asia, formerly the dominant supplier, has been replaced by South America, particularly in the East, and in the West, “Mexican tar” or “black tar” heroin from Mexico is the predominant form. The South American heroin (sold as a white powder) is frequently >90% pure, and this has resulted in increased availability of high-purity heroin from all sources. According to the Office of National Drug Control Policy, South American heroin ranges from 40% to 95% pure, and Mexican black tar heroin ranges from 5% to 64% pure.¹⁴ This has led to a new, younger user population, who can smoke or snort this high-purity heroin and avoid the stigma and hazards associated with needle use. As the addiction progresses and the user's “habit” (amount used daily) increases, however, the user will often begin injecting the drug. The DEA estimates there are roughly 800,000 heroin addicts in the United States. The 2006 National Survey on Drug Use and Health, which does not survey institutionalized populations, found the number of current heroin users in the

United States had increased from 136,000 in 2005 to 338,000 in 2006.¹³

Heroin is often sold in glassine bags referred to as “dime” (\$10) or “quarter” (\$25) bags. A dime bag contains 40 to 50 mg of heroin.¹⁵ Mexican tar, which looks and feels like sticky black roofing tar, is sold as a gummy, pasty chunk, the size of a matchhead, which is enough for two to five doses. The cost of a chunk of Mexican tar this size is \$20 to \$25. The cost of heroin dependence can range from \$20 to \$200/day, depending on the level of use.

Heroin Addiction

3. D.J. developed a “big habit” (tolerance developed, and his daily requirement of drug to maintain euphoria had increased). He could not “hustle” (obtain by any means) any more cash on a daily basis. When he tried “kicking” (abrupt cessation of drug use) the drug “cold turkey” (without any therapy for withdrawal symptoms), he became “dope sick” (typical heroin withdrawal symptoms), which was extremely unpleasant. He has been “chipping” (using only occasionally) since his withdrawal. Is D.J. “hooked” (addicted)?

Abstinence precipitated a withdrawal syndrome in D.J.; therefore, he is by definition physically addicted to heroin. The powerful ability of the drug to rapidly alleviate withdrawal symptoms results in reinforcement to continue using the drug. D.J.'s ongoing desire to continue using heroin despite his inability to afford it and his all-day hustling constitutes a psychological dependence on heroin.

Noticeable opioid physical dependence is highly variable, but it is assumed that the potential for an abstinence syndrome exists after repeated administration for only a few days.¹⁶

Opioid Withdrawal

4. D.J. arrives at the detoxification clinic 10 hours after his last dose of heroin. He is sweating and shaking and keeps yawning. Should he be treated for opioid withdrawal?

Six to 12 hours after the last dose of morphine or heroin (diacetylmorphine), patients addicted to heroin will typically develop symptoms of anxiety, hyperactivity, restlessness, and insomnia with yawning, sialorrhea, rhinorrhea, and lacrimation. There may also be profuse diaphoresis with concurrent shaking chills and pilomotor activity resulting in waves of gooseflesh of the skin (thus, the term “cold turkey”). Anorexia, nausea, vomiting, abdominal cramps, and diarrhea may occur. Severe back pain may accompany muscle spasms that cause kicking movements (“kicking the habit”). These symptoms are most severe 48 to 72 hours after the last opioid dose. D.J. is exhibiting typical heroin withdrawal symptoms, and supportive therapy would be appropriate.

During withdrawal, the heart rate and blood pressure may be elevated. Failure to take in food and fluids, combined with vomiting, sweating, and diarrhea, can result in marked weight loss, dehydration, ketosis, and acid-base imbalance. Rarely, cardiovascular collapse has occurred during the peak phase of opiate withdrawal.

The more dramatic symptoms of heroin withdrawal subside after 7 to 14 days of abstinence even without treatment; however, a return to complete physiologic equilibrium may require months or longer.¹⁷

The character, severity, and time course of withdrawal symptoms that appear when an opioid drug is discontinued depend on many factors, including the particular opioid, total daily dose, interval between doses, duration of use, intent of drug use, and the health and personality of the user. Unlike the withdrawal symptoms from sedative-hypnotic drugs, opioid withdrawal symptoms are seldom life-threatening.

Withdrawal From Different Opioids

5. R.F. a 33-year-old man, says he is addicted to methadone, but hours after his last dose he does not exhibit any signs of opioid withdrawal. Why is this reasonable?

Physiologic withdrawal symptoms from all opioid drugs are qualitatively similar but quantitatively different in onset, duration, and severity. Opioids with shorter durations of action tend to produce brief, intense abstinence syndromes, whereas those eliminated from the body at much slower rates produce prolonged but milder withdrawal syndromes. The abstinence syndrome of methadone is consistent with that expected for a long-acting opioid. Methadone withdrawal symptoms generally do not become apparent until 36 to 48 hours after the last dose.¹⁷ Although the symptoms are qualitatively similar to those of morphine and heroin, they are less severe overall but are most intense around the sixth day of abstinence, and persist for 14 days or more.¹⁵ R.F. could be telling the truth because his methadone withdrawal symptoms should not occur until 2 to 3 days after his last dose.

Iatrogenic Dependence

6. J.B., a 21-year-old man who underwent bowel surgery, required morphine 10 mg intramuscularly Q 4 hr for 10 days. Is J.B. physically dependent on morphine?

Physical dependence occurs in any patient after 2 to 10 days of continuous administration of an opioid.¹⁸ In the setting of the treatment of acute pain, the dependence is generally not clinically significant because the patient will taper the therapeutic dose naturally as the pain condition resolves. If the opioid is abruptly stopped, the patient may experience withdrawal symptoms, however the intensity of those symptoms varies depending on the individual's physiology, as well as the dose and duration of use of the opioid. Higher doses and longer times of administration are likely to produce more severe symptoms of withdrawal on cessation of opioid use.

Therapeutic physical dependence should not be confused with addiction. Physical dependence is defined as a neurobiological adaptation that occurs with chronic exposure, whereas addiction is a set of maladaptive behaviors involving adverse consequences owing to use of drugs, loss of control over drug use, and preoccupation with acquisition of the drug.¹ Physical dependence and tolerance (the need for increasing doses to achieve the initial effects of the drug) can occur in the setting of addiction, but are also expected, nonpathological sequelae of chronic opioid therapy.

Most studies evaluating the occurrence of opioid addiction resulting from the therapeutic treatment of pain have concluded the risk is low.¹⁹ Historically, a much greater problem has been the undertreatment of pain. It has been theorized that pain may

actually reduce the risk of addiction by attenuating the euphoric effects of opioids.¹⁸

Certain pharmacologic properties, such as high potency, rapid onset and shorter duration of action, and water solubility may increase the likelihood of abuse of that medication. Although all opioids have some abuse liability, some are intrinsically more abusible than others. For example, the controlled-release formulations have been promoted as less likely to cause addiction than immediate-release products, because when used as intended, the reinforcing properties of the opioid are reduced. When tablets, such as OxyContin, are crushed, however, the drug's controlled-release properties are compromised, and the result is much higher dosages than what is available in the immediate-release formulation tablets. Mixed agonist-antagonist opioids (pentazocine, nalbuphine, butorphanol) and partial mu agonist opioids (buprenorphine, tramadol) have less potential for abuse and addiction than the pure mu agonists (e.g., morphine, hydromorphone, oxycodone); however, abuse and addiction to all has been observed.¹⁸

The term "pseudoaddiction" has been coined to describe the inaccurate interpretation of certain "drug-seeking behaviors" in patients who are inadequately treated for pain.^{18,19} Their preoccupation actually reflects a need for pain relief, but is erroneously interpreted as addiction.

J.B. may experience a mild withdrawal syndrome on cessation of his morphine treatment, unless the doses are tapered.

Medical Complications

7. C.F., age 30, presented to the emergency department with violent shaking chills. She admitted that she was a heroin addict and was forced into "doing some cottons" because of an acute financial crisis. She now fears that she has "cotton fever." How should "cotton fever" be managed, and what other medical complications of heroin addiction might be suspected?

When heroin is prepared for self-administration, cotton is used as a filter to trap adulterants; thus, some of the drug remains trapped in the cotton. These crude filters are saved, and when money or drug availability is poor, water or other solvents are added to the "old cottons" to extract any remaining drug for intravenous (IV) use. "Cotton fever" is an acute febrile reaction. The onset is within 30 minutes of injection, with shaking chills, diaphoresis, postural hypotension, tachycardia, and low-grade fever. These symptoms are initially suggestive of sepsis, but most of the symptoms resolve without treatment in 2 to 4 hours, with complete recovery in 1 day. In the past, cotton fever was believed to be an allergic reaction to tiny cotton fibers injected with the drug, but a case report suggests that the causal agent is probably *Pantoea* (formerly *Enterobacter*) *agglomerans*, via a heat-stable endotoxin.²⁰ Cotton and cotton plants are heavily colonized with *P. agglomerans*.²¹ IV drug users will often use the term "cotton fever" to describe any short-term illness characterized by fever, chills, aches, and pains. C.F. should have blood cultures performed and receive empiric therapy with a broad-spectrum antimicrobial, such as a third-generation cephalosporin.

According to the Drug Abuse Warning Network (DAWN), heroin is consistently among the top three drugs reported in emergency department visits and drug-related deaths.^{22,23} Bacterial endocarditis, sepsis, embolism, septic and aseptic

abscesses, thrombophlebitis, cellulitis, and necrotizing fasciitis have also resulted from both improper sterilization of injection apparatus and needles and poor injection techniques.

The common practice of sharing “works” (needle and syringe) between friends has resulted in transmission of various infectious diseases. Chief among those is viral hepatitis, specifically the hepatitis C virus (HCV). Approximately 3.2 million Americans are infected with HCV and most of the cases resulted from injection drug use.²⁴ According to the Centers for Disease Control and Prevention (CDC), in the United States, human immunodeficiency virus (HIV) infection caused by injection drug use had an overall prevalence of 14% in 2005.²⁵ Other infectious diseases such as syphilis, tetanus, botulism, and malaria can be transmitted in a similar manner and should be considered when evaluating this patient.

Heroin Overdose

8. T.F., age 21, was unconscious after an alleged “OD” (overdose) on “smack” (heroin). He had a decreased respiratory rate of four breaths per minute, cyanosis, symmetrically “pinned” (maximally miotic or pinpoint) pupils, and a slightly decreased blood pressure. He has one “fresh track” (needle puncture wound) and several “old tracks” (healed scars from needle puncture wounds) in the antecubital fossa area. What is the immediate treatment of choice for this patient?

Immediate treatment includes airway management, cardiorespiratory support, and opioid reversal with naloxone. Naloxone is a full opioid competitive antagonist that rapidly reverses the respiratory depression and hypotension associated with overdose. The preferred route of administration is IV; if access cannot be gained, it may be given intramuscularly (IM), subcutaneously (SC), or by endotracheal tube.²⁶

Initial IV administration of 0.2 to 0.4 mg naloxone should be slow and should be discontinued if T.F. responds. It is not necessary to precipitate opioid withdrawal symptoms; the endpoint of naloxone therapy is a relative stabilization of the patient’s vital signs. A naloxone-precipitated, sudden-onset withdrawal syndrome is more severe than the symptoms produced by abstinence alone. Repetitive doses should be given if the patient remains unresponsive, up to a maximal dose of 10 mg of naloxone.²⁶ If the patient still has not responded, the diagnosis of opioid overdose should be reconsidered.^{26,27}

The duration of action of naloxone ranges from 20 to 60 minutes, depending on the dose and route of administration. Treatment of the methadone-overdosed patient will require serial dosing of naloxone every 20 to 60 minutes because the toxic effects of this long-acting opiate recur.²⁶ The patient must be carefully observed following the termination of naloxone therapy to detect any reappearance of opioid intoxication. An IV infusion of naloxone may be appropriate if high doses are needed or if the patient has recurrent respiratory depression.

Treatment of Opioid Dependence

9. A.X. age 27, has been addicted to heroin for 3 years but is tired of the street scene and wants to “get clean” (complete abstinence). He can no longer afford his growing daily habit but is not sure he can stop using opioids. He seems willing and determined

to receive treatment for his heroin dependence. What therapeutic options are available to him?

The ultimate goal of most detoxification programs is to transform the narcotic addict into a responsible, drug-free, emotionally stable, and productive member of society. Despite many claims, no program to date fulfills all of these goals. Furthermore, all programs either have a high recidivism rate or do not produce a drug-free state in the patient. Heroin addiction, or any other chronic, compulsive form of drug abuse, is a symptom of a wide range of problems in the addictive disease patient. Therefore, no single treatment modality can be universally applied to all patients.

Treatment options can be loosely divided into either *social model programs* or *medical model programs*. Either model may be inpatient or outpatient based. Social model programs use a nonmedical approach to detoxification and ongoing recovery. Detoxification usually involves the “cold turkey” method of abrupt cessation of the opioid without supportive therapy. Medical model programs are based on pharmacotherapeutic treatment managed by medical professionals and additionally offer recovery-oriented counseling. One therapeutic approach involves opioid substitution for detoxification or maintenance. Currently, methadone and buprenorphine are FDA-approved for these indications.²⁸ Another approach involves symptomatic treatment of withdrawal. The mainstay of this approach is the α_2 -agonist clonidine. A third approach uses rapid detoxification precipitated by an opioid antagonist under general anesthesia.

Methadone treatment for opioid dependence is federally regulated and is only available through specially licensed opioid treatment programs. The Drug Addiction Treatment Act of 2000 allows qualified physicians to prescribe Schedule III, IV, and V medications approved for the treatment of opioid dependence in an office-based setting.²⁹ Currently, only buprenorphine, a schedule III medication, is approved for this indication.

With A.X.’s apparently strong psychological addiction to heroin (he does not know if he can live without opioids) and his desire to be abstinent, it would seem appropriate to attempt gradual detoxification with intensive psychosocial counseling rather than maintenance therapy.

Substitution Pharmacotherapies for Opioid Dependence

Methadone Detoxification

10. A.X. starts a methadone detoxification program at a local methadone clinic. He claims to have a \$100/day habit. What is the recommended methadone dose for starting treatment?

Methadone is a synthetic, potentially addictive, orally acting opiate with a prolonged duration of action of 12 to 24 hours. Pharmacologically, it is qualitatively identical to morphine and other opioid analgesics. Pioneered by Dole et al.,³⁰ methadone substitution was considered the treatment of choice for opioid addiction by many researchers. It continues to be widely used today, but methadone has emerged as a drug of abuse and many deaths have resulted from its excessive use.^{26,31} In 2004, there were 3,800 deaths from methadone overdose, compared with 780 in 1999.¹⁵

Purportedly, methadone (at a dose of 80–150 mg or more) blocks the euphoriant effects of other opioids without

producing euphoria itself. This dose allegedly produces a high degree of cross-tolerance to other opioids so that it is extremely difficult to “get off” (obtain euphoria) with IV injection of other opioids. Addicts, however, have been able to obtain euphoria from doses of 60 to 100 mg of methadone. Furthermore, at lower maintenance doses of methadone that do not produce euphoria, addicts have been able to reach euphoric states through the concomitant IV administration of other opioids. The higher purity heroin available today has required even higher doses of methadone to achieve cross-tolerance.³²

Methadone detoxification involves stabilizing the patient on a daily methadone dose that is determined by the patient’s response based on objective symptoms of withdrawal. This may involve the use of standard rating scales for withdrawal, such as the Clinical Institute Narcotic Assessment (CINA).³³ Initially methadone may be given in 5 mg increments up to a total of 10 to 20 mg over the first 24 hours.³¹ Larger methadone doses (i.e., 20 mg starting dose) may be required for patients with larger habits. If initial withdrawal symptoms persist 2 to 4 hours after initial dose administration, the dose can be supplemented with another 5 to 10 mg. Federal regulations allow a maximum of 40 mg as initial dose unless a program physician documents that 40 mg was insufficient to suppress opioid withdrawal symptoms.³⁴ Once a stabilizing dose has been reached (usually, 40–60 mg/day, but may be as high as 120 mg/day), methadone is tapered by 20% a day for inpatients or 5% a day for outpatients.^{26,31,34} Studies have suggested that slow tapers are associated with better outcomes. The duration of the taper varies, but a period of 3 to 4 weeks is generally used. The gradual taper may last as long as 6 months. The most common side effects of methadone are constipation, sweating, and sexual difficulties. A Cochrane review of studies comparing methadone tapers with other detoxification methods (adrenergic agonists and other opioid agonists) found that programs vary widely in design, duration, and treatment objectives, but overall the effectiveness of the treatments was similar, with most patients relapsing to heroin use.³⁵ Persistent drug craving, often lasting months, probably accounts for the high relapse rate. Even temporary reductions in heroin use are seen as a benefit, however, because heroin use is associated with major health (HIV, hepatitis C) and social (crime) issues. Medical management of opioid dependence should be accompanied by psychosocial treatments, such as cognitive-behavioral therapies, behavioral therapies, and self-help groups, such as Narcotics Anonymous (NA).

A reasonable starting dose of methadone for A.X. would be 20 mg orally. An additional 5 to 10 mg could be administered after 2 to 4 hours for persistent withdrawal symptoms. The daily dose should be titrated upward every third day by 10 mg until he is stabilized on a methadone dose of 60 mg/day. The drug can then be tapered slowly (e.g., 3 mg/day) with A.X. on an outpatient over a period of 4 weeks, while attending counseling sessions and NA meetings.

Buprenorphine Detoxification

11. A.X. heard about a medication called buprenorphine that can be used instead of methadone. How might this medication be used for A.X.?

Buprenorphine, a synthetic partial opioid agonist, was approved by the FDA in October 2002 for the treatment of opi-

oid dependence. It is a partial agonist at mu receptors, and in opioid-dependent patients it prevents withdrawal symptoms. Because of its partial effects, it produces maximal “ceiling” analgesia with sublingual doses of 24 to 32 mg, a dosage equivalent to approximately 60 to 70 mg of oral methadone. This limits its use in the management of heroin addiction. Buprenorphine is associated with a milder withdrawal syndrome compared with full opioid agonists.

Buprenorphine has a long half-life owing to its prolonged occupancy on mu receptors and it produces a relatively mild withdrawal when discontinued. It is believed to be a safer alternative to methadone because life-threatening respiratory depression is much less likely to occur than with a pure mu agonist, unless another central nervous system (CNS) depressant is taken concurrently. Most deaths involving buprenorphine have been caused by a combination of the drug with benzodiazepines.^{28,36} Naloxone bolus doses often are ineffective in reversing respiratory depression caused by buprenorphine because of its prolonged occupancy on mu receptors. Evidence suggests that continuous infusion of naloxone is necessary to overcome buprenorphine-induced respiratory depression.³⁷

Because buprenorphine is a schedule III medication, it can be prescribed in an office-based setting under the Drug Addiction Treatment Act of 2000, as previously discussed. It is available as 2- and 8-mg tablets for sublingual use. The tablets contain buprenorphine hydrochloride alone (Subutex) or in combination with naloxone (Suboxone). The naloxone is poorly absorbed orally, and its presence in the combination tablets is to discourage the IV abuse of buprenorphine. Both tablet forms can be used in an inpatient setting, but Suboxone is preferred in the outpatient setting, to decrease the risk of diversion. When initiating buprenorphine, the first dose should not be given until >4 hours after the last dose of a short-acting opioid, such as heroin, or 24 hours after a long-acting opioid, such as methadone. Evaluation of objective opioid withdrawal signs may involve use of standard rating scales.³³ Induction dosing should begin with 2 or 4 mg on the first day, which can be repeated every 2 to 4 hours if withdrawal symptoms subside and then reappear, up to a maximum of 8 mg. The dose can then be titrated the second day in 2- to 4-mg increments to a dose of 12 to 16 mg.³⁸ Higher doses during induction may precipitate withdrawal symptoms. In the inpatient setting, the patient may be stabilized on a relatively low daily dose (e.g., 8 mg/day) and then tapered in increments of 2 mg/day over several days.²⁶ In the outpatient setting, the patient should be initially stabilized on a daily dose (probably 8–32 mg/day) of buprenorphine that suppresses withdrawal. The dose should then be gradually tapered over a period of 10 to 14 days. Buprenorphine is not associated with any significant adverse effects when used to manage opioid withdrawal. Buprenorphine detoxification should be accompanied by psychosocial treatments and support groups as mentioned.

A Cochrane review found that relative to clonidine, buprenorphine is more effective in alleviating opioid withdrawal symptoms; patients treated with buprenorphine stay in treatment longer, and are more likely to complete treatment.¹⁷ The severity of withdrawal appears to be similar for withdrawal managed with buprenorphine or methadone, but withdrawal symptoms may resolve more quickly with buprenorphine. The authors of the meta-analysis concluded that, although there is

limited evidence comparing buprenorphine with methadone, both agents have similar effectiveness in the management of opioid withdrawal. Buprenorphine has a higher unit-dose cost compared with methadone. A depot preparation of buprenorphine is being investigated for the management of opioid withdrawal.

Maintenance Therapy

12. A.X.'s friend B.P. also attends the methadone clinic but is on methadone maintenance. How is methadone used in maintenance therapy? Are there any maintenance alternatives?

Methadone maintenance is the most common form of pharmacologic treatment for opioid dependence. During methadone maintenance, heroin-dependent patients are stabilized on a dose of methadone that will be sufficient to suppress withdrawal symptoms for 12 to 24 hours without producing euphoria. Studies have shown that patients maintained on methadone doses of 60 mg or more had better outcomes than those maintained on lower doses.³² Most patients do well on a dose range of 60 to 120 mg/day, although some patients require more and some require less.³⁹ Drugs that induce CYP 450 enzymes can precipitate withdrawal in patients maintained on methadone. Drugs that inhibit CYP 450 enzymes extend the duration of methadone's effects. The drug is administered in one daily oral dose to maintain daily contact with the patient. With the aid of daily counseling and rehabilitation, most clinicians attempt to detoxify the patient eventually from methadone as well. Patients who relapse repeatedly despite supportive treatment may require long-term maintenance therapy.

The ultimate goal of methadone maintenance is controversial. By enabling addicts to escape from the illicit drug scene, review their present lifestyles, and reorient their goals, rehabilitation becomes possible. Early enthusiasm for methadone maintenance has now been tarnished by its use in the same abuse patterns as other opioids. Methadone is now a desired substitute for heroin among the addict population, although the "high" it provides is generally considered inferior to that of heroin, codeine, and other opioids.

Whether rehabilitation occurs or is even possible is confused by the lack of clear and widely accepted goals of therapy. The addition of social objectives to the therapeutic medical goal of cessation of heroin self-administration further confuses the issue. Some people believe the patient must remain completely drug-free for life (including methadone) to consider the treatment program a success. Others see opioid addictive disease as a disorder in which some opioid (methadone for example) must always be administered to the addict to correct the underlying biochemical pathology before any social rehabilitation can occur.

Medical staffing problems and disruption of the patient's employment schedules brought about by the necessity for daily doses of methadone stimulated a search for alternative drugs to methadone. "Take home" dosing, allowing patients to obtain more than a single day's dose of methadone for self-administration, has frequently led to drug diversion and heroin recidivism. Another alternative for maintenance therapy is buprenorphine (see Question 11). Most patients can be stabilized on 8 to 32 mg/day of buprenorphine.²⁶

Once stabilized, it may be possible to switch to alternate-day or three-times-a-week dosing schedules. As discussed, buprenorphine has the advantage of office-based availability, thus removing the stigma associated with attending a methadone clinic. There has been interest in developing office-based methadone treatment as well.

When levomethadyl acetate (removed from the US market in 2003 following reports of severe cardiac-related adverse events), buprenorphine, and high-dose methadone (60–100 mg) therapies were compared with low-dose methadone (20 mg)⁴⁰; all three therapies were effective in treating opioid dependence and were superior to low-dose methadone. Trials comparing 12 to 16 mg/day of buprenorphine with moderate doses of methadone (50–60 mg/day) have generally shown comparable outcomes, although higher doses of methadone (>80 mg) appear to be superior to buprenorphine. Buprenorphine may be best suited for patients with mild to moderate physical dependence.

Pain Management

13. T.A., a 44-year-old man maintained on 120 mg daily of methadone, is in severe pain owing to a fractured femur. What type of analgesic, and how much, can be used safely in this patient?

Neuroplastic changes in pain perception occur with chronic opioid use and can result in increased pain sensitivity, or hyperalgesia. In addition cross-tolerance to the analgesic effects extends to all opioids. Therefore, patients maintained on opioid agonist treatment for addiction may actually require higher doses of opioid agonist analgesics given at shorter intervals.⁴¹ Addiction relapse because of the use of opioid analgesics is less likely than relapse because of untreated pain. Careful clinical assessment for objective signs of pain will decrease the physician's concerns of being manipulated. For T.A., it would be appropriate to control his pain acutely using patient-controlled analgesia (PCA) with IV morphine. Given his narcotic tolerance, the initial PCA pump settings could include a 2-mg IV bolus dose of morphine with a 6-minute lock-out interval delivering a maximum of 20 mg/hour. T.A.'s pain should be evaluated and the regimen adjusted as needed to achieve adequate control. T.A.'s usual maintenance dose of methadone should be continued while he is receiving morphine for his acute pain. Many clinicians would divide the daily dose (e.g., 30 mg every 6 hours) to avoid excessive peak levels of narcotic. Opioid withdrawal should be strictly avoided in this patient because it is associated with hypersensitivity to painful stimuli, followed by exaggerated catecholamine and anxiety responses. The partial antagonist-agonist narcotics pentazocine (Talwin), butorphanol (Stadol), and nalbuphine (Nubain) should be avoided because their narcotic antagonist properties may precipitate opioid withdrawal symptoms when used in a methadone-maintained patient.

There is less experience in treating acute pain in patients maintained on buprenorphine.⁴¹ Buprenorphine's high affinity for the mu receptor risks competition with, or even displacement of, full opioid agonists. Naloxone should be on hand when opioid analgesics are used in the buprenorphine-maintained patient. Alternatively, the buprenorphine maintenance dose can

be converted to methadone for the duration of opioid analgesia treatment.

T.A. should be reassured that his methadone will be continued and his pain aggressively treated. T.A.'s physician should consult with the methadone maintenance program to verify methadone dose and alert them to any controlled substances used in his treatment that may be detected with drug testing.

Methadone in Pregnancy

14. J.R., age 28, has been maintained on 100 mg methadone daily for the past year. She is now 3 months pregnant. What is the teratogenic potential of methadone?

Methadone has been accepted since the late 1970s to treat opioid addiction during pregnancy.³⁴ Methadone maintenance was determined to be the standard of care for pregnant women with opiate addiction by a 1998 National Institutes of Health (NIH) consensus panel.⁴² Currently, methadone is the only opioid medication approved by the FDA for medication-assisted treatment of opioid addiction in pregnant patients. Women maintained on methadone frequently have regular menstrual periods, ovulate, conceive, and have normal pregnancies. Heroin-addicted mothers, however, generally experience more complicated pregnancies because their lifestyles often predispose them to a poor general state of health and precludes adequate prenatal medical care.⁴³ Infants born to heroin-addicted mothers may also be exposed to other substances (e.g., alcohol, cocaine, tobacco). These infants tend to be smaller, to weigh less at birth, and to be born prematurely compared with the children of women not using opiates.⁴³

Withdrawal During Pregnancy

15. Are there alternatives to methadone in the treatment of opioid-dependence in pregnancy? Should methadone be continued in J.R.?

J.R. should continue methadone maintenance to avoid precipitating a withdrawal syndrome. Withdrawal from methadone is not recommended for pregnant women.³⁴ A structured methadone maintenance program that provides access to counseling and medical care is probably at least as beneficial to the pregnancy as the pharmacologic prevention of withdrawal. Lowering the maternal methadone dosage is associated with decreased incidence and decreased severity of neonatal withdrawal symptoms.⁴⁴ Therefore, the dose of methadone should be titrated individually throughout the pregnancy. The neonate can be managed for either opioid-induced CNS depression or methadone withdrawal after delivery, as needed.

Methadone continues to be the standard of care for the management of opioid dependence in pregnancy; however, a growing body of evidence suggests buprenorphine may be a reasonably safe alternative.^{26,39} Also some evidence suggests that infants born to buprenorphine-maintained women have a lower incidence of neonatal abstinence syndrome.^{45,46}

Neonatal Addiction

16. Because methadone crosses the placental barrier, will J.R.'s infant exhibit opioid withdrawal symptoms after birth and, if so, how should they be managed?

Methadone crosses the placental barrier and can cause CNS and respiratory depression as well as opioid abstinence in the newborn. In one study, 46% of the infants born to methadone-maintained mothers exhibited withdrawal signs and required treatment for neonatal abstinence syndrome (NAS).⁴⁴ In general, the most common NAS symptoms include restlessness, tremors, a high-pitched cry, hypertonicity, increased reflexes, regurgitation, tachypnea, diarrhea, and sneezing. Seizures are associated with, but not necessarily caused directly by, opioid withdrawal in the neonate. The withdrawal symptoms in the newborn may be delayed for up to 3 days.

Management of the neonate's opioid withdrawal syndrome entails careful attention to hydration with demand feeding and symptomatic care. Mild withdrawal symptoms need no therapy, but moderate to severe symptoms may require 14 or more days of treatment. Therapy of neonatal withdrawal should begin when symptoms occur. Prophylactic therapy is not recommended.

Symptoms of physiologic addiction are usually apparent within 48 hours of birth. At this time, treatment can be initiated. Currently, NAS is treated with either morphine or phenobarbital. Studies have suggested that morphine is superior to phenobarbital in both decreasing time of treatment and need for higher intensity of care.^{45,47} Morphine can be started at a dose of 50 mcg/kg given orally four times daily and titrated to control symptoms. Once the NAS symptoms have stabilized, the dose can be decreased daily by 20% until discontinuation of the drug. Phenobarbital is preferred for the treatment of NAS in cases of combined dependence or benzodiazepine dependence.⁴⁵ If used, phenobarbital is instituted in doses of 5 to 10 mg/kg/day in the first 24 hours, then tapered symptomatically, usually about 20% per day. If J.R.'s infant displays opioid withdrawal symptoms (e.g., feeds poorly, becomes tremulous or agitated), morphine at a dosage of 50 mcg/kg orally given four times daily would be an appropriate intervention. This dosage is given until symptoms stabilize and then gradually tapered over the next week.

Breast-Feeding

17. Should J.R. breast-feed her infant?

Methadone is excreted into the breast milk of methadone-maintained mothers. The amount of methadone in the breast milk is unlikely, however, to have adverse effects on the infant.⁴⁸ Furthermore, studies have found minimal transfer of methadone into breast milk.³⁴ Breast milk offers advantages clearly beneficial to infants and J.R. should be encouraged to breast-feed her infant.

Opiate Antagonist Treatments

18. A.J. is a 41-year-old anesthesiologist seeking rehabilitation and reinstatement of his medical license following 5 years of fentanyl abuse. Are there any special considerations in chemical dependency treatment in health care providers? Would opiate antagonist treatment be appropriate for A.J.?

Experts suggest that the lifetime risk for substance abuse is higher among physicians than the general population.⁴⁹ The risk is largely based on access to drugs of abuse, and drug dependence is described as an "occupational hazard" for

health care providers. Abuse of fentanyl by anesthesiologists and abuse of meperidine by nurses has long been recognized. Fentanyl (injectable as well as transdermal formulations) and meperidine are primarily, but not exclusively, drugs of abuse among health care providers. Hospice workers and veterinarians also have access to high potency opioids. Medical residents in anesthesiology and psychiatry have higher rates of substance abuse than do residents in other specialties, and psychiatrists are more likely to abuse benzodiazepines than physicians in other specialties.⁴⁹ Fentanyl is associated with rapid development of dependence, intense tolerance, and drug-seeking behavior in addicted physicians over a period of months rather than years.

A comprehensive assessment of addicted health care providers is necessary to determine if professional impairment is present, and whether issues involving public health and safety or violations of ethical standards, such as professional boundary violations or improprieties, require that the health care provider be reported to his respective medical board. A physician's registration with the federal DEA may need to be suspended. It generally is accepted that physicians require longer durations of treatment because they are held to a higher standard of recovery owing to concerns of public safety, and they may be clever at concealing their illness.⁴⁹ Physicians should have structured posttreatment monitoring for at least 5 years.

If opioid addiction results from a process of classic and instrumental conditioning and is positively reinforced by self-administration and drug-seeking behavior, then narcotic antagonists may break this addiction cycle. The narcotic antagonists naloxone and naltrexone can block the euphoriant effects of heroin and other opiates, prevent the development of physical dependence, and afford protection from opioid overdose deaths. Of these two antagonists, only naltrexone appears to have any practical utility. Naloxone (Narcan) is impractical because of its short duration of action and its variable potency when taken orally. Naltrexone (Trexan) is orally active and provides a dose-related duration of opioid blockade. An oral dose of 100 mg of naltrexone will block opiate effects for 2 days, and 150 mg for 3 days. Thus, dosing on Monday, Wednesday, and Friday is possible and convenient for the patient. Naltrexone is also available in an injectable extended-release formulation for once-monthly use.⁵⁰ Patients selected for naltrexone therapy must be opioid free to avoid precipitation of withdrawal. For heroin or morphine dependent patients, a 4- to 7-day wait is recommended, whereas methadone addiction requires a 10- to 14-day wait. Patients who are highly motivated to abstain have been most successfully treated with this drug. A.J. is a good candidate for naltrexone therapy because of his desire to become rehabilitated and his need to remain drug-free despite continued access to opioids at work.

Ultrarapid Opiate Detoxification

19. Before A.J. can start naltrexone therapy, he must undergo fentanyl detoxification. Would rapid detoxification over a few hours be preferable to the more traditional detoxification methods for A.J.?

Ultrarapid opiate detoxification (UROD) has been advocated to shorten the opioid detoxification period by precipitat-

ing withdrawal with an opioid antagonist. The opioid antagonist causes rapid stripping of agonist from opioid receptors. UROD is performed under heavy sedation or general anesthesia so the patient does not consciously experience the acute withdrawal symptoms. The protocols for UROD vary in terms of the opioid antagonist (naloxone, nalmefene, or naltrexone), anesthetic agent, adjunctive medications, and duration of anesthesia. UROD has been performed as an outpatient or inpatient procedure, with costs ranging from \$7,500 to \$15,000.⁵¹

The UROD procedure includes risks, such as vomiting with aspiration; cardiovascular complications, including cardiac arrest; pulmonary edema; and death.⁵¹ Some patients have reported residual withdrawal symptoms over several days. Little information exists regarding referral to ongoing treatment or relapse rates after UROD.⁵² One randomized, controlled trial found no benefit of UROD over safer, less-expensive treatments using buprenorphine and naltrexone or clonidine and naltrexone.⁵¹ UROD has been criticized for being simply a "quick fix" that fails to address the underlying behavior changes necessary for recovery. Additionally, it subjects patients to possible morbidity and mortality when safer, established procedures are available. The high cost of UROD limits its accessibility. More studies are needed to evaluate the risks and benefits of this approach. UROD would probably not be recommended as a first-line detoxification method for A.J.

Symptomatic Therapy of Opioid Withdrawal

20. How can A.J.'s opioid withdrawal be managed symptomatically? He weighs 72 kg and his blood pressure is 130/80 mmHg.

Methadone treatment for addiction has its limitations (prescribing restrictions, protracted withdrawal, drug of dependence), and many patients prefer an alternative. The discovery of the ability of the α_2 -adrenergic agonist, clonidine, to ameliorate some of the opioid withdrawal symptoms, has led to its widespread use as a nonopioid alternative, despite that it is not approved for this indication in the United States. Other α_2 -adrenergic agonists (lofexidine, guanfacine, guanabenz acetate) have also been investigated.⁵³ Noradrenergic outflow from the locus ceruleus is increased during opioid withdrawal and is blocked by administration of mu agonist opioids. Symptoms of opioid withdrawal, therefore, are partly owing to excessive sympathetic activity in the locus ceruleus. Central α_2 -adrenergic agonists act on presynaptic autoreceptors to inhibit locus ceruleus noradrenergic outflow during mu agonist opioid withdrawal, thereby significantly reducing some of the symptoms.

Clonidine is therefore best used in a multidrug regimen (Table 83-1). The four primary symptoms of opioid withdrawal are musculoskeletal aches and pains, anxiety, insomnia, and gastrointestinal disorders. Contraindications to clonidine use include diastolic blood pressure <70 mmHg, concurrent dependence on sedative-hypnotics, and clonidine hypersensitivity or previous intolerance. The most common adverse effects are sedation and hypotension. A recent Cochrane review examined studies comparing clonidine with methadone taper and found no significant difference in efficacy between the two for the treatment of heroin or methadone withdrawal.⁵³ A separate Cochrane review did find buprenorphine to be more effective than clonidine in alleviating opioid withdrawal symptoms.¹⁷

Table 83-1 Symptomatic Therapy of Opiate Withdrawal

| Symptom | Medication | Dose |
|--------------------------------|--|-----------------------------------|
| Bone or joint pain | Ibuprofen | 800 mg Q 8 hr with food as needed |
| Muscle pain or cramps | Methocarbamol | 750 mg Q 6 hr as needed |
| Insomnia | Trazodone | 50–150 mg at bedtime |
| | Chloral hydrate | 500–1,500 mg at bedtime |
| | Flurazepam ^a | 30–90 mg at bedtime |
| | Doxepin | 50–100 mg at bedtime |
| Gastrointestinal hyperactivity | Belladonna alkaloids with phenobarbital ^b | Two tablets Q 8 hr as needed |
| | Dicyclomine ^b | 20 mg Q 6 hr as needed |
| Nausea | Prochlorperazine ^b | 10 mg Q 6 hr as needed |
| | Trimethobenzamide ^b | 300 mg Q 6 hr as needed |

^a Avoid in concurrent benzodiazepine dependence.

^b Anticholinergic effects also alleviate rhinorrhea, sialorrhea, diaphoresis, and lacrimation.

A sublingual or oral test dose of 0.1 mg (0.2 mg for patients >91 kg) of clonidine is given: if diastolic blood pressure remains >70 mmHg, additional doses may be instituted, usually as transdermal patches. Transdermal absorption of clonidine from patches (Catapres-TTS) avoids most of the problems encountered with oral therapy. The number of patches applied to a hairless area of the body (usually the upper back or scapular area) depends on the patient's lean body weight: <50 kg, clonidine 5 to 7.5 mg (two or three TTS-1 patches); 50 to 91 kg, 10 mg (two TTS-2 patches or one TTS-2 and two TTS-1 patches), and >91 kg, 10 to 15 mg (two or three TTS-2 patches). Patients <73 kg should use two of the TTS-1 patches and one TTS-2 patch so that one TTS-1 patch can be removed in the event of hypotensive complications. Patches are left on for 7 days, replaced with half the dosage during the second week, and then discontinued. Alternatively, oral clonidine can be used at a dose of 0.1 to 0.2 mg/dose two to four times daily to a maximum of around 1 mg/day for 2 to 4 days after cessation of opioids, then tapered and discontinued by 7 to 10 days.⁵³

Clonidine is also used in conjunction with naltrexone for rapidly withdrawing patients from opioid dependence. This technique has been shown to be safe and effective.²⁶ The withdrawal precipitated by naltrexone is avoided by pretreating the patient with clonidine. Limitations to this technique include the need to monitor the patient for the first 8 hours because of the potential severity of the precipitated withdrawal and the need for blood pressure monitoring. An advantage is the easy transition to opioid antagonist treatment.

A.J.'s blood pressure and drug history should be evaluated for clonidine therapy. Provided his diastolic blood pressure is >70 mmHg after the clonidine test dose, he can receive the clonidine patches (one TTS-2 and two TTS-1 patches) with additional medications to treat his withdrawal symptoms, along with daily intensive psychosocial counseling.

SEDATIVE-HYPNOTICS

The sedative-hypnotics are a diverse group of compounds with broad clinical uses, including anesthesia, treatment of anxiety, and treatment of insomnia. Ethanol, also a sedative hypnotic agent, continues to be the most widely abused substance in the United States and is discussed in Chapter 84, Al-

cohol Use Disorders. Benzodiazepines, which have replaced barbiturates in clinical practice, have become the prototypical sedative-hypnotic drugs of abuse. Other abused sedative-hypnotic drugs include carisoprodol and γ -hydroxybutyric acid (GHB). Carisoprodol, a nonscheduled skeletal muscle relaxant, has an active metabolite meprobamate, a sedative-hypnotic agent with known abuse potential.⁵⁴ GHB is a putative neurotransmitter abused for its euphoric and sedative-hypnotic effects.

Abstinence Syndromes Associated With Sedative-Hypnotic Dependence

21. During a year of therapy for anxiety, B.J. increased his dose of alprazolam to two 1-mg tablets five times a day. He has admitted to “doctor shopping” and buying alprazolam on the street to maintain his daily habit. Will he experience withdrawal symptoms if he suddenly discontinues alprazolam?

Patients who have been on long-term courses of therapeutic doses of sedative-hypnotics often experience withdrawal symptoms on abrupt discontinuation of therapy. Withdrawal syndromes seen with sedative-hypnotics are similar to those seen with alcohol withdrawal and can include insomnia, anxiety, tremors of the upper extremities, muscular weakness, anorexia, nausea, vomiting, and postural hypotension.⁵⁵ Postural hypotension may be of value in differentiating the abstinence syndrome from ordinary anxiety states. Generalized tonic-clonic seizures can occur as isolated seizures or as status epilepticus. The psychoses that develop resemble the delirium tremens produced by alcohol withdrawal and are usually characterized by disorientation, agitation, delusions, and hallucinations. During the delirium, hyperthermia and agitation can lead to exhaustion, rhabdomyolysis, cardiovascular collapse, or death. Abstinence from short-acting barbiturates and meprobamate produces symptoms that peak within 2 or 3 days. Discontinuation of short-acting benzodiazepines (e.g., lorazepam, oxazepam, alprazolam, temazepam) results in the abrupt onset of withdrawal symptoms, usually within 12 to 24 hours after the last dose. Long-acting agents, and those with active metabolites, have a gradual onset of milder withdrawal symptoms compared with the short-acting agents. Withdrawal symptoms

following chronic use of long-acting benzodiazepines typically peak on the fifth to eighth day after the last dose.⁵⁵

B.J. has been abusing alprazolam, taking more than the recommended maximum dose. Likely, he will experience withdrawal, possibly including seizures, if he were to abruptly discontinue the alprazolam. His withdrawal from this medication should be medically managed. He should undergo an initial physical examination and plan to be absent from his place of employment for at least a week to begin detoxification.

Treatment of Sedative Withdrawal

22. How should B.J.'s sedative-hypnotic dependence be treated?

In clinical practice, three general medication strategies are used for withdrawing patients from sedative-hypnotics: decreasing doses of the drug of dependence (tapering); substituting (and gradual taper) of phenobarbital for the drug of dependence; and the substituting (and gradual taper) of a long-acting benzodiazepine for the drug of dependence.⁵⁵ Gradual tapering of the drug of dependence is appropriate for patients with therapeutic dose dependence or those taking long-acting sedative-hypnotics, who are not currently abusing alcohol or other substances. A recent meta-analysis suggests that management of benzodiazepine monodependence by gradual taper is preferable to abrupt discontinuation.⁵⁶ The authors also noted that a potential value may exist with carbamazepine used as an adjunctive medication for benzodiazepine taper, but larger, controlled studies are needed. The patient who is abusing sedative-hypnotics already has a strong association between the drug of choice and certain desired effects. Therefore, to minimize exacerbating addictive disease, substitution and taper with a long-acting therapeutic agent is preferred. The pharmacologic rationale for phenobarbital substitution is that it is long acting, producing little changes in serum levels between doses, thereby preventing breakthrough withdrawal symptoms. Lethal doses are many times higher than toxic doses; and dysphoria occurs with elevated dose, rendering it undesirable for users. As a result, the abuse potential is low, and there is little to no street value.

The phenobarbital method is the one most generally applicable; it is widely used in drug treatment programs because it is the best choice for patients who have lost control of their benzodiazepine use or who are polydrug users. The method involves calculating a phenobarbital replacement dose for the total daily dose of the sedative-hypnotic being abused. The calculation is based on phenobarbital equivalents (Table 83-2). If multiple sedative-hypnotics are being used, the totals for each drug and alcohol (amount of pure ethanol) are summated. The total phenobarbital substitution dose should be given in divided doses, three or four times daily (to avoid dysphoria). Because

the calculated dosage is an estimate based on patient history, which may be inaccurate, it is advisable to administer a test dose if the calculated replacement dose is >180 mg/day. The test dose, generally one-third the total dose, is given to the patient, who is then observed for 1 to 2 hours. The patient is observed for mitigation of withdrawal symptoms as well as signs of overmedication, such as somnolence or incoordination. Once an appropriate dose is determined, the patient is usually stabilized on that dose for 1 to 2 weeks. Following stabilization, an open-ended taper of phenobarbital is instituted, with dosages reduced by 30 mg every 2 to 3 days as tolerated.⁵⁷

B.J. has an addiction to alprazolam and because it is a short-acting benzodiazepine, it is a poor choice for tapering his dosage. Phenobarbital should be substituted for alprazolam. His total dose of alprazolam is 10 mg/day, so he should receive 300 mg of phenobarbital divided three or four times a day.

γ -Hydroxybutyric Acid

23. L.S. has been attending "raves" (all-night dance parties) every weekend for the past few months. She has been taking "liquid ecstasy" at these parties and believes it is a safe drug because she heard it once was sold in health food stores. What drug is she likely taking, and what are the risks with its use?

γ -Hydroxybutyric acid (GHB), commonly referred to as "liquid ecstasy," is a potent "club drug." Once available as an over-the-counter nutritional supplement, primarily used by bodybuilders, the FDA removed it from the retail market in 1990 because of widespread reports of poisoning. In 2000 it was classified as a schedule I drug; however, a GHB-containing product, sodium oxybate, is available as a schedule III prescription drug for the treatment of cataplexy associated with narcolepsy. GHB prodrugs, γ -butyrolactone (GBL) and 1,4-butanediol are still available for purchase on the internet. GHB is found in mammalian brain tissue, where it is derived from conversion of its parent neurotransmitter, γ -aminobutyric acid (GABA).⁵⁸ It is believed to be a neurotransmitter. Experimental evidence suggests that the mechanism of action of exogenously administered GHB involves agonist activity at the GABA_B receptor.⁵⁸

γ -Hydroxybutyric acid has CNS depressant effects and is abused for its euphorogenic properties, disinhibition, and enhanced sensuality. Its psychic effects are similar to those of alcohol, and include increased libido, short-term anterograde amnesia, and a dreamy, altered sensorium. It has a steep dose-response curve, and common adverse effects include dizziness, nausea, weakness, agitation, hallucinations, seizures, respiratory depression, and coma. Its effects are synergistic with alcohol. GHB overdose may be fatal, and there is no antidote. Treatment for GHB overdose is primarily supportive.

Table 83-2 Hypnotic Dose Equivalent to 30 mg Phenobarbital⁵⁷

| | | |
|------------------------|-----------------------|----------------------|
| Pure ethanol 30–60 mL | Clonazepam 1–2 mg | Pentobarbital 100 mg |
| Alprazolam 1 mg | Diazepam 10 mg | Secobarbital 100 mg |
| Butalbital 100 mg | Flunitrazepam* 1–2 mg | Temazepam 30 mg |
| Carisoprodol 350 mg | Lorazepam 2 mg | Triazolam 0.5 mg |
| Chlordiazepoxide 25 mg | Oxazepam 30 mg | Zolpidem 5 mg |

*Not approved for use in the United States.

Highly addictive, tolerance and physical dependence can occur with regular use of GHB, and a withdrawal syndrome has been seen in people who have taken high doses of it (~18 g/day or more, although doses are variable in solution form) with frequent dosing (Q 1–3 hr).⁵⁸ Withdrawal symptoms can include muscle cramps, nausea, vomiting, tremor, anxiety, insomnia, tachycardia, restlessness, and delirium or frank psychosis. Death caused by pulmonary edema has been reported. Treatment of withdrawal involves supportive care, including use of benzodiazepines (e.g., lorazepam or diazepam) for sedation. Withdrawal can last up to 2 weeks.⁵⁸

Misrepresented sometimes as a natural and safe hypnotic, the low therapeutic index and the unknown purity of illicit supplies, particularly when sold in solution, make GHB a potentially dangerous drug. Physical dependency is a possibility as well. L.S. should be educated about GHB's potential risks. If she chooses to use GHB, she should be encouraged not to drink alcohol or use other drugs, not to drive, and to be cautious about the amount she ingests.

CENTRAL NERVOUS SYSTEM STIMULANTS

Cocaine

Cocaine is a naturally occurring alkaloid derived from the *Erythroxylon coca* plant, found mainly in the Andes Mountains of South America. Cocaine was first isolated in the 1800s and was a common ingredient in tonics and elixirs of the 1900s. The Harrison Narcotic Act of 1914 prohibited nonmedical use, and in 1970 it became a schedule II controlled substance. Today, it is second to marijuana as the most frequently used drug of abuse. According to the 2006 National Survey on Drug Use and Health, an estimated 35 million people in the continental United States have tried cocaine; 6 million people used cocaine within the previous year, and 2.4 million used cocaine at least once within a month before the survey.¹³ Cocaine is a CNS stimulant and has vasoconstrictive and local anesthetic properties. Cocaine's stimulant effects are primarily caused by blockade of reuptake of dopamine, norepinephrine, and serotonin. It also facilitates the release of dopamine and norepinephrine. This results in an overall increase in availability of neurotransmitters. Cocaine also has other indirect effects on neurophysiology, including effects on the endogenous opioid systems.^{59,60} Cocaine is associated with compulsive use. The powerful reinforcing effects of cocaine have been identified as occurring in brain regions rich in dopaminergic nerve terminals.

Dosage Forms and Routes of Administration

24. C.H. and his friends bought an “eight ball” (one eighth of an ounce) of “blow” (powdered cocaine). C.H. has only snorted cocaine, but one of his friends suggests they cook up some “rocks” to smoke. What are the distinctions between the various dosage forms of cocaine and their respective routes of administration?

In the manufacture of cocaine, organic solvents are used to solubilize the alkaloidal bases from the leaves, which are then precipitated to form a sticky material, called “pasta” or “cocaine paste.” The benzoylmethylecgonine (cocaine) in this “pasta” is separated from most of the other plant alkaloids, converted to the hydrochloride or other salts, precipitated, and

dried. This product is the white cocaine hydrochloride powder usually seen in the illicit market. The final product is usually “stepped on” or “cut” (diluted) with various adulterants to increase profits for the dealers. According to the DEA, in 2004 the average purity of cocaine was 84%.¹² Cocaine is usually purchased on the illicit market in quantities of gram or ounce increments. The cost varies geographically, but 1 g of powdered cocaine usually sells for \$100 in most cities.¹⁴

Powdered cocaine is generally snorted. Usually 10 to 25 mg of powdered cocaine is placed on a mirror or flat surface, formed into a line, and then insufflated through a straw or rolled dollar bill. A typical low to moderate user may consume 1 to 3 g/week. Cocaine powder can also be used for IV injection. The highly water-soluble powder is usually mixed with water and injected. When cocaine is injected simultaneously with heroin, this is known as a “speedball.”

Cocaine hydrochloride melts at a high temperature, destroying much of its psychoactivity in the process. Therefore, it is inefficient to smoke cocaine hydrochloride in this form. The use of “freebase” cocaine became popular during the late 1970s, as this form of cocaine has a lower melting point and can therefore be smoked, producing an intense rush. For freebase, the cocaine hydrochloride is dissolved into ethyl ether. When an alkali, such as bleach (sodium hypochlorite) or sodium bicarbonate, is added to this ethyl ether, the hydrochloride salt is cleaved from the free alkaloidal cocaine base. The sugars, salts, and some of the other water-soluble adulterants are precipitated out of solution, and the free alkaloidal base remains in the ethyl ether solution. When the ether is evaporated, the freebase of cocaine remains in a powder form. The synthesis of freebase is dangerous and the resultant product may contain residual organic solvents, thus making it highly volatile and putting the user at risk of burns.

In the mid-1980s a safer, easier method for extracting the cocaine base supplanted the traditional freebase process. In the manufacture of “crack,” cocaine hydrochloride is dissolved in water. When alkali (bleach or sodium bicarbonate) is added to this aqueous solution, the free alkaloidal base (“crack”) precipitates out while the salts and some adulterants stay in aqueous solution. The precipitate is commonly referred to as a “rock.” The size of the rock varies but generally ranges from one tenth of a gram to a half a gram. Rocks generally sell for \$10, but prices range from \$2 to \$40, depending on the size of the rock.¹⁴ Both manufacturing methods produce cocaine free alkaloidal base of 90% or greater purity. Smoking “crack” has surpassed snorting as the most common way to use cocaine.

Pharmacokinetics and Effects

25. C.H.'s friend gets some baking soda and water from the kitchen and proceeds to convert a few grams of their cocaine into “rock.” After smoking a few “hits” (doses), C.H. feels euphoric, energized, and self-confident. Are these typical cocaine effects?

C.H. is describing the typical euphoria associated with cocaine use. Cocaine generally produces a euphoriant action with a rapid onset and short duration. Snorting cocaine generally produces euphoria and stimulation within 2 minutes; smoking produces these effects within 6 to 8 seconds. Cocaine has a short elimination half-life of approximately 30 minutes owing to its rapid metabolism by plasma esterases.⁵⁹

An initial relaxed, euphoric, gregarious, talkative, hyperactive state characterizes the “high” of cocaine. Additionally, the person may report increased interest in sexual matters, diminished short-term memory, periods of intense concentration on one limited subject, diminished hunger, hypervigilance, and a peculiar, slightly out-of-body sense of one’s actions. Without additional doses of cocaine, these feelings usually resolve into a state of mild depression, fatigue, hunger, and sleepiness by 1 to 3 hours. Physiologic manifestations include mydriasis, sinus tachycardia, vasoconstriction with hypertension, bruxism, repetitive behavior, hyperthermia, and talkativeness. After a few hours, continuous self-administration of cocaine will begin to progress from euphoria to dysphoria and hallucinosis and then to psychosis. Some users engage in nonstop binges of self-administration until psychological toxicity develops.⁶¹

Adverse Effects

26. C.H. and his friends continue to smoke crack for the next 10 hours. C.H. decides to go out for a pack of cigarettes and collapses on the sidewalk outside his apartment. A passerby calls 911, and C.H. is rushed to the nearest emergency department in a semiconscious state. What has likely happened to C.H.?

Cocaine is the most frequently mentioned illicit substance in emergency department visits. In 2005, 448,481 cocaine-related visits to an emergency department were reported in the United States.²² The potential adverse effects associated with both acute and chronic use of cocaine are numerous and involve most organ systems in the body.

The cardiac complications associated with cocaine use include hypertension, arrhythmias, myocardial ischemia and infarction, dilated and hypertrophic cardiomyopathy, myocarditis, aortic dissection, and acceleration of atherosclerosis. These cardiac effects have occurred in individuals with and without underlying heart disease who have taken large or small doses by all routes of administration and may be associated with acute or chronic use. The cardiac events can occur before, during, or after other toxicities, such as seizures, and can be fatal. The mechanism of cocaine-induced myocardial infarction is most likely multifactorial, involving one or more of the following processes: coronary artery vasoconstriction, increased myocardial oxygen demand related to increased blood pressure and increased heart rate, increased platelet aggregation and thrombus formation, coronary vasospasm, and arrhythmia. The risk is greatest within the first hour following use.^{62,63} Frequent cocaine users are up to seven times more likely to suffer a heart attack than are nonusers.⁵⁹

The medical management of acute coronary syndromes differs when cocaine is the cause. Specifically, nonselective β -blocker therapy (i.e., propranolol) is contraindicated, thrombolysis should be used with caution, and nitrates and benzodiazepines are part of first-line therapy.²⁷ In patients with cocaine-associated chest pain, a 12-hour observation period to rule out myocardial infarction or ischemia is probably sufficient before discharge from a medical facility.⁶⁴

Cocaine has also been associated with cerebrovascular catastrophes. Stroke can occur as a result of increased blood pressure, vasoconstriction, or thrombosis. Seizures are another CNS complication. Seizures can occur with first use and are most often single, generalized tonic-clonic seizures. Most occur within 90 minutes of drug use, when drug plasma con-

centrations are highest. It is estimated that 10% of patients presenting to emergency departments with acute cocaine intoxication have seizures.⁶⁵

The route of cocaine administration also affects the nature of the adverse effects. For example, pulmonary complications, including pneumomediastinum, pneumothorax, pneumopericardium, acute exacerbation of asthma, diffuse alveolar hemorrhage, pulmonary edema, and “crack lung,” are associated with smoking crack cocaine. Crack lung is a syndrome of acute pulmonary infiltrates associated with a spectrum of clinical and histologic findings.⁶⁶ Snorting cocaine can lead to perforation of the nasal septum because of the drug’s local anesthetic and vasoconstrictive effects. IV use of cocaine has been associated with renal infarction, wound botulism, viral hepatitis, HIV infection, bacterial endocarditis, sepsis, and other infectious complications.⁶⁷ C.H. could be suffering from cardiovascular, cerebrovascular, or pulmonary complications caused by his crack smoking. His emergency department workup should be thorough and directed by his symptoms.

Cocaine Addiction

27. C.H. is released from the emergency department and returns home to find his friend with more crack. They resume smoking and binge for the next 4 days. They run out of drugs and money, and C.H. begins to “crash.” In desperation, he sells his skateboard to his neighbor for \$20, buys another rock, smokes it, and feels good again. Is C.H.’s cocaine usage pattern consistent with cocaine dependence?

C.H. continues to use cocaine despite adverse consequences (emergency department visit), uses it compulsively, suffers withdrawal symptoms, and alleviates his symptoms with further use. Per the DSM-IV criteria for substance dependence, C.H. is addicted to cocaine.¹

Prolonged or heavy use of cocaine has been associated with the development of tolerance to some of its central effects. Tolerance to cocaine’s euphoric effects has been shown to occur, but tolerance to its cardiovascular effects may be incomplete.⁶⁸ A withdrawal syndrome may follow long-term or binge use. The initial, acute symptoms, referred to as the “crash,” consist of depression, fatigue, craving, hypersomnolence, and anxiety. Anhedonia and hyperphagia soon follow. Although most symptoms are mild and resolve within 1 to 2 weeks, the dysphoria and anhedonia can persist for weeks. These symptoms do not produce profound physiologic changes and are generally not life-threatening.⁶⁸

Treatment of Addiction

28. C.H. decides to get clean and seeks help from a detox clinic. What therapeutic options are available to him?

Most cases of simple cocaine withdrawal do not require medical treatment. Multiple pharmacologic therapies to facilitate abstinence from cocaine have been, and continue to be, under investigation, however. Most studies have yielded variable results, and to date no drug exists that is proven effective in treating cocaine dependence.²⁶ Studies of dopamine agonists (amantadine, selegiline, levo-dopa/carbidopa, pergolide), antidepressants (desipramine, fluoxetine, bupropion), and carbamazepine have yielded inconsistent findings. Methylphenidate (Ritalin) has been investigated as “maintenance treatment” to

satisfy the cocaine addict's desire for further enhancement of mood; however, methylphenidate also can stimulate a powerful craving for the more intense euphoria of cocaine and has significant abuse potential. Recent research shows promise for topiramate, baclofen, tiagabine, disulfiram, and modafinil, but these findings require replication. A cocaine vaccine is currently under investigation. Psychosocial treatments focusing on abstinence have been effective in the treatment of cocaine dependence.²⁶ Cognitive-behavioral therapies and behavioral therapies, such as contingency management, along with 12-step-oriented individual counseling can be useful, although the efficacy of these therapies varies. Participation in a 12-step self-help group (AA, NA), as an adjunct to treatment, seems to predict less cocaine use.

Because currently no drug therapies are effective or approved by the FDA for the treatment of cocaine addiction, C.H. should receive psychosocial treatment, such as cognitive-behavioral therapy and relapse prevention.

Amphetamines

Central nervous system stimulants have been used both with and without social acceptance for thousands of years. The Chinese prepared ephedrine-containing products from a plant called Ma-Huang (*Ephedra vulgaris*).¹⁵ People in East Africa and the Arabian peninsula chew the leaves of the khat bush (*Catha edulis*) for the stimulating effects of the alkaloid cathinone.⁵⁹ Caffeine is consumed worldwide in a usually socially acceptable manner in the form of coffee and cola soft drinks. Amphetamine was synthesized in 1887, and methamphetamine in 1919. The legal sanctions against widespread prescribing of amphetamines in the 1970s restricted their supply and fostered a black market thriving on the illicit production of methamphetamine powder ("speed," "meth," "crank," "crystal meth"). During the 1990s, California and the West Coast experienced a dramatic resurgence of methamphetamine-related hospital admissions, poison center calls, and law enforcement actions. Methamphetamine abuse has since become a nationwide problem, prompting government restrictions on retail sales of ephedrine and pseudoephedrine (precursor chemicals used in the manufacture of methamphetamine). A new marketing tool developed by savvy drug dealers aimed at younger, new users involves bright coloring and flavoring (strawberry, cola, cherry, orange) added to crystal methamphetamine to help mask the bitter taste. According to the National Survey on Drug Use and Health for 2006, there were 731,000 current users of methamphetamine in America. The rate of lifetime methamphetamine use in 2006 (5.8%) was higher than in 2005 (5.2%), but lower than in 2002 (6.5%).¹³

Physical and Psychological Effects

29. D.C., a college student, used speed this past weekend when partying with his friends. He has a midterm examination in 2 days and is too tired to study, so one of his friends suggests snorting some more speed and then hitting the books. Will this help overcome his fatigue?

Methamphetamine produces CNS stimulation by enhancing the effects of norepinephrine, serotonin, and dopamine. This is accomplished by both blocking reuptake and stimulating release of these neurotransmitters. These effects are greater

for dopamine and norepinephrine than for serotonin. Methamphetamine is metabolized in the liver, and its half-life is 6 to 15 hours.⁵⁹

The powerful stimulating effects of amphetamine and methamphetamine have made their use popular among a wide variety of groups, including students, athletes, the military, dieters, and long-distance truck drivers. Initially, the user may experience alertness, euphoria, increased energy, the illusion of increased productivity, sociability, and decreased appetite. Continuous dosing, however, produces stereotypical grooming and other repetitive motions. Physiologic effects include bruxism, tremor, muscle twitching, mydriasis, hypertension, diaphoresis, elevated body temperature, nausea, dry mouth, weight loss, and malnutrition. Continued use over several days decreases productivity and is associated with disordered thoughts, paranoia, and psychosis. Tolerance develops very rapidly after continued use.⁵⁹

Illicit methamphetamine is commonly insufflated or injected and, less commonly, taken orally. In a pattern similar to that seen with smoking cocaine, users are now freebasing methamphetamine and smoking it. Crystal methamphetamine, known as "crystal meth" or "ice," became popular in Japan, Hawaii, and the US West Coast initially, but use has spread to other parts of the United States. Heating the crystals and smoking the vapor, as with crack, is a common route of administration; however, snorting and IV administration are also used. Absorption is rapid after smoking "ice," and the effects can last as long as 24 hours. Methamphetamine-induced psychosis may occur more frequently with the use of "ice." Acute pulmonary edema has also been reported following inhalation.⁶⁹ D.C. will probably be able to stay awake to study if he uses more methamphetamine; however, if he is up for too many days without sleep, his performance on the examination will likely suffer.

Adverse Effects and Toxicities

30. D.C. finds speed very much to his liking and begins to use it daily. He goes many days at a time without sleeping or showering and starts losing weight because he seldom has an appetite. His friends start calling him a "tweaker." He believes his friends are working with the DEA and tapping his phone. What is happening to D.C.?

D.C. is exhibiting classic signs of chronic methamphetamine abuse, which will likely progress if he continues using. A "speed freak" or "tweaker" (chronic methamphetamine user) is generally regarded even by other drug users as mentally unstable, aggressive, and emotionally labile, with unpredictable periods of violent, even homicidal, behavior. Chronic users characteristically develop complex paranoid delusional systems with hallucinations during extended periods of intoxication that may involve several sleepless days and nights of continuous methamphetamine administration. This "speed psychosis" may include tactile hallucinations, such as formication, the sensation of something crawling under the skin. Initial attempts at reassuring, reality-oriented communication ("talking down") may be successful for an acute psychotic episode. An extremely agitated, anxious, psychotic user, however, will often require administration of a benzodiazepine, such as diazepam or lorazepam. If psychosis persists, a high-potency neuroleptic, such as haloperidol, is preferred owing to its minimal

anticholinergic activity. Low-potency neuroleptics, such as chlorpromazine, with higher anticholinergic activity, may worsen symptoms of delirium and hyperthermia.⁶¹

The physiologic toxicity of stimulant drugs includes hypertension, stroke, seizures, hyperthermia, sexual dysfunction, dental caries, rhabdomyolysis, renal failure, cardiac arrhythmias and cardiomyopathies, myocardial infarction, and malnutrition.

The development of neurotoxicities involving dopaminergic and serotonergic neurons has been demonstrated in animals, but it is less clear if such toxicities develop in humans. Although some studies have shown loss of dopamine transporters, resulting in slower motor function and decreased memory, there is evidence of recovery with protracted abstinence.⁷⁰

Withdrawal and Treatment

31. D.C. is arrested for assault following a bar fight. He is held in the county jail and is unable to post bail. What withdrawal symptoms might he experience during incarceration?

D.C. will probably suffer intense cravings for methamphetamine and initial agitation, followed by fatigue and hypersomnolence. A withdrawal state following acute cessation of chronic stimulant use is generally the same as that previously described for cocaine (see Question 27). As with cocaine, the “crash” is notable for marked fatigue, depression, and anhedonia. Most symptoms are mild and will resolve within 1 to 2 weeks, although anhedonia and depression may persist.

Clinical studies investigating treatments for methamphetamine dependence have borrowed from the experience studying cocaine treatments. Currently no effective pharmacologic treatments have been proved effective for methamphetamine dependence. The most effective treatment so far appears to be cognitive-behavioral therapy.⁷¹

DISSOCIATIVE DRUGS: PHENCYCLIDINE, KETAMINE, AND DEXTROMETHORPHAN

Phencyclidine (phenylcyclohexylpiperidine) and ketamine are arylcycloalkylamine, dissociative, anesthetic agents. Phencyclidine (PCP) at one time was marketed as an IV anesthetic agent under the trade name of Sernyl.⁷² Subsequent reports of postanesthetic dysphoric reactions caused the drug to be withdrawn in 1965. It was reintroduced in 1967 as Sernylan and marketed as a veterinary anesthetic until 1978, when the manufacture and sale of the drug became illegal. Ketamine is currently used clinically as an anesthetic in both animals and humans. Ketamine is shorter acting and somewhat less potent than PCP.

Abuse of arylcycloalkylamines occurs primarily in large metropolitan areas. PCP is relatively easy to synthesize and is inexpensive, therefore it is often misrepresented as other street drugs, such as lysergic acid diethylamide (LSD), amphetamine, mescaline, or δ -9-tetrahydrocannabinol (THC). Ketamine (“K,” “Special K,” “Super K,” “cat valium”) is commonly used as a “club drug” and is sometimes misrepresented as 3,4-methylenedioxymethamphetamine (MDMA; ecstasy). Ketamine is often diverted from veterinarian supplies. PCP (“angel dust,” “dust”) in powdered form is often applied to parsley, marijuana (“dusted joint,” “superweed”), or tobacco

cigarettes and smoked. Oral, intranasal, and parenteral routes of administration are used by some. The combination of cocaine and PCP in a freebase smoking mixture is called “Space-Base.” Although ketamine is manufactured as an injectable liquid, it is frequently evaporated to a powder.⁷³ The powder can be snorted or compressed into tablets.

Dextromethorphan, an antitussive agent commonly found in over-the-counter cough remedies, has emerged as a drug of abuse, especially popular among adolescents. Its appeal may be because it is inexpensive, licit, lacks social disapproval associated with other drugs, available over-the-counter, and is believed to be safe because it is produced by a pharmaceutical company. Street names include “Skittles,” “DXM,” “Dex,” “Robo,” “C-C-C,” and “Red Devils.” Use is referred to as “dexing,” “robotripping,” and “robodosing.” Dextromethorphan is the d-isomer of the codeine analog of levorphanol. The metabolic byproduct of dextromethorphan, dextrophan, has weak *N*-methyl-D-aspartate (NMDA) antagonist properties.⁷⁴ When dextromethorphan is ingested in large doses, it produces effects similar to PCP or ketamine. When abused, doses range from 300 to 1,800 mg. The most commonly abused form is Coricidin HBP Cough and Cold (called “C-C-C” on the street) because it contains the highest concentration of dextromethorphan per dosage unit on the market (30 mg). Dextromethorphan is also available for sale on the internet in powdered form, which can be ingested orally or snorted. The dextromethorphan “high” can last 3 to 6 hours and can consist of euphoria, dissociation, hallucinosis, increased perceptual awareness, altered time perception, hyperexcitability, pressure of thought, disorientation; and increased blood pressure, heart rate, and body temperature; and blurry vision.^{74,75} Other ingredients found in the over-the-counter preparations, such as acetaminophen, chlorpheniramine, guaifenesin, and alcohol, may be problematic when ingested in large doses. According to the Drug Abuse Warning Network, an estimated 5,581 emergency department visits in 2004 involved nonmedical use of dextromethorphan.⁷¹ PCP is considered the typical dissociative drug, and review of its effects largely applies to ketamine and dextromethorphan as well.⁷³

Phencyclidine

Phencyclidine Intoxication

32. J.R., age 18, is brought to the emergency department by police for violent, combative behavior. Friends claim he was smoking a “dusted joint” (PCP applied to a marijuana cigarette). He appears agitated, diaphoretic, and disoriented. His blood pressure is 160/100 mm Hg, pulse 130 beats/minute, and temperature 101°F. He has vertical and horizontal nystagmus. Are these effects consistent with PCP intoxication?

J.R.’s symptoms are consistent with PCP intoxication. PCP and ketamine are noncompetitive antagonists of the NMDA receptor subtype of the major excitatory neurotransmitter, glutamate. The dose, route of administration, and serum concentration of phencyclidine all influence the pharmacologic effects of this drug and, thus, the symptoms of intoxication.⁷² PCP in low doses causes inebriation, ataxia, changes in body image, numbness, and a mind-body dissociative feeling. Horizontal, vertical nystagmus, or both are often present, and the anesthetic

effect of the drug raises the pain threshold. Amnesia can occur following intoxication.

As the dose of PCP increases, the patient may manifest agitation, combativeness, catatonia (ketamine users refer to this as a “k-hole”), and psychosis. The action of PCP on the autonomic nervous system becomes more prominent and is characterized by a confusing combination of adrenergic, cholinergic, and dopaminergic effects. A hypertensive response is typically encountered. Tachycardia, tachypnea, and hyperthermia may also be noted in the moderately intoxicated patient. The agitated, combative patient often has feelings of great strength. This, combined with the anesthetic effect of PCP, can result in serious injury because there is no pain sensation to stop the physical activity.

With large doses of PCP, marked CNS depression occurs and nystagmus may no longer be present. In addition to the physiologic effects noted earlier, respiratory depression, seizures, acidosis, and rhabdomyolysis may further compromise the patient’s condition. Rhabdomyolysis, particularly in the presence of acidemia, can result in acute renal failure.⁶¹ Opisthotonic posturing and muscular rigidity occur frequently in the severely intoxicated patient.

Medical Management of Intoxication

33. How should J.R. be treated?

Diagnosis of PCP intoxication should be confirmed through a blood or urine specimen. Currently, no clinically useful antidote to PCP exists, and treatment should be supportive. Environmental stimuli should be minimized. Even attempts to “talk down” the patient may trigger a combative response, and chemical restraints may be indicated. Physical restraints may increase risk of rhabdomyolysis and should be reserved for patients who pose threat of great danger to themselves or others. Benzodiazepines are useful in the management of the anxious, agitated patient with mild to moderate PCP intoxication. If benzodiazepines are insufficient, haloperidol (5 mg IM) is effective.⁵⁷ Low-potency neuroleptics should be avoided because a greater possibility of precipitating a hypotensive response or a seizure exists.

Hypertension may be managed with β -blockers or calcium channel blockers. Diazepam is a useful anticonvulsant for the management of PCP-induced seizures. Because extreme agitation, seizures, and hyperthermia can initiate rhabdomyolysis and secondarily cause myocardial, renal, or hepatic dysfunction, anxiolytics, neuroleptics, anticonvulsants, and cooling measures should be used as needed.

Management may also include attempts to increase elimination of PCP from the body. The urinary excretion of PCP (a basic compound) is enhanced when the urine is acidic; however, the amount excreted usually is not very large compared with the amount ingested.⁶¹ Activated charcoal in a dose of 1 g/kg given every 2 to 4 hours can prevent the intestinal reabsorption of this drug and promote its elimination.

Psychological and Prolonged Effects

34. J.R. is admitted for a 72-hour psychiatric evaluation. His history reveals that he is a chronic PCP abuser. What psychological adverse effects are associated with chronic use?

Chronic PCP use can result in long-term residual psychological symptoms, including anxiety, depression, and psychosis.⁶¹ Pharmacotherapy for these symptoms may be necessary. Prolonged psychiatric sequelae are almost always associated with premorbid psychopathology. Perceptual disorders, including auditory and visual hallucinations, such as after images seen following moving objects (“trails”), may also occur. Flashbacks (discussed in detail in the following section on LSD) have been reported after PCP use.

The DSM-IV does not recognize PCP withdrawal; however about one-fourth of heavy PCP users report symptoms following discontinuation of use.⁶¹ These symptoms include depression, anxiety, irritability, hypersomnolence, diaphoresis, and tremor. Animal studies have described a withdrawal syndrome, but it is unclear if a true withdrawal syndrome occurs in humans.⁷⁶ Currently, no pharmacologic treatments for PCP addiction exist. Some animal data indicate neurotoxicity; however, the long-term consequences and significance for humans is unknown and requires further study. Chronic users often complain of feeling “spaced”; they may be irritable and antisocial and feel depersonalized and isolated from people. Memory lapses, speech and visual disturbances, and confusion have been described in long-term users as well.

HALLUCINOGENS

Hallucinogens can be categorized as indole alkylamines (e.g., LSD, psilocybin, and dimethyltryptamine) or phenethylamines (e.g., mescaline; MDMA). LSD is considered the prototype hallucinogen. Although MDMA is classified as a phenethylamine, it has structural similarities to amphetamine and mescaline. It has been labeled an entactogen or empathogen because of its strong empathy-producing effects and mild hallucinogenic effects. The term *entactogen* can be translated as “a touching within.” Hallucinogens are commonly referred to as *psychedelics*.

In 2006, >35 million Americans reported using hallucinogens sometime in their lives, 3.9 million had used it in the past year, and >1 million had used it in the past month. The popularity of MDMA (ecstasy, X) has risen dramatically in recent years, partly because of its use as a “club drug.” In 2006, 12.2 million Americans reported using MDMA sometime in their lives, 2.1 million had used it in the past year, and 528,000 had used it in the past month.¹³

The usual pattern of use for hallucinogens is occasional self-administration for enhancement of recreational activities, such as dancing, or for “mind expansion.” Certain individuals may develop psychological dependence and use hallucinogens in a more chronic and compulsive manner.

LSD

Effects

35. B.T. attended a dinner party with a few close friends and the host suggested they all “trip” (take LSD) after dinner. B.T. had no previous experience with LSD but was very excited to try it. She took a “hit” (dose) and her host told her she should cancel all plans for tomorrow. What can she expect?

Perhaps the most famous of all hallucinogens, LSD-25, was first synthesized by Albert Hofmann of Sandoz Laboratories

in 1938.⁷³ It was developed as an analeptic agent but produced significant uterine stimulation and caused experimental animals to become excited or cataleptic. Five years later, while resynthesizing LSD-25 for further pharmacologic testing, Dr. Hofmann experienced a restlessness that forced him to go home. This was followed by 2 hours of intense visual hallucinations of kaleidoscopic images and colors. Later, he identified LSD-25 as a potent hallucinogen. Clinical experimentation produced hundreds of papers describing LSD as a drug that could facilitate psychotherapy, particularly in the management of addictive behavior. Widespread public self-experimentation with LSD for recreation and self-exploration, coupled with growing attention to adverse psychological consequences, led Sandoz to discontinue production of LSD-25 (as well as psilocybin, psilocin, and related congeners) in August 1965. The United States made LSD a schedule I controlled substance in 1970 after the proliferation of illicit suppliers to meet the huge public demand for this drug.

Although the mechanism of action of classic hallucinogens is not fully understood, they appear to predominately act as agonists or partial agonists at serotonin (5-HT) receptors, specifically the 5-HT₂ receptor.⁷⁷ LSD, one of the most potent hallucinogens known, is active at doses of 25 to 250 mcg. Most users take about 100 to 150 mcg of LSD for a significant effect. This dose produces mild to moderate sympathomimetic effects, profound visual hallucinosis, and the sensation of disordered integration of sensory input. For example, sounds and music are perceived as visual imagery, odors are felt, and inanimate objects assume lifelike qualities. In addition to these sensory-perceptual effects, psychic effects occur, such as depersonalization, dreamlike feelings, and rapid alterations of affect. These are accompanied by somatic effects, including dizziness, nausea, weakness, tremor, and tingling skin.^{73,77} These combined effects begin within an hour of ingestion of LSD and usually peak in intensity during the first 2 to 3 hours. After taking LSD, most people feel they have returned to a normal psychological state by 8 to 12 hours.

Within an hour after ingestion, B.T. will begin to experience altered sensations of her surroundings, in addition to some psychic and somatic effects.

Adverse Effects

36. After a few hours of “tripping,” B.T. begins to think she will never return to a normal state. She fears she has “slipped over the edge” and begins to panic. What is happening to her?

The most frequently encountered adverse reaction associated with the hallucinogenic drugs is a mental state of acute anxiety and fear, typically referred to as a “bad trip.” The hallucinogen experience is influenced by set (the user’s mental state and expectations of drug effects) and setting (the environment in which drug use takes place, including the social conditions). Users may be able to calm themselves without outside intervention. The initial therapy of people undergoing a bad trip is frequently called “reality therapy” and consists of “talking down” the fear and panic.^{61,77} This consists of getting the person to a quiet, relaxed setting and helping him or her focus on explanations for the uncertainties that are causing the panic. This process also tends to reassure the person that he or she is in a safe physical environment and that the drug effects will diminish in a few hours. Most of these bad trips are re-

solved during the state of intoxication (generally, 6–12 hours), but some last as long as 24 to 48 hours.

If the talk-down approach is not successful in resolving the panic, drug therapy can be considered. Sedation with an oral benzodiazepine (i.e., diazepam 10–30 mg) or a parenteral benzodiazepine (i.e., lorazepam 2 mg IM) will frequently alleviate the panic.⁶¹ Supportive talking down should be continued because the benzodiazepine will not stop the trip; it will simply sedate the patient. Haloperidol 2 mg IM may also be used if benzodiazepines are insufficient. Phenothiazines should not be used for initial management of bad trips because they have been associated with poor outcomes.⁶¹

With regard to adverse physical effects, classic hallucinogens have a high margin of safety, although patients should be monitored for seizures or elevations in body temperature, which may indicate a potential hyperthermic crisis. Anticonvulsant therapy may not be effective until body temperature has been lowered.⁶¹

B.T. is experiencing a bad trip. Her friends should try to “talk her down,” with reassurance that the effects of the drug will eventually wear off. If this approach is unsuccessful, she should be taken to the emergency room for pharmacologic treatment of her anxiety and panic.

Flashbacks and Long-Term Effects

37. B.T.’s friends “talk her down,” but she has heard that people sometimes have flashbacks after LSD use and is worried she will re-experience her bad trip. What are flashbacks? What are the long-term consequences of LSD use?

Use of hallucinogens can trigger a transient psychosis or unmask an underlying psychiatric disorder; however, a true psychotic episode is rare. Psychiatric conditions following hallucinogen use that persist more than a month are likely caused by pre-existing psychopathology.⁶¹ Hallucinogen use does not seem to be associated with any cognitive impairment.⁷⁸

Hallucinogen persisting perceptual disorder (HPPD), commonly referred to as *flashbacks*, is characterized by recurrences of part or all of the hallucinogenic drug experiences following a period of normal consciousness in a person who used the drug previously. The American Psychiatric Association’s DSM-IV includes diagnostic criteria for HPPD. The flashbacks may last from minutes to days or months (usually a few hours). The estimated prevalence of flashbacks varies widely in studies and the etiology is still unclear.⁷⁹ Flashbacks can occur spontaneously or be triggered by exercise, stress, or another drug (e.g., marijuana).⁶¹ Treatment remains anecdotal; no randomized, controlled trials have evaluated the efficacy of pharmacotherapy for HPPD.

LSD and other classic hallucinogens have low addiction potential. There does not appear to be a clinically important withdrawal syndrome associated with their use. The rapid development of tolerance that occurs with these drugs may explain the intermittent use patterns commonly seen.

MDMA

Effects

38. R.X. and her friend P.B. go to “raves” (all-night dance parties) every weekend and usually take ecstasy (MDMA). R.X. says

it makes her feel like “I love everyone around me,” and P.B. likes to be able to “dance all night without getting tired.” Are these effects common with MDMA?

Merck Pharmaceuticals patented MDMA in 1914, but it was not until the 1950s that its use was examined in animal studies, when the US Army Intelligence investigated it as a “brainwashing” agent. By the late 1970s, a few therapists and psychiatrists began using the drug with reported success in patients with a wide range of conditions.⁸⁰ MDMA produces a very manageable and comfortable entactogenic effect, during which the person has a clear sensorium. The experience can be recalled in detail, and the insights gained during the session can be incorporated into normal life. The public gave several names to this drug, such as ecstasy, XTC, Adam, and M&Ms. The media became aware of the anecdotal reports from both psychiatrists and people self-experimenting with MDMA. In 1985, the DEA made MDMA a schedule I drug. Subsequently, supplies of the drug proliferated in the public illicit marketplace, and its popularity soared. In 2001, following successful lobbying by researchers interested in reinstating MDMA in clinical practice, the FDA granted approval for a pilot study investigating the therapeutic use of MDMA in the treatment of posttraumatic stress disorder (PTSD).⁸¹ At the time of this writing, the study has nearly completed phase II. The FDA has also approved a phase II dose-response pilot study of MDMA-assisted psychotherapy in subjects with anxiety associated with advanced stages of cancer.

The effects of MDMA are mainly exerted by three neurochemical mechanisms: blockade of serotonin reuptake, stimulation of serotonin release, and stimulation of dopamine release.⁸² The common psychological effects of MDMA intoxication include an overall heightened sense of empathy, interpersonal closeness, increased acceptance of others, and a powerful sense of well-being.⁸³ The experience is influenced by set and setting. The amphetamine-like side effects include mydriasis, tachycardia, sweating, increased energy and alertness, bruxism, nausea, and anorexia.⁸⁴ Users generally ingest MDMA in tablet form and the onset of action is usually after 30 to 60 minutes. Some users take a “booster” dose after 2 hours. The usual duration of action of MDMA is 4 to 6 hours and the half-life is approximately 8 hours. MDMA users in the “rave” scene often “stack” multiple doses, and polydrug use is common. The combined use of ecstasy and LSD is referred to as “candy flipping.”⁸²

R.X.’s feelings of love for everyone are consistent with the empathogenic effects of MDMA, whereas P.B. is enjoying the amphetaminelike effects of increased energy to dance all night.

Adverse Effects

39. Several hours after taking MDMA, P.B. is still dancing. She begins to feel hot and realizes she is profusely sweating. On her way to the bar for a drink, she begins to feel confused and collapses to the floor. Her friends witness her having a seizure and call 911. What is happening to P.B.?

The “rave” scene, with its crowded conditions and often-high ambient temperatures, has contributed to many adverse effects associated with MDMA ingestion. Because of their increased physical activity, the “ravers” may become dehydrated. Additionally, supplies of MDMA have been notoriously unreliable. Many other drugs have been misrepresented

as MDMA, including other phenethylamines such as 3,4-methylenedioxyamphetamine (MDA) and paramethoxyamphetamine (PMA); amphetamine; cocaine; opiates; ketamine; and dextromethorphan. The common polydrug use practiced at “raves” compounds the problem. Dextromethorphan taken at high doses for its dissociative properties competes with MDMA for hepatic metabolism and its anticholinergic effects block perspiration, potentially leading to overheating.⁸⁰

The most dangerous adverse physical effect of MDMA is hyperthermia. MDMA has a slight affinity for the 5-HT₂ receptor, and the increased body temperature may be the result of this activation.⁸² The hyperthermia has led to rhabdomyolysis, and acute renal and hepatic failure, disseminated intravascular coagulation (DIC), and death.⁸⁵ DIC has been the most common cause of death. Treatment of hyperthermia involves cooling measures and IV fluids. Benzodiazepines (e.g., lorazepam 2 mg IM or IV) and dantrolene (1 mg/kg IV) may be helpful. Other adverse physical effects can include hypertension, cardiac arrhythmias, convulsions, cerebrovascular accident, hepatitis, and hyponatremia (from overingestion of water as a harm reduction measure to avoid hyperthermia).^{84,85} Although emergency room visits associated with MDMA use continue to be relatively rare, they increased dramatically (>2,000%) from 1994 to 2001, but have remained stable since.^{22,86} Adverse psychological effects are also possible, including anxiety, depression, panic attacks, agitation, paranoia, and rarely psychosis. The treatment of these psychological adverse effects is the same as for those associated with the classic hallucinogens, including “talk-down” therapy and benzodiazepine administration. P.B. may be suffering from MDMA-induced hyperthermia and needs urgent medical evaluation.

Long-Term Effects

40. R.X. has read in the newspaper that MDMA is associated with “brain damage” and is worried that she has caused permanent damage to her brain. What are the long-term effects of MDMA?

Animal studies have consistently demonstrated long-term MDMA-induced serotonin depletion. This has been evidenced by lower levels of serotonin, decreased metabolite levels, lowered levels of tryptophan hydroxylase, and loss of serotonin reuptake transporters.⁸⁰ MDMA damages serotonin axonal projections; axonal resprouting and regeneration do occur, but it is unclear if these new projections are damaged. Despite this evidence of neurotoxicity, no associated functional changes have been demonstrated.^{80,87}

Several retrospective studies in humans have claimed lowered cognitive performance in MDMA users compared with nonusers. These studies have serious methodologic flaws, including their retrospective design and failure to control for important confounding variables, such as other drug use and adulterant exposure and lifestyle factors.^{80,87} Well-controlled, prospective clinical trials are required to establish definitively any risk associated with MDMA ingestion.

Use of MDMA does not appear to produce physical dependence, but some users may become psychologically dependent. Tolerance to the empathogenic effects develops rapidly and may last 24 to 36 hours. This may explain in part the more common practice of sporadic dosing of the drug.⁸³ No

distinctive withdrawal syndrome has been described that would require pharmacologic treatment.

MARIJUANA

Marijuana is the most widely used illicit substance in the United States. In 2006, 97.8 million Americans reported using marijuana at some time in their lives, 25.3 million had used in the past year, and 14.8 million had used in the past month.¹³ The main psychoactive ingredient in the *Cannabis sativa* plant is THC, although the plant is known to contain more than 70 cannabinoids.⁸⁸ In the United States, the dried, chopped leaves and flowers of the *Cannabis* plant (grass, pot, weed, green bud, chronic, mary jane) are rolled into a cigarette paper (marijuana cigarette, known as a joint or blunt; a “roach” is the butt of the marijuana cigarette) or smoked in a pipe or water pipe (“bong”). Each joint usually weighs 0.5 to 1 g, for a THC content of about 5 mg (very weak), 30 mg (average), or 100 mg (highest-quality sinsemilla). The sinsemilla (Spanish for “without seeds”) growing technique involves separating the female plants from the males before pollination occurs. This results in female plants with higher amounts of THC, up to 14%.⁸⁹

A dramatic increase in the potency of marijuana has occurred over the past two decades. Marijuana average potency has increased 52.4% (from 5.34% THC to 8.14%) just within the last 5 years.¹² The raw resin of the *Cannabis* plant can be pressed into cakes, balls, or sticks, called hashish (“hash,” “temple balls”), which is smoked or eaten. Hashish can contain up to 12% THC. The oils can be extracted from the plant with organic solvents to produce “hash oil,” perhaps the most potent *Cannabis* derivative, with THC concentrations of up to 50%.⁸⁹ Commercial grade marijuana (marijuana not grown by the sinsemilla technique) sells on average for \$100 per ounce, but high-quality marijuana can cost \$600 per ounce.¹⁴

Researchers in cannabinoid neurobiology have discovered two cannabinoid receptors in the CNS: CB₁ and CB₂; however, additional receptors have been proposed. In addition, five endogenous cannabinoids (endocannabinoids) that act at the cannabinoid receptors have been discovered.^{90,91} The best-known are arachidonic acid ethanolamide (anandamide) and 2-arachidonoylglycerol (2-AG).⁹⁰

Marijuana’s therapeutic potential has been the center of much public controversy. Research on the effects of cannabinoids has led to several potential therapeutic uses, including relief of nausea and vomiting, appetite stimulation; treatment of pain, epilepsy, glaucoma, migraine, anxiety, depression, and movement disorders (Parkinson’s disease, Huntington’s disease, Tourette’s syndrome, multiple sclerosis); and providing neuroprotection after brain injury or cerebral ischemia.^{91,92} A synthetic form of THC, dronabinol, is available as prescription tablets, and a synthetic cannabinoid, nabilone, is available as capsules, but advocates of medicinal marijuana use argue that inhalation allows for faster onset and easier titration of the dose. In addition, nauseated patients want to avoid the oral route of administration. Future research may focus on developing a safer delivery system that will be reliable, rapid, and safe.⁹³ An oromucosal spray, Sativex, derived from botanical material, is under investigation in the United States. The principal active components are THC and cannabidiol. This cannabis extract

spray has been approved in Canada, and is also being used in the United Kingdom.

Effects

41. After school one day, P.H. is offered a “joint” by one of his friends. He smokes it and begins to feel light-headed and euphoric. He begins laughing at everything around him. Thirty minutes later he and his friend become very hungry (“the munchies”) and eat several candy bars. Are these effects consistent with marijuana use?

Yes. The pharmacologic effects sought by most users of cannabis products are sedation, mental relaxation, euphoria, and mild hallucinogenic effects, and these effects depend on set and setting. Other common effects that are usually perceived as pleasurable include silliness, subjective slowing of time, gregariousness, hunger, and mild perceptual changes of all the senses that engender an absorbing fascination with music, eating, and other sensual and sensory activities. The state of mind generated is referred to as “stoned,” “high,” “loaded,” “wasted,” and many other colloquial terms. Smoking marijuana typically causes numbness and tingling of the extremities, light-headedness, loss of concentration, and a floating sensation in the first 3 or 4 minutes. Some of these effects are probably caused by the hyperventilation associated with deep inhalation of the smoke (referred to as a “hit” or “toke”) and breath holding to allow maximal absorption from the lungs. Over the first 10 to 30 minutes, the user may experience tachycardia (possibly palpitations), mild diaphoresis, conjunctival injection, drying of the mouth, weakness, postural hypotension, periods of tremulousness, incoordination, and ataxia along with euphoria and the mental effects described above. These effects usually resolve by 1 to 3 hours and are followed by a 30- to 60-minute period of sleepiness before complete clearing and return to normal consciousness. Oral ingestion of cannabis products may delay the onset of effects by 45 to 60 minutes and prolong the duration.⁸⁹

Adverse Effects

42. P.H. smokes more marijuana with his friend. He liked it so much the first time, he decides to take several “hits” this time. He begins to think his friend is laughing at him and notices his heart is beating rapidly. He starts to panic. Is P.H.’s reaction caused by the marijuana?

Consistent with its widespread use, marijuana was the second most frequently mentioned illicit substance in emergency department episodes in the United States in 2005. A total of 242,200 marijuana-related emergency department visits were mentioned in 2005.²² Despite these numbers, cases have been documented of fatality in humans from marijuana overdose, and adverse effects tend to be self-limiting and often do not require medical treatment.

A syndrome consisting of anxiety, paranoia, depersonalization, disorientation, and confusion that can lead to panic states and incapacitating fear is perhaps the most frequently reported adverse effect of marijuana. Comforting reassurance (“talk down”) and reducing stressful stimuli can alleviate this condition. The dysphoria and anxiety usually resolve in a few

hours or less with such an approach. More severe incidents that evolve into panic reactions that are not resolved by sympathetic counseling may be relieved with oral benzodiazepine therapy in a dose equivalent to 5 to 10 mg of diazepam.⁶¹ These adverse psychological reactions to cannabis products commonly occur with inexperienced users, high doses, concomitant use of other psychoactive drugs, and overtly stressful situations. Severe reactions requiring pharmacologic therapy are rare.

Currently, there is much debate in the scientific community regarding the association of marijuana and psychosis. A review of the literature found that cannabis use increases the risk of developing psychotic disorders among vulnerable or predisposed individuals and negatively affects the course of pre-existing chronic psychosis.⁸⁸ Population statistics argue against a causal relationship.

Adverse physical effects can include slowed psychomotor responses and short-term memory loss. Slowed psychomotor responses have been shown in certain groups of acutely intoxicated subjects and chronic users. Short-term memory loss is a frequently documented acute, reversible effect of marijuana intoxication as well.

The paranoid ideation and panic reaction of P.H. could certainly be caused by the high dose and his inexperience with marijuana.

Long-Term Effects

43. P.H. continues to smoke marijuana daily. His parents discover his marijuana use and confront him, telling him it will make him stupid, unmotivated, and strung out, and may lead to the use of harder drugs. Are P.H.'s parents' concerns valid? What are possible long-term effects of marijuana use?

Chronic use of cannabis has been alleged to produce an “amotivational syndrome” characterized by apathy, lack of long-term goal achievement, inability to manage stress, and generalized laziness, but little scientific evidence supports such a syndrome.⁸⁹

Cognitive impairment can occur after heavy marijuana use, but appears to be reversible with abstinence.⁹⁴ The impairment is more pronounced, the longer the drug is used.⁸⁹ Other concurrent drug use may also contribute to cognitive impairment associated with marijuana use. Evidence of brain damage associated with marijuana use is equivocal.

The pulmonary complications of chronic heavy marijuana use are potentially significant. Chronic cough, sputum, wheezing, bronchitis, and cellular changes typical of chronic tobacco smokers are reported in chronic cannabis smokers.^{89,95} THC has been shown to be a potent bronchodilator. Both oral and smoked THC were shown to produce significant bronchodilation when given to healthy subjects. The bronchodilatory response in asthmatics given THC has been shown to be less vigorous.⁶⁶ Tolerance to these effects can develop after some weeks, and chronic marijuana smoking results in increased airway resistance and decreased pulmonary function.⁸⁹ Many of the same carcinogens in nicotine cigarettes are also found in marijuana smoke. Epidemiologic studies have suggested an association between marijuana smoking and certain cancers (lung, head and neck); however, controlled studies have not established such a link.^{96–98} *Aspergillus*-contaminated marijuana has been reported to cause pulmonary fungal infec-

tions in immunocompromised patients, who may be using the drug for its medicinal value.⁹⁹ Harm reductionists have recommended that immunocompromised patients microwave their marijuana before use.

Tolerance to the psychoactive effects of marijuana does develop. Chronic users may not experience the full range of effects as new users unless they abstain for several days or weeks to regain initial sensitivity to the cannabis, and chronic users can tolerate large doses that generally are toxic to novices. Tolerance develops rapidly to both physiologic and psychological effects of cannabis. Dependence characterized by a physical withdrawal syndrome occurs after chronic high-dose use of cannabis. The withdrawal syndrome can involve anxiety, depression, irritability, restlessness, decreased appetite, sleep disturbance, sweating, tremor, nausea, vomiting, and diarrhea.^{61,89} Dysphoria and malaise similar to that experienced with influenza can also occur. The cumulative dose of cannabis and duration of use necessary to produce dependence have varied significantly. The withdrawal syndrome is generally mild and self-limiting, and pharmacologic treatments usually are not required.

Marijuana has been labeled as a “gateway drug,” meaning that it will lead to the use of “harder” drugs, such as cocaine or heroin. Marijuana is the most widely used illicit drug, but use of drugs such as alcohol and tobacco often predates marijuana use. No studies have conclusively demonstrated a causal link between marijuana use and subsequent other drug use.⁸⁹

P.H.'s parents' concerns are understandable, but not entirely accurate. They should attempt to educate P.H. about the true risks involved with marijuana use, such as interference with studies, risk of pulmonary complications, and possible risk of dependence.

INHALANTS

The introduction of anesthetics (nitrous oxide, chloroform, and ether) to medicine in the early 1800s also promoted the widespread and popular recreational use of these inhalants for mind-altering recreational purposes. Today, abused inhalants include a wide variety of chemicals that are found readily in homes, workplaces, or purchased at retail establishments. Inhalants are commonly subdivided into three main categories: the volatile solvents (mostly hydrocarbons); volatile nitrites (amyl, butyl, isobutyl, cyclohexyl); and nitrous oxide (“laughing gas”). The fumes or vapors of these liquids, or paste in the case of glue, are directly inhaled out of their containers (“sniffing”); poured onto a rag which is held to the nose (“huffing”); poured into a plastic bag (“bagging”); or merely cupped in the hands and inhaled. Aerosols and gaseous substances such as nitrous oxide are also used to inflate a balloon and then inhaled out of the balloon by the user. These products can also be ingested orally or sprayed directly into the mouth. Volatile solvents include gasoline, toluene, kerosene, alcohols, airplane glue, lacquer thinner, acetone (nail polish remover), benzene (nail polish remover, model cement), naphtha (lighter fluid), plastic cement, liquid paper (i.e., White Out, usually containing 1,1,1-trichloroethane, also trichloroethylene and perchlorethylene), and many others. The volatile nitrites, once widely available, are prohibited by the Consumer Product Safety Commission but can still be found, sold in small bottles, labeled as “video head cleaner” or “room odorizer.” Amyl nitrite is used

medically as a vasodilator for treatment of angina and requires a prescription. The volatile nitrites are commonly referred to as “poppers,” because of the sound made when an ampule of amyl nitrite is broken open. The most commonly used inhalants are glue, shoe polish, toluene, and gasoline.^{100–102} The use of multiple products is common. Silver and gold paints are popular because they contain more toluene than paints of other colors.¹⁰³

In 2006, 22.8 million Americans reported using inhalants at some time in their lives, >2 million had used them in the past year, and 761,000 had used them in the past month.¹³ Unlike other drugs of abuse, inhalant use is most common among younger individuals (consistently highest annual prevalence among 8th graders) and tends to decline as youth grow older. The decline likely reflects that other drugs become available and are substituted, and that the inhalants are seen as “kids” drugs. Abuse of inhalants is believed to be popular among children and adolescents because of their low cost, easy availability, rapid onset, and low threat of legal intervention. Additionally, they are easily concealed. The 2006 Monitoring the Future (MTF) study found that 16.1% of 8th graders have abused inhalants.¹⁰⁴ The MTF and other national surveys of adolescents have found that after marijuana, inhalants are the second most widely used class of illicit drugs for 8th graders.⁹⁶ Most inhalant users, however, have used alcohol or cigarettes previously.¹⁰⁵ These surveys, most of which are administered in schools, likely underestimate the true prevalence, as a small but high risk group (incarcerated, homeless, and transient adolescents) are not included in the surveys. Historically, use of inhalants in the United States has been highest among native American youth and lowest among black and Asian youth.^{100,105}

It was previously believed that inhalant use was more prevalent in rural communities; however, recent surveys indicate use occurs in both urban and rural settings.¹⁰³ Inhalant use has been associated with polysubstance use, later IV drug use, delinquency, depression, suicidal behavior, antisocial personality disorder, and impaired family functioning.^{100,106,107} Some research has indicated inhalant use is more prevalent in lower socioeconomic groups, but recent studies have failed to show an association between use and family income.^{100,105} Inhalant use is not gender-specific; however, sustained abuse is more common in male users.^{100,103,107} Friends’ influence on drug use (peer pressure) has been shown to be the strongest predictor of drug use in adolescents.¹⁰⁸

Effects of Inhalants

44. H.K., age 14, has been pouring degreasing solvents, gasoline, and paint thinners onto a rag and “huffing” the fumes to produce intoxication. What clinical presentation might be expected in this young man?

Inhalant abuse includes a broad range of chemicals and they likely have different pharmacologic effects. In fact, the mechanisms of action of the volatile inhalants are poorly understood. Nearly all have CNS depressant effects. Evidence from animal studies suggests the effects and mechanism of action of volatile solvents are similar to those of alcohol and sedative hypnotics.^{103,109}

Gases and vapors are rapidly absorbed when inhaled and, because of their high lipophilicity, tend to distribute preferen-

tially to lipid-rich organs such as the brain and liver.¹⁰¹ Expired air is the major route of elimination, and most are metabolized to some extent.

Inhalation of these products produces a temporary stimulation and reduced inhibitions before the depressive CNS effects occur. Acute intoxication is associated with euphoria, giddiness, dizziness, slurred speech, unsteady gait, and drowsiness.¹⁰³ As the CNS becomes more deeply affected, illusions, hallucinations, and delusions develop. The user experiences a euphoric, dreamy high that culminates in a short period of sleep. The intoxicated state lasts a few minutes, but users may continue to inhale repeatedly over several hours.

Nitrous oxide is an antagonist of the NMDA subtype of the glutamate receptor.⁷² Its pharmacologic effects are poorly understood. It produces euphoria and symptoms of intoxication similar to those described for the volatile solvents.

The major effect of the volatile nitrites is the relaxation of all smooth muscles in the body, including the blood vessels. This usually allows a greater volume of blood to flow to the brain. The onset of effects takes 7 or 8 seconds and the effects last about 30 seconds. A certain “rush” occurs, which may be followed by a severe headache, dizziness, and giddiness. The volatile nitrites are frequently used in the context of sexual activity, particularly by homosexual males because of the effect of increased tumescence and relaxation of smooth muscle.¹¹⁰

Acute Complications of Inhalants

45. What acute complications may H.K. experience from inhalation of these solvents?

In 2005 the Drug Abuse Warning Network reported 4,312 emergency department visits were associated with inhalant use in the United States.²² Deaths from inhalant use are well documented and may occur from overdose or trauma (falls, drowning, hanging). Death from overdose is often caused by respiratory problems or suffocation after CNS depression.¹¹⁰ Deaths caused by asphyxiation, convulsions, coma, and aspiration of gastric contents have occurred.¹⁰³ Acute cardiotoxicity resulting in cardiac arrest is the most common cause of sudden death.¹⁰⁷ Referred to as “sudden sniffing death,” it is likely caused by “sensitization” of the myocardium to catecholamines, exacerbated by physical exercise, resulting in fatal ventricular arrhythmias. Nearly one-third of deaths resulted from first-time use and 90% of deaths are men.¹⁰⁷ A study of cases of inhalant abuse reported to US poison control centers found that three categories of inhalants were disproportionately responsible for most deaths: gasoline, air fresheners, and propane/butane.¹¹¹ The author of that study concluded that a potential exists for >200 deaths from volatile solvent abuse per year in the United States.

Toxicities of Inhalants

46. What toxicities are associated with chronic inhalation of solvents?

The wide variety of chemicals inhaled causes a tremendous range of toxicities. Toxicity depends on the chemical, and on the magnitude and duration of exposure. Complications can result from the effects of the solvents or other toxic ingredients, such as lead in gasoline. The lipophilicity of the volatiles enhances their toxicity. Injuries to the brain, liver,

kidney, bone marrow, and particularly the lungs can occur and they may result from the effect of heavy exposure or hypersensitivity. Inhalant abusers may develop irritation of the eyes, nose, mouth, including rhinitis, conjunctivitis, and rash.¹¹⁰ Methemoglobinemia has been associated with volatile nitrite use.¹⁰⁷

Many of the inhalants produce neurotoxicity, which can range from mild impairment to severe dementia. Studies reveal approximately 10% of chronic inhalant abusers develop evidence of neurotoxicity.¹⁰¹ Neurologic deficits include cognitive impairment, ataxia, optic neuropathy, deafness, and disorders of equilibrium. Loss of white matter, brain atrophy, and damage to specific neural pathways can result from chronic exposure to some inhalants.

Solvent abusers have been found to have impaired executive functions, including capacity for insight and behavioral self-control.¹⁰¹ Some damage to the nervous system and other organs may be at least partially reversible when inhalant use is discontinued.¹⁰³

Inhalant Abuse and Dependence

47. Are inhalants addictive?

Compulsive use has been documented with inhalants, although inhalant abuse and dependence is a neglected area of

research. Animal studies have shown some of the abused inhalants to have reinforcing properties.^{110,112} The DSM-IV sets criteria for inhalant abuse and dependence, but does not provide for physiologic dependence, and it is unclear if a true withdrawal syndrome occurs with chronic use of inhalants. Inhalant use is typically episodic in nature and, thus, users may not be exposed to levels with sufficient frequency necessary to develop physical dependence or tolerance. A review of national surveys of adolescents found 11% of past year users met the criteria for inhalant abuse or dependence.¹⁰⁰ A study of adolescents in drug treatment revealed that inhalant abuse or dependence is relatively uncommon in adolescent treatment programs.¹⁰⁶ Although many adolescents may try inhalants, few meet criteria for DSM-IV–defined inhalant use disorders. Volatile solvent abusers are particularly refractory to drug treatment.¹⁰⁸

ACKNOWLEDGMENT

The authors acknowledge James F. Buchanan, Howard E. McKinney, Gregory N. Hayner, Darryl S. Inaba, Jeffery N. Baldwin, and Blaine Benson for their authorship of previous editions of this chapter.

ALCOHOL CONTENT AND DEFINITIONS

Beverages containing alcohol (ethanol) have a wide range of ethanol content. Alcoholic proof is a measure of how much ethanol is in an alcoholic beverage, and is twice the percentage of alcohol by volume (ABV), the unit that is commonly used as percent. This system dates to the 18th century, and perhaps earlier, when spirits were graded along with gunpowder. A solution of water and alcohol “proved” itself when it could be poured on a pinch of gunpowder and the wet powder could still be ignited. If the gunpowder did not ignite, the solution had too much water in it and the proof was considered insufficient. A “proven” solution was defined as 100 degrees proof (100).^{1,2}

In the United States, the proof is twice the percentage of alcohol content measured by volume at a temperature of 60°F. Therefore “80 proof” is 40% alcohol by volume, and pure alcohol (100%) is “200 proof.” One hundred percent ethanol does not stay 100%, because it is hygroscopic and absorbs water from the atmosphere.

Alcohol is produced by yeast during the process of fermentation. The amount of alcohol in the finished liquid depends on the amount of sugar initially present for the yeast to convert into alcohol. Low alcohol beer is beer with very low or no

alcohol content. Legally, in the United States, beers containing up to 0.5% alcohol by volume can be called nonalcoholic. In some states (e.g., Minnesota, Colorado, and Utah), beer sold in supermarket chains and convenience stores must be <3.2% alcohol by weight (4% alcohol by volume or ABV). Alcohol content is generally listed by volume (e.g., a beer that is 4.0% by volume is about 3.2% by weight). Light beers range from 2% to about 4% ABV; beers range from 4% to 6% ABV; ales, stouts, and specialty brews can be as high as 10% ABV.

Depending on the strain of yeast, wines are produced at about 14% to 16% (28–32 proof), because that is the point in the fermentation process where the alcohol concentration denatures the yeast. Since the 1990s, a few alcohol-tolerant ‘super yeast’ strains have become commercially available, which can ferment up to 20%. Yeast organisms multiply as long as there is sugar to metabolize, gradually increasing the alcoholic content of the solution and killing off competing microorganisms, and eventually themselves. There are fortified wines with a higher alcohol concentration because stronger alcohol has been mixed with them. As this is usually done before fermentation is complete, these products contain a much higher quantity of sugar and therefore are typically sweet.

Stronger liquors are distilled after fermentation is complete to separate the alcoholic liquid from the remains of the source of sugar (e.g., grain, fruit). The idea of distillation is that a mixture of liquids is heated; the one with the lowest boiling point will evaporate first, followed by the one with the next lowest boiling point, and so on. Water and alcohol form a mixture called an *azeotrope* that has a lower boiling point than either one of them, so what distills off first is the mixture that is 95% alcohol and 5% water. Distilled liquor therefore cannot be stronger than 95% (190 proof). Other techniques can separate liquids that can produce 100% ethanol (called “absolute alcohol”), but they are used only for scientific or industrial purposes. A standard drink in the United States is considered to be 0.5 ounces or contain 15 grams of alcohol. This is equal to 12 ounces (355 mL) of 5% beer, 5 ounces (148 mL) of 12% wine, or 1.5 ounces (44 mL) of 40% spirits.^{1,2}

Epidemiology

Slightly more than half (50.9%) of Americans aged 12 or older, reported being current drinkers (at least one drink in the past 30 days) of alcohol in the 2006 National Survey on Drug Use and Health survey.³ This translates to an estimated 125 million people, which is similar to the 2005 estimate of 126 million people (51.8%). More than 57 million people (23.0%) aged 12 or older participated in binge drinking (five or more drinks on the same occasion; i.e., at the same time or within a couple of hours of each other, on at least 1 day in the past 30 days) in 2006. In 2006, heavy drinking (five or more drinks on the same occasion on each of 5 or more days in the past 30 days) was reported by 6.9% of the population aged 12 or older.³ In 2003, alcohol use disorders (AUD) in the United States accounted for 12,766 person deaths in alcohol-related traffic crashes, constituting almost 30% of the total traffic crash fatalities.⁴ Currently, >700,000 people a day in the United States receive treatment for alcohol dependence.⁵

Approximately 10% of Americans will be affected by alcohol dependence sometime during their lives.^{6,7} In 2001–2002, prevalences of *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition (DSM-IV) alcohol abuse and dependence were estimated to be 4.7% and 3.8%, respectively.⁸ Abuse and dependence were more common among males and among younger respondents. The prevalence of abuse was greater among whites than among blacks, Asians, and Hispanics. The prevalence of dependence was higher in whites, Native Americans, and Hispanics than Asians.⁸

Alcohol dependence is a chronic disorder with genetic, psychosocial and environmental factors influencing its development and manifestations. Although treatment outcomes have improved, still much remains to address unsuccessful treatment of alcohol abuse and dependence for many others.⁹ As defined by the DSM-IV,¹⁰ alcohol dependence is characterized by the preoccupation with alcohol use, use despite adverse consequences, as well as tolerance and withdrawal (Table 84-1).

Treatment of alcohol dependence consists mainly of psychological, social, and pharmacotherapy interventions aimed at reducing alcohol-related problems.¹¹ Treatment usually consists of two phases: detoxification and rehabilitation. Detoxification manages the signs and symptoms of withdrawal. Once detoxified, rehabilitation helps the individual avoid future problems with alcohol. Most rehabilitation treatments are psy-

Table 84-1 Diagnostic Criteria for Alcohol Abuse and Dependence¹⁰

DSM-IV defines **abuse** as a maladaptive pattern of substance use leading to clinically significant impairment or distress, as manifested by one (or more) of the following, occurring within a 12-month period:

1. Recurrent substance use resulting in a failure to fulfill major role obligations at work, school, home
2. Recurrent substance use in situations in which it is physically hazardous
3. Recurrent substance-related legal problems
4. Continued substance use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the substance

DSM-IV defines **dependence** as a maladaptive pattern of substance use, leading to clinically significant impairment or distress, as manifested by three (or more) of the following, occurring at any time in the same 12-month period:

1. Tolerance, as defined by either of the following:
 - A need for markedly increased amounts of the substance to achieve intoxication or desired effect
 - Markedly diminished effect with continued use of the same amount of substance
2. Withdrawal, as manifested by either of the following:
 - The characteristic withdrawal syndrome for the substance
 - The same (or a closely related) substance is taken to relieve or avoid withdrawal symptoms
3. The substance is often taken in larger amounts or over a longer period than was intended
4. There is a persistent desire or unsuccessful efforts to cut down or control substance use
5. A great deal of time is spent in activities to obtain the substance, use the substance, or recover from its effects
6. Important social, occupational or recreational activities are given up or reduced because of substance use
7. The substance use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance (e.g., continued drinking despite recognition that an ulcer was made worse by alcohol consumption)

chosocial, consisting of individual and group therapies, residential treatment in alcohol-free settings, and self-help groups, such as Alcoholics Anonymous. Although psychosocial treatments show effectiveness in reducing alcohol consumption and in maintaining abstinence, reviews of treatment studies report 40% to 70% of patients return to drinking within the year following treatment.¹² An evidence report prepared by the Agency for Health Care Policy and Research¹³ concludes that there is both a significant need to improve current alcohol treatments, as well as to develop new strategies.

Interest in using pharmacotherapies to improve treatments for alcohol dependence is growing.^{14,15} The rationale for pharmacotherapy is based on several considerations. Advances in neurobiology have identified neurotransmitter systems that initiate and sustain alcohol drinking; pharmacologic modification of these neurotransmitters or their receptors may alter dependence.¹⁶ Promising genetic research confirms that alcoholics are a heterogeneous population and that several gene variations can predispose some to increased alcohol use and other gene variations can confer protection.¹⁶ Animal models have identified pharmacologic agents that reduce alcohol consumption in animals, suggesting similar agents could reduce

alcohol consumption in humans. Finally, medications have improved the treatment of other addictive disorders, such as nicotine and opiate dependence, suggesting better pharmacotherapies may be developed for the treatment of alcoholism.

Risks and Benefits of Alcohol Consumption

The role of alcohol in the development of medical problems such as cardiovascular disease, hepatic cirrhosis, and fetal abnormalities is well documented. Alcohol use and abuse contribute to thousands of injuries, auto collisions, and violence.¹⁷ Alcohol can dramatically affect worker productivity and absenteeism, family interactions, and school performance.¹⁸ Some studies suggest, however, that individuals who abstain from using alcohol may also be at greater risk for a variety of conditions, particularly coronary heart disease (CHD), than people who consume small to moderate amounts of alcohol.¹⁹

Over the past 20 years, a number of studies have documented an association between moderate alcohol consumption and lower risk for CHD²⁰ and myocardial infarction (MI).²¹ Binge drinking after an MI, however, increases the risk of mortality.²² U.S. guidelines define moderate drinking as one drink or less daily for women or people aged 65 and older, and two drinks or less per day for men.²³ An association between moderate drinking and lower risk of CHD does not mean that alcohol is the cause of the lower risk. A review of population studies indicates that the higher mortality risk among abstainers may be attributable to socioeconomic and employment status, mental health, and overall health, rather than abstinence from alcohol use.²⁴ Benefits of moderate drinking on CHD mortality are offset at higher drinking levels by increased risk of death from other types of heart disease, cancer, cirrhosis, and trauma. The risk of a disease outcome from low to moderate drinking is less than the risk from either no drinking at all or heavier drinking. This produces a U-shaped curve when examining the association of alcohol consumption with rates of deaths from all causes.¹⁹

The exact mechanism by which alcohol use may be protective against morbidity in those with CHD is not clear. Some evidence indicates that different types of alcoholic beverages, such as red wines which are high in tannins, may lower blood lipids and fats by increasing antioxidants. It is also possible however that how a person drinks alcoholic beverages matters as well. For example, wines are ingested more slowly as they are typically consumed in moderate amounts with food. Binge drinking of any type of beverage, however, increases the risk of mortality from CHD in particular.²²

NEUROSCIENCE AND NEUROBEHAVIOR

Pharmacokinetics and Pharmacology

When consumed in amounts typical of normal social drinking, the absorption of ethanol from the stomach, small intestine, and colon is complete; however, the rate is variable. Peak blood ethanol concentrations after oral doses in fasting subjects generally are reached in 30 to 75 minutes, but several factors can influence the rate and extent of absorption.²⁵ The most rapidly absorbed formulations are carbonated beverages containing 10% to 30% ethanol. In contrast, high concentrations of alcohol can produce vasoconstriction in the gastrointesti-

nal (GI) mucosa, which results in slowed or even incomplete absorption of ethanol. Absorption of ethanol from the small intestine appears to be more rapid than any other part of the GI tract and does not depend on the presence or absence of food. Factors that control the rate of gastric emptying significantly control the rate of absorption by controlling the rate at which ethanol is delivered to the small intestine.^{26,27} For example, food in the stomach slows the absorption of ethanol, probably by slowing gastric emptying.

The level of intoxication achieved is not solely related to the plasma concentration. For any particular plasma concentration, greater cognitive impairment is seen during times when the plasma level is rising compared with when ethanol is primarily being eliminated. The degree of intoxication also appears to be directly related to the rate at which pharmacologically active plasma concentrations are attained. Alcohol negatively affects cognitive performance and has a differential effect on the descending versus ascending limb of the blood alcohol concentration curve. The latter finding may have important ramifications relating to the detrimental consequences of alcohol intoxication.²⁸

The blood alcohol level (BAL) or blood alcohol concentration (BAC) is calculated using the weight of ethanol in milligrams and the volume of blood in deciliters. This yields a BAC expressed as a proportion (i.e., 100 mg/dL or 1.0 g/L) or as a percentage (i.e., 0.10% alcohol). Ethanol concentrations are usually converted to equivalent blood alcohol concentrations for standardization purposes when measured in other body fluids. Ethanol in expired air or breath alcohol concentration is usually stated as grams per 210 liters of breath.

Breath alcohol measurement has been used as an estimate of blood ethanol concentrations since the 1970s. Breath measurement relies on the property of ethanol to partition from blood into inspired air. At equilibrium, the concentration of ethanol in the vapor depends on the ethanol concentration in the fluid and the temperature. If air is inhaled deeply into the lungs and the breath is held briefly, ethanol vapor rapidly diffuses out of the pulmonary capillary blood into air in the alveoli and the ethanol vapor in the alveolar air approaches the equilibrium concentration. The concentration of ethanol vapor in alveolar air at body temperature is a small fraction of the ethanol concentration in blood, which generally varies from person to person, depending on pulmonary blood flow and the diffusibility of alcohol. Regardless of variability, a uniform breath to blood ethanol partition coefficient of 1:2,100 has been defined for legal purposes in almost all countries, and is used to calibrate almost all breath alcohol measurement devices.²⁹

Specificity of alcohol metabolism affects an individual's sensitivity to alcohol, and vulnerability to specific behavioral and physiologic effects of alcohol. The alcohol dehydrogenase (ADH) pathway is the major enzyme system responsible for alcohol metabolism in humans. The main alcohol metabolism occurs with ADH isoenzymes, in the stomach (ADH6 and ADH7) and in the liver (ADH1, ADH2 and ADH3). The pathway involves conversion of ethanol to acetaldehyde by these ADH isoenzymes, resulting in the reduction of nicotinic-adenine dinucleotide (NAD) to NADH. In the second step, acetaldehyde is converted to acetate via the enzyme aldehyde dehydrogenase, which also reduces NAD to NADH. These are the rate-limiting steps in ethanol metabolism, and this route becomes saturated when large amounts of ethanol deplete NAD.²⁹

Acetate ultimately is converted to carbon dioxide and water. An additional pathway that is more involved in alcohol-dependent individuals than those who are not, involves the catalase pathway of peroxisomes and the microsomal ethanol oxidizing system (MEOS), in the smooth endoplasmic reticulum. The main functional component of the MEOS is the cytochrome P250 (CYP) 2E1.

Of a dose of ethanol, 90% to 98% is oxidized in the liver, with the remaining drug excreted unchanged in the alveolar air and urine. Ethanol metabolism formerly was described by zero-order kinetics; however, Michaelis-Menten and other nonlinear, concentration-dependent models are more accurate.^{30,31} In some situations, a portion of the absorbed dose of ethanol does not appear to enter the systemic circulation, suggesting first-pass metabolism. The relative contribution of hepatic versus gastric ADH to this response continues to be debated, however.^{32,33} Using a two-compartment, Michaelis-Menton pharmacokinetic model as well as experimental data, Levitt et al.^{34,35} suggest that gastric metabolism contributes negligibly to first-pass metabolism. In contrast, Lieber et al.³⁶ believe that gastric metabolism accounts for gender and ethnic differences in first pass metabolism. Estimates of total gastric ADH suggest that the enzyme can metabolize 0.9 to 1.8 g/hour of ethanol, depending on the concentration of ethanol consumed.³⁷ Although gastric alcohol dehydrogenase has a lower affinity for ethanol compared with hepatic alcohol dehydrogenase, it may be capable of exerting modest metabolic effects at alcohol concentrations found in the stomach after a drink. The extent of first-pass extraction tends to decrease as the dose of alcohol increases. This is likely because of saturation of alcohol dehydrogenase, regardless of the source. When plasma ethanol levels >0.2 g/mL, the alcohol dehydrogenase system becomes saturated. As hepatic alcohol dehydrogenase becomes saturated, there is increased unchanged excretion of alcohol. This results in a more intense odor of alcohol on the breath as the plasma ethanol concentration increases. The metabolism of alcohol also then tends to become nonlinear because of stimulation of CYP2E1, which produces metabolic tolerance to ethanol in chronic users.

Lower first-pass metabolism has been found in alcohol-dependent individuals, women, the elderly, and Japanese subjects.^{34,36} Gastric alcohol dehydrogenase may also play a role in the effect of food in reducing ethanol bioavailability. Food, by delaying gastric emptying, allows for more extensive gastric metabolism.³⁷

The accepted average rate of ethanol oxidation commonly reported in the medical literature is 0.15 g/mL/hour for men and 0.18 g/mL/hour for women.³⁸ Although this rate still is widely used for both legal and medical purposes, other data suggest wide variability in ethanol metabolism. For example, wide differences in alcohol dehydrogenase activity have been demonstrated and attributed to heredity and other causes.^{39,40} Chronic heavy drinkers frequently oxidize ethanol at twice the normal rates, with their metabolic rates returning to baseline after a period of abstinence.⁴¹ The rate of oxidation in chronic heavy drinkers may also increase with elevated blood ethanol levels.⁴¹ In contrast, patients with end-stage liver disease may progress to the point at which they have almost no metabolic capacity. Thus, serial determinations of plasma ethanol concentrations are needed to evaluate pharmacokinetic parameters in a particular patient.

Chronic alcohol use is associated with characteristic changes in the liver. Hyperlipidemia and fat deposition in the liver occur because of shunting of the excess hydrogen into fatty acid synthesis and direct oxidation of ethanol for energy instead of body fat stores being used for energy. Fatty liver is the first step in a sequence of events that ultimately leads to alcoholic cirrhosis. Accumulated acetaldehyde, which interferes with mitochondrial function by shortening and thickening microtubules, has been implicated as playing a role in the hepatotoxic process. The damaged microtubules then inhibit the secretory functions of the hepatocytes, which results in an increase in size and weight of the liver.⁴² Nutritional deficits and impaired hepatic protein metabolism may contribute as mechanisms of hepatotoxicity in chronic ethanol consumers.^{43,44} Although beyond the scope of this chapter, various other mechanisms of hepatotoxicity may be involved to various extents in producing damage to the liver.⁴⁵

Acetaldehyde is believed to play a role in most actions of alcohol.⁴⁶ Elevated acetaldehyde concentrations during ethanol intoxication cause the commonly seen sensitivity reactions, including vasodilatation and facial flushing, increased skin temperature, increased heart and respiration rates, and lowered blood pressure. Acetaldehyde also contributes to the sensations of dry mouth and throat associated with bronchoconstriction and allergic-type reactions, as well as nausea and headache. These adverse effects mediated by acetaldehyde certainly have the potential to protect drinkers against the excessive ingestion of alcohol, but acetaldehyde also has the potential to produce euphoric effects that may reinforce alcohol consumption. Acetaldehyde also contributes to the increased incidence of GI and upper airway cancers that are seen with increased incidence in heavy consumers of alcohol and which may also play a role in the pathogenesis of liver cirrhosis.

Ethanol ingestion can depress the central nervous system (CNS) through all the different stages of anesthesia. Tolerance to this effect occurs after chronic use such that a blood ethanol level of 0.150 g/mL will not produce apparent behavioral or neurologic dysfunction in persons who drink a pint or more of 80-proof liquor (or its equivalent) daily for several years.

Neurobiological Basis of Alcohol Dependence

Previously, theories of alcohol action suggested that alcohol dissolved in cellular membranes and increased membrane fluidity.⁴⁷ This action in turn altered the function of macromolecules in the cell membrane, leading to intoxication. More recent evidence indicates that alcohol binds to hydrophobic pockets of proteins, changing the structures of proteins and altering their function. Proteins that are particularly sensitive to alcohol include ion channels, neurotransmitter receptors, and enzymes involved in signal transduction.⁵ Notable neurotransmitters and their receptors include γ -aminobutyric acid (GABA), glutamate, dopamine (DA), serotonin (5-HT), adenosine, neuropeptide-Y (NPY), norepinephrine, cannabinoid receptors, and opioid peptides. These neurotransmitters or their receptors are potential targets for pharmacotherapy.

The key inhibitory neurotransmitter in the CNS is GABA, which is associated with a chloride-ion channel that is affected by low concentrations of alcohol. Normally, when GABA binds to the GABA_A receptor, the chloride channel opens, allowing negatively charged chloride ions to enter the cell and inhibiting

neuronal cell activity. In the presence of alcohol, GABA-induced inhibition is inhibited.⁴⁸ Receptor compensation for continual inhibition by alcohol is to reduce GABA_A receptor subunits.⁴⁹ Other sedative medications, such as benzodiazepines, also bind to the chloride channel at slightly different sites and facilitate GABA inhibition. The existence of a common receptor mechanism for the actions of alcohol and sedative-hypnotics accounts for the cross-tolerance between these substances.

Glutamate is the major excitatory neurotransmitter in the CNS. After concurrent events of α -amino-3-hydroxy-5-methyl-isoxazole-4 propionic acid (AMPA) depolarization and glutamate binding to *N*-methyl-D-aspartate (NMDA) receptors, a Ca²⁺ ion channel opens and makes the depolarization process more likely. Low doses of alcohol strongly inhibit NMDA receptors and inhibit neuronal activity.⁵⁰ After continual exposure to high doses of alcohol, NMDA receptors upregulate in an attempt to balance alcohol's inhibitory action. Thus, the combined effect of alcohol on GABA_A and glutamate is to inhibit excitation and facilitate sedation.

Several other ion channels and receptors neurotransmitters are also affected by alcohol. One of the serotonin (5-hydroxytryptamine or 5-HT) receptors, the 5-HT₃ receptor, is an ion-channel receptor. This receptor is particularly sensitive to the action of low doses of alcohol, and may result in an activation of serotonin and dopamine. Alcohol also modifies the activity of β -adrenergic and adenosine neurotransmitter receptors linked to adenylate cyclase through membrane-bound G-proteins. Low doses of alcohol can facilitate the activity of norepinephrine, serotonin, dopamine, endocannabinoid signaling system, and other neurotransmitter receptors linked to G-proteins.^{47,51,52}

Other lines of research also suggest important roles for NPY and the cannabinoid receptor 1 (CB1). NPY is a peptide neurotransmitter implicated in the control of food intake, cerebrocortical excitability, cardiovascular homeostasis, and integration of emotional behavior.⁵³ Evidence suggests that a polymorphism in the NPY gene, Leu7Pro, may be associated with alcoholism and that central NPY activity is recruited in response to ethanol consumption. Moreover, activation of NPY may act as a protective feedback mechanism to prevent high ethanol drinking.⁵³ Recent studies also show that the endocannabinoid signaling system plays a key role in the reinforcing effects of ethanol by mediating actions on the signal transduction coupled to G-proteins.⁵³ In particular, the cannabinoid receptor (CB1) is activated by delta-9-tetrahydrocannabinol (Δ^9 -THC), the major psychoactive component of marijuana, and stimulated by naturally occurring endogenous cannabinoid agonists. Chronic alcohol administration may downregulate CB1 receptors, facilitating a compensatory increase in endocannabinoids, subsequently influencing neurotransmitter release.⁵² Endogenous cannabinoid agonists are found to promote alcohol craving in animals and mimic the psychoactive effects of Δ^9 -THC.⁵² By contrast, an antagonist of the CB1 receptor, rimonabant, decreases food intake in animals as well as humans and decreases alcohol consumption in rodents.^{54,55}

On a neurobiological-behavioral level, the mesolimbic dopaminergic pathway from the ventral tegmental area to the nucleus accumbens is activated by most dependence-producing drugs, including alcohol, cocaine, opiates, and nicotine.^{56,57} Putatively, activation of this pathway mediates drug reward and

is responsible for the dependence-producing properties of all drugs of abuse.⁵⁸ Repeated alcohol use sensitizes the system, so that behavioral stimuli associated with alcohol also begin to release dopamine and to facilitate additional alcohol use.⁵⁹ Dopamine released by drugs of abuse are two- to tenfold that of natural rewards. This sensitization may account for the craving and preoccupation with alcohol, which are the hallmarks of alcohol dependence.

Cessation of chronic alcohol use results in an abstinence or withdrawal state of nervous system excitation that is dysphoric and negatively reinforcing. It has been suggested that abstinence contributes to alcohol craving and the preoccupation with alcohol use, in that dependent individuals will continue alcohol use to avoid this state.⁶⁰ As noted, chronic alcohol use causes GABA_A downregulation and NMDA upregulation, leading to CNS hyperactivity. The locus coeruleus, a nucleus of norepinephrine-containing cells in the pons, becomes hyperactive during withdrawal and is proposed as mediating some of the negative effects of withdrawal. Chronic alcohol and drug use alters gene expression and increases levels of adenylyl cyclase, upregulates cyclic adenosine monophosphate (cAMP)-dependent protein kinases, activates cAMP-response element binding protein (CREB) and several phosphoproteins in this brain region mediating tolerance and dependence.⁶¹

MANAGEMENT OF ACUTE ETHANOL INTOXICATION

Clinical Presentation

Toxicology

1. S.L. is brought to the emergency department (ED) unresponsive except to noxious stimuli. Her friends report an evening of heavy drinking to celebrate her 21st birthday. Her respirations are 8 breaths/minute and shallow. Blood pressure (BP) is 100/60 mm Hg, pulse is 100 beats/minute, and temperature is 36°C. A stat arterial blood gas determination reveals a pH of 7.29 (normal, 7.36–7.44), PCO₂ of 52 mmHg (normal, 35–45), and HCO₃ of 19 mEq/L (normal, 21–27). Why is S.L.'s respiratory status of concern?

Frequently, individuals reaching their 21st birthday consume alcohol in excess (e.g., attempt to have 21 drinks, often as quickly as during the first hour after turning 21). This can lead to lethal blood alcohol levels, particularly in those who are alcohol naive. In the medulla, ethanol can depress respirations by inhibiting the passive neuronal flux of sodium via a mechanism similar to that of general anesthetic agents.⁶² The enzyme Na⁺/K⁺-adenosine triphosphatase (ATPase) is inhibited, cAMP concentrations are reduced, and GABA synthesis is impaired. Ethanol is clearly a CNS depressant, and even the uninhibited behavior associated with its use is caused by preferential suppression of inhibitory neurons. More global neuronal inhibition is seen at high ethanol concentrations.

Treatment of alcohol intoxication is essentially supportive. In highly intoxicated patients, however, the prolonged slowing of the respiratory rate can lead to arrhythmias, cardiac arrest, and death, often accompanied by aspiration of vomit. Respiratory depression is responsible for the acid-base abnormality in S.L., which causes a respiratory acidosis. Even when blood ethanol levels are below those associated with medullary paralysis, a blunted respiratory response to hypercapnia and hypoxia

is seen.^{63,64} This makes the assessment of respiratory status a primary concern in severely intoxicated patients.

Management of Respiratory Depression

2. What therapy should be initiated to manage S.L.'s respiratory depression?

Highly intoxicated patients with depressed respiration such as S.L. require immediate supportive care that may include endotracheal intubation for respiratory support. This should be sufficient to restore her acid-base balance to within normal limits, because her acidosis is primarily of respiratory origin (pH 7.29, Pco₂ 52 mmHg). When metabolic acidosis is a significant component of the acid-base disturbance, it may be necessary to administer sodium bicarbonate. This should be done only in conjunction with appropriate respiratory support to prevent the development of hypercapnia.

S.L. was brought to the ED in a comatose state, and it is unknown whether she has ingested other drugs. She should be given 0.4 to 2 mg of naloxone (Narcan) because alcohol intoxication often is complicated by coingestion of other drugs and can rapidly reverse narcotic-induced respiratory depression. This dose can be repeated at 2- to 3-minute intervals for up to 10 mg, depending on the patient's response and the clinician's index of suspicion for ingestion of respiratory depressants other than alcohol. Naloxone has been used to reverse alcohol-induced coma, to reverse clonidine-induced coma, to treat septic or cardiogenic shock, and to treat acute respiratory failure,^{65,66} based on its postulated ability to reverse the effects of endogenous opiate-like agonists in the CNS.

Serum Ethanol Concentration

3. Thirty minutes later, the following laboratory results are reported: glucose, 49 mg/dL (normal, 70–110); sodium (Na), 142 mEq/L (normal, 135–147); potassium (K), 3.5 mEq/L (normal, 3.5–5.0); chloride (Cl), 104 mEq/L (normal, 95–105); HCO₃, 20 mEq/L (normal, 20–27); blood urea nitrogen (BUN), 18 mg/dL (normal, 5–22); creatinine, 0.9 mg/dL (normal, 0.6–1.1); and ethanol, 475 mg%. Based on the blood ethanol level, how severe is S.L.'s intoxication?

Chronic use of alcohol can produce significant tolerance, therefore, the blood alcohol level cannot be used as a sole determinant of physiologic status. By contrast, for alcohol naive patients such as new college students, BAC in the 0.30 mg% range can be fatal, although chronic drinkers can be awake and alert at such a level. The blood ethanol concentration generally correlates with the clinical presentation of the patient (Table 84-2), although tolerance varies among individuals. Impairment in motor function may become observable at levels of 0.05 mg%. Moderate motor impairment usually is seen at 80 g/L, which is the legal definition of intoxication in all states when driving. Respiratory depression may occur with ethanol concentrations 0.45 mg%.⁶⁷

The accepted median lethal dose (LD₅₀) for ethanol in humans is a blood concentration of 0.50 mg%, although fatalities have been reported with ethanol concentrations ranging from 0.295 to 0.699 mg%.^{68,69} Factors that may be associated with fatalities at lower ethanol concentrations include lack of tol-

Table 84-2 Blood Alcohol Relationship to Clinical Status

| Blood Ethanol Concentration | Clinical Presentation ^a |
|-----------------------------|--|
| 50 mg/dL (0.05 mg%) | Motor function impairment observable |
| 80 mg/dL (0.08 mg%) | Moderate impairment; legal definition of intoxication in all states when driving |
| 450 g/L | Respiratory depression |
| 500 g/L | LD ₅₀ for ethanol |

^aTolerance to alcohol varies among individuals.

erance to alcohol, ingestion of other drugs, heart disease, and pulmonary aspiration. For example, patients who died of combined ethanol and barbiturate ingestions had a mean ethanol concentration of only 0.359 mg%.⁶⁹ Therefore, the clinician should order a toxicologic screening panel of S.L.'s urine to rule out possible concurrent drug ingestion.

Acute Management

4. After S.L.'s respiratory support needs are attended, what other clinical conditions warrant attention?

In the alert intoxicated patient, general management is supportive and protective. Volume depletion resulting in hypotension often occurs in ethanol-intoxicated patients. Hypothermia also is a complication of severe intoxication and can contribute to hypotension. S.L.'s BP is not severely low and should normalize with fluid replacement and Trendelenburg bed positioning (i.e., foot of the bed is elevated such that the head is lower than the pelvis). Hypoglycemia most often occurs in conjunction with reduced carbohydrate intake. This situation is common in malnourished alcoholics but also might be particularly pronounced in S.L. if she were dieting. If intravenous (IV) fluids are given, thiamine administration should precede that of glucose, to prevent Wernicke's encephalopathy (see Question 10). Because she is hypoglycemic, 50 mL of 50% glucose solution should be administered to her by IV push (after administering 100 mg thiamine intramuscularly [IM]).⁷⁰ Additionally, administration of a short-acting benzodiazepine, such as lorazepam, should be considered. Although not appropriate at this time, if S.L. becomes violent or severely agitated, 2 to 5 mg of haloperidol IM or IV can be administered as needed.

5. What medical interventions can facilitate removal of ethanol from S.L.?

Gastrointestinal Decontamination

Gastric lavage may be useful if ingestion of other drugs is expected, or when the large consumption of alcohol is very recent. Activated charcoal absorbs ethanol poorly but should be administered when coingestion of other drugs is suspected. In addition to S.L.'s clinical presentation, information obtained from friends who brought her in to the hospital should be considered to assess concomitant drug and alcohol use by S.L.

Hemodialysis

Hemodialysis rapidly removes ethanol from the body,⁷¹ but the role of this treatment modality is unclear. In uncomplicated cases, it has been suggested that dialysis be initiated when

Table 84-3 Acute Alcohol Intoxication: Symptoms and Treatment

| Symptom | Course | Treatment |
|----------------------|---|--|
| Respiratory acidosis | Alcohol-induced respiratory depression; blunted response to hypercapnia and hypoxia | Endotracheal intubation for respiratory support |
| Coma | Alcohol-induced CNS depression; ingestion of other drugs | Gastric lavage, naloxone (Narcam) 1 mg, repeat every 2 to 3 minutes up to 10 doses, depending on response and suspicion of ingestion. Dialysis possible |
| Hypotension | Hypovolemia | IV fluid replacement |
| Hypoglycemia | Most often occurs in malnourished patients. Pyruvate is converted to lactate, rather than glucose, through gluconeogenesis. | 50% glucose (50 mL) by IV push |

CNS, central nervous system; IV, intravenous.

the blood ethanol concentration >0.6 mg%.⁶⁸ Ventilatory assistance and good supportive care usually are most important because respiratory depression is the primary cause of death in ethanol intoxication. With good supportive care, dialysis is generally unnecessary. Dialysis may be considered if the patient cannot be stabilized or has other complicating factors, such as coexisting disease states or ingestion of other drugs. The management of acute alcohol intoxication is summarized in Table 84-3.

MANAGEMENT OF ALCOHOL WITHDRAWAL

Signs and Symptoms

6. J.M. is a chef at a nursing home where his wife is the administrator. He drinks at work and was found unconscious and brought to the hospital. His wife states that J.M. regularly drinks half a gallon of vodka daily and has suffered an alcohol withdrawal seizure in the past. J.M.'s wife states that she does not believe that he ever abused street or prescription drugs. His blood alcohol concentration (BAC) on admission was 0.52 mg%. J.M. has a history of hepatic insufficiency secondary to cirrhosis. What signs and symptoms evident in a clinical diagnosis of alcohol withdrawal need to be monitored in J.M.? The following laboratory results are reported: Total bilirubin 0.4 mg/dL (normal, 0.2–1.2 mg/dL); direct bilirubin 0.2 (normal, 0–0.4 mg/dL); alkaline phosphatase 74 (normal, 35–131 U/L); aspartate aminotransferase (AST), 129 (normal, 11–36 U/L); alanine aminotransferase (ALT) 72 (normal, 6–43 U/L); blood urea nitrogen (BUN) 18 mg/dL (normal, 5–22 mg/dL); creatinine 0.8 mg/dL (normal, 6–1.3 mg/dL); glucose 101 mg/dL (normal, 70–110 mg/dL); uric acid 6.3 mg/dL (normal, 2.5–8.5 mg/dL); calcium 9.9 mg/dL (normal, 8.3–10.6 mg/dL); albumin 4.7 (normal, 3.3–4.9 g/dL); cholesterol 423 mg/dL (normal, <200 mg/dL); creatine kinase, 1,344 U/L (normal, <18 –198 U/L); sodium (Na), 143 mEq/L (normal, 132–147); potassium (K), 4.2 mEq/L (normal, 3.4–5.0); bicarbonate (HCO_3), 25.2 (normal, 17.0–30.6 mEq/L); chloride (Cl), 107 mEq/L (normal, 95–105); magnesium (Mg) 0.9 mg/dL, (normal, 1.5–3.1 mg/dL); γ -glutamyl transpeptidase (GGT) 992 U/L (normal 10–61 U/L)

For many alcohol-dependent individuals with significant physical dependence, a cluster of withdrawal symptoms known as “alcohol withdrawal syndrome” (AWS) may occur on cessation or reduction of alcohol consumption. Depending directly on the degree of physical dependence, AWS can range from creating significant discomfort to mild tremor to alcohol

withdrawal-related delirium, hallucinosis, seizures, and potentially death.^{72–73} A GGT of 992 U/L suggests that J.M. is a heavy drinker.

Patients may present with AWS in a variety of settings, because alcohol-dependent patients may be unrecognized and experience withdrawal after inpatient hospital admission for unrelated medical reasons. For example, a sample from a primary care practice indicated that 15% of patients presented with at-risk drinking patterns or identified alcohol-related problems.⁷⁴ Also a continual need exists to assess preoperatively surgical patients for possible alcohol dependence, to treat them adequately and prevent AWS-related complications during and after surgery.⁷⁵ Institutional protocols for support and treatment of AWS may vary considerably, and confusion often exists regarding standards of care.⁷⁶

The DSM-IV¹⁰ defines the set of criteria necessary for a diagnosis of AWS. Diagnosis requires cessation or reduction in alcohol use that has been heavy and prolonged, and two or more of the following developing within several hours to a few days after the first criterion: autonomic hyperactivity, increased hand tremor, insomnia, nausea or vomiting, transient hallucinations or illusions (tactile, visual, or auditory), psychomotor agitation, anxiety, and grand mal seizures. These symptoms must cause significant distress or impairment of important areas of functioning, and not be caused by a general medical condition or another mental disorder. Withdrawal-related seizure is considered a more severe manifestation of withdrawal, as is alcohol withdrawal delirium (AWD), or delirium tremens as traditionally called. AWD is estimated to have a mortality rate of approximately 5% of patients who go into alcohol withdrawal.⁷⁷ Recognized predictors for AWS complications include the duration of alcohol consumption, total number of prior detoxifications from alcohol, and previous withdrawal-related seizures and episodes of AWD.⁷⁸

7. How could the severity of J.M.'s withdrawal symptoms be assessed?

Of currently used instruments available for measuring the degree of withdrawal in an alcohol-dependent patient, the most commonly used is the revised Clinical Institute Withdrawal Assessment (CIWA-Ar).⁷⁹ Additionally the Sedation-Agitation Scale (SAS) could also be used to assess agitation.⁸⁰ The CIWA-Ar is a validated 10-item scale used for grading severity of alcohol withdrawal symptoms. The CIWA-Ar provides a final AWS score with a maximum of 67 points. A CIWA-Ar

Table 84-4 Comparison of Benzodiazepines Used for Alcohol Withdrawal

| Benzodiazepine | Onset of Action | Peak Level Onset | Pathway Metabolized | Elimination Half-life (hrs) | Comparative Dose |
|------------------|---------------------------------|--|--------------------------------|---|------------------|
| Chlordiazepoxide | Intermediate (PO) | 1–4 hrs (PO) | Hepatic | 3–29 (parent drug) 28–100 (metabolite) | 10 mg |
| Diazepam | Rapid (IV or PO) | 1–2 (PO) 1 hrs (IM) 8 min (IV) | Hepatic | 14–70 (parent drug) 30–200 (metabolites) | 5 mg |
| Lorazepam | Intermediate (PO) Rapid (IV) | 1–6 hrs (PO) 45–75 min (IM/SL) 5–10 min (IV) | Hepatic; no active metabolites | 8–24 | 1 mg |
| Oxazepam | Slow (PO) | 1–4 hrs (PO) | Hepatic; no active metabolites | 3–25 | 15 mg |

Onset of Action: Rapid, within 15 minutes; Intermediate, 15–30 minutes; Slow, 30–60 minutes. IM, Intramuscular; IV, intravenous; PO, oral; SL, sublingual.

rating of 8 points or less represents mild withdrawal and needs little pharmacologic support. A rating of 9 to 15 is associated with moderate withdrawal and may require some pharmacotherapy. A rating >15 corresponds to severe withdrawal, with an increased risk of seizures and AWD, and requires close monitoring. Treatment of AWS can be initiated based on a particular patient's CIWA-Ar score. Providers should also consider concomitant illnesses and medications when interpreting CIWA-Ar scores. Indeed, individual items in the scale are not specific to AWS, and likewise some manifestations of withdrawal may be blunted. The SAS can be used in combination with the CIWA-Ar to evaluate the level of agitation and consciousness of a patient, and be linked to administer benzodiazepines on a symptom-triggered regimen when a patient becomes agitated (for scores >4 on a 7-point scale).

Therapy

8. What drugs are demonstrated to be the most clinically effective for alcohol withdrawal particularly in a patient such as J.M. with evidence of cirrhosis?

Benzodiazepines

Benzodiazepines modulate anxiolysis by stimulating GABA_A receptors and, in doing so, substitute pharmacologically for alcohol.⁸¹

Evidence

Considered the drugs of choice for alcohol withdrawal for some time,^{75,81,82} long-acting benzodiazepines (e.g., chlordiazepoxide and diazepam) and short-acting agents (e.g., lorazepam and oxazepam) represent the most efficacious pharmacotherapies for the treatment of acute alcohol withdrawal.⁸³ They are effective in preventing both first seizures and subsequent seizures during alcohol withdrawal.⁸⁴ Longer-acting benzodiazepines may provide for easier weaning because they gradually self-taper on metabolism and excretion; this allows for less fluctuation in plasma drug levels.⁸⁵ Longer-acting benzodiazepines also cause fewer rebound effects and withdrawal seizures on discontinuation. Shorter-acting agents (e.g., lorazepam or oxazepam), which undergo hepatic metabolism but are oxidized to inactive metabolites, require more frequent dosing but may be more appropriate for alcoholics with liver disease and the elderly.^{82,86} Short-acting lorazepam and long-acting diazepam also demonstrate a higher potential for abuse because of a

shared rapid onset of action.⁷⁶ As all benzodiazepines appear equally effective in ameliorating the signs and symptoms of alcohol withdrawal, however, the choice of a benzodiazepine is dependent on factors such as pharmacokinetic properties, dosage formulation, presence of liver impairment, and ease of dosage titration (Table 84-4).⁷⁶

Benzodiazepines are shown to be more effective than placebo in reducing the signs and symptoms of alcohol withdrawal.⁸⁷ The results of a meta-analysis on treatments for alcohol withdrawal indicated a statistically significant decrease of 4.9 cases of delirium for every 100 patients treated with benzodiazepines.⁷⁶ Likewise, a significant difference was shown with treatment in regard to withdrawal-related seizures, with a reduction of 7.7 cases per 100 patients treated. In a Canadian meta-analysis, no difference was seen in adverse effects between benzodiazepines and alternative agents.⁸⁸ Even in elderly, cognitively impaired patients, benzodiazepines are recommended.⁸⁶ Notably, these patients may be at an even greater risk for adverse events related to ethanol withdrawal. (Refer to Table 84-5 for general AWS treatment guidelines.)

Dose

Two strategies for dosing benzodiazepines in AWS include fixed-schedule and symptom-triggered regimens. Fixed-schedule regimens involve a set dose and interval for the agent chosen, which is to be tapered off at specific times, usually starting on the second day of treatment. Symptom-triggered regimens depend on the use of a rating scale of withdrawal severity, such as the CIWA-Ar previously noted, which is repeated at set intervals. Medication is only administered if the scoring from the scale is above a predetermined threshold value for treatment. In this way, the risk of under- or overmedicating patients may be minimized, because dosing is guided by the degree of withdrawal symptoms. Several studies confirm that symptom-triggered regimens compared with fixed-dose regimens appear to result in a shorter duration of necessary therapy and less medication administered in total, an advantage that appears to come without any loss of efficacy.

The treatment challenge associated with individuals who are in alcohol withdrawal with a comorbid medical illness is illustrated by the case of a patient with AWS who has coronary artery disease. Such a patient may be more aggressively treated for withdrawal-related hypertension and thus treated with a β -blocker or clonidine. The result of such adjuvant treatment may be a reduced sensitivity of the CIWA-Ar owing to a masking of the patient's autonomic manifestations of

Table 84-5 Suggested Treatment Strategies for Alcohol Withdrawal Syndrome

| <i>Protocol</i> | <i>Special Considerations</i> | <i>Drug</i> | <i>Dose Range</i> | <i>Benefits</i> |
|---|---|---|--|--|
| Symptom-Triggered Regimen based on CIWA-Ar Score assessed as medically appropriate | Assess patient and administer one of these drugs every hour until CIWA-Ar = 8–10 for 24 hrs. | Chlordiazepoxide Diazepam Lorazepam | 50–100 mg 10–20 mg 2–4 mg | Less abuse potential for outpatients, low cost. Long-acting Available in IM and IV form—More appropriate in elderly and hepatic impairment |
| Fixed-Schedule Regimens (Provide additional medication as needed when symptoms are not controlled (i.e. CIWA-Ar = 8–10) | Consider if: Mild: CIWA-Ar 8–10; SBP >150 mmHg or DBP >90 mmHg; HR >100; T >100°F. Titrate dose. Moderate: CIWA-Ar 8–15; SBP 150–200 mmHg or DBP 100–140 mmHg; HR 110–140; T = 100°F to 101°F; Tremors, Insomnia and agitation. Titrate dose. Severe Withdrawal Symptoms: CIWA-Ar >15; SBP >200 mmHg or DBP >140 mmHg; HR >140; T >101°F; Tremors, Insomnia and agitation. Endpoint is sedation. | Example of fixed dosing schedule using lorazepam. | Mild: 1–2 mg PO every 4–6 hours as needed for 1–3 days Moderate: on days 1 and 2 give 2–4 mg PO four times a day. On days 3 and 4 give 1–2 mg PO four times a day. On day 5 give 1 mg by mouth twice a day. Severe: Give 1–2 mg IV every 1 hour while awake for 3–5 days. | Rapid onset of action; ease of administration. |
| Alternative Therapies | In patients with benzodiazepine allergy or when use of a benzodiazepine is deemed medically inappropriate. | Carbamazepine Gabapentin | Taper from 600–800 mg on day 1 down to 200 mg over 5 days. 400 mg TID for 3 days then 400 mg BID for 1 day then 400 mg for 1 day. | For both drugs: Non-addicting Few drug interactions Cause relatively little cognitive impairment. |
| Adjunctive Therapies | Adrenergic hyperactivity- | Clonidine | 0.1 mg twice daily as needed. | For mild to moderate hyperactivity |
| | Adrenergic hyperactivity | β -Blockers (e.g. atenolol) | 50 mg daily. | Shown to improve vital signs faster than oxazepam alone |
| | Adrenergic hyperactivity | Carbamazepine | 800 mg/day tapered down to 200 mg over 5 days. | Anticonvulsant activity |
| | Agitation, hallucinations, delirium | Neuroleptics (e.g. haloperidol) | 0.5–5 mg every hour; maximal dose 100 mg/day. | Rapid onset of action. |

BID, twice daily; CIWA-Ar, Clinical Institute Withdrawal Assessment; DBP, diastolic blood pressure; HR, heart rate; PO, oral; SBP, systolic blood pressure; TID, three times daily. Reprinted with permission from Guirguis AB and Kenna GA, Treatment Considerations for Alcohol Withdrawal Syndrome, U.S. Pharmacist; 2005.

withdrawal. This could then lead to a higher likelihood of undermedicating the patient for withdrawal and may put the patient at higher risk for severe sequelae from withdrawal. Because of these exclusion criteria, the symptom-triggered approach has not been tested in such populations or those with histories of severe withdrawal including seizures or delirium. Therefore, traditional fixed-dose regimens are recommended in these populations.⁷⁶

An effective approach is most likely to consider combining these two dosing strategies. For example, for a low-risk patient (no history of AWS or AWD, the patient consumes low weekly amounts of alcohol and no signs or symptoms of early

AWS) that patient receives a symptom-triggered regimen (e.g., lorazepam 1 mg every hour as needed). Alternatively, a high-risk patient (history of AWS, AWD, or withdrawal seizures, consume large daily amounts of alcohol, signs or symptoms of early AWS) receives fixed-dose lorazepam or diazepam with a tapering dose schedule and as needed benzodiazepine administration for uncontrolled alcohol withdrawal signs or symptoms.

Contraindications, Warnings, Interactions

Elderly patients, those with hepatic or renal insufficiency, and those with medical illnesses require close observation to

prevent overmedication. In patients receiving calcium channel blockers, β -blockers, and α_2 -adrenergic agonists, some signs of withdrawal such as hypertension, tachycardia, and tremor may not be apparent.

Summary

Patients with a history of severe withdrawal symptoms, withdrawal seizures, or delirium tremens; multiple previous detoxifications; concomitant psychiatric or medical illness; recent high levels of alcohol consumption; pregnancy; and lack of a reliable support networks should be considered for inpatient treatment regardless of the severity of their symptoms.

Many clinicians have adopted lorazepam as the drug of choice to treat AWS because it has no active metabolites and has an intermediate half-life. Therefore, alcoholic patients with liver disease are at less risk for developing toxicity from detoxification with lorazepam than other benzodiazepines. The choice of agent is based on pharmacokinetics. Diazepam and chlorthalidopoxide are long-acting agents that have been shown to be excellent in treating AWS. Because of the long half-life of these medications, withdrawal is smoother, and rebound withdrawal symptoms are less likely to occur. Lorazepam and oxazepam are intermediate-acting medications with excellent records of efficacy. Treatment with these agents may be preferable in patients who metabolize medications less effectively, particularly the elderly and those with liver failure. Lorazepam is the only benzodiazepine with predictable intramuscular absorption (if intramuscular administration is necessary). Rarely, it is necessary to use extremely high dosages of benzodiazepines to control the symptoms of alcohol withdrawal. Because clinicians often are reluctant to administer exceptionally high dosages, undertreatment of alcohol withdrawal is a common problem. Ultimately, controlled studies comparing the advantages and disadvantages of the various benzodiazepines in alcohol detoxification have not been performed, and no evidence exists to definitively support the use of lorazepam as the first-line agent in the treatment of AWS.

In most patients with mild to moderate withdrawal symptoms, outpatient detoxification is safe and effective, and costs less than inpatient treatment. If outpatient treatment is chosen, the patient and support person(s) should be instructed on how to take the prescribed medication, its side effects, the expected withdrawal symptoms, and what to do if symptoms worsen. Small quantities of the withdrawal medication, especially benzodiazepines, should be prescribed at each visit. Because close monitoring is not available in outpatient treatment, a fixed-schedule regimen should be used.

Given J.M.'s elevated liver enzymes, a reasonable approach would be to start with lorazepam. Shorter-acting agents, such as lorazepam that do not undergo extensive hepatic metabolism, are more appropriate for patients with evidence of hepatic insufficiency.

9. Is there an advantage to treating J.M. with an anticonvulsant given his history of seizures?

Anticonvulsants Evidence

Certain anticonvulsant agents show promise for a greater role in the treatment of alcohol withdrawal, although a place in treatment is still not definitive.^{93,94} Interest for their use include the possibility that anticonvulsants may curb the *kin-*

dling phenomenon suspected in withdrawal and may therefore be neuroprotective.⁸⁹ Kindling refers to long-term neuronal changes resulting from repeated detoxifications and may be associated with progressively worse AWS on subsequent detoxifications.⁹⁰ Additionally, anticonvulsants have low abuse potential and a minimal effect on cognition.⁹¹ Finally, benzodiazepines may increase the level of alcohol craving and relapse to alcohol use after abstinence.⁹²

The anticonvulsant agent, carbamazepine, widely used in Europe for AWS, effectively decreases the severity of withdrawal symptoms; it is comparable to the benzodiazepines in terms of adverse events and is equally effective as lorazepam in decreasing the symptoms of alcohol withdrawal.⁹² Although limited information is available on whether carbamazepine can reduce seizures or delirium associated with alcohol withdrawal in humans,⁷⁶ carbamazepine was found to be superior to lorazepam in preventing rebound withdrawal symptoms and reducing post-treatment drinking.⁹¹ Also, patients treated with carbamazepine had a better success rate for subsequent rehabilitation than those treated with benzodiazepines. In that study, carbamazepine was dosed on a tapering schedule of 600 to 800 mg divided through day 1, down to 200 mg as a single dose on day 5. It was as equally efficacious as lorazepam in reducing most withdrawal symptoms during detoxification, and was better at reducing anxiety and promoting sleep.⁹³ It should be noted that this study involved patients with mild-to-moderate AWS who were treated on an outpatient basis. An earlier study among alcohol-dependent inpatients with severe withdrawal symptoms found that carbamazepine was equally safe and effective as oxazepam.⁹⁴

The major concerns with the clinical use of carbamazepine are the risk of agranulocytosis or aplastic anemia, both potentially lethal conditions.⁸² Additionally, in a study comparing carbamazepine with lorazepam, pruritus was the most frequent side effect in 18.9% of patients.⁹² Strong evidence indicates human fetal risk with carbamazepine use (category D) and should only be considered if no other safer drugs can be used or are ineffective. Carbamazepine is not intended for outpatient use and can potentiate the sedative effects of alcohol.

Valproate sodium has been used in the treatment of AWS for many years, although most studies suggesting efficacy were open label.^{95,96} In a small trial of patients with uncomplicated AWS, valproate was equivalent to lorazepam in suppressing alcohol withdrawal symptoms.⁹⁶ One well-controlled study compared valproate and carbamazepine with placebo and reported a high rate of side effects and concluded that the initial dosages of these drugs (oral dose of 600 mg every 12 hours) were too high.⁹⁷ In a randomized, double-blind placebo-controlled trial evaluating the addition of divalproex with standard of care with benzodiazepines, divalproex reduced progression of withdrawal symptoms as measured by the CIWA-Ar, and likewise reduced benzodiazepine requirements.⁹⁸ The investigators speculated that a loading dose of divalproex could potentially increase the magnitude of these benefits. Use of valproic acid during pregnancy may cause teratogenic effects, such as spina bifida, or other neural tube defects. Use in women of childbearing potential for AWS is therefore not recommended (category D). Furthermore, no evidence exists for the use of valproic acid outside of a controlled setting such as inpatient detoxification.

Gabapentin is a U.S. Food and Drug Administration (FDA)-approved adjunctive treatment for partial seizures, and has been

studied in additional trials for off-label indications including AWS. Gabapentin is not metabolized in humans; it is eliminated via renal mechanisms and, therefore, is safe for use in those with compromised hepatic function. Additionally, because gabapentin does not induce or inhibit hepatic enzymatic function, the impact of potential drug interactions, such as with alcohol, is lessened. Its major side effects leading to discontinuance include somnolence (1.2%) and ataxia (0.8%). Gabapentin was administered to six patients in one trial,⁹⁹ and 49 patients in another.¹⁰⁰ The 5-day dosing schedule for both of these trials was 400 mg three times a day for 3 days, 400 mg twice a day for 1 day, and 400 mg for 1 day. The results of these trials suggest that gabapentin may be useful for patients with mild to moderate AWS. For example, in the second larger study,¹⁰⁰ those individuals who reported larger amounts of alcohol use before treatment required more as-needed benzodiazepines, suggesting that those with higher CIWA-Ar scores do not do as well on gabapentin.

If gabapentin is used, avoid abrupt withdrawal, which can precipitate seizures. Also, gabapentin should be used cautiously, and the dose appropriately reduced, in patients with compromised renal function. Because the drug can potentiate the sedative and respiratory depression effects of alcohol, it is important to ensure that the patient is alcohol-free. Although newer anticonvulsants, such as gabapentin, may be useful for some patients with mild or moderate AWS, benzodiazepines are still the drugs of choice for most patients.

Drugs having ant glutamatergic activity have also been studied, but more research is needed before clinicians can recommend their use. A placebo-controlled, randomized, single-blind trial, randomized 127 alcohol-dependent patients undergoing withdrawal, to receive placebo, diazepam 10 mg three times daily, lamotrigine 25 mg four times daily, memantine 10 mg three times daily, or topiramate 25 mg four times daily. Additional diazepam was allowed when the assigned medication failed to suppress withdrawal symptoms adequately. Only diazepam and lamotrigine were significantly superior to placebo in reducing CIWA-AR scores, although diazepam was most frequently associated with side effects.¹⁰¹

Summary

Currently, no specific indication exists for using anticonvulsants to treat alcohol withdrawal, yet because these agents are used internationally in the treatment of AWS, clinicians should be aware of this approach. Because gabapentin undergoes renal elimination, there is some advantage over lorazepam; however, support for gabapentin has been demonstrated in patients with mild to moderate AWS. At this time, no clear convincing evidence indicates that an advantage to using an anticonvulsant over lorazepam. Anticonvulsants, particularly carbamazepine and gabapentin, may offer advantages over benzodiazepines in some patients. Specifically, because they have low abuse potential and interact minimally with alcohol, anticonvulsants may eventually be an option for outpatient treatment, particularly for those who are at sufficiently low risk not to require hospitalization. Although gabapentin may be useful for some patients, benzodiazepines are still the drugs of choice for most patients, including J.M.¹⁰²

ADJUNCTIVE TREATMENTS

The hydration, electrolyte (especially, potassium and magnesium), and nutritional status of patients should be assessed at presentation. Support with IV fluids may be necessary in those patients with excessive losses through vomiting, sweating, and hyperthermia.⁹⁰ Thiamine and multivitamins should be routinely administered to patients in alcohol withdrawal. If IV fluids are given, thiamine administration should precede that of glucose, to prevent precipitation of Wernicke's encephalopathy.¹⁰³ Alcohol-dependent patients are deficient of thiamine and have a higher risk for developing Wernicke's encephalopathy.¹⁰⁴ Wernicke's encephalopathy is a disorder caused by thiamine deficiency. In 1881, Dr. Carl Wernicke, a Polish neurologist, described the condition as a triad of acute mental confusion, ataxia, and ophthalmoplegia. Korsakoff amnesic syndrome is a late neuropsychiatric manifestation of Wernicke's encephalopathy with memory loss and confabulation; hence, the condition is referred to as Wernicke-Korsakoff syndrome or psychosis. It is most often seen in alcohol-dependent patients, but it can also be seen in disorders associated with malnutrition such as long-term hemodialysis or patients with acquired immunodeficiency syndrome (AIDS).

Thiamine deficiency results in a diffuse decrease in cerebral glucose utilization. The body usually stores about 3 weeks of thiamine with daily requirements of about 1.5 mg. The body can absorb about 4.5 mg of a 100-mg oral dose of thiamine. Rapid correction of brain thiamine deficiency can occur with high plasma concentrations of thiamine, achieved by parenteral supplementation only because absorption of the oral thiamine by the GI tract is minimal, even with massive oral daily dosing.¹⁰⁴ According to the 2004 Evidence-Based Guidelines of the British Association of Psychopharmacology,¹⁰⁵ to prevent the neuropsychiatric effects of thiamine deficiency, patients should receive at least 100 mg IM on the first day and patients should be taking 100 to 200 mg/day of thiamine for up to 30 days. Because parenteral thiamine supplementation has been associated with anaphylactic reactions, it is only recommended as a slow IV injection in the presence of resuscitation facilities, although some reviews cite lower grade evidence in favor of oral thiamine supplementation during outpatient detoxification.¹⁰⁶

Several adjunctive medications, aside from the sedative-hypnotics, may serve ancillary roles in the therapy of AWS. Their selection should be based on treating specific symptoms associated with the syndrome. For instance, β -blockers (e.g., propranolol,¹⁰⁷ atenolol¹⁰⁸) or α_2 -adrenergic agonists (e.g., clonidine¹⁰⁹) can be used for moderate to severe hypertension or other autonomic manifestations. These agents can, however, mask symptoms of severe withdrawal that may herald the onset of a seizure without providing any antiseizure activity. Antipsychotics (e.g., haloperidol) can be used for managing hallucinations and severe agitation, but care must be used because these drugs can reduce the seizure threshold.^{81,102}

MANAGEMENT OF ALCOHOL DEPENDENCE

Screening for Alcohol Problems

Patients who are awake and cognitively responsive should be interviewed to assess their alcohol use history.¹¹⁰ Several instruments are available to screen and delineate the extent of a patient's alcohol use. Ultimately, time and purpose for use

are always major factors when deciding which instrument to use. The simplest screen to assess risk of alcohol abuse is to ask: During the past year on how many occasions have you had five or more drinks (for a man) or four or more drinks (for a woman) at one time?¹¹¹ An affirmative answer would suggest that further follow-up of the patient's alcohol use history is needed. A second tool called the **C-A-G-E** consists of four questions: (1) Have you ever felt you should Cut down on your drinking?; (2) Have people Annoyed you by criticizing your drinking?; (3) Have you ever felt bad or Guilty about your drinking?; (4) Have you ever felt you needed a drink first thing in the morning to steady your nerves or get rid of a hangover (Eye opener)? Positive responses to two questions suggest an alcohol problem (Table 84-6).¹¹² The Rapid Alcohol Problems Screen (RAPS4) is a short screen that has demonstrated effectiveness in an emergency setting.¹¹³ The RAPS4 questions assess heavy alcohol consumption. The Alcohol Use Disorders Identification Test (AUDIT), which was developed by the World Health Organization, has also been shown to be effective in screening individuals and distinguishing problem drinkers from others.¹¹⁴

Treatment Aims

It is important to keep in mind that unknown numbers of people with alcohol dependence heal themselves. These people have had the ability to just stop drinking. For a good many other patients who need assistance and who meet diagnostic criteria for substance abuse or dependence, psychosocial approaches are the foundation of treatment for these patients (Table 84-7). By contrast, should the patient need pharmacologic support, then consideration of a medication plan is entirely appropriate.

Table 84-6 Useful Screens for Assessing Alcohol Problems

The C-A-G-E Screening Questions (CAGE)

Have you ever felt you should Cut down on your drinking?
Have other people Annoyed you by criticizing your drinking?
Have you ever felt Guilty about drinking?
Have you ever taken a drink in the morning to calm your nerves or get rid of a hangover (Eye opener)?

The Rapid Alcohol Problems Screen (RAPS4)

Remorse: During the last year, have you had a feeling of guilt or remorse after drinking?
Amnesia: During the last year, has a friend or family member ever told you about things that you could not remember you said or did when you were drinking?
Perform: During the last year, have you failed to do what was normally expected of you because of drinking?
Starter: Do you sometimes take a drink when you get up in the morning?

Methods for Determining Recent Alcohol Consumption

Acute Consumption

- Blood alcohol
- Urine (Ethyl glucuronide)
- Saliva
- Breath

Recent Heavy Consumption

- Gamma-glutamyl transferase (GGT)
- Carbohydrate-deficient transferrin (CDT)
- Mean corpuscular volume (MCV)

Pharmacotherapy

The pharmacologic treatments of alcohol dependence focus on relapse prevention once detoxification is complete. Treatment

Table 84-7 Psychosocial and Behavioral Interventions Used with AUD

| Type of Therapy | Underlying Processes | Key Ingredients |
|---|---|---|
| Cognitive Behavioral Therapy (CBT) | The foundation is the belief that by identifying and monitoring maladaptive thinking patterns, patients can reduce or eliminate negative feelings and substance use. | Alter cognitive processes that lead to maladaptive behaviors of SUD Intervene in the behavioral chain that leads to substance use. Help patients deal with acute or chronic substance craving. Promote and reinforce the development of social skills and behaviors compatible with abstinence |
| Motivational Enhancement Therapy (MET) | Brief treatment is characterized by an empathetic approach in which the therapist helps to motivate the patient by asking about the pros and cons of the target behavior (e.g., substance use). | Develop discrepancy (e.g., comparing given behavior with peer norms) Eliciting self-motivational statements Listen with empathy Avoid argumentation Support self-efficacy |
| Medical Management (MM) | Brief 20-minute intervention by a health care professional (e.g., nurse, pharmacist, or physician). | Focus on medication adherence Monitor alcohol use Assess side effects Encourage 12-step meeting attendance Set goals Educate |
| Brief Behavioral Compliance Enhancement Therapy (BBCET) | Brief 10-minute intervention by a health care professional. | Focus on medication adherence Monitor alcohol use Assess side effects Allow patient to set goal |
| 12-Step Facilitation | Any support group that is a self-help group. Commonly called Alcoholics Anonymous, for example. | Find a support group one feels comfortable with Get a sponsor Work the 12 steps to recovery |

Table 84-8 Selected Double-Blind, Placebo-Controlled Trials for Alcohol Dependence

| Medication (dose) | Type of Agent | Weeks/Study Design | Alcoholic Subtype | Drinking/ Nondrinking Days | Craving | Relapse |
|--|-------------------------------------|------------------------------------|-------------------|-------------------------------|---------|---------|
| Disulfiram ¹¹⁷ (1 mg, 250 mg) | Aversive | 52/Double-blind placebo-controlled | AD | + | NR | NR |
| Naltrexone ¹⁶⁴ (50 mg) | Opiate antagonist | 12/Double-blind placebo-controlled | AD | + | +/0 | + |
| Naltrexone ¹⁷⁰ (50 mg) | Opiate antagonist | 12/Double-blind placebo-controlled | AD | + | + | + |
| Acamprosate ¹⁵⁰ (1,998 mg) | NMDA modulator | 48/Double-blind placebo-controlled | AD | + | 0 | + |
| Acamprosate ²⁰¹ (1,332 mg or 1,998 mg) | NMDA modulator | 24/Double-blind placebo-controlled | AD | + | + | + |
| Fluoxetine ²⁰² (60 mg) | SSRI | 12/Double-blind placebo-controlled | AD/Type A | 0 | NR | 0 |
| Fluoxetine ²⁰³ (60 mg) | SSRI | 12/Double-blind placebo-controlled | AD/Type B | – | NR | 0 |
| Sertraline ²⁰⁴ (200 mg) | SSRI | 12/Double-blind placebo-controlled | AD/MD | + | NR | NR |
| Sertraline ²⁰⁴ (200 mg) | SSRI | 14/Double-blind placebo-controlled | AD/Type A | + | NR | 0 |
| Ondansetron ²⁰⁵ (4 mcg/kg) | 5-HT3 antagonist | 12/Double-blind placebo-controlled | AD/Type B | 0 | NR | 0 |
| Ondansetron ²⁰⁵ (4 mcg/kg) | 5-HT3 antagonist | 12/Double-blind placebo-controlled | Early onset | + | NR | NR |
| Ondansetron ²⁰⁵ (4 mcg/kg) | 5-HT3 antagonist | 12/Double-blind placebo-controlled | Late onset | 0 | NR | NR |
| Topiramate ¹⁸¹ (up to 300 mg) | Mixed-action | 12/Double-blind placebo-controlled | AD | + | + | NR |
| Naltrexone ¹⁴⁴ (100 mg) or/and Acamprosate (3,000 mg) | Opiate antagonist NMDA modulator | 16/Double-blind placebo-controlled | AD | – | NR | NR |

+, medication significant compared with placebo ($p < 0.05$); –, significant difference favoring placebo; 0, no significant difference; ±, interaction of subgroup or trend favoring medication; AD, alcohol dependent; Early Onset, onset of alcohol problems <25 years; Late Onset, onset of alcohol problems >25 years; GAD, generalized anxiety disorder; MD, major depression; NR, data not reported; +, medication significant compared with placebo ($p < 0.05$); Type A, later onset of alcohol-related problems, severe dependence, fewer childhood risk factors, alcohol-related problems and psychopathological dysfunction; Type B, early onset of alcohol-related problems, increased number of childhood risk factors, family history of alcoholism, greater severity of dependence.

is intended to be an adjunct to psychosocial treatments (Table 84-7) and not used alone.¹¹⁵ To date, disulfiram, acamprosate, and naltrexone tablet and injection have been FDA approved for the treatment of alcohol dependence. In addition, several other drugs (Table 84-8) have shown varying degrees of success.^{115,116} (Table 84-9). Much is still unknown about the long-term rates of abstinence, how long these drugs should be used once patients are in treatment, the optimal doses, and whether the drugs are more effective in men or women or for which specific subpopulations.

11. R.M. is a 55-year-old man, weighing 140 pounds, who used to drink about 60 drinks a week before going through alcohol detoxification. R.M. is married, has a good job, and is now committed to remain alcohol abstinent. R.M. heard about a drug called disulfiram from a friend and is interested in using this medication to help him abstain from drinking. Is disulfiram an appropriate agent to consider for R.M.? Total bilirubin 0.3 mg/dL (normal, 0.2–1.2 mg/dL); direct bilirubin 0.1 (normal, 0–0.4 mg/dL); alkaline phosphatase 53 (normal, 35–131 U/L); AST 30 (normal, 11–36 U/L); ALT 35 (normal, 6–43 U/L); BUN 14 mg/dL (normal, 5–22 mg/dL); creatinine 1.0 mg/dL (normal, 0.6–1.3 mg/dL); glucose 123 mg/dL (normal, 70–110 mg/dL); uric acid 9.1 mg/dL (normal, 2.5–8.5 mg/dL); calcium 8.7 mg/dL (normal 8.3–10.6 mg/dL); albumin 4.0 (normal, 3.3–4.9 g/dL); cholesterol 255 mg/dL (normal, <200 mg/dL); creatine kinase 78 U/L (normal, <18–198 U/L); Na 132 mEq/L (normal, 132–147); K 3.3 mEq/L (normal, 3.4–5.0); HCO₃⁻ 22.6 mEq/mL (normal, 17.0–30.6 mEq/L); Cl, 109 mEq/L

(normal, 95–105); Mg 1.7 mg/dL (normal, 1.5–3.1 mg/dL), GGT 30 U/L (normal, 10–61 U/L).

DISULFIRAM

Disulfiram is an irreversible acetaldehyde dehydrogenase inhibitor that blocks alcohol metabolism leading to an accumulation of acetaldehyde. Disulfiram reinforces an individual's desire to stop drinking by providing a disincentive associated with increased acetaldehyde levels, resulting in headache, palpitations, hypotension, flushing, nausea, and vomiting when patients consume alcohol. Although results from clinical trials are inconsistent, some consensus has developed that oral disulfiram reduces the number of drinking days.¹¹⁵ Supervision of disulfiram administration leads to better outcomes, although not always in the order of a statistically significant effect.¹¹⁶

The primary predictor of success with disulfiram is the patient's commitment to total abstinence from alcohol. Although anecdotal reports of success are common, clinical evidence suggests disulfiram appears to be most effective for alcoholics who are involved in special high-risk situations (e.g. weddings, graduations) and particularly when administration is supervised.¹¹⁵

Evidence

Controlled clinical trials of disulfiram have failed to demonstrate consistently a therapeutic benefit.¹¹⁵ Double-blind,

Table 84-9 Recently Completed or Major Ongoing Drug Trials for Alcoholism

| Drug | Pros | Cons | Comments |
|--|--|---|---|
| Sertraline 200 mg/day | Selectively targeting LOA subtypes | Most likely little treatment benefit for EOA subtype | <i>N</i> = 160; 80 EOA and LOA; results not yet reported |
| Topiramate ¹⁸³ 300 mg (maximal dose) | Potentially mimics actions of alcohol without the reinforcement | Not tested in recently abstinent alcoholics; optimal dose unknown | <i>N</i> = 368; 14 weeks 6-week titration, 8 week maintenance and 7–16-day taper. Compared with placebo, topiramate significantly lowered % heavy drinking days (<i>p</i> = 0.002), drinks/drinking days (<i>p</i> = 0.006) and % of days abstinent (<i>p</i> = 0.002). |
| Ondansetron 4 mcg/kg twice a day | Treatment matching in EOA based on SERT may result; nominal side effects | Most likely little treatment benefit for LOA subtype | <i>N</i> = 320 160 with LL 5-HTTLPR and 160 with the SS/SL SERT. Results not yet reported. |
| Ondansetron 4 mcg/kg twice a day and Topiramate 300 mg (maximal dose) | The combination of ondansetron and topiramate may be additive among EOA | Ondansetron dosing by weight does not easily translate to clinical practice | <i>N</i> = 360 12 weeks; project ends 8/31/09 |
| Aripiprazole ²⁰⁶ 30 mg (maximal dose) | Multiple mechanisms of action | No preclinical or clinical data; not tested in actively drinking alcoholics; optimal dose unknown | <i>N</i> = 266 12 weeks; Also received weekly psychotherapy. Discontinuations (40.3% vs. 26.7%) and treatment-related adverse events (82.8% vs. 63.6%) were higher with aripiprazole than placebo. No significant difference compared with placebo in % days abstinent (<i>p</i> = 0.227), % subjects without a heavy drinking day or time to first drinking day. The aripiprazole group had fewer drinks per drinking day (<i>p</i> < 0.001). |
| Naltrexone injection ¹⁷⁶ 190 mg or 380 mg | Increased adherence | Pain management | 6 months; 380 mg of long-acting naltrexone (<i>n</i> = 205) or 190 mg of long-acting naltrexone (<i>n</i> = 210) or a matching volume of placebo (<i>n</i> = 209) each administered monthly and combined with 12 sessions of low-intensity psychosocial intervention. Compared with placebo, 380 mg of long-acting naltrexone resulted in a 25% decrease in the event rate of heavy drinking days (<i>p</i> = 0.02) and 190 mg of naltrexone resulted in a 17% decrease (<i>p</i> = 0.07). Sex and pretreatment abstinence each showed significant interaction with the medication group on treatment outcome, with men and those with lead-in abstinence both exhibiting greater treatment effects. |
| Naltrexone and Acamprostate ¹⁴⁴ 100 mg and 3 g (maximal doses) | Targeting positive and negative reinforcement | Not tested in actively drinking alcoholics | <i>N</i> = 1,383 16 weeks; patients receiving medical management with naltrexone, CBI, or both fared better on drinking outcomes, whereas acamprostate showed no evidence of efficacy, with or without CBI. No combination produced better efficacy than naltrexone or CBI alone in the presence of medical management. Placebo pills and meeting with a health care professional had a positive effect above that of CBI during treatment. |
| SR141716, Rimonabant | Unique mechanism of action; potentially useful for nicotine cessation and weight loss | Little research on drugs that block the endocannabinoid system (i.e., potential side effects) | <i>N</i> = 40 laboratory study of non-treatment-seeking volunteers using cannabinoid-1 antagonist |
| Naltrexone and Sertraline Gabapentin as an adjunct to Naltrexone for alcoholism | Combination may yield better abstinence rates Practical application to clinical practice. | Both drugs have gastrointestinal side effects | <i>N</i> = 198 Alaskan Native Americans; results not yet reported. Examine if alcoholics receiving naltrexone and adjunctive gabapentin will have less relapse than those treated with naltrexone alone. Project ends 8/31/07. |

CBI, combined behavioral intervention EOA, early-onset alcoholism; 5-HTTLPR, serotonin transporter polymorphism, LL, long-long 5-HTTLPR alleles; LOA, late-onset alcoholism; SS/SL, short-short 5-HTTLPR alleles/short-long 5-HTTLPR alleles.

placebo-controlled studies using disulfiram are difficult because the psychological deterrent to use is experienced by both treatment groups and those who relapse will be unblinded when they experience the pharmacologic interaction.

In the most rigorous clinical trial conducted in a population of veterans, no significant difference in abstinence rates was demonstrated between patients taking placebo, 1 mg or 250 mg of disulfiram.¹¹⁷ Patients randomized to receive 250 mg of disulfiram daily drank less frequently (significantly fewer

drinking days per year), however. Patients who were middle-aged and had social stability were more likely to benefit from disulfiram. In another trial in which administration was supervised, patients receiving disulfiram drank less alcohol and less frequently; however on randomization, patients were unblinded to their drug.¹¹⁸

The efficacy of disulfiram compared with other drugs such as naltrexone is poorly studied.¹¹⁹ Although no advantage was seen for combining disulfiram with naltrexone in dually diagnosed alcohol-dependent patients,¹²⁰ in one study, disulfiram combined with acamprosate resulted in increased days of cumulative abstinence.¹²¹

Dosing

The recommended starting dose of disulfiram is 250 mg once daily, with a range of 125 to 500 mg/day.¹²⁰ If a patient drinks and does not experience a disulfiram-ethanol reaction, the dose can be increased to 500 mg, as a significant proportion of patients may not experience a disulfiram-alcohol reaction at the usual 250 mg daily dose.^{122,123} Side effects are increased, however, at doses >250 mg. Dosing starts at least 12 to 24 hours after abstinence initiation (when the blood or breath alcohol concentration is zero). Treatment continues, depending on the particular needs of the individual, but is generally at least 90 days and maintenance therapy may be required for years.

Contraindications, Warnings, and Interactions

Because of the intense cardiovascular and physical changes that occur in the disulfiram-ethanol interaction, disulfiram is contraindicated in patients with cardiac disease, coronary occlusion, cerebrovascular disease, and renal or hepatic failure. At somewhat higher doses, psychotic reactions have occurred. Many clinicians avoid disulfiram use in elderly patients or in those with any significant medical illness (e.g., diabetes). It is not definitive that disulfiram causes fetal abnormalities when administered during pregnancy,¹²⁴ but some data are found regarding limb reduction anomalies in infants born to disulfiram-treated mothers taking disulfiram during the first trimester of pregnancy.¹²⁵ As a result, disulfiram should only be used during pregnancy if the expected benefit to the mother and fetus is greater than the possible risk to the fetus; however, it should be avoided in the first trimester (category C). No information is available about the safety of this medicine during breastfeeding.

Disulfiram can also be hepatotoxic and should be used cautiously in patients with liver disease. Liver function should be established at baseline and after 14 days of treatment and a complete blood count (CBC) and liver function tests (LFT) should be obtained every 6 months.¹²⁶

R.M. has normal hepatic function; however, LFT should be monitored at baseline and periodically during treatment. Although not all clinicians agree, most would recommend—at minimum—baseline LFT: ALT, AST, GGT and withholding disulfiram when LFT are more than three times upper limits of normal.¹²⁶ If elevated, repeat LFT every 1 to 2 weeks until normal, and then every 3 to 6 months if no elevations, with an awareness that increased LFT results may signal return to drinking rather than disulfiram toxicity.^{127,128} Persistently elevated LFT may also indicate viral hepatitis (B or C),

for which alcoholics have a higher risk, and thus the need to order a hepatitis profile. Currently no specific guidelines exist to determine whether a patient with elevated LFT should or should not receive treatment for alcoholism. Many clinicians anecdotally feel that as long as a patient's hepatic function is closely monitored, a reduction in alcohol use will lead to more normalized LFT. Wide ranges of psychiatric adverse effects include disorientation, agitation, depression, and behavioral changes such as paranoia, withdrawal and bizarre behaviors, and worsening of schizophrenia, especially at doses >250 mg daily.^{129–130} Disulfiram should be avoided or used very cautiously in persons with these conditions. Disulfiram can be used relatively safely at a dose of 250 mg daily in alcohol-dependent patients with co-occurring psychiatric disorders, including schizophrenia.^{120,131,132}

Disulfiram is a potent inhibitor of the CYP2E1 oxidase, and can interact with anticoagulants (warfarin), antiepileptics (phenytoin, carbamazepine), some benzodiazepines (e.g., diazepam but not lorazepam), and tricyclic antidepressants (amitriptyline, desipramine), potentially increasing the toxicity of these medications. Delirium can result in combination with monoamine oxidase inhibitors. Other important interactions can occur with metronidazole and omeprazole.¹³³

Patient Education

To receive optimal results with disulfiram, patients must receive regular counselling and be closely monitored for any changes in hepatic function. Patients should be advised that the involvement of significant others will facilitate their recovery. Having someone participate in helping to validate the administration process is known to lead to better outcomes. Discontinuation of disulfiram should occur only after consultation with the prescriber and counsellor involved. Common side effects of disulfiram include drowsiness, particularly in the first few weeks of treatment, a metallic or garlic taste, and sexual dysfunction. The dose can be taken at bedtime if drowsiness or tiredness occurs.

Patients must stop the medication for at least 3 days (up to 14 days in some) before being exposed to products containing alcohol. What cannot be overlooked is that patients taking disulfiram must be informed about the dangers of consuming even small amounts of alcohol in foods, in over-the-counter medications, in mouthwashes, and in use of topical lotions. Also, it is important to verify that the patients understand the necessary precautions and the consequences of alcohol use. The patient should call the prescriber to report any respiratory difficulty, nausea, vomiting, decreased appetite, dark colored urine, or a change in pigmentation in the skin or eyes (primarily yellowing).

Summary

Generally, given the special circumstances needed for success, disulfiram is generally not the drug of choice for treating alcoholism. The social, medical, and psychiatric status of a candidate is an important consideration in the use of disulfiram. Conditions that R.M. would appear to possess that may enhance the effectiveness of disulfiram include an agreement by R.M. to have his medication administration

supervised (in this case by his wife), a steady job, and his high level of motivation to sustain abstinence. R.M. should also receive counselling and support services on a regular basis.

12. T.M. is a 60-year-old woman who weighs 105 pounds, is 63 inches tall, and is actively drinking about 40–50 drinks a week. Her CIWA-Ar score is 8. T.M. wants a medication that will gradually reduce her alcohol use over time so that she can drink socially with friends. T.M. has heard of acamprosate and asked for some samples but she was refused. Why was she not a good candidate? Total bilirubin 0.8 mg/dL (normal, 0.2–1.2 mg/dL); direct bilirubin 0.2 (normal, 0–0.4 mg/dL); alkaline phosphatase 80 (normal, 35–131 U/L); AST 30 (normal, 11–36 U/L); ALT 23 (normal, 6–43 U/L); BUN 20 mg/dL (normal, 5–22 mg/dL); creatinine 1.2 mg/dL (normal, 0.6–1.3 mg/dL); glucose 91 mg/dL (normal, 70–110 mg/dL); uric acid 3.3 mg/dL (normal, 2.5–8.5 mg/dL); calcium 8.9 mg/dL (normal, 8.3–10.6 mg/dL); albumin 4.5 (normal, 3.3–4.9 g/dL); cholesterol 195 mg/dL (normal, <200 mg/dL); creatine kinase 190 U/L (normal <18–198 U/L); Na 143 mEq/L (normal, 132–147); K 4.2 mEq/L (normal, 3.4–5.0); HCO₃ 25.2 (normal, 17.0–30.6 mEq/L); Cl 110 mEq/L (normal, 95–105); BUN 14 mg/dL (normal, 5–22); magnesium 1.9 mg/dL, (normal, 1.5–3.1 mg/dL).

ACAMPROSATE

Acamprosate (Campral) has multiple actions, but is principally a glutamate and GABA modulator. In vitro and in vivo studies in animals suggest that acamprosate interacts with GABA and glutamate to restore the imbalance of neuronal excitation¹³⁴ and inhibition¹³⁵ caused by chronic alcohol use. The key mechanism of action is considered to be as a weak functional antagonist of the glutamate NMDA receptor possibly mediated through indirect modulation of the receptor site via antagonism at the mGluR5 receptor.¹³⁶ A series of meta-analyses and systematic reviews demonstrated that when used as an adjunct to psychosocial interventions, acamprosate improves drinking outcomes such as the length and rate of abstinence.^{115,137–139} This effect is doubtful if acamprosate is not initiated quickly after a detoxification.^{140,141} Evidence indicates that the effect of acamprosate on abstinence rate lasts after the treatment is stopped.¹⁴² The success of acamprosate, however, seems limited to European trials as recent U.S. trials failed to demonstrate significant results on primary outcome measures.^{143,144}

Acamprosate appears to be especially useful in a therapeutic regimen targeted at promoting abstinence and can be used in primary care settings as well as specialized addiction treatment programs.¹⁴⁵ Acamprosate has been studied in thousands of patients, primarily in Europe, and few contraindications to treatment exist. Little consistent information is found about patient characteristics that predict improvement while taking acamprosate. In a meta-analysis of all U.S. and European studies, predictors of abstinence were motivation, readiness to change, baseline abstinence, initial first week compliance, and living with a partner or child.¹⁴⁶ A pooled analysis of seven European trials, however, found no significant predictors of the abstinence outcome measures.¹⁴⁷ Candidates for acamprosate should be committed to abstinence and begin the medication after being abstinent from alcohol.^{148,149}

Evidence

In a systematic review of the efficacy data related to acamprosate,¹⁴⁸ proof for efficacy of acamprosate was strong. Moreover, several acamprosate studies have reported positive results. For example, in a study of 272 severely dependent alcoholics, patients receiving acamprosate showed a significantly higher continuous abstinence rate within the first 2 months of treatment compared with patients receiving placebo.¹⁵⁰ Of acamprosate treated patients, 40% were continuously abstinent over a 48-week period compared with 17% of those who received placebo.

Acamprosate has also been studied for periods of up to a year. In a long-term follow-up (12 months) after trial completion, acamprosate still maintained an effect on abstinence rates, but not on nondrinking days.¹⁵¹ Some studies have found limited to no efficacy,^{143,144,152–154} although two of the studies may have been underpowered.^{153,154} One of these studies also had a short treatment period,¹⁵⁴ and the other had a long delay in initiating treatment.¹⁵² In summary, most studies suggest that acamprosate is a safe and well tolerated drug for the promotion of alcohol abstinence.

Dose

Acamprosate is dispensed in 333 mg tablets and the usual dose is 666 mg/day three times daily.¹⁵⁵ Patients can be started on the full dose without titration. Acamprosate is not well absorbed from the GI tract and it takes several days to achieve desired blood levels of the medication. The medication appears to be safe and effective in alcoholics, with minimal side effects. It does not appear to produce sedation and does not cause drug dependence. Main adverse effects of acamprosate appear to be GI, including nausea, diarrhea, and bloating. Nausea or diarrhea can be usually managed with bismuth compounds, but if symptoms are severe or persistent, the dose should be reduced by one-third to one-half. Acamprosate has been used in trials for a year, but the duration of therapy depends on treatment success and the willingness of the patient to continue therapy indefinitely.

Contraindications, Warnings, and Interactions

Acamprosate should not be used in patients with impaired kidney function (CrCl <30 mL/minute), nor in patients who previously exhibited hypersensitivity to acamprosate. The dose should be 333 mg three times daily in patients with a CrCl between 30 and 50 mL/minute. Acamprosate should only be used during pregnancy when the benefit clearly outweighs the risk as the drug has been shown to be teratogenic (category C) in rats.¹⁵⁵ Tetracyclines may be inactivated by the calcium component in acamprosate during concurrent administration.¹⁵⁶ Naltrexone increases plasma levels of acamprosate, although the clinical significance of this interaction is unknown.^{157,158} Suicidal ideation, and attempted and completed suicides have occurred in patients taking acamprosate. Depression or suicidal ideation must be monitored.

Patient Education

Acamprosate must be used in combination with a psychosocial program such as combined behavioral intervention (CBI) or

regular Alcoholics Anonymous (AA) meetings. Acamprosate may be taken without regard to meals. The tablets should not be crushed and should be taken whole. Although no interaction with alcohol occurs, abstinence in combination with counseling and social support are required to attain optimal treatment. Patients should report persistent diarrhea, sudden or excessive weight gain, swelling of the extremities, respiratory difficulties, fainting, or thoughts of suicide.

Summary

Acamprosate was approved by the FDA for the maintenance of abstinence in alcohol-dependent individuals who are abstinent at treatment initiation. Despite a strong showing in many European trials, less favorable results compared with naltrexone were seen in recent U.S. studies, perhaps making acamprosate a good choice for heavily dependent patients coming out of detoxification with verifiable abstinence before starting the drug. Given that T.M. is not abstinent, and wishes to continue drinking socially, the evidence would suggest that she is not a good candidate for acamprosate.

13. T.M. is vacillating over whether or not she wants to continue drinking or not. T.M. is willing to attend weekly counseling sessions. T.M. has never taken a medication for alcoholism and now states that she is willing to stop drinking. Her primary care provider is considering naltrexone. Does the evidence support this choice, and what should be considered before choosing between the oral tablets or the monthly injection in this patient?

NALTREXONE

Naltrexone blocks the action of endorphins when alcohol is consumed, and this results in an attenuation of dopamine release at the nucleus accumbens thought to be crucially important to positive reinforcement, reward, and craving.⁶⁰ Although naltrexone therapy has been recommended for all alcohol-dependent patients who do not have a medical contraindication to its use, a survey of 1,388 U.S. physicians specializing in addiction reported that they prescribed naltrexone to an average of only 13% of their patients.¹⁵⁹ The main self-reported reasons why physicians did not prescribe naltrexone to more patients were that patients refused to take the medication or comply with prescribing regimens (23%), and that patients could not afford the medication (21%).

Evidence seems to support the use of naltrexone as an adjunct to psychosocial interventions^{122,139,145,160} with higher abstinence rates in short-term treatment¹⁶¹ and as a deterrent to progressing from a lapse to a full-blown relapse.¹¹⁵ Naltrexone is as efficacious as disulfiram and probably more efficacious than acamprosate.^{144,161–162} The addition of acamprosate to naltrexone does not enhance outcome.^{144,163}

Several studies indicate that naltrexone is most effective in patients with strong craving,^{164,165} poor cognitive status at study entry,¹⁶⁶ and high compliance.^{167,168} This observation is consistent with the demonstrated effect of naltrexone in reducing craving. Evidence also indicates that persons with a family history for alcoholism, early age at onset of drinking, and comorbid use of other drugs are more likely to benefit from naltrexone.¹⁶⁹

Evidence

A comprehensive review of pharmacotherapies for alcoholism concluded that naltrexone oral (ReVia) produced a consistent decrease in relapse rate to heavy drinking and in drinking frequency, although it did not enhance absolute abstinence rates.¹⁴⁹ More specifically, several studies using naltrexone report the opiate antagonist to be more effective than placebo in reducing relapse rates, in increasing a percent of nondrinking days,^{164,167,170} and in reducing craving in heavy drinkers.¹⁷¹ Yet other studies fail to demonstrate a significant difference with placebo.^{172,173} Several factors may explain the discrepancies in results of the different clinical trials with naltrexone. Many of the studies included small sample sizes and may lack the statistical power to demonstrate treatment effects.¹⁶² Several large sufficiently powered studies also reported negative results.^{172–174} Nonetheless, the COMBINE trial¹⁴⁴ clearly supports the effectiveness of naltrexone in that each of the groups of patients receiving naltrexone in conjunction with medical management had a higher percentage of days abstinent than those receiving placebo plus medical management without naltrexone or CBI. Naltrexone also reduced the risk of heavy drinking.

Naltrexone injection (Vivitrol), was approved by the FDA and released in June 2006. Injectable naltrexone is safe and well tolerated in alcohol-dependent individuals.¹⁷⁵ In two double-blind, randomized, placebo-controlled trials, the efficacy of once monthly long-acting injectable or depot forms of naltrexone was demonstrated,^{176,177} which suggests the advantage of increased compliance. Garbutt et al.¹⁷⁶ found men receiving naltrexone injection had significantly better treatment outcomes than women, and women who received naltrexone demonstrated no difference with those who received placebo. Additionally, because a robust effect was seen for naltrexone injection compared with placebo for people coming into the study abstinent, the FDA required the manufacturer to place a requirement for abstinence when starting the medication on its product information.

Dose

Naltrexone has been approved for use in the first 90 days of abstinence when the risk of relapse is highest. It has also been shown to be safe and well tolerated by patients for periods of up to a year. Treatment with naltrexone should continue based on the response to the medication. Discontinuation should only be considered in consultation with the health care provider. The usual dose of naltrexone is 50 mg daily, although doses of 25 mg to 100 mg daily have been reported to be effective, particularly in those with lower blood concentrations of the drug.¹⁷⁸ Side effects, such as nausea or headache, are more common in the initial few days of therapy. Starting with a 25-mg dose (half a tablet) for the first two to four daily doses may reduce the incidence of side effects. Anecdotally, some practitioners suggest that because of its long half-life, naltrexone may also be administered three times weekly in doses of 100 mg on Mondays, 100 mg on Wednesdays, and 150 mg on Fridays (or the equivalent of 50 mg daily). This method may facilitate supervised or observed administration of naltrexone, because only three (versus seven) observations are required per week.

The injection (380 mg) should be administered by deep IM injection into a gluteal muscle, alternating buttocks each

injection. No dose adjustment is required for mild or moderate renal or hepatic impairment, but naltrexone has not been studied in severe renal or hepatic impairment.

Contraindications, Warnings, Interactions

Naltrexone is contraindicated in patients with a history of sensitivity to naltrexone with acute hepatitis or liver failure; in those who are physically dependent on opiates, receiving opiate analgesics, or in acute opiate withdrawal. The benefit of using naltrexone during pregnancy should clearly outweigh the risk. The concurrent administration of naltrexone and opiate analgesics is contraindicated. To avoid triggering an acute abstinence syndrome, patients must be opiate free for a minimum of 7 to 14 days before initiating treatment with naltrexone, as substantiated with a urine drug test. Although rarely performed, a naloxone challenge test can be utilized before treatment with naltrexone to rule out concurrent use of opiates. Naltrexone is in the FDA pregnancy category C and it is unknown whether naltrexone passes into breast milk.

Naltrexone injection must be mixed and administered immediately. A special diluent is supplied in the carton and must be administered with the needle supplied with it in the carton. If there is a short delay (e.g., a few minutes) after suspension but before transfer into the syringe, the vial should be inverted a few times to resuspend the product and then transferred into the syringe for immediate use. Substitution of any of the supplied components is not recommended. If the milky white suspension clogs the needle during administration, the needle should be withdrawn from the patient, capped with the attached safety device, and replaced with the spare administration needle provided. The plunger should be gently pushed until a bead of the suspension appears at the tip of the needle. The remainder of the suspension can then be administered into an adjacent site, but in the same gluteal region. Should a patient miss a dose, the patient should be instructed to return as soon as possible to receive the next dose; however, no data exist regarding restarting treatment in patients who have missed appointments or discontinued their treatment.

A possible clinical concern with naltrexone tablets or long-acting injectable naltrexone is pain management. Any attempt to overcome the opiate blockade produced by naltrexone using exogenous opioids may result in fatal overdose. Should a patient be in pain after receiving an injection, the first drug of choice should be a nonopiate, such as a nonsteroidal anti-inflammatory drug (NSAID). If the patient is still in pain, an opiate can be used but it will most likely have to be administered in a higher dose and more frequently. When reversal of naltrexone blockade is required for pain management, patients should be monitored in a setting equipped and staffed for cardiopulmonary resuscitation and monitored for signs of respiratory depression.

Patient Education

Naltrexone tablets have been demonstrated to be more effective when used in combination with cognitive behavioral therapy (CBT) or psychosocial therapy. Therefore, to obtain the optimal long-term benefit, the patient must plan on meeting with a counselor and enroll in a behavior modification or support group program such as AA that supports their abstinence. Patients should be reminded not to use opiates or any medications not approved by the prescriber during treatment. Patients re-

ceiving naltrexone must be opiate free from 7 to 10 days as substantiated with a urine drug test and should be asked to wear some kind of identifier for medical emergencies. Particularly with naltrexone injection, documentation to alert medical personnel of naltrexone treatment is needed in case of trauma necessitating pain management.

Alert patients that naltrexone can cause nausea, headache, drowsiness, dizziness, or blurred vision. In a year-long safety study, the most common side effects were nausea, headache, anxiety, and sedation.¹⁷⁸ Should such side effects occur, reducing the dosage by one-half often reduces the side effects. Large doses of naltrexone can cause liver failure. Patients should report excessive tiredness, unusual bleeding or bruising, loss of appetite, pain in the upper right part of the stomach, any discoloration of the skin or eyes, a change in stool color or urine, thoughts of suicide, or signs of pneumonia.

An important consumer consideration to note is that, as of this writing, naltrexone injection costs about \$800 a month compared with <\$150 a month for a month supply of 50-mg tablets. Because the injection is new, some insurance plans might not pay for it, or it may be available on formulary but at a higher co-pay rate to the patient. This cost may represent a significant barrier to affordable treatment for many patients.

Summary

Naltrexone, CBT or a support group would appropriate for T.M. Current evidence suggests, however, that tablets rather than injection would be the most appropriate choice for T.M. Primary concerns would be poor hepatic function (which is normal) or previous failure with the medication. The primary consideration in this case is that no significant difference has been seen in drinking outcomes in women who received naltrexone or placebo injections.¹⁷⁶ While this perhaps anomalous result is still being investigated, sufficient support exists to prescribe naltrexone tablets in this patient. On the other hand, although everyone received a 1-hour low-intensity psychosocial intervention every other week, women compared with men in the control group reduced their alcohol use more than did men, suggesting that using a psychosocial approach such as CBT (Table 84-7) would benefit T.M.

14. T.M. reduces her alcohol use substantially, but is still drinking. Is there any advantage to the combination therapy of acamprosate with naltrexone?

The rationale for combining the drugs is that acamprosate reduces negative reinforcement and naltrexone attenuates positive reinforcement.⁶⁰ To test this hypothesis, a randomized, controlled study of 160 patients performed in Europe demonstrated that, although combining naltrexone and acamprosate was more effective than either placebo or acamprosate alone, adding acamprosate was not significantly more effective than naltrexone alone.¹⁶³ In a much larger study, the COMBINE trial randomized >1,300 individuals in a double-blind fashion to receive placebo, naltrexone, or acamprosate alone or in combination with medical management or combined behavioral therapy.¹⁴⁴ Results from this study suggest that acamprosate has no significant effect on drinking versus placebo, either by itself or with any combination of the other treatments in the study. Furthermore, patients receiving placebo and medical management (MM) from a health care professional (Table 84-7) had better outcomes than patients receiving CBI

(a CBT-like therapy that includes 12-step facilitation) alone. Based on the available evidence, it would not be reasonable to combine acamprosate with naltrexone.

OTHER DRUG THERAPY

15. W.W. is a 48-year-old male executive, who weighs 230 pounds and is 73 inches tall. He comes for help with his alcohol use, which he recognizes is out of control. He has previously tried disulfiram, naltrexone, and acamprosate and does not want the naltrexone injection. Currently, W.W. is drinking 55 drinks a week. His CIWA score is 9 (although he does not appear to need inpatient detoxification). His laboratory work reveals the following: Total bilirubin 0.4 mg/dL (normal, 0.2–1.2 mg/dL); direct bilirubin <1 (normal, 0–0.4 mg/dL); alkaline phosphatase 74 (normal, 35–131 U/L); AST 70 (normal, 11–36 U/L); ALT 89 (normal, 6–43 U/L); BUN 14 mg/dL (normal, 5–22 mg/dL); creatinine 1.1 mg/dL (normal, 0.6–1.3 mg/dL); glucose 151 mg/dL (normal, 70–110 mg/dL); uric acid 5.8 mg/dL (normal, 2.5–8.5 mg/dL); calcium 10.0 mg/dL (normal, 8.3–10.6 mg/dL); albumin 3.6 (normal, 3.3–4.9 g/dL); cholesterol 189 mg/dL (normal, <200 mg/dL); creatine kinase 90 U/L (normal, <18–198 U/L); Na 134 mEq/L (normal, 132–147); K 4.5 mEq/L (normal, 3.4–5.0); HCO₃ 29.2 (normal, 17.0–30.6 mEq/L); Cl 97 mEq/L (normal, 95–105); magnesium 2.3 mg/dL, (normal, 1.5–3.1 mg/dL). What other medications might be considered?

Topiramate

Topiramate is an FDA-approved medication found to have multiple mechanisms of action, including enhanced GABA_A inhibition that results in decreased dopamine facilitation in the midbrain thought to be of potential benefit in the treatment of addiction.¹⁷⁹ Additionally, there is antagonism of kainate to activate the kainate/AMPA glutamate receptor subtypes¹⁸⁰ and inhibition of type II and IV carbonic anhydrase isoenzymes.

Evidence

Topiramate is not FDA-approved for the treatment of alcoholism. Because the drug is coming off patent soon, it is unlikely the manufacturer will pursue an indication for topiramate in the treatment of alcohol dependence. Johnson et al.,¹⁸¹ in a randomized, double-blind, placebo-controlled trial used an escalating dose from 25 to 300 mg/day of topiramate or matching placebo in 150 men and women non-treatment-seeking alcoholics during the first 8 weeks of a 12-week period. Patients stayed at the same dose over the last 4 weeks of the study. All patients in the study received brief behavioral compliance enhancement therapy (BBCET) that was a 10- to 15-minute meeting with a health care professional (i.e., a pharmacist, nurse, nurse practitioner, physician, or physician assistant) that focused on resolving side effect issues and facilitated adherence (Table 84-7). Participants receiving topiramate reported significantly fewer drinks per day and drinks per drinking day, significantly fewer drinking days, significantly more days of abstinence, and significantly less craving than those on placebo. The evidence suggests that, although abstinence was not a goal at the start of the topiramate study, the medication may be more beneficial during the abstinence initiation phase of treatment.¹⁸² In a recently completed phase II clinical trial, the use of topiramate for alcohol dependence treatment was confirmed by outcomes demonstrating that topiramate recipients

showed a significantly greater lowering of percentage of heavy drinking days (mean difference, 8.4% [95% CI, 3.1–13.8], $p = 0.002$), drinks per drinking day (mean difference, 0.9 [95% CI, 0.3–1.5], $p = 0.006$), and a higher percentage of days abstinent (mean difference, -7.7% [95% CI, -12.5–2.9], $p = 0.002$). Using a repeated-measures mixed model, topiramate showed even greater efficacy over placebo ($p < 0.001$) for all comparisons.¹⁸³

In the treatment of alcohol dependence, topiramate is titrated from 25 mg/day up to 300 mg/day over 6 weeks (100 mg in the morning; 200 mg in the afternoon) or to the patient's maximal tolerable dose. Abrupt discontinuation of topiramate has been associated with seizures in patients without a history of seizures and, for this reason, gradual withdrawal of the drug (e.g., a 25% decrease in the dosage every 4 days over 16 days) is recommended.

16. W.W. also reports >2 week period of feeling worthless, suicidal ideation, a 29-pound weight loss over the last 6 weeks, hypersomnia, and lethargy. These symptoms have alternated with short periods (e.g., ~4 days) of feeling exhilarated, expansiveness, compulsive buying sprees, hyposomnia, and arguments with friends and coworkers. He does not report any psychotic episodes. How should patients with underlying psychiatric and alcohol use disorders be approached?

W.W. reports symptoms that appear consistent with bipolar II disorder (ruling out any other diagnosis) that would include a formal differential diagnosis of major depressive disorder and hypomania without psychosis. Clinicians must consider the potential for dual diagnosis disorders (e.g., depression, bipolar disorder, or schizophrenia) combined with substance dependence (e.g., as with alcohol). Tobacco and caffeine dependence are common. A significant number of individuals with mental health disorders also have an alcohol use disorders compared with the general population.¹⁸⁴ Increased comorbid conditions also lead to a poorer treatment prognosis.

Principles for the optimal treatment of patients with a dual diagnosis include the following: (a) Flexibility (e.g., while the goal of treatment may be abstinence, for some patients movement in the right direction is just as important to keep the person engaged in treatment). (b) Repetition (e.g., a constant refocusing of attention for avoiding alcohol and for confronting their psychiatric symptoms is a priority). (c) Counseling (e.g., matching patients to the appropriate intervention). These factors are all fundamental to long-lasting treatment success. Medications, when appropriate (e.g., early and vigorous drug intervention with nonaddictive medications) may also help the patient stay in treatment; however, every effort must be made to use medications that do not induce euphoria, cause dependence, and are effective and safe even during relapse.

Clinicians must distinguish between drug-induced and drug-related psychiatric disorders. Ideally, but often impractical, is to permit 3 to 4 weeks of abstinence to provide adequate information to determine the relationship off the alcohol use disorder with the psychiatric disorder. A complete drug use history, urinalysis, and blood or hair drug tests should be obtained. A comprehensive history, including age of onset of disorders, persistence of psychiatric illness during abstinence, and very importantly, family history, should provide adequate diagnostic information.

Patients with both drug use and psychiatric disorders constitute a substantial and challenging subpopulation. Treating

the alcohol use disorder alone predicts a poorer outcome for other disorders including early relapse. Early and aggressive treatment for each condition should be implemented. Furthermore, care must be taken to ensure that the medications prescribed are safe if combined with alcohol.

A few studies have evaluated the effectiveness of mood stabilizers (e.g., lithium, carbamazepine, divalproex, atypical antipsychotics, and topiramate) in the treatment of comorbid bipolar disorder and alcohol dependence.^{185,186} Some evidence suggests that topiramate may be helpful during the depressive phase of bipolar disorder¹⁸⁶ perhaps as a result of reducing alcohol use.¹⁸⁷ Clinicians should monitor weight loss,¹⁸⁸ worsening depression, and suicidal ideation in patients using topiramate.¹⁸⁹

17. Over an 8-week period, W.W. is taking 300 mg of topiramate a day and is only drinking 10 drinks a week. W.W. complains that he is experiencing pins and needles in his arms and hands. Is this related to symptoms of withdrawal or to topiramate?

It is likely that tingling in the extremities, called paresthesias, is a possible result of withdrawal from alcohol, the more probable reason for this occurrence (given the temporal relationship) is as a side effect of topiramate therapy. In addition to paresthesias, other prominent side effects include mental confusion, slowness in thinking, depression, and somnolence, which may be attenuated by titration when initiating therapy, and the development of renal calculi in about 1.5% of patients.¹⁸⁹ Adequate hydration is encouraged, particularly in patients who may be at risk for developing calculi.

Contraindications, Warnings, Interactions

Topiramate is contraindicated in those hypersensitive to the drug. Topiramate should be used with caution in those who have a history of urolithiasis, paresthesias, secondary angle closure glaucoma, renal or hepatic impairment, and conditions or therapies that predispose to acidosis (e.g., renal disease, severe respiratory disorders, status epilepticus, diarrhea, surgery, ketogenic diet, or drugs). Monitoring for hyperchloremic non-ionic-gap metabolic acidosis is essential, and, therefore, baseline chemistry (e.g., HCO_3^- and pH) should be assessed and monitored regularly thereafter. Metabolic acidosis can cause symptoms such as tiredness and loss of appetite, or more serious conditions including arrhythmia or coma. Topiramate has been found to be teratogenic in animal studies and is a pregnancy category C medication.¹⁸⁹

Concomitant use of oral contraceptives, phenytoin, carbamazepine, and valproic acid has been found to interact with topiramate.¹⁹⁰ Coadministration of another carbonic anhydrase inhibitor, such as acetazolamide, may increase the possibility of renal stone formation and should be avoided.

Patient Education

Patients should be advised not to adjust the dose or discontinue the medication without consulting a health care provider. Unless otherwise instructed, to prevent kidney stones and dehydration, patients should maintain adequate hydration and be advised to drink 2 to 3 L/day of fluid. Patients may be at risk for decreased sweating and increased body temperature and should therefore monitor their exercise, particularly in hot weather. Topiramate can cause drowsiness, dizziness, changes in memory, a change in taste (particularly with carbonated beverages), vision changes (particularly associated with increased

intraocular pressure), and pressure to the touch, loss of appetite or unplanned weight loss, and sudden changes in mood.

Summary

Evidence for the effectiveness of topiramate is promising, although more clinical research is needed on topiramate in efficacy and effectiveness trials, as well as determining the proper dose. Although W.W. has some liver impairment (AST and ALT twice the normal limit), some evidence supports the use of valproate as a good choice to treat the diagnosis of bipolar disorder and AUD in this particular patient¹⁹¹; drug levels must be monitored, however, because valproate is entirely metabolized by the liver. Topiramate, on the other hand, is renally metabolized and might be considered an adjunctive therapy if W.W. does not completely respond to the drug of first choice.

Baclofen

Baclofen promotes a balance between inhibition of release of GABA, mediated by presynaptic GABA_B receptors and inhibition of neuronal excitability mediated by postsynaptic GABA_B receptors.¹⁹² Putatively, agonism of GABA_B receptors also modulates mesolimbic dopamine neurons.¹⁹³ Baclofen is approved for use in the United States to reduce cramping, spasms, and muscle tightness.

Efficacy

Baclofen has been promoted for investigation by the National Institute on Alcohol Abuse and Alcoholism (NIAAA) for alcohol dependence.¹⁹⁴ Studies show that baclofen is effective in reducing alcohol self-administration¹⁹⁵ and motivation to consume alcohol in rats.¹⁹⁶ In a double-blind, placebo-controlled trial using baclofen, alcohol-dependent patients reported less craving, drank on fewer days, and had higher rates of total abstinence than those receiving placebo.¹⁹⁷

Summary

Because baclofen is metabolized by the kidneys, it would be an alternative adjunct to topiramate to treat the AUD diagnosis in W.W. The evidence for baclofen is limited and should only be considered an alternative if other approved drugs failed or W.W. was known to be allergic to topiramate.

DRUG INTERACTIONS

18. T.C. is a 32-year-old man who has been diagnosed with alcohol dependence and depression. He reports recent weight loss (20 pounds in the last month), excessive ‘sluggishness,’ an increased need for sleep (10–12 hours a day) and feelings of guilt and worthlessness. His depression is likely substance induced, but the importance of his alcohol use is largely ignored. T.C.’s primary care provider plans to start sustained-release bupropion for depression. Laboratory tests were performed at the visit but are not yet available. What should be considered when prescribing bupropion or any other medication to T.C. and what simple information should T.C. be given?

Prescription drug use and interactions with alcohol are fairly common with individuals diagnosed with alcohol abuse or dependence disorders. Alcohol–prescription drug interactions in patients diagnosed with AUD have been found to be as

high as 40%, with more than 20% taking medications with moderate to severe alcohol interactions.¹⁹⁸ The interaction of alcohol with the cytochrome P450 enzyme system may be complex, and depends on duration of consumption. Notably, short-term consumption leads to a competitive inhibition of the CYP2E1, whereas chronic use leads to induction of this enzyme. CYP2E1 induction leads to increased clearance of such drugs as alcohol itself, warfarin, diazepam, rifamycin, meprobamate, pentobarbital, and propranolol, with the effect on liver metabolism lasting for days to weeks after discontinuation of alcohol. More importantly, the CYP2E1 enzyme sys-

tem converts several substances into highly toxic metabolites. These include cocaine, enflurane and methoxyflurane, isoniazid, phenylbutazone, and acetaminophen. Through induction of this alternate pathway of drug metabolism, otherwise safe doses of drugs may become hepatotoxic. Carbamazepine is also known as a cytochrome P450 3A4 inducer, and can cause several problematic interactions on multiple medications.¹⁹⁸ Obviously, clinicians must consider the impact (e.g., on the liver) of prescribing drugs when patients are also abusing or dependent on alcohol.¹⁹⁹ (See Table 84-10 for more alcohol-drug interactions.)

Table 84-10 Ethanol Drug Interactions

| | |
|--------------------------------|---|
| Acetaminophen | Chronic excessive alcohol consumption increases susceptibility to acetaminophen-induced hepatotoxicity. Acute intoxication theoretically protects against acetaminophen toxicity because less hepatotoxic metabolite is generated. |
| Anticoagulants (oral) | Chronic ethanol consumption induces hepatic metabolism of warfarin, decreasing hypoprothrombinemic effect. Very large acute ethanol doses (>3 drinks/day) may impair the metabolism of warfarin and increase hypoprothrombinemic effect. Vitamin K-dependent clotting factors may be reduced in alcoholics with liver disease, also affecting coagulation. |
| Antidepressants | Enhanced sedative effects of alcohol and psychomotor impairment are possible. Acute ethanol impairs metabolism. Fluoxetine, paroxetine, fluvoxamine, and probably other serotonin reuptake inhibitors (SSRI) do not interfere with psychomotor or subjective effects of ethanol. |
| Ascorbic acid | Ascorbic acid increases ethanol clearance and serum triglyceride levels and improves motor coordination and color discrimination after ethanol consumption. |
| Barbiturates | Phenobarbital decreases blood ethanol concentration; acute intoxication inhibits pentobarbital metabolism; chronic intoxication enhances hepatic pentobarbital metabolism. |
| Benzodiazepines | Psychomotor impairment increased with the combination. |
| Bromocriptine | Ethanol increases gastrointestinal side effects of bromocriptine. |
| Caffeine | Caffeine has no effect on ethanol-induced psychomotor impairment. |
| Calcium channel blockers | Verapamil inhibits ethanol metabolism and increases intoxication. |
| Cephalosporin antibiotics | Ethanol produces flushing, nausea, headaches, tachycardia, and hypotension. Cephalosporin antibiotics that have an ethyltetrahydrothiol side chain produce this disulfiramlike reaction (e.g., cefoperazone, cefamandole, cefotetan). |
| Chloral hydrate | Elevation of plasma trichloroethanol (a chloral hydrate metabolite) and blood ethanol. Combined central nervous system (CNS) depression. Vasodilation, tachycardia, headache. |
| Chloroform | Ethanol increases chloroform hepatotoxicity. |
| Doxycycline | Chronic consumption of ethanol induces hepatic metabolism of doxycycline and may lower serum concentration of the antibiotic. |
| Erythromycin | Ethanol may interfere with absorption of the ethylsuccinate salt. Effects on other formulations are unknown. |
| Furazolidone | When ethanol is ingested, nausea, flushing, lightheadedness, and dyspnea may occur (i.e., a disulfiramlike reaction). |
| H ₂ antagonists | Cimetidine potentiates ethanol effects. Increases peak plasma ethanol concentrations and area under the plasma ethanol concentration time curve. CNS toxicity from increased cimetidine serum concentration. Nizatidine, and ranitidine may also increase blood alcohol levels slightly by inhibiting gastric alcohol dehydrogenase. Famotidine does not affect blood alcohol levels. |
| Isoniazid | Consumption of ethanol with isoniazid increases risk of hepatotoxicity. Tyramine-containing alcoholic beverages may cause hypertensive reaction. |
| Ketoconazole and metronidazole | When ethanol is ingested, nausea, flushing, lightheadedness, and dyspnea may occur (i.e., a disulfiramlike reaction may occur with metronidazole). A sunburnlike rash has been reported with ethanol consumption and ketoconazole. A similar reaction may occur with itraconazole, although no reports exist. |
| Meprobamate | Synergistic CNS depression. |
| Metoclopramide | Enhances sedative effects of ethanol. |
| Monoamine oxidase inhibitors | Tyramine-containing alcoholic beverages (e.g., wines, beer) may cause a hypertensive crisis. Pargyline may inhibit aldehyde dehydrogenase and cause a disulfiramlike interaction with ethanol. |
| Narcotic analgesics | Volume of distribution of intravenous meperidine increases with increasing ethanol consumption. Clinical significance unknown. Potential for enhanced CNS depression. |
| Oral hypoglycemic agents | Chlorpropamide, tolbutamide, and tolazamide may cause flushing, lightheadedness, nausea, and dyspnea if alcohol is ingested (i.e., a disulfiramlike reaction). |
| Paraldehyde | Possible metabolic acidosis. |
| Phenothiazines | Potentiates psychomotor effects of ethanol. |
| Quinacrine | Possible inhibits acetaldehyde oxidation. |
| Salicylates | Increases gastric bleeding associated with aspirin; may increase chance of gastrointestinal hemorrhage. |
| Tetrachloroethylene | Combined CNS depression. |
| Trichloroethylene | Flushing, lacrimation, blurred vision, tachypnea may occur when patients exposed to trichloroethylene drink alcohol. |

Summary

An alternative to bupropion should be considered particularly in light of the unavailability of T.C.'s laboratory test results. In this case, critical issues need to be considered, particularly hepatic function, which may be associated with an increased risk of seizures. Bupropion is extensively metabolized by the liver and should be used with extreme caution in patients with severe hepatic cirrhosis. In these patients, a reduced dose or frequency of administration is required, as peak plasma levels are substantially elevated, thereby increasing the risk of seizures. The dose should not exceed 150 mg every other day in patients with impaired hepatic function.²⁰⁰ Additionally, patients

should be told that the excessive use or abrupt discontinuation of alcohol may alter their seizure threshold and bupropion is therefore contraindicated in patients undergoing abrupt discontinuation of alcohol. Patients have also reported lower alcohol tolerance during treatment with bupropion. Patients, in general, should be advised that the consumption of alcohol should be minimized or avoided.²⁰⁰ Moreover a recent study demonstrated that one-third of patients with AUD prescribed drugs were never advised not to take their prescribed medication with alcohol.¹⁹⁸ The study also reported that bupropion, serotonin reuptake inhibitors (SSRI) and acetaminophen were the drugs most frequently involved in drug-alcohol interactions.

Long before Christopher Columbus traveled to the New World, tobacco use was widespread in the Americas—tobacco preparations were part of religious ceremonies for the Native Americans, and tobacco was also used medicinally. At that time, and for several subsequent centuries, little was known or suspected about the dangers of tobacco use. In retrospect, it is not surprising that these dangers were not recognized initially because the more pressing health issues at that time were related to life-threatening, acute diseases as opposed to chronic diseases such as those imposed by tobacco. However, it is now well established that tobacco is a detrimental substance, and its use dramatically increases a person's odds of dependence, disease, disability, and death.

Cigarettes are the only marketed consumable product that when used as intended will contribute to the death of half or more of its users.¹ Tobacco products are carefully engineered formulations that optimize the delivery of nicotine, a chemical that meets the criteria for an addictive substance: (a) nicotine induces psychoactive effects, (b) it is used in a highly controlled or compulsive manner, and (c) behavioral patterns of tobacco use are reinforced by the pharmacologic effects of nicotine.² As a major risk factor for a wide range of diseases, including cardiovascular conditions, cancers, and pulmonary disorders, tobacco is the primary known preventable cause of premature death in our society.³ During the 20th century, 100 million deaths were caused by tobacco, and currently, an estimated

5.4 million deaths occur annually.³ Unless tobacco control efforts are able to reverse this trend, the number of annual deaths is likely to exceed 8 million by the year 2030.⁴ According to Dr. Margaret Chan, Director-General of the World Health Organization, “Reversing this entirely preventable epidemic must now rank as a top priority for public health and for political leaders in every country of the world.”⁴

In the United States, smoking is responsible for approximately 438,000 premature deaths each year.⁵ In addition to the harm imposed on users of tobacco, exposure to secondhand smoke results in an estimated 50,000 deaths each year.⁶ Furthermore, enormous economic burden accompanies tobacco use. Each pack of cigarettes smoked costs society \$7.18 for associated medical care (\$3.45) and productivity losses (\$3.73), for a total of \$157 billion in annual health-related economic losses.⁵ Because of the health and societal burdens that it imposes, tobacco use and dependence should be addressed during each clinical encounter with all tobacco users.⁷

EPIDEMIOLOGY OF TOBACCO USE AND DEPENDENCE

Nicotine addiction is a form of chronic brain disease resulting from alterations in brain chemistry.⁸ Dr. Alan Leshner, former director of the National Institute on Drug Abuse, defines drug addiction as “compulsive use, without medical purpose, in the face of negative consequences.”⁸ The addictive properties of nicotine are well documented.

In the United States, experimentation with cigarettes and the development of regular smoking typically occur during adolescence, with 88% to 89% of adult smokers having tried their first cigarette by 18 years of age^{9,10} and 71% of adult daily smokers having become regular smokers by age 18.⁹ Because most teens who smoke at least monthly continue to smoke in adulthood,⁹ tobacco use trends among youth are a key indicator of the overall health trends for the nation.¹¹ According to the Centers for Disease Control and Prevention (CDC), the prevalence of current smoking (defined as having smoked at least one cigarette in the preceding 30 days) among high school students increased throughout the early and mid-1990s,¹² identifying an urgent need for tobacco prevention and cessation programs focused on younger age groups. These have led to subsequent decreases. In 2007, an estimated 21.6% of 12th graders (23.1% of males and 19.6% of females) had smoked one or more cigarettes in the past 30 days.¹³

Among adults, smoking prevalence varies by sociodemographic factors, including sex, race/ethnicity, education level, age, and poverty level. The CDC reported that in 2006, the percentage of current smokers (defined as having smoked 100 or more cigarettes during their lifetime and currently smoking every day or some days) was 20.8% (23.9% of men and 18.0% of women).¹⁴ Table 85-1 summarizes the smoking prevalence estimates for various population subgroups, stratified by sex. In 2006, the highest median prevalence of current smoking was evident in Kentucky (28.6%), and the lowest prevalence was observed in Utah (9.8%).¹⁵ An estimated 44.3% of cigarettes

Table 85-1 Percentage of Current Smokers^a Ages 18 Years and Older, by Sex and Selected Characteristics—National Health Interview Survey, United States, 2006

| Characteristic | Category | Men (n = 10,715) | Women (n = 13,560) | Total (n = 24,275) |
|-----------------------------|---|------------------|--------------------|--------------------|

smoked in the United States are among persons with mental illness.¹⁶

Factors Contributing to Tobacco Use

Tobacco addiction is maintained by nicotine dependence.¹⁷ Nicotine induces a variety of pharmacologic effects, described as follows, that lead to dependence.^{17,18} However, tobacco dependence is not simply a matter of nicotine pharmacology—it is a result of the interplay of complex processes, including the desire for the direct pharmacologic actions of nicotine, the relief of withdrawal, learned associations, and environmental cues (e.g., advertising, the smell of a cigarette, or observing others who are smoking).¹⁷ Physiological factors, such as pre-existing medical conditions (e.g., psychiatric comorbidities¹⁶) and one's genetic profile, also can predispose individuals to tobacco use. Notably, it has been estimated in twin studies that 40% to 60% of smoking is heritable.^{19–21} The rapidity with which nicotine, the addictive component of tobacco, is absorbed and passes through the blood-brain barrier contributes to its addictive nature. After inhalation, nicotine reaches the brain within seconds.¹⁷ As such, smokers experience nearly immediate onset of positive effects of nicotine, including pleasure, relief of anxiety, improved task performance, improved memory, mood modulation, and skeletal muscle relaxation.¹⁷ These effects, mediated by alterations in neurotransmitter levels, reinforce continued use of nicotine-containing products.

Nicotine Pharmacology

Nicotine (*Nicotiana tabacum*), which is composed of a pyridine ring and a pyrrolidine ring, is one of the few natural alkaloids that exist in the liquid state. Nicotine is a clear, weak base ($pK_a = 8.0$) that turns brown and acquires the characteristic odor of tobacco after exposure to air.^{22,23} In acidic media, nicotine is ionized and poorly absorbed; conversely, in alkaline media, nicotine is nonionized and well absorbed. Under physiological conditions ($pH = 7.3–7.5$), approximately 31% of nicotine is nonionized and readily crosses cell membranes.^{22,24} Given the relation between pH and absorption, the tobacco industry and pharmaceutical companies are able to titrate the pH of their tobacco products and nicotine replacement therapies (NRTs) to maximize the absorption potential of nicotine.^{17,25}

Once absorbed, nicotine induces a variety of central nervous system, cardiovascular, and metabolic effects. Nicotine stimulates the release of several neurotransmitters, inducing a range of pharmacologic effects such as pleasure (dopamine), arousal (acetylcholine, norepinephrine), cognitive enhancement (acetylcholine), appetite suppression (dopamine, norepinephrine, serotonin), learning (glutamate), memory enhancement (glutamate), mood modulation (serotonin), and reduction of anxiety and tension (β -endorphin and GABA).¹⁸ The dopamine reward pathway, a network of nervous tissue that elicits feelings of pleasure in response to certain stimuli, is central to drug-induced reward. Key structures of the reward pathway include the ventral tegmental area, nucleus accumbens, and prefrontal cortex (the area of the brain that is responsible for thinking and judgment). The neurons of the ventral tegmental area contain the neurotransmitter dopamine, which is released in the nucleus accumbens and in the prefrontal cortex. Immediately after inhalation, a bolus of nicotine enters

the brain, stimulating the release of dopamine, which induces nearly immediate feelings of pleasure, along with relief of the symptoms of nicotine withdrawal. This rapid dose response reinforces repeated administration of the drug and perpetuates the smoking behavior.¹⁸

Chronic administration of nicotine has been shown to result in an increased number of nicotine receptors in specific regions of the brain,²⁶ which is believed to represent upregulation in response to nicotine-mediated desensitization of the receptors and may play a role in nicotine tolerance and dependence.¹⁸ Chronic administration also leads to tolerance to the behavioral and cardiovascular effects of nicotine over the course of the day; however, tobacco users regain sensitivity to the effects of nicotine after overnight abstinence from nicotine, as shown in Figure 85-1.^{17,22} Notably, after smoking the first cigarette of the day, the smoker experiences marked pharmacologic effects, particularly arousal. No other cigarette throughout the day produces the same degree of pleasure/arousal. For this reason, many smokers describe the first cigarette as the most important one of the day. Shortly after the initial cigarette, tolerance begins to develop. Accordingly, the threshold levels for both pleasure/arousal and abstinence rise progressively throughout the day as the smoker becomes tolerant to the effects of nicotine. With continued smoking, nicotine accumulates, leading to an even greater degree of tolerance. Late in the day, each individual cigarette produces only limited pleasure/arousal; instead, smoking primarily alleviates nicotine withdrawal symptoms. Lack of exposure to nicotine overnight results in resensitization of drug responses (i.e., loss of tolerance). Most dependent smokers tend to smoke a certain number of cigarettes per day and tend to consume sufficient nicotine per day to achieve the desired effects of cigarette smoking and minimize the symptoms of nicotine withdrawal.²² Withdrawal symptoms include depression, insomnia, irritability, anxiety, difficulty concentrating, restlessness, and increased appetite.^{27–29} Tobacco users become adept at titrating their nicotine levels throughout the day to avoid withdrawal symptoms, maintain pleasure and arousal, and modulate mood.

Nicotine is extensively metabolized in the liver and, to a lesser extent, in the kidney and lung. Approximately 70% to 80% of nicotine is metabolized to cotinine, an inactive metabolite.^{17,24} The rapid metabolism of nicotine ($t_{1/2} = 2$ hours) to inactive compounds underlies tobacco users' needs for frequent, repeated administration. The half-life of cotinine, however, is much longer ($t_{1/2} = 18–20$ hours), and for this reason, cotinine is commonly used as marker of tobacco use as well as a marker for exposure to secondhand smoke.¹⁷ Cotinine cannot, however, differentiate between the nicotine from tobacco products and the nicotine from NRT products.

Nicotine and other metabolites are excreted in the urine. Urinary excretion is pH dependent; the excretion rate is increased in acidic urine. Nicotine is excreted in breast milk and can be detected in the blood and urine of infants of nursing smokers.^{23,24}

Drug Interactions With Smoking

It is widely recognized that polycyclic aromatic hydrocarbons (PAHs), present in appreciably large quantities in tobacco smoke, are responsible for most drug interactions with smoking.^{30,31} PAHs, which are the products of incomplete

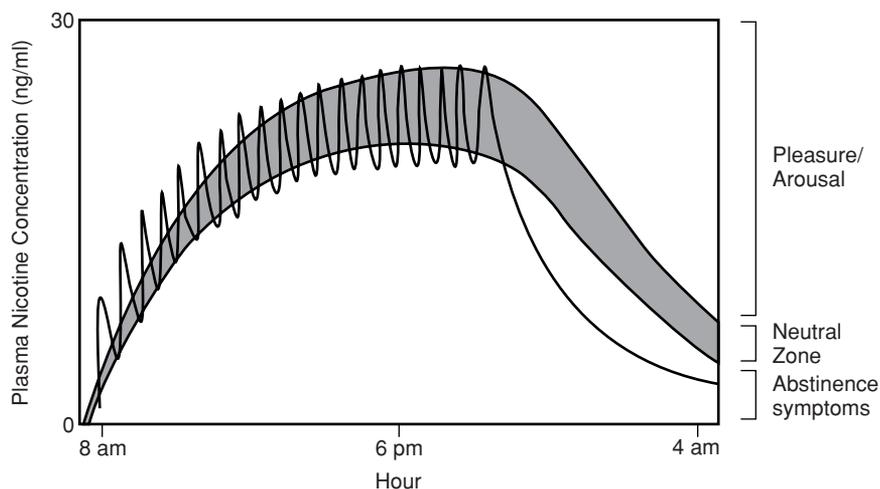

FIGURE 85-1 Nicotine addiction cycle throughout the day.

- The sawtooth line represents venous plasma concentrations of nicotine as a cigarette is smoked every 40 minutes from 8 am to 9 pm.
- The upper solid line indicates the threshold concentration for nicotine to produce pleasure or arousal.
- The lower solid line indicates the concentrations at which symptoms of abstinence (i.e., withdrawal symptoms) from nicotine occur.
- The shaded area represents the zone of nicotine concentrations (neutral zone) in which the smoker is comfortable without experiencing either pleasure/arousal or abstinence symptoms.

combustion of tobacco, are potent inducers of several hepatic cytochrome P450 microsomal enzymes (CYP1A1, CYP1A2, and possibly CYP2E1). Although other substances in tobacco smoke, including acetone, pyridines, benzene, nicotine, carbon monoxide, and heavy metals (e.g., cadmium), might also interact with hepatic enzymes, their effects appear to be less significant. Most drug interactions with tobacco smoke are pharmacokinetic, resulting from the induction of drug-metabolizing enzymes (especially CYP1A2) by compounds in tobacco smoke. Table 85-2 summarizes key interactions with smoking.^{30,32} Patients who begin smoking, or quit smoking, might require dosage adjustments for some medications.

Health Consequences of Tobacco Use

Smoking has a causal or contributory role in the development of a variety of medical conditions (Table 85-3).³ In the United States, tobacco use accounts for nearly 1 in 5 deaths, and an estimated 8.6 million persons suffer from chronic conditions attributable to smoking.³³ Among current smokers, chronic bronchitis is the most common condition (49%), followed by emphysema (24%). Among former smokers, the most prevalent condition is chronic bronchitis (26%), followed by emphysema (24%) and previous heart attack (24%). Lung cancer, the leading cause of cancer-related mortality for both men and women in the United States and a disease for which the 5-year survival rate is approximately 15%,³⁴ accounts for an estimated 1% of all smoking-attributable morbidity (i.e., among those who are living) in current smokers and 2% in former smokers.³³

Secondhand Smoke Exposure

Exposure to secondhand smoke, which includes the smoke emanating from burning tobacco and that exhaled by the smoker, results in an estimated 50,000 deaths annually, in addition to contributing to numerous diseases among nonsmoking chil-

dren and adults.⁶ Major conclusions of the 2006 Surgeon General's Health Effects of Involuntary Exposure to Tobacco Smoke⁶ report include (a) Many millions of Americans, both children and adults, are still exposed to secondhand smoke in their homes and workplaces despite substantial progress in tobacco control; (b) Secondhand smoke exposure causes disease and premature death in children and adults who do not smoke; (c) Children exposed to secondhand smoke are at an increased risk for sudden infant death syndrome, acute respiratory infections, ear problems, and more severe asthma. Smoking by parents causes respiratory symptoms and slows lung growth in their children; (d) Exposure of adults to secondhand smoke has immediate adverse events on the cardiovascular system and causes coronary heart disease and lung cancer; (e) The scientific evidence indicates that there is no risk-free level of exposure to secondhand smoke; and (f) Eliminating smoking in indoor spaces fully protects nonsmokers from exposure to secondhand smoke. Separating smokers from nonsmokers, cleaning the air, and ventilating buildings cannot eliminate exposures of nonsmokers to secondhand smoke. Supplementing evidence presented in the Surgeon General's report, in January 2006, the California Environmental Protection Agency designated secondhand smoke as a "toxic air contaminant" and, in addition to the list of diseases described in the Surgeon General's report, specified that exposure is associated with breast cancer in younger, primarily premenopausal women.³⁵

Benefits of Quitting

The 1990 Surgeon General's Report on the health benefits of smoking cessation describes numerous and substantial health benefits associated with quitting.³⁶ Benefits incurred soon after quitting (e.g., within 2 weeks to 3 months) include improvements in pulmonary function, circulation, and ambulation. Within 1 to 9 months of quitting, the ciliary function of

Table 85-2 Drug Interactions^a With Smoking

| <i>Drug/Class</i> | <i>Mechanism of Interaction and Effects</i> |
|---|--|
| Pharmacokinetic Interactions | |
| Alprazolam (Xanax) | ● Conflicting data on significance of a PK interaction. Possible ↓ plasma concentrations (up to 50%); ↓ half-life (35%). |
| Bendamustine (Treanda) | ● Metabolized by CYP1A2. Manufacturer recommends using with caution in smokers due to likely ↓ bendamustine concentrations, with ↑ concentrations of its two active metabolites. |
| Caffeine | ● ↑ Metabolism (induction of CYP1A2); ↑ clearance (56%). ● Likely ↑ caffeine levels after cessation. |
| Chlorpromazine (Thorazine) | ● ↓ Area under the curve (AUC) (36%) and serum concentrations (24%). ● ↓ Sedation and hypotension possible in smokers; smokers may need ↑ dosages. |
| Clozapine (Clozaril) | ● ↑ Metabolism (induction of CYP1A2); ↓ plasma concentrations (18%). ● ↑ Levels upon cessation may occur; closely monitor drug levels and reduce dose as required to avoid toxicity. |
| Erlotinib (Tarceva) | ● ↑ Clearance (24%); ↓ trough serum concentrations (2-fold). |
| Flecainide (Tambocor) | ● ↑ Clearance (61%); ↓ trough serum concentrations (25%). ● Smokers may need ↑ dosages. |
| Fluvoxamine (Luvox) | ● ↑ Metabolism (induction of CYP1A2); ↑ clearance (24%); ↓ AUC (31%) ↓ plasma concentrations (32%). ● Dosage modifications not routinely recommended but smokers may need ↑ dosages. |
| Haloperidol (Haldol) | ● ↑ Clearance (44%); ↓ serum concentrations (70%). |
| Heparin | ● Mechanism unknown but ↑ clearance and ↓ half-life are observed. Smoking has prothrombotic effects. ● Smokers may need ↑ dosages due to PK and PD interactions. |
| Insulin, subcutaneous | ● Possible ↓ insulin absorption secondary to peripheral vasoconstriction; smoking may cause release of endogenous substances that cause insulin resistance. ● PK & PD interactions likely not clinically significant; smokers may need ↑ dosages. |
| Irinotecan (Camptosar) | ● ↑ Clearance (18%); ↓ serum concentrations of active metabolite SN-38 (~40%; via induction of glucuronidation); ↓ systemic exposure resulting in lower hematologic toxicity and may reduce efficacy. ● Smokers may need ↑ dosages. |
| Mexiletine (Mexitil) | ● ↑ Clearance (25%; via oxidation and glucuronidation); ↓ half-life (36%). |
| Olanzapine (Zyprexa) | ● ↑ Metabolism (induction of CYP1A2); ↑ clearance (98%); ↓ serum concentrations (12%). ● Dosage modifications not routinely recommended but smokers may require ↑ dosages. |
| Propranolol (Inderal) | ● ↑ Clearance (77%; via side-chain oxidation and glucuronidation) |
| Ropinirole (Requip) | ● ↓ C _{max} (38%) and AUC (30%) in study with patients with restless legs syndrome. ● Smokers may need ↑ dosages. |
| Tacrine (Cognex) | ● ↑ Metabolism (induction of CYP1A2); ↓ half-life (50%); serum concentrations three-fold lower. ● Smokers may need ↑ dosages. |
| Theophylline (Theo Dur, etc.) | ● ↑ Metabolism (induction of CYP1A2); ↑ clearance (58–100%); ↓ half-life (63%). ● Levels should be monitored if smoking is initiated, discontinued, or changed. ● ↑ Clearance with second-hand smoke exposure. ● Maintenance doses are considerably higher in smokers. |
| Tricyclic antidepressants (e.g., imipramine, nortriptyline) | ● Possible interaction with tricyclic antidepressants in the direction of ↓ blood levels, but the clinical importance is not established. |
| Tizanidine (Zanaflex) | ● ↓ AUC (30–40%) and ↓ half-life (10%) observed in male smokers. |
| Pharmacodynamic Interactions | |
| Benzodiazepines (diazepam, chlordiazepoxide) | ● ↓ Sedation and drowsiness, possibly caused by nicotine stimulation of central nervous system. |
| Beta-blockers | ● Less effective antihypertensive and heart rate control effects; might be caused by nicotine-mediated sympathetic activation. ● Smokers may need ↑ dosages. |
| Corticosteroids, inhaled | ● Asthmatic smokers may have less of a response to inhaled corticosteroids. |
| Hormonal contraceptives | ● ↑ Risk of cardiovascular adverse effects (e.g., stroke, myocardial infarction, thromboembolism) in women who smoke and use oral contraceptives. Ortho Evra patch users shown to have 2-fold ↑ risk of venous thromboembolism compared to oral contraceptive users, likely due to ↑ estrogen exposure (60% higher levels). ● ↑ Risk with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women age 35 and older. |
| Opioids (propoxyphene, pentazocine) | ● ↓ Analgesic effect; smoking may ↑ the metabolism of propoxyphene (15–20%) and pentazocine (40%). Mechanism unknown. ● Smokers may need ↑ opioid dosages for pain relief. |

^aShaded rows indicate the most clinically significant interactions.

the lung epithelial cells is restored; initially, this might result in increased coughing as the lungs clear excess mucus and tobacco smoke particulates. Smoking cessation results in measurable improvements in lung function³⁷ (see Chapter 23, Fig. 23-1). Over time, patients experience decreased coughing, sinus congestion, fatigue, shortness of breath, and risk of pulmonary infection. One year after cessation, the excess risk of coronary heart disease is reduced to half that of continuing smokers. After 5 to 15 years, the risk of stroke is reduced to a rate similar to that of people who are lifetime nonsmokers, and 10 years after quitting, the chance of dying of lung cancer is approximately half that of continuing smokers. In addition, the risk of developing mouth, throat, esophagus, bladder, kidney, or pancreatic cancer is decreased. Finally, 15 years after quitting, the risk of coronary heart disease is reduced to a rate that is similar to that of people who have never smoked.³⁶ Smoking cessation can also lead to a significant reduction in the cumulative risk of death from lung cancer, for both men and women.³⁸

Quitting at ages 30, 40, 50, and 60 years is associated with 10, 9, 6, and 3 years of life gained, respectively. On average, cigarette smokers die approximately 10 years younger than do nonsmokers, and among those who continue smoking, at least half will die due to a tobacco-related disease. Persons who quit before age 35 add 10 years of life and have a life expectancy similar to those who have never smoked.¹ Reduction in smoking does not equate to a reduction in harm; even low levels of smoking (e.g., 1–4 cigarettes per day) have documented risks,^{39,40} and therefore, a reduction in the number of cigarettes smoked per day should be viewed as a positive step toward quitting, but should not be recommended as a targeted end point. For any patient who uses tobacco, the target goal is complete, long-term abstinence from all nicotine-containing products. Thus, it is never too late to quit and to incur subsequent benefits of quitting. But quitting earlier is clearly advantageous.

Tobacco Use and Dependence: Treatment Approaches

Most tobacco users attempt to quit without assistance, despite the fact that persons who receive assistance are more likely to be successful in quitting.^{7,41} Given the complexity of the tobacco-dependence syndrome and the constellation of factors that contribute to tobacco use, treatment requires a multifaceted approach. To assist clinicians and other specialists in providing cessation treatment to patients who use tobacco, the U.S. Public Health Service published the Clinical Practice Guideline for Treating Tobacco Use and Dependence. This document, which represents a distillation of more than 8,700 published articles,⁷ specifies that clinicians can have an important impact on their patients' ability to quit. A meta-analysis of 29 studies⁷ determined that compared with patients who do not receive an intervention from a clinician, patients who receive a tobacco cessation intervention from a physician clinician or a non-physician clinician are 2.2 and 1.7 times, respectively, more likely to quit (at 5 or more months after cessation). Although even brief advice from a clinician has been shown to lead to increased odds of quitting,⁷ more intensive counseling yields more dramatic increases in quit rates.⁷

Numerous effective medications are available for tobacco dependence, and clinicians should encourage their use by all patients attempting to quit smoking—except when medically contraindicated or with specific populations for which there is insufficient evidence of effectiveness (i.e., pregnant women, smokeless tobacco users, light smokers, adolescents).⁷ Although both pharmacotherapy and behavioral counseling are effective independently, patients' odds of quitting are substantially increased when the two approaches are used simultaneously. The estimated efficacies of various treatment strategies are shown in Table 85-4. Clinicians can have a significant impact on a patient's likelihood of success by recommending pharmacotherapy agents and by supplementing medication use with behavioral counseling as described later in this chapter.

Assisting Patients With Quitting

Behavioral Counseling Strategies

According to the Clinical Practice Guideline,⁷ five key components comprise comprehensive counseling for tobacco cessation: (a) asking patients whether they use tobacco, (b) advising tobacco users to quit, (c) assessing patients' readiness to quit, (d) assisting patients with quitting, and (e) arranging

Table 85-4 Efficacy of Treatment Methods for Tobacco Use and Dependence⁷

follow-up care. These steps are referred to as the “5 A’s” and are described, in brief, as follows. Figure 85-2 can be used as a guide for structuring counseling interventions.

- **Ask:** Screening for tobacco use is essential and should be a routine component of clinical care. The following question can be used to identify tobacco users: “Do you ever smoke or use any type of tobacco?” At a minimum, tobacco use status (current, former, never user) and level of use (e.g., number of cigarettes smoked per day) should be assessed and documented in the medical record. Also, consider asking patients about exposure to secondhand smoke.
- **Advise:** All tobacco users should be advised to quit; the advice should be clear and compelling, yet delivered with sensitivity and a tone of voice that communicates concern and a willingness to assist with quitting. When possible, messages should be personalized by relating advice to factors such as a

patient’s health status, medication regimen, personal reasons for wanting to quit, or the impact of tobacco use on others. For example, “Ms. Crosby, I see that you now are on two different inhalers. It’s important that you know that quitting smoking is the single most important treatment for your emphysema. I strongly encourage you to quit, and I would like to help you.”

- **Assess:** Key to the provision of appropriate counseling interventions is the assessment of a patient’s readiness to quit. Patients should be categorized as being (a) not ready to quit in the next month; (b) ready to quit in the next month; (c) a recent quitter, having quit in the past 6 months; or (d) a former user, having quit more than 6 months ago.^{7,42} This classification defines the clinician’s next step, which is to provide counseling that is tailored to the patient’s level of readiness to quit. As an example for a current smoker: “Mr. Malkin, are you considering quitting, maybe sometime in the next

| | |
|--|---|
| <p>STEP One: ASK about Tobacco Use</p> <p>☞ Suggested Dialogue</p> <ul style="list-style-type: none"> – “Do you ever smoke or use any type of tobacco?” – “I take time to talk with all of my patients about tobacco use—because it’s important.” – “Medication X often is used for conditions linked with or caused by smoking. Do you, or does someone in your household smoke?” – “Condition X often is caused or worsened by exposure to tobacco smoke. Do you, or does someone in your household smoke?” | <p>STEP Four: ASSIST with Quitting</p> <p>✓ Assess Tobacco Use History</p> <ul style="list-style-type: none"> • Current use: type(s) of tobacco used, brand, amount • Past use: <ul style="list-style-type: none"> – Duration of tobacco use – Changes in levels of use recently • Past quit attempts: <ul style="list-style-type: none"> – Number of attempts, date of most recent attempt, duration – Methods used previously—What did or didn’t work? Why or why not? – Prior medication administration, dose, compliance, duration of treatment – Reasons for relapse <p>✓ Discuss Key Issues (for the upcoming or current quit attempt)</p> <ul style="list-style-type: none"> • Reasons/motivation for wanting to quit (or avoid relapse) • Confidence in ability to quit (or avoid relapse) • Triggers for tobacco use • Routines and situations associated with tobacco use • Stress-related tobacco use • Social support for quitting • Concerns about weight gain • Concerns about withdrawal symptoms <p>✓ Facilitate Quitting Process</p> <ul style="list-style-type: none"> • Discuss methods for quitting: pros and cons of the different methods • Set a quit date: more than 2–3 days away but less than 2 weeks away • Recommend completion of a Tobacco Use Log • Discuss coping strategies (cognitive, behavioral) for key issues • Discuss withdrawal symptoms • Discuss concept of “slip” versus relapse • Provide medication counseling: compliance, proper use, with demonstration • Offer to assist throughout the quit attempt <p>✓ Evaluate the Quit Attempt (at follow-up)</p> <ul style="list-style-type: none"> • Status of attempt • Inquire about “slips” and relapse • Medication compliance and plans for discontinuation |
| <p>STEP Two: Strongly ADVISE to Quit</p> <p>Advice should be clear, strong, and personalized yet delivered sensitively, with a tone conveying concern for the patient’s health and a sincere commitment to help with quitting.</p> <p>☞ Suggested Dialogue</p> <ul style="list-style-type: none"> – “It’s important that you quit as soon as possible, and I can help you.” – “I realize that quitting is difficult. It is the most important thing you can do to protect your health now and in the future. I have training to help my patients quit, and when you are ready I will work with you to design a specialized treatment plan.” | <p>STEP Five: ARRANGE Follow-up Counseling</p> <p>✓ Monitor patients’ progress throughout the quit attempt. Follow-up contact should occur during the first week after quitting. A second follow-up contact is recommended in the first month. Additional contacts should be scheduled as needed. Counseling contacts can occur face-to-face, by telephone, or by e-mail. Keep patient progress notes.</p> <p>✓ Address temptations and triggers; discuss relapse prevention strategies.</p> <p>✓ Congratulate patients for continued success.</p> |
| <p>STEP Three: ASSESS Readiness to Quit</p> <pre> graph TD Q1[Does the patient now use tobacco?] -- YES --> Q2[Is the patient now willing to quit?] Q1 -- NO --> Q3[Did the patient use tobacco previously?] Q2 -- YES --> A1[Provide appropriate tobacco dependence treatment] Q2 -- NO --> A2[Promote motivation to quit] Q3 -- YES --> A3[Prevent relapse*] Q3 -- NO --> A4[Encourage continued abstinence] </pre> <p>* Relapse prevention interventions not necessary in the case of the adult who has not used tobacco for many years.</p> <p>Fiore MC, Jaen CR, Baker TB, et al. Treating Tobacco Use and Dependence: 2008 Update. Clinical Practice Guideline. Rockville, MD: U.S. Department of Health and Human Services, Public Health Service. May 2008.</p> | |

month?” The counseling interventions for patients who are ready to quit will be different from those for patients who are not considering quitting.

- **Assist:** When counseling tobacco users, it is important that clinicians view quitting as a process that might take months or even years to achieve, rather than a “now or never” event. The goal is to promote “forward progress” in the process of change, with the target end point being sustained abstinence.

When counseling patients who are not ready to quit, an important first step is to promote motivation. Some patients who are not ready to quit truly might not believe that they need to quit; however, most will recognize the need to quit but are simply not ready to make the commitment to do so. Often, patients have tried to quit multiple times, and failed, and thus are too discouraged to try again. Strategies for working with patients who are not ready to quit involves promoting motivation to quit, and this can be accomplished by applying the “5 R’s”⁷ (Table 85-5) and by offering to work closely with the patient in designing a treatment plan. Although it might be useful to educate patients about the pharmacotherapy options, it is inappropriate to prescribe a treatment regimen for patients who are not ready to quit. For patients who are not ready to quit, encourage them to seriously consider quitting by asking the following series of three questions:

1. *Do you ever plan to quit?*
Most patients will respond “yes,” in which case the clinician should continue with question 2. If they respond “no,” the clinician should strongly advise the patient to quit and offer to assist, if the patient changes his or her mind.
2. *How would it benefit you to quit later, as opposed to now?*
Most patients will agree that there is never an ideal time to quit, and procrastinating a quit date has more negative effects than positive.
3. *What is the worst thing that would happen if you were to quit now?*
This question probes patients’ perceptions of quitting, which reveals some of the barriers to quitting that can then be addressed by the clinician.

For patients who are ready to quit (i.e., in the next month), the goal is to work with the patient in designing an individualized treatment plan, addressing the key issues listed under the “Assist” component of Figure 85-2.³² Except when medically contraindicated or with specific populations for which there is insufficient evidence of effectiveness, patients should be encouraged to use pharmacotherapy (described later in this chapter) in combination with a behavioral intervention.⁷ The first steps are to discuss the patient’s tobacco use history, inquiring about levels of smoking, number of years smoked, methods

Table 85-5 Enhancing Motivation to Quit: The “5 R’s” for Tobacco Cessation Counseling⁷

- **Relevance**—Encourage patients to think about the reasons why quitting is important. Counseling should be framed such that it relates to the patient’s risk for disease or exacerbation of disease, family or social situations (e.g., having children with asthma), health concerns, age, or other patient factors, such as prior experience with quitting.
- **Risks**—Ask patients to identify potential negative health consequences of smoking, such as acute risks (shortness of breath, asthma exacerbations, harm to pregnancy, infertility), long-term risks (cancer, cardiac, and pulmonary disease), and environmental risks (promoting smoking among children by being a negative role model; effects of second-hand smoke on others, including children and pets).
- **Rewards**—Ask patients to identify potential benefits that they anticipate from quitting, such as improved health, enhanced physical performance, enhanced taste and smell, reduced expenditures for tobacco, less time wasted or work missed, reduced health risks to others (fetus, children, housemates), and reduced aging of the skin.
- **Roadblocks**—Help patients identify barriers to quitting and assist in developing coping strategies (Table 85-6) for addressing each barrier. Common barriers include nicotine withdrawal symptoms (Table 85-7), fear of failure, a need for social support while quitting, depression, weight gain, and a sense of deprivation or loss.
- **Repetition**—Continue to work with patients who are successful in their quit attempt. Discuss circumstances in which smoking occurred to identify the trigger(s) for relapse; this is part of the learning process and will be useful information for the next quit attempt. Repeat interventions when possible.

used previously for quitting (what worked, what did not work and why), and reasons for previous failed quit attempts. Clinicians should elicit patients’ opinions about the different pharmacotherapies for quitting and should work with patients in selecting the quitting methods (e.g., medications, behavioral counseling programs). Although it is important to recognize that pharmaceutical agents might not be appropriate, desirable, or affordable for all patients, clinicians should educate patients that medications, when taken correctly, can substantially increase the likelihood of success by making them more comfortable while quitting.

Patients should be advised to select a quit date that is more than 3 days but less than 2 weeks away. This time frame provides patients with sufficient time to prepare for the quit attempt, including mental preparation, as well as preparation of the environment, such as by removing all tobacco products and ashtrays from the home, car, and workspace and informing their family, friends, and coworkers about their upcoming quit attempt and requesting their support. Additional strategies for coping with quitting are shown in Table 85-6.³² Patients should be counseled about coping with withdrawal symptoms (Table 85-7)³² and medication use and compliance, and it is crucial to emphasize the importance of receiving behavioral counseling throughout the quit attempt. Finally, patients should be commended for taking important steps toward improving their health.

- **Arrange:** Because patients’ ability to quit increases when multiple counseling interactions are provided, arranging follow-up counseling is an important, yet typically neglected, element of treatment for tobacco dependence. Follow-up contact should occur soon after the quit date, preferably during the first week. A second follow-up contact is recommended within the first month after quitting.⁷ Periodically, additional follow-up contacts should occur to monitor patient progress, assess compliance with pharmacotherapy regimens, and provide additional support.

Relapse prevention counseling should be part of every follow-up contact with patients who have recently quit smoking. When counseling recent quitters, it is important to address challenges in countering withdrawal symptoms (Table 85-7)³² and cravings or temptations to use tobacco. A list of strategies for key triggers or temptations for tobacco use is provided in Table 85-6.³² Importantly, because tobacco use is a habitual

behavior, patients should be advised to alter their daily routines; this helps disassociate specific behaviors from the use of tobacco. Patients who slip and smoke a cigarette (or use any form of tobacco) or experience a full relapse back to habitual tobacco use should be encouraged to think through the scenario in which tobacco use first occurred and identify the trigger(s) for relapse. This process provides valuable information for future quit attempts.

TELEPHONE QUITLINES

Clinicians should become aware of local, community-based resources for tobacco cessation, including telephone quitlines. When time or expertise do not afford provision of comprehensive tobacco cessation counseling during a patient visit, clinicians are encouraged to apply a truncated 5 A’s model, whereby they *Ask* about tobacco use, *Advise* tobacco users to quit, and *Refer* patients to quit to a telephone quitline. This generally can be accomplished in less than one minute. Telephone services that provide tobacco cessation counseling have proliferated since the late 1990s; these services provide low-cost interventions that can reach patients who might otherwise have limited access to medical treatment because of geographic location or lack of insurance or financial resources. In clinical trials, telephone counseling services for which at least some of the contacts are initiated by the quit line counselor have been shown to be effective in promoting abstinence,⁷ and these positive results have been shown to translate into real world effectiveness.⁴¹ The addition of medication to quitline counseling significantly improves abstinence rates compared to medication alone.⁷ In addition, preliminary evidence suggests that quitlines are also effective for smokeless tobacco cessation.⁴³ The telephone number for the tollfree tobacco quitline is 1-800-QUIT NOW. In some states, clinicians can submit a fax referral form, on behalf of a patient, to the quitline. This form initiates a process whereby a quitline counselor then contacts the patient directly.

Pharmacotherapy Options

All smokers who are trying to quit should be encouraged to use one or more U.S. Food and Drug Administration (FDA)-approved pharmacologic aids for cessation; potential exceptions that require special consideration include medical contraindications or use in specific populations for which there is insufficient evidence of effectiveness (i.e., pregnant women, smokeless tobacco users, light smokers, adolescents).⁷

Table 85-6 Cognitive and Behavioral Strategies for Tobacco Cessation**Cognitive strategies**

Focus on *retraining the way a patient thinks*. Often, patients mentally deliberate on the fact that they are thinking about a cigarette, and this leads to relapse.

Patients must recognize that thinking about a cigarette does not mean they need to have one.

| | |
|---|--|
| Review commitment to quit, focus on downside of tobacco | Reminding oneself that cravings and temptations are temporary and will pass. Have patient announce, either silently or aloud, "I want to be a nonsmoker, and the temptation will pass." |
| Distractive thinking | Deliberate, immediate refocusing of thinking when cued by thoughts about tobacco use. |
| Positive self-talks, "pep talks" | Saying "I can do this" and reminding oneself of previous difficult situations in which tobacco use was avoided with success. |
| Relaxation through imagery | Centering of mind toward positive, relaxing thoughts. |
| Mental rehearsal, visualization | Preparing for situations that might arise by envisioning how best to handle them. For example, a patient might envision what would happen if he or she were offered a cigarette by a friend—the patient would mentally craft and rehearse a response, and perhaps even practice it by saying it aloud. |

Behavioral strategies

Involve *specific actions to reduce risk for relapse*. For maximal effectiveness, these should be considered prior to quitting, after determining patient-specific triggers for tobacco use. Here, we list some behavioral strategies for several common cues or triggers for relapse.

| | |
|----------------------------|---|
| Stress | Anticipate upcoming challenges at work, at school, or in personal life. Develop a substitute plan for tobacco use during times of stress (e.g., deep breathing, take a break/leave the situation, call supportive friend or family member, self-massage, use nicotine replacement therapy). |
| Alcohol | Drinking alcohol can lead to relapse. Patient should consider limiting/abstaining from alcohol during the early stages of quitting. |
| Other tobacco users | Quitting is more difficult if the patient is around other tobacco users. This is especially difficult if there is another tobacco user in the household. Patients should limit prolonged contact with individuals who are using tobacco during the early stages of quitting. Ask coworkers, friends, and housemates not to smoke or use tobacco in their presence. |
| Oral gratification needs | Have nontobacco oral substitutes (e.g., gum, sugarless candy, straws, toothpicks, lip balm, toothbrush, nicotine replacement therapy, bottled water) readily available. |
| Automatic smoking routines | Anticipate routines that are associated with tobacco use and develop an alternative plan. Examples: <i>Morning coffee with cigarettes</i> : change morning routine, drink tea instead of coffee, take shower before drinking coffee, take a brisk walk shortly after awakening. <i>Smoking while driving</i> : remove all tobacco from car, have car interior detailed, listen to a book on tape or talk radio, use oral substitute. <i>Smoking while on the phone</i> : stand while talking, limit call duration, change phone location, keep hands occupied by doodling or sketching. <i>Smoking after meals</i> : get up and immediately do dishes or take a brisk walk after eating, call supportive friend. |
| Postcessation weight gain | The majority of tobacco users gain weight after quitting. Most quitters will gain <10 lb, but there is a broad range of weight gain reported, with up to 10% of quitters gaining as much as 30 lb. Advise patient not to attempt to modify multiple behaviors at one time. If weight gain is a barrier to quitting, advise patient to engage in regular physical activity and adhere to a healthful diet (as opposed to strict dieting). Carefully plan and prepare meals, increase fruit and water intake to create a feeling of fullness, and chew sugarless gum or eat sugarless candies. Consider use of pharmacotherapy shown to delay weight gain (e.g., the 4-mg nicotine gum or lozenge or bupropion SR). |
| Cravings for tobacco | Cravings for tobacco are temporary and usually pass within 5–10 minutes. Handle cravings through distractive thinking, take a break, change activities/tasks, take deep breaths, or perform self-massage. |

Currently, the FDA-approved first-line agents⁷ include five NRT dosage forms, sustained-release bupropion (bupropion SR), and varenicline. Pharmacologic agents that have not received FDA approval for smoking cessation but are recommended as second-line agents⁷ include clonidine and nortriptyline.

The first approved medication for smoking cessation was the nicotine gum, which was marketed in 1984. This was later followed by the nicotine transdermal patch (prescription-only formulation in 1991 and nonprescription formulations in 1996), bupropion SR and nicotine nasal spray in 1996, the nicotine oral inhaler in 1997, the nicotine lozenge in 2002, and varenicline in 2006. Each product has been shown to be effective in promoting smoking cessation. Dosing information, precautions, and adverse effects for the first-line agents are shown in Table 85-8.

Table 85-8 Pharmacotherapy Options: Products, Dosing, and Adverse Effects (Continued)

| Gum | NRT Formulations | | | | Varenicline |
|--|--|--|--|--|---|
| | Lozenge | Transdermal Patch | Nasal Spray | Oral Inhaler | |
| Dosing | | | | | |
| ≥25 cigarettes/day: 4 mg <25 cigarettes/day: 2 mg | | | | | |
| Weeks 1–6: 1 piece Q 1–2 hr | First cigarette ≤30 minutes after waking: 4 mg | >10 cigarettes/day: 21 mg/day | 1–2 doses/hr (8–40 doses/day) | 6–16 cartridges/day Individualize dosing; initially use 1 cartridge Q 1–2 hr | Days 1–3: 0.5 mg PO Q am Days 4–7: 0.5 mg PO BID Weeks 2–12: 1 mg PO BID |
| Weeks 7–9: 1 piece Q 2–4 hr | First cigarette >30 minutes after waking: 2 mg | 14 mg/day × 2 weeks 7 mg/day × 2 weeks | One dose = 2 sprays (one in each nostril); each spray delivers 0.5 mg of nicotine to the nasal mucosa | • Best effects with continuous puffing for 20 minutes • Nicotine in cartridge is depleted after 20 minutes of active puffing | • Do not exceed 300 mg/day • Treatment should be initiated while patient is still smoking |
| Weeks 10–12: 1 piece Q 4–8 hr | Weeks 1–6: 1 lozenge Q 1–2 hr Weeks 7–9: 1 lozenge Q 2–4 hr Weeks 10–12: 1 lozenge Q 4–8 hr | ≤10 cigarettes/day: 14 mg/day × 6 weeks 7 mg/day × 2 weeks | • Maximum – 5 doses/hr – 40 doses/day • For best results, initially use at least 8 doses/day | • Patient should inhale into back of throat or puff in short breaths | • Set quit date 1–2 weeks after initiation of therapy • Allow at least 8 hours between doses |
| • Maximum, 24 pieces/day | • Allow to dissolve slowly (20–30 minutes) | • May wear patch for 16 hours if patient experiences sleep disturbances (remove at bedtime) | • Patients should not sniff, swallow, or inhale through the nose as the spray is being administered | • Do NOT inhale into the lungs (like a cigarette) but “puff” as if lighting a pipe | • Avoid bedtime dosing to minimize insomnia |
| • Chew each piece slowly | • Nicotine release may cause a warm, tingling sensation or tingle fades | • Duration: 8–10 weeks | • Duration: 3–6 months | • Open cartridge retains potency for 24 hours | • Dose tapering is not necessary |
| • Park between cheek and gum when peppery or tingling sensation appears | • Occasionally rotate to different areas of the mouth | | | | • Nausea and insomnia are usually temporary side effects |
| • Resume chewing when taste or tingle fades | • No food or beverages 15 minutes before or during use | | | | • Duration: 12 weeks; an additional 12-week course may be used in selected patients |
| • Repeat chew/park steps until most of nicotine is gone (taste or tingle does not return; generally 30 minutes) | • Duration: up to 12 weeks | | | | |
| • Park in different areas of mouth | | | | | |
| • No food or beverages 15 minutes before or during use | | | | | |
| • Duration: up to 12 weeks | | | | | |
| Adverse Effects | | | | | |
| • Mouth/jaw soreness | • Local skin reactions (erythema, pruritus, burning) | • Nasal and/or throat irritation (hot, peppery, or burning sensation) | • Mouth and/or throat irritation | • Mouth and/or throat irritation | • Insomnia |
| • Hiccups | • Headache | • Rhinitis | • Unpleasant taste | • Unpleasant taste | • Dry mouth |
| • Dyspepsia | • Sleep disturbances (insomnia, abnormal/vivid dreams) | • Sneezing | • Rhinitis | • Cough | • Nervousness/difficulty concentrating |
| • Hypersalivation | • Flatulence | • Cough | • Tearing | • Headache | • Rash |
| • Effects associated with incorrect chewing technique: – Lightheadedness – Nausea/vomiting – Throat and mouth irritation | • Insomnia | • Headache | • Sneezing | • Headache | • Constipation |
| | | | • Cough | • Headache | • Constipation |
| | | | • Headache | • Headache | • Seizures (risk is 1/1,000 [0.1%]) |
| | | | | | • Flatulence |
| | | | | | • Vomiting |
| | | | | | • Neuropsychiatric symptoms (rare; see PRECAUTIONS) |

^aMarketed by GlaxoSmithKline.^bTransdermal patch formulation previously marketed as Habitrol.^cMarketed by Pfizer.

NRT, nicotine replacement therapy; OTC, over the counter (nonprescription); Rx, prescription.

First-Line Agents

NICOTINE REPLACEMENT THERAPY

NRT increases success for quitting by reducing the physical withdrawal symptoms associated with tobacco cessation while the patient focuses on modifying his or her behavior and coping with the psychological aspects of quitting. In addition, because the onset of action for NRT is not as rapid as that of nicotine obtained through smoking, patients become less accustomed to the nearly immediate, reinforcing effects of inhaled tobacco. A meta-analysis of 111 controlled trials, enrolling more than 43,000 participants, found that all NRT formulations (gum, inhaler, lozenge, patch, and nasal spray) result in statistically significant improvements in abstinence rates when compared with placebo. Patients using NRT are 1.6 times as likely to quit smoking than are those receiving placebo.⁴⁴ Figure 85-3 depicts the concentration time curves for the various NRT formulations, compared with a cigarette and moist snuff (a form of smokeless tobacco). It can be seen that of the five NRT dosage forms, the nicotine nasal spray reaches its peak concentration most rapidly. The nicotine gum, lozenge, and oral inhaler have similar concentration curves, and the nicotine transdermal patch has the slowest onset, but offers more consistent blood levels of nicotine over a sustained period of time.

BUPROPION SR

Bupropion SR is an atypical antidepressant medication hypothesized to promote smoking cessation by blocking the reuptake of dopamine and norepinephrine in the central nervous system and possibly by acting as a nicotine receptor antagonist. These neurochemical effects are believed to modulate the dopamine reward pathway and reduce cravings for nicotine and symptoms of withdrawal.⁷ Use of bupropion SR approximately doubles the long-term abstinence rate when compared with placebo.^{7,45}

VARENICLINE

Varenicline is a partial agonist, highly selective for the $\alpha 4\beta 2$ nicotinic acetylcholine receptor.⁴⁶ The efficacy of varenicline in smoking cessation is believed to be the result of sustained, low-level agonist activity at the receptor site combined with competitive inhibition of nicotine binding. The partial agonist activity induces modest receptor stimulation leading to increased dopamine levels that attenuate the symptoms of nicotine withdrawal. In addition, by competitively blocking the binding of nicotine to nicotinic acetylcholine receptors in the central nervous system, varenicline inhibits the surges of dopamine release that occur immediately following inhalation of tobacco smoke. The latter mechanism may be effective in preventing relapse by reducing the pleasure associated with smoking.⁴⁷ A recent meta-analysis has found that varenicline (2 mg/day) more than triples the likelihood of long-term abstinence from smoking relative to placebo.⁷

Second-Line Agents

Although not FDA-approved specifically for smoking cessation, the prescription medications clonidine and nortriptyline are recommended as second-line agents.⁷ Lack of an FDA-approved indication for smoking cessation and side effect profiles currently prohibit these agents from achieving first-line classification.⁷

PHARMACOTHERAPY FOR TREATING TOBACCO USE AND DEPENDENCE

Transdermal Nicotine Patch

1. T.B. is a 32-year-old woman who is enrolled in a work-site smoking cessation program. During the previous group session, the cessation counselor discussed the various medications for

cessation. T.B. has set her quit date for 1 week from today, and she is interested in starting the nicotine transdermal patch. She is currently smoking 1 pack per day (PPD), which is a reduction from the 1.5 PPD she had been smoking for the past 10 years. T.B. reports she smokes several cigarettes in succession immediately after waking in the morning. She takes no medications and has no medical problems. Which nicotine transdermal product should T.B. select, and how should it be used?

Two different transdermal nicotine patch systems are currently marketed. Transdermal nicotine delivery systems consist of an impermeable surface layer, a nicotine reservoir, an adhesive layer, and a removable protective liner. The technology for delivery of nicotine across the skin varies by manufacturer. NicoDerm CQ uses a rate-controlling membrane. The generic patches (previously marketed as Habitrol) use drug-dispersion-type systems whereby release of nicotine is controlled by diffusion of the drug across an adhesive layer.⁴⁸ The currently marketed formulations (which continuously release nicotine over 24 hours) deliver nicotine more slowly than the gum, lozenge, nasal spray, and inhaler (Fig. 85-3). Plasma nicotine levels obtained via transdermal delivery are approximately 50% lower than those achieved with cigarette smoking but still alleviate the symptoms of withdrawal.⁴⁹

The efficacy of the transdermal nicotine patch is well documented with significantly improved abstinence rates relative to placebo (Table 85-4).^{7,44} A meta-analysis of 25 randomized, controlled trials found treatment with the nicotine patch (6–14 weeks) approximately doubled the likelihood of long-term abstinence compared to placebo.⁷

Dosing

The manufacturers' recommended dosages are listed in Table 85-8. In general, higher levels of smoking necessitate the use of higher-strength formulations and a longer duration of therapy. Ultimately, the starting dose, rate of tapering, and total duration of therapy must be individualized to the patient's baseline smoking levels, development of side effects (e.g., nausea, dyspepsia, nervousness, dizziness, sweating), and the presence or absence of withdrawal symptoms (Table 85-7). T.B. currently smokes 20 cigarettes per day, and thus she should initiate the regimen using the 21-mg/day patch.

Patient Education

Regardless of the product selected, T.B. should be instructed to apply the patch to a clean, dry, hairless area of skin on the upper body or the upper outer part of her arm at approximately the same time each day. To minimize the potential for local skin reactions, the patch application site should be rotated daily, and the same area should not be used again for at least 1 week. After patch application, T.B. should ensure that the patch adheres well to the skin, especially around the edges. The clinician should reassure T.B. that water will not reduce the effectiveness of the nicotine patch if it is applied correctly, and she may bathe, shower, swim, or exercise while wearing the patch. Finally, T.B. should be advised to discontinue use of the nicotine patch and contact a health care provider if skin redness caused by the patch does not resolve after 4 days, if the skin swells or a rash develops; if irregular heartbeat or palpitations occur; or if she experiences symptoms of nicotine overdose such as

nausea, vomiting, dizziness, diarrhea, sweating, weakness, or rapid heartbeat.

Adverse Reactions

2. Ten days later, T.B. calls to complain of an itchy rash that she believes is caused by the nicotine patch. She noticed the rash yesterday when she removed the first patch from her left upper arm. This morning, after removing the second patch from her right upper arm, she noticed a similar rash. T.B. describes the skin on her right arm as slightly red but not swollen; the rash on her left arm has only a faint trace of pink discoloration. Her last cigarette was 2 days ago. How should T.B. be managed at this time?

The most common side effects associated with the nicotine patch are local reactions (erythema, burning, and pruritus) at the skin application site. These reactions are generally caused by skin occlusion or sensitivity to the patch adhesives. Rotating the patch application sites on a daily basis minimizes skin irritation; nonetheless, skin reactions to the patch adhesives occur in up to 50% of patch users. Less than 5% of patients discontinue therapy because of a skin reaction.⁷ T.B. appears to be experiencing a mild skin reaction and should be reassured that it is normal for the skin to appear erythematous for up to 24 to 48 hours after the patch is removed. T.B. can apply topical hydrocortisone cream (0.5% or 1%) or triamcinolone cream (0.5%), or can take an oral antihistamine for symptomatic treatment.⁷ Because the rash on her left arm has nearly resolved, it is reasonable for T.B. to continue using the nicotine transdermal patch provided that the erythema is not too bothersome.

Other less common side effects associated with the transdermal nicotine patch include vivid or abnormal dreams, insomnia, and headache. Sleep disturbances likely result from nocturnal nicotine absorption. Patients experiencing troublesome sleep disturbances should be instructed to remove the patch prior to bedtime and apply a new patch as soon as possible after waking the following morning.⁷

The clinician should also provide behavioral counseling support by asking T.B. about the current quit attempt. Appropriate issues to address include her confidence in remaining tobacco free, situations in which she has been tempted to smoke and potential triggers for relapse, nicotine withdrawal symptoms, her social support system for quitting, and any other questions or concerns she might have. It is reasonable to review potential coping strategies (behavioral and cognitive; Table 85-6) and schedule a future follow-up call. The clinician should commend T.B. for her decision to quit, congratulate her for remaining tobacco free for 48 hours, and reassure her that skin irritation is a common, yet generally manageable, complication with the nicotine patch.

Product Selection Considerations

The primary advantage of the transdermal nicotine patch compared with other NRT formulations is that the patch is easy to use and conceal, releases a continuous dose of nicotine throughout the day, and requires administration only once daily. As a result, patients who have difficulty adhering to regimens that require taking multiple doses of medications throughout the day or those who want a simplified regimen are likely to

be more successful with the nicotine patch. Disadvantages of the patch include a high incidence of skin irritation associated with the patch adhesives and the inability to acutely adjust the dose of nicotine to alleviate symptoms of withdrawal. Finally, patients with underlying dermatologic conditions (e.g., psoriasis, eczema, atopic dermatitis) should not use the patch because they are more likely to experience skin irritation.⁷

Nicotine Gum

3. T.B. would like to discontinue the nicotine transdermal patch. She wants to know if the gum is an effective alternative.

Nicotine polacrilex gum is a resin complex of nicotine and polacrillin in a chewing gum base that allows for slow release and absorption of nicotine across the oral mucosa. The product is available as 2- and 4-mg strengths, in multiple flavors (regular, cinnamon, fruit, mint, and orange). The gum has a distinct, tobacco-like, slightly peppery, minty, or fruity taste and contains buffering agents (sodium carbonate and sodium bicarbonate) to increase the salivary pH, which enhances the buccal absorption of nicotine. The amount of nicotine absorbed from each piece is variable, but approximately 1.1 and 2.9 mg of nicotine are extracted from the 2- and 4-mg gum formulations, respectively.⁵⁰ Peak plasma concentrations of nicotine are achieved approximately 30 minutes after chewing a single piece of gum and then slowly decline thereafter (Fig. 85-3). Patients using short-term (6–14 weeks) or long-term (>14 weeks) treatment with nicotine gum are significantly more likely to remain abstinent compared to those receiving placebo (Table 85-4).⁷

Dosing

Table 85-8 outlines the manufacturer's recommended dosing schedule for the nicotine gum. Individuals who smoke <25 cigarettes per day should use the 2-mg strength, and those smoking more should use the 4-mg strength. During the initial 6 weeks of therapy, patients should use 1 piece of gum every 1 to 2 hours while awake. In general, this amounts to at least 9 pieces of gum daily. The "chew and park" method described here allows for the slow, consistent release of nicotine from the polacrillin resin. Patients can use additional pieces of gum (to the daily maximum of 24 pieces per day) if cravings occur between scheduled doses. In general, patients who smoke a greater number of cigarettes per day will require more nicotine gum to alleviate their cravings than will patients who smoke fewer cigarettes per day. It is preferable to use the gum on a fixed schedule of administration, tapering over 1 to 3 months rather than using it "as needed" to control cravings.⁷

Patient Education

Proper chewing technique is crucial when using the nicotine gum. Patients should be instructed to chew the gum slowly until a peppery, minty, or fruity taste, or a slight tingling sensation in the mouth is detected; this varies but generally occurs after about 15 chews. When the taste or tingling sensation is noted, the patient should "park" the gum between the cheek and gum to allow absorption of nicotine across the buccal mucosa. When the taste or tingling dissipates (generally after 1–2

minutes), the patient should resume chewing slowly. When the taste or tingle returns, the patient should stop chewing and park the gum in a different area in the mouth. Rotating the gum placement site within the mouth helps decrease the incidence of oral irritation. The chew/park steps should be repeated until most of the nicotine is extracted; this generally occurs after 30 minutes and becomes obvious when chewing no longer elicits the characteristic taste or tingling sensation.

Patients should be warned that the absorption and therefore effectiveness of nicotine gum might be reduced by acidic beverages (e.g., coffee, juices, wine, soft drinks),⁵¹ which transiently reduce the salivary pH. To prevent this interaction, patients should be advised not to eat or drink (except water) for 15 minutes before or while using the nicotine gum.

Product Selection Considerations

Advantages of nicotine gum include the fact that this formulation may be used to satisfy oral cravings and the 4-mg strength might delay weight gain.⁷ For these reasons, the gum may be particularly beneficial for patients who have weight gain concerns or for patients who report boredom as a trigger for smoking. The gum might also be advantageous for patients who desire flexibility in dosing and prefer the ability to self-regulate nicotine levels to manage withdrawal symptoms. Some patients may find that the viscous consistency of the gum makes it difficult to use because it sticks to dental work. Others may find it difficult or socially unacceptable to chew the gum so frequently. Nicotine gum should not be used by patients with temporomandibular joint (TMJ) conditions. Finally, to minimize adverse effects and derive maximal therapeutic benefit, it is imperative that patients use enough gum each day and use the correct chewing technique.

Nicotine Lozenge

4. How does the nicotine lozenge differ from the nicotine gum?

The nicotine polacrilex lozenge is a resin complex of nicotine and polacrillin in a sugarfree, light mint, or cherry-flavored lozenge. The product is available in 2- and 4-mg strengths, which are meant to be consumed like hard candy or other medicinal lozenges (e.g., sucked and moved from side to side in the mouth until fully dissolved). Because the nicotine lozenge dissolves completely, it delivers approximately 25% more nicotine than does an equivalent dose of nicotine gum.⁵² Like the nicotine gum, the lozenge also contains buffering agents (sodium carbonate and potassium bicarbonate) to increase salivary pH, thereby enhancing buccal absorption of the nicotine. Peak nicotine concentrations of nicotine with the lozenge are achieved after 30 to 60 minutes of use and then slowly decline thereafter (Fig. 85-3). In a trial evaluating the formulation currently available in the United States, the nicotine lozenge approximately doubled the 6-month abstinence rates compared with placebo (23.9% vs. 12.3%).⁵³ A recent meta-analysis of five studies using either the nicotine lozenge (nicotine polacrillin) or sublingual tablet (not available in the United States) concluded that the odds of abstinence at 6 or more months was 2.0 with the tablet/lozenge relative to placebo (95% CI, 1.6–2.5).⁴⁴

Dosing

Unlike other NRT formulations, which use the number of cigarettes smoked per day as the basis for dosing, the recommended dosage of the nicotine lozenge is based on the time to first cigarette (TTFC). Some experts believe that the best indicator of nicotine dependence is the need to smoke soon after waking.⁵⁴ Based on this method, people who smoke their first cigarette of the day within 30 minutes of waking are considered more highly dependent on nicotine than those who smoke their first cigarette more than 30 minutes after waking. Because the nicotine polacrillin lozenge has been studied using the TTFC as a dosage selector, the product is licensed for use in the following manner: Patients who smoke their first cigarette of the day within 30 minutes of waking should use the 4-mg strength lozenge, and patients who smoke their first cigarette of the day more than 30 minutes after waking should use the 2-mg strength lozenge. Patients are more likely to succeed if they use the lozenge on a fixed schedule rather than as needed. During the initial 6 weeks of therapy, patients should use 1 lozenge every 1 to 2 hours while awake. In general, this amounts to at least 9 lozenges daily. Patients can use additional lozenges (up to 5 lozenges in 6 hours or a maximum of 20 lozenges per day) if cravings occur between scheduled doses.

Patient Education

Similar to the gum, the nicotine lozenge is a specially formulated nicotine delivery system that must be used properly for optimal results. The lozenge should be allowed to dissolve slowly in the mouth; when nicotine is released from the polacrillin resin, a warm, tingling sensation may be experienced. The patient should occasionally rotate the lozenge to different areas of the mouth to reduce the potential for mucosal irritation. When used correctly, the lozenge should completely dissolve within 30 minutes. Patients should be counseled not to chew or swallow the lozenge because this increases the incidence of gastrointestinal-related side effects.

Because the nicotine in the lozenge is dissolved in saliva and absorbed through the buccal mucosa, patients should be cautioned that the effectiveness of the nicotine lozenge may be reduced by acidic beverages such as coffee, juices, wine, or soft drinks. As recommended for the nicotine gum, patients should be advised not to eat or drink (except water) for 15 minutes before or while using the nicotine lozenge.

Adverse Reactions

In general, the nicotine lozenge is well tolerated. The most common side effects include nausea, hiccups, cough, dyspepsia, headache, and flatulence. Patients who use more than one lozenge at a time, continuously use one lozenge after another, or chew or swallow the lozenge are more likely to experience dyspepsia or hiccups.

Product Selection Considerations

The nicotine lozenge is similar to the nicotine gum formulation in that it may be used to satisfy oral cravings, the 4-mg strength might delay weight gain,^{7,53} and patients can self-titrate therapy to acutely manage withdrawal symptoms. Because the lozenge does not require chewing, many patients find this to be a more discrete nicotine delivery system. The disadvantages of the lozenge are the fact that it requires frequent dosing, and the

gastrointestinal side effects (nausea, hiccups, and heartburn) may be bothersome.

Postcessation Weight Gain

5. T.B. is worried about gaining weight after she quits smoking. Is weight gain common after quitting, and if so, how can this be prevented?

Most tobacco users gain weight after quitting, and clinicians should neither deny the likelihood of weight gain nor minimize its significance.⁷ For nearly all patients, the health risks associated with postcessation weight gain are negligible compared to the risks of continued smoking.

Studies suggest that most quitters gain less than 10 lb, but there is a broad range of weight gain reported, with up to 10% of quitters gaining as much as 30 lb.⁷ In general, women tend to gain more weight than men. In a study of nearly 6,000 smokers who were followed up for 5 years after quitting, the average weight gain during the follow-up period was 19.2 and 16.7 lb among women and men, respectively.⁵⁵ For men and women, subgroups that are more likely to gain weight after quitting are African Americans, younger tobacco users (younger than 55 years), and heavier tobacco users (those smoking more than 25 cigarettes per day).

The weight-suppressing effects of tobacco are well known. However, the mechanisms to explain why most successful quitters gain weight are not completely understood. Smokers have been found to have an approximately 10% higher metabolic rate compared with nonsmokers.⁵⁶ In some studies, higher caloric intakes were documented after cessation.^{57,58} The increased caloric intake may result from an increase in appetite, improved sense of taste, or a change in the hand-to-mouth ritual through the substitution of tobacco with food.

In general, a patient is less likely to be successful if he or she attempts to change multiple behaviors at once. For this reason, strict dieting to prevent weight gain, especially during the early stages of quitting, is generally not recommended.⁷ T.B. should be counseled that the average weight gain of less than 10 lb is less detrimental to her overall health than is continued smoking. Because she is concerned about weight gain, it is reasonable for the clinician to recommend that T.B. engage in some form of regular physical activity. Even modest physical activity (e.g., walking 30 minutes daily) has been found to attenuate the weight gain associated with smoking cessation.⁵⁸ Although strict dieting is not recommended, T.B. should carefully plan and prepare meals to avoid binge eating, increase her water intake to create a feeling of fullness, chew sugarless gum, and limit alcohol consumption. Furthermore, T.B. may consider pharmacotherapy options that have been shown to delay weight gain—this would include the 4-mg nicotine gum or lozenge or bupropion SR.⁷ It is important to note, however, that once the medication is terminated, the quitter gains, on average, an amount of weight that is comparable to that which would have been gained in the absence of medication.⁷

Relapse Back to Smoking

6. During a follow-up contact, the clinician learns that T.B. smoked half a pack of cigarettes at a party over the weekend

and has relapsed to her previous smoking levels after not having smoked for just over a month. How should the clinician respond?

The clinician should thank T.B. for being honest about her smoking and ask her to discuss the circumstances during which the smoking occurred. At the time of her smoking, where was she, who was she with, how did she get access to cigarettes, and how was she feeling at the time? What, specifically, were the triggers for her relapse (e.g., alcohol, depression, friends who were smoking around her)? It is important that the clinician help the patient to use this information as part of the learning process, but it also is important to focus on the “positive,” such as T.B.’s ability to have remained tobacco free for more than 1 month. After being smoke free for more than 4 weeks, most physical effects of nicotine withdrawal have completely resolved, and thus, the relapse trigger for T.B. likely was psychological or situational and could be abated through application of effective coping techniques. After an informative discussion about the situation in which the smoking occurred, it is important that the clinician work with the patient in identifying strategies for avoiding relapse in the future (Table 85-6).

Smoking and Cardiovascular Disease

7. P.J. is a 62-year-old man admitted for an elective coronary artery bypass graft (CABG) procedure. His medical history is significant for angina, hypertension, dyslipidemia, peripheral vascular disease (PVD), and allergic rhinitis. He underwent a bilateral carotid endarterectomy procedure 2 years ago and had iliac artery angioplasty with stent placement 5 years ago for PVD. P.J.’s social history is significant for tobacco use (1.5–2 PPD) and alcohol (3–4 drinks/day). He is approximately 10 lb overweight. His preoperative laboratory results are significant for a total cholesterol of 270 mg/dL (desirable, <200), low-density lipoprotein cholesterol count (LDL-C) of 163 mg/dL (optimal, <70), high-density lipoprotein cholesterol count (HDL-C) of 35 mg/dL (low, <40), and triglycerides of 350 mg/dL (normal, <150). His medications before admission include atenolol 50 mg QD, aspirin 81 mg QD, isosorbide dinitrate 20 mg TID, atorvastatin 20 mg QD, fluticasone nasal spray (50 mcg/spray) 1 spray/nostril QD, and nitroglycerin 0.4 mg SL as needed. Which of P.J.’s chronic medical conditions may be caused or exacerbated by his tobacco use?

A wealth of evidence suggests that cigarette smoking is a major cause of cardiovascular disease and is responsible for approximately 138,000 premature cardiovascular-related deaths each year.⁵ Smoking is known to accelerate the process of atherosclerosis, leading to chronic cardiovascular disorders, including coronary heart disease, cerebrovascular disease, PVD, aortic aneurysm, and congestive heart failure.³ In addition, smoking greatly elevates the risk for acute cardiovascular events, including sudden death, myocardial infarction (MI), stroke, and reocclusion of coronary or peripheral vessels after graft surgery or angioplasty.^{3,59}

There are numerous plausible pathophysiological mechanisms whereby tobacco smoking contributes to the development of cardiovascular disease. Oxidant gases and other compounds in tobacco smoke are believed to induce a hypercoagulable state characterized by increased platelet aggregation and thrombosis, which greatly increases the risk of MI and

sudden death.^{59,60} The carbon monoxide in smoke reduces the amount of oxygen available to tissues and organs, including myocardial tissue, and may reduce the ventricular fibrillation threshold.⁵⁹ Smoking may accelerate atherosclerosis through effects on serum lipids; smokers tend to have higher levels of total cholesterol, LDL-C, and triglycerides and lower HDL-C than nonsmokers.³ Smoking increases the levels of inflammatory mediators (C-reactive protein, leukocytes, and fibrinogen), which may contribute to the development and progression of atherosclerosis.⁶¹ Finally, smoking stimulates the release of neurotransmitters (e.g., epinephrine, norepinephrine) that increase myocardial workload and induce coronary vasoconstriction leading to ischemia, arrhythmias, and sudden death.^{3,59}

P.J.’s hospital admission for a CABG procedure for coronary heart disease and angina, as well as previous procedures for peripheral vascular disease (angioplasty with stent placement) and cerebrovascular disease (bilateral carotid endarterectomy), are all conditions associated with chronic tobacco use. His elevated total cholesterol, LDL-C, and triglycerides and reduced HDL-C levels are consistent with smoking-induced dyslipidemia. Cigarette smoking in combination with P.J.’s other established cardiovascular risk factors (hypertension, dyslipidemia) have synergistically increased his risk for serious cardiovascular disease.^{3,59} Fortunately, the effects of smoking on lipids, coagulation, myocardial workload, and coronary blood flow appear to be reversible, and P.J.’s risk of developing further cardiovascular-related complications will markedly decrease if he is able to quit smoking.^{36,62} The clinician should approach this hospitalization as an opportunity to motivate and assist P.J. with quitting smoking.⁷ Furthermore, data suggest the initiation of intensive cessation counseling interventions in hospitalized patients is effective in achieving long-term abstinence.⁶³

8. The cardiothoracic surgeon has strongly advised P.J. to quit smoking. P.J. is willing to quit completely, but he is worried because he has tried to quit smoking “hundreds of times” and has never been able to quit for longer than 1 week. He expresses a desire for a medication to assist him during this quit attempt. He has tried the nicotine gum and transdermal patch during three previous quit attempts. He did not like the gum because it made his jaw sore. He had temporary success with the nicotine patch but found it to be less flexible than the gum. For example, when he needed extra nicotine during stressful situations, he could not apply a second patch. What treatment alternatives are reasonable for P.J.?

P.J. has failed treatment with the nicotine gum and transdermal patch. First-line treatment options that he has not tried include the nicotine lozenge (see question 4), nicotine nasal spray, nicotine inhaler, bupropion SR, and varenicline. P.J. might also be a candidate for combination therapy (see question 10).

Nicotine Nasal Spray

The nicotine nasal spray is an aqueous solution of nicotine available in a metered-spray pump for administration to the nasal mucosa. Each actuation delivers a metered 50-mL spray containing 0.5 mg of nicotine. Nicotine in the nasal spray is more rapidly absorbed than other NRT formulations (Fig. 85-3), with peak venous nicotine concentrations achieved within

11 to 18 minutes after administration.²⁴ Use of the nicotine nasal spray more than doubles long-term (>6 months) abstinence rates when compared to placebo (Table 85-4).^{7,44}

Dosing

A dose of nicotine (1 mg) is administered as two sprays, one (0.5-mg spray) in *each* nostril. The recommended initial regimen is one to two doses every hour while awake for 6 to 8 weeks. This may be increased, as needed, to a maximum recommended dosage of five doses per hour or 40 mg/day. For best results, patients should be encouraged to use at least eight doses per day during the initial 6 to 8 weeks of therapy because less frequent administration may be less effective. After 6 to 8 weeks, the dose should be gradually decreased over an additional 4 to 6 weeks.

Patient Education

Before using the nasal spray for the first time, the nicotine nasal spray pump must be primed. This is done by actuating the device into a tissue until a fine spray is visible (about six to eight times). When administering a dose, the patient should tilt the head back slightly and insert the tip of the bottle into the nostril as far as is comfortable. After actuation of the pump, the patient should not sniff, swallow, or inhale through the nose because this increases the irritant effects of the spray. Patients should wait 5 minutes before driving or operating heavy machinery (because of the increased likelihood of tearing, coughing, and sneezing).

Adverse Reactions

Side effects commonly reported with the nicotine nasal spray include nasal and throat irritation (hot peppery sensation), sneezing, coughing, watery eyes, and rhinorrhea. In clinical trials, 94% of patients report moderate-severe nasal irritation during the first 2 days of therapy; 81% of patients still reported mild-moderate nasal irritation after 3 weeks of therapy.⁷ Nasal congestion and transient changes in taste and smell have also been reported.⁷ Despite the high incidence of local adverse effects, with regular use during the first week, most patients become tolerant to the irritant effects of the spray.⁶⁴

Product Selection Considerations

The primary advantage in using the nicotine nasal spray is the ability to rapidly titrate therapy to manage withdrawal symptoms. However, because nicotine from the spray more rapidly penetrates the central nervous system, there may be higher likelihood of developing dependence during treatment. The nicotine nasal spray has a dependence potential intermediate between tobacco products and other NRT products. About 15% to 20% of patients continue to use the nicotine nasal spray for longer periods than recommended (6–12 months), and 5% use the spray at higher doses than recommended.⁷ Individuals with chronic nasal disorders (e.g., rhinitis, polyps, sinusitis) or severe reactive airway disease should not use the nicotine nasal spray because of its irritant effects. Exacerbation of asthma has been reported after use of the nicotine nasal spray.⁶⁵

Nicotine Inhaler

The nicotine inhaler consists of a two-piece plastic device designed to deliver nicotine contained in individual cartridges. Each foil-sealed cartridge contains a porous plug with 10 mg

of nicotine and 1 mg of menthol. Menthol is added to reduce the irritant effect of nicotine. Plastic spikes located on the interior of both mouthpiece components pierce the protective foil covering on the cartridge, allowing the release of 4 mg of nicotine vapor following inhalation.

Given that the usual pack-a-day smoker repeats the hand-to-mouth motion up to 200 times per day or 73,000 times each year, it is not surprising that many smokers find they miss the physical manipulation of the cigarette and associated behaviors that accompany smoking. The nicotine inhaler was designed to provide nicotine replacement in a manner similar to smoking while addressing the sensory and ritualistic factors that are important to many patients who smoke.⁶⁶

As a patient puffs on the inhaler, the nicotine vapor is delivered to the mouth and throat, where it is absorbed through the mucosa. Only a small amount (<5% of a dose) of nicotine reaches the lower respiratory tract.⁶⁷ With an intensive inhalation regimen (80 puffs over 20 minutes), about 4 mg of nicotine is delivered, and of that, 2 mg is absorbed.⁶⁸ Peak plasma nicotine concentrations with the inhaler are achieved after approximately 30 minutes of use²⁴ and then slowly decline thereafter (Fig. 85-3). Use of the nicotine inhaler approximately doubles long-term (>6 months) abstinence rates when compared to placebo (Table 85-4).^{7,44}

Dosing

During the initial 3 to 6 weeks of treatment, the patient should use one cartridge every 1 to 2 hours while awake. This should be increased, as needed, to a maximum of 16 cartridges per day. In clinical trials, most successful quitters used an average of 6 to 16 cartridges per day. The manufacturer recommends that each cartridge be depleted of nicotine by frequent continuous puffing over 20 minutes. The recommended duration of treatment is 3 months, after which patients may be weaned from the inhaler by gradual reduction of the daily dose over the following 6 to 12 weeks.

Patient Education

Patients should be instructed to inhale shallowly (as if puffing a pipe) to minimize the likelihood of throat irritation. When used correctly, 100 shallow puffs from the inhaler mouthpiece over 20 minutes approximates 10 puffs from one cigarette over 5 minutes.⁶⁶ The release of delivery of nicotine from the inhaler is temperature dependent and significantly reduced at temperatures below 40°F.^{7,66} In cold conditions, patients should store the inhaler and cartridges in a warm place (e.g., inside pocket).⁷ Conversely, under warmer conditions, more nicotine is released per puff. However, nicotine plasma concentrations achieved using the inhaler in hot climates at maximal doses will not exceed levels normally achieved with smoking.⁶⁶

As with other forms of NRT that are absorbed across the buccal mucosa, the effectiveness of the nicotine inhaler may be reduced by acidic foods and beverages, such as coffee, juices, wine, or soft drinks. Therefore, patients should be instructed not to eat or drink anything (except water) for 15 minutes before or while using the inhaler.

Adverse Reactions

The most common side effects associated with the nicotine inhaler include mouth/throat irritation (40%) and cough (32%).⁷ Most patients rated cough and mouth and throat irritation symptoms as mild, decreasing with continued use. Other

less common side effects are rhinitis, dyspepsia, hiccups, and headache. Adverse reactions necessitating discontinuation of treatment occurred in less than 5% of patients using the inhaler.

Product Selection Considerations

Patients who express a preference for therapy that can be easily titrated to manage withdrawal symptoms or one that mimics the hand-to-mouth ritual of smoking may find the nicotine inhaler to be an appealing option. Patients with underlying bronchospastic conditions should use the nicotine inhaler with caution because the nicotine vapor may be irritating and provoke bronchospasm.

Bupropion SR

Bupropion SR was the first non-nicotine medication FDA-approved for smoking cessation. Clinical trials involving enrolling nearly 10,000 patients over the past 16 years have confirmed its effectiveness as an aid for smoking cessation.⁴⁵ A recent meta-analysis found that bupropion SR treatment doubles long-term (>6 months) abstinence rates when compared to placebo (Table 85-4).⁷

Pharmacokinetics

Animal data suggest the absolute bioavailability of bupropion ranges from 5% to 20%. It undergoes extensive hepatic metabolism to three active metabolites; one of the metabolites, hydroxybupropion, is formed by the cytochrome P450 isoenzyme CYP2B6. Bupropion and its metabolites are eliminated in urine (87%) and feces (10%), with less than 1% being excreted unchanged in the urine. The half-life for bupropion is 21 hours, and its metabolites have a half-life range of 20 to 27 hours; steady-state plasma concentrations are reached within 5 and 8 days, respectively.⁶⁹

Dosing

Treatment with bupropion SR should be initiated while the patient is still smoking because approximately 1 week of treatment is necessary to achieve steady-state blood levels. Patients should set a target quit date that falls within the first 2 weeks of treatment, generally in the second week. The starting dose of bupropion SR is one 150-mg tablet each morning for the first 3 days. If the initial dose is tolerated, the dosage should be increased on the fourth day to the recommended maximum dosage of 300 mg/day (150 mg BID). Therapy should be continued for 7 to 12 weeks after the quit date; however, some patients might benefit from extended treatment. Whether to continue treatment with bupropion SR for periods longer than 12 weeks for smoking cessation must be determined for individual patients.⁶⁹ For patients experiencing side effects with the 300 mg/day regimen, Swan et al suggest that 150 mg/day is better tolerated and exhibits comparable long-term efficacy.⁷⁰ Similarly, Hurt and colleagues found no significant difference in long-term (>6 months) abstinence rates between subjects randomized to 150 mg/day or 300 mg/day.⁷¹

Patient Education

Patients should be instructed to follow the dosing regimen described previously. Advise patients experiencing insomnia to avoid taking the second dose close to bedtime. Inform patients that bupropion might cause dizziness, drowsiness, or reduced alertness, and caution should be exercised when driving or

operating machinery. Because alcohol use might increase the likelihood of seizures, patients should avoid or drink alcohol only in moderation while taking bupropion. Patients who consume alcohol regularly should be advised to talk with a health care provider about their alcohol use before initiating bupropion therapy because abrupt cessation of alcohol use while taking bupropion might increase the risk of seizure. Patients should also be advised not to take Zyban and Wellbutrin or generic bupropion formulations concomitantly to avoid dose-related adverse effects, including seizures.

Adverse Reactions

Adverse effects associated with bupropion therapy include insomnia (35%–40%) and dry mouth (10%)⁷; these usually lessen with continued use. Taking the second daily dose in the early evening, but no sooner than 8 hours after the first dose, might reduce insomnia. Less common side effects include headache, nausea, tremors, and rash. Seizures are a dose-related toxicity associated with bupropion therapy. For this reason, bupropion is contraindicated in patients with underlying seizure disorders and those receiving concurrent therapy with other forms of bupropion (Wellbutrin, Wellbutrin SR, and Wellbutrin XL). Bupropion also is contraindicated in patients with anorexia or bulimia nervosa, patients undergoing abrupt discontinuation of alcohol or sedatives (including benzodiazepines), and patients currently taking monoamine oxidase inhibitors due to the increased potential for seizures in these populations. In clinical trials for smoking cessation, the frequency of seizures with bupropion SR is <0.1% (seven seizures among 8,000 bupropion-treated patients),⁴⁵ which is comparable to the reported incidence of seizures (0.1%) with the sustained-release formulation (Wellbutrin) when used for the treatment of depression.⁷² For this reason, bupropion should be used with extreme caution in patients with a history of seizure, cranial trauma, patients receiving medications known to lower the seizure threshold, and patients with underlying severe hepatic cirrhosis. Animal studies suggest that seizures may be related to the peak plasma concentration of bupropion,⁷³ and as a precautionary measure, the manufacturer recommends that patients space the doses at least 8 hours apart and limit the total daily dose to no more than 300 mg.

Product Selection Considerations

Bupropion SR may be the drug of choice for patients who prefer to take oral medications (an alternative oral option is varenicline, described as follows). Because bupropion SR is simple to use (twice daily oral dosing), this agent may be preferable for patients with regimen compliance concerns (e.g., those unable to consistently use short-acting NRT formulations that require multiple daily doses). Bupropion SR may be particularly beneficial for use in patients with coexisting depression or in individuals with a history of depressive symptoms during a previous quit attempt. Finally, bupropion SR can be used safely in conjunction with NRT, and data suggest that this combination might be slightly more effective than monotherapy with either agent.^{7,74} Disadvantages of bupropion SR include a high prevalence of insomnia and the need to screen patients carefully to prevent the rare complication of seizures.

Varenicline

Varenicline is the most recent agent approved by the FDA for smoking cessation. Data from meta-analyses indicate that

varenicline significantly increases long-term abstinence rates relative to placebo and bupropion SR,⁷ with a pooled odds ratio of 3.1 for varenicline versus placebo for continuous abstinence at 6 months follow-up (Table 85-4). In clinical trials comparing varenicline with bupropion, varenicline was shown to be significantly superior at 52 weeks with an odds ratio of 1.7 (95% CI, 1.3–2.2).⁷⁵

Pharmacokinetics

Varenicline absorption is virtually complete after oral administration, and oral bioavailability is unaffected by food or time-of-day dosing. Once absorbed, varenicline undergoes minimal metabolism, with 92% excreted unchanged in the urine. Renal elimination is primarily through glomerular filtration, along with active tubular secretion, possibly via the organic cation transporter, OCT2.⁷⁶ The half-life is approximately 24 hours, and following administration of multiple oral doses, steady-state conditions are reached within 4 days.⁷⁷

Dosing

Treatment with varenicline should be initiated 1 week before the patient stops smoking. This dosing regimen allows for gradual titration of the dose to minimize treatment-related nausea and insomnia. The recommended dose of varenicline is 1 mg BID (taken as one 1-mg tablet in the morning and one 1-mg tablet in the evening) following a 1-week titration: 0.5 mg daily days 1 to 3, 0.5 mg twice daily days 4 to 7, and 1 mg twice daily weeks 2 to 12. For patients who have successfully quit smoking at the end of 12 weeks, an additional course of 12 weeks may be appropriate to increase the likelihood of long-term abstinence. Varenicline is excreted largely unchanged in the urine, and as such, should be used with caution in patients with severe renal dysfunction (<30 mL/minute). Dosage adjustments may be necessary.

Patient Education

The tablets are to be taken orally, after eating, with a full glass of water. Nausea and insomnia are side effects that are usually temporary. However, if these symptoms persist, patients should notify their provider so dosage reduction can be considered. The typical regimen is a 12-week course of therapy, and patients should be advised to comply with the prescribed dosage for the recommended duration.

Adverse Reactions

Varenicline is generally well tolerated. Common side effects ($\geq 5\%$ and twice the rate observed in placebo-treated patients) include nausea (30%), sleep disturbance (insomnia 18%; abnormal dreams 13%), constipation (8%), flatulence (6%), and vomiting (5%). Per the manufacturer's prescribing information, nausea was the most common adverse event associated with varenicline treatment. Nausea was dose dependent and generally described as mild or moderate and often transient; however, for some patients, it was persistent over several months. Initial dose titration was beneficial in reducing the occurrence of nausea. Approximately 3% of subjects receiving varenicline 1 mg BID discontinued treatment prematurely because of nausea. For patients with intolerable nausea, dose reduction should be considered.⁷⁶

Post marketing, there have been case reports of neuropsychiatric symptoms (behavior changes, agitation, depressed mood,

suicidal ideation or behavior) as well as reports of worsening of pre-existing psychiatric illness among patients being treated with varenicline. These reports are rare in comparison to the total number of patients using the medication, but nonetheless warrant ongoing surveillance. In 2008, the FDA alerted health care providers to advise patients and caregivers that patients should stop taking varenicline and contact their health care provider immediately if agitation, depressed mood, or changes in behavior that are not typical for them are observed, or if the patient develops suicidal ideation or suicidal behavior.⁷⁸ Patients with serious psychiatric illness such as schizophrenia, bipolar disorder, and major depressive disorder did not participate in the premarketing studies of varenicline, and as such, the safety and efficacy of the medications in these populations have not been established.⁷⁶

Product Selection Considerations

Varenicline is a first-line agent for the treatment of tobacco use and dependence.⁷ It offers a convenient oral dosing regimen and a new mechanism of action that might be particularly appealing for patients who have failed quit attempts with other first-line agents (e.g., NRT or bupropion SR). Its use has not been recommended in combination with other agents and therefore is currently limited to monotherapy. As with any of these medications, varenicline should be combined with behavioral counseling in order to maximize chances for a successful, long-term quit attempt. Given its potential for inducing negative neuropsychiatric effects, varenicline might not be the optimal choice for patients with a current or past history of psychiatric illness.

P.J. has tried the nicotine gum and transdermal patch during previous quit attempts. Because he was intolerant to the nicotine gum (it stuck to his dental work), this form of NRT is not appropriate. P.J.'s experience with the transdermal patch suggests he may benefit from a short-acting NRT formulation that allows for active administration and titration of drug as needed to alleviate symptoms of withdrawal. Other first-line therapies include the nicotine nasal spray, inhaler, and lozenge; bupropion SR; or varenicline. P.J. should not use the nicotine nasal spray because he has allergic rhinitis and may be more susceptible to the irritant effects of the spray. In addition, some data suggest that the bioavailability of nicotine is reduced in patients with rhinitis.⁷⁹ Furthermore, the safety and efficacy of the nasal spray in patients with chronic nasal disorders have not been adequately studied. Reasonable choices for P.J. therefore include bupropion SR, nicotine lozenge, nicotine inhaler, or varenicline. Any of these options are reasonable, and the choice of therapy should be dictated by P.J.'s individual preference. Alternatively, it is reasonable to consider combination therapy (see question 10).

Safety of Nicotine Replacement Therapy in Patients With Cardiovascular Disease

9. P.J. would like to try the nicotine inhaler. Is NRT safe for use in patients with cardiovascular disease?

Nicotine activates the sympathetic nervous system leading to an increase in heart rate, blood pressure, and myocardial contractility. Nicotine may also cause coronary artery vasoconstriction.⁸⁰ These known hemodynamic effects of

nicotine have led to doubts about the safety of using NRT in patients with established cardiovascular disease, particularly those with serious arrhythmias, unstable angina, or MI.

Soon after the nicotine patch was approved, anecdotal case reports in the lay press linked NRT (patch and gum) with adverse cardiovascular events (i.e., arrhythmias, MI, stroke). Since then, several randomized, controlled trials have evaluated the safety of NRT in patients with cardiovascular disease, including angiographically documented coronary artery stenosis, MI, stable angina, and previous coronary artery bypass surgery or angioplasty.^{81–83} The results of these trials suggest no significant increase in the incidence of cardiovascular events or mortality among patients receiving the nicotine patch when compared with placebo. However, because these trials specifically excluded patients with unstable angina, serious arrhythmias, and recent MI, the manufacturers of NRT products recommend that these agents be used with caution among patients in the immediate (within 2 weeks) post-MI period, those with serious arrhythmias, and those with unstable angina.⁷ It is notable, however, that NRTs (patch, nasal spray) have been shown to have fewer effects on biomarkers of cardiovascular risk than does smoking,⁸⁴ and smoking cessation has been shown to improve cardiovascular parameters with no negation of these improvements with use of NRT.⁸⁵

Although one methodologically weak case-control study raised questions regarding NRT use in intensive care settings,⁸⁶ NRT use in patients with cardiovascular disease has been the subject of numerous reviews, and it is widely believed by experts in the field that the risks of NRT in this patient population are small in relation to the risks of continued tobacco use.^{44,59,80,87,88} The 2008 Clinical Practice Guideline concludes that there is no evidence of increased cardiovascular risk with these medications.⁷ Although the use of NRT may pose some theoretical risk in a patient like P.J., cigarette smoking is far more hazardous to his health. Cigarettes, unlike NRT, deliver numerous toxins that induce a hypercoagulable state, reduce the oxygen-carrying capacity of hemoglobin, and adversely affect serum lipids. The amount of nicotine that P.J. would receive using the recommended dose of any NRT product will not exceed the amount he previously obtained from his 1.5–2 PPD smoking habit. The clinician should strongly encourage pharmacotherapy during P.J.'s current quit attempt. P.J. is 10 lb overweight; the additional risk imposed by a modest weight gain after smoking cessation likely will not be of clinical significance, compared with that of continued smoking.

Combination Therapy

10. J.B. is a 60-year-old man referred to the pulmonary clinic for further evaluation and management of his chronic obstructive pulmonary disease (COPD). He complains of decreased exercise tolerance and has noted increasing shortness of breath (SOB) with minimal exertion (e.g., while golfing or climbing stairs). He currently uses an albuterol inhaler (90 mcg/puff), 2 puffs Q 4 hr regularly for SOB. His medical history is otherwise unremarkable except for osteoarthritis controlled with acetaminophen 1 g TID. He has smoked approximately 1.5 to 2 PPD for more than 40 years. J.B. indicates he has made several quit attempts over the past year. On the first attempt (quitting “cold turkey”), J.B.

relapsed within 2 days. J.B. was smoke free for nearly 2 weeks on his second quit attempt (using the 4-mg nicotine lozenge), but he found it difficult to adhere to the frequent dosing schedule and relapsed shortly, discontinuing the lozenge. His most recent quit attempt was 6 months ago using varenicline (1 mg BID). After 1 month of abstinence, J.B. self-terminated varenicline (“I thought I didn’t need it anymore”) and relapsed within 2 weeks. On further questioning, J.B. states that he did not enroll in a behavioral counseling program or seek additional assistance (other than pharmacotherapy) during any of his quit attempts. He expresses an interest in smoking cessation but is discouraged by his inability to quit. On physical examination, coarse breath sounds that clear after coughing are noted. His chest x-ray results are normal. Spirometry reveals a forced expiratory volume in 1 second (FEV₁) of 2.8 L (72% of predicted) and a forced vital capacity (FVC) of 4.1 L (81% of predicted). His FEV₁/FVC ratio is 68%. He weighs 76 kg and is 72 in. tall. J.B. is concerned about his worsening pulmonary function and is committed to making another effort to quit. What treatment options are appropriate for J.B.?

Tobacco smoking is the single most important risk factor for the development of COPD, and most patients diagnosed with COPD are current or former smokers.⁸⁹ Medications (e.g., bronchodilators, anti-inflammatory agents) used to treat the symptoms of COPD have not been shown to alter the disease progression.⁸⁹ J.B.'s pulmonary function tests indicate he has stage II (moderate) COPD⁸⁹; given his worsening pulmonary symptoms, it is imperative that he stop smoking as soon as possible. J.B. should be advised that medications for COPD offer only limited symptomatic relief; the most important component of his treatment is smoking cessation.^{89,90} The clinician should commend J.B. for his interest in quitting and help him devise a patient-specific treatment plan.

In addition to monotherapy with any of the first-line agents, the 2008 Clinical Practice Guideline identified selected combinations of medications that can be considered in the initial treatment of tobacco dependence. Medication combinations that significantly increase long-term (>6 months) cessation rates relative to placebo and are recommended as first-line treatments include combination NRT and the nicotine patch in combination with bupropion SR (Table 85-4).⁷

Combination Nicotine Replacement Therapy

Combination NRT involves the use of a long-acting formulation (patch) in combination with a short-acting formulation (gum, lozenge, inhaler, or nasal spray). The long-acting formulation, which delivers relatively constant levels of drug, is used to prevent the onset of severe withdrawal symptoms, whereas the short-acting formulation, which delivers nicotine at a faster rate, is used as needed to control withdrawal symptoms that may occur during potential relapse situations (e.g., after meals, when stressed, or around other smokers). A recent meta-analysis found that the nicotine patch in combination with a short-acting NRT formulation (gum, inhaler, or nasal spray) was significantly more effective than single-agent NRT. The odds of long-term (>6 months) cessation was 1.4 with combination NRT compared to NRT monotherapy (95% CI, 1.1–1.6).⁴⁴

Nicotine Patch and Bupropion SR in Combination

The combination of bupropion SR and NRT has been evaluated in three long-term controlled trials. Patients receiving

combination therapy with bupropion SR and the nicotine patch in standard dosages were significantly more likely to quit than were patients randomized to the nicotine patch alone.⁷ The odds of long-term (>6 months) abstinence were 1.3, with the combination compared to nicotine patch monotherapy (95% CI, 1.0–1.8).⁷

TREATMENT SELECTION

Given the severity of J.B.'s condition and his willingness to quit now, the clinician should initiate treatment as soon as possible. His treatment should consist of pharmacotherapy in conjunction with behavioral counseling and appropriate follow-up.

Pharmacotherapy

The clinician should work with J.B. to select the most appropriate pharmacotherapy. As noted previously, appropriate options would include the various NRT formulations, bupropion SR, varenicline, or an effective combination of first-line agents. The choice of therapy is dictated by considerations such as individual patient preference for a given agent, previous experience with cessation medications, current medical conditions, previous levels of smoking, medication adherence issues, and the patient's out-of-pocket cost. For patients reporting a positive experience with a given medication, retreatment with the same agent or a combination of agents might be appropriate, with consideration given to increasing the dose, frequency, or duration of therapy. For patients reporting a negative experience with pharmacotherapy (e.g., poor adherence, side effects, palatability issues, cost), an alternative agent should be considered. Given J.B.'s previous adherence issues with the nicotine lozenge as monotherapy, it might be preferable to use a long-acting cessation medication such as the nicotine patch, bupropion SR, or varenicline. Combination therapy with the nicotine patch and a short-acting NRT formulation (used as needed) or bupropion SR would also be appropriate.

Behavioral Counseling

Although medications are effective alone in helping patients quit smoking, maximizing patients' chances for a long-term, successful quit attempt requires the use of one or more medications in combination with behavioral counseling. J.B.'s previous 1-month quit attempt highlights the successful impact of varenicline in this patient; however, the relapse is likely attributable to a shortened course of therapy and the absence of a behavioral counseling program. J.B. should be advised that the medications are designed to make patients more comfortable while quitting and that behavioral counseling is needed to address the "habit" of smoking by helping him cope with difficult situations and triggers for relapse. J.B. should be advised to (a) call the tollfree tobacco quitline at 1-800-QUIT NOW, (b) call the tollfree number that accompanies the selected medication (all medications include a free counseling program), (c) enroll in a local group program, (d) join an online quitting program such as Quitnet.com, or (e) request individualized counseling from a health professional with expertise in tobacco cessation. In addition, J.B. should be reminded that compliance with the medication regimen—daily compliance, as well as duration of therapy—will increase his chances of quitting for good. Clinician-delivered counseling might also include a personalized message to further enhance his motivation to quit. For example, the clinician could translate J.B.'s spirometry results

into an effective "lung age" (e.g., the age of the average healthy individual with similar spirometry values). Given J.B.'s height (72 in.) and FEV₁ (2.8 L), his estimated "lung age" is almost 80 years.⁹¹ This educational approach has been found to significantly increase long-term (12-month) quit rates in a recent controlled trial.⁹¹

Complementary Therapies

11. J.B. is worried about "taking more drugs" and asks whether one of the natural herbal products might be better for him than "prescription drugs."

Although many herbal and homeopathic products are available to help people quit smoking, data that support their safety and effectiveness are lacking. Most herbal preparations for smoking cessation contain lobeline, an herbal alkaloid with partial nicotine agonist activity. Although direct-to-consumer advertisements suggest that lobeline-containing preparations are safe and effective, a meta-analysis found no evidence to support the role of lobeline as an effective aid for smoking cessation.⁹² Likewise, nicobrevin (an herbal product not available in the United States that contains quinine, menthyl valerate, camphor, and eucalyptus oil),⁹³ hypnosis,⁹⁴ and acupuncture⁹⁵ have not been found to be effective treatments for smoking cessation.⁷ Furthermore, patients should be cautioned that herbal cigarettes are not safe alternatives because they result in the inhalation of other toxins present in smoke. J.B. should be advised that the efficacy of the herbal therapies are not well established, and use of these agents cannot be recommended at this time.

12. K.M. is a 47-year-old female who has been smoking cigarettes (2 PPD) for almost 30 years. She admits to numerous failed attempts over the past 10 years. K.M. states, "I've tried just about everything to help me quit, but nothing seems to work." K.M. has tried NRT (transdermal patch, lozenge, and inhaler), bupropion SR, varenicline, acupuncture, and hypnotherapy. On questioning, K.M.'s treatment regimens have been appropriate (e.g., correct dosages, duration of therapy). K.M. has enrolled in several worksite cessation classes throughout the years but admits to sporadic attendance due her stressful and unpredictable schedule (she is a paralegal in a busy law firm). Her medical history is significant for TMJ syndrome secondary to nocturnal bruxism (teeth grinding). K.M. is ready to quit now and states, "I want to go to my 30-year high school reunion [4 months from now] as a nonsmoker." What treatment options exist for patients failing first-line therapies?

For most smokers, the quitting process is characterized by a series of quit attempts and subsequent relapses. On average, former smokers report 10.8 quit attempts over a period of 18.6 years before achieving long-term cessation.⁹⁶ Most quit attempts are undertaken without assistance, and approximately 95% of attempts end in relapse.⁷ As emphasized in the 2008 Clinical Practice Guideline, clinicians should approach the treatment of tobacco dependence in a manner similar to the treatment of other chronic medical conditions such as diabetes, asthma, hyperlipidemia, and hypertension. By acknowledging the chronic nature of tobacco dependence, clinicians will appreciate the need for ongoing care (which includes patient education, behavioral counseling, and pharmacotherapy) rather than episodic care (e.g., a single treatment course or

periodic/occasional interventions).⁷ K.M. should be congratulated on her renewed interest in quitting, and the clinician should work with her to design an individualized treatment plan.

Second-Line Agents

CLONIDINE

Clonidine is a centrally acting α_2 -adrenergic agonist that reduces sympathetic outflow from the central nervous system. Clonidine is approved for use as an antihypertensive agent, but it is also effective in reducing the autonomic symptoms of both opioid and alcohol withdrawal. Studies of clonidine for smoking cessation have been inconsistent, but a recent meta-analysis concluded that clonidine treatment doubles long-term (>6 month) abstinence rates relative compared to placebo (Table 85-4).⁷ Dosages for tobacco cessation have ranged from 0.15 to 0.75 mg/day PO and 0.1 to 0.3 mg/day transdermally. The recommended starting dose is 0.1 mg BID or 0.1 mg/day transdermally, increasing by 0.10 mg/day/week as tolerated for up to 10 weeks.⁷ The high incidence of side effects, including dry mouth, sedation, dizziness, and constipation, relegate clonidine as a second-line agent reserved for individuals who have failed or are intolerant of first-line agents.

NORTRIPTYLINE

Nortriptyline, a tricyclic antidepressant, has demonstrated efficacy for smoking cessation, approximately doubling long-term (6-month) abstinence rates compared with placebo (Table 85-4).⁷ The regimen used for treating tobacco dependence is 25 mg/day, increasing gradually to a target dosage of 75 to 100 mg/day, for approximately 12 weeks.⁷ Because the half-life of nortriptyline is prolonged (up to 56 hours), therapy should be initiated at least 10 days before the quit date to allow it to reach steady-state concentrations at the target dose. The side effects most commonly observed with nortriptyline include sedation, dry mouth, blurred vision, urinary retention, lightheadedness, and tremor. This drug should be used with caution in patients with underlying cardiovascular conditions because of the risk of arrhythmias and postural hypotension.

High-Dose Nicotine Replacement Therapy

Plasma levels of nicotine achieved with NRT are generally much lower than those observed during regular smoking.^{64,97} Given this incomplete level of nicotine replacement, standard doses of NRT may be insufficient for some individuals, and in particular, for moderate-to-heavy smokers. Studies using transdermal nicotine in doses up to 44 to 63 mg/day suggest that high-dose NRT is safe.^{98–102} However, trials evaluating higher doses of NRT have yielded conflicting results. Some studies suggest higher doses of NRT may be more effective in heavy smokers,^{100,101,103} whereas others have demonstrated slight but not statistically significant improvements in cessation rates^{104,105} or no difference.^{106,107} When the results of six studies were pooled, the odds ratio for abstinence was 1.2 for high-dose NRT compared to conventional dose NRT (95% CI, 1.0–1.3), suggesting that high-dose NRT therapy may be advantageous in some patients.⁴⁴ This approach should be reserved for patients not able to quit using conventional doses of transdermal NRT.

Extended Use of Medications

In a minority of patients, extended duration medication therapy appears to be safe and effective. Long-term follow-up data from the Lung Health Study have found that approximately 15% of long-term quitters continued nicotine gum therapy with no serious side effects.¹⁰⁸ The 2008 Clinical Practice Guideline states that extended use of medications might be beneficial in individuals who report persistent withdrawal symptoms during treatment, those who have relapsed shortly after medication discontinuation, or those who are interested in long-term therapy.⁷ Clinicians should be aware that many of the medications (bupropion SR, varenicline, nicotine nasal spray and inhaler) are FDA approved for long-term (6-month) use.^{69,76,109,110} Although the goal should be complete abstinence from all nicotine-containing products, continued use of medicinal nicotine is substantially safer than any level of smoking.^{7,111}

K.M. has relapsed following appropriate treatment with several first-line agents, and the clinician should evaluate K.M.'s previous quit attempts, including the dates, methods used (behavioral and pharmacotherapy), and her perceptions of why these methods were ineffective. If K.M. believes a particular medication was more effective than others, it might be reasonable to use the same agent during her next quit attempt.⁷ Alternative approaches include the use of a different medication (including second-line agents) or a combination of medications⁷ (see question 10). Given that K.M. has TMJ, the nicotine gum formulation should not be used.

Drug Interactions With Smoking

13. M.K. is a new patient presenting to the pharmacy with a new prescription for Ortho Tri-Cyclen (norgestimate/ethinyl estradiol). The new patient history form completed by M.K. reveals that she is 32 years old, weighs 65 kg, and is 70 in. tall. She takes no prescription medications but occasionally uses loratadine 10 mg PRN for allergies and ibuprofen 400 mg PRN for dysmenorrhea. She has no significant medical history. Her father has hypertension and suffered an MI last year. Her mother has type 2 diabetes and dyslipidemia. Her social history is significant for tobacco use (1 PPD for 15 years), alcohol (1 glass of wine per night), and caffeine (5–6 cups of coffee daily). Are there any potential interactions with M.K.'s new prescription?

Smoking and Combined Hormonal Contraceptives

One of the most important, but often unrecognized, precautions to consider with oral contraceptive use is the potential interaction between tobacco smoke and estrogens in combination hormonal contraceptives. Estrogens are known to promote coagulation by altering clotting factor levels and increasing platelet aggregation. As described in question 7, substances present in tobacco smoke, including oxidant gases and other products of combustion, induce a hypercoagulable state increasing the risk of acute cardiovascular events. Exposure to both factors (smoking and high levels of estrogen) greatly increases the risk of thromboembolic and thrombotic disorders. Considerable epidemiologic evidence indicates that cigarette smoking substantially increases the risk of adverse cardiovascular events, including stroke, MI, and thromboembolism in women who use oral combination hormonal contraceptive agents.^{112,113} This

risk is age related, in that the absolute risk of death from cardiovascular disease in oral contraceptive users who smoke is 3.3 per 100,000 women ages 15 to 34 years compared with 29.4 per 100,000 women ages 35 to 44 years. To put this in perspective, the corresponding risk of death from cardiovascular disease in *nonsmoking* women who use oral contraceptives is much lower, with a death rate of 0.65 per 100,000 women ages 15 to 34 years and 6.21 per 100,000 women ages 35 to 44 years.¹¹⁴ Because of the increase risk of adverse cardiovascular events, current guidelines from the American College of Obstetricians and Gynecologists (ACOG) and the World Health Organization (WHO) state that combination estrogen-progestin contraceptives should not be used in women who are older than 35 years of age and smoke.^{115,116} These organizations recommend the use of progestin-only contraceptives (oral and injectable formulations) and intrauterine devices in this population.^{115,116}

M.K. is 32 years of age, and despite her heavy smoking status (20 cigarettes per day), oral contraceptive use is not contraindicated at this time. However, the clinician should strongly advise M.K. to quit smoking and assess her readiness to do so. M.K. should be informed that if she continues to smoke while using oral combined hormonal contraceptives, her risk of developing a blood clot, stroke, or heart attack will continue to increase over time. Her family history (father with recent MI and mother with diabetes and hyperlipidemia) suggests that she may be genetically predisposed to cardiovascular disease, and thus, efforts to minimize preventable risk factors should be encouraged to reduce the likelihood that she will develop cardiovascular-related complications in the future.

14. M.K. is not considering quitting smoking at this time and does not want to discontinue her oral contraceptives because she is sexually active and needs a reliable form of birth control. She wonders if the new low-dose birth control pills or other formulations (e.g., patch, vaginal ring) are safer for smokers.

Combined oral contraceptives available in the United States contain estrogen in doses ranging from 20 to 50 mcg of ethinyl estradiol. The results of *in vitro* studies have shown that oral contraceptives containing ≥ 50 mcg of ethinyl estradiol induce greater procoagulatory effects than do preparations containing either 30 mcg or 35 mcg of ethinyl estradiol; formulations containing 20 mcg of ethinyl estradiol appear to have little or no adverse effects on coagulation.^{117,118} Early epidemiologic reports linking oral contraceptive use and severe cardiovascular events were largely observed in women using oral contraceptives containing > 50 mcg of ethinyl estradiol.¹¹⁹ Since then, manufacturers have reduced the dose of estrogen in oral contraceptives such that the majority of preparations available in the United States contain 20 to 35 mcg of ethinyl estradiol.¹²⁰

In 2001, the U.S. Surgeon General stated that lower-dose oral contraceptives may be associated with a reduced risk for coronary heart disease (CHD), compared with higher-dose formulations. Despite this conclusion, the report cautioned that heavy smokers who use oral contraceptives still have a greatly elevated risk for CHD.¹²¹ Consistent with the Surgeon General's cautionary statement, a recent study found that women who smoked > 25 cigarettes per day had a 20-fold higher risk of MI than nonsmoking women who used oral contraceptives.

Interestingly, the elevated risk was independent of the dose of estrogen in the oral contraceptive; women using preparations containing > 50 mcg of estrogen were no more likely to experience an MI than were women using preparations containing < 50 mcg of estrogen. There was only one case involving the use of a preparation containing 20 mcg of estrogen, and thus, the safety of this dose could not be evaluated.¹²²

Serum estrogen levels obtained with the vaginal ring are significantly lower than those achieved with either transdermal or oral combined contraceptive formulations,¹²³ and theoretically, the contraceptive vaginal ring might be a safer formulation for women who smoke. However, because the contraceptive patch and vaginal ring are relatively new, and their safety has not been established among women who smoke, guidelines issued by the ACOG state that the same precautions for the use of oral combined contraceptives should apply to these newer formulations as well.¹¹⁶

M.K.'s prescribed oral contraceptive agent (Ortho Tri-Cyclen) is a triphasic formulation containing 35 mcg of ethinyl estradiol in combination with weekly increasing doses of norgestimate (0.18, 0.215, and 0.25 mg) throughout each monthly cycle. Although some clinicians recommend the use of low-dose (20-mcg) estrogen preparations in smokers, the available evidence suggests that the prescribed regimen poses no additional risk in M.K. However, if M.K. increases her smoking levels to > 25 cigarettes per day, some data suggest that her risk for an MI is increased.¹²² The clinician should inform M.K. that there are currently no studies demonstrating a reduced risk of adverse cardiovascular events in smokers using oral contraceptives containing low doses (e.g., 20 mcg) of estrogen or the newer transdermal and vaginal ring formulations. In the absence of data, only smoking cessation can be advocated to definitively reduce the risk of stroke, MI, and thromboembolism in women who use combined hormonal contraceptives.

Behavioral Counseling

Although M.K. is not considering quitting at this time, it is appropriate for the clinician to apply the 5 R's (Table 85-5) to promote motivation to quit. This counseling should be *relevant* to M.K.'s situation and should highlight the *risks* of continued tobacco use, such as her elevated risk for thromboembolic and thrombotic disorders (associated with continued use of oral contraceptives). M.K. should be asked to think about the *rewards* of quitting and any potential *roadblocks* to quitting. At subsequent encounters, the clinician should sensitively assess M.K.'s tobacco use status and motivation to quit, and offer assistance with quitting when M.K. is ready. If M.K. decides to quit, it would be important to reassess her caffeine intake because caffeine levels have been reported to increase by 56% in patients who quit smoking.³⁰

NONCIGARETTE FORMS OF TOBACCO

Smokeless Tobacco

Classification

15. T.M. is a 29-year-old man who presents to the clinic for evaluation of a painless "white patch" along his lower left gumline, which he noted several weeks ago while flossing his teeth. His social history is significant for the use of smokeless tobacco (consumes

one can of Copenhagen moist snuff every 2–3 days), cigarettes (1 pack per week), and alcohol (one to two beers daily). T.M. reports he has “dipped” for the past 10 years but only recently started smoking “socially” in the evenings when out with friends. He is in otherwise excellent health and takes no medications. What is smokeless tobacco?

Smokeless tobacco is a term used to describe forms of tobacco that are not burned and inhaled but rather held in the mouth to allow absorption of nicotine across the oral (buccal) mucosa. Smokeless tobacco products in the United States are broadly categorized as either chewing tobacco or snuff. Chewing tobacco, which is generally available in loose-leaf, plug, and twist formulations, is chewed or held in the cheek or lower lip. Snuff, which is commonly available as loose particles or sachets resembling mini tea bags, has a much finer consistency and is generally held in the mouth and not chewed. Most snuff formulations in the United States are classified as moist snuff, and users place a small amount (a “pinch”) between the cheek and gum (also known as dipping) and suck on the moist mass of tobacco for 30 minutes or longer. Dry snuff, which is generally sniffed or inhaled through the nostrils, is less commonly used. Newer formulations including “spitless” moist snuff (e.g., Snus), and lozenges containing compressed tobacco powder are being marketed as cigarette substitutes for situations where smoking is prohibited.¹²⁴

Epidemiology

According to the U.S. Department of Health and Human Services, in 2006, an estimated 8.2 million Americans ages 12 years and older (3.3%) had used smokeless tobacco in the past month. Males (6.6%) were more likely than females (0.3%) to be current users.¹²⁵ The prevalence of smokeless tobacco use is highest among individuals between the ages of 18 and 25 and is substantially higher among American Indians, Alaskan Natives, residents of the southern United States, and persons living in rural areas.^{125,126}

Pharmacokinetics

Absorption of nicotine from chewing tobacco and snuff is pH dependent, with more nicotine absorbed across the buccal mucosa under alkaline conditions. Smokeless tobacco manufacturers manipulate the nicotine content and pH of their products by adding alkaline buffering agents and changing the tobacco processing methods to control the delivery of nicotine. For example, a “starter” formulation such as Skoal Bandits has a lower nicotine content and is more acidic (pH = 5.4) to increase tolerability. Once dependence has been established, users generally advance to more alkaline, higher nicotine content products such as Skoal Fine Cut (pH = 7.6) and Copenhagen (pH = 8.6), which are capable of delivering higher levels of nicotine.¹²⁶ As depicted in Figure 85-3, the nicotine from smokeless tobacco is absorbed less rapidly than from cigarette smoke, and the peak levels generally occur after 20 to 30 minutes. Plasma levels of nicotine decline slowly even after removal of tobacco from the mouth because of the gradual release of nicotine from mucous membranes and the possible intestinal absorption of nicotine from swallowed tobacco.¹²⁷ Although the rate of nicotine absorption from cigarettes exceeds that from smokeless tobacco, the extent of absorption does not. In fact, regular smokeless tobacco users experience

comparable exposure to nicotine and are as likely to develop physical dependence as are regular smokers.^{126,128}

16. On examination, a superficial whitish lesion with moderate wrinkling of the tissue adjacent to the mandibular left canine and premolars is noted. In addition, there is localized gingival recession and moderate brown staining of the enamel surfaces. T.M. reports that he routinely places snuff between his lower left cheek and gum. He asks if the lesion might be cancerous and wonders if it is related to his snuff use. What are the health consequences of smokeless tobacco use?

Users of smokeless tobacco are often under the mistaken impression that these formulations are a “safe” alternative to smoking cigarettes because it is not inhaled. In addition to the cosmetic concerns (e.g., halitosis, staining of teeth), the use of smokeless tobacco is associated with numerous adverse health effects,¹²⁸ including the following:

Soft Tissue Alterations/Leukoplakia

Smokeless tobacco users commonly develop an oral soft tissue condition called leukoplakia or “snuff dipper’s lesion.” These white-colored patches or plaques, which are observed in approximately 15% of chewing tobacco users and 60% of snuff users, generally develop at mucosal sites in contact with the tobacco.^{128,129} Of concern is the fact that a small percentage of these lesions may transform into squamous cell carcinomas.^{126,130} Following cessation, the oral leukoplakia appears to regress or completely disappear in the majority of cases.^{130,131}

Periodontal Effects

In addition to the soft tissue alterations noted previously, regular users of smokeless tobacco are at significant risk for the development of gingival recession (complete or partial loss of the tissue covering the root of the tooth), caries, and tooth abrasion. The loss of gingival tissue, observed in up to 27% of smokeless tobacco users, generally occurs at sites constantly exposed to tobacco.¹²⁹ The high sugar content found in many smokeless tobacco products in contact with exposed tooth root tissue might account for the increased incidence of dental caries in smokeless tobacco users.^{126,128,129}

Cancer

The most serious consequence of smokeless tobacco use is an increased risk of developing oral and pharyngeal cancers; the risk appears to be dose related with heavy, long-time users being more likely to develop oral cancer compared with nonusers.¹²⁸ Smokeless tobacco contains 28 known carcinogens, including tobacco-specific nitrosamines, polycyclic aromatic hydrocarbons, and radioactive polonium-210, all of which are in direct contact with mucosal tissues for prolonged periods.¹³²

Although smokeless tobacco products do not yield many of the risks associated with the inhalation of combusted tobacco (e.g., pulmonary disease, lung cancer), these products impose harm and should not be recommended as aids for smoking cessation, particularly because safer, more effective products (i.e., medications labeled for smoking cessation) are available.^{124,128,133}

T.M. is presenting with an oral mucosal lesion commonly observed in smokeless tobacco users. His long-standing history

of snuff use and characteristic white, wrinkled lesion appearing at a site where he habitually places snuff are consistent with leukoplakia. T.M. should be informed that the lesion is most likely caused by his chronic snuff use, and he should be strongly advised to quit. With continued exposure to carcinogens present in smokeless tobacco, there is an increased risk that the leukoplakia will undergo malignant transformation. The presence of an identifiable tobacco-induced oral lesion might serve as a powerful motivator for a quit attempt. If he is able to quit snuff use, the gum tissue will likely normalize over a period of 6 weeks.¹³¹ If the lesion persists, he should be referred for biopsy and further diagnostic evaluation. Finally, T.M. already has evidence of localized gingival recession, which increases his risk for serious periodontal disease and further dental-related complications. These periodontal problems will progress as long as he continues to use smokeless tobacco.

Treatment

17. T.M. relates that his new girlfriend is a “militant” non-smoker who is likely to stop dating him if he does not quit. He is aware that tobacco is “bad for him” and is worried about developing oral cancer. He believes it will not be difficult to quit smoking because he smokes so little. He is more worried about stopping the use of snuff and wants to know if there are any medications to help him quit.

Despite the known health risks and high prevalence of smokeless tobacco use, there are limited evidence-based recommendations to guide clinicians in the treatment use smokeless tobacco use.⁷ In a recent meta-analysis, Ebbert et al.¹³⁴ reviewed the results of 20 randomized, controlled trials evaluating behavioral counseling and pharmacotherapy interventions for smokeless tobacco use, and their findings are summarized as follows.

BEHAVIORAL THERAPY

Behavioral interventions, including the use of self-help materials (written manuals, pamphlets, videotapes), brief (15- to 20-minute) counseling sessions, telephone support, oral examination with feedback, computerized gradual reduction of tobacco, and use of non-tobacco oral substitutes (herbal and mint snuff, chewing gum), have been shown to significantly increase long-term (>6 month) cessation rates (OR 1.6; 95% CI, 1.4–1.8) compared with control interventions. Interventions that appear to be particularly effective in promoting abstinence among smokeless tobacco users compared to control interventions include telephone support (OR 2.1; 95% CI, 1.7–2.6) or oral examination with clinician-delivered feedback (OR 1.9; 95% CI, 1.1–3.2).¹³⁴

NICOTINE REPLACEMENT THERAPY

To date, the nicotine patch and gum are the only NRT formulations that have been evaluated in randomized controlled trials for smokeless tobacco cessation. A pooled analysis of trials evaluating long-term (>6-month) quit rates did not find a statistically significant improvement with the nicotine patch (OR 1.2; 95% CI, 0.9–1.5) or nicotine gum (OR 1.0; 95% CI, 0.6–1.6) when compared to placebo.¹³⁴ Encouraging results from a small open-label trial suggest the nicotine lozenge may

be effective for cessation of smokeless tobacco use, but these findings are preliminary.¹³⁵ Overall, data from controlled trials suggest NRT is not effective in the treatment of smokeless tobacco use, but further studies are necessary.^{7,134}

BUPROPION SR

Bupropion SR for smokeless tobacco cessation has been evaluated in two small randomized, controlled trials with a follow-up duration of at least 6 months. A pooled analysis of these trials failed to find a statistically significant improvement in cessation rates relative to placebo (OR 0.9; 95% CI, 0.5–1.6).¹³⁴

The 2008 Clinical Practice Guideline recommends that smokeless tobacco users receive counseling interventions similar to those recommended for smokers.⁷ Based on the available evidence, it appears that behavioral interventions are effective in the treatment of smokeless tobacco use. Limited data suggest that pharmacotherapy with bupropion SR or NRT is ineffective. However, more research is necessary to determine whether combination pharmacotherapy and counseling will provide improved cessation rates in smokeless tobacco users. T.M. should be provided with behavioral counseling tailored to his stage of readiness to quit—if he is ready to quit in the next 30 days, a treatment plan should be devised. If he is not ready to quit in the next 30 days, motivational counseling should be applied using the 5 R’s (Table 85-5). Because oral examination with patient feedback appears to promote quitting, T.M. should be referred to a dental provider for additional monitoring and follow-up. T.M. has specifically asked about the use of pharmacotherapy as a cessation aid, and although data do not support the use of bupropion SR or NRT because of insufficient evidence of effectiveness, these agents might be considered. T.M. should also be informed that a non-tobacco oral substitute (herbal and mint snuff) in combination with behavioral counseling is also effective.¹³⁴

Cigars

18. R.N., a 40-year-old man who currently smokes 1 PPD of cigarettes, would like to know whether cutting down to one to two cigars per day is a safe alternative to cigarette smoking.

Cigars are conventionally defined as “any roll of tobacco wrapped in leaf tobacco or in any substance containing tobacco.”¹³⁶ The types of cigars available in the United States vary and include *little* cigars (shaped like cigarettes and weighing <1.3 g); *small* cigars or cigarillos (some with a plastic mouthpiece and weighing between 1.2 and 2.5 g); *regular* cigars (usually rolled to a tip on one end and banded; generally weighing between 5 and 17 g); and *premium* cigars (expensive, generally hand rolled, and weighing >22 g).^{136,137} Cigar tobacco is generally air cured and produces smoke with a more alkaline pH, which allows for buccal absorption of nicotine.¹³⁸

Cigar consumption has significantly increased over the past decade.¹³⁹ According to the U.S. Department of Health and Human Services, in 2006, an estimated 13.7 million Americans ages 12 years or older (5.6%) had smoked one or more cigars in the past month. The prevalence of cigar use was highest among individuals ages 18 to 25 years (12.1%); males (9.3%) were more likely than females (2.1%) to be current

cigar smokers.¹²⁵ Some data suggest that the increased consumption is due to a greater prevalence of occasional cigar smoking by previous nonsmokers, particularly among those of higher socioeconomic status.¹³⁶ This trend is likely the result of enhanced marketing and promotional efforts by the tobacco industry; cigar advertisements often depict celebrities or athletes associating cigar smoking with glamour, affluence, and success.^{136,140} Increasing numbers of former cigarette smokers switching to cigars and experimentation among adolescents with cigar smoking may also play a role.¹³⁶

Exactly how much nicotine an individual might obtain from a single cigar is difficult to determine or generalize because cigar weight and nicotine content vary widely from brand to brand and from cigar to cigar. Most cigars range in weight from about 1 to 22 g; a typical cigarette weighs less than 1 g. The nicotine content of ten commercially available cigars studied in 1996 ranged from 10 to 444 mg. In comparison, U.S. cigarettes have a relatively narrow total nicotine content range (mean = 13.5 ± 0.1 mg) per cigarette.¹⁴¹ Relating these data, Henningfield et al. concluded that it is possible for one large cigar to contain as much tobacco as an entire pack of cigarettes and deliver enough nicotine to establish and maintain dependence.¹³⁸

The adverse health effects of cigar smoking have been well described and include an increased risk of cancer of the lung, oral cavity, larynx, esophagus, and pancreas. In addition, cigar smokers who inhale deeply are at increased risk for developing cardiovascular disease and COPD.¹³⁶ Cigarette smokers who switch to smoking only cigars decrease their risk of developing lung cancer, but their risk is markedly higher than if they were to quit smoking altogether.¹³⁶

R.N. should be counseled that switching from cigarette smoking to low-level daily cigar smoking will not reduce his risk for developing a tobacco-related disease. The amount of nicotine delivered by one to two cigars per day is capable of sustaining his dependence on nicotine. In addition, former cigarette smokers are more likely to inhale deeply, which further increases the risk of cancer and cardiovascular and pulmonary disease. The clinician should strongly advise R.N. to quit smoking cigarettes and that switching to cigars is not a safe alternative.

Bidis and Clove Cigarettes

19. K.K. is a 16-year-old male who has been suspended from school after his third offense for smoking on campus. K.K. began experimenting with bidis and kreteks a few years ago and then started smoking cigarettes “socially” with his friends. For the past year, he has been smoking about a half-pack of cigarettes per day. What are bidis and kreteks?

Bidis

Bidis are small, hand-rolled cigarettes imported to the United States primarily from India and other Southeast Asian countries. They consist of finely ground tobacco wrapped in a brown tendu or temburni leaf. Bidis, which are similar in appearance to marijuana cigarettes, are readily available in tobacco shops and ethnic stores and via Internet retailers in a variety of flavors (e.g., chocolate, vanilla, strawberry, cherry, mango, orange) and tend to be more popular among younger smokers.¹⁴² In a

U.S. survey of nearly 64,000 adults (≥18 years) in 15 states, young adults (18–24 years) reported the highest rates of ever (16.5%) and current (1.4%) bidi use.¹⁴³ In 2006, an estimated 2.3% of 12th graders had smoked bidis in the past year.¹²⁵ In a previous survey in Massachusetts, reasons cited by urban adolescents for smoking bidis were that they were better tasting, less expensive, safer, and easier to buy than traditional cigarettes.¹⁴⁴

Although bidis contain less tobacco than standard cigarettes, studies have shown they produce substantial amounts of tar, nicotine, and carbon monoxide.^{145,146} A study using standardized smoking machine testing methods found that bidis deliver three times the amount of carbon monoxide and nicotine and nearly five times the amount of tar found in standard cigarettes.¹⁴⁵ Because of the low combustibility of the tendu leaf wrapper, bidis must be puffed constantly to remain lit. As a result, bidi smokers inhale more frequently and more deeply, thereby markedly increasing the delivery of tar and other toxins.¹⁴⁴ Most bidis do not have a traditional filter tip, which further increases exposure to toxic constituents present in smoke. However, a filter does not confer added safety, as evidenced by a study that found that bidi cigarettes containing a filter actually delivered higher levels of tar, nicotine, and carbon monoxide when compared with unfiltered bidi brands. In this study, the filtered bidi cigarettes contained a small wad of cotton instead of the usual cellulose acetate filter found in American cigarettes. The investigators speculated that the inefficient cotton filter and the slightly larger size of the filtered bidi brands led to the observed higher yields of inhaled toxins.¹⁴⁶

Although by law all packages of bidis sold in the United States must contain the Surgeon General warning about the hazards of smoking, spot-checks in various retail outlets have shown that many of these products are not labeled with health warnings.¹⁴⁷ The absence of federally mandated warning labels may lead to the false impression that these products are safer than other forms of tobacco. However, studies in India have shown that bidi smokers have a comparable or greater risk of developing tobacco-related respiratory, cardiovascular, and neoplastic disease than cigarette smokers. Even low levels of bidi smoking (1–7 bidis/day) are associated with an elevated risk of death (risk ratio estimate, 1.3) compared to nonsmokers. Higher levels of bidi smoking (≤8 bidis/day) incur an even higher risk of death (risk ratio estimate, 2.2).¹⁴⁸

Clove Cigarettes

Clove cigarettes or “kreteks” are cigarettes imported from Indonesia containing a mixture of approximately 60% to 70% tobacco and 30% to 40% minced cloves.¹⁴² Although usage data in adults are not available, in 2006, an estimated 6.2% of 12th graders had smoked kreteks in the past year.¹²⁵ Data from smoking machine tests have found that clove cigarettes deliver twice as much nicotine and carbon monoxide and three times as much tar as conventional cigarettes.¹⁴⁹ In addition to the hazards associated with smoking, clove cigarette use has been implicated in causing rare cases of hemorrhagic pulmonary edema, pneumonia, bronchitis, and hemoptysis.^{150–152} It has been speculated that eugenol, a compound possessing local anesthetic properties and present in large quantities in clove cigarette smoke, might be toxic to pulmonary tissue. The anesthetic effects of eugenol might also place users at an increased

risk of pulmonary aspiration resulting from an impaired gag reflex.¹⁵²

There is concern among some experts that experimentation with noncigarette tobacco (kreteks, bidis, cigars) provides an alternative form of nicotine exposure to individuals who might not otherwise smoke cigarettes. This concern is heightened by recent data that suggests susceptible youth can become addicted to nicotine shortly (within 1–2 days) after smoking initiation.¹⁵³ K.K. began experimenting with bidis and clove cigarettes before he smoked cigarettes socially. It is difficult to know whether K.K.'s previous use of bidis and clove cigarettes led to regular cigarette smoking, but these products can deliver nicotine levels capable of inducing and sustaining dependence.

Water Pipes

20. L.B.C. is a 19-year-old college freshman who resides in an on-campus dormitory. She has been invited by several of her hallmates to “hang-out” at a local hookah bar for the evening. What is hookah, and is this form of tobacco “safe”?

Hookah or water pipe smoking is an ancient method of tobacco use whereby users inhale smoke that is passed through water. Water pipe nomenclature is region specific and includes names such as “hookah” (Africa and Indian subcontinent); “narghile” (Israel, Jordan, Lebanon, Syria); “shisha,” “boory,” or “goza” (Egypt, Saudi Arabia); and “hubble bubble” (many regions).¹⁵⁴

A water pipe is a multicomponent apparatus consisting of a mouthpiece, hose, water bowl, body, and head. Maassel (a mixture of tobacco, dried fruit pulp, honey, and molasses in a variety of flavors) is placed in the head and then covered with perforated aluminum foil. Small pieces of burning charcoal are placed on top of the foil. Following inhalation, heat emanating from the burning charcoal is drawn through the tobacco mixture generating smoke. A vacuum created in the water bowl causes the smoke to “bubble” through the water and collect in the air space above the water. The cooled smoke is then transported to the user through the hose and mouthpiece during inhalation.¹⁵⁴

Hookah bars and cafes, many of which are in close proximity to college campuses, have been emerging throughout the United States,¹⁵⁵ and data suggest this form of tobacco use is becoming increasingly popular among young adults.^{156,157} Recent surveys estimate a 13% to 20% prevalence of current water pipe smoking (use within the previous 30 days) among U.S. college students.^{156,158} Although many water pipe users assume that the water will filter out toxins and believe this form of smoking is less harmful than cigarette smoking,^{156,157,159} data are lacking to substantiate this belief. Indeed, studies have found that water pipe smokers who inhale are exposed to nicotine and other toxins in levels that are comparable to or exceed those found in cigarette smoke,^{160–162} suggesting that water pipe smoking is not “safe.” Furthermore, preliminary data suggest that water pipe smokers are at risk for developing dependence and other adverse health-related conditions associated with smoking.¹⁵⁴

Definition

Anemia is a reduction in red cell mass. It often is described as a decrease in the number of red blood cells (RBC) per cubic millimeter (mm³) or as a decrease in the hemoglobin concentration in blood to a level below the normal physiologic requirement for adequate tissue oxygenation. The term *anemia* is not a diagnosis, but rather an objective sign of a disease. Diagnostic terminology for anemia requires the inclusion of the pathogenesis (e.g., megaloblastic anemia secondary to folate deficiency, microcytic anemia secondary to iron deficiency). An exact diagnosis is important to the understanding of the problem and to implement specific therapy to correct the anemia.

Pathophysiology

Anemia is a symptom of many pathologic conditions. It is associated with nutritional deficiencies and acute and chronic

diseases; it also can be drug induced. Anemia can be caused by decreased red cell production, increased red cell destruction, or increased red cell loss. If the anemia is caused by decreased red cell production, it may be the result of disturbances in stem cell proliferation or differentiation. Anemias caused by increased red cell destruction can be secondary to hemolysis, whereas increased red cell loss may be caused by acute or chronic bleeding. Anemias associated with acute blood loss, those that are iron related, and those caused by chronic disease comprise most of all anemias.¹ Classifications of anemias according to pathophysiologic and morphologic characteristics are shown in Table 86-1.

Normally, RBC mass is maintained by feedback mechanisms that regulate levels of erythropoietin (EPO), a hormone that stimulates proliferation and differentiation of erythroid precursors in the bone marrow. Two types of erythroid precursors reside in the bone marrow: the burst-forming unit,

Table 86-1 Classifications of Anemia**Pathophysiologic (Classifies Anemias Based on Pathophysiologic Presentation)****Blood Loss**

Acute: trauma, ulcer, hemorrhoids

Chronic: ulcer, vaginal bleeding, aspirin ingestion

Inadequate Red Blood Cell ProductionNutritional deficiency: B₁₂, folic acid, iron

Erythroblast deficiency: bone marrow failure (aplastic anemia, irradiation, chemotherapy, folic acid antagonists) or bone marrow infiltration (leukemia, lymphoma, myeloma, metastatic solid tumors, myelofibrosis)

Endocrine deficiency: pituitary, adrenal, thyroid, testicular

Chronic disease: renal, liver, infection, granulomatous, collagen vascular

Excessive Red Blood Cell Destruction

Intrinsic factors: hereditary (G6PD), abnormal hemoglobin synthesis

Extrinsic factors: autoimmune reactions, drug reactions, infection (endotoxin)

Morphologic (Classifies Anemias by Red Blood Cell Size [Microcytic, Normocytic, Macrocytic] and Hemoglobin Content [Hypochromic, Normochromic, Hyperchromic])**Macrocytic**

Defective maturation with decreased production

Megaloblastic: pernicious (vitamin B₁₂ deficiency), folic acid deficiency**Normochromic, normocytic**

Recent blood loss

Hemolysis

Chronic disease

Renal failure

Autoimmune

Endocrine

Microcytic, hyperchromic

Iron deficiency

Genetic abnormalities: sickle cell, thalassemia

G6PD, glucose-6-phosphate dehydrogenase.

erythroid (BFUe) and colony-forming unit, erythroid (CFUe). The BFUe is the earliest progenitor, which eventually develops into a CFUe. BFUe is moderately sensitive to EPO and is under the influence of other cytokines (e.g., interleukin [IL]-3, granulocyte-macrophage colony-stimulating factor [GM-CSF]). In contrast, CFUe is highly sensitive to EPO and differentiates into erythroblasts and reticulocytes. Of EPO, 90% is produced in the kidney; liver synthesis accounts for the remaining 10%. Reduced oxygen-carrying capacity is sensed by renal peritubular cells, and this stimulates release of EPO into the bloodstream. Patients with chronic anemia may have a blunted and inadequate response for the degree of anemia present.

Detection**Signs and Symptoms**

Signs and symptoms of anemia vary with the degree of RBC reduction as well as with the time interval over which it develops. Onset of anemia can be acute or can develop slowly, resulting in tissue hypoxia caused by the decreased oxygen-carrying capacity of the reduced red cell mass. As a result, perfusion

to nonvital tissues (e.g., skin, mucous membranes, extremities) is decreased to sustain tissue perfusion of vital organs (e.g., brain, heart, kidneys). Slowly developing anemias can be asymptomatic initially or include symptoms such as slight exertional dyspnea, increased angina, fatigue, or malaise. Uncorrected tissue hypoxia can lead to a number of complications in quality of life, cognition, and respiratory and gastrointestinal (GI) systems. Changes in the blood hemoglobin concentration also lead to changes in the kidney tissue oxygen tension, as discussed previously.^{1,2}

In severe anemia, a hemoglobin (Hgb) <8 mg/dL, heart rate, and stroke volume often increase in an attempt to improve oxygen delivery to tissues. These changes in heart rate and stroke volume can result in systolic murmurs, angina pectoris, high output congestive heart failure, pulmonary congestion, ascites, and edema. Thus, anemia is generally not well tolerated in patients with cardiac disease. Skin and mucous membrane pallor, jaundice, smooth or beefy tongue, cheilosis, and spoon-shaped nails (koilonychia) also may be associated with severe anemia of different causes of anemia.

History

A thorough history and physical examination are essential because of the complexity of the pathologic conditions associated with anemia. A time line, which begins with the onset of symptoms (and surrounding events) and extends to current status, is important. Because longstanding anemias can indicate hereditary disorders, the family history should be noted. Past Hgb or hematocrit (Hct) determinations, transfusion history, as well as occupational, environmental, and social histories may be valuable. Finally, a medication history can help eliminate drug reactions or interactions as the cause of the anemia.

Physical Examination

On physical examination of a patient with anemia, pallor is most easily observed in the conjunctiva, mucous membranes, nail beds, and palmar creases of the hand. In addition, postural hypotension and tachycardia can be seen when hypovolemia (acute blood loss) is the primary cause of anemia. Patients with B₁₂ deficiency may exhibit neurologic findings, which include changes in deep tendon reflexes, ataxia, and loss of vibration and position sense; all are consistent with nerve fiber demyelination. Patients with anemia from hemolysis may be slightly jaundiced from bilirubin release. Manifestations of hemorrhage can include petechiae, ecchymoses, hematomas, epistaxis, bleeding gums, and blood in the urine or the stool.

Laboratory Evaluation

Although anemia may be suspected from the history and physical examination, a full laboratory evaluation is necessary to confirm the diagnosis, establish its severity, and determine its cause. A list of the routine laboratory evaluations used in the workup for anemia is found in Table 86-2. The cornerstone of this evaluation is the complete blood count (CBC). Normal hematologic values can be found in Table 86-3. Male patients have higher hematocrit (Hct) values than do female patients. The Hct is increased in individuals living at altitudes above 4,000 feet in response to the diminished oxygen content of the atmosphere and blood.

The morphologic appearance of the RBC provides useful information about the nature of the anemia. Microscopic

evaluation of the peripheral blood smear can detect the presence of macrocytic (large) RBC, which usually are present when anemia results from a vitamin B₁₂ or folic acid deficiency; microcytic (small) RBC usually are associated with iron deficiency anemia. Acute blood loss generally is associated with normocytic cells.

Together with the information gained from the history and physical examination, the routine laboratory evaluation can provide sufficient information to distinguish between the most common forms of anemia (Fig. 86-1). If still not identified after routine evaluation, problems such as autoimmune disease, collagen vascular disease, chronic infection, endocrine disorders, or drug-induced destruction may be causing the anemia. When uncertainty exists or an abnormal peripheral blood smear is noted, a bone marrow aspiration with biopsy is indicated.

There are many causes of anemia. This chapter is limited to the most common anemias managed with drugs. Hemolytic anemias are covered in Chapter 87, Drug-Induced Blood Disorders. Before proceeding, the reader should review the basic hematologic laboratory tests used to evaluate and monitor anemia (see Chapter 2: Interpretation of Clinical Laboratory Tests).

IRON DEFICIENCY ANEMIA

Iron deficiency is a state of negative iron balance in which the daily iron intake and stores are unable to meet the RBC and other body tissue needs. The body contains approximately 3.5 g of iron, of which 2.5 g are found in Hgb. A significant amount of iron is stored as ferritin or aggregated ferritin (hemosiderin) in the reticuloendothelial cells of the liver, spleen, and bone marrow and by hepatocytes. Ferritin circulates at concentrations that reflect total iron body stores. Only a small fraction of iron is found in plasma (100 to 150 mcg/dL), and most is bound to transferrin, the transport protein.

Despite the continuing turnover of RBC, iron stores are well preserved because the iron is recovered and reutilized in new erythrocytes. Only about 0.5 to 1 mg/day of iron is lost from urine, sweat, and the sloughing of intestinal mucosal cells that contain ferritin in men and in non-menstruating women. Menstruating women lose approximately 0.6% to 2.5% more iron per day.³ Pregnancy and lactation are other common sources of iron loss.

Individuals with normal iron stores absorb roughly 10% of ingested dietary iron. The average American diet contains 6 mg of elemental iron/1,000 Kcal. Thus, the average daily intake ranges between 10 and 12 mg, enough to replace the 1 mg lost daily (based on 10% absorption). For menstruating, pregnant, or lactating women, however, the daily iron intake requirement may be as high as 20 mg.

Iron, which is absorbed from the duodenum and upper jejunum by an active transport mechanism, is enhanced in the presence of an acidic gastric environment. Dietary iron, which is primarily in the ferric state, is converted to the more readily absorbed ferrous form in the acid environment of the stomach. It is the ferrous form that binds to transferrin for its journey to the bone marrow, where it is incorporated into the Hgb of mature erythrocytes.

Gastrointestinal absorption of iron is increased from the usual 10% to as much as three- to fivefold in iron deficiency states or when erythropoiesis occurs at a more rapid rate.³ Animal sources of iron, heme iron, are better absorbed than plant sources, nonheme iron. A gastrectomy or vagotomy may decrease the conversion of the ferric form of iron to the ferrous state, thereby diminishing iron absorption. In addition, certain foods and drugs can complex with iron, decreasing its absorption.

Anemia caused by iron deficiency is the most common nutritional deficiency worldwide. Although iron deficiency anemia has many causes (Table 86-4), blood loss is considered one of the more common. Each milliliter of whole blood contains 0.5 mg of iron, whereas each milliliter of packed RBC contains 1 mg of iron. Common causes of chronic blood loss include peptic ulcer disease, hemorrhoids, ingestion of GI irritants, menstruation, multiple pregnancies, and multiple blood donations.

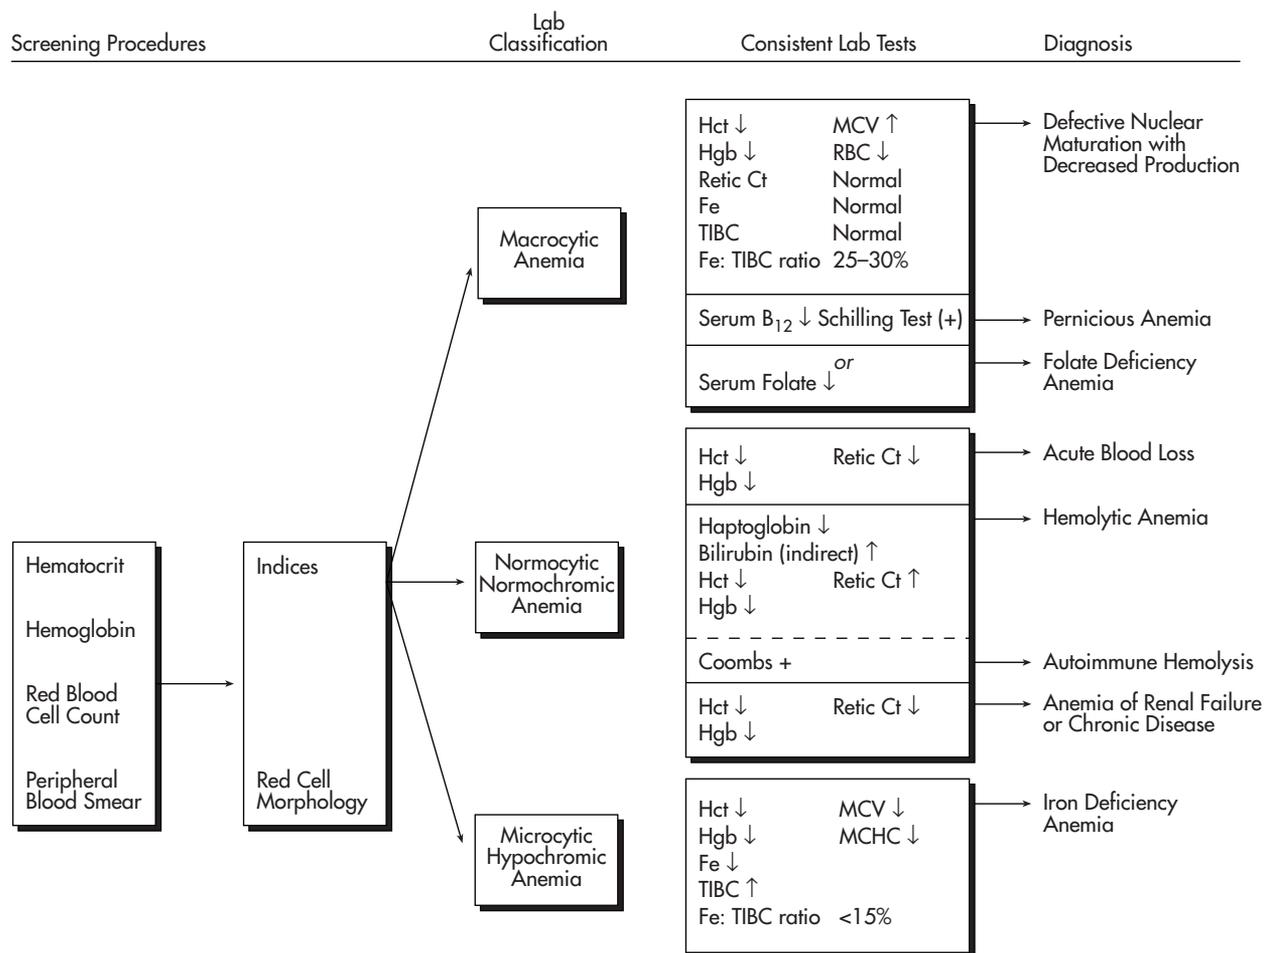

FIGURE 86-1 Laboratory diagnosis of anemia.

Dietary reference intakes (DRI) for iron are listed in Table 86-5. The increased amounts of iron required by pregnant or lactating women are difficult to obtain through diet alone; thus, oral iron supplementation generally is necessary. Although maternal iron usually provides term infants with sufficient stored iron for the first 6 months, infants 6 months to 3 years of age experience rapid growth and a threefold increase in blood volume, which can increase the risk of iron deficiency. Premature infants have reduced iron stores and thus require replacement therapy. Supplementation of 10 to 15 mg/day of iron may be required for up to the first year of life. Maintenance iron

therapy for healthy older infants and children is roughly 1 to 2 mg/kg/day (not to exceed 20 mg/day). If iron deficiency develops in the pediatric patient, 3 to 6 mg/kg/day of elemental iron should be administered in two to three divided doses.⁴

Predisposing Factors

1. D.G., a 35-year-old woman, is seen in the clinic. Her chief complaints include weakness, dizziness, and epigastric pain. She has a 5-year history of peptic ulcer disease, a 10-year history of heavy menstrual bleeding, and a 20-year history of chronic headaches. She has two children who are 1 and 3 years of age. D.G. is currently taking tetracycline (250 mg BID) for acne, ibuprofen

| Menstruating women | 18 |
| Pregnant women | 27 |
| Lactating women | 9 |
| Vegetarians | 16 |

(400 mg PRN) headaches, and daily esomeprazole (40 mg). A review of her systems is positive for decreased exercise tolerance. Physical examination reveals a pale, lethargic, white woman appearing older than her stated age. Her vital signs are within normal limits; her heart rate is regular at 100 beats/min. Her examination is notable for pale nail beds and splenomegaly.

Significant laboratory results include the following: Hgb, 8 g/dL (normal, 14 to 18); Hct, 27% (normal, 40% to 44%); platelet count, 800,000/mm³ (normal, 130,000 to 400,000); reticulocyte count, 0.2% (normal, 0.5% to 1.5%); mean corpuscular volume (MCV), 75 μm³ (normal, 80 to 94); mean corpuscular hemoglobin (MCH), 23 pg (normal, 27 to 31); mean corpuscular hemoglobin concentration (MCHC), 30% (normal, 33% to 37%); serum iron, 40 μg/dL (normal, 50 to 160); serum ferritin, 9 ng/mL (normal, 15 to 200); total iron-binding capacity (TIBC), 450 g/dL (normal, 250 to 400); and 4+ guaiac stools (normal, negative).

Iron deficiency is determined to be the cause of D.G.'s anemia. An upper GI series with a small bowel follow-through are planned to evaluate her persistent epigastric pain. What factors predispose D.G. to iron deficiency anemia?

[SI units: Hgb, 80 g/L; Hct, 0.27; MCV, 75 fL; MCH, 23 pg; MCHC, 0.3; iron, 7.16 μmol/L; ferritin, 9 μg/L; TIBC, 80.87 μmol/L; platelets, 800 × 10⁹/L; reticulocyte, 0.002]

Several factors predispose D.G. to iron deficiency anemia. Her history of heavy menstrual bleeding and the 4+ stool guaiac indicate menstrual and GI sources of blood loss. The GI blood loss may be secondary to D.G.'s chronic use of nonsteroidal anti-inflammatory drugs, recurrent peptic ulcer disease, or both.

Many women of childbearing age have a borderline iron deficiency that becomes more evident during pregnancy because of the increased iron requirements.⁵ D.G. has given birth to two children. Therefore, her iron stores have been repeatedly taxed in recent years. In addition, absorption of dietary iron may be compromised by her use of proton pump inhibitors and tetracycline (see Question 6).

Signs, Symptoms, and Laboratory Tests

2. What subjective or objective signs, symptoms, and laboratory tests are typical of iron deficiency in D.G.?

D.G.'s constitutional symptoms of weakness and dizziness could be a result of her severe anemia. Generally, until the anemia is severe, such symptoms occur with equal frequency in the nonanemic population. The most important signs and symptoms of iron deficiency anemia are related to the cardiovascular system and are a reflection of the imbalance between the ongoing demands for oxygen against a diminishing oxygen supply. D.G.'s increased heart rate, decreased exercise tolerance, and pale appearance are consistent with tissue anoxia and the cardiovascular response that may be seen in iron deficiency anemia.

D.G.'s iron deficiency has advanced to symptomatic anemia. In patients who are not yet symptomatic, however, depletion of iron stores can be detected by measuring ferritin, the iron storage compound. Although ferritin is primarily an intracellular protein, serum concentrations of ferritin correlate closely with iron stores with only a few exceptions.^{6,7} Ferritin, an acute-phase reactant, is generally found in higher levels in patients with inflammatory disorders and liver disease.⁸ A

serum ferritin level <12 ng/mL is consistent with iron deficiency. An increased TIBC also can reflect depletion of storage iron, but it is less sensitive than serum ferritin. Thus, in iron deficiency, the serum ferritin concentration is low, whereas the TIBC is usually high; both of these parameters can be detected before the clinical manifestations of anemia are apparent. These abnormalities persist and worsen as the patient progresses to anemia as illustrated by D.G.'s laboratory values. If the TIBC is low or normal, rather than high, in association with a low serum ferritin, other causes of anemia (e.g., malignancy, infections, or inflammatory disorders) should be considered. In these situations, further documentation (e.g., bone marrow examination) is necessary to determine the cause of the anemia.^{9,10}

D.G.'s low serum iron, low serum ferritin, and elevated TIBC are typical of the laboratory findings associated with iron deficiency anemia. Serum transferrin receptor levels, which reflect the amount of RBC precursors available for active proliferation, are increased in iron deficiency.¹¹

After the iron in the storage compartment is depleted, heme and hemoglobin synthesis are decreased. In severe iron deficiency, the RBC become hypochromic (low MCHC) and microcytic (low MCV). Usually, the RBC indices do not become abnormal until the Hgb concentration falls to <12 g/dL in male patients or <10 g/dL in female patients. D.G.'s corpuscular indices indicate that her anemia is hypochromic and microcytic.

About 10% of patients who are iron deficient experience neutropenia and either thrombocytopenia or thrombocytosis. Thrombocytosis can occur in 50% to 75% of patients with hypochromic anemia secondary to chronic blood loss. The thrombocytosis (e.g., 800,000 platelets) in D.G. returns to normal after adequate treatment with iron. The reticulocyte count provides an estimate of effective red cell production and is usually normal or low in iron deficiency anemia. D.G. has a reticulocyte count of 0.2% (normal, 0.5 to 1.5%), which also is compatible with iron deficiency anemia.

In the workup of a microcytic, hypochromic anemia, the stool should be examined for occult blood. D.G. has a 4+ stool guaiac, which suggests blood loss via the GI tract. Further diagnostic evaluations (e.g., endoscopy, GI films) are necessary to determine the underlying problem.

In summary, D.G.'s signs, symptoms, and laboratory findings all support the diagnosis of an iron deficiency anemia.

Iron Therapy

Oral Iron Dosing

3. How should D.G.'s iron deficiency be managed? What dose of iron should be given to treat D.G.'s iron deficiency anemia and for how long?

The primary treatment for D.G. should be directed toward control of the underlying causes of anemia, which in this case are many. D.G.'s iron stores are low because of GI blood loss, multiple childbirths, heavy menstrual flow, decreased dietary iron absorption, and perhaps, an inadequate diet. Therefore, the cause of her GI blood loss should be corrected, her dietary intake should be analyzed and modified, and supplemental iron should be prescribed to replenish her stores and correct the anemia.

The usual adult dose of ferrous sulfate is 325 mg (one tablet) administered three times daily, between meals. If no iron is being lost through bleeding, the required daily dose of elemental iron can be calculated using a formula that assumes that 0.25 g/dL/day is the maximal rate of hemoglobin regeneration.

$$\begin{aligned} \text{Elemental iron (mg/day)} &= 0.25 \text{ g Hgb}/100 \text{ mL blood/day} \\ &\quad (5,000 \text{ mL blood})(3.4 \text{ mg Fe}/1 \text{ g Hgb}) \\ &= 40 \text{ mg Fe/day}/20\% \text{ absorption (approximate absorption} \\ &\quad \text{rate in iron-deficient states)} \\ &= 200 \text{ mg Fe/day} \\ &= 1,000 \text{ mg ferrous sulfate/day (ferrous sulfate} \\ &\quad \text{contains 20\% elemental iron)} \\ &= 325 \text{ mg TID ferrous sulfate} \end{aligned}$$

Product Selection

4. What are the differences between iron products? Which is the product of choice?

The ferrous form of iron is absorbed three times more readily than the ferric form. Although ferrous sulfate, ferrous gluconate, and ferrous fumarate are absorbed almost equally, each contains a different amount of elemental iron.¹² Table 86-6 compares the iron content of several oral iron preparations to assist in making appropriate treatment choices for patients.

PRODUCT FORMULATION

Product formulation is of considerable importance in product selection. Some believe that the more expensive, sustained-release (SR) iron preparations are inherently better. SR preparations fall into three groups: (a) those claimed to increase GI tolerance or decrease side effects, (b) those formulated to increase bioavailability, and (c) those with adjuvants claimed to enhance absorption. Because these products can be given once daily, increased compliance is an additional claim.

Anecdotal claims that SR iron preparations cause fewer GI side effects have not been substantiated by controlled studies. In fact, these products transport iron past the duodenum and proximal jejunum, thereby reducing the absorption of iron.¹³ Because poor absorption and poor hematologic responses might occur with ferrous sulfate SR capsules, they should not be used for initial treatment.

Adjuvants are incorporated into many iron preparations in an attempt to enhance absorption or decrease side effects. Several products contain ascorbic acid (vitamin C), which maintains iron in the ferrous state. Doses up to 1 g increase iron absorption by only 10%; however, smaller doses of vitamin C (e.g., 100 mg) do not significantly alter iron absorption.¹⁴

Table 86-6 Comparisons of Iron Preparations

| Preparation | Dose (mg) | Fe ⁺⁺ Content (mg) | Fe (%) |
|-------------------------|-----------|-------------------------------|--------|
| Ferrous sulfate | 325 | 65 | 20 |
| Ferrous fumarate | 324 | 106 | 33 |
| Ferrous gluconate | 300 | 34 | 11 |
| Feosol tablets | 200 | 65 | 33 |
| Slow Fe (time released) | 160 | 50 | 31 |

Table 86-7 Combination Iron Products

| Drug | DOSS (mg) | Vitamin C (mg) | Fe ⁺⁺ Content (mg) |
|---------------------------|-----------|----------------|-------------------------------|
| Ferro-Grad 500 (Filmtabs) | 0 | 500 | 105 |
| Vitron C | 0 | 125 | 66 |
| Ferro DSS/Ferro-Sequel | 100 | 0 | 50 |

DOSS, dioctyl sodium sulfosuccinate; docusate sodium; Fe, iron.

Table 86-7 lists a number of combination products that contain a stool softener or vitamin C.

Stool softeners are added to iron preparations to decrease the side effect of constipation. Generally, these combinations contain suboptimal doses of stool softener and are unwarranted. If constipation does develop, appropriate doses of stool softeners should be taken.

In summary, D.G. should take the least expensive iron preparation containing ferrous sulfate, gluconate, or fumarate. In general, generic preparations of iron salts without adjuvant agents provide the best value.

Goals of Therapy

5. What are the goals of iron therapy? How should D.G. be monitored?

The goals of iron therapy are to normalize the Hgb and Hct concentrations and to replete iron stores. Initially, if the doses of iron are adequate, the reticulocyte count will begin to increase by the third to fourth day and peak by the seventh to tenth day of therapy. By the end of the second week of iron therapy, the reticulocyte count will fall back to normal. The Hgb response is a convenient index to monitor in outpatients. Hematologic response is usually seen in 2 to 3 weeks with a 1 g/dL increase in hemoglobin and a 6% increase in the hematocrit. D.G.'s anemia can be expected to resolve in 1 to 2 months; however, iron therapy should be continued for 3 to 6 months after the hemoglobin is normalized to replete iron stores.^{14,15} Therapy duration is related to the absorption pattern of iron. During the first month of therapy, as much as 35 mg of elemental iron is absorbed from the daily dose. With time, the percentage of iron absorbed from the dose decreases, and by the third month of therapy, only 5 to 10 mg of elemental iron is absorbed.

Patient Information

6. What kind of information should be provided to D.G. when dispensing oral iron? What can be done if she experiences intolerable GI symptoms (e.g., nausea, epigastric pain)?

Iron should be dispensed in a childproof container, and D.G. should be told to store it in a safe place away from children. Accidental ingestion of even small amounts (three to four tablets) of oral iron can cause serious consequences in small children¹⁶ (see Chapter 5, Managing Acute Drug Toxicity). D.G. should be told that oral iron therapy produces dark stools. She should try to take her iron on an empty stomach because food, especially dairy products, decreases the absorption by 40% to 50%.^{17,18}

Gastric side effects, which occur in 5% to 20% of patients, include nausea, epigastric pain, constipation, abdominal cramps, and diarrhea. Constipation does not appear to be dose

related, but side effects (e.g., nausea and epigastric pain) occur more frequently as the quantity of soluble elemental iron in contact with the stomach and duodenum increases.⁴ To minimize gastric intolerance, oral iron therapy can be initiated with a single tablet of ferrous sulfate 325 mg/day; the dose is increased by increments of one tablet per day every 2 to 3 days until the full therapeutic dose of ferrous sulfate, 325 mg three times daily, can be administered.²

D.G. also should be educated about potential drug interactions that can occur with iron therapy. Currently, she is taking a proton pump inhibitor, which is thought to inhibit serum iron absorption by increasing the pH of the stomach and decreasing the solubility of ferrous salts.^{19,20} In addition, antacids can increase stomach pH and certain anions (carbonate and hydroxide) also are thought to form insoluble complexes when combined with iron. Although it is unclear whether this has an impact on therapy, one study showed a therapeutic dose of liquid antacid (containing aluminum hydroxide and magnesium hydroxide) does not significantly alter absorption of iron in adults who are mildly deficient in iron.²¹ Although the clinical significance of this is undetermined, D.G. should be advised to take her iron at least 1 hour before or 3 hours after the proton pump inhibitor dose.

D.G. also is taking tetracycline for the treatment of acne. Because the absorptions of both iron and tetracycline are decreased when administered concomitantly, the iron should be taken 3 hours before or 2 hours after the tetracycline dose as well.²²

Parenteral Iron Therapy

INDICATIONS

7. When would parenteral iron therapy be indicated for D.G.?

Several indications exist for parenteral iron administration. Failure to respond to oral iron therapy would prompt a re-evaluation of D.G. Causes of oral therapy failure can include nonadherence, misdiagnosis (e.g., inflammation), malabsorption (e.g., sprue, radiation enteritis, duodenal or upper small intestine resection), and continuing blood loss equal to or greater than the rate of RBC production. Malabsorption can be evaluated by measuring iron levels every 30 minutes for 2 hours after the administration of 50 mg of ferrous sulfate. If her plasma iron levels increase by >50%, absorption is adequate. Besides failure to respond to oral therapy as one indication for parenteral iron administration, other indications include intolerance to oral therapy, required antacid therapy, or significant blood loss in patients refusing transfusion. All can warrant injectable iron therapy.³ In D.G.'s case, if malabsorption is documented, she would be a candidate for injectable iron.

PREFERRED ROUTE

8. What is the preferred route of parenteral iron administration?

Iron can be given parenterally in the form of ferric gluconate (Ferrlecit), iron dextran (INFeD and Dexferrum), and iron sucrose (Venofer). Iron dextran, the oldest of the parenteral iron agents, is U.S. Food and Drug Administration (FDA)-approved for the treatment of iron deficiency when oral supplementation is impossible or ineffective. In this particular formulation, iron is a complex of ferric hydroxide and dextran. Iron dextran can

be administered undiluted intramuscularly or by very slow intravenous (IV) injection. Although not included in the labeling approved by the FDA, iron-dextran injection is commonly diluted in 250 to 1,000 mL 0.9% NaCl and administered by IV infusion. IV administration is preferred to intramuscular (IM) administration when muscle mass available for an IM injection is limited; when absorption from the muscle is impaired (e.g., stasis, edema); when uncontrolled bleeding is a risk (e.g., secondary to hemophilia, thrombocytopenia, anticoagulation therapy); and when large doses are indicated for therapy.

In a few instances, IM iron dextran is the preferred treatment (e.g., patients with limited IV access). In these cases, undiluted drug should be administered using a Z-track technique to avoid staining the skin. (The skin should be pulled laterally before injection; then the drug is injected and the skin is released to avoid leakage of dextran into the subcutaneous tissue.) IM iron dextran is absorbed in two phases. In the first 72 hours, 60% of the dose is absorbed, whereas the remaining drug is absorbed over weeks to months.²³

Infusion rates of undiluted IV iron dextran should not exceed 50 mg (i.e., 1 mL) per minute. The upper limit of each daily dose is based on the patient's weight and should not be >100 mg/day. Although the data are limited, total dose iron-dextran infusion is given in clinical practice and has proved to be effective and convenient.²⁴ Infusions generally are given over 1 to 6 hours to minimize local pain and phlebitis.⁴ The total dose method of administration can be associated with a higher prevalence of fever, malaise, flushing, and myalgias.

Ferric gluconate and iron sucrose are parenteral iron formulations, which are FDA approved for the treatment of iron deficiency anemia in patients undergoing chronic hemodialysis and receiving supplemental EPO.⁴ Ferric gluconate can be administered undiluted as a slow IV injection (rate not to exceed 12.5 mg/minute) or as an IV infusion (125 mg ferric gluconate in 100 mL 0.9% NaCl over 1 hour). Likewise, iron sucrose can be administered undiluted as a slow IV injection (rate not to exceed 20 mg/minute) or as an IV infusion (dilute in a maximum of 100 mL 0.9% NaCl and infuse at a rate of 100 mg over 15 minute). Iron requirements in these patients typically exceed 1 to 2 g and, therefore, multiple doses of ferric gluconate and iron sucrose are needed to achieve the total dose of iron.

DOSAGE CALCULATION

9. How is a total dose of iron dextran for IV infusion that would be needed to achieve a normal hemoglobin value for D.G. and to replenish her iron stores calculated? How quickly should she respond?

The total dose of iron dextran to be administered can be determined using the following equation:

$$\text{Iron (mg)} = [\text{Weight (pounds)} \times 0.3] \\ [100 - \{100(\text{Hgb})/14.8\}]$$

where *Hgb* is the patient's measured hemoglobin (g/dL). The equation uses the person's weight (in pounds) and assumes that an Hgb of 14.8 g/dL is 100% of normal. Children weighing <30 lb should be given 80% of the calculated dose because the normal mean Hgb in this population is lower.

For patients with anemia resulting from blood loss (e.g., hemorrhagic diatheses) or patients receiving chronic dialysis,

the iron requirement is based on the estimate of iron contained in the blood lost. In this case, the following equation should be used:

$$\text{Iron (mg)} = \text{Blood loss (mL)} \times \text{Het (the patient's measured Het expressed as a decimal fraction)}$$

This formula assumes that 1 mL of normochromic blood contains 1 mg of iron.

After parenteral administration, iron dextran is cleared by the reticuloendothelial cells and processed. The iron is then released back into the plasma and bone marrow. Because the rate of iron incorporation into hemoglobin does not exceed that achieved by oral iron therapy, the response time is similar to that of oral iron therapy, and the Hgb can be expected to increase at a rate of 1.5 to 2.2 g/dL/week during the first 2 weeks and by 0.7 to 1.6 g/dL/week thereafter until normal values are attained.

SIDE EFFECTS

10. What side effects can be expected from parenteral iron therapy?

Anaphylactoid reactions can occur in <1% of patients treated with parenteral iron therapy.^{4,25,26} This reaction is more commonly associated with iron dextran than with ferric gluconate and iron sucrose.^{25,26} As a result, a 25-mg test dose of iron dextran should be given IM or by IV infusion over 5 to 10 minutes. If headache, chest pain, anxiety, or signs of hypotension are not experienced, the remainder of the dose can be administered parenterally. Nevertheless, delayed reactions (e.g., fever, urticaria, arthralgias, and lymphadenopathy) have occurred 24 to 48 hours after large doses of IV iron dextran and have lasted 3 to 7 days in 1% to 2% of patients.²⁷ A test dose is not indicated for ferric gluconate and iron sucrose because of the lower incidence of serious anaphylactoid reactions with these agents. Other side effects seen with parenteral iron agents include hypotension, nausea and vomiting, cramps, and diarrhea. Parenteral iron medications should not be mixed with (or added to) other medications or parenteral nutrition solutions for IV infusion.

MEGALOBlastic ANEMIAS

Megaloblastic anemia is a common disorder that can have several causes: (a) anemia associated with vitamin B₁₂ deficiency; (b) anemia associated with folic acid deficiency; or (c) anemia caused by metabolic or inherited defects associated with decreased ability to utilize vitamin B₁₂ or folic acid.²⁸

Megaloblastosis results from impaired DNA synthesis in replicating cells, which is signaled by a large immature nucleus. RNA and protein synthesis remain unaffected, and the cytoplasm matures normally. Megaloblastic changes can be observed microscopically in RBC and in proliferating cells (e.g., in the cervix, skin, GI tract).²⁹

Although the clinical effects of vitamin B₁₂ and folic acid deficiencies can differ in various organ systems, they are similar in their effects on the hematopoietic system. Typically, macrocytic anemia develops slowly and can be identified by large, oval, well-hemoglobinized red cells; anisocytosis; and nuclear remnants. The reticulocyte count is low and the bilirubin level is elevated. Thrombocytopenia is present and the platelets are large. Leukopenia occurs with hypersegmenta-

tion of polymorphonuclear leukocyte nuclei. If biopsied, the bone marrow is markedly hypercellular. Nuclear immaturity is present, but the megaloblasts have normal maturation of the cytoplasm. Iron stores in the marrow are increased as a result of the intramedullary hemolysis. Symptoms include fatigue; exaggeration of pre-existing cardiovascular or pulmonary problems; a sore, pale, smooth tongue; diarrhea or constipation; and anorexia. Edema and urticaria also may be present.

Vitamin B₁₂ Deficiency Anemia

Vitamin B₁₂ Metabolism

Deficiency and poor utilization of vitamin B₁₂ are two mechanisms for the development of megaloblastic anemia. Cobalamin (vitamin B₁₂) is naturally synthesized by microorganisms, but because humans are incapable of doing so, vitamin B₁₂ must be provided nutritionally. Animal protein, and roots and legumes of plants provide dietary sources of vitamin B₁₂. Meats richest in vitamin B₁₂ include oysters, clams, liver, and kidney; moderate amounts of vitamin B₁₂ are found in muscle meats, milk products, and egg yolks.

The typical Western diet contains 5 to 15 mcg/day of vitamin B₁₂, an amount sufficient to replace the 1 mcg lost daily. The total body stores of vitamin B₁₂ range from 2,000 to 5,000 mcg, 50% to 90% of which is stored in the liver.³⁰ Because body stores are extensive, 3 to 4 years are required before symptoms of vitamin B₁₂ deficiency develop.

In the stomach, the vitamin B₁₂ is released from protein complexes and bound to intrinsic factor, which protects it from degradation by GI microorganisms. Intrinsic factor is essential for the absorption of vitamin B₁₂. Specific mucosal receptors in the distal small ileum allow for attachment of the intrinsic factor: B₁₂ complex. B₁₂ is then transferred to the ileal cell and finally to portal vein blood. The intrinsic factor mechanism is saturated by 1.5 to 3 mcg of B₁₂; however, passive diffusion can occur when B₁₂ is present in large quantities.

After vitamin B₁₂ is absorbed, it is bound to specific β-globulin transport proteins, transcobalamin I, II, and III. Transcobalamin II is responsible for transporting B₁₂ through cell membranes and delivering it to the liver and other organs. All three of the transport proteins prevent loss of B₁₂ in the urine, sweat, and other body secretions. In the liver, vitamin B₁₂ is converted to coenzyme B₁₂, which is essential for hematopoiesis, maintenance of myelin throughout the entire nervous system, and production of epithelial cells.^{31,32}

Pathogenesis and Evaluation of Vitamin B₁₂ Deficiency

Vitamin B₁₂ deficiency can result from (a) decreased intake, absorption, transport, and utilization; or (b) increased requirements, metabolic consumption, destruction, and excretion. Strict vegetarians most frequently present with signs and symptoms of vitamin B₁₂ deficiency. This population also can be iron deficient and the microcytosis of iron deficiency anemia can mask the vitamin B₁₂ deficiency-induced macrocytic appearance of RBC. Other causes of vitamin B₁₂ deficiency include inadequate proteolytic degradation of vitamin B₁₂ from protein, or congenital intrinsic factor deficiency. In addition, the gastric mucosa may be unable to produce intrinsic factor under conditions such as partial gastrectomy, autoimmune destruction (e.g., Addisonian or juvenile pernicious

anemia), or destruction of the gastric mucosa from caustic agents.

Pernicious anemia can result in vitamin B₁₂ deficiency. It can be caused by chronic atrophic gastritis accompanied by reduced intrinsic factor and hydrochloric acid secretion or acquired as a result of gastrectomy, pancreatic disease, or malnutrition. Pernicious anemia occurs commonly in patients with thyrotoxicosis, Hashimoto's thyroiditis, vitiligo, rheumatoid arthritis, or gastric cancer. Anti-intrinsic factor antibodies have been observed in the serum of some patients with pernicious anemia.

The onset of the pernicious anemia is insidious. Patients generally do not feel well for 6 to 12 months and often complain of at least two of the following triad of symptoms: weakness, sore tongue, and symmetric numbness or tingling in the extremities. The neurologic symptoms of vitamin B₁₂ deficiency are associated with a defect in myelin synthesis and often are described as stocking-glove peripheral neuropathy or nonspecific complaints (e.g., tinnitus, neuritis, vertigo, headaches). Patients with neurologic symptoms have difficulty determining position and vibration sense and have an increase in deep tendon reflexes. These symptoms may progress to spastic ataxia, motor weakness, and paraparesis. Interestingly, no correlation exists between the extent of neurologic manifestations and the severity of anemia. Anorexia, pallor, and dyspnea on exertion are bothersome symptoms that may overshadow the diagnostic triad.

Laboratory Evaluation

In general, the serum vitamin B₁₂ level reliably reflects vitamin B₁₂ tissue stores. False low vitamin B₁₂ concentrations may be observed in patients with folic acid deficiency, transcobalamin I deficiency, multiple myeloma, pregnancy, or in those who take very large doses of vitamin C. Falsely elevated vitamin B₁₂ concentrations may be observed in patients with myeloproliferative diseases, hepatomas, autoimmune diseases, monoclastic leukemias, and histiocytic lymphomas.³³ Measuring serum methylmalonic acid and homocysteine levels may assist in differentiating between folate and vitamin B₁₂ deficiency. Once vitamin B₁₂ therapy has been instituted, serum levels of these chemicals decrease if true vitamin B₁₂ deficiency is present.

The cause of vitamin B₁₂ deficiency may be determined by the use of antibody testing (antiparietal cells and anti-intrinsic factor antibodies). Patients with pernicious anemia are not able to absorb vitamin B₁₂ because intrinsic factor is not available for binding. Some patients produce intrinsic factor but are still unable to absorb dietary vitamin B₁₂. Malabsorption can be caused by intestinal bacteria that usurp vitamin B₁₂, achlorhydria, pancreatic insufficiency, inadequate disassociation of vitamin B₁₂ from proteins, or lack of intrinsic factor receptors secondary to ileal loops, bypass, or surgical resection.³⁴

Pernicious Anemia

SIGNS, SYMPTOMS, AND LABORATORY FINDINGS

11. C.L., a 60-year-old Scandinavian man, is seen by a private physician. C.L. has a 1-year history of weakness and emotional instability. He also complains of a painful tongue, alternating constipation and diarrhea, and a tingling sensation in both feet. Perti-

nent findings on physical examination include pallor, red tongue, vibratory sense loss in the lower extremities, disorientation, muscle weakness, and ataxia.

Significant laboratory findings include the following: Hgb, 9 g/dL (normal, 14 to 18); Hct, 29% (normal, 42% to 52%); MCV, 110 μm³ (normal, 76 to 100); MCH, 38 pg (normal, 27 to 33); MCHC, 34% (normal, 33% to 37%); reticulocytes, 0.4% (normal, 0.5% to 1.5%); poikilocytosis and anisocytosis on the blood smear; white blood cell (WBC) count, 4,000/mm³ (normal, 3,200 to 9,800); platelets, 105,000/mm³ (normal, 130,000 to 400,000); serum iron, 80 μg/dL (normal, 50 to 160); TIBC, 300 g/dL (normal, 200 to 1,000); ferritin, 150 ng/mL (normal, 15 to 200); RBC folate, 300 ng/mL (normal, 140 to 460); serum vitamin B₁₂, 100 pg/mL (normal, 200 to 1,000); and anti-intrinsic factor antibody, positive. What signs, symptoms, and laboratory findings are typical of pernicious anemia in C.L.?

[SI units: Hgb, 90 g/L; Hct, 0.29; MCV, 110 fL; MCH, 38 pg; MCHC, 0.34; reticulocytes, 0.004; WBC count, 4,000/mm³ × 10⁹/L; platelets, 105,000/mm³ × 10⁹/L (normal, 250 to 400); iron, 14.38 μmol/L; TIBC, 53.91 μmol/L; ferritin, 150 μL; RBC folate, 679.8 nmol/L; vitamin B₁₂, 73.78 pmol/L]

C.L.'s signs and symptoms are classic for pernicious anemia. This disease occurs equally in both sexes (primarily in individuals of northern European descent), with an average onset of 60 years. Pernicious anemia develops from a lack of gastric intrinsic factor production, which causes vitamin B₁₂ malabsorption and, ultimately, vitamin B₁₂ deficiency. C.L.'s signs and symptoms of vitamin B₁₂ deficiency include painful red tongue, loss of lower extremity vibratory sense, vertigo, and emotional instability.

The elevated MCV suggests megaloblastic anemia. Folate and iron are two other factors that can affect the MCV and should be evaluated during the workup of a patient for anemia. In this case, C.L.'s folate and iron levels are normal, but his serum vitamin B₁₂ level is low. The presence of poikilocytosis and anisocytosis observed in the blood smear represent ineffective erythropoiesis. Other cell lineages also may be affected in the bone marrow. Erythroid hypercellularity, along with a decrease in the myeloid cells (leukocytes and platelets), increases the erythroid:myeloid ratio in C.L. The patient's low serum vitamin B₁₂ levels and the low results obtained from the Schilling test are compatible with the diagnosis of pernicious anemia.

TREATMENT

12. How should C.L.'s pernicious anemia be treated? How soon can a response be expected?

C.L. should receive parenteral vitamin B₁₂ in a dose sufficient to provide not only the daily requirement of approximately 2 mcg, but also the amount needed to replenish tissue stores (about 2,000 to 5,000 mcg; average, 4,000 mcg). To replete vitamin B₁₂ stores, cyanocobalamin can be given IM in accordance with various regimens. C.L. may receive 100 mcg of cyanocobalamin daily for 1 week, then 100 mcg every other day for 2 weeks, followed by 100 mcg every 3 to 4 days for 2 to 3 weeks. A monthly maintenance dose of cyanocobalamin (100 mcg) would then be required for the remainder of C.L.'s life. Another treatment option may be cyanocobalamin (1,000 mcg) once a week for 4 to 6 weeks followed by 1,000 mcg/mo for lifetime maintenance therapy.²⁹ IM or deep subcutaneous administration provides sustained release of vitamin B₁₂ with

better utilization compared with rapid IV infusion. An oral or intranasal cyanocobalamin gel is also available for maintenance therapy, after the patient has achieved hematologic remission.

With adequate vitamin B₁₂ therapy, the following response can be expected: Neurologic symptoms should improve within 24 hours. However, with longstanding vitamin B₁₂ deficiency, several months may pass before some symptoms are relieved; other symptoms may never resolve. Hematologic parameters should begin to improve within the first few days. The bone marrow becomes normoblastic within 48 hours, the reticulocyte count should peak around day 5 of therapy, and the Hct should return to normal in 1 to 2 months. Because the rapid production of RBC can increase potassium demand, serum potassium should be monitored and potassium supplementation provided as necessary. Peripheral blood counts should be obtained every 3 to 6 months to evaluate the adequacy of therapy. If maintenance therapy is discontinued, pernicious anemia will recur within 5 years.

Oral Vitamin B₁₂

13. What factors affect the oral absorption of vitamin B₁₂? When is oral vitamin B₁₂ therapy an effective alternative to parenteral therapy?

The amount of vitamin B₁₂ that can be absorbed orally from a single dose or meal ranges from 1 to 5 mcg; approximately 5 mcg of vitamin B₁₂ is absorbed daily from the average American diet. The percentage of vitamin B₁₂ absorbed decreases with increasing doses. About 50% of a 1 to 2 mcg dose of vitamin B₁₂ is absorbed, whereas only about 5% of a 20 mcg dose is absorbed.³⁵ Doses >100 mcg must be ingested to absorb 5 mcg of vitamin B₁₂. Oral therapy for pernicious anemia using high dosages of oral cyanocobalamin (1,000 to 2,000 mcg) may be indicated in certain patients, especially those who refuse or cannot receive parenteral therapy.^{36,37} Overall, oral vitamin B₁₂ therapy is considered safe and effective.³⁸ Patients can be given 1,000 to 2,000 mcg/day for 1 month, followed by 125 to 500 mcg/day as maintenance treatment.³⁹ Issues of noncompliance or lack of response with oral therapy places the patient at substantial risk for significant neurologic damage. Patients receiving oral vitamin B₁₂ therapy should be monitored more frequently to ensure compliance with therapy.

Anemias After Gastrectomy

14. F.M. has just undergone a total gastrectomy for recurrent nonhealing ulcers. What form(s) of anemia would be expected to develop in a patient after gastrectomy? Should F.M. receive prophylactic vitamin B₁₂?

Partial or total gastrectomy often results in anemia, particularly pernicious anemia, because the source of intrinsic factor is lost, and oral vitamin B₁₂ absorption will be impaired. The hematologic and neurologic abnormalities associated with B₁₂ deficiency do not develop until existing vitamin B₁₂ stores are depleted (about 2 to 3 years). Nevertheless, prophylactic vitamin B₁₂ should be administered to this patient after total gastrectomy. Because the vitamin B₁₂ stores are not currently depleted, maintenance therapy, as discussed in Question 12, should be adequate for F.M.

Malabsorption of Vitamin B₁₂

SIGNS AND SYMPTOMS

15. P.G., a 55-year-old woman, complained of progressive confusion and lethargy 9 months ago. A CBC at that time revealed only mild leukocytosis. Today, she comes to the emergency department with a 4-week history of frequent (three to five per day) stools containing bright red blood. She reports continued lethargy, dizziness, ataxia, and paresthesias in her hands and feet.

Laboratory findings of interest include the following: Hgb, 12.8 g/dL (normal, 12 to 16); MCV, 90 μm³ (normal, 76 to 100); iron, 150 mcg/dL (normal, 50 to 160); B₁₂, 94 pg/mL (normal, 200 to 1,000); folate, 21 ng/mL (normal, 7 to 25); hypersegmented polymorphonuclear leukocytes (PMN); bilirubin, 3.0 mg/dL (normal, 0.1 to 1.0); and lactate dehydrogenase (LDH), 520 U/L (normal, 50 to 150). A subsequent bone marrow aspirate demonstrates megaloblastic erythropoiesis, giant metamyelocytes, and a low stainable iron. A barium swallow and follow-through show numerous jejunal and duodenal diverticuli. Jejunal and duodenal aspirates reveal aerobic and anaerobic bacterial overgrowth. What signs, symptoms, and laboratory findings are typical for vitamin B₁₂ deficiency in P.G.?

[SI units: Hgb, 120 g/L; MCV, 90 fL; iron, 25.87 mcmol/L; B₁₂, 69.35 pmol/L; folate, 47.59 nmol/L; bilirubin, 51.3 mcmol/L; LDH, 520 U/L]

The signs and symptoms in P.G. that are consistent with B₁₂ deficiency include confusion, dizziness, ataxia, and paresthesias. Other signs and symptoms may be caused by other underlying conditions. For example, her lethargy may be the result of prolonged blood loss secondary to diverticulitis.

Notably, P.G. initially presented with a mild leukocytosis. Evaluation 9 months later shows a low Hgb, a low serum vitamin B₁₂ level, and hypersegmented PMN. The high LDH and bilirubin levels reflect intramedullary hemolysis of megaloblastic RBC consistent with vitamin B₁₂ deficiency, even though the MCV is within normal limits. The presence of megaloblastic erythropoiesis and giant metamyelocytes in the bone marrow also is consistent with vitamin B₁₂ deficiency.

P.G.'s history of bloody stools and diverticuli suggests substantial long-term blood loss, which increased demand for iron and vitamin B₁₂ to replace RBC. Concurrent iron deficiency can mask megaloblastic changes in RBC, which explains the suspiciously normal MCV (dimorphic anemia). The serum folate concentration is also falsely normal. Although the RBC folate level is likely to be low, serum folate concentrations are normal because monoglutamated folates leak from cells into the serum in vitamin B₁₂ deficient states.

TREATMENT

16. How should P.G.'s vitamin B₁₂ deficiency be treated?

The cause of vitamin B₁₂ malabsorption must be corrected before P.G. is given oral vitamin B₁₂ therapy. The presence of diverticuli is not the cause of vitamin B₁₂ malabsorption because diverticuli typically do not extend into the distal ileum. Instead, given P.G.'s medical history, the most likely cause of vitamin B₁₂ malabsorption is bacterial usurpation of luminal vitamin B₁₂. P.G. should first be treated with a broad-spectrum antibiotic (e.g., tetracycline) or a sulfonamide for 7 to 10 days, then begin daily oral vitamin B₁₂ supplementation to replenish her body stores. In this case, normal levels of intrinsic factor permit oral therapy. The recommended daily dose of vitamin

B₁₂ is 25 to 250 mcg. Following antibiotic therapy, P.G. also should begin to absorb vitamin B₁₂ in her diet.

Folic Acid Deficiency Anemia

Folic Acid Metabolism

Folate is abundant in virtually all food sources, especially fresh green vegetables, fruits, yeast, and animal protein. As a result of food fortification, the average American diet provides 50 to 2,000 mcg of folate per day; however, excessive or prolonged cooking (>15 minutes) in large quantities of water destroys a high percentage of the folate that is contained in food.⁴⁰ Human requirements for folate vary with age and depend on the rate of metabolism and cell turnover but are generally 3 mcg/kg/day.⁴⁰ The minimal daily adult requirement of folate is 50 mcg, but because absorption from food is incomplete, a daily intake of 200 mcg is recommended. Folate requirements are increased in conditions in which the metabolic rate and rate of cellular division are increased (e.g., pregnancy, infancy, infection, malignancies, hemolytic anemia). The following are estimates of daily folate requirements based on age and growth demands: children, 80 mcg; infants, 65 mcg; pregnant or lactating women, 400 to 800 mcg.^{37,40,41}

Dietary folic acid is in the polyglutamate form and must be enzymatically deconjugated in the GI tract to the monoglutamate form before it is absorbed. Once absorbed, the inactive dihydrofolate (FH₂) must be converted to active tetrahydrofolate (FH₄, folinic acid) by dihydrofolate reductase (DHFR).

In contrast to the large stores of vitamin B₁₂, the body's folate stores are relatively small (about 5 to 10 mcg). Therefore, deficiency and subsequent megaloblastic anemia can occur within 3 to 4 months of decreased folate intake.

Predisposing Factors

Folate deficiency is most commonly associated with alcoholism, rapid cell turnover, and dietary deficiency. In alcoholics, the daily intake of the folate contained in food may be restricted or absent. In addition, enterohepatic recirculation of folate can become impaired by the toxic effect of alcohol on hepatic cells. Folate deficiency also can develop during the third trimester of pregnancy as a result of a marginal diet and the rapid metabolism of the fetus. Folate coenzymes are required for most metabolic pathways (Fig. 86-2). Therefore, folate deficiency will develop in any condition of rapid cellular turnover (e.g., hemolytic anemias, hemoglobinopathies, sideroblastic

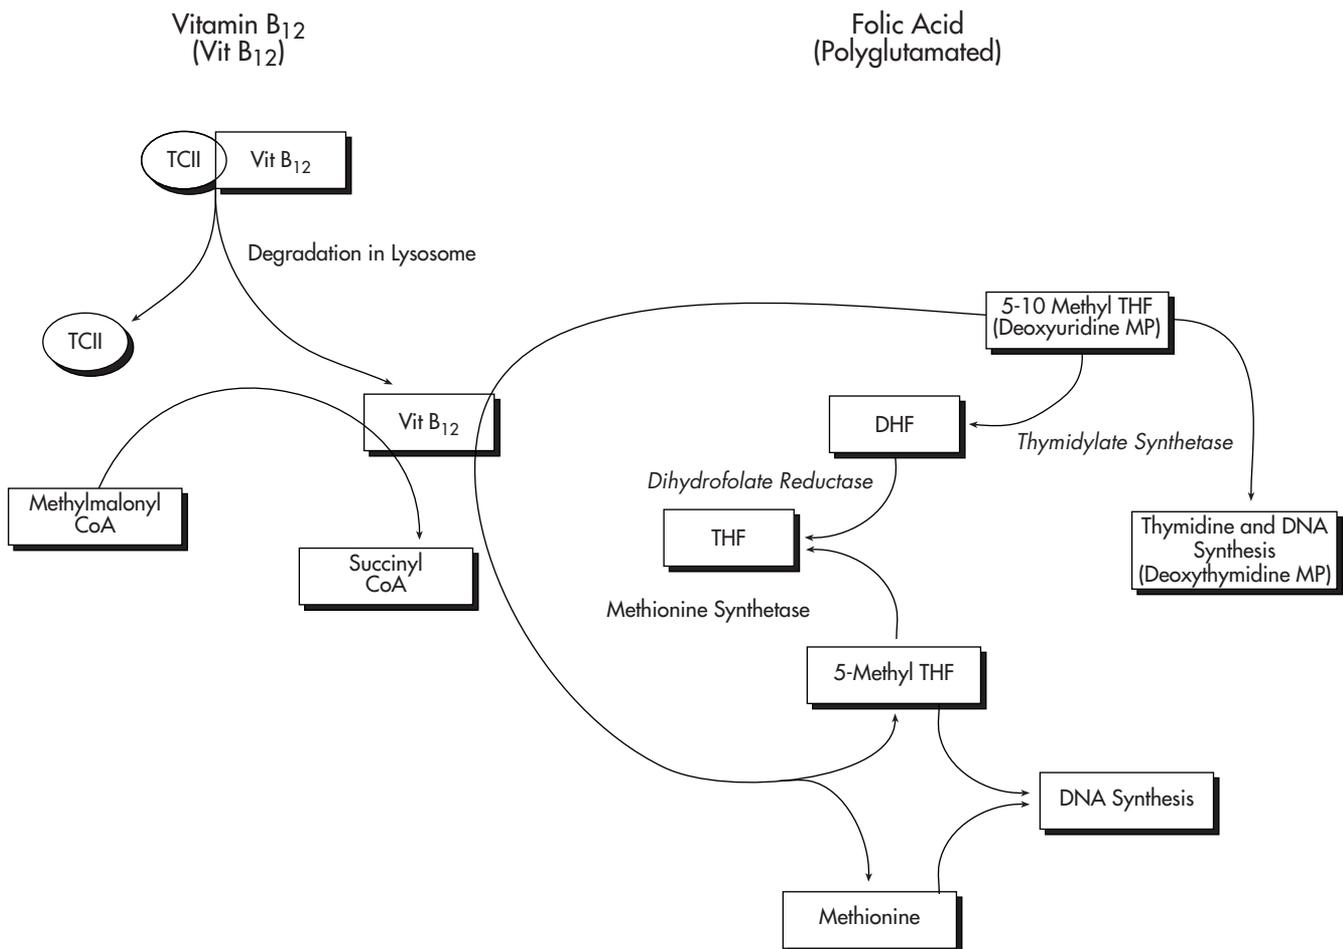

FIGURE 86-2 Intracellular metabolic pathways. Vitamin B₁₂ and folic acid are both necessary for nucleic acid precursors used for DNA synthesis. DHF, dihydrofolate; MP, monophosphate; TCII, transcobalamin II; THF, tetrahydrofolate.

anemia, leukemias, lymphomas, multiple myeloma) or a diet lacking in folate (e.g., food faddism or a weight-loss diet). Folate deficiency also can occur with chronic hemodialysis, diseases that impair absorption from the small intestine (e.g., sprue, regional enteritis), extensive jejunal resections, and drugs that alter folate metabolism (e.g., trimethoprim, pyrimethamine, methotrexate, sulfasalazine, oral contraceptives, anticonvulsants).^{37,42–44} Few patients have inborn errors of folate metabolism.⁴⁵

The evaluation of megaloblastic anemia must be thorough because indiscriminate use of “shotgun” hematonic therapy can be dangerous. Large doses of folate can partially reverse hematologic abnormalities caused by vitamin B₁₂ deficiency; however, folate cannot correct neurologic damage caused by vitamin B₁₂ deficiency. Therefore, folate deficiency absolutely must be differentiated from vitamin B₁₂ deficiency before folate therapy is initiated. Otherwise, the progression of the neurologic sequelae of vitamin B₁₂ deficiency can occur.

17. T.J., a malnourished-appearing woman in her second trimester of pregnancy, presents to the local health clinic for her regular checkup. She is a multiparous, 22-year-old woman who ran away from home when she was 16. T.J. has a 7-year history of excessive alcohol intake and has been using cocaine frequently for 3 years. She lives with her boyfriend and her 19-month-old daughter. During both pregnancies, T.J. lost 8 to 10 lb during the first trimester secondary to nausea, vomiting, and anorexia. Her only complaints are dyspnea on exertion, palpitations, and diarrhea.

Pertinent laboratory values include the following: Hct, 25.5% (normal, 40% to 44%); MCV, 112 μm^3 (normal, 76 to 100); MCH, 34 pg (normal, 27 to 33); RBC, $1.1 \times 10^6/\text{mm}^3$ (normal, 3.5 to 5.0); folate, 30 ng/mL (normal, in RBC 140 to 960); serum vitamin B₁₂, 250 pg/mL (normal, 200 to 1,000); reticulocytes, 1% (normal, 0.5 to 1.5); platelets, 75,000/ mm^3 (normal, 130,000 to 400,000); WBC count, 2,000/ mm^3 (normal, 3,200 to 9,800) with hypersegmented PMN; LDH, 450 U/L (normal, 50 to 150); and bilirubin, 1.5 mg/dL (normal, 0.1 to 1). T.J. is not taking any prescription medications. What factors make T.J. at risk for folate deficiency?

[SI units: Hct, 0.255; MCV, 112 fL (normal, 76 to 100); MCH, 34 pg (normal, 27 to 33); RBC count, $1.1 \times 10^9/\text{L}$ (normal, 3.5 to 5); folate, 67.98 nmol/L (normal, 317 to 2175); vitamin B₁₂, 184 pmol/L; folate, 184.45 pmol/L (normal, 150 to 750); reticulocytes, 0.01; platelets, $75 \times 10^9/\text{L}$ (normal, 130 to 400); WBC count, $2 \times 10^9/\text{L}$; LDH, 450 U/L (normal, 50 to 150); bilirubin, 25.65 mmol/L (normal, 2 to 18)]

T.J. has had a history of risk factors for folate deficiency since she was 16 years of age. The diagnosis of folate deficiency is plausible, considering folate deficiency can develop in a matter of weeks to months. As with most patients who are folate deficient, T.J. has more than one risk factor for folate deficiency. Cocaine and alcohol, together with multiparity complicated by anorexia, nausea, and vomiting, could lead to poor nutrition. Alcohol has toxic effects on the intestinal mucosa and interferes with folate utilization by the bone marrow. T.J. should be asked specifically about her dietary habits and recent weight history. She may have a folate-poor diet for financial reasons or because she is overcooking her food. Alternatively, cocaine may be causing anorexia. The nutritional intake of people who abuse alcohol and drugs is often poor.

Diagnosis and Management

18. Which laboratory values support the diagnosis of folate deficiency? How should T.J. be treated and monitored?

T.J.’s laboratory values reflect macrocytic anemia (Hct, 25.5%; MCV, 112 μm^3) with pancytopenia (reduced number of RBC, WBC, and platelets). Serum vitamin B₁₂ concentrations reflect normal vitamin B₁₂ stores, but folate stores are inadequate as exemplified by the low RBC folate concentration, pancytopenia, and macrocytic anemia.

Serum folate concentrations generally reflect folate balance over the past 3 weeks, although one balanced meal can raise serum levels and falsely elevate body stores. Tissue folate stores are more accurately reflected by the RBC polyglutamated folate content, which is approximately 10 to 30 times the corresponding serum folate concentrations.⁴⁶ Hemolysis or vitamin B₁₂ deficiency causes leakage of monoglutamated folates from cells, thereby falsely elevating serum folate levels.^{28,29,47}

T.J. should be counseled regarding her nutritional and social habits. Because the estimated total body folate store is only about 5 to 10 mcg, 1 mcg of folic acid given daily for 2 to 3 weeks should be more than adequate to replace her storage pool of folate. Higher dosages (up to 5 mcg) may be needed, however, if absorption is compromised by alcohol or other factors.⁴⁸ Once stores are replenished, T.J. should continue folate supplements throughout her pregnancy and lactation period. She should be reassessed after the course of therapy to determine response to therapy and if the cause of the folate deficiency has been corrected. Supplementation with folic acid 1 mcg/day may be required as long as risk factors are present. T.J.’s fetus is unlikely to develop folate deficiency because maternal folate is preferentially delivered to the fetus (see Chapter 46).

T.J.’s response to therapy can be monitored by several different parameters. Although bone marrow aspirates are not obtained routinely, the RBC morphology should begin to revert back to normal within 24 to 48 hours after therapy is initiated, and hypersegmented neutrophils should disappear in the periphery in about 1 week. Serum chemistry and hemogram studies should begin to normalize within 10 days. The reticulocyte count should increase by day 2 to 3 and peak by day 10. LDH and bilirubin values should normalize in 1 to 3 weeks. Finally, the anemia should be corrected in 1 to 2 months. Once anemia is corrected, 0.1 mcg of folate as a nutritional supplement should be adequate for maintenance treatment. If patients with underlying vitamin B₁₂ deficiency are inappropriately treated with folate, neurologic sequelae will persist, and macrocytic anemia will abate but will not resolve completely.

SICKLE CELL ANEMIA

Pathogenesis

Sickle cell anemia is an inherited hemoglobin disorder characterized by a DNA substitution where the β -globin gene is located. Hemoglobin is a quaternary structure composed of two α -globin chains and two β -globin chains ($\alpha_2\beta_2$) in adults. The β -globin gene locus encodes several globin gene products during the course of development. These products result from

transcription of the embryonic globin gene (ϵ), duplicated fetal genes (γ), and adult genes (β and δ). During fetal development, the γ -globin is the primary β -globin expressed, forming fetal hemoglobin (HbF or $\alpha_2\gamma_2$). Normally, the period from birth to approximately 3 to 6 months of age is marked by the replacement of γ -globin with β -globin, giving rise to the adult form of hemoglobin (HbA, $\alpha_2\beta_2$). Low levels of γ -globin persist throughout life, and HbF, present in F cells, may account for approximately 1% of the total hemoglobin content.^{49,50} β^S represents the inheritance of the sickle β -globin gene.⁵¹

Sickle cell anemia results from a DNA substitution of thymidine for adenine in the glutamic acid codon, forming a B6 valine instead of glutamic acid.⁵⁰ The hemoglobin produced from such a substitution has a more negative charge than normal HbA, and the deoxygenated state favors hemoglobin aggregation and polymerization, which forms sickled RBC.^{49,50} Sickled RBC are more rigid and may become “lodged” when passing through microvasculature, resulting in vascular occlusions.

In addition, the sickled RBC surface contains rearranged aminophospholipids, which augments the ability of the RBC to initiate coagulation, adhere to vascular endothelium, and activate complement. Abnormal interactions with other cell types produce several complications such as anemia, vaso-occlusive episodes, and multiorgan damage.⁴⁹ For these reasons, much effort has been focused on neonatal diagnosis to reduce morbidity and mortality in children <3 years of age.⁵²

More than one inheritance pattern results in abnormal hemoglobin polymerization. Patients with sickle cell anemia are homozygous, inheriting a sickle gene from each parent ($\alpha_2\beta^S_2$), whereas patients with sickle cell trait are heterozygous and have inherited the sickle cell gene from one parent and the HbA gene from the other parent ($\alpha_2\beta^A\beta^S$). Other inheritance patterns include patients with a sickle cell gene and an HbC gene (where glutamic acid is substituted for lysine B6 [$\alpha_2\beta^S\beta^C$]). Finally, patients may inherit the sickle cell gene and the β -thalassemic gene ($\alpha_2\beta^S\beta^{\text{thal}}$), in which case the clinical course is less severe than with patients diagnosed with sickle cell anemia.⁵³ Hematologic abnormalities are more commonly observed in patients with sickle cell anemia and less often in those with sickle cell HbC disease or sickle cell B₀-thalassemia.^{49,50}

Laboratory Evaluation

Patients who have inherited the sickle cell gene are diagnosed by electrophoretic procedures that separate different forms of Hgb. Fetal hemoglobin levels vary among patients. The WBC and platelet counts often are elevated, but the WBC differential is normal.⁴⁹ The reticulocyte count can range from 5% to 15%, and the MCV may be elevated. If MCV values are within the normal range, iron deficiency or B₀-thalassemia must be considered. Sickled cells may also be visually observed in poorly oxygenated blood of a patient with sickle cell anemia. In contrast, a patient with the sickle cell trait should have normal RBC morphology and WBC, reticulocyte, and platelet counts. Sickled cells are rarely observed. In patients with sickle cell B₀-thalassemia, hematologic abnormalities vary, depending on the amount of HbA present. This form may be difficult to distinguish from sickle cell anemia; RBC microcytosis may be the only differentiating parameter.⁴⁹

Clinical Course and Management

Patients carrying the sickle cell trait experience milder symptoms than those with sickle cell anemia. The kidney is commonly affected by microinfarction, which occurs in the renal medulla and impairs the kidney's ability to concentrate urine. During pregnancy, an increased frequency of urinary tract infections and hematuria are seen. However, vaso-occlusive events are uncommon. If they do occur, they usually are caused by hypoxic conditions resulting from excessive exercise or high altitudes.

Sickle cell HbC disease is usually associated with few clinical complications. These patients may have normal physical examination findings with only splenomegaly. Patients are at risk for bacterial infections and, because of elevated Hgb levels, they may suffer from ocular, orthopedic, and pulmonary vaso-occlusive events.^{49,53}

Treatment of sickle cell anemia is largely directed toward prophylaxis against infections and supportive management of vaso-occlusive crises. The clinical course among patients with sickle cell disease is variable and difficult to predict. Some patients suffer from a multitude of health problems. Organs such as the kidneys, retina, spleen, and bones are frequent sites of vaso-occlusive events because these sites have a relatively low pH and oxygen tension. Complications (e.g., pain, anemia, and infections) as well as cardiac, pulmonary, neurologic, hepatobiliary, obstetric/gynecologic, ocular, dermatologic, or orthopedic complications can occur. The management of these complications is organ specific and aimed at supportive interventions.

Hemolytic Anemia

Hemolytic anemia is caused by splenic sequestration of abnormal RBC. Sequestration reduces the RBC life span from 120 days to 15 to 25 days and elevates the reticulocyte count. Erythropoietin response is typically blunted for the degree of anemia, which can be a result of concurrent kidney dysfunction. Some patients may even experience aplastic anemia (bone marrow failure) when extensive hemolysis is accompanied by inadequate bone marrow response. It is usually self-limiting, however. Human parvovirus (HPV) B19 is a common cause of transient red cell aplasia (TRCA) with up to 67% of infections resulting in a hematologic change typical of aplasia.⁵⁴ Nearly 70% of all cases of homozygous sickle cell patients are HPV B19 seropositive by 20 years of age.⁵⁵ Hemolytic anemia can also present in patients with glucose-6-phosphate dehydrogenase deficiency. Cardiac manifestations include high-output failure secondary to anemia. Management of the underlying anemia may include splenectomy following the first splenic sequestration event. Alternatively, patients can be treated with transfusions and careful observation.^{49,56}

Infections

Infections commonly occur in patients with sickle cell anemia because the complement pathway, granulocyte function, and B-cell immunity may be altered. Also, impaired splenic function increases the risk for infection from polysaccharide-encapsulated bacteria such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Neisseria meningitidis*, and *Salmonella typhimurium*. Pneumonia caused by *S. pneumoniae*, mycoplasma, or viruses can worsen hypoxia, causing

progression to vaso-occlusion and acute chest syndrome (chest pain in the presence of a local infiltrate on chest radiograph). Because of such complications, the prophylactic administration of penicillin has significantly reduced morbidity and mortality from pneumonia in children <3 years of age⁵⁷, but prophylaxis is recommended to be continued through age 5.⁵¹ Pulmonary complications from pneumonia or vascular occlusion also can lead to right-sided heart failure. Other infectious conditions such as osteomyelitis from *S. aureus* or *S. typhimurium* or urinary tract infections caused by *Escherichia coli* are common complications in patients with sickle cell anemia.^{49,51} Because of their susceptibility to infections, antibiotic therapy should be instituted at the earliest sign of infection. Vaccines that are recommended for patients with homozygous sickle cell include all standard pediatric vaccines as well as pneumococcal 23-valent polysaccharide vaccine at 2 and 5 years of age with a booster every 10 years.⁵¹ Because patients with sickle cell typically respond poorly, only 50% of patients will be protected by vaccination.⁵⁸

Vascular Occlusion Episodes

Vascular occlusion episodes, or “sickle cell crises,” cause severe pain and organ damage. The pain typically lasts 2 to 6 days and should be managed with narcotic analgesics (morphine or morphine derivatives). Narcotic addiction may occur over time but can be prevented by providing the patient with only a few days supply of analgesics following the crisis.^{49,51}

Neurologic Complications

Neurologic complications are age dependent. Stroke most commonly occurs in the first decade of life, whereas intracerebral hemorrhage is a complication associated with adulthood. Primary prevention of stroke with RBC transfusions, targeted to maintain HbS level <30%, reduce the incidence of stroke in high risk patients by 92%.⁵⁹ If a stroke occurs, approximately 50% of patients experience recurrent strokes within 3 years unless they are treated by chronic RBC transfusion therapy.⁵⁰ Preliminary evidence suggests that transitioning from RBC transfusions to chronic hydroxyurea might be an alternative option to prevent secondary stroke, is being further investigated.^{60,61}

Renal and Genital Complications

Renal and genital complications are common in sickle cell disease because the environment (hypoxic, acidotic, and hypertonic) predisposes the renal medulla or corpus cavernosum to infarction. As a result, patients might experience reduced potassium excretion, hyperuricemia, hematuria, hyposthenuria, and renal failure. Patients with renal disease generally have inappropriately low levels of EPO as well. Men experiencing occlusion of the corpus cavernosum can experience acute or chronic priapism. Conservative management includes IV fluid administration and pain control. Refractory cases may require surgery.^{49,51}

Microinfarctions

Microinfarctions often produce ophthalmic, hepatic, orthopedic, and obstetric/gynecologic complications as well. Other references address these topics in more detail.^{49,56}

Treatment for Frequent Vaso-occlusive Crises

Hemoglobin F (HbF) has a protective effect against hemoglobin polymerization. Investigators have observed that patients with HbF levels >20% experience a relatively mild or benign course with fewer vaso-occlusive crises.⁴⁶ Hydroxyurea has been found to increase HbF synthesis, which, in turn, may decrease sickling of RBC and the occurrence of disease-related complications.^{48,62,63} Hydroxyurea is used prophylactically in patients with recurrent moderate to severe vaso-occlusive crises, but not in treatment of the crises. The use of hydroxyurea in the sickle cell population should be carefully weighed for risk-versus-benefit, because this drug is a cytotoxic agent associated with bone marrow suppression. Patients taking hydroxyurea should have bone marrow studies performed before therapy and periodically during therapy.⁶⁴ Other adverse effects of hydroxyurea include GI effects (nausea, vomiting, diarrhea), dermatologic effects (macular papular rash, pruritus), and potential risk of developing a secondary neoplasm (leukemia) with prolonged use. The treatment dose of hydroxyurea for sickle cell anemia is 15 to 35 mg/kg/day. Following initiation of hydroxyurea therapy, blood counts should be monitored closely and the dose adjusted accordingly. Several clinical trials evaluating hydroxyurea show improvement in the clinical course of patients with sickle cell anemia.^{62,65} Other areas of potential promise for the treatment of sickle cell anemia include bone marrow transplantation and gene therapy.^{66,67}

Clinical Assessment

19. J.T., an 18-year-old man with sickle cell anemia, presented to the emergency department with the chief complaint of rapid onset of abdominal pain and shortness of breath. Since infancy, J.T. has been severely incapacitated by his disease.

During early childhood, he experienced several episodes of acute pain, swelling of the hands and feet, and jaundice. Three years before this admission, J.T. required a left hip replacement secondary to bony infarctions. Recently, frequent blood transfusions have reduced the frequency of sickling crises.

Physical examination reveals J.T. as a thin black man in acute distress and with scleral icterus. He has a pulse of 110 beats/minute, a respiratory rate of 18 breaths/minute, and a temperature of 98.6°F. His lungs are clear, and cardiac auscultation reveals a hyperdynamic pericardium and a systolic murmur at the left sternal edge. Splenomegaly is noted, and a chest radiograph reveals only cardiomegaly.

A CBC is obtained. Notable results include the following: Hgb, 5.5 g/dL (normal, 14 to 18); Hct, 25% (normal, 42% to 52%); WBC count, 5,000/mm³ (normal, 3,200 to 9,800); platelets, 325,000/mm³ (normal, 130,000 to 400,000); reticulocyte count, 1% (normal, 0.5 to 1.5%); bilirubin, 5.8 mg/dL (normal, 0.1 to 1.0); serum creatinine (SrCr), 3.0 mg/dL (normal, 0.6 to 1.2); and blood urea nitrogen (BUN), 52 mg/dL (normal, 1 to 18). The peripheral blood smear shows target cells with an occasional sickled cell. What signs and symptoms are consistent with sickle cell anemia? What is J.T.'s current complication?

[SI units: Hgb, 55 g/L; Hct, 0.25; WBC count, 5 × 10⁹/L; platelets, 325 × 10⁹/L; bilirubin, 99.18 μmol/L; SrCr, 265.2 μmol/L; BUN, 18.56 mmol/L urea]

Based on the presence of splenomegaly and anemia with target and sickled cells, J.T. currently is presenting with an acute

splenic sequestration crisis. Splenomegaly rapidly evolves over several hours and is accompanied by progressive anemia. The low reticulocyte count is consistent with acute sequestration because a reticulocyte response would be expected if the anemia had developed in recent days. J.T.'s inadequate reticulocyte response may reflect rapid progression of the anemia, HPV B19 infection, or a blunted EPO response secondary to compromised renal dysfunction. The hyperdynamic pericardium and systolic murmur are consistent with the high cardiac output required to deliver oxygen in an anemic state.

20. How should J.T. be treated?

J.T.'s signs and symptoms are sufficiently serious to justify transfusion therapy. In addition, J.T. should be adequately hydrated, considering his elevated serum creatinine and BUN. Because patients with sickle cell anemia often lose the ability to concentrate urine, they may become dehydrated, which further contributes to cell sickling. Pain control also should be aggressively instituted for J.T.'s comfort and should be continued for a few days after hospital discharge (also see Chapter 8, Pain and its Management). Splenectomy may be indicated in instances of severe splenomegaly, repeated infarction, or pain in adults, and it is indicated when crises occur in children. Those patients with sickle cell anemia who are bedridden should be placed on chronic heparin therapy to prevent vascular occlusions and deep vein thrombosis.

ANEMIA OF CHRONIC DISEASE

Anemia of chronic disease (ACD) refers to a mild to moderate anemia associated with a number of disorders (e.g., rheumatoid arthritis [RA], systemic lupus erythematosus, chronic infections, chronic renal failure, acquired immunodeficiency syndrome [AIDS], neoplastic disease).⁶⁸ Because of the common occurrence of such conditions, ACD is encountered frequently and has been estimated to be the second most common anemia behind iron deficiency. Most often, ACD is a normochromic, normocytic anemia, although red cells may be hypochromic and microcytic in some patients. Serum iron and total iron-binding capacity are most often decreased, whereas iron stores (as reflected by serum ferritin) are usually normal or increased. Erythropoietin levels in the serum may be increased, although not to an extent appropriate for the degree of anemia. This implicates bone marrow failure, in the setting of increased EPO, as the primary cause of the anemia associated with chronic diseases.⁶⁹

Although the pathogenesis of ACD is not well understood, inflammatory cytokines are thought to play a major role in its development through multiple mechanisms.⁶⁸ Interferon- α (IFN- α), - β (IFN- β), - γ (IFN- γ), tumor necrosis factor- α (TNF- α), and IL-1 inhibit burst BFUe and CFUe proliferation and differentiation. Competition for EPO receptors by IFN- γ and TNF- α may possibly lead to EPO resistance. IL-1 and TNF- α also inhibit hepatic and renal expression of EPO messenger RNA (mRNA), further contributing to the development of ACD. Interleukin-6 (IL-6) promotes expression of hepcidin, a 25-amino acid protein produced in hepatocytes.⁷⁰ Hepcidin alters iron hemostasis by decreasing duodenal iron absorption and inhibiting the release of reticuloendothelial iron stores leading to hypoferrremia and, therefore, blunted bone marrow erythrocyte production.

Management of mild to moderate ACD usually focuses on the underlying disease process. Anemia of chronic disease is not usually progressive or life-threatening, although it generally affects a patient's quality of life. Patients may require blood transfusions for symptomatic anemia. Unless a concurrent deficiency of vitamin B₁₂, folate, or iron exists, administration of vitamin supplements is not of value. Recombinant human EPO (rhEPO) has been used successfully to treat ACD in patients with RA, AIDS, some neoplastic diseases, and chronic kidney disease⁶⁸; however, medication costs can be significant and may outweigh benefits from the treatment of modest anemia.⁷¹ Patients are less likely to respond to rhEPO if baseline serum EPO and inflammatory cytokine levels are elevated. Although serum iron often is decreased, reticuloendothelial iron stores are usually adequate, and treatment with iron is not warranted.⁶⁸

Human Recombinant Erythropoietin Therapy

Human recombinant erythropoietin therapy is indicated for use in anemia associated with end-stage renal disease, drug-induced anemia (chemotherapy and zidovudine therapy), AIDS; in patients with low endogenous EPO levels; and with autologous blood transfusions for elective surgery. Previously, blood transfusions temporarily deterred symptomatic anemia of chronic disease; however, transfusion therapy is associated with risks such as hepatitis, viral infections, iron overload, treatment-related acute lung injury (TRALI), and immunogenic reactions. Studies with rhEPO show that response is both dose dependent and dependent on the underlying cause of anemia.^{72,73} Variables that may predict patient response are both patient specific and disease specific and are not always reliable. For example, response to rhEPO in chronic renal failure is dose related and can vary among patients with chronic renal failure.⁷⁴ Repeated dose escalations may occur during therapy until a desirable hemoglobin response is achieved.^{75,76} Approximately 75% of patients with cancer respond to rhEPO.⁷⁷ Response in this population also is dose related, and therapeutic doses are often higher in those patients than in those with renal failure. Lower rhEPO response rates are seen in patients who have received intensive chemotherapy or radiotherapy.⁷³ In evaluating response to rhEPO, parameters such as increased serum ferritin, decreased transferrin saturation, increased corrected reticulocyte count, decreased transfusion requirements, and increased Hgb and Hct values have been used. Lack of response to rhEPO therapy in all patient populations is most commonly associated with iron deficiency.^{68,78} The ability of rhEPO to stimulate the production of erythrocytes normal in both size and hemoglobin concentration is highly dependent on the availability of functional iron.⁷⁸

Darbepoetin alfa is an erythropoiesis-stimulating protein that differs from rhEPO by the addition of two carbohydrate chains. The significance of the additional carbohydrate chains is an increased sialic acid content that results in decreased clearance, and a serum half-life for darbepoetin alfa that is three times longer than that of rhEPO. These kinetic differences allow darbepoetin alfa to be administered less frequently than rhEPO. Similar to rhEPO, hemoglobin response to darbepoetin is dose related. Most patients with chronic kidney disease^{79,80} and cancer achieve the desired hemoglobin response with

Table 86-8 Therapeutic Uses and Regimens for Recombinant Human Erythropoietin (rhEPO)^a

| Anemia Pathogenesis ^b | Epoetin Alfa ^c | | Darbepoetin Alfa ^c | | Time to Respond (wk) | Overall Response Rate (%) |
|---|------------------------------|--------------------------------------|-------------------------------|---|----------------------|--|
| | Dose (U/kg) | Frequency | Dose(mcg/kg) | Frequency | | |
| Acquired immunodeficiency syndrome (AIDS) | 100 | 3 × /wk | | | 8–12 | 17–35 |
| Chemotherapy-induced malignancy | 150 or 40,000 U (total dose) | 3 × /wk or once a week, respectively | 2.25 or 500 mcg (total dose) | Once a week or once every 3 weeks, respectively | 2–8 | 32–61 ^d 48–83 ^e |
| Renal insufficiency | 50–100 | 3 × /wk | 0.45 | Once a week | 2–8 | 90–97 |

^aAdult dosing: twelve- to sixteen-week course of rhEPO therapy.

^bPatients with AIDS with endogenous erythropoietin levels ≤ 500 U/L; zidovudine dose $\leq 4,200$ mg/wk.

^cModerate dose escalation is indicated if a partial response is observed after 4 to 8 weeks of therapy.

darbepoetin treatment.⁸¹ Table 86-8 illustrates current therapeutic uses of rhEPO and darbepoetin alfa.

Renal Insufficiency-Related Anemia

21. K.S., a 35-year-old man with a 25-year history of diabetes mellitus, is diagnosed with renal failure and placed on hemodialysis three times weekly. One year later, K.S. is noted to have become increasingly transfusion dependent for correction of his anemia. Significant laboratory values include the following: Hgb, 7 g/dL (normal, 14 to 18); Hct, 26% (normal, 42% to 52%); ferritin, 360 ng/mL (normal, 15 to 200); and serum iron, 98 μ g/dL (normal, 50 to 160). In addition, K.S. complains of constant fatigue, poor appetite, and a low energy level. What treatments are available to correct K.S.'s anemia?

[SI units: Hgb, 70 g/L; Hct, 0.26; ferritin, 1265.4 mmol/day; iron, 17.55 μ mol/L]

Unlike the anemia associated with most chronic diseases, the hematocrit of patients with chronic renal failure often is markedly reduced. The cause of the anemia is complex but involves reduced EPO production and a shortened RBC life span. Previously, these patients were treated with transfusions and androgens.⁸² Although effective, repeated transfusions cause complications, such as iron overload, infections, reactions to leukocyte antigens, or the development of cytotoxic antibodies.

Because EPO is secreted in the kidney in response to anoxia and is responsible for normal differentiation of RBC from other stem cells, rhEPO is used to treat anemia in patients with renal failure who are undergoing hemodialysis, and K.S. is a candidate for this therapy. A dose-dependent rise in Hct is observed in patients with end-stage renal disease at a usual dosage range of epoetin alfa 50 to 100 U/kg three times weekly or darbepoetin alfa 0.45 mcg/kg. Patients such as K.S. who have renal insufficiency appear to be predisposed to rhEPO-induced hypertension. Adverse effects include functional iron deficiency preceded by an elevated reticulocyte count and a change in the rate of hematocrit rise.⁸³ Seizures also have been reported in approximately 5% of patients with end-stage renal disease⁷⁵ (also see Chapter 32, Chronic Renal Disease). Targeting higher concentrations of Hgb (> 12 g/dL) are associated with increased mortality and adverse effects.⁸⁴

Malignancy-Related Anemia

22. T.K. is a 45 year-old woman with non-Hodgkin's lymphoma diagnosed 2 months ago. She is being seen for her third of six cycles of chemotherapy. She complains of shortness of breath and fatigue when she walks up stairs. The only medication T.K. takes is ibuprofen 200 mg PRN for occasional headaches. Her CBC indicates the following: Hgb, 9.7 g/dL (normal, 12 to 16); Hct, 29% (normal, 40% to 44%); MCV, 90 μ m³ (normal, 81 to 99); MCHC, 30% (normal, 33% to 37%); serum erythropoietin, 29 U/L (normal, 4 to 26). The peripheral smear shows normochromic and normocytic RBC. What is the most likely cause of T.K.'s anemia? What is the appropriate treatment?

T.K. appears to have malignancy-related anemia, which is often characterized as anemia of chronic disease or is chemotherapy induced. This anemia is generally normocytic and normochromic and develops when a disease has persisted for > 1 to 2 months. Generally, the anemia is mild or moderate, with a limited number of distinguishing characteristics. As with T.K., the anemia is often asymptomatic or mildly symptomatic (weakness, decreased exercise tolerance). RBC hypochromia may or may not be present, and RBC size is generally normal unless the patient has an underlying iron deficiency anemia. The reticulocyte count is usually low or within normal limits. Both the serum iron and TIBC are decreased and transferrin saturation is usually less than normal.⁸⁵ Serum ferritin is a reliable measurement of iron stores in patients with chronic disease. Serum ferritin usually is increased, but may be normal; if the anemia is caused by iron deficiency, ferritin values will be decreased. A bone marrow aspirate would reveal an elevated hemosiderin content. Factors that can influence the incidence of chronic anemia in patients with cancer are the type of malignancy, the stage and duration of disease; the type, schedule and intensity of treatment; and history of prior myelosuppressive chemotherapy or radiation.⁷³ Although the prevalence of malignancy-related anemia is difficult to quantify, about 50% to 60% of patients with non-Hodgkin's lymphoma, multiple myeloma, or treatment for ovarian and lung cancer develop anemia that requires blood transfusions. The myelosuppressive and anemia-inducing effects of platinum agents (e.g., cisplatin, carboplatin), are well known.⁸⁶ These and other myelosuppressive agents are widely used in the treatment of many malignancies,

and patients receiving therapy should be appropriately monitored for the development of anemia. Anemia of chronic disease does not respond to treatment with iron, vitamin B₁₂, or folic acid, unless there is an associated vitamin deficiency. Therapy is directed at treatment of the underlying disease, if possible. Large, randomized, multicenter trials have failed to show a clinical benefit to using erythropoietic stimulating agents (ESA) in anemia which is not chemotherapy-induced.⁸⁷ Furthermore, mortality was either increased or trended in that direction in recent trials of anemic patients with head, neck, breast, and lung cancer receiving ESA.⁸⁸ Because of these findings, a black-box warning was added to epoetin alfa and darbepoetin alfa product information to advise about increases in serious adverse events or disease progression for these patient populations.⁸⁹⁻⁹¹ ESA are not recommended for anemic patients with cancer who are not receiving chemotherapy or radiotherapy.⁸⁹⁻⁹¹

In T.K.'s case, the clinician may choose from a number of anemia management options. For example, the current course of chemotherapy can be delayed to allow for hematologic recovery and resolution of anemia symptoms. Alternatively, an RBC transfusion can be given to relieve her symptoms and allow her to better tolerate chemotherapy. In addition, erythropoietic therapy with epoetin alfa or darbepoetin alfa also should be considered. Treatment with epoetin alfa or darbepoetin alfa increases Hct and Hgb, decreases the need for blood transfusions, and improves quality of life. In clinical studies, response rates are 70% to 80%. Therapy is very well tolerated, with most adverse events being attributable to chemotherapy or the underlying disease. Unlike in the chronic kidney disease population, hypertension is infrequently experienced in patients with cancer.⁹²⁻⁹⁴

If treatment with epoetin alfa is desired for T.K., therapy can be administered at an initial dose of 150 U/kg subcutaneously three times a week.⁹⁵ Alternative dosing regimens, such as 10,000 U three times a week or 40,000 U once a week, have proved to be safe and effective in terms of hematopoietic, quality of life, and transfusion effects.^{93,96} Response can be assessed initially by monitoring the reticulocyte count, which should peak by day 10 of treatment. A positive rhEPO response also can be predicted by observation of an increased serum ferritin and decreased transferrin saturation. Epoetin alfa usually is administered for a minimum of 4 weeks, although an increase in Hgb and Hct values should be noted after 2 to 4 weeks. If no hematopoietic response (increase in Hgb by 1 to 2 g/dL) is noted by the fourth to eighth weeks, an additional 4 to 8 weeks of therapy should be considered at an increased dose.⁹⁷ Common dose escalation schedules include 300 U/kg three times a week if initially treated with 150 U/kg three times a week dosing^{97,98} or 60,000 U once a week if initially on 40,000 U once a week dosing.⁹⁹ The most common cause of nonresponse to erythropoietic therapy is iron deficiency. Functional iron deficiency occurs when iron stores are unable to be mobilized at a rate sufficient to satisfy the increased demand brought about by amplified bone marrow activity, which occurs with erythropoietic therapy.⁹⁷ Nonresponders should be evaluated for functional iron deficiency and given iron supplement, as appropriate, at any point during erythropoietic therapy. For those who do not respond despite appropriate dose modifications, continuation of therapy for >6 to 8 weeks is not beneficial.¹⁰⁰ Once hemoglobin and hematocrit parameters have increased

sufficiently to relieve symptoms, the epoetin alfa dose should be reduced every 2 to 3 weeks until the lowest dose required to maintain these levels has been reached. In addition to laboratory monitoring, patients should be asked about their symptoms, such as fatigue, exercise tolerance, and quality of life at frequent intervals while on therapy.

Darbepoetin alfa is also a treatment option for T.K. Initial dosing of darbepoetin alfa is 2.25 mcg/kg subcutaneously once a week.⁸¹ Also, clinical studies of darbepoetin 200 mcg administered every 2 weeks and 300 mcg or 500 mcg administered every 3 weeks have reported beneficial hematopoietic effects and decreased transfusion requirements.^{93,94,101} Therapy response should be monitored in the same manner as epoetin alfa, with dose escalation considered after 6 weeks of therapy for nonresponders.⁷⁶

AIDS-Related Anemia

23. J.M., a 37-year-old man, is currently calling his primary physician with complaints of acute worsening of shortness of breath and pounding in his chest. J.M. has a known history of AIDS and has had recent episodes of *Pneumocystis carinii* pneumonia (PCP) and cytomegalovirus (CMV) esophagitis. J.M. also has complained of frequent diarrhea. Trimethoprim-sulfamethoxazole was given intravenously for treatment of PCP; however, J.M. complained of fever while on maintenance therapy. J.M. is currently taking the following medications: dapsone 100 mg/day PO for PCP prophylaxis, ganciclovir 325 mg IV Monday through Friday for CMV prophylaxis, indinavir 800 mg PO Q 8 hours, lamivudine 150 mg PO BID, zidovudine 300 mg PO BID, fluconazole 100 mg/day PO PRN for thrush, and Imodium liquid 5 mL PRN for diarrhea.

The only remarkable findings on physical examination include a respiratory rate of 24 breaths/min and a heart rate of 120 beats/minute. A chest examination reveals that J.M. is tachypneic and has bilateral dry rales. The Hickman catheter in the left subclavian vein appears dry and clean. Further workup of J.M.'s illness includes an unremarkable chest radiograph and negative cultures of the blood and sputum. The CBC includes normal WBC and platelet counts. Abnormal values include the RBC count of 3,300/mm³ (normal, 4,500 to 6,200), Hgb of 9.1 mg/dL, Hct of 28% (normal, 42% to 54%), and a CD4 of 387 cells/mm² (normal, 440 to 1,600). The morphology of the RBC was moderately anisocytic, normochromic, and normocytic. What factors can contribute to J.M.'s anemia?

[SI units: RBC count, $3.3 \times 10^9/L$ (normal, 4.5 to 6.2); Hgb, 91 g/L; Hct, 0.28 (normal, 0.42 to 0.54)]

Anemia occurs in >70% of patients with AIDS and correlates with the severity of the clinical syndrome.¹⁰² In this patient population, anemia is a risk factor for early death.¹⁰² Common symptoms such as fatigue, breathlessness, and difficulties in mental concentration may contribute to this patient population's decreased quality of life.¹⁰³ Antibody responses against RBC have been documented in patients with AIDS,¹⁰⁴ although their role in the pathogenesis of AIDS has been challenged (see Chapter 69, Pharmacotherapy of Human Immunodeficiency Virus Infection, and Chapter 70, Opportunistic Infections in HIV-Infected Patients). Anemia occurs more often in patients with opportunistic infections (*Mycobacterium avium intracellulare*, *Cryptococcus neoformans*, and *Histoplasma*

capsulatum), viruses (CMV, herpes simplex viruses type 1 and 2, and parvovirus B-19), or neoplasms.¹⁰⁵ Approximately 1% of all AIDS-related anemias are related to parvovirus and can be treated and reversed with IV gammaglobulin.¹⁰⁶ Enhanced production of cytokines, such as TNF- α , also may be correlated with hematologic abnormalities.⁶⁹ Anemia can be a consequence of various human immunodeficiency virus (HIV) drugs (e.g., zidovudine, zalcitabine, didanosine, lamivudine)^{107–109} or other drugs often used to treat AIDS-associated illnesses (e.g., bone marrow suppressive chemotherapy, ganciclovir, trimethoprim-sulfamethoxazole, dapsone).⁴³ Kaposi's sarcoma and lymphoma, which impair normal bone marrow function, also can result in anemia in this population.

Iron stores usually are adequate in patients with AIDS; yet, the characteristics of anemia are similar to those present in anemia of chronic disease: low serum iron and iron-binding capacity or an elevated serum ferritin. Vitamin B₁₂ deficiency is a contributing cause to anemia in 15% to 30% of these patients^{110–112} and is correlated with progression to AIDS.¹¹³ Vitamin B₁₂ malabsorption can result from HIV-infected mononuclear cells within the lamina propria¹¹⁴ or abnormal binding of vitamin B₁₂ to transport proteins. Alterations in the utilization of vitamin B₁₂ and folate^{110,115} can place a patient at risk for hematologic toxicity of drugs such as zidovudine and trimethoprim. Patients with AIDS generally do not respond to vitamin B₁₂ supplementation, however.¹¹⁶

As illustrated by J.M., HIV-associated anemia has a characteristic RBC morphology, which is normochromic and normocytic. Mild anisocytosis and poikilocytosis also may be observed. Zidovudine-associated anemia is typically macrocytic.¹¹⁷

Erythropoiesis is often defective in patients with AIDS, as reflected by an inappropriately low reticulocyte count and an increased or blunted erythropoietic response for the degree of anemia.^{118,119} Treatment with rhEPO therapy increases the quality of life and Hgb in HIV-infected adult patients regardless of zidovudine use, CD4+ count, or viral load.¹²⁰

J.M. has many risk factors for anemia of chronic disease, including AIDS and its accompanying predisposition

to malignancy and infection. He is also taking many medications (ganciclovir, zidovudine, and dapsone) that can induce anemia.

24. J.M.'s physician determines that J.M.'s endogenous erythropoietin level is 737 U/L (normal, 4 to 26). Is J.M. a candidate for rhEPO? How can the best response to rhEPO be predicted? What would an appropriate starting dosing regimen be?

Patients taking zidovudine ($\leq 4,200$ mg/week) who have baseline EPO levels < 500 IU/L experience a significantly higher rate of increase in hematocrit compared with patients with high baseline EPO levels.¹²¹ A patient who develops macrocytic anemia with moderate EPO response (< 500 IU/L) may require moderate transfusion support in response to zidovudine. A patient who develops normocytic anemia with a high EPO response (> 500 IU/L) may have substantial transfusion requirements.¹²² A significant reduction in transfusion requirements has been observed in those patients with macrocytic anemia with moderate EPO response who are given rhEPO 40,000 U subcutaneously once weekly. Therefore, rhEPO may be considered appropriate treatment for patients whose baseline EPO level is < 500 IU/L.

J.M.'s anemia is less likely to respond to rhEPO than patients who have endogenous EPO levels < 500 U/L. (Note: Although this level far exceeds normal, high values are often seen in anemias of chronic disease.) An rhEPO trial of therapy may be initiated at 40,000 U once weekly. J.M. should be followed by evaluating his RBC indices in another 6 to 8 weeks. If he responds appropriately, the rhEPO dosage may be decreased to the lowest dose necessary to prevent symptoms or RBC transfusions. If J.M. has not responded after 4 weeks of therapy, the dose should be increased to 60,000 U once weekly.¹²³ If J.M. does not respond to 60,000 U, it is unlikely that he will benefit from further rhEPO therapy.

ACKNOWLEDGMENT

We gratefully acknowledge Ann Bolinger, Jim Koeller, Carla Van Den Berg, and Dan Bestul for their contributions to this chapter.

DRUG-INDUCED AUTOIMMUNE PURE RED CELL APLASIA 87-16

Definitions 87-16
Exogenous Epoetin and Pure Red Cell Aplasia 87-16

OVERVIEW**Definitions**

Drug-induced injuries of the blood are termed *blood dyscrasias*. In this chapter, blood dyscrasias refer to adverse effects that usually are not predictable or are not a direct extension of a drug's pharmacologic action, and they occur in an unknown, although usually small, number of persons exposed to the agent in question. Thus, the decrease in white blood cell (WBC) count that is seen in many patients receiving marrow suppressant cancer chemotherapy would not be considered a blood dyscrasia. The same reaction in someone receiving phenytoin for a seizure disorder would be considered a blood dyscrasia. Exceptions exist and are addressed as necessary. The five major types of drug-induced blood dyscrasias presented are (a) hemolytic anemia, (b) thrombocytopenia, (c) agranulocytosis or neutropenia, (d) aplastic anemia, and (e) pure red cell aplasia. A consensus conference proposed standardized definitions and general criteria for drug-induced blood dyscrasias.¹ These definitions are discussed in specific sections of the chapter. Older reports have used similar, although

not necessarily identical definitions and criteria, and not all authors have adopted these standards.

Epidemiology

One study suggests that a substantial proportion of blood dyscrasias could be attributable to drug treatment.² Accurate estimates of the incidence of drug-induced injuries, including drug-induced blood dyscrasias, are generally not obtainable. Controlled clinical trials provide incidence estimates of common adverse reactions; however, rare, serious events might not be detected because of the relatively small number of subjects exposed to drugs in clinical trials.

Adverse drug reaction reporting systems such as the U.S. Food and Drug Administration's (FDA) Medwatch program rely on spontaneous reports by health professionals and patients, and do not capture all adverse events. Thus, spontaneous reports cannot provide a reliable numerator for calculating the incidence of adverse reactions. Likewise, prescription sales data used to approximate a denominator in an incidence calculation can only estimate the true number of persons exposed to a drug.

Under-reporting is a widely recognized problem in postmarketing adverse reaction reporting systems. Studies have documented that only 10% to 15% of serious adverse reactions are reported.^{3,4}

Spontaneous reporting systems by themselves do not give an accurate insight into the incidence of adverse drug reactions, and often spontaneous adverse event reporting rates are misinterpreted as the incidence of adverse reactions.

The FDA has addressed the misinterpretation of event reporting rates in some drug safety labeling changes. For example, thrombotic thrombocytopenic purpura (TTP) was not seen during clinical trials with the antiplatelet drug ticlopidine (Ticlid), but U.S. physicians reported approximately 100 cases between 1992 and 1997. Based on an estimated patient exposure of 2 to 4 million, and assuming an event reporting rate of 10% (the true rate is not known), the incidence of ticlopidine-associated TTP could be as high as 1 case in every 2,000 to 4,000 patients exposed to the drug.⁵

Spontaneous reporting of suspected drug-induced blood dyscrasias is of greatest value in hypothesis generation and for the detection of new associations. Under specific conditions, spontaneous reports analyzed with prescription sales data can give a fairly accurate estimate of the relative and absolute risk. Calculating the risk using exposure data expressed in patient years might underestimate the risk for long-term treatment. For example, if the risk is highest during the first 3 months of treatment the denominator will include a long period of low risk. On the other hand, risk could be overestimated for short-term treatment when the number of prescriptions is probably a less inaccurate denominator.

In addition to under-reporting, selective reporting is another problem. As a result, spontaneous reports are particularly vulnerable to bias when comparing risks with different drugs within a class or between drug classes. Comparative risk estimates, although vital, are complicated when old drugs are compared with new drugs. In situations when the risk is higher at the beginning of treatment, a population treated with a new drug will always contain a higher proportion of vulnerable patients than those who have tolerated an older drug over time. The best comparison in such cases is to include only first-time users in both groups.⁶

For these reasons, spontaneous reporting data must be interpreted with caution. Spontaneous reporting systems have been developed for signal generation and, thus, must sacrifice specificity for sensitivity. This can lead to possible false associations. Moreover, some well-known associations (e.g., heparin and thrombocytopenia) are not reported because the association already has been established. Voluntary reporting of suspected drug-induced blood dyscrasia and other adverse drug events to the FDA is critical to the prompt identification of drug-induced safety-related problems.

DRUG-INDUCED HEMOLYTIC ANEMIA

Drug-induced hemolysis refers to an increased rate of red cell destruction, caused directly or indirectly by a drug. Destruction can occur within the blood vessels (intravascular hemolysis) or outside the vascular space (extravascular hemolysis). Anemia develops when the rate of hemolysis exceeds the rate that bone marrow is capable of replacing destroyed cells.

Drugs can induce red cell destruction by several mechanisms. The first is by a direct toxic effect on cells as a result

of genetically determined enzymopathies or hemoglobinopathies. The red blood cells (RBC) of patients with these inherited abnormalities are predisposed to lysis when exposed to drugs or chemicals that would otherwise not have any predictable toxic effect. Second, several drugs can elicit an immune response that results in destruction of normal RBC. This occurs idiosyncratically (i.e., patients cannot be identified prospectively as being predisposed).⁷

More than 70 drugs are known to cause either positive direct antiglobulin tests (DAT) or immune hemolysis. Second- and third-generation cephalosporins, diclofenac, fludarabine, carboplatin, oxaliplatin, and β -lactamase inhibitors are among the drugs associated with severe or fatal hemolysis.^{8,9}

Intravascular Hemolysis

Many drug-induced hemolytic anemias related to genetically determined red cell defects, as well as some classified as immune-mediated, are caused by destruction of RBC within the vessels. Free hemoglobin, a potentially nephrotoxic substance, is released into the bloodstream. The amount of hemoglobin released from erythrocytes during extensive hemolysis overwhelms the mechanisms that usually are capable of efficiently removing hemoglobin (Hgb) from the circulation. Free Hgb initially binds tightly to haptoglobin, a circulating α -globulin. The resulting hemoglobin-haptoglobin complex is too large to be filtered at the glomerulus and is removed from the circulation by the fixed macrophages of the reticuloendothelial system. This occurs primarily in the liver, where the heme portion of the hemoglobin molecule is converted to bilirubin, iron is conserved, and serum levels of haptoglobin fall. Laboratory changes characteristic of hepatic hemoglobin and bilirubin metabolism resulting from extravascular hemolysis (e.g., hyperbilirubinemia, urobilinogenuria) also are observed. If the hemoglobin-binding capacity of haptoglobin is exceeded, either by an acute, severe, or ongoing hemolysis, some hemoglobin will be renally filtered.

The cells of the proximal tubule reabsorb hemoglobin, but as in the case of glucose, there is a threshold concentration beyond which free hemoglobin will spill into the urine. The reabsorbed hemoglobin is degraded to bilirubin and the iron is converted to ferritin and hemosiderin. Bilirubin could appear in the urine and, as the hemoglobin-injured tubular cells slough, so will hemosiderin. Hemoglobin not bound to haptoglobin or filtered at the glomerulus is metabolized to methemoglobin, the heme moiety of which can then dissociate and bind to the circulating β -globulin, hemopexin. In severe hemolysis, the heme moiety of methemoglobin binds with circulating albumin to form methemalbumin; serum hemopexin levels will decrease and methemalbumin will be detectable in the serum. Heme dissociates from albumin and binds to newly synthesized hemopexin as depleted hemopexin supplies are replaced (Fig. 87-1).

Extravascular Hemolysis

Most immune-mediated, drug-induced RBC destruction occurs extravascularly. Reticuloendothelial cells phagocytize the RBC. The heme portion of hemoglobin is metabolized to unconjugated (indirect) bilirubin, which complexes loosely with albumin in the bloodstream and is transported to the liver where it is conjugated with glucuronic acid. When the

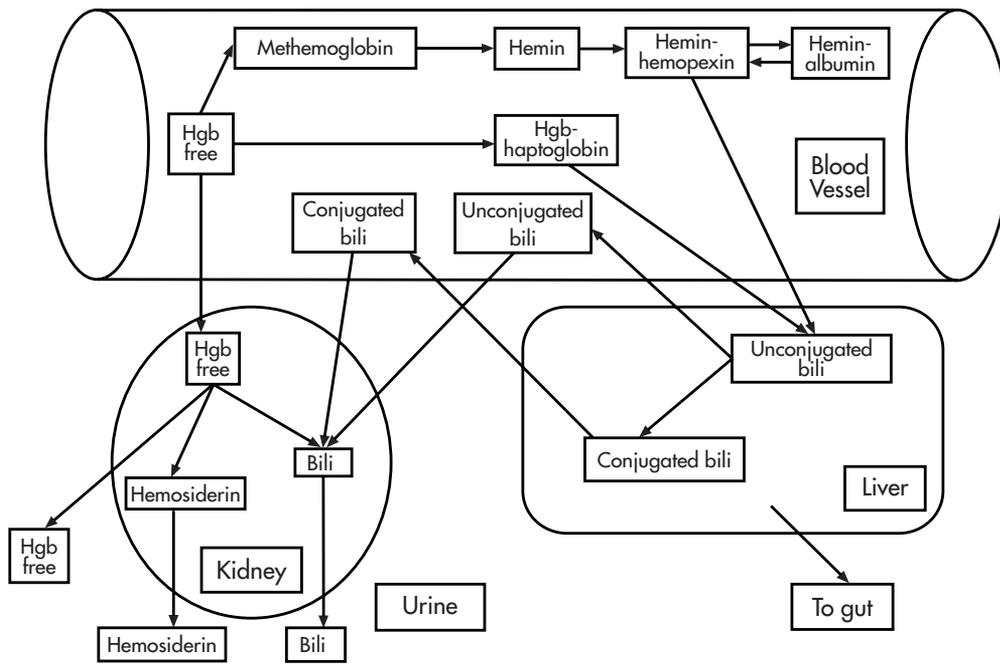

FIGURE 87-1 Intravascular hemolysis. (See Figure 2-1 in Chapter 2, Interpretation of Clinical Laboratory Tests, for bilirubin metabolism after secretion into the gut.)

increased rate of bilirubin formation exceeds the ability of the liver to conjugate it, the serum concentration of indirect bilirubin increases and clinical jaundice can result. The conjugated (direct) bilirubin is passed from the liver to the intestine where it is metabolized to urobilinogen. Most urobilinogen is excreted in the feces, but part is reabsorbed and enterohepatically recycled with some urobilinogen appearing in the urine (also see Fig. 2-1 in Chapter 2, Interpretation of Clinical Laboratory Tests).

Glucose-6-Phosphate Dehydrogenase Deficiency

Etiology

Red blood cells deficient in glucose-6-phosphate dehydrogenase (G6PD) are susceptible to hemolysis when exposed to oxidative stress. The hexose monophosphate shunt in RBC is responsible for maintaining glutathione in the reduced state. Glutathione is an antioxidant that prevents oxidation of hemoglobin to methemoglobin. Nicotinamide adenine dinucleotide phosphate-oxidase (NADPH) is required to keep glu-

tathione in the reduced state and G6PD is needed to reduce NADP to NADPH (Fig. 87-2). When RBC are deficient in G6PD, the amount of NADPH is inadequate to keep glutathione in the reduced state, free radicals accumulate intracellularly, and the oxidation of hemoglobin to methemoglobin cannot be prevented. Heinz bodies (condensations of precipitated, denatured hemoglobin) appear in the RBC. The now fragile cells are removed from the circulation (lysed) prematurely, primarily while passing through the splenic pulp. It is unclear whether methemoglobin contributes to Heinz body formation or is merely a concomitant occurrence. The degree of hemolysis is related both to the oxidant potential of the drug and the dose.¹⁰

Epidemiology

Deficiency of G6PD is the most common metabolic disorder of RBC and it has been estimated to affect over 400 million individuals worldwide.¹¹ The disorder is sex linked with transmission from mother to son. Although the defect will be fully expressed in males, female heterozygotes have a mix

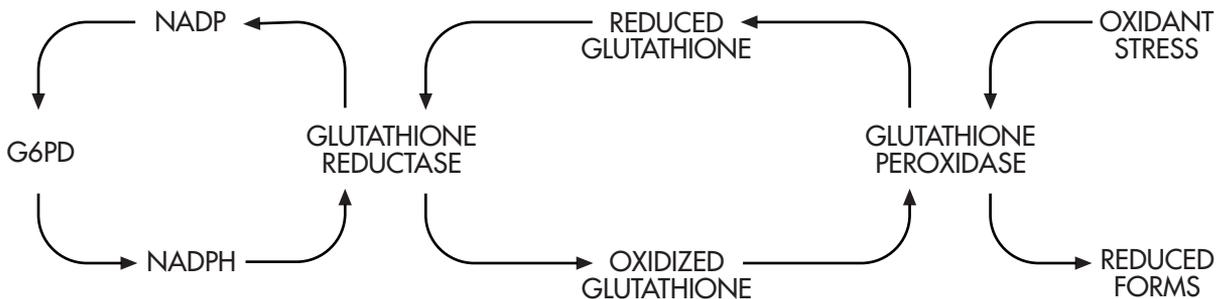

FIGURE 87-2 Nicotinamide adenine dinucleotide phosphate-oxidase (NADPH) is required to keep glutathione in the reduced state, and glucose-6-phosphate dehydrogenase (G6PD) is needed to reduce NADP to NADPH.

of both normal and deficient RBC and correspondingly less severe manifestations of disease. Many variant forms of the enzyme have been identified, but the two most common are the A-type (African) and the Mediterranean type. The less severe A-variant affects about 10% of American blacks. G6PD activity in the A-type usually is 5% to 15% of normal. In this situation, patients remain asymptomatic except for episodes of hemolysis precipitated by oxidant stress. Mediterranean-type deficiency is associated with low levels of G6PD enzyme activity (e.g., in some patients <1% of normal). The RBC are more susceptible to lysis in those with Mediterranean deficiency than those with A-type deficiency. The more severe forms of G6PD deficiency are most prevalent in people of southern European ancestry, particularly Sardinian Italians, Greeks, and Kurdish Jews in whom the prevalence is approximately 50%.¹² Other groups affected by G6PD variants include Sephardic Jews, American Indians, and those of Asian or Arabian ancestry.¹³ Cases have been reported rarely in western European and Scandinavian populations.

Classification

Deficiency of G6PD is genetically heterogeneous and about 400 different enzyme mutations have been reported.¹² The World Health Organization (WHO) has established criteria to categorize different variant enzymes into five classes. Class I variants are associated with chronic nonspherocytic hemolytic anemia (CNSHA); class II variants have a G6PD activity of <10% of normal; class III variants have an activity of 10% to 60% of normal; class IV variants have near-normal activity and no clinical manifestations; and class V variants have increased activity.¹⁴ The degree of hemolysis in all classes is related both to the degree of enzyme deficiency and the strength of the precipitating stimulus.

In the case of drugs, both the oxidant potential of the drug and the dose contribute to severity. Even topical administration of 1% silver sulfadiazine in a patient with extensive burns and 10% G6PD activity has resulted in significant RBC destruction.¹⁵ Nondrug inducers of hemolysis include infection, diabetic ketoacidosis, unknown factors during the neonatal period, and ingestion of fava beans. Fava beans (*Vicia faba*), also known as broad beans, are a common dietary staple in some parts of the world and can cause severe hemolysis in some G6PD-deficient patients.

Features

1. F.S., a 55-year-old, Italian-American man, noted suprapubic pain and burning on urination. Laboratory data included the following values: Hgb, 14.0 g/dL (normal, 12–16 g/dL); hematocrit (Hct), 43.6% (normal, 38%–48%); WBC count, 7,500/mm³ (normal, 4,000–11,000/mm³); reticulocyte count, 0.5% (normal, 0.2%–2.0%); and normal serum electrolytes, bilirubin, prothrombin time (PT), and activated partial thromboplastin time (aPPT). Urinalysis (UA) was notable for 20 to 50 WBC/per high-power field (HPF) and moderate bacteria. A tentative diagnosis of cystitis was attributed to prostatic hypertrophy. Urine was sent for culture, and F.S. was given a prescription for co-trimoxazole (Bactrim, Septra) one double-strength tablet twice daily (BID).

Four days later, F.S. returned to the clinic noting that, although his original symptoms had resolved, he was experiencing tiredness and that his urine had become dark. Current laboratory

values are as follows: Hgb, 9.9 g/dL; Hct, 32.5%; WBC count, 9,100/mm³; corrected reticulocyte count, 11%; total bilirubin, 3.8 mg/dL (normal, <1.0 mg/dL); and direct bilirubin, 0.7 mg/dL (normal, <1.0 mg/dL). UA now reveals 0 to 5 WBC/HPF, no bacteria, and 4% blood. The urine also is positive for bilirubin and urobilinogen. Physical examination is unremarkable except for scleral icterus and a mild tachycardia.

How is the clinical picture of F.S. compatible with drug-induced hemolysis caused by G6PD deficiency?

[SI units: Hgb, 140 g/dL and 99 g/dL, respectively (normal, 120–160); Hct, 0.436 l and 0.325 l, respectively (normal, 0.36–0.48); WBC, 7.5×10^9 L and 9.1×10^9 L, respectively (normal, 4.0–11.0); reticulocytes, 0.005 and 0.11, respectively (normal, 0.001–0.024); bilirubin, 65 μ mol/L (total), 12 (direct)]

This clinical picture in a man of Mediterranean descent is strongly suggestive for sulfamethoxazole-induced hemolysis caused by G6PD deficiency. F.S.'s asymptomatic hemolysis began 1 to 4 days after the drug was begun. F.S.'s serum hemoglobin concentration began to fall and his urine became dark secondary to increased levels of urobilinogen. In severe cases, weakness and abdominal or back pain may occur and the urine may become nearly black (because of pyrolic substances produced from degradation of Heinz bodies). As F.S.'s levels of indirect bilirubin rise, the presence of scleral icterus is noted. Reticulocytosis is evident and could be attributed to the body's attempt to increase RBC production. In patients with class III deficiency, the hemoglobin will begin to rise toward normal in about 1 week because the younger RBC with greater G6PD activity begin replacing the older, hemolysed RBC. Even with continued drug ingestion, symptoms, if any, resolve and the appearance of the urine becomes normal. With class II deficiency, even the younger RBC are destroyed and significant hemolysis with anemia continues unless the drug is stopped. A G6PD deficiency can be confirmed by assaying G6PD activity. In F.S.'s case, it is too early to determine with certainty the outcome if the drug were to be continued; the prudent course would be to discontinue the co-trimoxazole and substitute an appropriate nonoxidant agent. A cephalosporin or quinolone antibiotic is a possible alternative; at this point, culture results should be available and can be used to guide therapy.

2. Why did F.S.'s urine test positive for blood when no RBC were present?

The urine tests for blood are based on the ability to detect hemoglobin even after some or all of the RBC have disintegrated and are no longer visible microscopically on HPF. Therefore, hemoglobin in the urine will result in a positive urine test for blood. In this case, a positive test for hemoglobin in the absence of RBC helps differentiate hemoglobinuria caused by hemolysis from true hematuria.

Drugs

3. F.S. expresses surprise when he is informed of this reaction to co-trimoxazole, because he has taken sulfa drugs in the past without difficulty. Do all sulfa drugs have the same potential for inducing hemolysis in patients with G6PD deficiency?

Many oxidant drugs have been reported to cause hemolysis in G6PD-deficient patients. In many cases, causality has not been well established. Several drugs, particularly antipyretic and antibiotic agents, have been implicated in causing

Table 87-1 Drugs and Chemicals Associated With Hemolysis in G6PD Deficiency

hemolysis when, in fact, hemolysis may have been precipitated by the infections for which the drugs were prescribed. Other drugs have been implicated through the use of in vitro enzyme stability tests. The response of RBC in this enzyme stability test does not necessarily correlate with significant in vivo hemolysis, and this test also fails to measure the effect of drug metabolites. The most reliable method of testing for hemolytic potency is to administer the drug in question to normal volunteers who have been infused with Chromium (Cr)-labeled G6PD-deficient RBC.¹¹

Drug-induced hemolysis in G6PD-deficient patients can be somewhat confusing. Sulfamethoxazole, alone or in combination as co-trimoxazole, causes hemolysis in class II deficiency, but class III-deficient patients may be at low risk if the daily dose is 3.2 g or less.¹⁶ Sulfisoxazole does not cause significant hemolysis at usually prescribed doses. Therefore, F.S.'s hemolytic response to sulfamethoxazole, but not to sulfisoxazole, is consistent with existing data. Table 87-1 lists other drugs associated with significant hemolysis.

Management

4. How should F.S.'s G6PD deficiency be treated?

Other than discontinuation and avoidance of drugs and substances known to cause hemolysis, no specific therapy exists for G6PD deficiency. If hemolysis is severe, RBC transfusion may be necessary. The patient should be well hydrated to maintain a good urine flow to prevent or attenuate renal toxicity from hemoglobin. Vitamin E and oral selenium have been suggested as possible treatments for G6PD deficiency; however, neither has proved of value.¹² F.S. should be cautioned regarding his G6PD deficiency and the deleterious effects of certain drugs.

Immune Hemolytic Anemia

Drug molecules are potentially antigenic, but they are generally too small to elicit antibody production by themselves. They can, however, serve as haptens and be immunogenic when combined with some larger molecules (e.g., cell membranes, circulating proteins). Likewise, drug metabolites, particularly highly reactive metabolites, can act as haptens (e.g., penicillin and its penicilloyl by-product).¹⁷ Diclofenac has been associated with reports of immune hemolytic anemia and less frequently with immune thrombocytopenia.¹⁸ A metabolite of diclofenac has also been identified as a cause of acute immune hemolytic anemia.^{19,20}

Coombs' Test (Antiglobulin Test)

5. R.L., a 53-year-old man, is admitted with gas gangrene of the left leg. His leg was amputated below the knee, and he was given gentamicin 120 mg every 8 hours and penicillin G 4,000,000 units every 4 hours along with aggressive local care. On the ninth hospital day, his Hct was 30%, decreased from 41% 4 days previously. No signs of bleeding were found. Further evaluation revealed a corrected reticulocyte count of 8% (no baseline drawn), elevated indirect bilirubin, and a positive direct Coombs' test. What is the significance of a positive DAT or Coombs' test in R.L.?

[SI units: Hct, 0.3 l and 0.41 l, respectively; reticulocytes, 0.08 l]

The Coombs', or antiglobulin, test can detect both antibody coating of RBC and circulating immunoglobulins directed against RBC. A DAT is the most important laboratory test in establishing immune hemolysis. The result of this test will direct further investigation. A positive DAT supports, but does not prove, an immune-mediated hemolytic process. The DAT detects IgG class immunoglobulin or complement, or both, on RBC. As few as 100 to 200 molecules of IgG per RBC can be detected by the laboratory. The DAT may be negative even when the patient is hemolyzing, if there are <150 IgG molecules per RBC. Polyspecific antiglobulin serum must be used for the initial DAT to allow detection of both IgG and complement. If the DAT is positive, subsequent testing with monospecific anti-IgG and anti-C3 should be performed. Positive anti-IgG or IgG + C3 indicates warm autoimmune hemolytic anemia. Positive anti-C3 only indicates either drug-induced hemolytic anemia or cold autoimmune hemolytic anemia.²¹

The DAT does not tell whether hemolysis is occurring and, in fact, several drugs, including R.L.'s penicillin, are known to cause a positive test without significant RBC destruction.

Mechanisms

6. How does penicillin cause hemolytic anemia? Why is R.L.'s penicillin a likely cause of his anemia?

The three basic mechanisms by which drugs are thought to cause immunologic hemolytic anemia are (a) a high-affinity hapten-type reaction; (b) a reaction precipitated by low-affinity binding to RBC, either via a low-affinity hapten-type reaction or by circulating immune complex formation, also known as an *innocent bystander reaction*; and (c) an autoimmune reaction (Table 87-2). Because R.L. is receiving 24 million units of penicillin per day, his hemolytic anemia is likely caused by penicillin.

HIGH-AFFINITY HAPTEN-TYPE REACTION: PENICILLIN

Penicillin is the prototype for the high-affinity hapten-type of immunologic drug-induced hemolytic anemia. Penicillin and penicillin metabolites bind strongly to the RBC membrane in a dose-related fashion and are detectable on the cells of nearly all patients receiving >10 million units/day²² or when penicillin blood levels are high (e.g., presence of diminished renal function). About 3% of patients receiving high-dose penicillin will produce IgG directed against the penicillin-membrane complex as detected by a positive Coombs' test.²³ Antibody-coated RBC in a small number of cases are then recognized and destroyed in significant numbers extravascularly by the macrophages of the reticuloendothelial

Table 87-2 Drug-Induced Immunologic Hemolytic Anemia

| Mechanism | Process | Common Drugs | Comment |
|---|---|---|---|
| High-affinity hapten-type reaction | Drug binds tightly to RBC membrane surface; immunoglobulins then form against the drug-membrane complex | Cephalosporins, penicillin, tetracycline | Penicillin is the classic prototype of this dose-related reaction |
| Low-affinity hapten-type reaction or immune complex formation | Drug binds to either (a) low-affinity specific antigenic loci on the cell membrane or (b) to circulating proteins to form an immune complex that adheres loosely to RBC. Lysis via complement activation ensues | Acetaminophen, ASA, chlorpromazine, chlorpropamide, hydrochlorothiazide, INH, PAS, phenacetin, probenecid, quinidine, quinine, rifampin, sulfonamides | Subsequent to hemolysis, the drug or immune complex dissociates from RBC fragments, adheres to another RBC, and repeats the process. Small doses can cause large-scale hemolysis. Quinidine is the prototype drug |
| Autoimmune reaction | Drug stimulates production of anti-RBC antibodies. Autoantibodies coat RBC and extravascular lysis occurs | Levodopa, mefenamic acid, methyldopa, procainamide, ceftriaxone, cefotetan | Methyldopa is the prototype drug for autoimmune hemolysis |

ASA, acetylsalicylic acid; INH, isoniazid; PAS, para-aminosalicylate sodium; RBC, red blood cell.

system, primarily in the spleen.²⁴ Other drugs reported to produce high-affinity hapten-type hemolysis, although much less frequently than penicillin, are tetracycline and tolbutamide.

First-generation cephalosporins (e.g., cephalothin) infrequently have been reported to cause immune hemolytic anemia. Severe, sometimes fatal, immune hemolytic anemia has been associated with second- and third-generation cephalosporins,²⁵ especially cefotetan.²⁶

Of 43 cases of drug-induced immune hemolytic anemia that were referred to a single laboratory for investigation over 8 years, 38 were found to be caused by a cephalosporin (35 by cefotetan, 3 by ceftriaxone). Of the 38 cases, 11 (29%) resulted in fatal immune hemolytic anemia; 8 deaths were caused by cefotetan and 3 by ceftriaxone. The fatal cases were sometimes associated with either renal failure or disseminated intravascular coagulation, or both.²⁶

The possibility of cefotetan-induced immune hemolytic anemia should be investigated in any patients (particularly healthy young women) who have received prophylactic cefotetan and experienced unexpected anemia after gynecologic or obstetric procedures.

7. Has R.L.'s clinical course been consistent with penicillin-induced hemolytic anemia, and how quickly will the problem resolve once the drug is discontinued?

R.L.'s case is consistent with penicillin-induced hemolytic anemia. Anemia is subacute in onset, usually developing after 7 to 10 days of high-dose therapy. R.L.'s anemia developed after 9 days of treatment. In most cases, no other signs suggest an allergic reaction, and other cell lines rarely are involved. R.L.'s laboratory values are typical of those seen in extravascular hemolysis. The DAT is strongly positive, and the indirect antiglobulin test (IAT) is positive only for penicillin. Hemolysis of decreasing severity can continue for some time after the drug is discontinued, probably because of cell-bound penicillin.

LOW-AFFINITY BINDING: QUINIDINE

Mechanisms

8. H.J. is a 63-year-old woman whose physician prescribed quinidine sulfate 200 mg QID for an "irregular heartbeat." She

has taken quinidine for this problem in the past, but stopped taking it 6 months ago. She comes to the emergency department (ED) today with fever, chills, and shakes. H.J. is found to have an Hct of 24%, and her urine tests positive for blood. What drug-induced problem is compatible with this picture?

[SI unit: Hct, 0.24]

The second mechanism by which drugs cause immune hemolysis is through a low-affinity binding process. The classic explanation for this type of hemolysis involves the binding of the offending drug, or drug metabolite, to circulating serum proteins to form a complete antigen. Antibodies, usually IgM, are produced and combine with this antigen to create a circulating immune complex. This immune complex, in turn, is adsorbed onto the surface of an RBC, where it triggers activation of complement. The RBC is lysed and the immune complex, which has a low affinity for the cell membrane, dissociates and goes on to a second RBC to repeat the process. It is this "recycling" of the drug-antibody complex that explains why only small doses of drug are needed to cause large scale hemolysis in previously sensitized patients. Because antibodies are not directed against the cell itself, the RBC is destroyed as an innocent bystander, and thus this immune complex-mediated cell destruction has been termed an innocent bystander reaction. The direct Coombs' test is positive only against complement because washing will remove the immune complexes from the cells.

H.J.'s quinidine is the prototype drug for the immune-complex form of immunologic hemolytic anemia. The innocence of the RBC in this reaction has been questioned, however.^{27,28} An alternative explanation for findings in patients such as H.J. is the "low-affinity hapten." According to this hypothesis, the drug or a metabolite binds to a specific antigenic site on the cell membrane. It then forms a complete antigen or causes a conformational change in the membrane that reveals previously protected neoantigenic sites (sites that will not be recognized as "self" by the immune system). Antibodies directed against the new antigen are produced and bind to it, complement is activated, and cell lysis ensues. Because the drug has a relatively low affinity for its binding site, it is free to go on to another cell and repeat the process. Only cells with the particular drug-binding site would be able to form

the drug-antigenic site-antibody complex needed to activate complement. The high degree of antigenic specificity inherent in this model applies to the immune destruction of WBC and platelets as well as RBC (see the following discussion) and helps explain why different drugs have a propensity to affect one cell line more frequently than others.²⁷

Quinidine is being promoted for use in combination with dextromethorphan for emotional lability and diabetic peripheral neuropathy.^{29,30} As a result, practitioners should be aware that patients might be receiving quinidine for off-label uses.

Features

9. Why are H.J.'s symptoms more severe than those of R.L. with high-affinity haptent-type hemolysis?

The symptoms in hemolytic anemia are related to the degree of anemia produced (relative to the baseline blood count) and the severity or rapidity of hemolysis. Immune complex-mediated hemolysis frequently results in more rapid RBC destruction and more acute symptoms. The hemolysis is largely intravascular; therefore, large amounts of free hemoglobin can be released, resulting in hemoglobinuria and possible acute renal failure caused by the renal-toxic effect of hemoglobin.

Management

10. How should H.J.'s case be managed at this point?

The suspected causative agent, quinidine in this case, should be discontinued and an alternative agent selected. A good urine flow should be maintained, with or without urinary alkalinization, to prevent or attenuate renal failure. RBC transfusion might be needed in symptomatic patients or in patients such as H.J. because of a significantly decreased Hct (e.g., H.J.'s hematocrit is 24%). Immune-complex hemolysis resolves soon after the drug is discontinued because the drug must be in the serum to cause hemolysis. An acute, severe RBC destruction can result from even a single dose of drug in a sensitized patient; therefore, this type of hemolysis should not be rechallenged. The patient should be educated about the cause of this reaction and instructed to strictly avoid future use of quinidine or quinine. (See Question 15 and Table 87-2 for other drugs associated with immune complex hemolysis.)

Temafloxacin (Omniflox), a fluoroquinolone, was removed from the U.S. market in 1992 only 6 months after its approval because of frequent reports of serious hemolysis. The hemolysis, with or without organ system dysfunction, became known as the *temafloxacin syndrome*. About 189,000 prescriptions were written for temafloxacin during this brief period.³¹

The core structure of fluoroquinolones resembles that of quinine and quinidine, both of which are known to cause immune hemolytic anemia and thrombocytopenia. Other marketed fluoroquinolones with the same core structure have caused neither a comparable number nor a comparable spectrum of adverse reactions. Interestingly, the structure of temafloxacin most closely resembles that of trovafloxacin (Trovan), a fluoroquinolone that was withdrawn from European markets in June 1999 and whose use was severely restricted in the United States because of hepatotoxicity.^{31,32}

In a review of 95 cases of hemolysis associated with temafloxacin, renal dysfunction occurred in 57% of cases, 63% of which required dialysis.³³ The mean onset of symptoms (fever, chills, jaundice) was 6.4 days. Patients who reacted to

the first dose of temafloxacin were significantly more likely to have taken quinolone antibiotics in the past, thereby, suggesting a typical anamnestic response and implying cross-reactivity between temafloxacin and other quinolones.

The available data did not permit an accurate estimate of the incidence rate for temafloxacin syndrome. Although an estimate of the number of prescriptions dispensed was available, information about samples given from physicians' offices was not reliable, and thus the denominator (i.e., total number of patients) exposed to temafloxacin could not be determined accurately. More importantly, the actual number of temafloxacin-associated hemolysis cases (i.e., the numerator) was unclear because of probable under reporting.

Autoimmune Reaction: Methyl dopa

The third mechanism by which drugs cause immune RBC destruction is by an autoimmune process. Methyl dopa (Aldomet) was once the most common cause of hemolysis via this mechanism; however, methyl dopa now is seldom prescribed in the United States because of the availability of better antihypertensive agents. Procainamide (Pronestyl),³⁴ as well as the second- and third-generation cephalosporins, particularly cefotetan (Cefotan) and ceftriaxone (Rocephin), also have been associated with immune-mediated hemolytic anemia.³⁵ In one report, ceftriaxone was implicated in 19 cases of immune-hemolytic anemia involving 9 children and 10 adults. Six of the children and 3 of the adults died.³⁶

Treatment of autoimmune-hemolytic anemia consists of drug discontinuation and RBC transfusion if anemia is severe. Hemolysis resolves gradually over the following several weeks to months, but the antiglobulin test may remain positive for years. Despite the similarity of drug-induced autoimmune-hemolytic anemia with the idiopathic variety, for which the role of corticosteroid therapy is well established, evidence supporting the use of steroids in patients with severe or life-threatening drug-induced autoimmune hemolysis is anecdotal at best.^{37,38}

DRUG-INDUCED THROMBOCYTOPENIA

Cases of suspected drug-induced thrombocytopenia are frequently reported to spontaneous adverse drug reaction reporting systems.^{39,40} Thrombocytopenia is defined as a decrease in platelet count to $<100,000/\text{mm}^3$.¹ Drugs can cause thrombocytopenia by three primary mechanisms: (a) immune-mediated suppression or destruction of platelets; (b) decreased production of platelets through direct suppression of thrombopoiesis; and (c), in the case of heparin, an apparently dose-related, non-immune direct effect on circulating platelets. It appears that immune platelet destruction occurs through reactions analogous to immunologic RBC destruction.

Most drugs causing thrombocytopenia appear to do so through immune mechanisms, although it has been difficult to distinguish between immune and toxic effects on thrombopoiesis. Well over 100 drugs have been implicated as causes of thrombocytopenia, most in the form of case reports. It is often difficult to determine the cause of a low platelet count, particularly in acutely ill patients undergoing numerous procedures and receiving a large number of potentially platelet-toxic drugs.⁴¹ Diagnostic errors also can result in over- or under-reporting of drug-induced thrombocytopenia.⁴²

The class of antithrombotic drugs, the glycoprotein IIb/IIIa (GPIIb-IIIa) receptor antagonists (GPRA), has been associated with episodes of thrombocytopenia that are sometimes life threatening. Immune-mediated thrombocytopenia associated with GPRA resembles the classic syndrome of the quinine type with respect to the severity of thrombocytopenia, the risk of bleeding, and anaphylactoid reactions.⁴³ Severe or profound thrombocytopenia occurs in about 1% of patients treated with abciximab (Reopro), and in about 0.2% to 1% of patients treated with eptifibatid (Integrilin).⁴⁴ The incidence appears to be higher with subsequent exposure to the drug, its use with clopidogrel, or in elderly patients. Treatment with intravenous immunoglobulin G (IVIG) after severe thrombocytopenia related to abciximab was of no clinical benefit.⁴⁵ Although available data are limited, some reports suggest that the oral ligand-mimetic inhibitors have higher incidents of thrombocytopenia.⁴⁶

Vancomycin-induced immune thrombocytopenia, confirmed by the presence of vancomycin-dependent antiplatelet antibodies, occurred in 29 patients treated with vancomycin based on data in 2007. The mean nadir platelet count in these patients was 13,600/mm³, and severe bleeding occurred in 10 patients (34%).⁴⁷

Thrombocytopenia and acute onset hemolytic anemia, which were fatal in some cases, have been reported with oxaliplatin (Eloxatin), a new platinum derivative used in colorectal cancer.⁹

In a rigorous 1998 review of 515 case reports of drug-induced thrombocytopenia, a definite or probable causal role for a drug was documented in 247 instances (48%).⁴⁸ Among the 98 drugs described in these reports, quinidine was mentioned in 38 reports, gold in 11, and trimethoprim-sulfamethoxazole in 10. Of the 247 patients described, 23 (9%) had major bleeding and 2 (0.8%) died because of the bleeding.

Suppressed Production: Thiazides

Mechanisms

11. J.Y., a 56-year-old man with mild hypertension, started taking hydrochlorothiazide 25 mg/day. Routine blood work at this time showed an adequate platelet estimate (>150,000/mm³). The platelet estimate after 2 weeks of therapy was likewise normal. At a 1-month follow-up visit, however, J.Y.'s complete blood count (CBC) revealed a decreased platelet estimate, and a subsequent platelet count was 78,000/mm³. He reported no unusual bleeding, the physical examination was unremarkable, and the CBC was otherwise unchanged. Why should the differential diagnosis include hydrochlorothiazide as a possible cause of J.Y.'s thrombocytopenia?

[SI units: platelet counts, >1.5 × 10¹⁵/L and 0.78 × 10¹⁵/L, respectively]

Drugs should always be considered in evaluating blood dyscrasias. Thiazide diuretics as well as furosemide are known to be associated with thrombocytopenia. Drug-dependent antiplatelet antibodies have been identified in the serum of some patients with thrombocytopenia who also were taking thiazides,^{49,50} suggesting an immune process. In most cases, however, antibodies are not demonstrable and marrow examination typically reveals decreased megakaryocytes, findings more consistent with suppression of platelet production. Thrombocytopenia recurs with rechallenge only after 1 to 4

weeks of drug administration, further supporting a nonimmune process. Although some cases of thiazide-induced thrombocytopenia might have an immunologic basis, the more common mechanism probably is one of direct marrow suppression.

Features

12. A bone marrow examination reveals only decreased megakaryocytes, and the initial workup fails to reveal other reasons for a low platelet count. Why is J.Y.'s clinical picture compatible with thiazide-induced thrombocytopenia?

J.Y.'s course to this point has been typical of thrombocytopenia caused by decreased thrombopoiesis. The onset of thrombocytopenia was delayed and gradual (rather than sudden) and, as usually the case, the thrombocytopenia in J.Y. was not associated with fevers, rash, or other signs of immune reaction. The degree of platelet reduction frequently is mild (J.Y.'s platelets were 78,000/mm³) and, without other risk factors, bleeding is relatively uncommon unless thrombocytopenia is severe.

Management

13. How should J.Y. be treated and monitored?

With discontinuation of hydrochlorothiazide, the platelet count would be expected to return to normal within about 2 weeks in J.Y. The drug should be discontinued and the platelet count should be monitored to verify resolution of the thrombocytopenia. J.Y. also should be monitored for signs of bleeding until recovery. For treatment of his hypertension, a suitable alternative agent should be prescribed. As always, J.Y. should be advised to avoid this drug in the future and to inform future caregivers of this reaction.

Immune Destruction: Quinine/Quinidine, Sulfamethoxazole/Sulfisoxazole, and Gemcitabine

Mechanisms and Features

15. K.B., a 65-year-old man, began taking quinine sulfate 300 mg at bedtime (HS) for nocturnal leg cramps. He stopped taking the drug after 2 weeks when he read that stretching exercises might help. Three months later, with worsening cramps, he resumed taking the drug. The next morning he noted small, purple splotches on his skin that had not been present the previous evening. This problem became worse throughout the day, particularly on his lower legs, causing him to seek medical attention. When questioned, he recalled experiencing a hot, flushed sensation shortly after taking the quinine dose but thought little of it. Why might quinine be responsible for these events?

Quinine and quinidine are well-studied causes of drug-induced immune thrombocytopenia. When patients have been sensitized through previous exposure to the drug in question, constitutional symptoms (e.g., warmth, flushing, chills, headache) can occur soon after the first dose. The platelet count falls precipitously, often to low levels, with bleeding (should it occur) commencing within hours or days of ingestion. Petechiae, purpura, and hemorrhagic oral bullae are common early signs, but patients can present with overt bleeding as the first indication of a drug reaction. Thrombocytopenia also can occur during initial exposure to the drug, but this normally requires 7 to 10 days of therapy during which time antibodies are formed. Careful questioning of a patient with an acute reaction

who denies having previously taken the drug often will reveal previous drug use of which the patient was unaware. Exposure to the small amounts of quinine in tonic beverages is a typical example.

A number of quinine-induced hemolytic uremic syndrome (HUS) have been reported. It is an important cause of acute, often irreversible, renal failure. The clinical manifestations of HUS are inappropriate endothelial cell (EC) activations with secondary activation of both platelets and coagulation cascade that lead to thrombocytopenia, microangiopathic anemia, and leukocytosis.⁵¹

Quinine is still used, however, for the treatment of nocturnal leg cramps. The FDA ordered firms to stop marketing unapproved quinine products in late 2006 because of serious safety concerns including thrombocytopenia. At least 15 reports of quinine-HUS appear in the medical literature.⁵² Gemcitabine (Gemzar), although unrelated to this particular patient, also has been associated with renal toxicity and at least 26 cases of gemcitabine-associated HUS.^{53,54}

K.B.'s clinical and laboratory features are compatible with a low-affinity hapten-type reaction (see section on immune hemolytic anemia above). In patients with thrombocytopenia, quinine and quinidine-dependent antiplatelet antibodies react with the GPIIb/IX or GPIIb/IIIa platelet membrane complex⁵⁵ and, in some patients, more than one antibody may be present. Similar findings with sulfamethoxazole and sulfisoxazole have been reported.⁵⁶ A high degree of antibody specificity is indicated by the low cross-reactivity of quinine/quinidine and sulfamethoxazole/sulfisoxazole antibodies, despite the structural similarities of the drugs.

Management

16. How should K.B.'s acute reaction be treated?

Treatment consists of drug discontinuation and support. The platelet count usually begins to rise within 3 to 4 days and returns to normal in 1 to 2 weeks as the drug and its metabolites are cleared from the body and platelet destruction stops. Platelet transfusions are reserved primarily to control active bleeding because transfused platelets are destroyed rapidly when given during the acute process. Although the use of corticosteroids has not been demonstrated to either reduce bleeding or alter the course of the reaction, some recommend their use.⁵⁷ Rechallenge with the suspected drug can result in a potentially fatal reaction and should not be attempted for either diagnostic or therapeutic reasons except under the most extreme conditions. In the case of quinine/quinidine, sensitivity to one does not absolutely preclude use of the other because the antibodies are isomerically specific. Nevertheless, cross-reactivity has been documented;⁵⁸ thus, it would be prudent to avoid either substance. The patient should be advised of his serious drug "allergy" and warned to avoid future use of this drug. In this case, K.B. also should be warned against consuming beverages that contain quinine.

Heparin

Mechanisms

17. M.U., a 65-year-old woman with a painful, swollen left leg, was admitted to the hospital to rule out deep vein thrombosis (DVT). A heparin infusion was begun after an appropriate load-

ing dose. The diagnosis of DVT was confirmed by noninvasive venous testing and warfarin was started on the fourth day; the plan was to discontinue heparin after several days of heparin/warfarin overlap. Pain and swelling had resolved by the fourth day with bed rest, leg elevation, and anticoagulation. In the evening of the seventh day, M.U. experienced a recurrence of her symptoms despite an aPPT within the desired range and an international normalized ratio (INR) of 2.2. Her platelet count, which had been 225,000/mm³ on admission, was now 54,000/mm³. Why is M.U.'s thrombocytopenia likely to be drug induced?

[SI units: platelet count, 2.25 and 0.54 × 10¹⁵/L, respectively]

Heparin is the most common cause of drug-induced thrombocytopenia. Heparin can affect platelet counts by two separate mechanisms. Some patients experience a mild to moderate decrease in platelet count occurring early in therapy, which may resolve despite continued drug administration.⁵⁹ This appears to be caused by a direct platelet-aggregating effect of heparin leading to reversible platelet clumping and undercounting by electronic counters, which cannot distinguish between single platelets and platelet aggregates.⁶⁰ Counts rarely drop below 50,000/mm³, the phenomenon is transient, and complications are unlikely. This form of heparin-induced thrombocytopenia (HIT) is classified as HIT type I.

The more threatening form of HIT, which is less common, is classified as HIT type II. Heparin binds relatively weakly to platelets and forms a heparin–platelet factor 4 complex,^{61,62} which either serves as a complete hapten or results in a conformational change that exposes membrane neoantigens that normally are concealed.^{63,64} IgG directed against this complex causes platelet activation via the platelet Fc receptors. This type of HIT can lead to potentially devastating thromboembolic sequelae. Table 87-3 characterizes the two types of HIT.⁶⁵

Heparin-dependent aggregation of donor platelets exposed to M.U.'s serum would help confirm the diagnosis of HIT. Most widely used is the platelet aggregation test, which measures the aggregation of normal donor platelets by patient serum or plasma with heparin. This test is simple, inexpensive, based on a technique that is in use in most hemostatic laboratories, and can provide a result within 2 to 3 hours. This test, when performed properly (the concentration of heparin and the quality of donor platelets used is important), is reportedly highly specific with a low incidence of false-positive results.^{66,67} The test is not highly sensitive, however; that is, a negative test does not

Table 87-3 Characteristics of Type I and II Heparin-Induced Thrombocytopenia

| | Type I | Type II |
|-------------------------|------------------|---|
| Frequency | 10%–20% | 2%–30% |
| Timing of onset | 1–4 days | 5–10 days |
| Nadir platelet count | 100,000/ μ L | 30,000–55,000/ μ L |
| Antibody mediated | No | Yes |
| Thromboembolic sequelae | None | 30%–80% |
| Hemorrhagic | None | Rarely |
| Sequelae management | Observe | Cessation of heparin, alternative anticoagulation, additional therapy |

From reference 62, with permission.

rule out HIT. A second test to detect heparin-dependent IgG antibodies, the ¹⁴C-labeled serotonin-release assay, is more sensitive but may not be as specific. One study used the test in 387 patients treated with unfractionated heparin or enoxaparin (Lovenox) after orthopedic surgery, including 12 patients suspected of having HIT.⁶⁸ Of the 20 who tested positive, only 6 actually had thrombocytopenia defined as a platelet count of <150,000/mm³ after >5 days of therapy.

Incidence

Although rates of heparin-induced thrombocytopenia as high as 24% to 31% have been reported,⁶⁹ reviews of subsequent prospective studies using full doses of heparin and defining thrombocytopenia as a platelet count of <100,000/mm³ noted a 2.9% to 5.4% incidence of HIT with bovine source heparin and 1.1% to 2.7% with porcine heparin.⁷⁰ The reason for the apparent difference between the two sources of heparin has not been demonstrated clearly, but might be related to differences in charge, degree of sulfation, or average molecular weights.

Heparin-induced thrombocytopenia appears to be more common with full-dose heparin therapy, but it has occurred with various doses. The incidence of thrombocytopenia with prophylactic heparin (5,000 U every 8 to 12 hours subcutaneously) is lower than with full-dose heparin. Thrombocytopenia has even been reported in association with heparin flushes (<500 U/day)⁷¹ and heparin-coated pulmonary artery catheters.⁷² Saline flushes, when substituted for heparin flushes whenever possible, minimize the potential for HIT.⁷³ Female patients might be at greater risk for HIT; therefore, the use of low molecular weight heparin (LMWH) to minimize the potential of HIT, theoretically should be of greatest value in women having surgical thromboprophylaxis.⁷⁴

Although not common, HIT in critically ill patients is one potential etiology to be considered when the platelet count falls to <150 × 10⁹/L or by >50% from baseline. Thrombocytopenia purportedly occurs in 23% to 41% of patients in critical care units and it is associated with mortality rates of 38% to 54%: the reported mortality rate associated with HIT is 10% and 20%.⁷⁵

The effectiveness of LMWH, when compared with unfractionated heparin for the prevention of postoperative thrombosis, could not be determined in a meta-analysis of studies because of the variable quality of the clinical trials in the analysis.⁷⁶ The LMWH are purported to be associated with a lower incidence of HIT compared with unfractionated heparin.⁷⁷ Notable differences in the incidence of HIT between the individual LMWH needs further study.

Practitioners involved in selecting a drug for inclusion into a medication formulary should not only conduct a thorough, independent literature search, but also should review FDA drug-approval documents. For example, the FDA safety review for fondaparinux (Arixtra) noted that the prevalence of thrombocytopenia with enoxaparin (3.1%) was similar to that with fondaparinux (2.9%) in preapproval clinical trials.

Features

18. How is the onset of M.U.'s thrombocytopenia typical of thrombocytopenia induced by heparin?

M.U.'s platelet count of 54,000/mm³ was noted 7 days after the initiation of heparin and consistent with the time

frame commonly associated with thrombocytopenia caused by heparin. Heparin-induced thrombocytopenia typically occurs within 6 to 12 days of therapy; however, thrombocytopenia can occur much earlier, particularly in previously sensitized patients.⁷⁸ The thrombocytopenia can be profound, but the platelet count can remain above 100,000/mm³ despite relatively large decreases in total count.⁷⁹ Once heparin is discontinued, platelets usually return to normal over the course of 4 to 7 days, although recovery can be delayed.

Thrombotic/Embolic Complications

19. What is the relationship between M.U.'s thrombocytopenia and the recurrence of her symptoms?

Heparin-induced thrombocytopenia can be complicated by the occurrence of embolic and thrombotic episodes.⁷⁹ Some patients with heparin-induced thrombocytopenia develop antibodies that deposit on vascular endothelial cells, creating a nidus for thrombus formation.⁸⁰ In others, the procoagulant properties of heparin-activated platelets can accelerate coagulation at sites of pre-existing thrombosis, resulting in extension of thrombi in the venous circulation (i.e., "red clots"). Formation of large platelet aggregates (i.e., "white clots") in the arterial circulation can result in stroke or arterial occlusion with or without secondary thrombus formation. The incidence of thromboembolic events, as a complication of HIT, has been reported as high as 75% to 88%.⁷⁸ Thromboembolic phenomena associated with heparin-induced thrombocytopenia can be difficult to distinguish from treatment failure and disease recurrence, particularly if the platelet count has not been monitored. Recognition of heparin-associated thrombosis or embolism is important because either is associated with significant morbidity and mortality. In addition, such a high degree of platelet activity can sometimes result in heparin resistance, probably caused by release of platelet factor 4 (antiheparin factor). In M.U.'s case, heparin likely has induced thrombocytopenia and a resultant recurrence of her left leg thrombosis.

Management

20. How should M.U. be treated at this point?

Warfarin therapy should not be postponed once the diagnosis of thrombosis has been established.⁸¹ The prompt initiation of warfarin would permit discontinuation of heparin before the usual onset of heparin-induced thrombocytopenia. Warfarin was delayed in M.U.'s case, but because she is almost fully anticoagulated on warfarin after 4 days of overlap therapy with heparin, the heparin can be discontinued. She should be monitored carefully for signs of pulmonary embolism or further extension of her DVT and observed for signs of bleeding. Surprisingly, bleeding is uncommon in this setting.

Unlike M.U., patients with HIT often are not yet fully stabilized with warfarin, and management decisions are not so easily made. The full benefits of oral anticoagulants are delayed for several days; therefore, they are not immediately effective for treatment of DVT. Antiplatelet agents and dextran-40 have been used in this setting.⁷⁸ Although antiplatelet drugs can attenuate or stop further platelet aggregation, they are ineffective in treating either heparin-induced or underlying thrombotic disease and could worsen the risk of bleeding. Corticosteroids are not useful in this situation.

The LMWH preparations to anticoagulate patients with heparin-induced thrombocytopenia have been successful in anecdotal reports; however, routine use of LMWH in patients with heparin-dependent antiplatelet antibodies is potentially hazardous because in vitro cross-reactivity and unfavorable clinical outcomes after substitution have been reported. The low-molecular-weight heparinoid, danaparoid, cross-reacts with standard heparin-dependent antibodies 0% to 19.6% of the time as compared with 25.5% to 94% cross-reactivity of various LMWH (e.g., dalteparin and ardeparin).^{82,83}

Ancrod (Viprinex), a defibrinogenating agent that reduces blood coagulability by degrading fibrinogen, has been successful in patients with heparin-induced thrombocytopenia when given in doses sufficient to decrease fibrinogen levels to as low as 50 to 100 mg/dL.^{84,85}

Hirudin, a natural anticoagulant from the leech *Hirudo medicinalis*, and its synthetic congeners, bivalirudin (Angiomax) and lepirudin (Refludan), can inhibit coagulation in patients with HIT by binding to sites of circulating and clot-bound thrombin.^{86,87} These are approved for use in patients with, or at risk of, HIT or heparin-induced thrombocytopenia and thrombosis syndrome (HITTS) undergoing percutaneous coronary intervention (PCI).⁸⁸ Antihirudin antibodies have been observed in about 40% of patients with HITTS treated with lipirudin.⁸⁹ The direct thrombin inhibitor, argatroban, also can be utilized for the prophylaxis or treatment of thrombosis in patients with HIT and in patients with, or at risk for, HIT undergoing PCI.⁹⁰

Heparin-induced thrombocytopenia is a life-threatening medical emergency. Awareness of the clinical presentation of this condition and being able to differentiate HIT from other causes of thrombocytopenia are critical in avoiding serious outcomes. The immediate discontinuation of heparin is essential and treatment with therapeutic doses of an alternative nonheparin anticoagulant must be initiated without delay.⁹¹

Ticlopidine (Ticlid) and Clopidogrel (Plavix)-associated Thrombotic Thrombocytopenic Purpura

Thrombotic thrombocytopenic purpura is a life-threatening, multisystem disease characterized by thrombocytopenia, microangiopathic hemolytic anemia, neurologic changes, progressive renal failure, and fever, with about a 10% to 20% mortality. The cause of TTP is unknown; however, drugs (e.g., penicillin, antineoplastic chemotherapy agents, oral contraceptives, ticlopidine) have been associated with the syndrome.

In a review of 60 cases of ticlopidine-associated TTP, ticlopidine had been prescribed for <1 month in 80% of the cases, and platelet counts had been normal within 2 weeks of the onset of TTP in most patients. Mortality rates were higher among patients who were not treated with plasmapheresis (50% vs. 24%; $p < 0.05$). In these cases, the onset of ticlopidine-associated TTP was difficult to predict, despite close monitoring of platelet counts.⁹²

In a retrospective cohort study, 19 cases of ticlopidine-associated TTP occurred in 43,322 patients treated with ticlopidine who had a PCI and received a coronary stent during a 1-year period from 1996 to 1997. The mean time of ticlopidine treatment before the diagnosis of TTP was 22 days (range, 5–60 days). The case fatality rate was 21% (4 of 19), with all 4 deaths occurring in patients not treated with plasmaphere-

sis. No deaths occurred among the 13 patients who received plasmapheresis.⁹³

In one postmarketing surveillance, ticlopidine was associated with 259 fatalities, with TTP accounting for 40 of the deaths. Ticlopidine's manufacturer revised the drug's professional product labeling in 1998 to include a black box warning describing an estimated incidence of ticlopidine-associated TTP of 1 in 2,000 to 1 in 4,000 patients.⁹⁴

Clopidogrel (Plavix), as ticlopidine, is a thienopyridine derivative with a chemical structure identical to ticlopidine, except for the addition of a carboxymethyl side group. Active surveillance by blood bank medical directors, hematologists, and the drug's manufacturer has identified cases of clopidogrel-associated TTP.⁹⁵

DRUG-INDUCED NEUTROPENIA

Definitions

Several terms are used to refer to abnormally low numbers of WBC. The broadest description, *leukopenia*, simply denotes a total WBC count of $<3,000/\text{mm}^3$. *Granulocytopenia* describes a granulocyte count of $<1,500$ granulocytes/ mm^3 (including eosinophils and basophils), whereas *neutropenia* refers to a neutrophil count (segmented polymorphonucleocytes and band forms) of $<1,500/\text{mm}^3$. *Agranulocytosis* is defined as a severe form of neutropenia, with total granulocyte counts $<500/\text{mm}^3$.¹ Authors, however, use variable definitions when reporting drug-induced WBC dyscrasias. The term agranulocytosis has been used to describe granulocyte counts ranging from <100 to $<1,000/\text{mm}^3$.

Epidemiology

Agranulocytosis is the most common fatal adverse drug reaction, accounting for 26% of all drug-related deaths and 64% of deaths caused by blood dyscrasias in one series.⁹⁷ The mortality rate was about 30% in the 1960s and 1970s,⁹⁸ and about 16% at six hospitals from 1970 to 1989 based on data from a diagnosis by exclusion methodology.⁹⁹ Mortality rates from more recent reports would be expected to be lower because of advances in medical care. In the elderly, who are over-represented in all published series of agranulocytosis, the estimated mortality rate from idiosyncratic drug-induced agranulocytosis in 2004 was 5% to 10%.¹⁰⁰

Mechanisms

Drugs cause neutropenia by two basic mechanisms. One is immunologically mediated, either through peripheral destruction of circulating neutrophils or immune suppression of marrow precursors. The second is through a direct, toxic effect on marrow precursors.¹⁰¹

Immune Versus Direct Mechanisms: Penicillins

MECHANISMS

21. S.T., a 54-year-old woman with a WBC count of $12,200/\text{mm}^3$ (82% neutrophils, 3% band forms, 7% monocytes, 8% lymphocytes) was treated for cellulitis with nafcillin 2 g every 4 hours IV. On the 13th day of therapy, her WBC count was $2,200/\text{mm}^3$ with 28% neutrophils and 5% bands. At this time, S.T. was

experiencing no new symptoms and remained afebrile. Why might her neutropenia be attributable to nafcillin?

Administration of penicillins and, to a lesser extent, cephalosporins, in large doses for prolonged periods purportedly results in neutropenia in up to 15% of cases.¹⁰² The problem seems to occur only rarely within the first week of therapy and most often in patients receiving high doses of these β -lactam antibiotics for >2 weeks.¹⁰³ S.T. has been receiving high-dose nafcillin (i.e., 12 g/day) for about 2 weeks. Despite this apparent dose relationship, controversy exists whether the neutropenia is immune mediated or caused by toxic suppression of granulocyte development in the marrow. Drug- or metabolite-dependent antigranulocyte antibodies have been noted in patients receiving penicillin^{104,105} and cephalosporins.¹⁰⁶ Furthermore, serum from a patient with ceftriaxone-associated agranulocytosis could suppress in vitro proliferation of an early WBC precursor, granulocyte-macrophage colony-forming units (CFU-GM).¹⁰⁷ These findings are consistent with cases of drug-induced agranulocytosis that did not appear to be dose related. In contrast, others have demonstrated dose-dependent inhibition of granulocyte colony growth in vitro, thereby supporting the premise that β -lactam-induced neutropenia is caused by a direct toxic effect on granulopoiesis.¹⁰⁸

Evidence indicates a potentially important role for reactive metabolites. Reactive metabolites are short lived and produced locally by cells such as neutrophils and neutrophil precursors in the marrow. In predisposed persons, the suggestion is that certain drugs could be converted to reactive metabolites that can then either directly damage precursor cells or cause formation of neoantigens, which would subsequently initiate an immune response directed against the now altered cell.¹⁰⁹ The common finding of apparent maturation arrest of granulocyte precursors on marrow examination is compatible with either toxic suppression or an immune effect on precursors. Fever, rash, and eosinophilia in patients with penicillin-induced neutropenia imply an immune process in many cases despite an apparent dose relationship. Overall, despite significant advances in knowledge, it can be concluded that the mechanisms by which antibiotics cause neutropenia are heterogeneous, and that more study is needed to understand these mechanisms. A few reports implicating > 100 drugs as having caused neutropenia provide some insights into mechanisms.

MANAGEMENT

22. How should S.T. have been monitored while receiving high doses of a drug known to be associated with neutropenia?

First, the need for high dosages of drug and long duration of therapy should be reassessed in light of the subjective and objective data (e.g., well-being of the patient, temperature, WBC count, tissue inflammation and pain, culture and sensitivity) that are consistent with cellulitis in this patient. Depending on the situation, some infections do not require maximal antibiotic dosage to achieve bacteriologic and clinical cure, and a shorter course with a lower dose of nafcillin, if appropriate, is considerably less likely to be associated with nafcillin-induced neutropenia. Another consideration might be the selection of a drug dose based on body size, as is the case in pediatric patients, rather than following the common practice of using standardized dosing for all adults.¹¹⁰ Of course, doses should always be altered appropriately for impaired organ function

(e.g., renal insufficiency). The WBC count should be monitored carefully, particularly after the second week of therapy, and the patient should be observed for unexplained fevers and rashes.

23. How should S.T. be treated at this point?

The suspected offending drug, nafcillin in this case, should be discontinued and replaced by an effective antimicrobial with a dissimilar chemical structure (e.g., a fluoroquinolone, vancomycin) if continued therapy is needed for cellulitis. The selection of a substitute antibacterial should be based on culture and sensitivity testing or, if cultures are negative, empirically for likely causative organisms (e.g., *Staphylococcus aureus*, *S. epidermidis*). Vancomycin also has been implicated as a possible cause of drug-induced neutropenia.¹¹¹

S.T.'s WBC count would be expected to return to normal within several days. Although the neutropenia potentially can resolve after merely decreasing the drug dose, this approach is not without risk and should be considered only if an alternative is unavailable. The patient should be monitored for fever or other signs of new or recurrent infection until the neutropenia has resolved. The precise course of action will be determined by the clinical situation. In S.T.'s case, the nafcillin was discontinued with subsequent hematologic recovery and without recurrence of the original infection.

Idiosyncratic Toxic Effect: Phenothiazines

MECHANISMS

24. J.K., a 34-year-old woman with schizophrenia, was found on routine blood testing to be moderately neutropenic. She started taking chlorpromazine (Thorazine) 8 weeks ago when she began hearing voices warning her that she was being followed by the Central Intelligence Agency (CIA) and that her brain had been bugged. Her chlorpromazine dose was quickly titrated up to 400 mg/day, which she has been taking for 6 weeks with a good clinical response. J.K. has no medical problems and takes no other medications. How likely is it that J.K.'s chlorpromazine is the cause of her neutropenia?

Phenothiazines are one of the most common causes of drug-induced neutropenia, chlorpromazine being the model drug.^{112,113} These drugs induce neutropenia through toxic suppression of granulocyte production in the marrow of sensitive patients. In experiments using cultured bone marrow from normal subjects, and from patients who had become neutropenic during chlorpromazine therapy, DNA synthesis resulting in defective granulocyte proliferation occurred in at least half of the patients taking chlorpromazine.¹¹⁴ The marrow of patients who do not become neutropenic apparently compensate for this interference in DNA synthesis through proliferation of drug-resistant clones of committed stem cells. Patients who go on to develop neutropenia apparently do not have adequate compensatory mechanisms.

FEATURES

25. Why is J.K.'s presentation typical of phenothiazine-induced neutropenia?

As in J.K.'s case, the most common presentation of phenothiazine-induced neutropenia would be that of decreased numbers of neutrophils. Patients usually remain asymptomatic

unless they become infected. Phenthiazine-induced neutropenia rarely occurs in <2 weeks or later than 10 weeks into therapy, although latent periods of 3 months have been reported. J.K.'s 6 weeks of chlorpromazine therapy certainly falls within this usual time frame, and her total dose of 10.8 g also is representative of the doses usually associated with chlorpromazine-induced neutropenia. A total cumulative dose of 10 to 20 g of chlorpromazine usually is required; neutropenia occurs only rarely in patients taking less than this amount of the drug. Patients who have developed neutropenia while taking high doses of chlorpromazine have subsequently been treated with reduced dosages uneventfully. Rechallenge with high doses again results in a delayed-onset fall in the neutrophil count. In addition, approximately 10% of patients taking chlorpromazine will experience a transient leukopenia, which resolves despite continuation of the drug.¹¹⁵ Severe neutropenia is much less common; elderly women appear to be at increased risk. Most other phenothiazine derivatives, with the exception of promethazine (Phenergan), also have been reported to cause neutropenia, although none have been studied as extensively as chlorpromazine.

MANAGEMENT

26. How should J.K. be treated at this point?

No specific therapy is indicated at this time because J.K. is asymptomatic. Although it is possible that the neutropenia might resolve with a simple dose reduction of chlorpromazine, the most prudent course would be to withhold the drug completely until the WBC count returns to normal. Subsequently, the patient could be restarted at a lower dose with close hematologic monitoring, or an alternative neuroleptic agent with less propensity for marrow suppression could be substituted. A more potent phenothiazine or a nonphenothiazine neuroleptic would be preferable because the risk of agranulocytosis appears related to the absolute amount of phenothiazine taken.

27. How quickly should J.K.'s WBC count return to normal once chlorpromazine has been discontinued?

A peripheral hematologic response following the discontinuation of chlorpromazine will be delayed by 4 to 6 days but will then improve rapidly. In some cases, the increase in granulocytes may be preceded or accompanied by a monocyte increase, and myelocytes, metamyelocytes, and band forms may appear in relatively large numbers during the early recovery phase. The neutrophil numbers and total WBC count then rapidly return to normal, sometimes with a WBC count "overshoot" into the 15,000 to 20,000/mm³ range. Recovery usually is complete within about 2 weeks.

Colony-stimulating Factors

28. How can the rate of WBC recovery be hastened?

Patients with drug-induced agranulocytosis or drug-induced neutropenia have been treated with the granulocyte colony-stimulating factor (G-CSF, filgrastim, Neupogen) and granulocyte-macrophage colony-stimulating factor (GM-CSF, sargramostim, Leukine, Prokine); however, the overall impact of CSF on clinical outcomes is difficult to assess when based on anecdotal case reports. The expectation that granulocyte

recovery will be hastened by precursor stimulation cannot be assumed. The time for granulocyte recovery is highly variable and this variability could be sufficiently great to attribute an increase in granulocyte count to either the administration of CSF or to a coincidental increase that would have occurred independent of any additional intervention. Likewise, it is difficult to determine whether patient outcomes would have been different had CSF not been used.

In a review of 70 cases of drug-induced agranulocytosis treated with G-CSF or GM-CSF, peripheral granulocyte recovery time was 1.2 days with mild granulocytopenia, 2.6 days for moderate, and 5.8 days for those with severe granulocytopenia.¹¹⁶ No difference was noted between G-CSF (mean dose 4 g/kg/day) and GM-CSF (mean dose 7 g/kg/day). The mortality rate was 5%. In a comparison to previous reports in which CSF were not used, recovery time was faster and mortality was lower, but these conclusions are limited by the use of historical controls and the biases inherent in such reviews. Clinicians are much more likely to report cases that are successes rather than failures.

In two randomized, controlled trials, neutrophil recovery time was shortened, but no differences were noted in survival or duration of hospitalization in patients with cancer chemotherapy-induced neutropenia when CSF were administered.^{117,118} Although it would not be reasonable to extrapolate these results to the treatment of drug-induced neutropenia, it does appear that hastened white cell recovery does not necessarily result in improved clinical outcomes.

At present, therapeutic trials of CSF are not appropriate as first-line treatment to hasten WBC recovery in drug-induced agranulocytosis or neutropenia. It should also be noted that significant complications related to CSF use for drug-induced agranulocytosis have been reported.¹¹⁹

Because J.K. currently is asymptomatic, use of CSF is not indicated.

Idiosyncratic Toxic Effect: Clozapine (Clozaril), Olanzapine (Zyprexa)

29. Why would it be reasonable (or unreasonable) to administer an atypical neuroleptic such as clozapine (Clozaril) to treat J.K.'s schizophrenia subsequent to her recovery from chlorpromazine-induced neutropenia?

Clozapine, a dibenzodiazepine neuroleptic, initially appeared to have a favorable adverse effect profile; however, cases of clozapine-induced neutropenia soon were reported.¹²⁰ When discovery of the neutropenia was delayed and clozapine was not promptly discontinued, eight fatalities resulted. As a result, when clozapine was approved for use in the United States for severely ill schizophrenic patients, who were refractory to standard antipsychotic drug treatment, it was available only to patients through a privately contracted drug distribution system, which incorporated mandatory weekly WBC counts and specific criteria for intensified monitoring of patients. Although this drug distribution system was discontinued in 1991, a national registry has continued to collect patient and blood count information; thereby, providing what probably is the most complete postmarketing blood dyscrasia database for any drug available for general use.

In the United States, leukopenia developed in 2.95% of 99,502 patients treated with clozapine through 1994; agranulocytosis occurred in 0.38% of cases, and the death rate was

0.012%.¹²¹ Similarly in the United Kingdom and Ireland, 2.9% of the patients developed neutropenia, 0.8% developed agranulocytosis, and fatal agranulocytosis occurred in 0.03%.¹²² The rate of agranulocytosis is lower than the originally estimated 1% to 2%, which could partly be owing to a 97% rate of compliance with the registry protocol for screening for previous blood dyscrasias, monitoring WBC counts weekly, and prompt discontinuation of therapy when neutropenia was noted. The 12 deaths reported represent a fatality rate of 3.2% of agranulocytosis cases, a number that compares favorably with the overall reported population-based rates. In an earlier report of the first 11,555 U.S. patients, the first 6 months of clozapine therapy was the period of greatest risk; only one case of agranulocytosis occurred after a year and a half of clozapine treatment.¹²³ The risk of agranulocytosis increased with age and was higher in women.

In most, but not all patients, agranulocytosis is preceded by a steady decline in WBC over a period of at least 4 weeks. Nevertheless, leukopenia was not present within 8 days of development of agranulocytosis in 24% of cases. After the discontinuation of clozapine, recovery from agranulocytosis usually occurred within 2 weeks.

A history of clozapine-induced leukopenia might be a risk factor for hematologic reactions to olanzapine (Zyprexa). Eleven reports of olanzapine-induced hematologic reactions (i.e., leukopenia, granulocytopenia, neutropenia, pancytopenia, anemia) were reported to Canadian regulatory authorities through July 2000; in 5 of these cases, the patient had a history of a hematologic reaction with clozapine.¹²⁴

J.K. is not at increased risk for clozapine-induced hematologic toxicity because there does not appear to be cross-reactivity between clozapine and other psychotropic agents, including chlorpromazine.^{125,126} Clozapine, however, is not indicated for J.K. because she is not refractory to more typical neuroleptic therapy.

Immune Peripheral Destruction: Metamizole or Dipyrone

30. What drugs have been most commonly associated with acute onset agranulocytosis?

More than two-thirds of the cases of agranulocytosis have been attributable to drugs. The most common drugs associated with agranulocytosis are antithyroid medications and sulfonamides, but almost all classes of drugs have been implicated.¹²⁷ According to British reports, neutrophil dyscrasia is the most common life-threatening adverse event with the thionamides, carbimazole and propylthiouracil.¹²⁸ The nonsteroidal anti-inflammatory drug (NSAID), metamizole, also known as dipyrone, was withdrawn from the market in the United States in 1979 because of its association with fatal agranulocytosis. Nevertheless, metamizole is still available in other countries, and travelers to these countries are exposed to this drug.¹²⁹ Metamizole also is reportedly the most common drug sold to Mexican immigrants by illegal pharmacies in California near the U.S.–Mexican border. This drug also is promoted on the internet by pharmacies specializing in veterinary compounding and it is unknown whether these pharmacies compound metamizole for human use. The risk of developing agranulocytosis from metamizole varies widely and can be partly explained by geographic disparities and differences in use patterns.¹³⁰

DRUG-INDUCED APLASTIC ANEMIA

Aplastic anemia is defined as bicytopenia or pancytopenia, with bone marrow biopsy evidence of decreased cellularity and absence of infiltration and significant fibrosis. The term *pancytopenia* is applied when anemia (Hgb <10 g/dL), neutropenia, and thrombocytopenia are present; and the term *bicytopenia* is applied when two of these three abnormalities are present.¹ Diagnostic criteria also have been established for cases of bicytopenia or pancytopenia with less definitive bone marrow findings. Drugs and chemicals are implicated in 25% to 50% of the cases of aplastic anemia, which is the rarest, most poorly understood, and most serious of the drug-induced blood dyscrasias.

The most serious complication of aplastic anemia is the high risk of infection secondary to the absence of neutrophils. In these patients, overwhelming bacterial sepsis and, especially, fungal infections are the most frequent causes of death.¹³² Mortality rates are approximately 10% to 40%; however, patient age, severity of marrow suppression, availability of well-matched marrow transplant donors, and improved treatments influence survival rates.¹³¹ Prognosis is worst for severely affected patients (i.e., severe bone marrow changes and two of the following three criteria: [a] neutrophils <500/mm³, [b] corrected reticulocytes <1%, or [c] platelets <20/mm³).

The underlying pathophysiology of aplastic anemia, including drug-induced mechanisms, remains incomplete despite advances in the understanding of hematopoiesis. An autoimmune process (possibly with genetic predisposition) probably is involved in the pathogenesis of aplastic anemia, even in drug-induced cases.^{133,134} Immunosuppressive therapy appears effective for both drug-induced and non-drug-related cases of aplastic anemia. Aplastic anemia caused by direct damage to the pluripotent stem cell (PSC) by toxic insult (e.g., drugs) and true immune-mediated marrow failure might have a common basis in the complex interactions between hematopoiesis and the lymphocyte or monocyte-produced cytokines.

Chloramphenicol

Hundreds of cases of chloramphenicol-induced aplastic anemia have been reported. The aplastic anemia from chloramphenicol is unpredictable; it occurs in about 1:20,000 to 1:30,000 persons and is not related to either dose or duration of use. Chloramphenicol inhibits DNA synthesis and studies from the cells of patients, who have recovered from chloramphenicol-induced aplastic anemia, suggest that some patients might be more sensitive to chloramphenicol's ability to inhibit DNA synthesis.^{135,136} A reactive nitrosometabolite of chloramphenicol can affect DNA synthesis irreversibly at low concentrations,¹³⁷ and two dehydrometabolites (produced by enterobacteria in the colon) also can be toxic to lymphocytes.¹³⁸ Some patients can be predisposed, perhaps genetically, to chloramphenicol-induced aplasia mediated by one or more of these metabolites. The role of enteric bacteria in the pathogenesis of chloramphenicol-induced aplastic anemia might prove to be the most important factor because this adverse effect primarily has been associated with the oral route of administration of this drug.¹³⁹ Nevertheless, intravenous^{140,141} and ocular^{142,143} routes of chloramphenicol administration also have been implicated in aplastic anemia.

Chloramphenicol also can cause an anemia that is dose related, predictable, and reversible. This anemia results from chloramphenicol-induced inhibition of iron utilization and clinically appears with reticulocytopenia, maturation arrest of committed precursors in all cell lines, increased serum concentration of iron, and increased total iron-binding capacity (TIBC). Anemia resulting from inhibited iron utilization with reticulocytopenia and increased serum iron concentrations is common in patients receiving large doses of chloramphenicol. Discontinuation of the drug results in complete recovery.

Importance of a Careful History

31. P.D., a 62-year-old man, notes gradually increasing tiredness and lack of energy over the past month. He seeks medical help after unsuccessful self-medication with stress-formula vitamins. His only other medical problem is osteoarthritis for which he has been taking diclofenac (Voltaren) 50 mg three times daily (TID) for the past 6 months, as well as aspirin 360 mg four to six times daily on an as needed basis. Physical examination is unremarkable except for pallor, several bruises on various parts of the body, and findings typical of osteoarthritis. A blood count, however, reveals an Hgb of 6.2 g/dL, a corrected reticulocyte count of 0.5%, a WBC count of 1,800/mm³ with 50% neutrophils, and a platelet count of 35,000/mm³. Diagnostic considerations include drug-induced aplastic anemia. What additional information is needed before P.D.'s anemia might be attributed to a drug-induced etiology?

[SI units: Hgb, 62 g/L; reticulocytes, 0.005 I; WBC 1.8 × 10¹²/L; platelets 0.35 × 10¹⁵/L]

Although drug-induced aplastic anemia is a possibility, a more complete medical history is needed. Many drugs and chemicals can cause marrow aplasia, which might not be apparent until long after the last exposure. The family history should be examined for family members who have experienced “blood problems” or sensitivity to drugs or substances. Social history also is important because occupations or military service can provide important information about past or present possible exposure to chemicals. For example, an employee in a paint factory could be exposed to industrial chemicals known to cause aplastic anemia, or a farmer might be exposed to marrow-toxic insecticides. Finally, an exhaustive drug history is mandatory. Use of all drugs past and present, prescription and nonprescription, legal or illegal, regardless of route of administration, should be elicited and documented. This, of course, is true whenever a drug-induced disease is suspected. The relationship between exposure to a causative agent and the onset of aplastic anemia often is not readily apparent and careful scrutiny is needed to uncover a possible association.¹⁴⁴ In one case, a child developed aplastic anemia from use of an herbal remedy 5 weeks before clinical presentation.¹⁴⁵ The product was analyzed with gas chromatography and mass spectrometry and found to contain unlabeled diclofenac and phenylbutazone, two drugs associated with aplastic anemia.

Features

32. A more complete history fails to reveal any additional pertinent information. Which of P.D.'s drugs is most likely to have caused this problem?

A number of commonly used drugs (e.g., NSAID, sulfonamides, antithyroid drugs, antiepileptics, psychotropics, cardiovascular drugs, gold, penicillamine, allopurinol) have been associated with pancytopenia or aplastic anemia.¹⁴⁶

One year after FDA approval of felbamate (Felbatol) for partial seizures in adults and for Lennox-Gastaut syndrome in children, prescribers were urged to discontinue felbamate use, unless absolutely necessary, because of the potential for aplastic anemia. In all cases, patients had been on the drug for at least 2.5 months. Clinicians were cautioned that even close monitoring cannot protect against the occurrence of aplastic anemia with this drug.¹⁴⁷

Three cases of dose-dependent, reversible pancytopenia were observed after 2 weeks of linezolid (Zyvox) antibiotic treatment. These cases have features similar to those of the reversible form of chloramphenicol toxicity.¹⁴⁸ Warnings were added to the drug's professional product labeling, cautioning that complete blood counts should be performed weekly in patients who receive linezolid, particularly in those who receive the drug for longer than 2 weeks. Patients with pre-existing myelosuppression receiving concomitant drugs that produce bone marrow suppression, or those with a chronic infection who have received previous or concomitant antibiotic therapy also are at higher risk for pancytopenia or aplastic anemia. Discontinuation of linezolid should be considered in patients who develop or have worsening myelosuppression.¹⁴⁹

The aplastic anemia that has been reported in 57 patients treated with ticlopidine (Ticlid) has been attributed to a direct effect on the PSC. No effective monitoring exists to prevent this adverse effect. Recombinant growth factors do not appear to shorten the neutropenic period.¹⁵⁰

The professional product labeling for interferon β -1 α (Avonex) warns of pancytopenia. Decreased peripheral blood counts in all cell lines, including pancytopenia and thrombocytopenia, have been reported. In some cases, platelets counts were <10,000/mm³, and pancytopenia can reoccur on challenge with this drug. Patients using interferon β -1 α should be monitored closely for these disorders.¹⁵¹

P.D.'s diclofenac has been associated with the development of aplastic anemia. The risk of aplastic anemia with diclofenac has been estimated to occur in about 1 in 150,000. Salicylates have also been linked with aplastic anemia in some,¹⁵² but not all,¹⁴⁶ studies. Diclofenac is the most likely culprit among P.D.'s drugs, but aspirin cannot be ruled out.

33. What subjective and objective data in P.D. are typical of an initial presentation of aplastic anemia?

The symptoms of aplastic anemia at initial presentation usually are nonspecific and are directly related to deficiencies within the suppressed cell lines. P.D.'s pallor, tiredness, and lack of energy likely are caused by anemia. His easy bruisability can be attributable to thrombocytopenia and exacerbated by aspirin. Patients can experience more severe symptoms. For example, when the anemia is severe, high-output congestive heart failure, angina pectoris, and intermittent claudication can occur. When thrombocytopenia is significant, petechiae, purpura, nose bleeds, oozing of blood from the gums, and hemorrhage can be manifested. Symptoms such as oral lesions, fever, and infection can be secondary to leukopenia.

White blood cell counts typically are low at the initial presentation of aplastic anemia, however, the degree of leukopenia varies. The anemia generally is normochromic and either normocytic or macrocytic; and the serum hemoglobin concentration can be as low as 3 g/dL. The serum concentrations of erythropoietin, iron, and transferrin saturation usually are high because erythroid iron-consuming activity is low. Reticulocyte counts generally are low. The WBC count can be low normal or low, but absolute neutropenia almost always is present. P.D.'s WBC count of $1,800/\text{mm}^3$ with 50% neutrophils (absolute neutrophil count = $1,800 \text{ mm}^3 \times 50\% = 900/\text{mm}^3$) is compatible with this hematologic profile. Total lymphocyte count is affected least and can remain within normal limits until leukopenia becomes severe. Likewise, the platelet count may be near normal or, more commonly, severely depressed. The erythrocyte sedimentation rate (ESR) usually is elevated and bone marrow usually is hypocellular with evidence of fatty replacement.

Management

34. Further evaluation, including bone marrow biopsy, confirms the diagnosis of aplastic anemia. No causes other than drugs are identified. What interventions would facilitate P.D.'s recovery?

First and foremost, as is true in the treatment of most drug-induced diseases, all suspected causative agents should be discontinued. In this case, both diclofenac and aspirin should be stopped. In addition, supportive measures should be initiated as needed.

The approach to treatment is based first on disease severity. Patients with mild aplastic anemia have a relatively benign short-term prognosis and can be treated conservatively. The two basic approaches to treating severe aplastic anemia are bone marrow transplant and immunosuppression.

Bone Marrow Transplantation

Bone marrow transplantation from an HLA antigen-identical sibling donor, if available, achieved about a 72% to 90% long-term survival rate in children and adults <40 to 45 years of age by the mid-1990s.¹⁵³⁻¹⁵⁵ Acute and chronic graft-versus-host disease (GVHD) has been a frequent complication of transplant recipients.¹⁵⁶ In one study, GVHD surprisingly was experienced in 4 of 33 transplants from genetically identical twins.¹⁵⁷

Immunosuppression

Immunosuppression is the treatment of choice for older patients and for young patients without suitable bone marrow donors, and it can be appropriate for some patients who would otherwise be transplant candidates.¹⁵⁸ Antithymocyte globulin (ATG) or antilymphocyte globulin (ALG) is administered daily for 8 to 10 days along with a corticosteroid (methylprednisolone 1 mg/kg/day or equivalent) to attenuate the adverse effects of the globulin. Addition of 3 months or more of cyclosporine to the regimen appears to be more effective than ATG or ALG alone.¹⁵⁹ It is postulated that the antilymphocyte activity of these agents results in immunosuppression and inhibits release of PSC-suppressant cytokines responsible for marrow failure. An intradermal skin test of 0.1 mL of a 1:1,000

dilution of ATG along with saline control is recommended before the first infusion.¹⁶⁰

Androgens

Androgen treatment no longer has a first-line role in the treatment of aplastic anemia and is generally reserved for patients who have failed on immunosuppressants.¹⁶¹ The use of androgenic steroids as an adjunct to ATG is controversial. Although most trials have failed to demonstrate clear benefit, numerous questions regarding patient selection, timing and duration of therapy, choice of agent, and dosing, any of which can affect results, have been raised.^{162,163}

Colony-stimulating Factors

Use of G-CSF and GM-CSF has increased neutrophil counts^{164,165} and erythropoietin has increased red cell counts¹⁶⁶ in cases of aplastic anemia. It appears that response, when it occurs, is limited primarily to a subset of patients with nonsevere depression of the cell line in question, and that the response lasts only as long as treatment continues. Interleukin-3 (IL-3) was reported to improve responsiveness to G-CSF in a patient who had not responded to G-CSF alone.¹⁶⁷ The authors speculate this may have been because of an IL-3-induced increase in the number of progenitor cells or an increased responsiveness of those cells to the CSF. One author noted a possible link between G-CSF use and subsequent development of myelodysplasia and leukemia in three children treated with G-CSF for severe aplastic anemia.¹⁶⁸ At this time, therapeutic trials of CSF are not appropriate as first-line treatment of severe aplastic anemia.¹⁶⁹

Because P.D.'s disease is not severe, discontinuing the drugs and transfusing RBC are the only treatments indicated at this time. It is not possible to predict whether his blood counts will improve once the causative agents are discontinued.

DRUG-INDUCED AUTOIMMUNE PURE RED CELL APLASIA

Definitions

Pure red cell aplasia (PRCA) is a term used for a type of anemia that affects the erythroid cell line. PRCA is a rare condition that has been associated with autoimmune, viral, and neoplastic diseases as well as drug treatment. Other terms (e.g., erythroblastic hypoplasia, erythroplasia, erythroblastopenia, erythroid hypoplasia, red cell agenesis) have been used to describe this particular marrow disorder. PRCA can be classified as an acute, self-limited type; a chronic type; and, either constitutional or acquired. PRCA was first described in 1922.^{170,171}

Acquired PRCA might arise in association with thymoma, lymphoid cancer, rheumatoid arthritis, and hepatitis B virus or parvovirus infections. It has also been attributed to drugs, particularly phenytoin, chlorpropamide, and isoniazid. PRCA caused by neutralizing antibodies to erythropoietic proteins also has been described.^{172,173}

Exogenous Epoetin and Pure Red Cell Aplasia

Through September 2002, 155 world-wide reports were made of PRCA in patients treated with epoetin alfa (Eprex) confirmed by bone marrow aspirations. Of these, 112 reports had documented the presence of neutralizing antibodies with a high

affinity and specificity against the protein moiety of epoetin. All but one of these cases were reported in patients with chronic renal failure.¹⁷⁴

Eprex, which is marketed outside the United States, accounts for most PRCA cases. Almost all of these cases involved patients with chronic kidney dysfunction who had received epoetin by subcutaneous injection.¹⁷⁵

When an unexplained progressive drop in hemoglobin levels in the presence of low reticulocyte counts is detected, PRCA is suspected. Treatment with epoetin must be discontinued immediately, and testing for erythropoietin antibodies and bone marrow aspiration should be performed. Patients with suspected PRCA should not be switched to another epoetin treatment. Diagnosis of PRCA is usually confirmed when the bone marrow evaluation shows a virtual absence of red blood cell precursors. Patients diagnosed with epoetin-induced autoimmune PRCA are lifelong transfusion-dependent.^{173,176}

Patients who were diagnosed with PRCA before the introduction of epoetin therapy were rarely found to have antibodies against endogenous erythropoietin. One possibility is that a difference in the carbohydrate structure of exogenous epoetin and endogenous erythropoietin creates an epitope on the epoetin polypeptide to which an antibody binds, thereby inactivating

both epoetin and the endogenous hormone. The antierythropoietin antibodies are not directed against the carbohydrate moiety on erythropoietin. Removal of the carbohydrate structure by enzymatic digestion had no effect on the antibody affinity for the erythropoietin protein.^{173,176}

The precise mechanism of epoetin-induced PRCA is uncertain. Possibilities suggested as the cause of PRCA with epoetin- α are the subcutaneous route of administration and a change in the stabilizer used in the final product formulation or both. Epoetin- α is reported to be sensitive to physical stresses, such as elevated temperature, exposure to light, or extreme shaking.¹⁷⁷ The subcutaneous route is contraindicated for epoetin- α use in patients with chronic renal failure.¹⁷⁴

The estimated exposure-adjusted incidence of PRCA between 2001 and 2003 is 18 cases per 100,000 patient-years for Eprex formulated with without human serum albumin and 6 cases per 100,000 patient years for a formulation with human serum albumin. The incidence of PRCA peaked in 2001; since then, interventions have resulted in a reduction of more than 80% in the incidence of this dyscrasia caused by Eprex.¹⁷⁵ The increased incidence of PRCA with Eprex, compared with epoetin- α produced in the United States, suggests fundamental differences in the two products.¹⁷⁸

INTRODUCTION TO NEOPLASTIC DISORDERS

Cancer (neoplasm, tumor, or malignancy) is not a single disease; rather, it is a group of diseases characterized by uncontrolled growth and spread of abnormal cells. Cancer cells do not respond to the normal processes that regulate cell growth, proliferation, and survival, and they cannot carry out the physiologic functions of their normal differentiated (mature) counterparts. Often, cancer cells are described as poorly differentiated or immature. Other characteristics of cancer cells include their ability to invade adjacent normal tissues and break away from the primary tumor (metastasize) and travel through the blood or lymph to establish new tumors (metastases) at a distant site. Their ability to stimulate the formation of new blood vessels (angiogenesis) and their endless replication potential

further contribute to their continued growth and survival.¹ Cancers can arise in any tissue in the body and may be classified as benign or malignant. If malignant cancer cells are allowed to grow uncontrollably, they can eventually result in the death of the patient, whereas benign cancer cells cannot spread by tissue invasion or metastasize.

Cancer Statistics

Each year, the American Cancer Society (ACS) publishes the estimated number of new cases and number of cancer-related deaths. The National Cancer Institute (NCI) publishes cancer statistics that also include cancer risk, prevalence, and survival information.² The ACS estimates that 1 of 2 American men and 1 of 3 American women will eventually develop cancer

Table 88-1 Leading Sites of New Cancer Cases and Deaths in the United States, 2007, Excluding Basal and Squamous Cell Skin Cancers and In Situ Carcinomas Except Urinary Bladder

| New Cancer Cases | | Cancer Deaths | |
|----------------------|-----|----------------------------|-----|
| Prostate | 26% | Breast | 26% |
| Lung and bronchus | 15% | Lung and bronchus | 15% |
| Colon and rectum | 10% | Uterine corpus | 6% |
| Urinary bladder | 7% | Melanoma of skin | 4% |
| Kidney | 4% | Non-Hodgkin lymphoma | 4% |
| Non-Hodgkin lymphoma | 4% | Thyroid | 4% |
| Oral cavity | 3% | Kidney | 3% |
| Leukemia | 3% | Ovary | 3% |
| Pancreas | 2% | Pancreas | 2% |
| All other sites | 19% | All other sites | 22% |

and that approximately 1,444,920 new cases of cancer will be diagnosed in 2007.³ The most common cancers and causes of cancer deaths in adult Americans are illustrated in Table 88-1. The incidence of cancer and cancer-related deaths can be affected by both age and ethnic background with the incidence greater in the elderly and black populations.⁴ Other factors that can increase an individual's risk for developing a cancer include environmental and lifestyle factors, genetic predisposition, immunosuppression, and exposure to one or more potential carcinogens.⁵

Etiology

Cancers arise from the transformation of a single normal cell. An initial "event" causes damage or mutation to the cell's DNA. These events may include lifestyle, environmental, or occupational factors, as well as some medical therapies (e.g., cytotoxic chemotherapy, immunosuppressive therapy, or radiation therapy) and hereditary factors (Table 88-2). Currently, cigarette smoking is probably the most significant single factor that contributes to the development of cancers. The ACS estimates that tobacco use is responsible for approximately 180,000 cancer deaths per year.³ In addition, approximately one-third of expected cancer deaths in 2007 are thought to result from preventable causes, such as physical inactivity, obesity, nutrition, and other lifestyle factors.^{3,6}

Progress in our understanding about the development of cancer at the molecular level has led to the recognition that cancer is a genetic disease. Two gene classes, oncogenes and tumor-suppressor genes, play a major role in the pathogenesis of cancer. Damage to cellular DNA can result in mutations that lead to the development of oncogenes and loss or inactivation of tumor suppressor genes. Oncogenes are genes whose overactivity or presence in certain forms can lead to the development of cancer. Oncogenes arise from normal genes called *proto-oncogenes* through genetic alterations such as chromosomal translocations, deletions, insertions, and point mutations.

Growth and proliferation of normal cells are influenced by proteins, known as *growth factors*. When growth factors bind to receptors on the cell surface, they activate a series of enzymes within the cell that stimulate cell signaling pathways and gene transcription proteins in the nucleus, which encode

for proteins that regulate cell growth and proliferation. The coordination and integration of cellular signaling processes are referred to as *signal transduction*. Proto-oncogenes are responsible for encoding several components of signal transduction pathways, including growth factors, growth factor receptors,

Table 88-2 Carcinogens Associated With an Increased Risk of Cancer

| Carcinogenic Risk Factor | Associated Cancer(s) |
|--|---|
| Environmental | |
| Ionizing radiation (radon gas emitted from soil containing uranium deposits) | Leukemia, breast, thyroid, lung |
| Ultraviolet radiation | Skin melanoma |
| Viruses | Leukemia, lymphoma, nasopharyngeal, liver, cervix |
| Occupational | |
| Asbestos | Lung, mesothelioma |
| Chromium, nickel | Lung |
| Vinyl chloride | Liver |
| Aniline dye | Bladder |
| Benzene | Leukemia |
| Lifestyle | |
| Alcohol | Esophagus, liver, stomach, oropharynx, larynx |
| Dietary factors | Colon, breast, gallbladder, gastric |
| Tobacco | Lung, oropharynx, pharynx, larynx, esophagus, bladder |
| Medical Drugs | |
| Diethylstilbestrol | Vaginal in offspring, breast, testes, ovary |
| Alkylating agents | Leukemia, bladder |
| Azathioprine | Lymphoma |
| Phenacetin | Bladder |
| Estrogens, tamoxifen | Endometrial |
| Cyclophosphamide | Bladder |
| Etoposide | Leukemia |

signaling enzymes, and DNA transcription factors. Abnormal forms or excessive quantities of these stimulatory proteins disrupt normal cell growth-signaling pathways, leading to excessive growth and proliferation and, ultimately, a malignant transformation. For example, the epidermal growth factor receptor (EGFR) is a member of a family of type I receptor tyrosine kinases, which trigger cell signaling pathways that influence cell growth, proliferation, survival, tissue invasion, and metastases.⁷ The family includes four related receptors: EGFR (also referred to as ErbB1 or HER1), ErbB2 (HER2, HER2/neu), ErbB3 (HER3), and ErbB4 (HER4). These receptor proteins are composed of an extracellular binding domain, a transmembrane segment, and an intracellular protein tyrosine kinase domain. In cancer cells, the receptors can become activated through receptor binding to the extracellular ligand, resulting in heterodimerization (different members of the receptor family) or homodimerization (like members of the receptor family).⁸

Ligand-independent receptor dimerization can occur as well and is the principal form of activation of HER2, because HER2 does not bind to any known ligands.⁹ The EGFR signaling pathway is depicted in Figure 88-1. Activation of the receptor protein tyrosine kinase leads to autophosphorylation of tyrosine and other intracellular substrates that initiate downstream cellular signaling events.⁷ An important signaling route is the Ras-Raf-MAP kinase pathway, which regulates transcription of molecules that are associated with cell proliferation, sur-

vival, and malignant transformation.⁷ Other important routes for signaling include the phosphatidylinositol 3-kinase (PI3K)-protein-serine/threonine kinase Akt and the stress-activated protein kinase pathways.⁷ EGFR is frequently overexpressed in human tumors, including cancers of the lung, head and neck, bladder, breast, ovary, prostate, colon, and glioblastoma.⁷ Amplification of the HER2/neu gene or overexpression of the protein is present in 10% to 34% of invasive breast cancers.¹⁰ Increased EGFR or HER2/neu expression in several cancers is associated with a more aggressive cancer growth pattern and poorer clinical outcome.⁷

Tumor-suppressor genes are normal genes that encode for proteins that suppress inappropriate cell division or growth. Gene losses or mutations of these genes can cause these proteins to become inactivated, eliminating the normal inhibition of cell division. Alterations in a third class of genes, DNA repair genes, are also implicated in cancer. DNA repair genes encode for proteins that correct errors that may arise during DNA duplication. Mutations in these genes further contribute to the accumulation of genetic changes that promote cancer progression.

Table 88-3 lists examples of genes frequently associated with human cancers. Multiple genetic mutations, including activation of oncogenes and loss or inactivation of tumor-suppressor genes within a cell, are necessary for malignant transformation.¹¹ Separate genetic changes are required for tumor invasion of normal tissues and metastases.

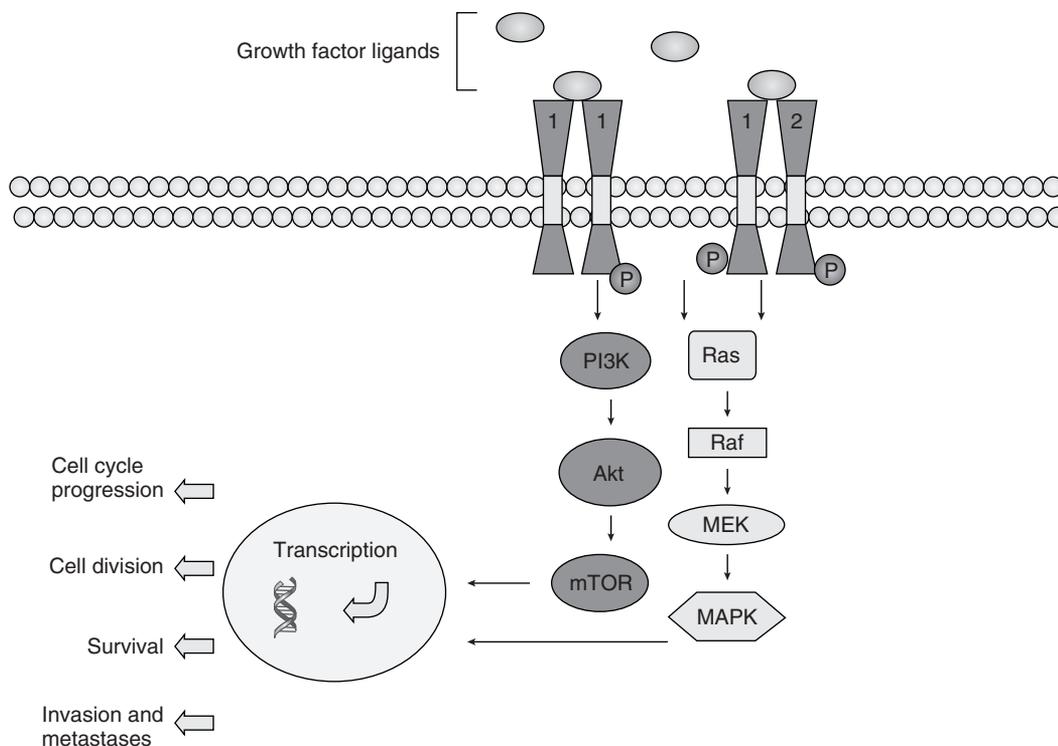

FIGURE 88-1 Epidermal growth factor signaling. Members of the ErbB receptor family become activated by dimerization. Ligand binding to the extracellular domain of epidermal growth factor receptor (EGFR) leads to receptor activation through homodimerization or heterodimerization with other ErbB receptors. Activation of the receptor tyrosine kinase results in tyrosine autophosphorylation and a series of phosphorylations of intracellular substrates that influence cell growth stimulatory signaling and other cellular activities.

Table 88-3 Some Genes Involved in Human Cancers¹¹**Oncogenes****Genes for Growth Factors or Their Receptors**

| | |
|--------|--|
| PDGF | Codes for platelet-derived growth factor; involved in glioma (a brain cancer) |
| erb-B | Codes for the receptor for epidermal growth factor; involved in glioblastoma (a brain cancer) and breast cancer |
| erb-B2 | Also called <i>Her-2</i> or <i>neu</i> ; codes for a growth factor receptor; involved in breast, salivary gland, and ovarian cancers |
| RET | Codes for a growth factor receptor; involved in thyroid cancer |

Genes for Cytoplasmic Relays in Stimulatory Signaling Pathways

| | |
|-------|--|
| K-Ras | Involved in lung, ovarian, colon, and pancreatic cancers |
| N-Ras | Involved in leukemias |

Genes for Transcription Factors That Activate Growth-Promoting Genes

| | |
|-------|--|
| c-Myc | Involved in leukemias and breast, stomach, and lung cancers |
| N-Myc | Involved in neuroblastoma (a nerve cell cancer) and glioblastoma |
| L-Myc | Involved in lung cancer |

Genes for Other Kinds of Molecules

| | |
|-------|---|
| Bcl-2 | Codes for a protein that normally blocks cell suicide; involved in follicular B-cell lymphoma |
| Bcl-1 | Also called <i>PRAD1</i> ; codes for cyclin D1, a stimulatory component of the cell-cycle clock; involved in breast, head, and neck cancers |
| MDM2 | Codes for an antagonist of the p53 tumor-suppressor protein; involved in sarcomas (connective tissue cancers) and others cancers |

Tumor-Suppressor Genes**Genes for Proteins in the Cytoplasm**

| | |
|-------|--|
| APC | Involved in colon and stomach cancers |
| DPC-4 | Codes for a relay molecule in a signaling pathway that inhibits cell division; involved in pancreatic cancer |
| NF-1 | Codes for a protein that inhibits a stimulatory (Ras) protein; involved in neurofibroma and pheochromocytoma (cancers of the peripheral nervous system) and myeloid leukemia |
| NF-2 | Involved in meningioma and ependymoma (brain cancers) and schwannoma (affecting the wrapping around peripheral nerves) |

Genes for Proteins in the Nucleus

| | |
|------|--|
| MTS1 | Codes for the p16 protein, a braking component of the cell-cycle clock; involved in a wide range of cancers |
| RB | Codes for the pRB protein, a master brake of the cell cycle; involved in retinoblastoma and bone, bladder, and small-cell lung and breast cancer |
| p53 | Codes for the p53 protein, which can halt cell division and induce abnormal cells to kill themselves; involved in a wide range of cancers |
| WT1 | Involved in Wilms tumor of the kidney |

Genes for Proteins Whose Cellular Location Is Not Yet Clear

| | |
|-------|--|
| BRCA1 | Involved in breast and ovarian cancers |
| BRCA2 | Involved in breast cancer |
| VHL | Involved in renal cell cancer |

ease. Does taking anti-inflammatory medications alter the risk of cancer?

Cancer chemoprevention focuses on suppressing or reversing carcinogenesis in the early phases and preventing the development of invasive cancer. Also, much has been learned about the differences that exist among people and the interindividual variability in their inherited susceptibility to carcinogenic exposures.¹² This type of information will be useful in the design of a chemoprevention program that can be personalized for a specific individual. Chemoprevention strategies can be categorized as primary prevention (i.e., preventing cancer in a healthy individual at high risk), secondary prevention (i.e., preventing cancer in an individual with a premalignant lesion), or tertiary prevention (i.e., preventing a second primary cancer in an individual already cured of a prior malignancy).¹³ Chemoprevention may involve treatment with nutrients or natural or synthetic chemicals that exert their protective effects by reversing the abnormal differentiation, inhibiting proliferation, or inducing apoptosis (programmed cell death) of premalignant cells. Other agents can act to block the uptake of carcinogens into cells, inhibit the activation of procarcinogens by various enzymes, or directly detoxify activated carcinogens.¹⁴ Specific phases of carcinogenesis that are current targets for chemoprevention include genes that direct tumorigenesis and metastasis, cell signaling pathways, and genetic (i.e., chromosomal) instability common to malignancies.^{14,15}

Chemoprevention studies are designed to detect changes in the incidence of cancer, as well as the rate of regression, progression and recurrence of premalignant lesions. Because long-term, perhaps even lifelong, therapy with an effective chemoprotectant may be necessary, ideal chemoprotectants should be safe and inexpensive. Once-daily dosing (or less) is desirable to maximize adherence. Another important aspect of effective chemoprevention is the ability to identify individuals at high risk for specific cancers through genetic susceptibility assessments, biomarkers of lifestyle or environmental exposures, or detection of premalignant cellular changes or lesions. These individuals are most likely to benefit from chemoprevention or should be encouraged to participate in a clinical trial. Findings from several large trials are described in Table 88-4.

Colon cancer is the second leading cause of cancer death; therefore, the search for agents that can lower the risk for this disease is warranted. In colorectal cancer cells and adenomatous polyps, elevated levels of cyclooxygenase-2 (COX-2) enzyme, messenger RNA, and protein can be found and these are associated with increased proliferation and resistance to apoptosis. The action of cyclooxygenase may enhance the conversion of several procarcinogens into carcinogens, the production of oxygen-free radicals, and otherwise stimulate cell proliferation.¹⁴ One option, therefore, is to recommend that M.S. discuss the use of aspirin or another nonsteroidal anti-inflammatory drug (NSAID) with her primary health care provider. These agents potentially reduce the risk of colon cancer, although their benefit in the general population has not been established.¹⁶ In randomized, controlled clinical trials, aspirin, sulindac, and celecoxib have reduced the development of new or recurrent adenomas in high-risk patients.^{16–20} Although aspirin has been shown to prevent adenomatous polyp formation, its use was associated with increased risk for stroke and serious bleeding. For patients with previous colorectal cancer,

Prevention**Chemoprevention**

1. M.S., a 37-year-old woman, asks about taking medications to reduce her risk of cancer. Her mother died several years ago of colon cancer, and she fears that she also will develop the dis-

Table 88-4 Large, Randomized Chemoprevention Trials

| <i>Trial</i> | <i>Agent</i> | <i>Population</i> | <i>Duration of Intervention (yr)</i> | <i>Endpoints</i> | <i>Outcomes</i> |
|---------------------------------|-----------------------------|--|--------------------------------------|---------------------------------|---|
| Anti-inflammatory Agents | | | | | |
| Sandler et al. ¹⁷ | Aspirin | Patients with history of colorectal cancer (N = 635) | 1 | Colorectal adenoma recurrence | Positive: lower relative risk for recurrent adenomas and time to detection of first adenoma. |
| Baron et al. ¹⁸ | Aspirin | Patients with a history of colorectal adenomas (N = 1,121) | 1 | Colorectal adenoma recurrence | Positive: lower relative risk for advanced neoplasms. Nonsignificant increases for stroke and serious bleeding in the aspirin group. |
| Chan et al. ²¹ | Aspirin | Patients with colorectal carcinoma (N = 130,274) | | Colorectal carcinoma recurrence | Positive: lower incidence for cancers that overexpress cyclooxygenase 2 (COX-2) but not for cancers with weak or absent COX-2 expression. |
| APC ¹⁹ | Celecoxib | Patients with colorectal adenomas (N = 2,035) | 3 | Colorectal adenoma recurrence | Positive: lower incidence for adenomas. Increased risk for cardiovascular events. |
| PreSAP ²⁰ | Celecoxib | Patients with colorectal adenomas (N = 1,561) | 3 | Colorectal adenoma recurrence | Positive: lower incidence for adenomas. |
| Antiestrogens | | | | | |
| BCPT ²² | Tamoxifen | Women of higher-than-average risk of breast cancer (N = 13,000) | 5.7 | Newly diagnosed breast cancer | Positive: reduced the risk of invasive and noninvasive cancers and the occurrence of estrogen receptor-positive tumors; tamoxifen received an indication for chemoprevention from the U.S. Food and Drug Administration |
| MORE ²⁴ | Raloxifene | Postmenopausal women with osteoporosis (N = 7,705) | 3 | Newly diagnosed breast cancer | Positive: reduced the risk of invasive cancers. |
| IBIS-I ²³ | Tamoxifen | Women of higher risk of breast cancer | 5 | Newly diagnosed breast cancer | Positive: risk-reducing effect persists for at least 10 yrs; higher risk for deep-vein thrombosis and pulmonary embolism, but not after tamoxifen stopped. |
| STAR ²⁵ | Tamoxifen versus raloxifene | Postmenopausal women at high risk for breast cancer (N = 19,747) | 5 | Newly diagnosed breast cancer | Positive: raloxifene as effective as tamoxifen for reducing risk of invasive breast cancer; lower risk of thromboembolic events. |

recent studies suggest that aspirin's use for preventing further tumorigenesis will be more beneficial for those with prior tumors that overexpress COX-2 compared with those that do not overexpress it.²¹ Celecoxib use also prevents adenomatous polyp formation, but cardiovascular risk is also increased.^{19,20}

Finally, M.S. should be encouraged to modify her lifestyle in ways that reduce her overall risk of cancer. These include maintaining a healthy body weight, following a healthy diet, participating in a regular exercise program, avoiding tobacco and other known carcinogens, and avoiding or limiting alcohol consumption.

2. J.M., a 45-year-old woman, tells you that her twin sister was recently treated for breast cancer. She heard on the news that relatives of breast cancer patients are at higher risk for developing the disease and that a drug is now available that can prevent breast cancer. Should J.M. consider taking something to prevent breast cancer?

The Breast Cancer Prevention Trial (BCPT) of the National Surgical Adjuvant Breast Project (NSABP) enrolled 13,000 women who were at higher-than-average risk of developing

breast cancer.²² The trial demonstrated that the risk of invasive breast cancer was reduced by 49% in subjects treated with tamoxifen. During the 69-month follow-up period, 175 of the 6,599 women enrolled in the placebo arm developed invasive breast cancer, compared with 89 of the 6,576 women enrolled in the tamoxifen arm ($p < 0.00001$). Women in this trial received tamoxifen 20 mg/day orally for 5 years. It is important to note that women in the tamoxifen arm had a higher incidence of pulmonary embolism (relative risk [RR], 3.01) and endometrial cancer (RR, 2.53). These risks were greatest in women >50 years of age. The results of this trial led the U.S. Food and Drug Administration (FDA) to approve tamoxifen for the prevention of breast cancer in high-risk women. Longer term, some of the adverse effects associated with tamoxifen therapy (deep vein thrombosis and pulmonary embolism) appear to decrease with time (i.e., 5 years after completion of therapy).²³ Raloxifene, a selective estrogen receptor modulator approved for prevention of osteoporosis, also has been shown to reduce the risk of invasive breast cancer in women with osteoporosis. Patients receiving raloxifene showed an increased risk of thromboembolic disease, but they did not show an increased risk of endometrial cancer in this single trial.²⁴ Results from

a randomized clinical trial comparing tamoxifen and raloxifene (STAR P-2) demonstrated that raloxifene 60 mg/day for 5 years is as effective as tamoxifen 20 mg/day in reducing the risk of invasive breast cancer, and has a lower risk for thromboembolic events.²⁵ Raloxifene may not be as beneficial as tamoxifen for noninvasive breast cancer because a nonstatistically higher risk for noninvasive breast cancer was found for subjects in the raloxifene group.

Because her sister developed breast cancer before menopause, J.M. may be at a higher-than-average risk for developing breast cancer and she may benefit from preventive therapy. J.M. should discuss the benefits and risks of chemoprevention with her primary health care provider.

Vaccines

3. M.M., a 35-year-old woman, asks you about vaccines to prevent cervical cancer. She heard that a vaccine is now available. Should M.M. consider this vaccine for herself or her daughter? Would this substitute for Pap smear screening?

Human papillomavirus (HPV) is primarily transmitted through sexual contact, and serotypes 16 and 18 (HPV-16, -18) cause approximately 70% of cervical cancers.²⁶ It is difficult to show that an intervention prevents cancer, because the time between exposure of the virus and tumorigenesis can be protracted. This would require several years and possibly decades to demonstrate efficacy; hence, key surrogate markers, such as cervical intraepithelial neoplasia, are used to assess efficacy. The FUTURE I and FUTURE II trials prospectively randomized 17,622 women between the ages of 15 and 26 years to receive either placebo or GARDASIL (Human Papilloma Virus Quadrivalent Vaccine).^{27,28} Subjects received three injections over 6 months and were followed >3 years. The primary endpoint, occurrence of cervical intraepithelial neoplasia was reduced significantly in the vaccine group compared with the placebo group. No effect was observed on previously existing lesions, however, suggesting that the benefit for this vaccine appears to be limited to those with no prior exposure to the virus. The HPV serotypes present in the quadrivalent vaccine include types 6, 11, 16, and 18. At least 15 oncogenic HPV serotypes are not included in the vaccine, thus the vaccine does not prevent the possibility of contracting cervical cancer caused by the less common serotypes. Other vaccines that cover additional serotypes are under evaluation in clinical trials. Efficacy has also not been established in women >26 years of age who might be expected to have had more lifetime sexual partners, nor has it been tested for men. HPV screening should continue for all vaccinated women, because the vaccine does not cover all serotypes of HPV and the duration of vaccine induced anti-HPV immunity is unknown.

Diet

Diet has been linked to the development of colon, prostate, and breast cancers. Worldwide, colon cancer is the third most common cancer in the Western world,²⁹ but it is relatively uncommon in Africa and Asia, except Japan.³⁰ Epidemiologic studies show that the incidence of colon cancer in a population increases as individuals migrate from a low-incidence region to a high-incidence region, suggesting that diet or other environmental factors have an important impact on the etiology of colon cancer.³⁰ Western diets tend to contain more fat and less

fiber compared with diets of low-incidence regions. Randomized trials, however, have been unable to show a benefit of high dietary fiber intake in reducing the recurrence of colorectal adenomas in people who have undergone resection of colorectal polyps.¹² Furthermore, the consequences of supplementing fiber in the diet may produce confounding factors, such as decreased fat intake, decreased caloric intake, and even weight loss. Nevertheless, the ACS advocates a healthy diet that consists of vegetables, fruit, whole grains, and fiber and is low in fat and limits red meats.

Similar to the incidence of colon cancer, migrant studies suggest that diet, environmental, or social factors play a role in the cause of prostate cancer, particularly in Asian men.³¹ An increasing incidence of prostate cancer has been observed in Japan, which is thought to be associated with a shift toward a more westernized diet.³¹ In women, the risk of breast cancer is increased with obesity and physical inactivity, but an association with high-fat diet is less clear.³² Furthermore, environmental or lifestyle factors influence the risk of breast cancer. For example, even moderate alcohol consumption has been associated with an increased risk of breast cancer.³³

Sun Exposure

Most risk factors associated with skin cancer are uncontrollable variables, with the exception of sun exposure and other forms of ultraviolet radiation. The interaction between ultraviolet radiation and skin cancers is complex, because nonmelanomas (e.g., basal cell and squamous cell carcinomas) are associated with total cumulative ultraviolet radiation exposure, whereas melanomas are associated with intermittent sun exposure.³⁴ The risk of melanoma is further increased in people who have a history of five or more severe sunburns in their lifetime, particularly during adolescence.³⁴ A rising incidence of melanoma skin cancers is thought to be caused by excessive, intermittent sun exposures—particularly among individuals who travel to sunny regions during the winter and to depletion of the ozone layer in the stratosphere.³⁴ Prevention is simply based on limiting sun exposure. The ACS guidelines recommend avoiding or limiting sun exposure from 10 AM to 4 PM when the ultraviolet rays are the strongest. Protective clothing, including a hat, sunglasses, and long-sleeved shirt and pants, and sunscreens are also advised to minimize exposure. The protective effects of sunscreens alone against melanoma, particularly for intentional sun exposure, is controversial.³⁵ To reduce the risk of skin cancer, individuals should be cautioned to limit direct sun exposure whenever possible.

Tumors

Growth

CELL CYCLE TRANSITION

Cancer cells, as with normal cells, proceed through a specific and orderly set of events during cellular replication referred to as the cell cycle (Fig. 88-2). The cell cycle contains four phases (S, M, G₁, and G₂) of activity, each responsible for a different task necessary for cell division. During the first activity phase, the M phase, the cell undergoes mitosis, the process of cell division. After mitosis, the cell enters the first gap or resting phase (G₁). During the G₁ phase, the cell makes the enzymes necessary for DNA synthesis. The synthesis of

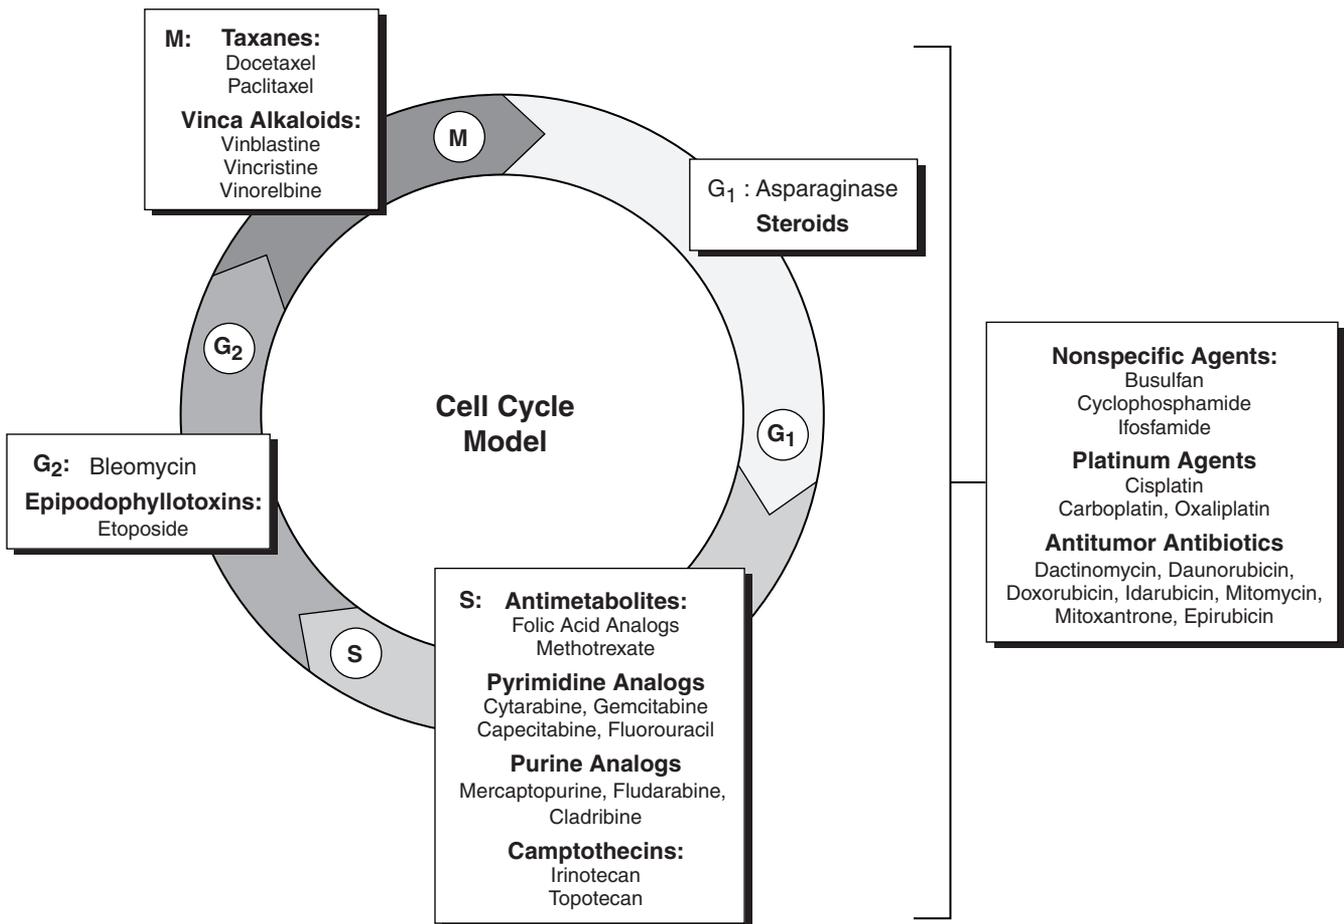

FIGURE 88-2 Cell cycle and effects of cytotoxic drugs on phases of the cell cycle.

DNA occurs during the next activity phase called the S phase. After the S phase, the cell enters a second gap phase (G_2). RNA and other proteins are synthesized during this gap phase to prepare for cell division during the M phase. The cells that complete mitosis may (a) continue to proceed through the cell cycle to divide again, (b) differentiate or mature into specialized cells and eventually die, or (c) enter a third resting phase called G_0 .³⁶

Proliferation of normal cells (or cell renewal) is under fine control to balance the loss of mature functional cells with the production of new cells. As mentioned, proto-oncogenes and tumor-suppressor genes provide the stimulatory and inhibitory signals, respectively, that regulate the cell cycle. The transition of cells through the cell cycle is an ordered, tightly regulated process, which involves a series of checkpoints that assess these signals and the number and integrity of the cells.³⁶ *Cyclins*, a group of interacting proteins found in the nucleus, and cyclin-dependent kinases (CDK), make up the molecular machinery that regulates passage of cells through various phases of the cell cycle. The cyclins combine with the CDK to form complexes that act as molecular switches. A molecular switch allows the cell to move through a critical restriction point that occurs late in the G_1 phase to the S phase. If insufficient amounts of cyclins or CDK are present during the G_1 phase, the cell will not enter the S phase to start cell division. Cells that pass through this

point are irreversibly committed to the next phase of the cell cycle.³⁶ A decline in the level of the CDK complex signals the end of the phase.

The levels of cyclins and CDK are influenced by several factors, such as transcription of cyclin genes, degradation of cyclins, activities of CDK inhibitors, and the transfer of phosphate groups to various proteins and enzymes. Cues from the cell's external environment are transmitted to the nucleus via growth factor receptor signaling pathways, which influence formation of cyclins and cyclin-CDK complexes. The complexes generate phosphate groups from molecules of adenosine triphosphate (ATP) and transfer them to a protein called a retinoblastoma protein (pRB). If the pRB acquires enough phosphate groups, it will release the transcription factors the cell needs to make proteins essential for a cell division. Naturally occurring CDK inhibitors block cell cycle progression in response to inhibitory growth signals.

In cancer cells, the regulation and function of cyclins, CDK, and inhibitory proteins may be disrupted by a malignant transformation, or these proteins can undergo changes that cause a malignant transformation. Defects in these processes that are common in human cancers include deletion of the RB gene, a tumor suppressor gene that encodes for pRB, and dysregulation of the CDK through over-activation of CDK or loss of CDK inhibitors.³⁷ Without appropriate pRB regulation of cell cycle

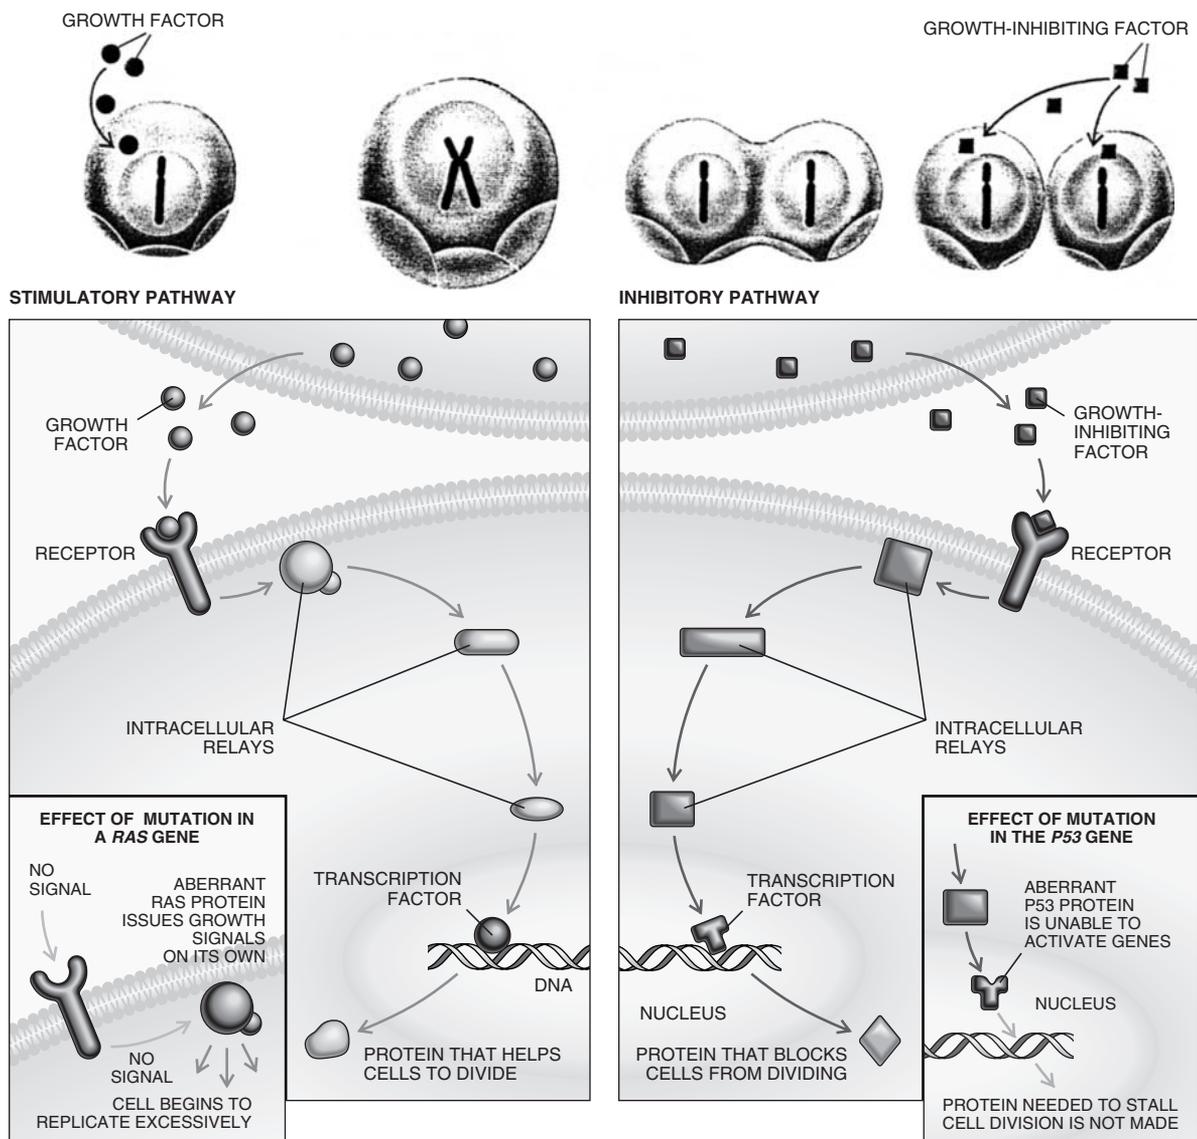

FIGURE 88-3 Normal stimulatory and inhibitory cell growth pathways and related effects of gene mutations on cell proliferation. (From reference 127, with permission.)

transition from the G_1 to the S phase, excessive cell proliferation can occur. Loss or mutation of a second tumor suppressor gene, p53, is also common in human cancers, and is associated with the resistance of cancer cells to undergo cell cycle arrest or apoptosis (e.g., programmed cell death). In normal cells, the p53 gene is responsible for temporarily arresting cell growth in response to biochemical or molecular damage until the damage can be repaired.³⁸ If the damage cannot be repaired, apoptosis is a normal cell suicide process that is initiated to prevent genetically damaged cells from growing uncontrollably. Figure 88-3 illustrates the normal stimulatory and inhibitory cell growth pathways and related effects of gene mutations on cell proliferation.

SURVIVAL

If the stimulatory and inhibitory growth signals do not program the cell to stop dividing, mechanisms, such as apoptosis and senescence (aging), can help control excessive cell divi-

sion. Because abnormalities in the proto-oncogenes and tumor suppressor genes that regulate these processes are present in cancer cells, the balance between cell renewal and loss of mature (senescent) cells is disrupted. Also, cancer cells are less dependent on receiving stimulatory signals from external growth factors.³⁸ Furthermore, cancer cells possess unlimited replication potential, owing to their ability to activate telomerase.^{1,39} Telomerase is an enzyme that synthesizes sequences of telomeres, thereby enabling cells to proliferate endlessly. The expression of telomerase in most normal human cells is suppressed but it is reactivated in most cancer cells.^{38,39} Telomeres are repeats of DNA and DNA-binding proteins that form the ends of eukaryotic chromosomes.³⁹ Telomere loss occurs with each successive cell replication and, after a critical length is reached, the cell undergoes irreversible growth arrest (replicative senescence).³⁹ Unlike normal cells, in which a finite telomere sequence regulates their life span, cancer cells are capable of immortality through their ability to maintain their telomeres

indefinitely. Strategies to inhibit telomerase activity in cancer cells comprise one of many new molecular approaches that are being studied. Efforts are underway to target key genes, proteins, and receptors that facilitate cancer cell growth.

Spread

4. D.J., a 14-year-old boy, presented to the emergency department with a painful, swollen right leg. X-ray examination confirmed a fracture that appeared to be caused by a tumor mass in the bone. Biopsy confirmed osteogenic sarcoma. A routine chest x-ray study showed three nodules that were also believed to be malignant tumors. Does D.J. also have lung cancer? Are the tumors in D.J.'s lungs related to the sarcoma in his leg?

The tumor nodules in D.J.'s lung are most likely metastases from the sarcoma in his leg. The ability of cancer cells to disseminate and form metastases represents their most malignant characteristic. Tumor metastases to distant sites generally have a greater effect than the primary tumor on the frequency of complications and the patient's quality of life (see Complications of Malignancy). Metastases also have a greater effect than the primary tumor on mortality, with metastases associated with most cancer-related deaths. Consequently, individuals diagnosed with metastases face a worse prognosis.

Cancer cells must develop new blood vessels to supply nutrients to the cells and to spread to distant sites (metastasize). In response to low oxygen supply (hypoxia) and other factors, the cancer cells and surrounding tissues secrete growth factors that stimulate the growth of the new blood vessels (or angiogenesis) from existing blood vessels in the surrounding normal host tissue. Although many growth factors secreted by the tumor can be considered angiogenic, vascular endothelial growth factor (VEGF), platelet derived growth factor (PDGF), and basic fibroblast growth factor (bFGF) are considered those most important for sustained endothelial cell growth. Once released by the tumor cells, these growth factors bind to tyrosine kinase receptors on the surface of endothelial cells of existing blood vessels and activate a series of intracellular relay proteins that transmit a signal to genes in the nucleus to produce factors required for new endothelial cell growth.⁴⁰ Once the older endothelial cells become activated by the growth factors, they begin making matrix metalloproteinase enzymes (MMP). These enzymes destroy the extracellular matrix of the surrounding cells, allowing the older endothelial cells to invade the extracellular matrix and begin cell division.⁴⁰ This process of invasion and proliferation is repeated several times until new blood vessels are formed.

Tumor cells can utilize these newly formed blood vessels to facilitate their spread to distant locations. They must break away from the primary tumor and travel to other sites in the body to form metastases. Normally, cells adhere to both other cells and the extracellular matrix. The cell-to-cell adhesion molecules are called *cadherins*, and the cell-to-extracellular matrix molecules are called *integrins*. In cancer cells, these molecules are often absent, allowing tumor cells to easily move away from the primary tumor mass.

Once a tumor cell breaks off, it can move through the body to form metastatic sites. Two primary pathways, the blood vessels and the lymphatics, play a critical role in determining the location of metastatic sites (Table 88-5). A tumor cell can travel only to a distant site that receives blood or lymph from the pri-

Table 88-5 Common Cancers and Sites of Metastases

| Cancer | Most Common Sites of Metastases |
|-------------------|--|
| Bladder | Pelvis, lymph nodes |
| Breast | |
| • Premenopausal | Lymph nodes, skin, lung, liver, bone, brain |
| • Postmenopausal | Lymph nodes, bone, soft tissue |
| Colon | Lymph nodes, liver, lung, adrenals, ovary, bone |
| Lung | |
| • Non–small-cell | Lymph nodes, liver, bone, brain, adrenals |
| • Small-cell | Lymph nodes, bone, liver, bone marrow, brain |
| Lymphomas | |
| • Hodgkin disease | Liver, spleen, stomach, bone marrow, lung |
| • lymphoma | |
| • Non-Hodgkin | Gastrointestinal tract, bone marrow, liver, lung, central nervous system |
| Ovary | Peritoneum, lung |
| Prostate | Lymph nodes, bone, liver |

mary site. Usually, tumor cells spread to the first capillary bed they encounter after their release from the primary tumor. If the primary site drains its blood supply into the vena cava, the cancer cells will reach the capillary bed in lung. Similarly, if the primary site drains its blood supply into the portal circulation, the cancer cells will reach the capillary bed in the liver. In addition, cancer cells can potentially pass through the first capillary bed they encounter and enter the arterial circulation. If malignant cells reach the arterial circulation, they can distribute to other organs and tissues throughout the body. Growth conditions (e.g., growth factors, physiologic conditions) within a tissue or organ also can determine the location of a metastatic site. After a cancer cell establishes a metastatic site, it must again undergo angiogenesis to ensure continued growth. Together, angiogenesis and hematogenous or lymphatic spread help cancer cells invade healthy tissues and increase morbidity and mortality associated with the disease.

Screening and Early Detection

Standardized screening tests can help identify disease in asymptomatic individuals (screening) or help diagnose a disease in symptomatic individuals (early detection). Ideally, a screening test should be quick and simple to maximize compliance with screening recommendations. The cancer screening tests recommended by the ACS meet four basic requirements: (a) there must be good evidence that the test is effective in reducing morbidity or mortality (e.g., effective treatment must be available for the screened disease); (b) the benefits of the test should outweigh its risks; (c) the costs of the test should be in balance with its presumed benefits; and (d) the test should be practical and feasible within the existing health care setting. Various professional organizations, including the ACS, regularly publish recommendations for cancer screening^{3,41} (Table 88-6).

Recommendations for cancer screening tests have been in existence for decades. As advances are made in screening techniques and the management of certain cancers, recommendations for cancer screening are updated as new information becomes available. Although the concepts of cancer screening and early cancer detection seem intuitively beneficial,

Table 88-6 Guidelines for Screening Cancer

| | <i>American Cancer Society</i> [†] | <i>National Comprehensive Cancer Network</i> |
|------------------------------|---|---|
| Self-Examination | | |
| Breast self-examination | 20 yr: monthly | 20 yr: encouraged |
| Testicular self-examination | Not recommended | Not recommended |
| Skin | Not recommended | Not recommended |
| Clinician Examination | | |
| Clinical breast examination | 20–39 yr: every 3 yr 40 yr: annually | 20–39 yr: every 1–3 yr 40 yr: annually High risk: begin earlier and more frequently, depending on risk |
| Digital rectal examination | Colon: not recommended Prostate: if life expectancy 10 yr, 50 yr (normal risk) or 40–45 yr (high risk): annually | Not recommended |
| Pelvic examination | 18 yr: annually | 18 yr or within 3 yr of onset of sexual activity: annually |
| Sigmoidoscopy | Normal risk, 50 yr: every 5 yr, preferably with annual FOBT, as alternative to colonoscopy every 10 yr or double-contrast barium enema every 5 yr High risk: begin earlier than age 50 yr and/or more frequently | Normal risk, 50 yr: every 5 yr with annual FOBT, as alternative to colonoscopy every 10 yr or double-contrast barium enema every 5 yr High risk: begin earlier than age 50 yr and more frequently, depending on risk |
| Colonoscopy | Normal risk, 50 yr: every 10 yr as alternative to annual FOBT, sigmoidoscopy every 5 yr, or double-contrast barium enema every 5 yr High risk: begin earlier than age 50 yr and more frequently | Normal risk, 50 yr: every 10 yr with annual FOBT, as alternative to sigmoidoscopy every 5 yr, or double-contrast barium enema every 5 yr High risk: begin earlier than age 50 yr and more frequently, depending on risk |
| Laboratory Tests | | |
| Stool guaiac | 50 yr: annually High risk: begin earlier than age 50 yr: annually | 50 yr: annually |
| Prostate specific antigen | If life expectancy 10 yr, 50 yr (normal risk), or 40–45 yr (high risk): annually | Normal risk, life expectancy 10 yr, 50 yr: annually High risk, life expectancy 10 yr, 45 yr: annually |
| Pap smear | 21 yr or within 3 yr of onset of sexually activity if earlier: annually (regular Pap test) or every 2 yr (liquid-based Pap test) 30 yr: every 2–3 yr if three normal prior consecutive Pap test results 70 yr: optional if three or more normal prior consecutive Pap test results and no abnormal Pap test results in the last 10 yr | 21 yr or within 3 yr of onset of sexually activity if earlier: annually (regular Pap test) or every 2 yr (liquid-based Pap test) 30 yr: every 2–3 yr if three normal prior consecutive Pap test results 70 yr: optional if three or more normal prior consecutive Pap test results and no abnormal Pap test results in the last 10 yr |
| Mammogram | 40 yr: annually High risk: begin earlier than age 40 yr and/or have additional tests or more frequent testing | 40 yr: annually High risk: begin earlier and more frequently, depending on risk |

[†]Listed year is age at which screening begins.
CBE, clinical breast examination; FOBT, fecal occult blood test.

particularly for cancers for which treatments are available, the acceptance of various cancer screening recommendations remains controversial. The question that still needs to be answered is, “Will screening alter the natural history of the disease or simply detect the disease earlier without changing patient morbidity?” The NCI is following up more than 154,000 men and women who enrolled in the Prostate, Lung, Colorectal and Ovary (PLCO) Cancer Screening Trial to determine whether screening affects morbidity or mortality. One-half of participants have specific screening tests; the other half receives routine health care. Because the testing and follow-up occur over 16 years, the results will be unavailable for several years. Interestingly, cancer screening may not alter the mortality or morbidity associated with various cancers. Recent can-

cer statistics show that patients are still being diagnosed with potentially curable cancers late in the course of the disease, despite the introduction of these recommendations two decades ago.

As new information becomes available, the various professional organizations modestly change their cancer screening recommendations. Only minor changes have been made to the recommendations since the ACS first published its guidelines, because a newly discovered tumor marker or diagnostic procedure must first be validated as a screening test. New tests should fit the four basic requirements the ACS used to develop the current guidelines, including cost:benefit ratio. Because a new screening test could add substantial costs to an already stressed health care system, its costs, benefits, and risks should

be evaluated thoroughly before it is recommended for routine use. Screening recommendations also accommodate patients who are at higher than average risk for developing cancer owing to genetic, environmental, and lifestyle factors.

Diagnosis and Staging

The histologic diagnosis of a tumor is the most important determinant of how a malignancy will be treated. This is because a tumor's histologic classification influences its natural history, pattern of progression, and responsiveness to treatment. A surgical biopsy or excision of the primary tumor, followed by a microscopic and a biochemical evaluation by a pathologist, can provide the most accurate histologic diagnosis. Thereafter, staging can begin.

5. J.S. is diagnosed with breast cancer after a large breast mass was biopsied. Chemotherapy, radiation, and surgery all play an important role in the treatment of breast cancer. How does a clinician decide which treatment modalities are most appropriate for J.S.?

The stage of the cancer, as well as the histologic diagnosis, significantly influences both the treatment and prognosis. Staging is the process that determines the extent or spread of the disease. For J.S., staging is crucial to guide therapy. If her disease is limited to her breast, surgery followed by radiation, chemotherapy, or both or hormonal therapy would be recommended. If the cancer has spread beyond the breast, however, surgery may not be recommended. J.S. should immediately consider systemic therapy (chemotherapy or endocrine therapy) if she has advanced disease.

Staging schemas have been developed for all major types of cancers. For solid tumors, the most widely used and accepted staging classification is the TNM system, which incorporates the size of the primary tumor (T), the extent of regional lymph node spread (N), and the presence or absence of metastatic spread to distant organs (M). Within each TNM category, the extent of cancer involvement is related to prognosis. Determining the stage of the cancer often requires tests that can physically or radiographically measure the size of the primary tumor (e.g., radiographs, computed tomography [CT] scans, or magnetic resonance imaging [MRI] scans), dissect and pathologically examine regional lymph nodes, and assess the patient for evidence of tumor spread. In addition, positron emission tomography [PET] scans are being used more frequently to help determine whether tissues contain cancerous cells. To find evidence of a metastatic site, clinicians perform tests that assess the most likely sites of tumor metastases (Table 88-5) and they evaluate symptoms (e.g., pain) or signs (e.g., swelling, abnormal laboratory findings) that may indicate tumor involvement at a distant site.

An example of the TNM classification for solid tumors is shown in Table 88-7. Most solid tumor staging systems also incorporate the TNM classification into broader groups or stages to facilitate comparison among patient populations. Whereas the TNM system adequately stages solid tumors, this staging system does not adequately stage hematologic malignancies, including leukemias, lymphomas, and multiple myelomas. Because hematologic malignancies occur in the blood cells and lymphatic tissues that are widely distributed throughout the body, the TNM staging system cannot sufficiently describe

Table 88-7 Staging of Breast Carcinoma

TNM Classification^a

Primary Tumor (T)

| | |
|----|---|
| T1 | Tumor 2 cm in greatest dimension |
| T2 | Tumor >2 cm but not >5 cm in greatest dimension |
| T3 | Tumor >5 cm in greatest dimension |
| T4 | Tumor of any size with direct extension to chest wall or skin |

Regional Lymph Nodes (N)

| | |
|----|---|
| N0 | No regional lymph node metastasis |
| N1 | Metastasis to movable ipsilateral axillary lymph node(s) |
| N2 | Metastasis to ipsilateral axillary lymph node(s) fixed to one another or other structures |
| N3 | Metastasis to ipsilateral internal mammary lymph node(s) |

Distant Metastasis (M)

| | |
|----|---|
| M0 | No distant metastasis |
| M1 | Distant metastasis (includes metastasis to ipsilateral supraclavicular lymph nodes) |

Stage Grouping

| | | | |
|------------------------|-------|------------|----|
| Stage I | T1 | N0 | M0 |
| Stage II _A | T0 | N1 | M0 |
| | T1 | N1 | M0 |
| | T2 | N0 | M0 |
| Stage II _B | T2 | N1 | M0 |
| | T3 | N0 | M0 |
| Stage III _A | T0 | N2 | M0 |
| | T1 | N2 | M0 |
| | T2 | N2 | M0 |
| | T3 | N1, N2 | M0 |
| Stage III _B | T4 | N0, N1, N2 | M0 |
| Stage III _C | Any T | N3 | M0 |
| Stage IV | Any T | Any N | M1 |

^a See text for full explanation of TNM system of classification. TNM, tumor-node-metastasis.

these diseases. To define the extent of disease, guide treatment, and provide prognostic information, specific staging systems have been developed for various hematologic malignancies. Examples of widely accepted staging systems for hematologic malignancies include the Rai system for chronic lymphocytic leukemia and the Ann Arbor system for lymphomas.

Staging systems for some tumors include other characteristics to further determine the stage and prognosis of the disease. These characteristics may include clinical signs or symptoms or biochemical characteristics of the tumor. For example, the staging system used for Hodgkin disease includes a notation for constitutional symptoms (i.e., fever, night sweats, and weight loss). Studies indicate that these symptoms confer a poorer prognosis and could indicate the need for more intensive therapy. A subscript "B" (e.g., stage II_B) next to the stage indicates the patient has experienced these symptoms, whereas the subscript "A" indicates the patient has not experienced these symptoms.

Tumor staging is done at the time of initial diagnosis and periodically during treatment to assess the patient's response to therapy. Staging should also be repeated when (a) evidence shows that the cancer has either progressed during treatment or recurred following therapy to establish the most appropriate second-line therapy and (b) to enable measurement of response to that therapy.

Table 88-8 Signs and Symptoms Associated With Common Cancers

| Cancer | Local ^a | Distant ^b |
|------------|--|--|
| Bladder | Hematuria; bladder irritability; urinary hesitancy, frequency or urgency; dysuria; flank or pelvic pain | Edema of lower extremities and genitalia |
| Breast | Breast lumps; nipple retraction, dimpling, discharge; skin changes; axillary lymphadenopathy | Bone pain; elevated LFT; hypercalcemia |
| Colorectal | Change in bowel habits; in stool caliber; occult bleeding; constipation | Elevated LFT, CEA, and alkaline phosphatase; obstruction; hepatomegaly; perforation |
| Lung | New cough; hoarseness hemoptysis, dyspnea; unresolving pneumonias; chest wall pain; pain; dysphagia; effusion; tracheal obstruction | Anorexia; weight loss; elevated LFT; bone pain, hypercalcemia; jaundice; lymphadenopathy; osteoarthritis; neurologic (brain metastases and neuromuscular disorders); SIADH |
| Lymphomas | Painless lymphadenopathy | Fever; night sweats; weight loss; bone or retroperitoneal pain; hepatomegaly; splenomegaly; abnormal CBC |
| Melanoma | Change in size, color, or shape of a pre-existing nevus | Lymphadenopathy; elevated LFT |
| Ovarian | Abdominal pain, discomfort, or enlargement; postprandial flatulence; vaginal bleeding; abdominal mass; urinary frequency; constipation, nausea; dyspepsia; early satiety | Peripheral neuropathies; pleural effusion; thrombophlebitis; elevated LFT; abdominal distention or pain; Addison or Cushing syndrome |
| Prostate | Urinary hesitancy; nocturia; poor urine stream; dribbling; terminal hematuria | Bone pain; elevated acid phosphatase, PSA, and alkaline phosphatase |
| Testicular | Painless enlargement; epididymitis; gynecomastia; back pain; infertility or erectile dysfunction | Elevated β hCG, α -fetoprotein, LD |

^aLocal effects include those produced by the primary tumor.

^bDistant effects include those associated with metastatic spread and paraneoplastic syndromes. Many cancers may not produce symptoms in the early stages, and diagnosis at that time depends on early detection and screening efforts.

CBC, complete blood count; CEA, carcinoembryonic antigen; hCG, beta human chorionic gonadotropin; LD, lactate dehydrogenase; LFT, liver function tests; PSA, prostate-specific antigen; SIADH, syndrome of inappropriate antidiuretic hormone secretion.

Clinical Presentation

The initial signs and symptoms of malignant disease are variable and predominantly depend on the histologic diagnosis, the location (including metastases), and the size of the tumor. Pain secondary to compression, obstruction, and destruction of adjacent tissues and organs is the most common presenting symptom. Other common initial symptoms reported by patients with cancer include anorexia, weight loss, and fatigue. Table 88-8 lists the common signs and symptoms associated with specific cancers. Some symptoms, however, may be obscured by a concomitant illness, such as chronic lung disease in patients with lung cancer. Whereas most tumors cause signs and symptoms early in the course of the disease, some cancers do not cause symptoms until late in the course of the disease and after significant tumor growth. In either of these circumstances, early diagnosis may be difficult. Thus, individuals at a higher-than-average risk should be screened regularly to help detect early disease.

6. P.N., a 59-year-old woman, presents with shortness of breath, fatigue, anorexia, weight loss, and abdominal pain and distention that have worsened significantly over the previous 3 weeks. An evaluation showed a large mass surrounding the head of her pancreas with biopsy results that confirm pancreatic adenocarcinoma. The staging workup confirmed the presence of distant metastases. Her husband states that she was previously an active person, but that she most recently has been unable to dress herself or participate in normal daily activities. He states that she spends most of the day in bed. Will her activity level influence the type of treatment that she can receive?

The description of P.N.'s daily activities indicates that she has a relatively poor performance status. Performance status is a measure of the functional capacity of the patient and reflects

a patient's ability to ambulate, care for him- or herself, and carry out normal activities. For several tumors, a poor pretreatment performance status is associated with a decreased ability to tolerate treatment, decreased tumor response to treatment, and a worsened clinical outcome. In these cases, especially if the cancer is not known to respond well to treatment, a less aggressive treatment regimen may be recommended. For this reason, the performance status of a patient is important to assess at the time of staging evaluation and periodically during treatment. Different scales (i.e., Karnofsky score, Eastern Cooperative Oncology Group [ECOG]) can be used to determine performance status. The World Health Organization (WHO) performance scale is depicted in Table 88-9. Because P.N. has a WHO performance status of 3, her oncologist may recommend a less aggressive, less toxic treatment plan. Because other conditions could be responsible for her symptoms, P.N. should undergo a careful evaluation. Depression is a common problem in patients with cancer and, with treatment, can lead to improved patient outcomes.

7. G.D., a 68-year-old man, presents with lethargy, weakness, and nausea. His wife states that he does not take any medications

Table 88-9 World Health Organization (WHO) Performance Status Classification in Cancer

| | |
|---|---|
| 0 | Able to carry out all normal activity without restriction |
| 1 | Restricted in physically strenuous activity but ambulatory and able to carry out light work |
| 2 | Ambulatory and capable of all self-care but unable to carry out work |
| 3 | Capable of only limited self-care; confined to bed or chair 50% or more of waking hours |
| 4 | Completely disabled; not capable of any self-care; confined to bed or chair |

and only occasionally consumes alcohol. He has smoked two packs of cigarettes per day for the past 45 years. Routine laboratory tests reveal a serum sodium (Na) of 129 mEq/L (normal, 135–147). His chest radiograph shows a large mass in his right lung, which is consistent with malignancy. Is the hyponatremia related to G.D.’s lung cancer?

[SI unit: Na, 129 mmol/L (normal, 135–147)]

G.D.’s hyponatremia is likely caused by the syndrome of inappropriate antidiuretic hormone (SIADH) secretion caused by ectopic production of ADH (see Chapter 12, Fluid and Electrolyte Disorders) by his lung carcinoma. Although most signs and symptoms can be associated with the tumor, patients occasionally report symptoms or show clinical signs that are distant to the primary tumor site or metastases. These signs or symptoms, called *paraneoplastic effects*, are produced by substances secreted by the tumor. Table 88-10 lists some of the common paraneoplastic effects.

Complications of Malignancy

Cancer can have a profound effect on the patient’s quality of life and his or her ability to tolerate appropriate therapy. For example, patients with malnutrition secondary to anorexia, me-

chanical obstruction, or pain may not tolerate some therapies because of significant physical debility. Tumor involvement of the liver, kidneys, or lungs also can complicate therapy by causing significant organ dysfunction and metabolic disturbances. In addition, compression or obstruction could produce a “mass effect” by impairing normal organ or tissue function and causing pain or other uncomfortable physical effects. Life-threatening physical effects that require immediate intervention include obstruction of the superior vena cava, spinal cord compression, and brain metastases.

TREATMENT

8. T.J., a 40-year-old man with no significant medical history, presents to his physician with complaints of abdominal pain, nausea and vomiting, weakness, and weight loss. On physical examination, he is noted to be slightly icteric, and the only significant laboratory abnormality is mild anemia (hemoglobin [Hgb], 11 g/dL [normal, 14–18], hematocrit [Hct], 33% [normal, 39%–49%]). A CT scan of the abdomen reveals a mass present in the peripancreatic area that is suggestive of malignancy. T.J. is referred to a surgeon who explains that the first step in evaluating the mass is to obtain a tissue biopsy. T.J. asks the surgeon why he cannot remove all of the mass rather than take only part of it. He also wants to know whether this malignancy will be treated with surgery, radiation, chemotherapy, hormones, or immunotherapy. What is the basis for determining which cancer treatment modality is best suited for T.J.?

[SI units: Hgb, 110 g/L (normal, 140–180); Hct, 0.33 (normal, 0.39–0.49)]

Because a tissue diagnosis of malignancy has not been made, the appropriateness of more extensive surgery for T.J. can not be determined at this time. The choice of specific therapy depends not only on the histology and stage but also on the patient’s predicted tolerance of the side effects and complications of the various treatment options. The goal of therapy should always be to cure the patient when possible. No matter what therapeutic options are under consideration, the likelihood of curing the patient is greater when the tumor burden is low. In most cases, either surgery or radiation therapy is the initial choice of therapy for localized tumors.

Surgery

Surgery is the oldest modality available to treat patients with cancer. With the recent advances in surgical techniques and an improved understanding of the patterns of tumor growth and spread, surgeons can now perform successful resections for an increasing number of patients. Surgery can play a significant role in preventing (e.g., removal of colonic polyps or cervical dysplasia), diagnosing, and staging various cancers (e.g., biopsy for histologic evaluation). Surgery can also be used to manage cases of both localized and advanced tumors. When surgery provides definitive (i.e., curative) therapy for a localized tumor, the surgeon removes the tumor plus a margin of normal tissue surrounding the tumor. For extensive, localized tumors that cannot be completely removed, patients may undergo surgery to resect the tumor partially in an attempt to improve the likelihood that subsequent chemotherapy or radiation therapy may successfully kill the tumor. Cytoreductive surgery may be useful only if effective therapies are available to treat the

Table 88-10 Paraneoplastic Syndromes Associated With Cancers

| Syndrome | Cancer |
|--|---|
| Dermatologic | |
| Sweet syndrome | Hematologic malignancies and various carcinomas |
| Endocrine | |
| Addison syndrome | Adrenal carcinoma, lymphomas, and ovarian cancer |
| Cushing syndrome | Lung, thyroid, testicular, adrenal, and ovarian cancers |
| Hypercalcemia (not associated with bone metastases) | Lung cancer |
| Syndrome of inappropriate antidiuretic hormone secretion | Lung and head and neck cancers |
| Hematologic or Coagulation | |
| Anemia | Various cancers |
| Autoimmune hemolytic anemia | Chronic lymphocytic leukemia, lymphomas, ovarian cancer |
| Disseminated intravascular coagulation | Acute progranulocytic leukemia, lung and prostate cancers |
| Thrombophlebitis | Lung, breast, ovarian, prostate, and pancreatic cancers |
| Neuromuscular | |
| Dermatomyositis and polymyositis | Lung and breast cancers |
| Myasthenic syndrome (Eaton-Lambert syndrome) | Small-cell lung, gastric, and ovarian cancers |
| Sensory neuropathies | Small-cell lung and ovarian cancers |

residual disease. Patients with limited metastatic disease (e.g., one or a few metastases at a single site) also may benefit from surgical resection of the metastases if the primary tumor can be controlled with other treatments. Cytoreductive surgery for limited metastatic disease includes resecting pulmonary metastases for sarcomas, hepatic metastases for colorectal cancer, and solitary brain metastases. Patients with metastatic disease also can have surgery to relieve pain or improve functional abnormalities caused by the advanced tumor (e.g., gastrointestinal obstruction). Patients can have palliative surgery to improve their quality of life without prolonging survival. Thus, surgery plays a critical role in cancer treatment.

Radiation Therapy

Radiation therapy can be used to eradicate localized tumor masses. Not all cancers are sensitive to the lethal effects of radiation, so this modality has limited application in the treatment of some cancers (Table 88-11). For others, however, radiation therapy provides potential advantages over surgery. For instance, radiation therapy could encompass a wider area around the tumor and remove the tumor from regions of the body where surgery cannot safely reach. Radiation therapy also can be used when surgery could result in considerable disability or disfigurement. Radiation allows patients to receive treatment to multiple sites simultaneously. The usefulness of radiation therapy can be limited by its toxic effects on normal tissues that surround the tumor, however, and these can be exacerbated if patients receive chemotherapy concomitantly or shortly after radiation therapy. Chemotherapy that follows completion of radiation therapy can produce a “radiation recall” of local toxicity which manifests as skin redness, and swelling and peeling at the radiation site. An established limit exists to the “dose” of radiation that can be delivered, depending on the type of tissue (e.g., bone, liver, brain) that is affected. Two methods are used most often to administer radiation to tumors. External-beam radiotherapy uses a radiation source (typically, a super-voltage electrical machine) that is located a certain distance from the site of intended treatment. Brachytherapy involves placement of radioactive seeds, pellets, or needles within or close to the site of the tumor. Newer radiation therapy techniques, including intraoperative radiation, hyperfractionated

radiation, stereotactic radiosurgery, intensity modulated radiation therapy (IMRT), computerized three-dimensional conformal treatment planning, and chemoradiosensitization (e.g., concomitant radiation-sensitizing chemotherapy), may reduce associated toxicities, enhance tumor responsiveness, and improve its clinical usefulness.⁴²

Not all cancers can be cured by surgery or radiation therapy. Some patients have tumors that have already metastasized at the time of initial diagnosis, whereas others have tumors that could not be completely eradicated with treatment or have recurred some time after primary therapy with surgery or radiation therapy. In these circumstances, the tumor cells have been released from the primary tumor. Systemic treatments, including chemotherapy, endocrine therapy, signal transduction pathway inhibitors, antiangiogenic agents, and biologic response modifiers, generally offer the only hope of rendering the patient free of disease. Although chemotherapy was developed to treat advanced cancers, these agents are now used to treat many stages of malignant diseases.

Chemotherapy

Cytotoxic Chemotherapy

The era of cytotoxic chemotherapy can be traced to World War II, when an explosion of mustard gas produced bone marrow and lymphoid hypoplasia in seamen exposed to the gas.⁴³ This incident led to the use of alkylating agents (derivatives of mustard gas) in the treatment of Hodgkin disease and other lymphomas.⁴⁴

MECHANISM OF ACTION

Classic cytotoxic chemotherapy kills cancer cells by damaging DNA, interfering with DNA synthesis, or otherwise inhibiting cell division. Chemotherapy agents have been classified by their effect on the cell cycle or their mechanism of action. Agents that affect the cell only during a specific phase of the cell cycle often are referred to as *phase-specific agents* or *schedule-dependent agents*. In contrast, agents that affect the cell during any phase of the cell cycle are often referred to as *phase-nonspecific agents* or *dose-dependent agents* (Fig. 88-2). As the understanding of cancer biology continues to grow, other mechanisms of cytotoxicity have been identified for many chemotherapy agents.

The specific mechanisms of action for several chemotherapy agents are described in Table 88-12. Because most agents affect the cell cycle, their lethal effects are not realized until the cells proceed through the cycle. These drugs are most cytotoxic to tumor cells with a high growth fraction (see Tumors: Growth) and least cytotoxic to tumor cells arrested in the G_0 phase.

CELL KILL

Rodent studies done during the 1960s demonstrated that the number of tumor cells killed by the chemotherapy is proportional to the dose when the growth fraction is 100% (i.e., all cells are dividing) and the tumor cells are sensitive to the agent.^{45,46} For example, if a dose of chemotherapy reduces the tumor burden from 10^{10} to 10^8 cells, the same dose administered when only 10^7 cells are present should reduce the tumor burden to 10^5 cells. This theory has become known as the cell-kill or log-kill hypothesis (Fig. 88-4).

Table 88-11 Malignancies Frequently Treated With Radiation Therapy

| |
|---|
| Acute lymphocytic leukemia (CNS radiation) |
| Brain tumors |
| Breast cancer |
| Head and neck cancers, squamous cell |
| Lung cancer |
| • Non–small-cell lung cancer |
| • Small-cell lung cancer (CNS radiation in limited stage disease) |
| Lymphomas |
| Neuroblastoma |
| Prostate cancer |
| Rectal cancer |
| Testicular, seminoma |

(continued)

Table 88-12 Clinical Pharmacology of Commonly Used Chemotherapy Agents (Continued)

| Agents (Trade Name) | Mechanism of Action | Pharmacokinetic Characteristics | Major Toxicities |
|---|--|--|--|
| Daunorubicin, liposomal (Daunoxome) Inj: 50 mg/vial | Antitumor antibiotic; intercalates into DNA double helix; topoisomerase II–mediated DNA damage; produces oxygen-free radicals | $t_{1/2\alpha} = 4$ min; $t_{1/2\beta} = 36$ min; $t_{1/2\gamma} = 11$ hr; Cl 21 L/hr/m ² ; Vd = 113 L | Peripheral edema; bone marrow suppression; hypersensitivity reaction |
| Docetaxel (Taxotere) Inj: 40 mg/mL | Taxane; promotes microtubule assembly and arrests cell cycle in G ₂ and M phases | Extensive binding to tissues; known routes of elimination only account for 50%–60% of dose; extensively metabolized by liver; $t_{1/2\alpha} = 40$ min; $t_{1/2\beta} = 45$ –55 hr; 20%–30% biliary excretion; 14%–23% excreted in urine as parent and metabolites | Myelosuppression; mucositis; nausea, vomiting; alopecia; cumulative cardiac toxicity; dose-related acute ECG changes; severe tissue damage if extravasated |
| Doxorubicin (Adriamycin, Rubex) Inj: 10, 20, 50, 100, 150, 200 mg/vial | Antitumor antibiotic; intercalates into DNA double helix; topoisomerase II–mediated DNA damage; produces oxygen-free radicals | | |
| Doxorubicin, liposomal (Doxil) Inj: 20 mg | Antitumor antibiotic; intercalates into DNA double helix; topoisomerase II–mediated DNA damage; produces oxygen-free radicals | | |
| Epirubicin (Ellence) Inj: 50 mg/25 mL, 200 mg/100 mL | Anthracycline antitumor antibiotic; intercalates into DNA double helix; topoisomerase II–mediated DNA damage; produces oxygen-free radicals. | $t_{1/2\alpha} = 3$ min, $t_{1/2\beta} = 2.5$ hr, $t_{1/2\gamma} = 33$ hr; protein binding 77%; epirubicin or metabolite excretion in bile (35%) or urine (20%); plasma clearance reduced 35% in patients ≤ 70 yr | Myelosuppression; nausea, vomiting, diarrhea, mucositis, alopecia; cumulative dose-related cardiomyopathy, acute ECG changes; severe tissue damage (if extravasated); |
| Erlotinib (Tarceva) Oral tablets: 25, 100, and 150 mg | Small molecule inhibitor; epidermal growth factor receptor (EGFR) tyrosine kinase antagonist. | Oral bioavailability 60%; food increases bioavailability to 100%; protein binding approximately 93%; hepatic metabolism primarily CYP3A4 and also CYP1A1 and CYP1A2; $t_{1/2}$ approximately 36 hr | Diarrhea, acne-form rash, appetite loss, interstitial lung disease |
| Etoposide (VePesid) Inj: 100 mg/5 mL Cap: 50 mg | Epipodophyllotoxin; produces DNA strand breaks by inhibiting topoisomerase II; arrests cells in late S or early G ₂ phase | Oral bioavailability 37%–67% (average 50%); 30%–40% excreted rapidly in the urine (70% of excreted drug is unchanged); terminal $t_{1/2} = 6$ –8 hr; 6%–15% excreted in bile; >2% excreted in feces | Myelosuppression; nausea, vomiting; alopecia; mucositis; hypotension (related to rapid-infusion); hypersensitivity reactions; fever; bronchospasm |
| Fluorouracil Inj: 500 mg/vial | Antimetabolite; incorporates into RNA, interferes with RNA function; inhibits thymidylate synthase and inhibits DNA synthesis | $t_{1/2} = 6$ –20 min; 90% hepatically metabolized. | Mucositis; diarrhea, myelosuppression; dermatologic, nausea, vomiting |
| Gemcitabine (Gemzar) Inj: 200 mg/vial or 1,000 mg/10 mL | Antimetabolite; inhibits ribonucleotide synthesis reductase and inhibits DNA synthesis | Parameters dependent on infusion; $t_{1/2} = 32$ –94 min or 245–638 min; V = 50 L/m ² or 370 L/m ² | Bone marrow suppression; flulike syndrome; nausea, vomiting; edema |
| Gemtuzumab ozogamicin (Mylotarg) Inj: 5 mg/20 mL | Monoclonal antibody; linked to a calicheamicin cytotoxic derivative; targets CD33 antigen on leukemic blast cells; binding introduces cytotoxic into cells, causing DNA strand breakage and cell death | $t_{1/2}$ calicheamicin 45 hr (total) and 100 hr (unconjugated); $t_{1/2}$ antibody 72 hr; probably undergoes hepatic metabolism but metabolic studies have not been performed | Myelosuppression (severe); hypersensitivity and infusion reactions; pulmonary events (dyspnea, pleural effusion, pulmonary infiltrates, acute respiratory distress syndrome); hepatotoxicity; nausea, vomiting |

| | | | |
|--|---|--|--|
| Ibritumomab tiuxetan (Zevalin) Inj: 10 mg/10 mL, 50 mg/50 mL | Monoclonal antibody; Yttrium-90 (Y-90)-linked antibody directed against the CD20 antigen on malignant B lymphocytes; binds to antigen and releases radiation (β particles) which induces cell damage and death | Mean effective $t_{1/2}$ for Y-90 = 30 hr; median of 7.2% of injected radioactivity recovered in urine over 7 days; Y-90 particle decay $t_{1/2}$ = 64 hr. | Infusion reactions (hypotension, angioedema, hypoxia, bronchospasm); asthenia, chills, nausea; myelosuppression; see also rituximab |
| Idarubicin (Idamycin) Inj: 5, 10 mg/vial | Antitumor antibiotic; intercalates into DNA double helix; topoisomerase II-mediated DNA damage; produces oxygen-free radicals. | Terminal $t_{1/2}$ = 15–18 hr | Myelosuppression; mucositis; anorexia; nausea, vomiting; diarrhea; fever; alopecia |
| Imatinib mesylate (Gleevec) Tab: 100 mg, 500 mg | Tyrosine kinase inhibitor; inhibits kinases for Ber-Abl, platelet-derived growth factor (PDGF), c-kit, and stem cell factor, thereby inhibiting cell proliferation and inducing apoptosis | Mean bioavailability = 98%; C_{max} 2–4 hr; $t_{1/2}$ of imatinib (18 hr) and major metabolite (40 hr); plasma protein binding 95%; hepatically metabolized via CYP3A4; eliminated as unchanged drug in feces (20%) and urine (5%); interpatient variability in clearance = 40%; susceptible to alterations in clearance with CYP3A4 inducers and inhibitors | Fluid retention, edema; nausea, vomiting, diarrhea; rash, fatigue, muscle cramps, musculoskeletal pain; intratumoral bleeding; myelosuppression, hepatic toxicity |
| Irinotecan (Camptosar) Inj: 20 mg/mL | Camptothecin; inhibits DNA-strand religation by binding topoisomerase I-DNA complex. | $t_{1/2}$ = 6 hr; 36%–68% protein bound | Diarrhea; cholinergic syndrome; myelosuppression |
| Isofamide (Ifex) Inj: 1, 3 g/vial | Alkylating agent; metabolites generates reactive intermediates that cross-link DNA | Parameters are dose and schedule dependent; 60%–80% excreted in urine as unchanged drug or metabolite within 72 hr | Myelosuppression; hemorrhagic cystitis (should be administered with MESNA); nephrotoxicity; neurotoxicity; anorexia; nausea, vomiting; alopecia |
| Mercaptopurine (Purinethol) Tab: 50 mg | Antimetabolite; metabolites incorporated into DNA or RNA and inhibit purine synthesis. | Oral absorption highly variable; $t_{1/2}$ γ = 20–60 min; elimination primarily hepatic. | Myelosuppression; anorexia, nausea, vomiting; hepatic toxicity (biliary stasis) |
| Methotrexate Tab: 2.5 mg Inj: 25, 50, 100, 200, 250, 1,000 mg/vial | Antifolate; inhibits dihydrofolate reductase and depletes reduced folates and inhibits DNA synthesis | Oral absorption appears to be better with smaller doses; exhibits interpatient bioavailability; “third space” collections of fluid may provide a reservoir for drug accumulation; $t_{1/2}$ = 1.5–3.5 hr; $t_{1/2}$ = 8–15 hr; 90% dose excreted in urine within 24 hr | Myelosuppression; nephrotoxicity; hepatotoxicity; mucositis, pulmonary toxicity; neurotoxicity |
| Oxaliplatin (Eloxatin) Inj: 50 mg/10 mL; 100 mg/20 mL | Nonclassical alkylating agent; binds to DNA to form interstrand cross-links and adducts | $t_{1/2}$ α = 0.43 hr; $t_{1/2}$ β = 16.8 hr; $t_{1/2}$ γ = 391 hr; Vd ultrafilterable platinum = 440 L; extensive and irreversible plasma protein binding (>90%); nonenzymatically biotransformed; renal primary route of elimination: 54% at 5 days | Anaphylactic or anaphylactoid reactions; peripheral sensory neuropathy, sensitivity to cold, jaw spasm, dysphagia; nausea, vomiting, diarrhea, fatigue; pulmonary fibrosis |
| Paclitaxel (Taxol) Inj: 30 mg/vial | Taxane; promotes microtubule assembly and arrests cell cycle in G ₂ and M phases. | <10% excreted in urine; liver and biliary primary routes of elimination; $t_{1/2}$ α = 0.3 hr; $t_{1/2}$ β = 1.3–8.6 hr | Hypersensitivity reactions (premedications recommended); cardiac disturbances; sensory neuropathy; myalgia; arthralgia; myelosuppression |

(continued)

Table 88-12 Clinical Pharmacology of Commonly Used Chemotherapy Agents (Continued)

| Agents (Trade Name) | Mechanism of Action | Pharmacokinetic Characteristics | Major Toxicities |
|--|---|--|--|
| Pemetrexed (Alimta) Inj: 500 mg/20 mL | Multitargeted antifolate; disrupts folate metabolic pathway through inhibition of thymidylate synthase, dihydrofolate reductase, and glycylamide ribonucleotide formyl transferase | Protein binding approximately 81%; 70%–90% excreted unchanged renally; $t_{1/2}$ 2–4 hr | Rash, diarrhea, leukopenia, neutropenia, thrombocytopenia |
| Rituximab (Rituxan) Inj: 100 mg/10 mL, 500 mg/50 mL | Monoclonal antibody; lyses B cells by recruiting immune effectors | $t_{1/2}$ variable | Tumor lysis; hypersensitivity reactions; mucocutaneous reactions; lymphopenia |
| Sorafenib (Nexavar) Tabs: 200 mg | Multikinase enzyme inhibitor; raf kinase inhibitor; angiogenesis blockade (VEGFR), PDGFR, Flt3, c-KIT, p-38 | Bioavailability 38%–49%; take on empty stomach; protein binding 99.5%; hepatic metabolism primarily CYP3A4 and UGT1A9; $t_{1/2}$ 24–48 hr | Hypertension, rash, hand-foot syndrome, diarrhea, myelosuppression |
| Sunitinib (Sutent) Cap: 12.5, 25, and 50 mg | Multikinase enzyme inhibitor; angiogenesis inhibitor; VEGFR, PDGFR, bFGF inhibition | Protein binding: 95% for parent molecule and primary metabolite; hepatic metabolism primarily CYP3A4; $t_{1/2}$ 40–60 hr for parent molecule and 80–110 hr for metabolite | Skin discoloration, rash, diarrhea, myelosuppression, prolonged QT interval |
| Tositumomab (Bexxar) Inj: 35 mg/2.5 mL, 225 mg/16.1 mL | Monoclonal antibody; iodine-131 (I-131)-linked antibody directed against the CD20 antigen on malignant B lymphocytes; binds to antigen and induces apoptosis, complement- or antibody-dependent cell cytotoxicity; ionizing radiation induces cell damage and death | Total body clearance influenced by high tumor burden, extent of splenomegaly and bone marrow involvement; I-131 eliminated in urine (98% of administered dose); I-131 and particle decay $t_{1/2}$ = 8.04 days | Hypersensitivity reactions; myelosuppression; hypothyroidism; nausea, vomiting, abdominal pain, diarrhea; myelodysplastic syndrome, acute leukemia |
| Trastuzumab (Herceptin) Inj: 440 mg/30 mL | Monoclonal antibody; inhibits proliferation of human tumor cells that express HER2 proto-oncogene | $t_{1/2}$ = 5.8 hr; Vd = 44 mL/kg. | Cardiomyopathy; diarrhea; nausea, vomiting; hypersensitivity reaction |
| Vincristine (Oncovin) Inj: 1, 2, 5 mg/vial; 2-mg pre-filled syringe | Vinca alkaloid; reversibly inhibits mitosis; binds to microtubule protein, tubulin and ultimately inhibiting formation of mitotic spindles | $t_{1/2\alpha}$ = <1 min; $t_{1/2\beta}$ = 7.4 min; $t_{1/2\gamma}$ = 164 min | Neurotoxicity (primarily distal neuropathy that affects sensory and motor abilities); autonomic neuropathies (high dosages); SIADH; vesicant (if extravasated) |
| Vinorelbine (Navelbine) Inj: 10 mg/1 mL; 50 mg/5 mL | Vinca alkaloid; reversibly inhibits mitosis; binds to microtubule protein, tubulin and ultimately inhibits formation of mitotic spindles | <20% excreted in urine; $t_{1/2\alpha}$ = 2–6 min; $t_{1/2\beta}$ = 1.9 hr; $t_{1/2\gamma}$ = 20–40 hr | Leukopenia; neurotoxicity; DTR; vesicant (if extravasated) |

Cap, capsule; CSF, cerebrospinal fluid; DTR, deep tendon reflexes; GI, gastrointestinal; Inj, injection; PT, prothromboplastin time; PPT, partial thromboplastin time; SIADH, syndrome of inappropriate antidiuretic hormone secretion; $t_{1/2\alpha}$, α -half-life; $t_{1/2\beta}$, β -half-life; $t_{1/2\gamma}$, γ -half-life; Tab, tablet.

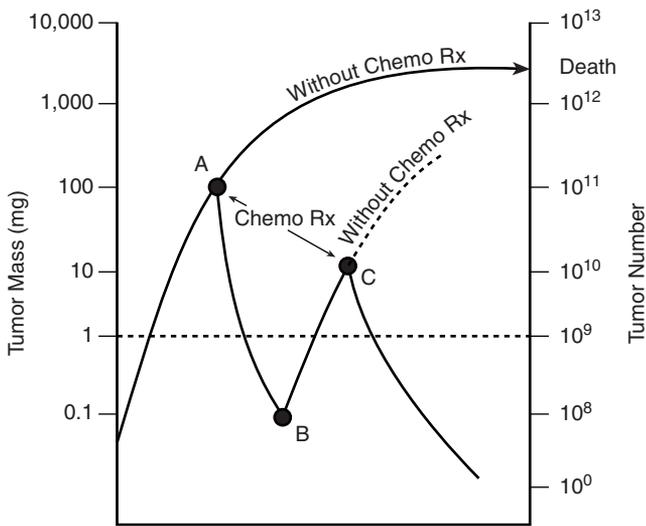

FIGURE 88-4 The growth rate of a tumor is initially very rapid and eventually slows as it approaches 10^{11} cells. Two trillion (2×10^{12}) cells or 2 kg of tumor is lethal to humans. An effective chemotherapy treatment given at point A will decrease the tumor number to point B. Regrowth of the tumor will occur during the recovery period until further chemotherapy is given at point C.

FACTORS THAT INFLUENCE RESPONSE TO CHEMOTHERAPY

In the clinical setting, tumor cells do not always decrease predictably with each successive course of chemotherapy. This is because the growth fraction of human tumors is not 100% and because the cell population is heterogeneous and some are resistant to chemotherapy. In patients with large tumors showing a plateau-like growth curve, the fraction of cells killed with each treatment is usually low. The ability of this model to predict cell kill adequately is also limited by the need to administer chemotherapy in cycles (e.g., every 2, 3, or 4 weeks) to allow normal cells to recover from the toxic effects of chemotherapy. During the recovery period, tumor cells can start to replicate again. Therefore, successful treatment requires administration of the next course of therapy before the tumor has grown to its previous size. The objective of successive chemotherapy courses is a further decrease in size of tumor mass. Other factors that influence cell kill include dose intensity, schedule, drug resistance, tumor site, and a patient's performance status.

Dose Intensity

Dose intensity is defined as the chemotherapy dose per unit time over which treatment is given (e.g., $\text{mg}/\text{m}^2/\text{week}$). Drug resistance might be overcome by escalating the dose intensity of drugs. This can be increased by (a) increasing the dose of chemotherapy per cycle, and (b) shortening the interval between cycles. Unnecessary lengthening of the interval between successive courses of chemotherapy or decreasing the dose can negatively affect treatment outcomes. Evidence suggests that reducing a dose can cause treatment failure in patients with chemotherapy-sensitive tumors who are having their first chemotherapy treatment.⁴⁷ Studies with animal models suggest that lower doses may eradicate the bulk of the tumor mass, but residual tumor cells left behind could ultimately be responsible for disease recurrence. A direct relationship between dose intensity and response rate also has been reported in several

human tumors, including breast cancer, lymphomas, advanced ovarian cancer, and small-cell lung cancer.^{48,49} Dose-dense treatment schedules have been designed to decrease the time period between chemotherapy administration, based on the theory that this would be more effective in reducing the residual tumor burden between treatments than escalating doses.⁵⁰ Dose-intensive therapy has not consistently improved the overall cure rate of most solid tumors, however.

The dose intensity for most chemotherapy regimens is limited by the major dose-related toxicity, bone marrow suppression. To minimize this toxicity and administer higher doses, patients have received hematopoietic growth factors, autologous stem cell transplantations, and altered schedules of drug delivery.^{51–53}

Schedule Dependency

The schedule of chemotherapy administration is an important determinant of response. It influences dose intensity largely by affecting toxicity.⁴⁷ In some circumstances, changing the administration schedule can reduce the toxicity sufficiently to allow patients to receive higher total doses or more frequent courses of therapy, thereby increasing the dose intensity. The optimal schedule is also influenced by the pharmacokinetics of the agent. For example, phase-specific agents can exert their cytotoxic effects only when the cell is in a particular phase of the cell cycle. If a phase-specific agent with a short half-life is administered by intravenous (IV) bolus, a significant number of tumor cells will probably not cycle through the vulnerable phase of the cell cycle during exposure to the agent. Comparatively, the same agent administered by frequent IV bolus or continuous infusion could expose more cells to the agent during the vulnerable phase.⁵⁴

Drug Resistance

9. B.C. is a 39-year-old man with an aggressive non-Hodgkin lymphoma (NHL). At the time of diagnosis, B.C. had enlarged cervical lymph nodes, dyspnea, and a large mediastinal mass noted on chest x-ray examination. Chemotherapy was initiated with the CHOP regimen, which consists of cyclophosphamide, doxorubicin, vincristine, and prednisone. After the first course of chemotherapy, B.C.'s lymphadenopathy was greatly reduced. Chest x-ray examination repeated after the second course of therapy showed marked improvement. When he returned for his fourth cycle of chemotherapy, recurrent lymphadenopathy was noted and the chest radiograph confirmed enlargement of the mediastinal mass. Why is B.C.'s cancer growing despite continued chemotherapy, and how should his treatment be altered?

Most likely B.C.'s cancer is now growing because the tumor has become resistant to the chemotherapy; therefore, it would be wise to discontinue the CHOP regimen. Biochemical resistance to chemotherapy is the major impediment to successful treatment with most cancers.⁴⁷ Resistance can occur de novo in cancer cells or develop during cell division as a result of mutation.⁴⁷ In 1979, a proposed mathematical model predicted that tumor cells mutate to drug resistance at a rate related to the genetic instability of the tumor.⁵⁵ Thus, the probability that a tumor mass will contain resistant clones is related to both the rate of mutation and the size of the tumor. Many specific mechanisms now have been identified by which cancer cells resist the activity of cytotoxic agents (Table 88-13).

Table 88-13 Possible Mechanisms of Anticancer Drug Resistance

| Mechanism | Chemotherapy Agents |
|--|--|
| • Proficiency in repair of DNA | Cisplatin, cyclophosphamide, melphalan, mitomycin, mechlorethamine |
| • In drug activation | Cytarabine, doxorubicin, fluorouracil, mercaptopurine, methotrexate, thioguanine |
| • In drug inactivation | Cytarabine, mercaptopurine |
| • In cellular uptake of drug | Methotrexate, melphalan |
| • In efflux of drug (multidrug resistance) | Doxorubicin, daunorubicin, etoposide, vincristine, vinblastine, teniposide, docetaxel, paclitaxel, vinorelbine |
| • alternative biochemical pathways | Cytarabine, fluorouracil, methotrexate |
| • alterations in target enzymes (DHFR, topoisomerase II) | Fluorouracil, hydroxyurea, mercaptopurine, methotrexate, thioguanine, etoposide, teniposide, doxorubicin, daunorubicin, idarubicin |

Some cell lines that become resistant to a single chemotherapy agent may also be resistant to structurally unrelated cytotoxic compounds. This phenomenon is called *pleiotropic drug resistance* or *multidrug resistance* (MDR).⁵⁶ Cell lines that display this type of resistance generally are resistant to natural product cytotoxic agents such as the vinca alkaloids, antitumor antibiotics, epipodophyllotoxins, camptothecins, and taxanes. The primary mechanism believed to be responsible for MDR is an increase in P-glycoprotein in the cell membrane. This protein mediates efflux of the chemotherapy agent, causing a decreased accumulation of drug within the cell (the site of drug activity).⁵⁶ Other transport proteins have been implicated in resistance to chemotherapy, as well.⁵⁷

Drugs known to inhibit P-glycoprotein (e.g., verapamil, cyclosporine, quinidine) have been investigated as potential adjunctive therapies to reduce resistance. Dosages of the agents required to inhibit P-glycoprotein have been associated with significant morbidity. Enhanced efficacy is, as of yet, unproved with newer investigational agents that can inhibit P-glycoprotein. A second type of MDR is mediated by altered binding to topoisomerase II, an enzyme that promotes DNA strand breaks in the presence of anthracyclines and epipodophyllotoxins.⁵⁸ Because of the likelihood of MDR, B.C. should receive a chemotherapy regimen that does not include chemotherapy agents inactivated by the MDR mechanism. An alternative regimen, such as high-dose methotrexate with leucovorin rescue, would be appropriate because this regimen is effective against NHL and is not affected by the MDR gene.

Tumor Site

The cytotoxic effects of chemotherapy agents are related to the time the tumor is exposed to an effective concentration of the agent (i.e., concentration \times time [C \times T]). The dosage regimen, including the dose, infusion rate, route of administration, lipophilicity, and protein binding, can influence the concentration-time product. Other factors, such as tumor size and location, can also critically affect an agent's cytotoxicity. As tumors grow larger, their degree of vascularity lessens,

making it more difficult for agents to penetrate the entire tumor mass. Tumors located in sites of the body with poor drug penetration (e.g., the brain) may not receive a sufficient concentration to provide effective kill.

Pharmacogenetics

Antitumor activity and adverse effects of chemotherapy agents are associated with the presence of genetic polymorphisms that can affect the metabolism and disposition of drug. For example, irinotecan is a prodrug that is metabolized to the active compound, SN-38. Individuals with the UGT1A1*28 allele can have decreased activity of the glucuronidating enzyme that removes SN-38 from the circulation. As a result, these patients are at increased risk for experiencing grades 3 or 4 neutropenia.⁵⁹ Tamoxifen is an example of a targeted agent that is metabolically activated by cytochrome P450 2D6 enzyme to form endoxifen. Individuals who have the CYP2D6*4 allele are at greater risk for tumor recurrence than patients with the common allele, presumably because less of the active molecule is formed.⁶⁰ The first example is a polymorphism in an enzyme that affects the ability of the body to remove the active drug and thereby increases unwanted toxicity, whereas the second example is a polymorphism that affects activation to a compound responsible for most of its antitumor activity. A third example relates to the presence of the drug target at the tumor site. Approximately 20% to 30% of patients with early stage breast cancer have tumors that overexpress the HER2/neu growth factor receptor. These patients have more aggressive cancers and shorter survival than those who do not have the overexpressed HER2 receptor. Trastuzumab is a humanized anti-HER2 monoclonal antibody that is effective in treating tumors that overexpress this growth factor receptor. Hence, HER2 amplification status is an important component in the workup of patients with breast cancer, and it represents an example of altered genetic expression of drug target at the tumor site.⁶¹

Combination Chemotherapy

10. K.K. has advanced Hodgkin disease and is to begin chemotherapy today with the ABVD (doxorubicin [Adriamycin], bleomycin, vinblastine, and dacarbazine) regimen. She is reluctant because of her fear of side effects. She asks if, rather than receiving all four drugs today, she could receive just one and if it does not work then try another one?

CHOICE OF AGENTS

Although single-agent chemotherapy can cause significant early regressions of Hodgkin disease, acute lymphocytic leukemia, and adult NHL, most tumors show only a partial, very short response to single-agent therapy. Recognition that single-agent cytotoxic chemotherapy rarely produced prolonged remission led to the simultaneous use of multiple cytotoxic chemotherapy agents. The optimal activity of adding targeted agents to cytotoxic chemotherapy is less easy to predict. Bevacizumab and trastuzumab are most effective when given in combination with cytotoxic chemotherapy (for colorectal and breast cancers, respectively); agents such as tamoxifen are less effective. Because knowledge about how to combine targeted agents with cytotoxic chemotherapy is limited, this discussion centers around combinations of cytotoxic agents for which there is more long-term experience. In Hodgkin disease,

the use of combination cytotoxic chemotherapy results in long-term, disease-free survival for >60% of patients. If K.K. were to receive single-agent therapy, her disease would not be cured. Combination chemotherapy is absolutely recommended to provide her with the best chance for long-term, disease-free survival. She should be reassured that appropriate measures, including prophylactic antiemetic therapy, will be taken to reduce her chances of both acute and chronic toxicities.

Combination chemotherapy provides broader coverage against resistant cell lines within the heterogeneous tumor mass. Table 88-14 lists examples of commonly used chemotherapy regimens. Several principles provide the basis for selecting the agents to be included in a chemotherapy regimen:

- Only agents with demonstrable single-agent activity against the specific type of tumor should be used in combination therapy.
- All agents in the regimen should have different mechanisms of action.
- Agents should not have overlapping toxicities so that the severity and duration of acute and chronic toxicities are minimized.
- All agents in the regimen should be used in their optimal dose and schedule.

APPLICATIONS

Several treatment concepts are noteworthy of discussion. These center around chemotherapy given for recurrent or refractory tumors and the timing of administration, relative to other treatment modalities such as surgery.

Primary Chemotherapy

Primary chemotherapy is defined as first-line treatment and, in the case of leukemia, it is referred to as *induction chemotherapy*. Choice of primary chemotherapy is governed by observations made from clinical trials that demonstrate that a given regimen has the highest known activity against the tumor. Second-line or salvage chemotherapy is administered after the tumor has become refractory to primary therapy or if the patient is unable to tolerate first-line therapy. Chemotherapy is the primary treatment modality used for hematologic malignancies, as well as a number of solid tumors that have metastasized at the time of diagnosis or have recurred at metastatic sites after initial therapy. Chemotherapy is frequently used in different ways during the course of an individual's malignancy (Fig. 88-5). Primary chemotherapy can be either curative or palliative, depending on the specific type of tumor. Following induction therapy for leukemia, patients may receive additional chemotherapy in an attempt to further eradicate residual disease and improve their chances for long-term survival. Postremission therapy (i.e., following induction therapy) can include consolidation, intensification, and maintenance treatment phases.

Adjuvant Chemotherapy

11. F.R., a 36-year-old woman with no other medical problems, recently underwent a lumpectomy and radiation therapy for breast cancer. She has been told that the cancer no longer exists; however, she also is told that she should now receive 6 months of chemotherapy. She knows that chemotherapy will cause her

to vomit, lose her hair, gain weight, and place her at risk for life-threatening infections. Why would chemotherapy be recommended now when she is disease free?

Some patients may have unrecognized micrometastases or residual disease after primary treatment. These patients have a high probability of disease recurrence, even though the primary treatment may have successfully removed all visual evidence of the primary tumor. To eradicate any undetectable tumor, the patient could receive systemic therapy after initial curative surgery (or radiation therapy). Systemic chemotherapy administered after primary therapy is referred to as *adjuvant chemotherapy*. Because the tumor burden is relatively low at this time, adjuvant chemotherapy should immediately follow primary therapy. For adjuvant therapy to provide any benefit, the risk of recurrence must be high, and effective agents must be available to eradicate the tumor. Adjuvant therapy is considered standard treatment in the treatment of breast and colorectal cancer, but it also has benefited selected patients with ovarian cancer, Ewing sarcoma, Wilms tumor, and other malignancies.⁴⁷ (also see Chapter 91, Solid Tumors.) Because it is impossible to predict which patients have unrecognized disease, it is difficult to determine which patients should receive adjuvant therapy. To help with these decisions, clinicians frequently consider histologic and cytogenetic characteristics of the primary tumor that are associated with high risk of relapse. Some patients who may never relapse will undergo adjuvant chemotherapy, however.

Neoadjuvant Chemotherapy

Neoadjuvant chemotherapy is the therapy given before the primary treatment in patients who present with locally advanced tumors (e.g., large tumors or those that are impinging on surrounding vital structures) that are unlikely to be cured with primary surgery or radiation therapy. The objective is to reduce the tumor mass with neoadjuvant therapy (chemotherapy or hormonal therapy), thereby increasing the likelihood of eradication by subsequent surgery or radiation therapy. Neoadjuvant therapy also can lessen the amount of radical surgery that the patient needs, which can preserve cosmetic appearances and function of the surrounding normal tissues. The tumor can be resistant to the neoadjuvant therapy and continue to grow, however, making surgery or radiation even more difficult. Patients may also experience toxicities with the neoadjuvant therapy that may delay surgery or impair postsurgical healing. Locally advanced tumors in which neoadjuvant chemotherapy has been shown to improve survival rates include stage III_A non-small-cell lung cancer, stage III breast cancer, sarcomas, esophageal cancers, laryngeal cancer, bladder cancer, and osteogenic sarcoma.⁴⁷

Administration

SYSTEMIC

Systemic chemotherapy is most commonly administered by the IV route, either as a bolus injection (generally <15 minutes), a short infusion (15 minutes to several hours), or a continuous infusion (lasting 24 hours to several weeks). Some systemic chemotherapy agents can be administered by the oral route, whereas other agents can be administered by the intramuscular or subcutaneous route. No matter which route of administration is selected for therapy, the individual administering the chemotherapy should be proficient in administering

Table 88-14 Representative Chemotherapy Regimens^a

| <i>Acronym</i> | <i>Agents</i> | <i>Cycle</i> | <i>Acronym</i> | <i>Agents</i> | <i>Cycle</i> |
|--------------------------|---|---|--|--|---------------------------------------|
| Breast Cancer | | | Ovarian Cancer | | |
| CMF | Cyclophosphamide ¹⁰⁶ Methotrexate Fluorouracil | Every 28 days | CP | Cyclophosphamide ¹¹⁷ Cisplatin | Every 21 days |

^aOriginal citations should be consulted for dosage adjustments owing to toxicity or underlying organ dysfunction.

the agent by the chosen route and be aware of the most common acute and chronic toxicities associated with the chemotherapy. All aspects of drug administration should be discussed with the patient before starting chemotherapy, including any adverse events they may experience during or after the injection and throughout therapy. Printed patient educational materials are recommended to supplement oral instructions.

Currently, most patients receive chemotherapy through a central venous catheter to reduce some of the potential problems associated with recurrent IV administration. Some chemotherapy agents are potent vesicants or irritants if they are extravasated from the vein (see Chapter 89, Adverse Ef-

fects of Chemotherapy). Other agents can produce severe irritation and pain to peripheral veins, which can lead to sclerosis and thrombosis. Other potential problems associated with the IV route include unsatisfactory venous access secondary to obesity, prior IV therapy with irritant drugs, or advanced age. Therefore, permanent central venous access devices, such as tunneled central venous catheters (e.g., the Broviac, Hickman, Groshong) or subcutaneous ports (e.g., Port-A-Cath or Infuse-A-Port) are commonly used in patients receiving chemotherapy. A peripherally inserted central catheter (PICC) line is non-permanent but it can be maintained and used for venous access for extended periods of time.

Table 88-15 Local or Regional Routes of Administration of Cancer Chemotherapy

| <i>Route of Administration</i> | <i>Cancer Managed With Alternative Route</i> |
|---|--|
| Intrathecal or intraventricular | Leukemia, lymphoma |
| Intravesicular | Bladder cancer |
| Intraperitoneal | Ovarian cancer |
| Intrapleural | Malignant pleural effusions |
| Intra-arterial | Melanoma, sarcoma |
| Hepatic artery | Liver metastases |
| Chemoembolization (intra-arterial or intravenous) | Colon cancer, rectal cancer, carcinoid, liver metastases |

REGIONAL

Although chemotherapy was initially developed for systemic use, techniques have been developed to locally administer agents to specific sites of the body affected by the tumor (Table 88-15). Regional or local chemotherapy allows high concentrations of agents to be achieved at the site of the tumor while reducing systemic exposure and subsequent toxicity. On the other hand, undetectable metastases at distant sites may not be exposed to the chemotherapy, allowing continued growth of the tumor mass.

Assessing Response to Therapy

A very important step in the process of treating a patient with chemotherapy is to assess his or her response to treatment. The assessment should evaluate the chemotherapy's antitumor and toxic effects, as well as its effect on the patient's overall quality of life and survival. Re-evaluation should occur at regularly scheduled intervals during treatment and should include a physical examination, laboratory tests, and repeat diagnostic tests (radiologic or other tests such as bone marrow biopsy, bronchoscopy) used to stage the cancer. Usually, only tests that previously were positive for the tumor are repeated unless new signs or symptoms suggest additional metastases.

Several standard criteria are used to define the patient's response to treatment (Table 88-16). The use of standardized criteria in clinical trials evaluating new therapies is especially important because it helps define the potential use of new therapies compared with standard treatments. Criteria used to assess the antitumor effects include direct measures of the tumor size, duration of response, and patient survival.⁶² Parameters used to assess the toxic effects include the incidence and severity of specific toxicities. Several standardized toxicity grading scales are used to assess toxicity associated with chemotherapy; however, the NCI Common Toxicity Criteria (CTC) are the most commonly used.^{63,64}

Because the toxicities associated with many chemotherapy agents are potentially severe, it is important to evaluate the risk of the treatment in relation to the potential benefit. The benefits of a treatment regimen should outweigh the negative effects it has on the physical, mental, and social well-being of the patient. To monitor a patient's quality of life, several comprehensive assessment tools have been developed.⁶⁵ In addition, other clinical benefits (e.g., reduced pain, decreased use of analgesics, weight gain, improved performance status) have been recognized by the FDA as acceptable criteria for measur-

Table 88-16 Response Criteria for Evaluating Effects of Chemotherapy of Target Lesion

Complete Response (CR)

Disappearance of all target lesions

Partial Response (PR)

At least a 30% decrease in the sum of the longest diameter (LD) of target lesions, taking as reference the baseline sum LD

Progressive Disease (PD)

At least a 20% increase in the sum of the LD of target lesions, taking as reference the smallest sum LD recorded since the treatment started or the appearance of one or more new lesions

Stable Disease (SD)

Neither sufficient shrinkage to qualify for PR nor sufficient increase to qualify for PD, taking as reference the smallest sum LD since the treatment started

Disease-Free Survival

Time from documentation of complete response until disease relapse or death.

Overall Survival

Time from treatment until time of death.

ing a patient's quality of life and for approving new chemotherapy agents.

12. G.K. is a 67-year-old woman who was recently diagnosed with metastatic bladder cancer. Her symptoms include widespread pain, anorexia, and fatigue. She began receiving a combination chemotherapy regimen and has received three cycles of treatment. A recent CT scan of her abdomen showed marked shrinkage at several sites of tumor and her pain has decreased. How long should she continue to receive chemotherapy?

Because G.K.'s tumor is responding well to treatment, she should continue to receive therapy as long as her tumor is responding and she does not experience intolerable or life-threatening treatment-related toxicities. For some cancers (e.g., non-small-cell lung cancer), continued administration of chemotherapy after a certain number of treatment cycles is not associated with further benefit to patients, because toxicity becomes an overriding issue.

TUMOR MARKERS

Tumor markers are biochemical indicators commonly found in abnormally high concentrations with a cancer. The ideal tumor marker should be produced and released primarily by the cancer cells (or by other tissues in response to the tumor) at levels proportional to the tumor mass. Surgical removal of the tumor or a therapeutic response to chemotherapy or radiation therapy should cause the level of the marker to decline. In addition, the ideal tumor marker should be detectable at very low levels, so tumors may be detected at sizes smaller than conventional diagnostic tests such as radiographs or CT scans permit.⁶⁶ Few tumor markers fulfill these criteria sufficiently to be clinically useful as the sole screening or diagnostic test

Table 88-17 Clinically Useful Tumor Markers

| <i>Tumor Marker</i> | <i>Cancers Commonly Associated With Increased Markers</i> |
|------------------------------------|---|
| CA-19-9 | Pancreatic |
| CA-15-3 | Breast |
| CA-27-29 | Breast |
| Neuron-specific enolase | Neuroblastoma, small-cell lung cancer |
| α -Fetoprotein (AFP) | Liver |
| CA-125 | Ovarian, testicular—nonseminoma |
| Carcinoembryonic antigen (CEA) | Colon, lung |
| Human chorionic gonadotropin (hCG) | Trophoblastic, testicular |
| β_2 -Microglobulin | Multiple myeloma |
| Prostate-specific antigen (PSA) | Prostate |

(Table 88-17). These markers are also used as confirmatory tests and as part of follow-up care to detect recurrent disease. In most cases, tumor markers lack specificity for the tumor, and they could be elevated owing to other disease states. Patients who have elevated levels of a tumor marker at initial diagnosis should have elevated levels with disease recurrence. Other techniques used to detect very low levels of recurrent cancer

in leukemias and lymphomas (e.g., minimal residual disease) include real-time quantitative PCR (RT-PCR) analysis of immunoglobulin or gene arrangements or chromosome aberrations in cells.⁶⁷ By detecting cancer recurrence at its earliest state, treatments may be more successful.

13. Describe other agents used to treat cancer beyond those that are considered cell-cycle specific or non–cell-cycle specific.

Endocrine Therapy

Endocrine therapy can be used to treat several common cancers, including breast, prostate, and endometrial cancers, which arise from hormone-sensitive tissues (Table 88-18). These tumors grow in response to endogenous hormones that trigger growth signals by binding to specific receptors located on a cell membrane or within the cytoplasm of a cell. Current endocrine therapies inhibit tumor growth by blocking the receptors or by eliminating the endogenous hormone feeding the tumor. (Note: Interruption of hormonal secretion also can be achieved through surgical removal of hormone-producing organs). Not all tumors arising from hormone-sensitive tissues respond to endocrine manipulation. Lack of response could be associated with hormone-resistant tumor cells or inadequate suppression of the endogenous feeding hormones.⁶⁸

Table 88-18 Endocrine Therapy Used for Hormone-Sensitive Tumors

| <i>Class</i> | <i>Drug</i> | <i>Dosage</i> | <i>Side Effects</i> | <i>Indication</i> |
|---------------------------|-----------------------------|---|---|--------------------|
| Antiestrogens | Tamoxifen | 10–20 mg PO BID | Disease flare, hot flashes, nausea, vomiting, edema, thromboembolism, endometrial cancer | Breast |
| | Toremifene | 60 mg PO daily | | |
| Aromatase inhibitors | Fulvestrant | 250 mg IM every month | Hot flashes, nausea, fatigue, insomnia, increased risk of bone fractures | Breast |
| | Anastrozole | 1 mg PO daily | | |
| | Letrozole | 2.5 mg PO daily | | |
| LHRH analogs ^a | Exemestane | 25 mg PO daily | Lethargy, rash, postural dizziness, ataxia, nystagmus, nausea | Breast, prostate |
| | Aminoglutethimide | 250 mg PO QID with hydrocortisone 40 mg PO daily | | |
| | Leuprolide | 7.5 mg SC every 28 days | | |
| Antiandrogens | Goserelin | 3.6 mg SC every 28 days | Gynecomastia, hot flashes, breast tenderness, hepatic dysfunction, diarrhea | Prostate |
| | Triptorelin | 3.75 mg IM every 28 days | | |
| | Flutamide | 250 mg PO TID | | |
| Progestins | Bicalutamide | 50 mg PO daily | Weight gain, hot flashes, vaginal bleeding, edema, thromboembolism | Breast, prostate |
| | Nilutamide | 300 mg PO daily for 30 days, then 150 mg PO daily | | |
| Estrogens | Medroxyprogesterone acetate | 400–1,000 mg IM every week | Nausea, vomiting, fluid retention, hot flashes, anorexia, thromboembolism, hepatic dysfunction | Anorexia Breast |
| | Megestrol acetate | 10–40 mg PO QID | | |
| Androgens | Ethinylestradiol | 1 mg PO TID | Deepening voice, alopecia, hirsutism, facial or truncal acne, fluid retention, menstrual irregularities, cholestatic jaundice | Breast |
| | Conjugated estrogens | 2.5 mg PO TID | | |
| | Fluoxymestrone | 10 mg PO BID | | |

^aLeuprolide and triptorelin also available in extended release and depot formulations.

BID, twice daily; IM, intramuscular; PO, orally; QID, four times daily; SC, subcutaneously; TID, three times daily.

Signal Transduction Pathway Inhibitors

By understanding the mechanisms by which cancer cells exhibit unregulated growth and immortality, and possess the ability to invade tissues and metastasize,¹ it has been possible to design drugs that inhibit these processes. The EGFR, HER2/neu, and VEGF signaling pathways can be blocked by monoclonal antibodies that inhibit receptor tyrosine kinase activation by binding to the extracellular domain. Small molecules that directly inhibit tyrosine kinase activation by competing with ATP for binding to the intracellular tyrosine kinase domain have been developed, as well.⁷ A potential advantage of targeting the tyrosine kinase activity of the receptor should be the ability to inhibit cells that do not overexpress the receptor on their surface or have mutated forms of the receptor that result in its activation. The first commercially available receptor tyrosine kinase inhibitor was imatinib mesylate, also known as STI-571. Imatinib mesylate specifically inhibits the Abl and c-KIT kinases and platelet-derived growth factor receptors α and β .⁶⁹ This agent is active against chronic myelogenous leukemia and gastrointestinal stromal tumors and is under investigation for other malignancies that are dependent on the activity of the Bcr-Abl or c-KIT tyrosine kinases.

Inhibition of the 26S proteasome, which is responsible for the intracellular degradation of ubiquitinated proteins, can induce apoptosis in a wide variety of cancer cell lines.⁷⁰ VEGF, bFGF, MMP, and receptor tyrosine kinases that are activated in endothelial cells subsequent to endothelial cell activation are also targets for antiangiogenic agents. Unlike most cytotoxic chemotherapeutic agents, bone marrow suppression is not a frequent dose-limiting side effect of signal transduction pathway inhibitors. Because of their mechanism of action, their effects are exerted primarily through inhibition of cell growth rather than through direct cytotoxicity. Occasionally, however, significant tumor regression is observed. Based on current knowledge, treatment regimens that incorporate use of these agents with cytotoxic drugs are most likely to have the greatest impact on patient outcomes in cancer treatments.

Angiogenesis Inhibition

Angiogenesis, the main process for new blood vessel formation postnatally, occurs during wound healing and disease states such as cancer. It occurs through remodeling, migration, and proliferation of pre-existing blood vessels. As discussed in an earlier section, endothelial cells receive stimuli such as VEGF and PDGF from tumor cells.^{71,72} These factors trigger cell proliferation and secretion of such factors as MMP, collagenase, and tissue plasminogen activators. These proteases enable the proliferating endothelial cells to invade tissue space and to form new vessels. These tumor vessels often differ phenotypically from normal vessels. Hence, a strategy for inhibiting tumor growth is possible, because agents can be designed to target this process, and thereby starve tumors of nutrients and oxygen. Two classes of molecules have been developed to block angiogenesis: antibody molecules and small molecule inhibitors. Bevacizumab is an example of an antibody molecule that binds to VEGF and inhibits binding to the VEGF receptor. It is approved for use in patients with colorectal cancer and advanced non-small-cell lung carcinoma (NSCLC).^{73,74} Sunitinib and sorafenib, which are both small molecule in-

hibitors, act as antagonists at several locations along the signaling pathways that promote angiogenesis.^{75,76} Both of these orally administered agents are approved for use in patients with renal cell carcinoma and are under evaluation for use in treating other solid tumors. Shown in Figure 88-6 is a summary of the angiogenic process and key signaling pathways where anti-angiogenic agents interact.

Biologic Response Modifiers

Biologic response modifiers used to treat cancers include proteins (vaccines), antibodies (monoclonal and polyclonal), and growth factors. These agents can be used to kill cancer cells or to bolster the host's defense mechanisms. An individual's immune system plays a crucial role in developing or eradicating cancer. Normally, an intact immune system can protect the host against malignant cells and infectious pathogens, but current evidence shows that individuals with "weakened" immune systems face an increased risk of developing cancer. For example, individuals with acquired immunodeficiency syndrome (AIDS) face an increased risk of developing lymphomas compared with the normal population. Other individuals with weakened immune systems, including neonates and the elderly, also face an increased risk of developing cancer. Bolstering an individual's immune system could help prevent or treat a malignancy. Some evidence shows that malignancies can undergo spontaneous regression, especially during periods of immune activation (e.g., an acute bacterial infection).⁷⁷ Current biologic response modifiers aim to bolster an individual's immune response, as well as provide a direct cytotoxic effect.

Interferon- α

The first recombinant cytokine to become available for the treatment of cancer was interferon- α . This interferon affects tumor cells through several different mechanisms, including (a) a direct antiproliferative effect; (b) an immunomodulatory effect on natural killer cells, T cells, B cells, and macrophages; (c) an induction of tumor cell antigens; and (d) a differentiating effect on tumor cells. Interferons also possess antiangiogenic effects.⁴⁰ Current studies show that interferon- α has antitumor effects against several human malignancies.⁷⁸ Interferon- α is sometimes given in combination with radiation therapy, other biologic response modifiers, or chemotherapy agents.

Interleukin-2

Interleukin (IL)-2 is a recombinantly produced lymphokine that has numerous immunoregulatory functions. In normal cells, IL-2 stimulates both T- and B-cell proliferation and differentiation.⁷⁹ The idea to use IL-2 to treat cancer arose from the observation that lymphoid cells incubated with IL-2 developed the capacity to lyse tumor cells (lymphokine-activated killer [LAK] cells).^{80,81} This observation led to the development of some adoptive immunotherapies. Initial studies showed that patients with advanced tumors, such as renal cell carcinoma and melanoma, experienced tumor regression after receiving IL-2. Subsequent studies using high dosages of IL-2 also reported responses in similar patient populations with advanced disease.⁸¹⁻⁸³ High-dose IL-2 therapy is accompanied by significant, dose-related toxicity. The most serious

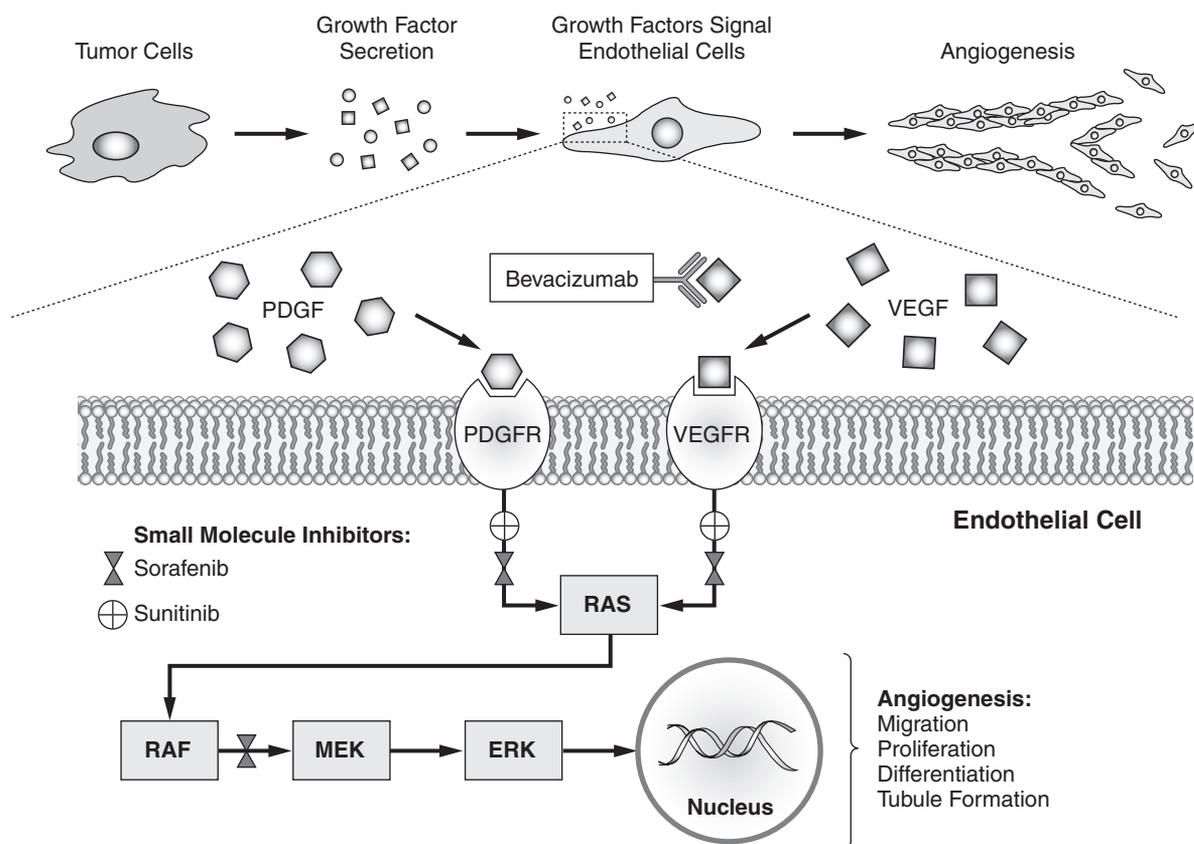

FIGURE 88-6 Angiogenesis and antiangiogenic agents. Tumor cells signal new blood vessel formation through secretion of growth factors such as vascular endothelial growth factor (VEGF) and platelet-derived growth factor (PDGF), which interact and activate receptor tyrosine kinase signaling within the endothelial cells. Subsequent cascade signaling downstream activates the cell nucleus and initiates angiogenesis through endothelial cell proliferation, migration, differentiation, and tubule formation. Agents that block this signaling process are shown as bevacizumab (monoclonal antibody blocks VEGF), and sorafenib and sunitinib (small molecule inhibitors) that block several different targets associated with the angiogenic process. RAF, MEK, ERK-Kinase enzymes.

toxicities (hypotension, pulmonary edema, oliguria, increased bilirubin) occur secondary to a diffuse capillary leak that develops during IL-2 therapy. These signs usually resolve promptly after discontinuing therapy.

HANDLING OF CYTOTOXIC DRUGS

Impact on the Pharmacy

14. The administrator of a health plan recently has announced that two medical oncologists will be joining the professional staff. Previously, patients were referred to outside oncologists, and no cytotoxic drugs were prepared or administered at the clinics. What implications will the addition of these physicians have on the pharmacy department?

New approaches to cancer treatment will affect three areas of the pharmacy department: the budget, the policies and procedures for safe drug handling, and the staff education program. The pharmacy department will need to increase its budget to accommodate the additional personnel and to purchase new equipment, supplies, supportive care medicines, and chemotherapy agents. To estimate the projected increase in the budget, a pharmacist should meet with oncologists to discuss

the anticipated volume of chemotherapy orders, the chemotherapy agents they are likely to prescribe, and the supportive care medicines they plan to use. All new chemotherapy agents and supportive care medicines (e.g., antiemetic therapy, analgesics) should be added to the health plan formulary. In addition, the pharmacist should determine the projected use of investigational agents, clinical pharmacy services that will be needed, and any plans to develop an ambulatory infusion program. The department must create new policies and procedures to ensure safe handling of chemotherapy agents by all personnel. These should be conveyed to all personnel through a staff education program, because safe handling of chemotherapy agents can significantly decrease the risk of medication errors and injuries.

Medication Errors

In recent years, several chemotherapy-related medication errors that resulted in death or permanent disability have been highly publicized. These devastating events have brought significant attention to the entire drug use process in oncology and have identified several factors that appear to contribute to the risk (Table 88-19). In particular, the use of abbreviations, verbal orders, multiple-day regimens, poor-quality carbon

Table 88-19 Factors That May Increase the Risk of Medication Errors Involving Chemotherapy

| Contributing Factor | Recommendation |
|--|--|
| Verbal orders | Do not accept; accept only written signed orders. If not possible, have two health professionals accept verbal orders, have written policy regarding verbal orders. |
| Multiple-day drug courses (e.g., etoposide 50 mg/m ² × 5) | Use standardized order forms or format. Order should clearly state total dose to be administered each day and actual dates of administration (e.g., etoposide 50 mg/m ² /day = 100 mg/day on 3/1, 3/2, 3/3, 3/4, and 3/5/07). Orders should also explicitly state infusion guidelines, other specific instructions (e.g., administer 30 min after antiemetic) and other pertinent patient information such as body surface area, weight, height, and age. |
| Trailing zeros following decimal points (e.g., 50.0 mg) or the decimal point may be lost or overlooked on carbon or fax copies | Do not permit trailing zeros. Leading zeros before decimal points should be required (e.g., 0.5 mg) so that the decimal point will not be overlooked. |
| Orders written by prescribers unfamiliar with chemotherapy | Require orders to be written by appropriately credentialed practitioners. |
| Use of abbreviations | Only approved generic names should be used when ordering chemotherapy or documenting regimens in patient records |
| Wide variability in chemotherapy doses that may be appropriate for different disease states or combinations | Educate all practitioners involved in the chemotherapy use process (physicians, nurses, pharmacists) regarding commonly used regimens and make printed or electronic resources to verify doses and regimens readily available. Institutional dosing guidelines are recommended. |
| Inappropriate interpretation of orders | Two pharmacists should verify orders at the point of entry and nurses should reverify before administration. All practitioners should be instructed to resolve all questions before dispensing or administration. |
| Labeling errors | Labels should be double-checked and include all pertinent information including route of administration. Syringe labels should be directly attached to the syringe. |
| Poor communication or confusion regarding chemotherapy | Written institutional policies and procedures should address every aspect of the chemotherapy use process, including ordering, preparing, dispensing, administering, and documenting. |

orders, poor facsimile medication orders, and incorrect references have contributed to a number of reported medication errors. Several groups have responded to the problem by issuing policy recommendations to minimize such errors.^{84–87}

Risks

15. What are the potential risks of handling cytotoxic drugs, and what resources are available to assist the Pharmacy director and the pharmacy staff in the development of policies and procedures?

For almost two decades, the potential hazards of chemotherapy agents have received considerable attention. Many of these agents are carcinogenic, teratogenic, or mutagenic in animal models and in humans at therapeutic doses.^{88–91} The danger to health care personnel handling such agents results from both the inherent toxicities of the agents and the extent to which the workers are exposed during drug handling.⁹² Various studies have attempted to assess the effect of occupational exposure to hazardous drugs by health care workers. These studies included measurements of urine mutagenicity, chromosomal damage, drug absorption, and, most recently, the level of contamination that occurs in the work areas used for drug preparation and administration.^{92–102} Although somewhat controversial, the documentation of urine mutagenicity or chromosomal damage was thought to be a direct result of cytotoxic exposure. Other reports correlate these observations of reproductive and birth defect risks in pregnant workers handling cytotoxic drugs.^{101,103} Results of these reports together with the toxicities observed in patients receiving therapeutic doses led the American Society of Hospital Pharmacists to conclude that health

care workers both inside and outside the pharmacy exposed to hazardous drugs whenever they are received, stored, prepared, administered, or disposed may be absorbing these drugs and may be at risk for adverse outcomes.⁹²

In response to the concerns regarding occupational exposure to hazardous drugs, several groups have published guidelines for the safe handling of these agents in the workplace (i.e., storage, preparation, administration, and disposal).^{92,104,105} These documents can be helpful to the pharmacy department when developing policies and procedures.

Policies and Procedures

16. What specific policies and procedures are necessary, and what other departments should be consulted during the development and implementation of the handling guidelines?

Policies must be developed that address the entire scope of potential occupational exposures within the workplace. These policies should include (a) a worker's "right to know" of potential hazards; (b) an education and training program for workers involved with hazardous drug handling; (c) a quality assurance program to monitor adherence to safe handling procedures; and (d) guidelines for workers attempting to conceive a child, who become pregnant, or who are nursing.

Specific procedures that outline the appropriate handling of hazardous agents during all aspects of institutional storage, use, and disposal should be developed. These procedures should include guidelines that outline the appropriate (a) storage in the receiving and storeroom areas, (b) preparation and administration of parenteral formulations, (c) manipulation and dispensing of oral and topical formulations, (d) the clean up of

spills, (e) management of acute exposures, and (f) disposal of hazardous agents and supplies used to prepare and dispense chemotherapy. If the oncology program includes ambulatory infusion or home care components, procedures should also be developed for the appropriate handling and disposal of these products in the home.

Other departments that may be affected by these guidelines include the medical staff, nursing, housekeeping (in the clean up of spills and equipment), maintenance (upkeep of equipment), and the receiving area (where cytotoxic drugs may be received from suppliers). The institutional safety office and legal staff also should be consulted to help devise the policies and procedures.

Necessary Equipment and Supplies

17. What equipment and supplies are necessary for handling hazardous drugs?

Various equipment and supplies can minimize occupational exposure in the health care workplace by protecting both the worker and the environment. All handling guidelines recommend that manipulations (e.g., reconstitution, admixing) of hazardous drugs be done in a class II biologic safety cabinet (BSC) to provide maximal protection for the worker and the work environment. Reports of measurable levels of chemotherapy agents found in work areas despite the use of BSC have renewed concerns regarding worker safety.¹⁰⁴ It is not clear how the work areas became contaminated, although the very

low vapor pressure of cyclophosphamide at room temperature may result in the release of particles too small to be retained by the high-efficiency particulate air filters within the BSC. Additional research will be required to assess whether other chemotherapy agents vaporize under similar circumstances and subsequently expose individuals in the work area. Workers also should wear gloves (one or two pairs) and a disposable, closed-front gown of lint-free, low-permeability fabric with a solid front, long sleeves, and knit cuffs. In addition, only syringes and IV sets with Luer-Lok fittings should be used. Final products (e.g., syringes, IV bags or bottles) should be placed in sealable containers such as zipper-closure plastic bags and clearly labeled as a hazardous drug. Other supplies that may be necessary for the sterile product preparation area include plastic-back paper liners for the bottom surface of the BSC and 0.2-mm hydrophobic filters.

The disposal of hazardous waste also requires specific receptacles, which should be placed in all areas where workers handle these drugs. Disposal of these agents should follow institutional and state and local regulations. Materials for the clean up of spills (e.g., absorbent material, plastic bags or containers, protective garments) also must be kept in all areas where hazardous drugs are stored, prepared, or administered.

ACKNOWLEDGMENT

The author and editors would like to acknowledge the contribution of Drs. Lisa E. Davis and Celeste Lindley, authors of this topic in the previous edition.

LONG-TERM COMPLICATIONS OF CHEMOTHERAPY 89-33

- Second Malignancies After Chemotherapy 89-33
 - Acute Myeloid Leukemia (AML) 89-33
- Fertility and Teratogenicity 89-34
 - Effects on Oogenesis 89-34
 - Effects on Spermatogenesis 89-34
 - Teratogenicity 89-35

Chemotherapy agents are toxic to cancer cells and also to various host tissues and organs. The adverse effects of chemotherapy can be classified as common and acute toxicities, specific organ toxicities, and long-term complications. Common and acute toxicities generally include adverse effects that occur as a result of inhibition of host cell division. Host tissues most susceptible to chemotherapy include tissues with renewal cell populations, such as lymphoid tissues, bone marrow, and epithelium of the gastrointestinal (GI) tract and skin. Some other common and acute toxicities (e.g., nausea and vomiting, hypersensitivity reactions) frequently occur in patients shortly after chemotherapy. Specific organ toxicities often are attributed to a unique uptake of the chemotherapy agent by the organ or a selective toxicity of the agent to the organ. Long-term complications are toxicities that occur months to years after

chemotherapy. These long-term toxicities occur secondary to continued immunodeficiencies or from permanent damage to the organ cells from the specific therapy. Acute and chronic toxicities can overlap. For example, many specific organ toxicities are evident within days following treatment, whereas other specific organ toxicities are not evident until months after treatment. Despite the overlapping definitions, this classification system provides some framework to discuss the adverse effects associated with chemotherapy.

The toxicities associated with chemotherapy are the most important factors limiting the use of potentially curative doses. Therefore, all discussions regarding the benefits of chemotherapy agents must include a discussion of toxicities associated with their use. Concerns regarding the toxicities of chemotherapy include the incidence, predictability, severity, and

reversibility of the adverse effects. Although the incidence and predictability may be well defined in specific patient populations, the incidence often varies depending on individual susceptibility. In addition, the specific chemotherapy agent, dose intensity, and treatment duration can influence the incidence of several adverse effects. The specific adverse effects that an individual patient will experience can be difficult to predict, however. Because several toxicities do have well-defined characteristics, clinicians treating patients with chemotherapy should be aware of the most common adverse effects.

Clinicians should also be aware of patient-specific factors, such as the stage of disease, concomitant illnesses, and concurrent medications, which could cause signs or symptoms that mimic the adverse effects associated with chemotherapy. Many patients have significant disease involvement and impairment of organ function because of the malignant cells. In addition, most patients with cancer commonly receive many other medications, including antibiotics and analgesics that can cause additional adverse effects or interact with chemotherapy. When the patient reports a new symptom, it may be difficult to determine whether it is secondary to chemotherapy, concurrent medications, or disease progression. Therefore, the clinician needs to be aware of the presentation, management, and prevention of the most common toxicities that could affect patients receiving chemotherapy.

COMMON AND ACUTE TOXICITIES

Hematologic Toxicities

Effects of Chemotherapy on Bone Marrow

The bone marrow contains a population of pluripotent stem cells capable of self-renewal and differentiation into any mature blood cell. At some point, their progeny commit to either the myeloid or the lymphoid cell line. The myeloid stem cell further commits to developing into an erythrocyte, megakaryocyte, granulocyte, or monocyte. After committing to a particular cell line, bone marrow precursor cells undergo a series of divisions (mitosis) to increase the number of cells. The cells then undergo several developmental stages to mature and differentiate into their final forms and leave the bone marrow (postmitotic). The total time required for a cell to pass through the mitotic and postmitotic pool under normal resting conditions is ~10 to 14 days. This process is regulated by several cytokines; although many cytokines have been identified, only a few are now produced through recombinant DNA technology. These growth factors can expand the mitotic pool and accelerate maturation and differentiation. Ultimately, these growth factors decrease the total time spent in these stages ~5 to 7 days.

The development and circulating life span of hematopoietic cell lines determines the severity of the depression of that cell line (nadir) and the time course of peripheral cytopenias. Because red blood cells (RBC) survive approximately 120 days in the peripheral blood, clinically significant anemia is not likely to occur if RBC production is impaired for a short period of time. Instead, anemia usually develops slowly after several courses of chemotherapy. In contrast, platelets survive ~10 days and granulocytes survive approximately 6 to 8 hours. This is why granulocytopenia generally occurs before thrombocytopenia, but both granulocytopenia and throm-

bocytopenia may be observed after the first or subsequent courses of chemotherapy. The depression of peripheral blood cells following chemotherapy can help determine the dosage and concurrent chemotherapy for subsequent courses. Life-threatening granulocytopenia or thrombocytopenia often necessitates some action to minimize the risk of adverse effects with additional chemotherapy. Previously, clinicians usually reduced the dose of the myelosuppressive agent. The availability of colony-stimulating factors (CSFs) and interleukin-11 (oprelvekin), however, provides an alternative approach to preventing severe neutropenia or thrombocytopenia following myelosuppressive chemotherapy.

MYELOSUPPRESSION

1. J.T., a 45-year-old, 59-kg man with no significant past medical history, presents to the university hospital with complaints of cough and shortness of breath (SOB). Chest radiograph reveals a lesion in the right upper lobe; bronchoscopy washings and cytologic examination are positive for small-cell lung cancer (SCLC). A workup for metastases is negative. J.T. is diagnosed with limited SCLC. His physicians plan to initiate radiation therapy to the right upper lobe with concurrent chemotherapy, to include carboplatin targeted to an area under the concentration-time curve (AUC) of 5 mg/mL/minute on day 1, topotecan 0.5 mg/m² daily on days 1 through 3, and etoposide 100 mg/m²/day orally (PO) on days 4 through 6. Discuss with J.T. the toxicities that might be expected to occur with this regimen. What effects on the bone marrow can be anticipated and how might they clinically appear in J.T.? What factors can influence the incidence and severity of these adverse effects? When can J.T. expect these effects to occur?

Although several toxicities are commonly associated with carboplatin, topotecan, and etoposide, the most predictable and dangerous toxicity associated with this regimen is myelosuppression. This chemotherapy regimen can significantly affect any cell line, including RBC, neutrophils, and platelets, and the cytopenias can cause significant morbidity or mortality. Decreased RBC can cause anemia, and patients usually present with fatigue and decreased exercise tolerance. Having low neutrophil counts significantly increases a patient's risk for bacterial infections. Moreover, reduced platelets can cause thrombocytopenia, which can cause bleeding from the GI and genitourinary tracts.

Both patient- and agent-related factors can significantly influence the degree of cytopenia a patient faces after chemotherapy. Agent-related factors include the chemotherapy agent, dose intensity, and dose density. Because most chemotherapy treatments are not given as a single agent, the effects of concurrent chemotherapy may intensify the myelosuppressive effect of an individual agent. Host factors that specifically may affect the cellularity of the bone marrow compartment also influence the degree of cytopenia. They include the following:

1. Patient age. Younger patients are generally better able to tolerate chemotherapy than elderly patients because they have a more cellular marrow with a decreased percentage of marrow fat.
2. Bone marrow reserve. Certain diseases might present with tumor cells in the bone marrow, such as leukemias and some lymphomas, in which case the bone marrow does not have a healthy reserve of normal hematopoietic cells to help in the recovery process.

3. The degree of compromise from previous chemotherapy, radiation therapy, or both. Prior chemotherapy and radiation therapy to fields involving marrow-producing bone reduce bone marrow reserves.
4. The ability of the liver or kidney to metabolize and excrete the compounds administered. If agents that depend on the liver or the kidney for metabolism to inactive metabolites or for excretion are administered to patients with specific organ insufficiencies, they can cause greater toxicities, including longer cytopenias secondary to lack of clearance.

These factors, along with the kinetics of the stem cells, can help clinicians predict the severity and duration of cytopenia observed following therapy.

With most myelosuppressive agents, the patient's white blood cell (WBC) and platelet counts begin to fall within 5 to 7 days of chemotherapy administration, reach a nadir within 7 to 10 days, and recover within 14 to 26 days. Phase-specific chemotherapy agents, such as the plant alkaloids and antimetabolites, cause a fairly rapid onset of cytopenia that recovers faster than the cytopenias occurring after treatment with phase-nonspecific agents, such as alkylating agents and anti-tumor antibiotics. For poorly understood reasons, nitrosureas typically produce severe, delayed neutropenia and thrombocytopenia 4 to 6 weeks after therapy. Other agents that exhibit this pattern include mitomycin and mechlorethamine. All of these chemotherapy agents exert their cytotoxic effects during the resting phase of the cell cycle. The nitrosureas as well as mitomycin and mechlorethamine can, however, cause two neutropenic nadirs; the first nadir occurs at the conventional time expected for phase-nonspecific agents and the second nadir occurs approximately 4 to 6 weeks after therapy. Many combination regimens that use these agents recommend 6-week cycles to avoid treatment before the second nadir. Most other myelosuppressive regimens recommend dosing intervals of 3 to 4 weeks to allow the bone marrow time to recover. Many of the targeted therapies do not exhibit bone marrow suppression, because their action is toward a specific molecular event rather than an entire metabolic process. Because these novel agents do not have overlapping myelosuppressive effects, they may be ideal agents to add to regimens that are known to cause cytopenias.

All the agents included in J.T.'s regimen have marked myelosuppressive activity. J.T. should be carefully counseled to contact his physician or report to the emergency department (ED) if he experiences signs or symptoms of an infection (including fever) or bleeding. Typically, these symptoms occur 10 to 14 days after the first day of chemotherapy.

Prevention

2. About 9 days after the first course of chemotherapy, J.T. developed a severe sore throat and fever. He was admitted to the hospital and treated with intravenous (IV) antibiotics. At the time, his WBC count was 300 cells/mm³. His fever resolved after 3 days, and all cultures were negative for bacterial growth. It is now 3 weeks after chemotherapy, and he is scheduled to receive a second course. Should he receive the same doses he was given initially?

Previously, the chemotherapy doses would have been reduced (usually by 25%) for all subsequent cycles for any patient who experienced febrile neutropenia. Although a dose reduc-

tion can clearly cause less neutropenia, it can also compromise the response and survival of patients with chemotherapy-sensitive tumors. Because J.T.'s cancer (i.e., limited-stage small cell lung cancer), is both chemosensitive and potentially curable, a dosage reduction is undesirable. To minimize the risk of neutropenia with future therapy, CSFs can be administered to J.T. to prevent potential complications associated with neutropenia.

The prophylactic administration of CSFs can be used to protect against the myelosuppressive effects of chemotherapy. Three CSFs, granulocyte colony-stimulating factor (G-CSF [filgrastim]) and granulocyte-macrophage colony-stimulating factor (GM-CSF [sargramostim]) and a pegylated long-acting form of filgrastim, pegfilgrastim, are available in the United States. These products were approved by the U.S. Food and Drug Administration (FDA) to enhance neutrophil recovery after chemotherapy. Pegfilgrastim was developed with the aim of providing the same pharmacologic benefit as filgrastim while offering the advantage and convenience of fewer injections. Evidence-based clinical practice guidelines for the use of CSFs have been developed by the American Society of Clinical Oncology (ASCO).¹ These guidelines recommend primary prophylaxis for all patients receiving chemotherapy regimens that have been previously reported to cause an incidence of ~20% of febrile neutropenia. A CSF used in these patients can reduce both the incidence of febrile neutropenia and need for hospitalizations and broad-spectrum antibiotics. Two randomized phase III clinical trials have shown that the risk of neutropenic fever is reduced when primary prophylaxis is used in regimens with a known incidence of ~20% neutropenia. In one trial, 928 patients with breast cancer receiving docetaxel 100 mg/m² every 21 days were randomized to receive placebo or pegfilgrastim 6 mg subcutaneously (SQ) 24 hours after chemotherapy. Patients who received pegfilgrastim had a lower incidence of febrile neutropenia (1% vs. 17%, respectively) and hospitalizations (1% vs. 14%, respectively).² A trial in patients (*N* = 171) with SCLC receiving a dose-intense regimen containing cyclophosphamide 1,000 mg/m² day 1, doxorubicin 45 mg/m² day 1, and etoposide 100 mg/m² days 1 to 3 every 21 days was conducted. Patients were randomized to receive prophylactic antibiotics with or without G-CSF. The rate of febrile neutropenia over all five cycles given was 32% with prophylactic antibiotics alone versus 18% with antibiotics and G-CSF.³ Because the regimen J.T. received does not typically produce a 20% incidence of febrile neutropenia, a CSF was not recommended for him after his first course of chemotherapy. Because J.T. did experience febrile neutropenia and he has a potentially curable malignancy, a CSF is indicated with subsequent courses of chemotherapy to prevent additional febrile episodes.

3. How are CSFs dosed to prevent chemotherapy-induced neutropenia?

The recommended initial dose of filgrastim (G-CSF) is 5 mcg/kg/day as a single daily subcutaneous (SC) injection, and the recommended initial dose of sargramostim (GM-CSF) is 250 mcg/m²/day as an SC injection. Pegfilgrastim is given at a dose of 6 mg once per cycle as an SC injection regardless of patient weight. The ASCO guidelines state that rounding the dose of either agent to the nearest vial size may enhance

patient convenience and reduce cost without clinical detriment. Because commercially available vials contain either 300 or 480 mcg of G-CSF, adult patients <75 kg should receive 300 mcg daily and adult patients >75 kg should receive 480 mcg daily.¹ Because of differences in commercially available vial sizes, the weight breakpoint for GM-CSF is slightly different; patients who weigh >60 kg should receive 500 mcg daily and patients who weigh <60 kg should receive 250 mcg daily.

The ASCO guidelines also recommend a shorter duration of treatment than does the manufacturer. The manufacturer recommends that therapy with filgrastim or sargramostim continue until the patient's neutrophil count is >10,000 cells/mm³ after the expected chemotherapy nadir. This is based on the observation that the neutrophil count falls roughly 50% after discontinuing a CSF. The risk of bacterial infection is highest, however, in patients with neutrophil counts of <500 to 1,000 cells/mm³; patients with neutrophil counts >500 to 1,000 cells/mm³ are not thought to be at high risk for developing bacterial infections. Thus, many clinicians elect to discontinue CSF when the neutrophil count reaches 2,000 to 4,000 cells/mm³ following the chemotherapy nadir. This reduces the number of treatment days and the cost associated with therapy without placing the patient at excessive risk for bacterial infections. The ASCO guidelines support this recommendation to discontinue CSF earlier.

To prevent chemotherapy-induced neutropenia, either pegfilgrastim, filgrastim, or sargramostim is used. Many patients find that a single injection of pegfilgrastim is more convenient with fewer injections to receive. Two pivotal, randomized, blinded multicenter phase III trials have evaluated the efficacy of single-dose pegfilgrastim in the prevention of chemotherapy-induced neutropenia in patients with high-risk stage II, stage III, and stage IV breast cancer.^{4,5} The patients ($N = 310$)⁴ ($N = 157$)⁵ received four cycles of doxorubicin 60 mg/m² and docetaxel 75 mg/m² chemotherapy on day 1 of each cycle and were randomized to either single-dose pegfilgrastim on day 2 or filgrastim 5 mcg/kg/day from day 2 until the absolute neutrophil count (ANC) was >10,000 cells/mm³ for a maximum of 14 doses. In one study, the pegfilgrastim was a 6-mg fixed dose⁵ and in the other study the pegfilgrastim dose was based on weight (100 mcg/kg).⁴ The primary endpoint was duration of severe grade IV neutropenia (ANC <500 cells/mm³ in cycle 1). Secondary endpoints included the degree of ANC nadir, time to recovery, incidence of grade IV neutropenia and incidence of febrile neutropenia. In these phase III breast cancer trials, no significant difference in duration of grade IV neutropenia was seen between the pegfilgrastim and filgrastim groups (1.7 vs. 1.8 days, respectively,⁴ and 1.8 vs. 1.6 days, respectively⁵). The incidence of severe neutropenia after chemotherapy was similar in the pegfilgrastim and filgrastim arms. In patients treated with pegfilgrastim, the incidence of febrile neutropenia over four cycles of chemotherapy in the two pivotal phase III trials^{4,5} was lower than in the patients treated with filgrastim. In the larger of the trials, this difference was clinically significant ($p = 0.029$). The time to ANC recovery was defined as the time from chemotherapy administration until the ANC increased to >2,000 cells/mm³. In the larger phase III trial,⁴ the mean time to recovery was 9.3 days in the pegfilgrastim group compared with 9.7 days in the filgrastim group. In all studies, pegfilgrastim has been well tolerated. From these data, it appears that a single 6-mg dose of pegfil-

grastim is at least equivalent to daily SC injections of filgrastim but offers advantages with respect to convenience and patient comfort.

In summary, J.T. should be given either G-CSF 300 mcg/day or GM-CSF 250 mcg/day SC beginning the day after his last dose of chemotherapy. Treatment should continue until the ANC is >2,000 to 4,000 cells/mm³. Alternatively, J.T. could receive a single 6-mg injection of pegfilgrastim the day after chemotherapy administration. Patients should not require more than one dose of pegfilgrastim for chemotherapy-induced neutropenia. Self-regulation of pegfilgrastim serum levels, related to its pegylation, is almost entirely dependent on neutrophil receptor-mediated clearance. Serum levels of pegfilgrastim will remain elevated during neutropenia induced by chemotherapy, and decline on recovery of neutrophil counts.⁶ Aside from high cost and inconvenience, the only negative effect of G-CSF therapy is mild transient bone pain. Bone pain is most commonly experienced when patients begin to recover peripheral blood cells following their nadir. The proposed mechanism suggests the stimulatory effect of G-CSF on granulopoiesis causes the pain. Most patients commonly report pain in bone marrow-rich areas, such as the sternum and pelvic regions. They should be advised that the bone pain experienced during marrow recovery is normal and usually is relieved with analgesic agents.

Treatment

4. If J.T. was not given G-CSF and presented with febrile neutropenia, would G-CSF therapy be helpful?

Because the duration of neutropenia is the most significant prognostic factor in patients with established febrile neutropenia, the major benefit of CSFs is their ability to reduce the duration of neutropenia. CSFs accelerate hematopoiesis by expanding the mitotic pool of committed progenitor cells and shortening the time spent in the postmitotic pool from 6 days to 1 day. If CSFs reduce the duration of neutropenia in patients who present with febrile neutropenia, then morbidity, mortality, and cost should be significantly reduced.

The ability of CSFs to reduce the duration of neutropenia in patients with established febrile neutropenia has been addressed in numerous randomized, double-blind, placebo-controlled trials,⁷ and two meta-analyses of trials have also been completed.^{1,8,9} The combined data for G-CSF and GM-CSF reveal minimal to moderate benefit in reducing hospital stays. Additionally, no differences in mortality were reported with the use of CSFs in this setting. Furthermore, questions have been raised as to whether all patients with febrile neutropenia require hospitalization. Several studies have shown equal efficacy and safety with increased cost effectiveness of outpatient treatment of febrile neutropenia.¹⁰⁻¹² Although CSFs do appear to hasten neutrophil recovery, the true cost-to-benefit ratio associated with the use of these products in established febrile neutropenia remains to be determined. The ASCO guidelines currently do not support routine use of CSFs in patients with febrile neutropenia, although they do recognize that certain patients with febrile neutropenia and high risk features predictive of clinical deterioration (e.g., age >65 years, pneumonia, fungal infection, hypotension, sepsis syndrome, uncontrolled primary disease) may benefit from use of CSFs.

5. Fourteen days after his fourth course of chemotherapy, J.T.'s platelet count is 7,000 cells/mm³. Although he has no evidence of bleeding, the clinician decides to administer a prophylactic platelet transfusion. Would oprelvekin be helpful in preventing the need for further platelet transfusions?

Oprelvekin is indicated to prevent severe thrombocytopenia and reduce the need for platelet transfusions following myelosuppressive chemotherapy in patients with nonmyeloid malignancies at high risk for developing severe thrombocytopenia. Because carboplatin has a cumulative myelosuppressive effect on platelet precursors, J.T. is at risk for developing severe thrombocytopenia with future courses of chemotherapy. In a randomized, double-blind clinical trial, oprelvekin reduced the need for platelet transfusions in about 20% of patients who were similar to J.T.¹³ The recommended dose is 50 mcg/kg/day SC until the postnadir platelet count is >50,000 cells/mm³ or up to 21 days following chemotherapy.¹⁴ Side effects can be mild to moderate and include peripheral edema, dyspnea, and pleural effusions. Because only about 20% of patients respond to oprelvekin, J.T. may still require additional platelet transfusions. In addition, the cost:benefit ratio of oprelvekin compared with platelet transfusions has not been demonstrated in clinical trials. Based on current evidence, J.T. should not receive oprelvekin at this time.

Anemia and Erythropoietin

6. Is erythropoietin useful in cancer patients with anemia?

Anemia usually is not a dose-limiting toxicity commonly associated with chemotherapy, because RBCs survive ~120 days. Chemotherapy predominantly affects RBCs by causing anisocytosis and macrocytosis. These effects are related to inhibition of DNA synthesis, and they predominantly occur following treatment with antimetabolites, including folic acid analogs, hydroxyurea, purine antagonists, and pyrimidine antagonists. Anemia commonly does not accompany these changes in RBC size. In addition, chemotherapy-induced effects on RBC are rarely the sole factor contributing to the low hemoglobin (Hgb) levels that necessitate an RBC transfusion.

Nevertheless, anemia commonly occurs in cancer patients secondary to the primary disease. The exact mechanism by which this anemia occurs is not well understood. Impaired erythrocyte response to erythropoietin, reduced hematopoietic precursors caused by chemotherapy or radiation therapy, and disrupted marrow architecture caused by invasion of malignant cells may all play a role. Erythropoietin has been shown to ameliorate anemia associated with cancer and chemotherapy, reduce the need for transfusions, and enhance the patient's quality of life.¹⁵⁻¹⁷

Two erythropoiesis-stimulating agents (ESA) are currently available for patient use. Recombinant human erythropoietin (r-HUEPO, epoetin- α) is approved for use in cancer patients receiving chemotherapy. Multiple dosing strategies have been suggested and evaluated in clinical trials. One recommended starting dose for r-HUEPO is 150 U/kg three times per week rounded to a standard dose of 10,000 U, consistent with the vial size, which is significantly higher than the recommended dose for anemia of renal failure. Alternatively, 40,000 U once weekly has also been shown to be effective and may be more convenient for patients.¹⁸ These initial doses should be given for 4 weeks. If the Hgb increases <1 g/dL, then the dose should

be increased to 300 U/kg three times weekly or 60,000 U once weekly. Up to 8 weeks of treatment may be required to decrease transfusion requirements significantly. Only about 50% of patients respond (i.e., reduce their requirement for transfusion or report a significant decrease in symptoms) to erythropoietin, so patients who do not respond positively within 6 to 8 weeks should discontinue therapy. Because pretreatment erythropoietin levels do not consistently correlate with the rate and likelihood of response, clinicians cannot predict which patients will respond to therapy.¹⁹ Adverse effects, such as hypertension, seizures, and angina, that can occur in patients with renal failure following a rapid dose escalation or normalization of hematocrit, have not been observed in patients with cancer; however, reviews of clinical trials in cancer patients have shown an increased risk for thromboembolic events.

Darbepoetin- α (Aranesp) is an ESA closely related to erythropoietin that is produced in Chinese hamster ovary cells by recombinant DNA technology. It stimulates erythropoiesis by the same mechanism as erythropoietin. Darbepoetin, also approved for the treatment of chemotherapy-related anemia, is distinguished from erythropoietin by its approximately three-fold longer half-life and greater biologic potency. This allows for an extended dosing interval relative to erythropoietin. Two dose-finding studies in 429 patients found that darbepoetin- α 1.5 mcg/kg, once per week, achieved the same mean hemoglobin change from baseline as that of recombinant human erythropoietin dosed at 150 U/kg, three times a week. At a dose of 3 mg/kg weekly, darbepoetin- α elicited a hematopoietic response after 2 weeks similar to that produced by r-HUEPO 40,000 to 60,000 U once per week.^{20,21} Additionally, in a multicenter open-label study of darbepoetin, 500 mcg every 3 weeks was effective in increasing and maintaining hemoglobin levels and was well tolerated.²² The FDA-approved starting doses of darbepoetin are 2.25 mcg/kg weekly or 500 mcg SC every 3 weeks. Darbepoetin may be increased to 4.5 mcg/kg weekly if no positive response is seen within 6 weeks of the initial dose.²²

Epoetin- α and darbepoetin- α have been studied in head-to-head prospective comparison trials as well as evaluated in multiple large meta-analyses and systematic literature reviews, and have been shown to be equal in efficacy, including hemoglobin responses and decreases in transfusions.²²⁻²⁶ ESAs may provide a safe and effective treatment for chemotherapy-associated anemia. ESAs are not recommended in the treatment of anemia in cancer patients caused by underlying diseases when patients are not receiving chemotherapy.

Epoetin- α and darbepoetin- α are indicated only for cancer patients actively receiving chemotherapy to reach and maintain a target hemoglobin level of 11 g/dL. Data have been reviewed by the FDA from four trials in cancer patients receiving ESAs. Collectively they show a higher risk of serious side effects, including thromboembolism, and increased mortality in patients with hemoglobin levels >12 g/dL and in those patients not receiving chemotherapy.²⁷ The use of erythropoietin agents in patients with cancer is rapidly evolving. Clinical practice guidelines from the American Society of Hematology and American Society of Clinical Oncology have provided updated recommendations and precautions regarding the use of ESA. These guidelines serve as an excellent resource for incorporating the use of ESA into current clinical practice.²²

Chemotherapy and Coagulation

7. What effect does chemotherapy have on blood coagulation?

Patients with cancer might develop bleeding secondary to chemotherapy-induced thrombocytopenia or thrombosis after chemotherapy. Bleeding can occur after treatment with L-asparaginase or the pegylated formulation PEG-L-asparaginase, which can inhibit the synthesis of fibrinogen and other specific coagulation factors produced by the liver under the influence of vitamin K.^{28,29} L-Asparaginase has a widespread effect on protein synthesis, and many plasma protein factors are depressed shortly after treatment with this agent. A patient receiving L-asparaginase can often develop a prolonged prothrombin time (PT) and partial thromboplastin time (PTT). Bleeding or thrombosis occurring as a direct result of changes in coagulation factors has not been frequently reported or conclusively documented, however. Coagulation factors may return to normal levels with continued administration of the agent, which suggests that the impairment of protein synthesis created by L-asparaginase is partially overcome by the liver. Specific treatment of prolonged PT and PTT with coagulation factors, fibrinogen, or vitamin K is not indicated.

THROMBOTIC EVENTS

Thrombotic events have been associated with the administration of chemotherapy.³⁰ Evidence of intravascular coagulation from plasma fibrinopeptide A, a specific activation peptide of fibrinogen, has been reported after starting chemotherapy.³¹ Conversely, a decrease in fibrinolytic activity reflected by a decrease in functional plasminogen activator also has been reported.³¹ Other protein abnormalities associated with thrombosis, including a decrease in the anticoagulant proteins C and protein S (free and total),^{32,33} have occurred after chemotherapy. Deficiencies of these proteins have been reported to result in spontaneous thrombosis. Although chemotherapy can potentially increase a patient's risk of thrombosis, the underlying disease can also affect risk.

Assessing the risk of thrombosis from administration of chemotherapy is complicated because many cancers are associated with an increased incidence of thrombosis. This is particularly true in tumors of the GI tract and acute promyelocytic leukemia. Trousseau³⁴ first reported an increased incidence of venous thrombosis in patients with cancer, and many investigators have since confirmed the relationship of multiple or migratory venous thrombosis in up to 15% of patients with cancer.³⁵ Up to one-third of apparently healthy adults who develop otherwise unexplained deep vein thrombosis eventually are proved to have a malignancy.^{36,37} Removal of the tumor often causes thrombotic episodes to disappear. Although warfarin or low-molecular-weight heparin therapy is indicated, thrombosis associated with cancer is often resistant to anticoagulant therapy.

Initiating treatment for acute promyelocytic leukemia commonly is associated (i.e., up to 85%) with disseminated intravascular coagulation.³⁸ The lysed tumor cells appear to release procoagulant materials following chemotherapy. Use of heparin to minimize risk of coagulation is controversial. Some investigators have reported excellent results in patients treated almost entirely with blood product support (e.g., fibrinogen, antithrombin III) without heparin.³⁸

Several chemotherapy agents have been associated with thrombosis risk, including antiangiogenic therapies such as thalidomide, lenalidomide, and bevacizumab. Thalidomide and lenalidomide in combination with other chemotherapy agents has been associated with venous thromboembolic events when used in the treatment of multiple myeloma and other diseases.^{39,40} Prophylaxis may be warranted, although optimal strategies are not defined and have not been studied in randomized trials.

Bevacizumab is associated with both arterial thrombosis and bleeding events. A retrospective analysis of five trials of patients receiving chemotherapy for colorectal, breast, or non-small-cell lung cancers revealed a 3.8% incidence of arterial thrombosis in patients receiving chemotherapy and bevacizumab versus 1.7% in chemotherapy alone.⁴¹ Severe major bleeding events have been reported in patients with metastatic colorectal cancer and life-threatening pulmonary hemorrhage and hemoptysis have been described in those with non-small-cell lung cancer; however, most bleeding events associated with bevacizumab use were minor.⁴²

Other factors can cause patients to develop thrombosis. Most patients receiving cancer chemotherapy often have other illnesses that may predispose them to developing thrombosis. In addition, surgical procedures and bedrest can increase the risk of thrombosis. Clinicians should maintain a high index of suspicion when a patient with cancer presents with signs or symptoms of thrombosis.

Gastrointestinal Tract Toxicities

The GI tract may be second only to the bone marrow in its susceptibility to toxic effects produced by chemotherapy. GI toxicities include nausea and vomiting, oral complications, esophagitis, and lower bowel disturbances.

Nausea and Vomiting

Nausea and vomiting are common and serious toxicities associated with many chemotherapy agents. Chemotherapy agents, their metabolites, or neurotransmitters may stimulate dopamine or serotonin receptors in the GI tract, the chemoreceptor trigger zone, or the central nervous system (CNS), which ultimately act on the vomiting center. Emesis most commonly occurs on the first day of chemotherapy and often persists for several days thereafter.⁴³ Most patients who receive traditional chemotherapy agents require antiemetics before and after chemotherapy for several days to control these symptoms. The most appropriate antiemetic regimen is based on patient- and agent-specific factors. Some of the novel targeted therapy agents carry some risk of emetogenicity, although it is generally milder. Guidelines are beginning to incorporate some of these targeted agents into their emetogenic classification schema based on incidence of nausea and vomiting in clinical trials (see Chapter 7, Nausea and Vomiting).

Complications of the Oral Cavity

Complications of the oral cavity include mucositis (or stomatitis), xerostomia (dry mouth), infection, and bleeding. Approximately 40% of patients treated with chemotherapy develop oral complications, and virtually all patients who receive radiation therapy to the head and neck develop oral complications.⁴⁴ These toxicities occur because of the nonspecific effects of

Table 89-1 Topical Medications for Oral Complications of Chemotherapy and Radiation Therapy

| <i>Problem</i> | <i>Products</i> | <i>Use</i> |
|--|--|---|
| Xerostomia | Pilocarpine 5-mg tablet plus Saliva substitutes and/or Sugar-free hard candy; sugar-free gum; ice chips | 1–2 tablets TID to QID Rinse or spray PRN PRN |
| Mucositis <i>Generalized</i> | Dyclonine hydrochloride (HCl) 0.5% or 1% solution or Viscous lidocaine 2% solution or Diphenhydramine capsules (125 mg) plus Dyclonine 1% 30 mL plus Nystatin 1 mL and 120 mL Maalox or Diphenhydramine plus nystatin plus hydrocortisone (various formulations) or Sucralfate suspension (8 tablets in 40 mL sterile water plus 40 mL 70% sorbitol; shake well and add water to 120 mL) | Swish and expectorate 5–15 mL Q 2–3 hr PRN Swish and expectorate 5–15 mL Q 2–3 hr PRN |
| <i>Localized</i> | Benzocaine in Orabase | Apply to affected dried area Q 2–3 hr; not to be used in the presence of an infection |
| Local bleeding (gingival) | Topical thrombin solution | Apply to affected area with gauze sponge and hold in place with pressure for 30 min; do not remove formed clots |
| Mucosal surface bleeding | Aminocaproic acid | Swish and expectorate 250 mg Q 4 hr for up to 12 hr |
| General infection | Chlorhexidine gluconate 0.12% oral rinse | Rinse BID after breakfast and at HS for 30 sec; do not swallow |
| Prevention and treatment of oral candidiasis | Nystatin oral suspension or Clotrimazole troche 10 mg | Rinse and swallow (if tolerated) 500,000–1,000,000 units TID to QID Dissolve 1 tablet 5 times/day |
| Prevention of caries | Acidulated fluoride rinse or Neutral fluoride rinse or Stannous fluoride gel 0.4% or Sodium fluoride gel 1.1% | Rinse daily for 1 min with 5–10 mL; do not swallow; switch to neutral fluoride if mucositis is present Rinse daily for 1 min with 5 mL; do not swallow; switch back to acidulated fluoride rinse when mucositis resolves Brush daily at HS; swish for 30 sec; expectorate and rinse Brush daily at HS; swish for 30 sec; expectorate and rinse |

BID, twice daily; HS, at night; PRN, as needed; QID, four times daily; TID, three times daily.

chemotherapy on cells undergoing rapid division, including the cells of the mouth that undergo rapid renewal with a turnover time equal to 7 to 14 days. Chemotherapy reduces the renewal rate of the basal epithelium and can cause mucosal atrophy, as well as glandular and collagen degeneration.⁴⁵ Radiation therapy to the head and neck also causes mucosal atrophy by decreasing cell renewal. Radiation can also cause fibrosis of the salivary glands, muscles, ligaments, and blood vessels and damage to the taste buds.⁴⁶

The combined effects of chemotherapy and radiation therapy on the oral mucosa can also cause infection and bleeding in the oral cavity. Infection and bleeding occurs when treatment causes bone marrow suppression, including thrombocytopenia and neutropenia. Because the oral mucosa is highly vascular and frequently traumatized, bleeding occurs commonly with low platelet counts. In addition, chemotherapy and neutropenia can alter the extensive microbial flora harbored in the oral cavity, thus leading to oral infections. Oral complications often compound one another, however. For example, xerostomia can

accelerate the development of mucositis as well as the formation of dental caries and local infection. Mucositis can clearly predispose the oral cavity to local bleeding and infection, as well as sepsis. These oral complications can also cause varying degrees of discomfort and adversely affect the patient's ability to eat, which potentially can lead to a compromised nutritional status. Topical treatments of oral complications are summarized in Table 89-1.

XEROSTOMIA

8. J.B. is a 55-year-old man with newly diagnosed, locally advanced head and neck cancer. Neoadjuvant chemotherapy with cisplatin, methotrexate, and fluorouracil, followed by a 2-week course of radiation therapy (200 rads/day for three cycles) and surgical resection of persistent residual disease are planned. A review of systems suggests that J.B. has poor oral hygiene, and a decision is made to consult the dental department of the university hospital before initiating radiation and chemotherapy. Is

J.B. at risk for developing oral complications of chemotherapy? Is there anything that should be done at this point to decrease his risk?

J.B. is at high risk for several of the oral complications previously described. Xerostomia, one of the most frequent side effects of radiation therapy to the head and neck, occurs secondary to radiation-induced changes to the salivary glands. Evidence supports a direct relationship between the dose of radiation to the salivary glands and the extent of glandular changes.⁴⁷ In most patients treated with <6,000 rads, radiation-induced changes to the salivary glands are reversible within 6 to 12 months after the end of therapy. J.B., however, also will be receiving chemotherapy agents (i.e., methotrexate, fluorouracil) that can cause xerostomia and enhance the toxicity to the salivary glands. Clinically, xerostomia has been caused by as little as two to three radiation doses of 200 rads.⁴⁷

Damage to the salivary glands causes various effects, including a loss of salivary buffering capacity, lower salivary pH, no mechanical flushing, and decreased salivary IgA. In addition, xerostomia can alter the sense of taste, causing some patients to lose their ability to differentiate between sweet and salty foods and others to report a bitter taste. Xerostomia also commonly causes caries. Caries and decalcification may become sufficiently severe to compromise tooth integrity and cause fracture. Because saliva is no longer available to help clear bacteria from the mouth, xerostomia also predisposes patients to infection secondary to the increases in oral bacteria. Administering a chemoprotectant before chemotherapy or radiation therapy may help reduce these adverse effects.

Amifostine

Amifostine, an organic thiophosphate chemoprotectant agent, is approved to reduce the incidence of moderate to severe xerostomia in patients having postoperative radiation treatment for head and neck cancer when the radiation port includes a substantial portion of the parotid glands. A randomized, clinical trial demonstrated that the incidence of xerostomia was reduced by about 30% in patients receiving 200 mg/m² as a 3-minute IV infusion 15 to 30 minutes before each fraction of radiation.⁴⁸ Guidelines published by ASCO support the use of amifostine to reduce the incidence of acute and late toxicity in patients receiving fractionated radiation therapy for head and neck cancer.⁴⁹ Amifostine cannot, however, prevent xerostomia from occurring in all patients. Amifostine is not used widely for the prevention of radiation-induced xerostomia secondary to its cost and adverse effect profile. Intravenous amifostine can cause nausea and vomiting as well as hypotension. Subcutaneous administration of the agent causes fewer GI effects and less hypotension, but increases the risk of injection site reactions. Because of these toxicities, >20% of patients discontinue amifostine before completing their radiation.⁵⁰

Other Treatments and Prevention

If xerostomia occurs, treatment can stimulate existing salivary flow and replace lost secretions. Relatively low doses of systemically administered pilocarpine (5–10 mg orally three times daily) may stimulate salivary flow and produce clinically significant benefits in patients with postradiation xerostomia.⁵¹ Dose-related adverse effects include cholinergic effects, such as sweating, rhinitis, headache, nausea, and abdominal cramps. Sucrose-free hard candy and sugar-free chewing gum can also

stimulate salivation, but these treatments are typically considered oral comfort agents. Saliva substitutes can also provide oral comfort to patients with xerostomia. Commercially available saliva substitutes generally are recommended for use before meals and at bedtime. They are available in several formulations, including sprays, rinses, and chewing gums. Patients who find one product or formulation unacceptable or unsuccessful may benefit from experimenting with other formulations or product lines. Studies have shown that salivary substitutes containing carboxymethylcellulose or hydroxyethylcellulose are more effective in relieving dryness than water- or glycerin-based solutions.^{52,53} Other treatment modalities attempt to prevent the complications associated with xerostomia.

Prevention of radiation-induced caries is best accomplished by aggressively using fluorides.⁵⁴ Generally, acidulated fluorides are the most effective, although neutral fluorides may be more acceptable to patients with mucositis. Patients are instructed to rinse daily for 1 minute with 5 to 10 mL of a fluoride rinse. Stannous fluoride gels 0.4% or sodium fluoride gel 1.1% tooth brushing agents may be also be used by patients to minimize their risk of caries. Meticulous attention to oral hygiene with regular dental checkups and avoidance of sucrose is essential to minimize the development of caries.

In general, a dentist should see patients who will be receiving radiation therapy to the head and neck or chemotherapy agents with a high risk of oral complications before starting therapy. This includes patients with hematologic malignancies who will most likely experience severe myelosuppression for prolonged periods. Oral evaluation before therapy, intervention to eliminate potential sources of infection or irritation prior to therapy, and preventive measures taken during therapy can dramatically decrease the frequency of oral complications.⁵⁵ Given J.B.'s risk factors, a dental examination is indicated before initiating therapy.

MUCOSITIS AND STOMATITIS

9. J.B. successfully completed his first 2-week course of combined chemotherapy and radiation therapy; however, 3 days into his second 2-week cycle, he complains of generalized burning, discomfort, and pain on the ventral surface of his tongue. On clinical observation, both the ventral surface of his tongue and the floor of his mouth appear erythematous, and several discrete lesions are present in both areas. What is the most likely explanation for J.B.'s new onset of symptoms? What treatment is indicated at this time?

J.B.'s symptoms are consistent with therapy-related mucositis. As discussed, this complication occurs as a nonspecific effect of chemotherapy agents and radiation therapy on the basal epithelium of the mouth. Nonkeratinized mucosa is affected most often. Thus, the buccal, labial, and soft palate mucosa; the ventral surface of the tongue; and the floor of the mouth are the most common sites of involvement. Although lesions are usually discrete initially, they often progress to produce large areas of ulceration. The lesions typically do not progress outside the mouth, but they may extend to the esophagus and involve the entire GI tract. Signs and symptoms generally occur about 5 to 7 days after chemotherapy or at almost any point during radiation therapy. The antimetabolites (e.g., methotrexate, fluorouracil, and cytarabine) and the antitumor

antibiotics are the chemotherapy agents that most commonly produce direct stomatotoxicity. Lesions generally regress and resolve completely in ~1 to 3 weeks, depending on their severity.

Patients with mucositis can present with various symptoms, but they often complain of pain so severe that parenteral opioid analgesics are required for relief. Other signs or symptoms include decreased ability to eat and speak, and local or systemic infections. Bacterial, fungal, or viral infections can occur. Although different microbial agents can cause a characteristic lesion, the lesion's appearance usually does not always correlate with the infectious agent. This particularly occurs in patients with neutropenia who cannot mount a full inflammatory response. In these individuals, the clinical appearance of an infected lesion may be muted relative to the presence or number of pathogens. Under normal conditions, the mucosa provides a natural barrier to the entry of normal oral flora, but the broken mucosa allows pathogens access to the bloodstream. The patient could develop life-threatening infection or sepsis in addition to a local infection. After assessing the complications associated with mucositis, the patient should be treated to minimize discomfort and morbidity.

Treatment

Treatment of mucositis is palliative. Topical anesthetics, including viscous lidocaine or dyclonine hydrochloride 0.5 or 1%, often are recommended. Equal portions of kaolin, diphenhydramine, and magnesium- or aluminum-containing antacids can be used for their anesthetic and astringent properties. Many institutions may compound mouthwash products containing these ingredients as well as antibiotics, nystatin, or corticosteroids. Corticosteroids provide anti-inflammatory properties, and the antibiotics and antifungals provide antibacterial or antifungal properties. Another topical agent, sucralfate, may provide some benefit by coating the lesion and reducing discomfort. All of these topically applied products are only used for symptom control, and data supporting superior efficacy of one product over another in relieving pain are lacking.

All the topical anesthetic-containing preparations are recommended for use as “swish-and-spit” preparations. Generally, 5 to 10 mL is used three to six times a day. The longer the patient can hold the solution in the mouth, the longer the contact, and, theoretically, the better the symptom relief. Therefore, patients should be advised to hold and swish the solution around the mouth for as long as possible before spitting it out. Other treatment options include topical benzocaine in Orabase and ice chips. For small localized lesions, ointments such as benzocaine in Orabase may be applied after the affected area has been dried with a sponge. Patients may also find ice chips soothing. Most patients, however, require systemic analgesics to alleviate the pain.

Gelclair is a bioadherent oral gel containing polyvinylpyrrolidone and sodium hyaluronate (but no alcohol or anesthetic agent). It provides an adherent barrier over the mucosal surfaces, thereby shielding oral lesions from the effect of food, liquids, and saliva.⁵⁶ Controlled clinical data are lacking. In a study of 20 patients with head and neck cancer undergoing radiation therapy presenting with mucositis, Gelclair was compared with standards of care, including sucralfate and lidocaine. No significant difference was found between the two study populations in relieving general pain.⁵⁷

Table 89-2 Guidelines for the Management of Stomatitis

1. Remove dentures to prevent further irritation and tissue damage.
2. Maintain gentle brushing of teeth with a soft toothbrush.
3. Avoid mouthwashes or rinses that contain alcohol because they may be painful and cause drying of the mucosa. Consider normal saline or sodium bicarbonate oral swishes.
4. Lubricants, such as artificial saliva, may loosen mucus and prevent membranes from sticking together. Avoid mineral oil and petroleum jelly because they can be aspirated.
5. Apply local anesthetics for localized pain control, especially before meals (may add an antacid or an antihistamine). Systemic opioid analgesics may be required to control pain associated with severe mucositis.
6. Ensure that adequate hydration and nutrition are maintained:
 - Eat a bland diet, avoiding spiced, acidic, and salted foods.
 - Avoid rough food; process in a blender if necessary.
 - Use sugar-free gum or sugar-free hard candy to stimulate salivation and facilitate mastication.
 - If necessary, provide intravenous nutritional support.
 - Avoid extremely hot or cold foods.
 - Use shakes with nutritional supplements or ice cream.

J.B. appears to have a mild case of stomatitis or mucositis at this time; however, the lesions may progress over the next several days. Appropriate treatment may include the use of any of the topical products listed in Table 89-1. Table 89-2 lists additional guidelines for managing stomatitis.

Prevention

10. Could J.B.'s mucositis have been prevented?

Historically, treatment of chemotherapy- and radiation-induced mucositis has been aimed at reducing symptoms once they occur and avoiding further trauma to the oral mucosa. Cryotherapy has been marginally effective in reducing the severity of chemotherapy-induced mucositis.⁵⁸ Ice chips are placed in the mouth 5 minutes before chemotherapy begins and retained for 30 minutes. Theoretically, this will reduce blood flow to the mouth, thereby protecting the dividing cell population from toxins.

Glutamine is an important substrate for rapidly proliferating tissue. In two randomized trials, oral glutamine supplementation was associated with a reduction in the severity and duration of oral pain after chemotherapy. In one trial of bone marrow transplant (BMT) recipients, glutamine significantly reduced the severity and duration of oropharyngeal mucositis in those who had received autologous transplants, but not in those who had received allogeneic transplants.⁵⁹ In contrast, glutamine failed to prevent mucositis in two trials of patients receiving standard-dose fluorouracil-based chemotherapy.⁶⁰

Chlorhexidine gluconate 0.12% also may reduce the frequency and severity of mucositis infection,^{61,62} although not all studies have shown a benefit. This solution should be used twice daily as a rinse. Side effects include occasional burning (thought to be caused by the product's alcohol content, which can be reduced by diluting it with water) and superficial brown tooth staining, which polishes off easily. Chlorhexidine may reduce the frequency and severity of mucositis by eliminating microorganisms in the oral cavity.

Despite these prophylactic measures, none of these aforementioned methods have a definitive benefit. To date, the only

medication with proven efficacy is palifermin, a keratinocyte growth factor, approved for patients with hematologic malignancies having BMT to reduce the incidence and duration of severe oral mucositis. Efficacy was established in a phase III multicenter, randomized, placebo-controlled double-blind trial ($N = 212$) comparing palifermin 60 mcg/kg/day IV starting 3 days before the conditioning regimen and continuing days 0, 1, and 2 of transplant with placebo. Palifermin demonstrated a reduction in severe mucositis of 63% versus 98%, respectively, and duration of mucositis of 6 days versus 9 days, respectively.⁶³ Palifermin's use is limited thus far and has not shown proven efficacy in other patient populations at risk for mucositis. Other methods for decreasing the incidence and severity of mucositis symptoms include reducing the dose of radiation or chemotherapy, but doing so comes at the risk of compromising treatment outcomes. Stomatitis remains the dose-limiting toxicity for several chemotherapeutic regimens.

Esophagitis

Chemotherapy and radiation therapy can also damage the mucosa lining the esophagus. Although dysphagia is a common symptom reported by patients with esophagitis, other causes of dysphagia should be ruled out. Because patients receiving myelosuppressive chemotherapy may develop infectious esophagitis, bacterial, viral, and fungal cultures should be completed to rule this out before starting treatment for esophagitis. Symptomatic management of esophagitis is similar to the management of mucositis. Other treatment modalities, including behavioral modifications and other medications (e.g., H₂-receptor antagonist, antacids, and proton pump inhibitors) may help reduce esophageal irritation and improve comfort. Patients with severe esophagitis should be carefully monitored to ensure adequate oral hydration and nutritional intake and instructed to avoid acidic or irritating foods. Symptoms should resolve in 1 to 2 weeks as myelosuppression resolves.

Lower GI Tract Complications

Lower GI tract complications associated with chemotherapy include malabsorption, diarrhea, and constipation. These complications may be related to structural changes that occur to the GI tract after chemotherapy or radiation therapy. Several investigators noted villus atrophy and cessation of mitosis within GI crypts in patients and animals treated with combination chemotherapy.^{64–66} Other investigators noted swelling and dilation of mitochondria and endoplasmic reticulum and shortening of the microvilli. These or other changes to the small and large bowel can cause decreased absorption of medications that are primarily absorbed in the upper portion of the small intestine. Decreased absorption has been documented with several drugs with narrow therapeutic indexes, including phenytoin, verapamil, and digoxin following chemotherapy.^{67–69} Patients receiving medications for concurrent illnesses should be carefully monitored for new signs or symptoms of adverse effects.

Chemotherapy-induced intestinal changes also may be responsible for diarrhea, which frequently occurs with regimens containing irinotecan, high-dose cytarabine, or fluorouracil. Unlike diarrhea, constipation is rare. The vinca alkaloids, which produce colicky abdominal pain, constipation, and adynamic ileus caused by autonomic nerve dysfunction (see Neurotoxicity section), can cause chemotherapy-induced constipation. Additionally, constipation is a problematic side effect

of therapy with thalidomide. Constipation should be treated prophylactically with stool softeners and mild stimulants. The true incidence of diarrhea and constipation associated with chemotherapy is difficult to discern, however, because many medications (e.g., opioid analgesics, antiemetics, antacids) and situations (e.g., immobility) commonly associated with cancer and chemotherapy can cause these symptoms as well.

DIARRHEA

11. B.G., a 60-year-old woman with recurrent colorectal cancer refractory to fluorouracil, is beginning her first course of irinotecan 125 mg/m² weekly for 4 weeks followed by a 2-week rest period. What instructions should she receive regarding the management of diarrhea should she experience this complication?

Irinotecan can cause severe diarrhea, both early and late, in the course of chemotherapy. The early- and late-onset diarrhea appears to be mediated by different mechanisms. Early-onset diarrhea (within 24 hours after treatment) may be mediated by parasympathetic stimulation. Patients often report other cholinergic symptoms, such as rhinitis, increased salivation, miosis, lacrimation, diaphoresis, flushing, and abdominal cramping as well. These symptoms can be prevented or managed with atropine IV or SC 0.25 to 1 mg. Late-onset diarrhea (generally occurring >24 hours after treatment) can be prolonged leading to dehydration, electrolyte imbalances, and significant morbidity. Patients should promptly receive loperamide 4 mg with the first episode of diarrhea and repeat doses equal to 2 mg every 2 hours until 12 hours have passed without a bowel movement.⁷⁰ For patients who do not respond to initial therapy, some clinicians recommend higher doses equal to 4 mg every 2 hours. Fluid and electrolyte replacement should also be administered, if necessary. With the potential severe complications associated with irinotecan-associated diarrhea, prompt treatment cannot be overemphasized.

If a patient fails to respond to adequate doses of loperamide, the somatostatin analog, octreotide, can be used to manage the diarrhea. Randomized trials comparing loperamide with octreotide in patients with acute leukemia or those undergoing BMT found loperamide to be more effective.^{71,72} Nevertheless, some evidence shows that octreotide may be used to successfully manage diarrhea associated with fluorouracil and other high-dose chemotherapy regimens.^{73–75} Octreotide produces antisecretory activity in the gut and promotes the absorption of sodium, chloride, and water from luminal content. Patients should receive doses ranging from 100 to 2,000 mcg SC three times daily or 20 to 40 mg of long-acting octreotide.^{74,75} Although responses seem to correlate with octreotide dose, more studies are needed to determine the optimal dose. Based on current evidence, octreotide should be limited to second-line therapy for chemotherapy-associated diarrhea.

Dermatologic Toxicities

Dermatologic toxicities associated with chemotherapy include alopecia, hypersensitivity reactions, extravasations, and hyperpigmentation. Toxicities, including alopecia, nail changes, dry skin, and blistering, occur when chemotherapy agents reduce or inhibit mitosis in the epidermis and nail matrix. Other chemotherapy agents can cause various skin reactions when they interact with ultraviolet (UV) light or radiation.

Dermatologic toxicities also can occur when chemotherapy agents with vesicant properties extravasate from the veins into surrounding soft tissue. In addition, some agents produce specific skin eruptions, nonspecific eruptions, or “rashes” by unknown mechanisms. Several reviews serve as excellent references.^{76,77}

Alopecia

PATHOGENESIS

12. C.W., is a 45-year-old woman with recently diagnosed breast cancer, who underwent lumpectomy. She will receive 20 fractions or courses of radiation therapy to the affected breast. She will also receive chemotherapy to minimize her risk of recurrence. She is in the clinic today to receive the first of six cycles of cyclophosphamide, doxorubicin, and fluorouracil (CAF regimen). Although C.W. had minimal problems with surgery, she particularly fears receiving combination chemotherapy. You start counseling C.W. about the most common toxicities by reviewing the likelihood and management of myelosuppression, nausea, and vomiting. C.W. is appropriately attentive as you discuss these issues with her; however, her overriding concern is whether or not she will lose her hair. Is C.W.’s concern typical of most cancer patients? How would you respond?

C.W.’s concern regarding hair loss is typical of cancer patients starting chemotherapy. In fact, several investigators have reported that hair loss ranks second only to nausea and vomiting as a patient’s greatest fear. Because hair bulb cells replicate every 12 to 24 hours, the cells are susceptible to various chemotherapy agents. Normally, hair follicles independently move cyclically through phases of growth (anagen), involution, or transition (catagen), and rest (telogen). Although most persons normally lose about 100 scalp hairs a day, patients with cancer can lose substantially more. Because ~85% to 90% of hair follicles are in the anagen phase, chemotherapy agents may partially or completely inhibit mitosis or impair metabolic processes in the hair matrix. These effects can cause a thinned or weakened hair shaft or failure to form hair. Even mild trauma, such as normal hair grooming or rubbing the head on a pillow, can fracture the thinned hair shaft and cause hair loss. Hair loss usually begins 7 to 10 days after one treatment, with prominent hair loss noted within 1 or 2 months. Other terminal hairs, such as beards, eyebrows, eyelashes, axillary, and pubic hair can be affected; however, these effects are somewhat variable, depending on the rate of mitosis and the percentage of hairs in the anagen phase.⁷⁸

C.W. should be informed about the expected onset of hair loss, and she should be reassured that alopecia caused by chemotherapy is reversible. She can expect her hair to begin regenerating 1 to 2 months after therapy is completed. The color and texture of her hair may be altered; the new hair may be lighter, darker, or curlier as it regrows. Agents most commonly associated with severe alopecia are listed in Table 89-3.

PREVENTION

Several interventions have been proposed to prevent scalp hair loss during chemotherapy. These procedures attempt to prevent chemotherapy agents from circulating to the hair follicles with either an occlusive scalp tourniquet or an ice cap that produces a localized hypothermia and vasoconstriction. Recognizing that such devices create a refuge for tumor cells,

Table 89-3 Single Agents Associated With Alopecia, Pigmentation Changes, and Nail Disorders

| | Frequent | Occasional |
|-----------------------|------------------|------------------|
| Alopecia ^a | Cyclophosphamide | Mechlorethamine |
| | Ifosfamide | Thiotepa |
| | Fluorouracil | Methotrexate |
| | Dactinomycin | Vinblastine |
| | Daunorubicin | Vincristine |
| | Doxorubicin | Etoposide |
| | Bleomycin | Carmustine |
| | Vindesine | Hydroxyurea |
| | Paclitaxel | Cytarabine |
| | Irinotecan | Topotecan |
| | Epirubicin | Gemcitabine |
| | Docetaxel | Erlotinib |
| | Etoposide | Sorafenib |
| | Mitoxantrone | |
| | Pigmentation | Busulfan |
| Fluorouracil | | Methotrexate |
| Doxorubicin | | Dactinomycin |
| Bleomycin | | Daunorubicin |
| Epirubicin | | Hydroxyurea |
| Capecitabine | | Ifosfamide |
| | | Thiotepa |
| Nail | | Cyclophosphamide |
| | | Fluorouracil |
| | | Daunorubicin |
| | | Doxorubicin |
| | | Bleomycin |
| | | Hydroxyurea |
| | | Epirubicin |
| | | Docetaxel |
| | | Paclitaxel |
| | | Capecitabine |
| | | Erlotinib |
| | | Gefitinib |
| | | Sorafenib |
| | | Sunitinib |

^a Degree and onset of alopecia depend on dose, administration schedule, delivery rate and route, and various agent combinations.

these procedures are contraindicated in patients with hematologic malignancies and in others at risk for scalp metastases. Concerns regarding the efficacy and safety of these devices have prevented them from availability in the U.S. market.^{78,79}

C.W.’s concern is a legitimate one expressed by many patients with cancer, not just patients with breast cancer. C.W. is likely to experience near or complete hair loss, depending on the thickness of her hair and its growth rate. She should be told how to minimize the effect of alopecia on her appearance through the use of hair pieces or stylish head scarves, turbans, or hats. She also should be referred to volunteer groups and organizations that can help her through this difficult time. Hair pieces are tax deductible as a medical expense and are covered by some health insurance policies. If C.W. thinks she will use a hair piece, she should be advised to select a wig before hair loss begins.

Skin and Nail Changes

13. Besides alopecia, what other skin or nail changes should C.W. anticipate?

Several skin and nail changes have been associated with chemotherapy, which C.W. may find disturbing. The major consequences of these toxicities are cosmetic, however, and they usually resolve within 6 to 12 months after discontinuing chemotherapy.

NAIL CHANGES

The growth of fingernails and toenails is arrested in a manner similar to hair growth. A reduction or a cessation of mitotic activity in the nail matrix causes a horizontal depression of the nail plate. Within weeks, these pale horizontal lines (“Beau’s lines”) begin to appear in the nail beds. They are most commonly seen in patients receiving chemotherapy for >6 months. These growth arrest lines move distally as the nail grows and normally disappear from the fingernails in ~6 months. Nail changes including hemorrhagic onycholysis, discoloration, and acute exudative paronychia are seen in ~40% of patients receiving paclitaxel and docetaxel.⁷⁶ Some other nail pigmentation changes that can occur following therapy with cyclophosphamide, fluorouracil, daunorubicin, doxorubicin, and bleomycin are less well understood.^{81–83} Brown or blue lines deposit as horizontal or vertical bands in the nails. These lines are seen more commonly in dark-skinned patients. As with Beau’s lines, these pigmentation lines generally grow out with the nail.

DERMATOLOGIC PIGMENT CHANGES

Dermatologic pigment changes are among the most common and least well understood side effects of chemotherapy. Hypopigmentation has been reported occasionally in patients receiving chemotherapy, but hyperpigmentation is most frequently reported. Usually, hyperpigmentation is not associated with an identifiable cause or systemic toxicity. It usually occurs following treatment with a wide variety of chemotherapy agents, including antitumor antibiotics, alkylating agents, and antimetabolites. Most agents cause a diffuse, generalized hyperpigmentation, but the pigmentation changes can also be localized, involving only the mucous membrane, hair, or nails. Busulfan, cyclophosphamide, fluorouracil, dactinomycin, and hydroxyurea are examples of specific agents that can cause widespread cutaneous hyperpigmentation.^{76,84–87}

Various chemotherapy agents can cause significantly diverse patterns of hyperpigmentation. A peculiar serpiginous hyperpigmentation can occur over veins used to administer fluorouracil and bleomycin.^{88,89} Some investigators have attributed this phenomenon to a subclinical phlebitis. Hyperpigmentation has also been noted over pressure points after the use of bleomycin. Bleomycin can also cause peculiar linear or flagellate streaks of hyperpigmentation. Because of their characteristic location and appearance, these streaks may result from scratching during therapy; however, attempts to reproduce these lesions iatrogenically have not been successful. Thiotepa has been reported to cause hyperpigmentation in areas of skin occluded by bandages, which may be caused by secretion of thiotepa in sweat.⁹⁰ Interestingly, skin contact with thiotepa has been reported to cause hypopigmentation.⁹¹ Topical contact with mechlorethamine and carmustine also has caused hyperpigmentation.^{92,93} Although hyperpigmentation reactions commonly affect the skin, some rare reactions are noted in hair. Methotrexate can cause hyperpigmented banding of light-colored hair. This phenomenon has been described

in a patient receiving intermittent high-dose methotrexate and has been referred to by some investigators as the “flag sign” of chemotherapy.⁹⁴ To minimize a patient’s concern regarding these pigment changes, they should receive counseling before treatment.

As previously stated, pigment changes that occur in patients receiving chemotherapy are basically a cosmetic concern. It is important to anticipate these distressing side effects and educate patients in appropriate cases. At this time, C.W. should receive counseling, explaining that these side effects may occur because she will be receiving several agents that have been implicated in producing both diffuse, as well as localized, cutaneous nail hyperpigmentation. She should be reassured that pigment changes usually resolve with time.

HAND–FOOT SYNDROME

Some patients receiving chemotherapy may develop tender, erythematous skin on the palms of their hands and sometimes on the soles of their feet. Patients may also complain of tingling, burning, or shooting sensations in their hands or feet usually not described as painful. These signs and symptoms may resolve after several days, or they may progress to bullous lesions that can desquamate. This reaction is referred to as *chemotherapy-associated acral erythema* or the *palmar-plantar erythrodysesthesia syndrome*. Agents reported to cause this reaction include cytarabine, fluorouracil, doxorubicin, liposomal doxorubicin, methotrexate, capecitabine, and hydroxyurea. Additionally, both sunitinib and sorafenib-multiple receptor tyrosine kinase inhibitors- have been associated with hand-foot syndrome.^{95,96} No specific therapy exists for hand-foot syndrome. Typically, the offending agent is discontinued at least until recovery occurs.

ACNEIFORM–ERYTHEMATOUS RASH

The most common toxicities reported with the new epidermal growth factor receptor inhibitors are skin related and are probably due to inhibition of the tyrosine kinase pathways in EGFR-dependent tissues, including keratinocytes in the skin. Several EGFR inhibitors currently available include erlotinib and lapatinib, which are small molecule tyrosine kinase inhibitors that target the intracellular domain of the EGFR. Cetuximab and panitumumab are monoclonal antibodies that target the extracellular domain of EGFR. Skin effects occur in >50% of patients who receive these treatments and are reported to be dose dependent. A pustular or maculopapular eruption appears on the upper body, face, and scalp in the first 1 to 2 weeks of treatment. The rashes are predominantly grade 1 or 2 in severity, may be associated with dry skin and itching, and completely resolve without sequelae when the drug is discontinued.⁹⁷ Evidence suggests that the severity of the skin rash is associated with increased efficacy of this class of agents. In a retrospective analysis of a phase III trial in patients with NSCLC receiving erlotinib, those who developed a rash had a significantly longer survival time than those who did not. Survival was reported to be 1.5 months in patients with no development of skin rash versus 8.5 months in those with grade 1 rash, and 19.6 months in patients exhibiting a grade 2 or 3 rash.⁹⁸ Evidence for correlation between skin rashes and positive response rates has also been seen in patients receiving cetuximab for colorectal cancer.⁹⁹ No supportive therapy has, however, been proven to reduce or prevent this bothersome

side effect. No randomized, controlled studies have evaluated therapeutic options for relief or treatment of the acneiform rash. Moisturizing creams, steroid creams, sunscreen, antibiotics (e.g., topical clindamycin or systemic tetracyclines), and topical calcineurin inhibitors (e.g., pimecrolimus cream) have been used to manage the effects with varying results. Patients are also advised to minimize sun exposure. All of these agents have demonstrated activity in some patients, but none have worked consistently in all. Therefore, if one agent is not successful, alternative agents may be tried.⁹⁷

DRY SKIN

Many chemotherapy agents (especially bleomycin, hydroxyurea, and fluorouracil) can cause dry skin with fine scaling on the surface. Normally, sebaceous and sweat glands provide lipids, lactates, and other products that contribute to the pliability and moisture retention of the stratum corneum. In patients receiving chemotherapy, the dry skin may be caused by the cytostatic effect of chemotherapy agents on sebaceous and sweat glands. Topical application of emollient creams may provide some symptomatic relief of this dryness.

Interactions With Radiation Therapy

14. C.W. recently completed her course of total breast radiation therapy. She also plans to leave for a 1-week vacation in Florida 3 days after this clinic visit. Are there any interactions between radiation therapy and sunlight exposure with chemotherapy agents? Are there any specific precautions C.W. should take, or signs and symptoms of toxicity that she should know about?

The interactions between chemotherapy and radiation therapy or UV light (from both external beam and natural sources) can be divided into radiation enhancement or sensitization, radiation recall, photosensitivity reactions, and sunburn reactivation (Table 89-4). Several excellent reviews are available that describe each of these interactions in detail. A discussion of the important principles of the interaction between radiation therapy and chemotherapy follows.^{100–102}

A synergistic interaction between a small number of chemotherapy agents and radiation therapy results in an enhanced radiation effect. This may be caused by an agent's ability to interfere with radiation repair. Radiation therapy can alter the molecular structure of DNA, but excision repair allows cells to remove small, damaged portions of one strand of DNA and insert new bases using the other strand as a template. This repair mechanism requires several enzymes, including DNA polymerase. Chemotherapy agents can interfere with some of the enzymes and synthetic mechanisms needed to rejuvenate damaged cells. Although the synergistic effects of radiation therapy and chemotherapy are often exploited therapeutically for the treatment of solid tumors, these reactions can inadvertently cause undesirable reactions in non-neoplastic tissues, such as the skin, esophagus, lung, and GI tract. The skin is the most common target of radiation reactions. These reactions can produce severe tissue necrosis, which can compromise organ function and delay or mandate discontinuation of future treatment courses.

These reactions may be further classified as either *radiation sensitization* or *radiation recall* reactions. The primary distinction between radiation sensitization reactions and radiation recall reactions lies in the temporal relationship between radiation therapy and chemotherapy. Generally, sensitization reactions occur when chemotherapy is given concurrently or within 1 week of radiation therapy. In comparison, recall reactions occur several weeks to years after radiation therapy, when a chemotherapy agent causes an inflammatory reaction in tissues previously treated with radiation. Radiation recall is independent of previous, clinically apparent radiation damage. Not surprisingly, the chemotherapy agents that have been associated with radiation recall reactions are the same as those that cause radiation sensitization reactions. Agents most commonly associated with these reactions include the antitumor antibiotics dactinomycin, epirubicin, and doxorubicin; however, other agents, such as bleomycin, fluorouracil, capecitabine, hydroxyurea, methotrexate, etoposide, vinblastine, gemcitabine, oxaliplatin, and paclitaxel, also can cause radiation reactions. Chemotherapy may also interact with UV light to cause similar reactions.^{100–103}

Because UV light has sufficient energy to cause photochemical changes in biologic molecules, chemotherapy agents can interact with it. The subsequent reactions are usually less severe than reactions that occur with radiation therapy, and they may be caused by a different mechanism. Photosensitivity reactions, defined as enhanced erythema responses to UV light, have been reported with dacarbazine, fluorouracil, methotrexate, and vinblastine. Methotrexate can also reactivate sunburns, causing a similar, but less severe reaction compared with the radiation recall reactions described previously. The reaction can be more severe than the initial sunburn, resulting in severe blisters, and it usually occurs only in patients who receive large doses of methotrexate. Other agents cited infrequently to cause photoreactivation include paclitaxel, docetaxel, and gemcitabine. Although the precise incidences of photosensitivity reactions caused by chemotherapy agents are unknown, they may be more common than generally believed. For example, photosensitivity may account for many of the erythematous periodic rashes attributed to allergy.

C.W. received doxorubicin and fluorouracil, both of which can interact with radiation therapy. Although not commonly

Table 89-4 Chemotherapy and Radiation Reactions^{76,100,103}

| Radiation Enhancement Reactions | | |
|----------------------------------|--------------|--------------|

| Reactions With Ultraviolet Light | | |
| Phototoxic reactions | | |
| Dacarbazine | Thioguanine | Methotrexate |
| Fluorouracil | Vinblastine | Mitomycin |
| Reactivation of sunburn | | |
| Methotrexate | | |

reported, doxorubicin also can cause some increased erythema in the specific area of skin treated with radiation. Because C.W. may have an increased risk for a photosensitivity reaction, she should be advised to avoid direct exposure to the sunlight for several days to a week after chemotherapy. Although no data exist regarding the efficacy of sunscreens in this patient population, C.W. should be advised to use a protective sunscreen with a high sun protective factor (SPF) when she cannot avoid sun exposure. Furthermore, she should periodically assess her skin's reaction to the sun with intermittent periods of rest and observation throughout the day.

15. How will C.W. know if she has a radiation reaction? How should she be treated if such a reaction occurs?

If C.W. has a radiation reaction, she will experience “easy burning” and erythema or redness, followed by dry desquamation. With a more severe reaction, small blisters (vesicles) and oozing can develop. Necrosis with persistent painful ulceration can also occur in more severe cases. Postinflammatory hyperpigmentation or depigmentation may follow. The severity of the reaction can help determine the best treatment option.

Treatment options vary, depending on reaction severity. Milder cases can be treated with topical steroids in an emollient cream base and cool wet compresses. Necrosis and ulcers are notoriously difficult to treat, however, because radiated skin does not heal well. Ulcers are often treated with surgical débridement to keep the ulcer clean. Even when the ulcers are clean, exudation and bacterial contamination can be persistent. Radiation reactions that occur in tissues other than the skin (e.g., the lungs, esophagus, GI tract) often are treated with oral corticosteroids, although data regarding the efficacy of these agents in ameliorating the symptoms or reducing the extent of damage are lacking. If C.W. experiences any of these signs or symptoms, she should immediately seek medical attention.

Irritant and Vesicant Reactions

16. C.W. complained of pain and burning at the injection site immediately following the administration of her third course of IV chemotherapy with cyclophosphamide, doxorubicin, and fluorouracil. She described the sensation as being distinctly different from the mild discomfort she had experienced with previous chemotherapy. Physical examination of the injection site revealed mild erythema and slight induration. What types of local reactions can occur after the administration of chemotherapy?

Several distinct types of local reactions (ranging from transient local irritation to severe tissue necrosis of the skin, surrounding vasculature, and supporting structures) have been reported following chemotherapy^{104,105} (Table 89-5). Some of these reactions (particularly those associated with anthracyclines) may be caused by local hypersensitivity reactions. These reactions usually are characterized by immediate local burning, itching, and erythema. Some patients may also experience a “flare” reaction along the length of the vein used for treatment. Hypersensitivity reactions usually are self-limited and subside within a few hours. Administration of the antihistamine, diphenhydramine, before the next course of chemotherapy may reduce the severity or duration of hypersensitivity reactions.^{106,107} More severe reactions, including irritation of the vein (or phlebitis) caused by the irritant properties of an agent or a diluent, can occur following chemotherapy.

Table 89-5 Chemotherapeutic Drugs Reported to Produce Local Toxicities¹⁰³⁻¹⁰⁵

| Potential Vesicants | |
|---------------------|--------------|
| Dactinomycin | Epirubicin |
| Daunorubicin | Streptozocin |
| Doxorubicin | Vinblastine |
| Idarubicin | Vincristine |
| Mechlorethamine | Paclitaxel |
| Mitomycin | Oxaliplatin |
| Potential Irritants | |
| Carmustine | Etoposide |
| Cisplatin | Mitoxantrone |
| Dacarbazine | Melphalan |
| Vinorelbine | Vindesine |
| Cyclophosphamide | Teniposide |

Extravasation occurs when IV medications are accidentally administered into the surrounding tissue, either by leakage or by a needle puncturing the vein, causing direct exposure to surrounding tissues. Local reactions resulting from the extravasation of agents with vesicant or irritant properties may be more severe. All agents with vesicant properties potentially can produce these devastating reactions. Agents known to bind to DNA (i.e., the anthracyclines) have the propensity to produce the most severe damage. Treatment with a chemotherapy agent with these properties can produce phlebitis and pain, and extravasations can cause local irritation or soft tissue ulcers, depending on the agent, and the amount and concentration of the extravasated drug. In addition, no clear agreement exists regarding the vesicant potential of many chemotherapy agents, and various references may categorize agents differently based on their vesicant or irritant properties. Initially, it may be impossible to distinguish a local irritant reaction from a vesicant extravasation; therefore, if an agent with vesicant or irritant properties has been administered, the reaction should be treated as a potential extravasation.

Patients who experience an extravasation can show a range of different signs or symptoms. Infiltration of a vesicant into tissue often produces a severe burning sensation that may persist for hours. In some cases, however, no immediate symptoms or signs are evident. In the days to weeks that follow, the skin overlying the extravasation site may become reddened and firm. The redness may gradually diminish or progress to ulceration and necrosis.^{108,109}

17. What factors increase the risk of extravasation, and what administration techniques and precautions can minimize these risks?

Several factors have been associated with an increased risk of extravasation and subsequent tissue damage following administration of chemotherapy. Risk factors include (a) generalized vascular disease commonly found in elderly and debilitated patients or in patients who have undergone frequent venipuncture and treatment with irritating chemotherapy (the latter causes venous fragility and instability or decreased local blood flow); (b) elevated venous pressure, which typically occurs in patients with an obstructed superior vena cava or venous drainage after axillary dissection; (c) prior radiation therapy to

the injection site; (d) recent venipuncture in the same vein; and (e) use of injection sites over joints, which increases the risk of needle dislodgement.¹⁰⁵ In addition, tissue damage may be more severe if extravasation occurs in areas with only a small amount of subcutaneous tissue (e.g., the back of the hand or wrist) because wound healing is more difficult and exposure of deeper structures, such as the tendons, is increased.¹⁰⁷ These risks have led to the increased use of central catheters in patients receiving vesicant chemotherapy.

Extravasations of agents with vesicant properties can produce devastating tissue damage that can potentially cause loss of an extremity or death. To prevent significant morbidity or mortality, major emphasis must be placed on prevention. All caretakers who administer agents with vesicant or irritant properties should be skilled in IV drug administration and receive special instruction before administering these agents. The patient also must be told how agent administration should feel and to report immediately any change in sensation, including pain, burning, or itching. Recommendations to reduce the risk of local complications during cytotoxic agent administration are outlined in Table 89-6.

18. The oncology nurse believes that the doxorubicin may have extravasated during C.W.'s chemotherapy administration. How

Table 89-7 Suggested Procedures for Management of Suspected Extravasation of Vesicant Drugs¹⁰³⁻¹⁰⁵

1. Stop the injection immediately, but do not remove the needle. Any drug remaining in the tubing or needle, as well as the infiltrated area, should be aspirated.
2. Contact a physician as soon as possible.
3. If deemed appropriate, instill an antidote in the infiltrated areas (via the extravasated intravenous needle if possible).
4. Remove the needle.
5. Apply ice to the site and elevate the extremity for the first 24–48 hr (if vinca or podophyllotoxin, use warm compresses).
6. Document the drug, suspected volume extravasated, and the treatment in the patient's medical record.
7. Check the site frequently for 5–7 days.
8. Consult a surgeon familiar with extravasations early so that the surgeon can periodically review the site, and if ulceration begins, the surgeon can rapidly assess if surgical débridement or excision is necessary.

should this be managed? Do management guidelines differ for other vesicant agents?

Immediate management of a potential vesicant extravasation should include stopping the injection if the entire agent has not been administered. Various other recommended measures may minimize vesicant exposure and subsequent tissue damage (Table 89-7). These include application of cold compresses to the extravasation site and elevation of the extremity. Cold compresses have been shown to cause vasoconstriction, which can help to localize the extravasation and allow time for local vessels to displace the extravasated agent, whereas warm compresses are thought to induce vasodilation, increase drug distribution and absorption, and therefore decrease localized drug concentrations. Warm compresses are recommended for vinca alkaloids and epipodophyllotoxins.^{104,105} With the exception of these two classes of agents, cooling has been shown more effective than warm compresses. Specific antidotes thought to inactivate the extravasated agent have been suggested; however, many of these antidotes are based on observations in few patients or animal models, and their effectiveness, in many cases, is unsubstantiated. Antidotes recommended in some guidelines may actually worsen tissue damage (e.g., sodium bicarbonate for doxorubicin). Recommended treatments for suspected extravasation of vesicant agents are outlined in Table 89-8.^{104,105}

Because doxorubicin skin damage may be related to the formation of toxic free oxygen radicals, a free radical scavenger may prevent ulceration. Dimethylsulfoxide (DMSO) is a potent free radical scavenger that penetrates all tissue planes. In pig and rat models, topical DMSO has decreased doxorubicin-induced skin ulcers.¹¹⁰ Several series of case reports and a single-arm clinical study have reported that topical application of DMSO can safely and effectively manage an extravasation with an anthracycline.^{111–116} DMSO also has been reported to be beneficial in patients with mitomycin extravasations.¹¹⁵

Hypersensitivity Reactions

All cancer chemotherapy agents except altretamine, the nitrosureas, and dactinomycin, have produced at least an isolated instance of a hypersensitivity reaction.¹¹⁷ All types of hypersensitivity reactions can occur with chemotherapy agents,

Table 89-6 Guidelines for Administration of Cytotoxic Agents¹⁰³⁻¹⁰⁵

Administration of chemotherapy should be performed only by persons familiar with its toxic effects.

The site of infusion is selected with consideration of visualization of the vessel, its size, and potential damage if extravasation occurs in the following order of preference: forearm > dorsum of the hand > wrist > antecubital fossa.

- Limbs with compromised circulation (e.g., invading neoplasm, axillary dissection, severe bruising) should not be used.
- The lower extremities should not be used.
- Pre-existing IV lines should not be used because the site may already have occult vein or tissue irritation or phlebitis.

A 23- or 25-gauge scalp vein ("butterfly") needle is inserted into the vein. Only one venipuncture should be performed on a vein to avoid leakage. The wings of the needle should be lightly taped in place with care not to obscure the injection site so that it can be visualized during injection. Test the integrity of the IV line by injecting a small volume of saline solution and withdrawing a small amount of blood. If extravasation of the saline is obvious, select another vein or a site proximal on the same vein to avoid upstream leakage.

Administer the drug at the recommended rate (preferably through the tubing of an IV running by gravity to assess for back pressure).

During the administration, question the patient about discomfort, check for blood return by aspirating the syringe gently, observe the continuous flow of the running IV, and visualize the IV site frequently. If line patency is in doubt at any time, the injection should be stopped and an alternate site selected.

After administration, the IV line should be flushed with at least 10 mL of saline or other IV fluid to flush the needle and tubing of all drug. If multiple drugs are to be given, the IV should be flushed between each drug.

Apply pressure with sterile gauze for 3–4 minutes after the needle is removed. Inspect the site before applying a bandage.

IV, intravenous.

Table 89-8 Recommended Extravasation Antidotes¹⁰³⁻¹⁰⁵

| Class/Specific Agents | Local Antidote Recommended | Specific Procedure |
|---|-----------------------------------|--|
| Alkylating Agents Cisplatin ^a Oxaliplatin Mechlorethamine | 1/6 M solution sodium thiosulfate | Mix 4 mL 10% sodium thiosulfate USP with 6 mL of sterile water for injection, USP for a 1/6-M solution. Into site, inject 2 mL for each mg of mechlorethamine or 100 mg of cisplatin extravasated. |
| Mitomycin-C | Dimethylsulfoxide 99% (w/v) | Apply 1–2 mL to the site Q 6 hr for 14 days. Allow to air dry; do not cover. |
| Anthracyclines | Cold compresses | Apply immediately for 30–60 min for 1 day. |
| Doxorubicin | Dimethylsulfoxide 99% (w/v) | Apply 1–2 mL to the site Q 6 hr for 14 days. Allow to air dry; do not cover. |
| Daunorubicin | Dimethylsulfoxide 99% (w/v) | Apply 1–2 mL to the site Q 6 hr for 14 days. Allow to air dry; do not cover. |
| Vinca alkaloids | Warm compresses | Apply immediately for 30–60 min, then alternate off/on every 15 min for 1 day. |
| Vinblastine | Hyaluronidase | Inject 150 U into site. |
| Vincristine | Hyaluronidase | Inject 150 U into site. |
| Epipodophyllotoxins ^a | Warm compresses | Apply immediately for 30–60 min, then alternate off/on every 15 min for 1 day. |
| Etoposide | Hyaluronidase | Inject 150 U into site. |
| Teniposide | Hyaluronidase | Inject 150 U into site. |
| Taxanes | Cold compresses | Apply immediately for 30–60 min Q 6 hr for 1 day. |
| Docetaxel | Hyaluronidase | Inject 150 U into site. |
| Paclitaxel | Hyaluronidase | Inject 150 U into site. |

^aTreatment indicated only for large extravasations (e.g., doses one-half or more of the planned total dose for the course of therapy).
w/v, weight per volume.

although type I is the most common reaction documented following chemotherapy. Type I hypersensitivity reactions are immediate reactions that are most often immunologically mediated, although there are other possible mechanisms for type I hypersensitivities. Anaphylactic or IgE-mediated reactions occur when an antigen interacts with IgE bound to a mast cell membrane, causing degranulation of mast cells. Major signs and symptoms of type I reactions include urticaria, angioedema, rash, bronchospasm, abdominal cramping, and hypotension. Although many reactions associated with chemotherapy agents probably are immunologically mediated, other mechanisms may cause type I reactions. Other mechanisms include the degranulation of mast cells and basophils through a direct effect on the cell surface that releases histamine and other vasoactive substances. Activation of the alternative complement pathway also can release vasoactive substances from mast cells. When non-IgE-mediated mechanisms account for the symptoms of a type I reaction, it is called an *anaphylactoid reaction*.

Many of the type I hypersensitivity reactions produced by chemotherapy agents appear to be mediated by non-IgE mechanisms. Although little research has been conducted on the mechanism of these reactions, two features suggest that they are not mediated by IgE. First, many reactions occur during or immediately after administration of the first dose. This is in contrast to immunologic reactions that require prior exposure (i.e., one must be sensitized before becoming hypersensitized). In addition, certain symptoms or symptom complexes are more diagnostic of immunologically mediated disorders. These symptoms include urticaria, angioedema, bronchospasm, laryngeal spasm, cytopenias, arthritis, mucositis, vasculitic syndromes, and vesicular dermatitis. If not experiencing any of these symptoms after the first dose, the patient most likely did not experience an immunologically mediated hypersensitivity reaction.

Although the spectrum of symptoms and their severity vary widely in the case reports, most hypersensitivity reactions that occur with chemotherapy agents are classified as grade 1 (tran-

sient rash, mild) or grade 2 (mild bronchospasm, moderate) by the National Cancer Institute (NCI) Common Terminology Criteria for Adverse Events.¹¹⁸ Furthermore, a patient who has had a reaction to an agent that is not immunologically mediated safely can receive future courses of chemotherapy if he or she receives appropriate premedication. For example, appropriate premedication allows many (>60%) patients who have previously experienced a hypersensitivity reaction secondary to paclitaxel to continue therapy; this also reduces the incidence of hypersensitivity reactions associated with short duration infusions (i.e., 3 hours). (See Table 89-9 for NCI common toxicity criteria.)¹¹⁸ Other chemotherapy agents can commonly cause hypersensitivity reactions after the first and subsequent doses of chemotherapy.

The other types of hypersensitivity reactions are less commonly documented with chemotherapy administration. Type II is hemolytic anemia. Type III results from deposition of antigen-antibody complexes that form intravascularly and in tissues that can result in tissue injury. Sensitized T lymphocytes that react with antigens causing a release of lymphokines are responsible for type IV reactions.¹¹⁷ Chemotherapy agents most frequently reported to produce hypersensitivity reactions and their characteristic reactions are listed in Table 89-10. Most valuable information stems from patient series and case reports. However, they often providing conflicting and contradictory information, particularly with respect to incidence, severity, characteristic symptoms, time course, and the success of rechallenge. If a patient experiences a hypersensitivity reaction and the clinician decides to continue therapy with this regimen, a full review of all of the relevant literature as well as manufacturer's data is advised. Several excellent reviews are available to assist in this effort.^{103,117}

MONOCLONAL ANTIBODIES

19. S.R., a 58-year-old man with metastatic colorectal cancer, has progressed through four cycles of FOLFOX (oxaliplatin 85 mg/m² IV on day 1, leucovorin 100 mg/m² IV on days 1, 2, and

Table 89-9 National Cancer Institute Common Terminology Criteria for Adverse Events (CTCAE)¹¹⁸

| Diarrhea | Increase of <4 stools/day over baseline; mild increase in ostomy compared with baseline | Increase of 4–6 stools/day over baseline; IV fluids indicated <24 hr; moderate increase in ostomy output compared with baseline; not interfering with ADL | Increase >7 stools/day over baseline; incontinence; IV fluids >24 hr; hospitalization; severe increase in ostomy output compared with baseline; interfering with ADL | Life-threatening consequences (e.g., hemodynamic collapse) |

ADL, activities of daily living; IV, intravenous; LLN, lower limit of normal; PO, orally; TPN, total parenteral nutrition; WBC, white blood cell count.

fluorouracil 400 mg/m² IV bolus, followed by 600 mg/m² IV over 22 hours on days 1, 2) plus bevacizumab 10 mg/kg. He also progressed through two cycles of FOLFIRI (irinotecan 180 mg/m² on day 1, leucovorin 100 mg/m² IV on days 1, 2, and fluorouracil 400 mg/m² IV bolus, followed by 600 mg/m² IV over 22 hours on days 1, 2). S.R. now presents to the clinic for his first weekly dose of cetuximab (400 mg/m² IV load, followed by 250 mg/m² IV weekly). Discuss the toxicities that S.R. may expect and when they might appear. How should these side effects be managed? S.R. asks how these side effects can be prevented.

The most common toxicities observed in patients receiving cetuximab include rash, diarrhea, hypomagnesemia, headache, nausea, and hypersensitivity reactions. Infusion-related reactions occur in 15% to 20% of patients receiving their first infusion with severe hypersensitivity reactions (including allergic and anaphylactic reactions) occurring in 1% to 3% of patients. The reactions are related to the infusion of cetuximab and generally occur during or within 1 hour of completing the first dose. Patients should be premedicated with diphenhydramine before the infusion. The infusion can be stopped or the rate decreased if S.R. begins experiencing these effects. The skin rash and dry skin presenting after cetuximab administration is related to its mechanism of inhibiting EGFR and was the most common side effect seen in clinical trials. The rash occurred in ~80% of patients and appeared in the first 1 to 3 weeks of therapy. Grade 3 or 4 skin rashes occurred in 5% to 10% of patients.¹¹⁹

Several of the monoclonal antibodies (e.g., rituximab, trastuzumab, and cetuximab) can cause more hypersensitivity reactions than traditional chemotherapy agents. These agents are genetically engineered humanized monoclonal antibodies containing foreign proteins that can trigger the reaction. During the first infusion with trastuzumab, ~40% of patients experience a symptom complex, mild to moderate in severity, which consists of chills, fever, or both. These symptoms usually do not recur with subsequent injections.¹²⁰ In comparison, ~80% of patients receiving rituximab may experience an infusion-related reaction ranging from fever, chills, and rigors to severe reactions (7%) characterized by hypoxia, pulmonary infiltrates, adult respiratory distress syndrome, myocardial infarction, ventricular fibrillation, or cardiogenic shock with the first dose. Approximately 40% of patients receiving rituximab develop infusion-related reactions with subsequent infusions (5%–10% severe).¹²⁰ Treatment of these reactions follows the recommendations for treatment of hypersensitivity reactions that occur with more traditional agents.

Treatment

Recommended treatment of hypersensitivity reactions is reviewed in Table 89-11. If a patient develops a severe type I hypersensitivity reaction to any chemotherapy agent, the treatment should be stopped. If a structural analog or another agent in the same chemical class is an effective treatment for the same cancer, subsequent therapy should use the analog or

Table 89-10 Cancer Chemotherapeutic Agents Commonly Causing Hypersensitivity

| Drug | Frequency | Risk Factors | Manifestations | Mechanism | Comments |
|---------------------------------------|---|---|--|---|---|
| L-Asparaginase ^{117,282,283} | 10%–20% | Increasing doses; interval (weeks to months) between doses; IV administration; history of atopy or allergy; use without prednisone, 6-MP and/or vincristine | Pruritus, dyspnea, agitation, urticaria, angioedema, laryngeal spasm | Type I | Substitute PEG-L-asparaginase, but up to 32% may demonstrate mild hypersensitivity |
| Paclitaxel ^{121,284,285} | Up to 10% first or second dose | None known | Rashes, dyspnea, bronchospasm, hypotension | Nonspecific release of mediators; Cremophor | Premedicate with diphenhydramine, corticosteroids, and H ₂ -receptor antagonists Paclitaxel protein-bound particles (Abraxane) may be substituted and better tolerated in some patients Etoposide may be substituted in some cases; decrease rate of infusion Carboplatin may be substituted in some cases but cross-reactivity has been reported All patients rechallenged have prompt return of symptoms Cross-reactivity documented, but incidence and likelihood unknown Not technically classified as HSR; premedicate with acetaminophen and diphenhydramine |
| Teniposide ^{286–291} | 6%–40%; can occur with first dose | Increasing doses or number of doses; young age or leukemia | Dyspnea, wheezing, hypotension, rash, facial flushing | Type I versus nonspecific; Cremophor | |
| Cisplatin ^{292–297} | Up to 20% intravesicular 5%–10% systemic; case reports of hemolytic anemia | Increasing number of doses Anemia: none known | Rash, urticaria, bronchospasm Anemia: hemolytic anemia | Type I Anemia: type III | |
| Procarbazine ^{298–303} | Up to 15%; case reports | None known | Urticaria | Type I | |
| Anthracyclines ^{304–310} | 1%–15% depending on anthracycline | None known | Pneumonitis Dyspnea, bronchospasm, angioedema | Type III Unknown; nonspecific release | |
| Bleomycin ^{311–313} | Common | Lymphoma | Fever (up to 42°C), tachypnea | Endogenous pyrogen release | |
| Rituximab ³¹⁴ | First treatment 80%; subsequent treatments 40% | Female gender; pulmonary infiltrates, CLL or mantle cell lymphoma | Fevers, chills, occasional nausea, urticaria, fatigue, headache, pain, pruritis, bronchospasm, SOB, angioedema, rhinitis, vomiting, ↓ BP, flushing | Unknown; related to manufacturing process | Stop or ↓ infusion rate by 50%; provide supportive care with IV fluids, acetaminophen, diphenhydramine, vasopressors PRN |
| Trastuzumab ³¹⁵ | First treatment 40%; subsequent treatments rare | None known | Chills, fever, occasional nausea or vomiting; pain, rigors, headaches, dizziness, SOB, ↓ BP, rash, asthenia | Unknown, related to manufacturing process | Manage with acetaminophen, diphenhydramine, meperidine |
| Cetuximab ³¹⁶ | First treatment 1.5%–20%; Grade 3–4 3%; subsequent treatments uncommon | None known | Airway obstruction (bronchospasm, stridor, hoarseness), urticaria, hypotension, or cardiac arrest | | Premedicate with diphenhydramine; stop or decrease infusion rate; provide supportive care with epinephrine, corticosteroids, IV antihistamines, bronchodilators, and oxygen PRN |
| Alemtuzumab ³¹⁷ | ~90% with IV administration in first week | None known | Hypotension, rigors, fever, shortness of breath, bronchospasm, chills, rash | Unknown | Dose titration over several days; substitute with SC administration rather than IV; premedicate with acetaminophen, diphenhydramine, meperidine |
| Docetaxel ³¹⁸ | 0.9% with premedication | None known | ↓ BP, bronchospasm, rash, flushing, pruritus, SOB, pain, fever, chills | Unknown | Premedicate with acetaminophen, dexmethasone, and diphenhydramine |
| Doxorubicin ³¹⁹ liposomal | 6.8% | None known | Flushing, SOB, angioedema, HA, chills, ↓ BP | Unknown, related liposomal components | Stop infusion; restart at a lower rate |

Type I: antigen interaction with IgE bound to mast cell membrane causes degranulation. Drug binding to mast cell surface causes degranulation. Activation of classic or alternative complement pathways produces anaphylatoxins. Neurogenic release of vasoactive substances. Type III: antigen-antibody complexes form intravascularly and deposit in or on tissues.
BP, blood pressure; CLL, chronic lymphocytic leukemia; HA, headache; HSR, hypersensitivity reaction; IV, intravenous; 6-MP, 6-mercaptopurine; PEG-L-asparaginase, pegaspargase; PRN, as needed; SC, subcutaneous; SOB, shortness of breath.

Table 89-11 Prophylaxis and Treatment of Hypersensitivity Reactions From Antitumor Drugs**Prophylaxis**

IV access must be established.
 BP monitoring must be available.
 Premedication
 Dexamethasone 20 mg PO and diphenhydramine 50 mg PO 12 and 6 hr before treatment, then the same dose IV immediately before treatment
 Consider addition of H₂-antagonist with similar schedule
 Have epinephrine and diphenhydramine readily available for use in case of a reaction.
 Observe the patient up to 2 hr after discontinuing treatment.

Treatment

Discontinue the drug (immediately if being administered IV).
 Administer epinephrine 0.35–0.5 mL IV Q 15–20 min until reaction subsides or a total of 6 doses are administered.
 Administer diphenhydramine 50 mg IV.
 If hypotension is present that does not respond to epinephrine, administer IV fluids.
 If wheezing is present that does not respond to epinephrine, administer nebulized albuterol solution 0.35 mL.
 Although corticosteroids have no effect on the initial reaction, they can block late allergic symptoms. Thus, administer methylprednisolone 125 mg (or its equivalent) IV to prevent recurrent allergic manifestations.

BP, blood pressure; IV, intravenous; PO, orally.

other agent to minimize the risk of future reactions. If the reaction is mild or moderate, the patient may continue with the same chemotherapy if treatment is preceded by methods to prevent or minimize hypersensitivity reactions. General recommendations for preventing anaphylactoid reactions are found in Table 89-10. Pretreatment with prednisone and diphenhydramine significantly decreases the frequency and severity of anaphylactoid reactions; however, the effect of H₂-receptor antagonists and epinephrine remains controversial. Because the success of these preventive measures depends on the cause of the reaction (immunologic or anaphylactoid), the aforementioned characteristics of type I reactions should be used to assess the underlying pathogenesis. In addition, other chemicals present in the formulation or other agents administered concomitantly with the chemotherapy can cause the hypersensitivity reaction. Potential allergens included in the diluent or formulation of chemotherapy agents include Cremophor EL (present in paclitaxel and teniposide), polysorbate 80 (present in docetaxel), and benzyl alcohol (present in the parenteral form of methotrexate and cytarabine). Recognizing potential allergens can significantly affect treatment of the current reaction and minimize the risk of future reactions.

PACLITAXEL PROTEIN-BOUND PARTICLES

To reduce the hypersensitivity reactions observed with paclitaxel, a new formulation has been produced, paclitaxel protein-bound particles (Abraxane), which is an albumin-bound form of paclitaxel. Because paclitaxel protein-bound particles formulation is Cremophor EL-free and less likely to cause hypersensitivity than traditional paclitaxel, it is not necessary to premedicate patients with steroids and antihis-

tamines. The albumin-bound formulation is approved for patients with metastatic breast cancer after failure of a previous regimen containing an anthracycline. Doses between the two agents are not comparable; the recommended dose of paclitaxel protein-bound particles is 260 mg/m² every 21 days for six cycles. Although fewer hypersensitivity reactions are associated with this formulation, myelosuppression remains a dose-limiting toxicity.¹²¹

SPECIFIC ORGAN TOXICITIES**Neurotoxicity****Cytarabine and L-Asparaginase**

20. A.L., a 39-year-old woman with acute lymphoblastic leukemia, has been admitted to the hospital for induction chemotherapy. Cytarabine 5 g IV Q 12 hr for eight doses, vincristine 2 mg IV push weekly, prednisone 100 mg/day, L-asparaginase 15,000 U/day for 14 days, and allopurinol 300 mg/day are ordered. Laboratory data obtained on admission include a WBC count of 120,000 cells/mm³ (normal, 3,200–9,800), with 9% neutrophils (normal, 54%–62%), 11% lymphocytes (normal, 25%–33%), and 80% blasts and a uric acid of 7.5 mg/dL (normal, 2–7). On day 3, A.L. is confused and she has difficulty performing a finger-to-nose neurologic examination. After 3 weeks, she complains of numbness in her hands and feet. In addition, the clinician notes an eyelid lag and ataxia. A.L. also complains of severe constipation. What is the possible cause of A.L.'s mental status? Should chemotherapy be continued?

[SI unit: uric acid, 446 mmol/L]

High dosages of cytarabine (>1 g/m² in multiple doses) are associated with CNS toxicity in 15% to 37% of patients.^{122, 123} These neurotoxicities are dose and schedule related. Doses >18 g/m² per course increase the frequency of neurotoxicity. Older patients are more susceptible than younger patients, and the prevalence seems higher in subsequent versus initial courses of therapy. As illustrated by A.L., neurotoxicity may become evident within a few days after treatment with cytarabine and, most commonly, the neurotoxicity is manifested by a generalized encephalopathy with symptoms such as confusion, obtundation, seizures, and coma. Cerebellar dysfunction, presenting as ataxia, gait and coordination difficulties, dysmetria (inability to arrest muscular movement when desired and lack of harmonious action between muscles when executing voluntary movement), also is commonly observed in patients receiving high-dose cytarabine therapy. These neurologic symptoms may partially resolve over days to weeks after discontinuation of therapy. Other neurologic toxicities reported with cytarabine include progressive leukoencephalopathy and chemical meningitis. Leukoencephalopathy typically presents with progressive personality and intellectual decline; dementia; hemiparesis; and, sometimes, seizures. Chemical meningitis can occur with intrathecal administration of cytarabine (see Chapter 90, Hematologic Malignancies). These neurotoxicities also can occur following treatment with other chemotherapy agents, including L-asparaginase.

L-Asparaginase often causes encephalopathy, which presents most commonly as lethargy and confusion.¹²⁴ Severe cerebral dysfunction occurs occasionally, and patients may

present with stupor, coma, excessive somnolence, disorientation, hallucination, or severe depression. Symptoms can occur early (within days of administration of L-asparaginase) or late, depending on the treatment schedule.¹²⁵ The acute syndrome usually clears rapidly, but the delayed syndrome can last several weeks.

A.L.'s symptoms most likely are the result of CNS toxicity caused by both cytarabine and L-asparaginase. A decision regarding further treatment with these agents is complicated because decreasing the dose of cytarabine or L-asparaginase could compromise the likelihood of a complete remission. Although L-asparaginase-induced CNS neurotoxicities are usually reversible, high-dose cytarabine cerebellar toxicity may not be. Therefore, the clinician may decide to continue treating A.L. with modified doses.

Other Agents

21. What other chemotherapy agents produce CNS toxicity?

Other agents that produce CNS toxicities include methotrexate, fluorouracil, interferon- α , interleukin-2, fludarabine, altretamine, carmustine, procarbazine, ifosfamide, oxaliplatin,

and nelarabine (Table 89-12). Recognition of neurotoxicity resulting from chemotherapy is often difficult because of comorbid conditions such as metastatic disease and other paraneoplastic syndromes, but it is important in assessing the need for potential dose modifications or even discontinuation of the agent. Several reviews provide detailed explanations of signs and symptoms, mechanisms, and potential treatments for chemotherapy-induced neurotoxicities.^{125,126}

METHOTREXATE

Methotrexate causes little or no neurotoxicity when administered orally or intravenously in the usual doses; however, high-dose IV methotrexate (usually $>1 \text{ g/m}^2$) can occasionally cause acute encephalopathy. Similar to that caused by other agents, the encephalopathy that occurs following therapy with methotrexate is usually transient and reversible. Other patients may develop a progressive leukoencephalopathy following high-dose IV methotrexate. The risk of leukoencephalopathy increases with higher cumulative doses of methotrexate and concomitant cranial radiation therapy.^{127–129} As with intrathecal cytarabine, intrathecal methotrexate can cause a chemical

meningitis and, less commonly, myelopathy or paraplegia. Patients receiving intrathecal therapy or high-dose methotrexate should be carefully monitored for signs and symptoms associated with neurotoxicity.

FLUOROURACIL

Fluorouracil can cause acute cerebellar dysfunction characterized by the rapid onset of gait ataxia, limb incoordination, dysarthria, and nystagmus.^{130,131} Cerebellar dysfunction occurs in approximately 5% to 10% of patients receiving fluorouracil at all treatment schedules in common use and can present weeks to months after beginning therapy. A more diffuse encephalopathy presenting as headache, confusion, disorientation, lethargy, and seizures can also occur. These symptoms can be reversed if fluorouracil is discontinued or the dose is reduced. Other neurotoxicities observed with fluorouracil include rare reports of optic neuropathy and decreased vision. As with methotrexate, patients should be carefully monitored for signs and symptoms associated with neurotoxicity.

INTERFERON- α

Interferon- α can cause a neurologic complex characterized by headache and encephalopathy (weakness, confusion, lethargy). The symptoms occur in one-third of patients receiving interferon and can cause severe reactions in 10%. Severe reactions include coma, obtundation, major depression, and suicidal behavior. Elderly patients receiving high dosages may be more susceptible to these effects. Symptoms typically begin after several weeks of therapy and usually resolve within 3 weeks after dose attenuation or discontinuation of therapy. If further treatment is warranted, lower doses should be used.¹³²

FLUDARABINE AND OTHER PURINE ANALOGS

Fludarabine can cause severe neurotoxicity when used at doses >90 mg/m² for 5 to 7 days.^{133–135} Symptoms include altered mental status, photophobia, amaurosis (blindness that usually is temporary without change in the eye itself), generalized seizures, spastic or flaccid paralysis, quadriparesis, and coma. Some patients die even when therapy is discontinued. This neurotoxicity, however, is not usual with the current recommended dosage of 25 mg/m²/day for 5 days. Mild neurologic symptoms are typically reported, but severe neurotoxicity^{135,136} and optic demyelination can occur occasionally.¹³⁷ Patients with signs or symptoms suggestive of significant neurotoxicity should receive a neurologic examination and, if warranted, therapy should be discontinued. Nelarabine has dose-limiting neurotoxicity reported in ~64% of patients treated in phase I and II clinical trials. Clinical presentation includes severe somnolence, convulsions, and peripheral neuropathy ranging from paresthesias to motor weakness. Several cases of ascending peripheral neuropathies and demyelination have been reported. Therapy should be stopped if grade 2 toxicity is present because some cases have been irreversible.¹³⁸

CARMUSTINE AND OTHER AGENTS

Carmustine and other alkylating agents cause little or no neurotoxicity in the usual IV doses, but higher dosages can increase the incidence of these adverse effects. Carmustine produces encephalopathy associated with confusion or seizures with a dose >600 to 800 mg/m².¹³⁹ Concurrent cranial radio-

therapy and intracarotid administration may increase the risk of neurotoxicity.^{140,141} Other agents reported to produce CNS toxicity include ifosfamide,^{142,143} procarbazine,¹⁴⁴ altretamine,¹⁴⁵ and cisplatin.^{146–149} These agents have been associated with encephalopathy that manifests as confusion, lethargy and, in some instances, psychosis and depression. When a patient presents with any signs or symptoms of neurotoxicity, that patient should receive a neurologic examination followed by a dose reduction or discontinuation of therapy. Ifosfamide is associated with an encephalopathy thought to result from one of its metabolites, chloroacetaldehyde. The incidence ranges from 10% to 20%; it presents hours to days after initiation of treatment with confusion and disorientation and is generally self-limiting. Methylene blue has been used for both prevention and treatment. Risk factors for this complication include a history of ifosfamide-induced encephalopathy, renal dysfunction, low serum albumin, and abdominal disease.^{150,151}

Peripheral Nerve Toxicity

22. What is causing A.L.'s numbness?

Paresthesia (numbness and tingling) involving the feet and hands (or both) is an early subjective symptom of vincristine neurotoxicity, which often appears within the first few weeks of therapy. This peripheral nerve toxicity commonly is bilateral and symmetric and is often referred to as a “stocking-glove” neuropathy. Symptoms initially consist of paresthesias, loss of ankle jerks, and depression of deep tendon reflexes. Areflexia (absent reflexes) typically occurs in about 50% to 70% of patients treated with a cumulative dose >6 to 8 mg. Although older patients appear to be more susceptible to paresthesias than younger ones, almost all complain of paresthesias following combination chemotherapy that incorporates vincristine or vinblastine. Pain and temperature sensory loss is usually more pronounced than vibration and proprioception sensory loss. Patients also may display motor weakness with a foot drop or muscle atrophy. Motor weakness, which can become the most disabling symptom associated with vincristine neurotoxicity, can occasionally cause muscle wasting. Although some patients develop muscle atrophy, true muscle weakness seldom occurs after treatment with vincristine. Stumbling and falling that can occur with this peripheral neuropathy is not usually caused by muscle weakness; instead, it occurs in the dark when patients lose proprioception because they lack visual orientation. These complications are either partially or completely reversible, but recovery often takes several months.^{152,153}

23. What other agents may cause similar complaints of numbness?

Other agents that often share the peripheral nerve toxicity of vincristine include vinblastine, vinorelbine, cisplatin, etoposide, oxaliplatin, paclitaxel, docetaxel, bortezomib, thalidomide, and lenalidomide. Other agents causing peripheral nerve toxicity include those commonly associated with CNS toxicity. Unlike the vinca alkaloids, most of these agents cause numbness only and not a loss of reflexes, paresthesias, or weakness. These side effects generally are not dose limiting and are usually reversible. Several reviews provide detailed references for this information.^{154,155}

Oxaliplatin causes peripheral neuropathies that differ from those associated with the use of cisplatin. Oxaliplatin-induced

neurotoxicity manifests as an acute neurosensory complex as well as a cumulative sensory neuropathy. Hyperexcitability of peripheral nerves causes an 85% to 95% incidence of paresthesia and dyesthesias of the hands, feet, and the perioral region. Laryngeal dyesthesias have been described as well. These effects are precipitated by exposure to cold. The cumulative dose-limiting chronic neuropathy is described as a sensory neuropathy that is reversible several months after completion of therapy. Dose modifications for patients with persistent neurotoxicities have been developed and include delaying therapy until their condition improves.^{156,157} Prevention of these reactions with infusions of magnesium and calcium were evaluated in a retrospective study of patients ($N = 161$) with advanced colorectal cancer receiving regimens of oxaliplatin, fluorouracil, and leucovorin. Calcium gluconate 1 g IV and magnesium sulfate 1 g IV 15 minutes before and immediately after completion of the oxaliplatin administration led to fewer patient withdrawals because of toxicity (4% vs. 31%, respectively). Relative to the control group, fewer treated patients developed distal paresthesias (7% vs. 26%, respectively) and less acute distal and lingual paresthesias. Additionally, no patients in the calcium–magnesium group demonstrated pseudolaryngospasm. Those in the calcium–magnesium group were less likely to develop chronic grade 2 and 3 neuropathy at the end of treatment (20% vs. 45%, respectively). Importantly, calcium and magnesium infusions have not been shown to decrease efficacy.¹⁵⁸ Consequently, calcium and magnesium infusions are given routinely with oxaliplatin administration.

Cranial Nerve Toxicity

24. What is the significance of A.L.'s lid lag?

Cranial nerve toxicity occurs in 1% to 10% of patients receiving vinca alkaloids, and most patients present with ptosis or ophthalmoplegia,^{153,159} probably related to damage to the third cranial nerve. Toxicity to other cranial nerves can cause trigeminal neuralgia, facial palsy, depressed corneal reflexes, and vocal cord paralysis.¹⁶⁰ Other nerve toxicities associated with the vinca alkaloids include jaw pain, which can occur after the first or second injection¹⁶⁰; the pain usually resolves spontaneously and does not recur with subsequent doses. Several of the cranial nerve toxicities, especially with vincristine, may be dose limiting because evidence shows an increased prevalence with increasing doses. A.L.'s eyelid lag probably is caused by vincristine.

25. Do other chemotherapy agents produce cranial nerve toxicity?

Ifosfamide, vinblastine, and cisplatin have been reported to cause cranial neuropathies. Intra-arterial administration of chemotherapy agents such as carmustine may increase the risk of encephalopathy and cranial neuropathies.

Ototoxicity, characterized by a progressive, high-frequency, sensorineural hearing loss, commonly occurs with cisplatin,^{161,162} most likely as a result of a direct toxic effect on the cochlea. Ototoxicity occurs more frequently at higher dosages, worsens with concurrent cranial radiation therapy, and appears to be more pronounced in children. The reversibility of cisplatin ototoxicity is questionable. At some centers, routine audiometric tests are performed in patients receiving cisplatin; as a result, these centers have a greater percentage of

patients with documented decreases in audio acuity than others. Early cessation of cisplatin may result in greater hearing improvement. Although ototoxicity appears to be a major toxicity associated with cisplatin, it is not commonly caused by other platinum analogs. For example, only 8 of 710 (1.1%) patients who received carboplatin experienced clinical hearing deficits, mainly tinnitus.¹⁶³ If ototoxicity is suspected, a hearing test should be performed and therapy discontinued if alternate treatments are available.

Autonomic Neuropathy

26. What is the cause of A.L.'s constipation, and how might this problem have been prevented?

Vincristine, as well as vinblastine, commonly causes an autonomic neuropathy. The earliest symptoms (colicky abdominal pain with or without constipation) are reported by one-third to one-half of patients receiving these agents.^{153,159} Because severe constipation can progress to or include adynamic ileus, prophylactic laxatives are recommended on a regular basis for patients receiving vincristine and vinblastine. Stimulant laxatives such as the senna derivatives or bisacodyl are believed to be the most effective agents, and stool softeners also may be used concurrently. No compelling evidence suggests, however, that laxatives prevent constipation. Other less-frequent manifestations of autonomic dysfunction associated with vinca alkaloids include bladder atony with urinary retention, impotence, and orthostatic hypotension.^{164,165} Patients should be monitored carefully for these signs or symptoms and receive appropriate management following diagnosis.

Cardiac Toxicities

Doxorubicin

27. D.A., a 35-year-old man with stage IV Hodgkin's disease, is receiving CHOP (cyclophosphamide 750 mg/m² IV day 1, doxorubicin 50 mg/m² IV day 1, vincristine 2 mg IV day 1, and prednisone 100 mg PO days 1–5) and concurrent radiation therapy to a large mediastinal mass. He comes to the clinic to receive his fifth cycle of CHOP and complains of tachycardia, shortness of breath (SOB), and a nonproductive cough. Physical examination reveals neck vein distention, pulmonary rales, and ankle edema. What is the most likely cause of D.A.'s current symptoms?

D.A. is experiencing symptoms of congestive heart failure (CHF) most likely caused by doxorubicin therapy. Doxorubicin, an anthracycline antibiotic, can cause a dose-dependent cardiomyopathy that generally occurs with repeated administration. Doxorubicin causes myocyte damage by a mechanism that differs from its cytotoxic effect on tumor cells. Because myocytes stop dividing in infancy, they presumably would not be affected by an agent whose cytotoxicity relies on actively cycling cells. Many mechanisms have been proposed to explain the cardiac toxicity associated with doxorubicin.^{166,167} The association of anthracycline-induced cardiotoxicity with other agents administered concomitantly, monitoring techniques, and therapies to prevent and treat this condition have been reviewed.¹⁶⁸

D.A.'s presentation is fairly typical of doxorubicin-induced cardiomyopathy, although he has no significant risk factors usually associated with CHF. The total cumulative dose of

doxorubicin is the most clearly established risk factor for the CHF.^{166,167,169} Patients, such as D.A., who are receiving bolus doses of doxorubicin at the standard 3-week interval face little risk of CHF until a total dose of 450 mg/m² to 550 mg/m² has been reached. After a patient has received a total dose >550 mg/m², the risk of CHF rises rapidly. Patients receiving <550 mg/m² of doxorubicin face a 0.1% to 1.2% risk of developing CHF. Comparatively, patients receiving >550 mg/m² face a risk that rises more or less linearly; the probability of CHF in patients receiving a total dose of 1,000/m² may be nearly 50%.¹⁶⁹

Other factors that could increase D.A.'s risk of developing doxorubicin cardiomyopathy include mediastinal radiation therapy, pre-existing cardiac disease, hypertension, and age. Young children, as well as older patients, are likely to experience CHF at a lower cumulative dose. Concurrent chemotherapy agents (e.g., cyclophosphamide, etoposide, mitomycin, melphalan, trastuzumab, paclitaxel, vincristine, bleomycin) may also potentiate doxorubicin cardiac toxicity.¹⁶⁸ When patients receive paclitaxel and doxorubicin, the risk of cardiac toxicity appears to be related to the sequence and proximity of the infusions. In a pharmacokinetic study, paclitaxel increased the AUC of doxorubicin and its active metabolite, doxorubicinol, when paclitaxel administration immediately preceded doxorubicin. Therefore, doxorubicin should be given at least 30 minutes before paclitaxel. The relationship between risk factors and the total cumulative dose of doxorubicin is sufficiently strong to warrant guidelines restricting the total cumulative dose of doxorubicin to 450 mg/m² in patients with one or more identified risk factors (high-risk patients) and to 550 mg/m² in patients without risk factors (low-risk patients).

It is unusual that D.A., a 35-year-old man who has received a cumulative dose of only 200 mg/m² of doxorubicin, would be presenting with symptoms of CHF. Mediastinal radiation therapy, cyclophosphamide, or undiagnosed cardiac disease may, however, have contributed to this event. In addition, Hodgkin's disease involving the myocardium may be responsible for this presentation.

28. Is routine cardiac monitoring recommended in patients receiving doxorubicin?

Prevention of cardiomyopathy is achieved primarily by limiting the total cumulative dose. Limiting the total dose, however, cannot entirely prevent the cardiomyopathy for two reasons. First, individual tolerance to doxorubicin varies such that cardiotoxicity may occur before the arbitrary dose limit; second, some clinical situations warrant exceeding the dose limit to achieve positive chemotherapeutic outcomes.

Early efforts to prevent cardiomyopathy focused on monitoring systolic time intervals, QRS voltage loss, or ST-T segment changes on an electrocardiogram (ECG). These changes were too nonspecific or occurred too late to be useful, however; serial echocardiography has some usefulness in children.^{170,171} Other current state-of-the-art monitoring for anthracycline cardiomyopathy includes radionuclide ventriculography (RNV) and endomyocardial biopsy. The use of radionuclide ventriculography (also referred to as radionuclide cardiac angiography; gated blood pool imaging; multiple gated acquisition [MUGA]) for early detection of doxorubicin-induced cardiac dysfunction has been investigated extensively.¹⁷² RNV can ac-

curately detect functional cardiac status, but it is not particularly sensitive in detecting patients who have early myocyte damage. Augmenting the RNV with exercise appears to give a more accurate picture of functional cardiac reserve. Because myocyte damage usually occurs days to weeks after treatment with doxorubicin, the RNV should be obtained just before, rather than just after, a course of the agent. Although guidelines vary, most institutions recommend obtaining an RNV before starting therapy with doxorubicin. Additional RNV should be obtained when a patient shows signs or symptoms of CHF or when low-risk patients receive cumulative doses >450 mg/m² or high-risk patients receive >350 mg/m², if additional doses are planned. Most guidelines recommend stopping doxorubicin or obtaining an endomyocardial biopsy when there is an absolute decrease in the RNV >10% to 20%, the RNV is <40%, or the RNV fails to increase >5% with exercise. The ASCO currently recommends frequent cardiac monitoring after doses >400 mg/m².⁴⁹ The study should be repeated after patients receive >500 mg/m² and with every additional dose of 50 mg/m². The guidelines published by ASCO support the recommendations to discontinue therapy when patients show clinical signs or symptoms of CHF or if the left ventricular ejection fraction decreases below institutional normal limits.⁴⁹

Endomyocardial biopsies, along with a quantitative assessment of morphologic changes, provide the most specific evaluation of myocardial damage induced by anthracyclines. Progressive myocardial pathology is graded on a scale (the Billingham Score) of 0 (no change from normal) to 3 (diffuse cell damage in >35% of total number of cells with marked change in cardiac ultrastructure).¹⁷³ The prevalence of abnormal RNV and the appearance of signs and symptoms of CHF correlate with biopsy scores. Usually, a significant change in cardiac function is not seen with scores <2 to 2.5. Several investigators have evaluated the predictive value of this technique. With a score of 2, a patient has less than a 10% chance of developing heart failure if 100 mg more of doxorubicin is given.¹⁷⁴⁻¹⁷⁶ There are occasional false-negative biopsy findings, and fatal CHF has been encountered in at least one patient with a relatively normal (1.0) biopsy score.¹⁷⁷ The most significant risk associated with endomyocardial biopsy is perforation of the right ventricle with associated tamponade; this occurs rarely and depends largely on the experience of the operator.

In summary, RNV and endomyocardial biopsy are complementary procedures that when used together with clinical evaluation can provide a degree of confidence in predicting tolerance to additional doxorubicin dosing. The endomyocardial biopsy provides a distinct advantage by allowing early myocyte damage to be appreciated before the RNV changes or the patient shows signs or symptoms of CHF.

Other Agents

29. How do the other members of the anthracycline class compare with doxorubicin in terms of cardiotoxicity and clinical usefulness?

DAUNORUBICIN

Daunorubicin differs structurally from doxorubicin only by hydroxylation of the fourteenth carbon. Unlike doxorubicin, daunorubicin is primarily used to treat hematologic malignancies, such as acute myeloid leukemia. During its initial clinical

evaluations, clinicians lacked a good understanding of this drug's dose-schedule-relationship to toxicity, and it became known on some hospital wards as "the red death." Doxorubicin became favored to treat solid tumors because daunorubicin caused excessive mucositis and myelosuppression when patients received antileukemic dosages to treat these tumors. Since then, clinical trials have given clinicians a better understanding of daunorubicin's side effects and how to provide better supportive care. Daunorubicin safely produces clinical responses in patients with Hodgkin's disease, non-Hodgkin's lymphomas (NHL), melanoma, sarcomas, lung carcinomas, breast carcinomas, and GI tract carcinomas.¹⁷⁸ In randomized trials comparing daunorubicin and doxorubicin, daunorubicin caused less mucositis and a lower incidence of colonic damage and perforation.¹⁷⁹ Cardiac toxicities are similar for both drugs, however, although somewhat higher cumulative doses of daunorubicin are typically tolerated.¹⁸⁰ Risk factors for CHF appear to be the same, and similar assessments should be undertaken to monitor for cardiotoxicity.

IDARUBICIN

Idarubicin is an anthracycline that is approved for the treatment of acute leukemias. Although idarubicin appears less cardiotoxic than doxorubicin in animal models¹⁸¹ and daunorubicin in some early clinical trials,^{182–184} other studies show equivalent myelosuppressive doses can cause cardiotoxicity comparable to that of doxorubicin and daunorubicin.^{185,186} Until additional studies adequately define the cumulative dose associated with cardiotoxicity, patients receiving idarubicin should be routinely monitored for signs and symptoms of CHF.

EPIRUBICIN

Epirubicin is another anthracycline approved by the FDA for adjuvant therapy of breast cancer after surgical resection. As with the other anthracyclines, epirubicin can cause a dose-dependent, potentially fatal CHF. CHF occurs in 1.6% of patients receiving 700 mg/m² and in 3.3% of patients receiving 900 mg/m². Risk factors for cardiotoxicity include a history of cardiovascular disease, prior or concomitant radiation therapy to the mediastinum or pericardium, previous therapy with other anthracyclines or mitoxantrone, or concomitant use of other cardiotoxic medications. Cumulative doses should not exceed 900 mg/m², which may result in toxicity.¹⁸⁷ Patients receiving epirubicin should receive cardiac monitoring with continued therapy to minimize the risk of severe CHF.

MITOXANTRONE

Mitoxantrone is an anthracenedione that is structurally similar to the anthracyclines. Mitoxantrone is typically one-fifth the dose of doxorubicin or 12 to 14 mg/m² every 3 weeks. The important risk factors for mitoxantrone cardiotoxicity include a history of mediastinal radiation, cardiovascular disease, and anthracycline exposure. Predicting mitoxantrone cardiotoxicity is similar to that of doxorubicin and daunorubicin. In patients without risk factors, the risk for cardiotoxicity does not begin to rise significantly until patients receive about 160 mg/m². This dose is equivalent to about 800 mg/m² of doxorubicin. For patients who previously received doxorubicin (mean cumulative dose, 239 mg/m²), the risk starts to rise when the cumulative mitoxantrone dose reaches about 100 mg/m².^{188–190} The guidelines suggested for monitoring doxorubicin-induced

cardiotoxicity should be followed with mitoxantrone therapy to minimize the risk for CHF.

Prevention

30. Can CHF be prevented by the use of a different dose or dosing schedule or by agents that protect the myocardium?

Altering the dose schedule of doxorubicin to more frequent, smaller doses while maintaining dose intensity has consistently resulted in reduction of cardiotoxicity without obvious compromise of antitumor effects.^{191–196} Several reports suggest that peak plasma levels, as well as cumulative dose, have an important relationship to doxorubicin cardiotoxicity. Low doses of doxorubicin administered weekly or prolonged continuous IV infusions (48–96 hours) can be relatively cardiac sparing, allowing higher cumulative doses to be administered. In a retrospective, uncontrolled study of 1,000 patients receiving weekly doxorubicin, a total dose of 900 to 1,200 mg/m² of doxorubicin given in weekly fractions had the equivalent cardiotoxicity of 550 mg/m² given in every-3-week fractions.¹⁹² Although well-designed studies comparing cardiac toxicity following bolus doses with fractionated therapy or continuous infusion are lacking, treatment that incorporates these alternative schedules should be considered in patients with pre-existing risk factors or patients who will be receiving total doses of >450 to 550 mg/m². The concurrent use of drugs that might minimize the risk of cardiotoxicity without compromising efficacy can be considered as well.

Dexrazoxane is a chemoprotectant that reduces the incidence and severity of cardiomyopathy. It is indicated in women with metastatic breast cancer who have received a cumulative doxorubicin dose of 300 mg/m². The recommended dosing ratio of dexrazoxane:doxorubicin is 10:1 slow IV push 30 minutes before starting doxorubicin. Currently, the ASCO guidelines do not support the routine use of dexrazoxane in patients unless a plan exists to continue doxorubicin beyond a total cumulative dose >300 mg/m². Clinical trials are evaluating the benefits of dexrazoxane in children and patients receiving other anthracyclines. Some evidence supports the use of dexrazoxane in patients receiving epirubicin.¹⁹⁷

Another approach to protecting against doxorubicin cardiotoxicity focuses on delivering anthracycline encapsulated in liposomes. A phase III trial of women (*N* = 509) with metastatic breast cancer showed that efficacy with liposomal pegylated doxorubicin may be similar to conventional doxorubicin with decreased cardiotoxicity.¹⁹⁸ More data are needed in adjuvant settings. Additionally, the equivalent dose of liposomal preparations to conventional doxorubicin is not confirmed.

Management

31. How should doxorubicin- or other anthracycline-induced CHF be managed clinically?

Anthracycline-induced CHF presents similarly to other forms of biventricular CHF and occurs between 0 to 231 days after the last dose of doxorubicin (mean, 33 days). Anthracycline-induced CHF should be treated with diuretics, activity restriction, inotropic agents, and vasodilators, but these measures often are ineffective. The clinical course varies, with some patients showing stable disease and others showing

improvement. Before cardiotoxicity was a widely recognized toxicity, the course of anthracycline-induced CHF was characterized by a rapid progression that generally led to death in a few weeks. The clinical outcome is better now, perhaps because anthracycline therapy is promptly discontinued after initial presentation and there are better treatments for CHF. These include the use of spironolactone, beta blockers, and angiotensin-converting enzyme (ACE) inhibitors, which have decreased morbidity and mortality in non-anthracycline-induced CHF. Enalapril was evaluated to determine if it would prevent cardiac function decline in a randomized, double-blind, placebo-controlled study of pediatric cancer patients who were at least 2 years out from treatment with anthracyclines and had evidence of CHF. Patients received enalapril at 0.05 mg/kg/day and this dose was progressively escalated to 0.10 mg/kg/day, and finally 0.15 mg/kg/day if there were no side effects. Although enalapril did not increase exercise intolerance, it did increase left ventricular end-systolic wall stress (LVESWS) in the first year of treatment. Side effects included dizziness, hypotension, and fatigue. The follow-up to the study was ~3 years, so the long-term benefits of enalapril are not known.¹⁹⁹

Other Cardiac Toxicities

32. What other chemotherapy agents have been associated with cardiac toxicities?

Electrocardiographic changes have been observed during or after treatment with doxorubicin, other anthracyclines, cisplatin, etoposide, paclitaxel, cyclophosphamide, mechlorethamine, and arsenic. Most commonly, ECG changes involve ST-T segment changes, decreases in voltage, T-wave flattening, and atrial and ventricular ectopy. Other ECG abnormalities may be seen as well. Most studies suggest that arrhythmias occur in 6% to 40% of patients receiving bolus doxorubicin.²⁰⁰ Paclitaxel also caused significant arrhythmias and conduction defects in phase I and II trials²⁰¹; most patients developed sinus bradycardia. Arsenic, used in the treatment of relapsed acute promyelocytic leukemia, can cause QT interval prolongation and complete atrioventricular block. QT prolongation can lead to a torsade de pointes-type ventricular arrhythmia. Before initiating therapy, an ECG should be performed and serum electrolytes, including potassium and magnesium, should be assessed and corrected. Additionally, all drugs that are known to prolong the QT interval should be discontinued.²⁰² All other chemotherapy agents occasionally cause a rhythm disturbance, but these are limited to a few scattered reports and should not be considered clinically significant. Therapy should not be discontinued unless the patient develops a serious cardiac arrhythmia.

FLUOROURACIL

Fluorouracil has been associated with angina pectoris and myocardial infarction. Angina may occur in 1.6% to 18%^{203–205} of patients receiving fluorouracil and appears to occur with an increased incidence in patients with a history of ischemic cardiomyopathy or in patients receiving 5-day infusions. Angina has been associated with both initial and subsequent courses. Although ischemia occurs most frequently during continuous infusion, it occasionally is delayed 3 to 18 hours after fluorouracil administration and has been reported

after an oral dose. The cause of fluorouracil cardiotoxicity is uncertain. Direct myocyte damage is suggested from animal studies; however, human studies suggest that coronary artery spasm is the most likely cause of angina. Because the chest pain associated with fluorouracil responds to nitrates, this problem, theoretically, could be managed prophylactically or therapeutically with long-acting nitrates or calcium channel blockers.²⁰³ Other agents (including vincristine, vinblastine, etoposide, paclitaxel, and bleomycin) can cause chest pain or infarction based on case reports in the literature.¹⁶⁸

ALKYLATING AGENTS

Myocardial necrosis rarely has been reported with alkylating agents, including cyclophosphamide, ifosfamide, busulfan, and mechlorethamine. Typically, cardiotoxicity occurs when patients receive high doses, such as the doses used for hematopoietic cell transplantation. Pericarditis and hemorrhagic myocardial necrosis also have been reported in these cases. Risk factors are similar to those associated with doxorubicin and daunorubicin; however, a clear relationship between dose and cardiac dysfunction has not been demonstrated consistently in all case reports.¹⁶⁸

TRASTUZUMAB

Signs and symptoms of CHF (e.g., dyspnea, increased cough, peripheral edema, S₃ gallop, and reduced ejection fraction) have been reported in 3% to 7% of patients receiving trastuzumab single-agent therapy. Of these patients, 5% had New York Heart Association (NYHA) class III or IV heart failure. The use of trastuzumab in combination with chemotherapy in patients (*N* = 469) with metastatic breast cancer showed a 27% incidence of cardiotoxicity compared with an overall 8% incidence in the anthracycline alone arm. In these same patients, the incidence of NYHA class III or IV heart failure was 16% in the trastuzumab and chemotherapy arm versus 3% in patients receiving anthracyclines alone. Additionally, heart failure occurred in the combination paclitaxel and trastuzumab arm with an overall incidence of 13% and 2%, class III and IV, respectively, versus a 1% incidence in the paclitaxel alone arm.²⁰⁶ The toxicity seems to be direct and not dependent on cumulative dose or treatment duration. Trastuzumab-associated cardiac toxicity usually responds to standard medical treatment or discontinuation of the drug.²⁰⁷ Before and periodically during treatment with trastuzumab, patients should undergo cardiac evaluation to assess left ventricular ejection fraction. Therapy should be discontinued if patients develop a clinically significant decrease in left ventricular function.

MULTITARGETED TYROSINE KINASE INHIBITORS AND MONOCLONAL ANTIBODIES

The multitargeted tyrosine kinase inhibitors exhibit a range of cardiovascular toxicities. Because these new agents are dosed chronically, more long-term toxicities may occur with longer follow-up. Imatinib has been associated with the development of CHF. A case series described 10 patients who presented with NYHA class III and IV heart failure, a mean of 7.2 ± 5.4 months (range 1–14 months) from initiation of therapy. The mean ejection fraction was 25% ± 8%. Patients receiving imatinib should be monitored for symptoms and signs of heart failure.²⁰⁸ Imatinib and dasatinib have also been associated with heart failure, ventricular dysfunction,

chest pain, and pericardial effusions.²⁰⁹ Sunitinib has been associated with a decline in cardiac ejection fraction in 4.7% to 6% of patients in phase II studies in metastatic renal cancer, although most patients were asymptomatic.^{210,211} An increased risk of myocardial ischemia and infarction has been observed with the use of sorafenib in patients with metastatic renal cell cancer in a phase III study.²¹² Additionally, hypertension has been associated with sorafenib, sunitinib, and bevacizumab. Bevacizumab-related hypertension may be dose-related; it can occur at any time during therapy and is reported to have a 22% to 32% incidence. Hypertension is usually grade 3 or less and can be controlled with standard antihypertensive medications.²¹³ Patients receiving these agents should be routinely monitored for CHF and hypertension.

Nephrotoxicity

Cisplatin

33. T.J., a 58-year-old man with nonresectable head and neck cancer, is being treated with cisplatin 100 mg/m² IV on day 1 and fluorouracil 1 g/m²/day IV for 5 days. He presents today for the third cycle of this regimen. A 24-hour urine analysis for creatinine collected by T.J. at home revealed a creatinine clearance of 75 mL/minute, down from 110 mL/minute at baseline. Other abnormalities include serum magnesium (Mg) of 1.2 mEq/L (normal, 1.6–2.2 mg/dL); all other electrolyte values are within normal range. Is cisplatin responsible for T.J.'s decreased glomerular filtration rate (GFR) and serum magnesium levels?

[SI units: Cl_{Cr}, 1.25 mL/sec; Mg, 0.6 mmol/L]

Cisplatin, a heavy-metal complex, is widely used clinically because it has activity against various solid tumors. The major dose-limiting toxicity of cisplatin is nephrotoxicity, and various renal and electrolyte disorders, both acute and chronic, have been associated with cisplatin. In the early 1970s, before the need for vigorous hydration was recognized, cisplatin often caused acute renal failure. Today, with the use of vigorous hydration, acute renal failure is uncommon; however, tubular dysfunction and decreased GFR remain problematic.

Morphologic damage is greatest in the straight segment of the proximal renal tubules where the highest concentration of platinum occurs. Acute and cumulative renal tubular damage have been demonstrated by increased urinary excretion of proximal tubular enzymes, such as β_2 -microglobulin, alanine aminopeptidase, and *N*-acetyl glucosamine. Increases in proximal tubular enzymes correlate well with urinary excretion of protein and magnesium as well as decreased reabsorption of salt and water in the proximal tubules. T.J. has hypomagnesemia, which is the most common electrolyte abnormality caused by cisplatin. Hypomagnesemia appears to be dose related and may occur after a single treatment. Despite replacement with oral magnesium, renal losses of magnesium and decreased serum magnesium levels can persist for months or even years after completion of cisplatin therapy. Hypocalcemia and hyponatremia occur less frequently. The cause of these electrolyte abnormalities is thought to be similar to that of hypomagnesemia in that a proximal tubular defect occurs that interferes with reabsorption of these electrolytes.^{214–216}

Chronic renal toxicity associated with cisplatin presents as a decrease in the GFR. Published reports suggest that the GFR

decreases by 12% to 25% in most patients receiving multiple courses.^{214,215} The decrease appears to be persistent and only partially reversible. An increase in serum creatinine or a decrease in creatinine clearance does not necessarily reflect the decline in GFR. The renal function of patients receiving cisplatin therapy should be evaluated because dosage reductions may be necessary if the creatinine clearance decreases. Methods that estimate creatinine clearance based on serum creatinine should be avoided, especially in patients with borderline renal function, because poor correlation has been demonstrated in some cancer patient populations. In addition, changes in creatinine clearance are not always reflected by changes in serum creatinine in these patients. Creatinine clearance should be determined using a 12- to 24-hour urine collection for creatinine.

T.J.'s decreased GFR and low serum magnesium likely are caused by cisplatin therapy. Although a dose reduction of cisplatin generally is not recommended for creatinine clearances in this range, the clinician should provide T.J. with adequate and aggressive hydration to prevent cisplatin nephrotoxicity. In addition, T.J. should receive an oral magnesium supplement, although diarrhea usually limits the use of the oral route when large doses are necessary. IV administration should be used if higher magnesium doses are required. Patients should undergo frequent measurements of their electrolytes, including magnesium, to minimize potential complications.

PREVENTION

34. What measures should be taken to prevent cisplatin nephrotoxicity in T.J.?

Several measures have been used to minimize or prevent cisplatin-induced nephrotoxicity, including hydration with saline, mannitol, and prophylactic magnesium. The patient should be vigorously hydrated with 2 to 3 L of normal saline over 8 to 12 hours to maintain a urine output of 100 to 200 mL/hour for at least 6 hours after treatment with cisplatin.^{217–219} A loop diuretic (e.g., furosemide) may be required in elderly patients to eliminate excess sodium or in patients with compromised cardiac reserve, but these diuretics should not be used routinely to prevent nephrotoxicity. Mannitol (25–50 g) may be administered just before chemotherapy to prevent cisplatin-induced renal artery vasoconstriction, which can increase the concentration of platinum in the renal tubules.^{219,220} Most patients may also benefit from prophylactic magnesium supplementation. Patients who received prophylactic magnesium 16 mEq IV daily during a 5-day course of cisplatin followed by 60 mEq orally (20 mEq three times daily) between courses experienced less nephrotoxicity compared with those who received no supplements in a prospective trial of 16 patients with testicular carcinoma.²²¹

Although most of these preventive measures can adequately minimize the risk of nephrotoxicity, amifostine, an organic thiophosphate that is a chemoprotectant, is also available. It is indicated for reducing the cumulative renal toxicity associated with repeated administration of cisplatin in patients with advanced ovarian cancer. Amifostine's mechanism is based on the assumption that oxygen-free radicals generated by cisplatin and radiation therapy are toxic to normal cells. It preferentially enters normal cells where it generates an active thiol metabolite, which scavenges the free radicals. A pivotal clinical trial demonstrated that pretreatment with amifostine significantly

reduced grade 4 neutropenia, nephrotoxicity, and neurotoxicity. No evidence indicated that amifostine interfered with the antitumor activity of cisplatin or cyclophosphamide.²²² This trial, along with several others, suggests that amifostine may prevent other toxicities associated with chemotherapy, including neurotoxicity, neutropenia, and ototoxicity. The ASCO guidelines currently support the use of amifostine for the prevention of nephrotoxicity and neutropenia; its use to prevent ototoxicity or neurotoxicity is not supported.⁴⁹

The recommended dosage of amifostine is 910 mg/m² administered once daily as a 15-minute IV infusion starting 30 minutes before chemotherapy. Because amifostine can cause significant hypotension, all antihypertensives should be discontinued 24 hours before treatment. In addition, patients should receive IV saline and remain in the Trendelenburg position during the infusion. If a patient experiences significant decreases in systolic blood pressure or signs or symptoms of hypotension during the infusion, treatment with amifostine should be stopped temporarily. In most cases, the systolic blood pressure returns to near normal 5 minutes after interruption of the infusion. Any patient who appears hypotensive or dehydrated should not receive amifostine. Additional adverse reactions include infusion-related flushing, fever or chills, dizziness, hiccups, sneezing, and severe nausea and vomiting.⁴⁹ Using amifostine in combination with traditional preventive measures may significantly reduce the incidence of cisplatin-induced nephrotoxicity.

35. At what point would cisplatin therapy be discontinued in a patient with a diminished GFR?

Guidelines to modify the dosage of cisplatin in patients with decreased renal function are available. Most suggest a 50% dosage reduction when the GFR decreases to 30 to 60 mL/minute and discontinuation when the GFR falls to <10 to 30 mL/minute.²¹⁴ Percentage dose reductions generally refer to the recommended dose for a specific cancer in a given combination chemotherapy regimen. Because the cisplatin dose ranges from 50 mg/m² to 150 mg/m², the precise dose for a patient with a GFR of <60 mL/minute must be individualized to the situation. If the tumor responds to carboplatin, substitution should be considered because it does not cause nephrotoxicity. The dose of carboplatin when calculated by the Calvert equation²²³ adjusts for with decreased GFR. Carboplatin is primarily excreted by the kidneys. Other

agents requiring dose adjustments or omission are given in Table 89-13.

Other Nephrotoxic Agents

36. What other chemotherapy agents can cause nephrotoxicity? What are the clinical consequences of nephrotoxicity produced by these agents?

PROXIMAL TUBULE DYSFUNCTION

Other agents reported to cause renal tubular defects include streptozocin, lomustine, carmustine, ifosfamide, and azacytidine.²²⁴ Nephrotoxicity appears to be related to the total cumulative dose for streptozocin, carmustine, and lomustine. Comparatively, a clear relationship between dosage and renal tubular toxicity with ifosfamide has not been established; however, the renal abnormality associated with high doses of bolus ifosfamide did lead to the use of fractionated doses.²²⁴ Most patients show signs and symptoms consistent with proximal tubular dysfunction.

The primary renal lesion associated with each of these agents occurs in the proximal renal tubule, and patients show several electrolyte imbalances, such as loss of protein, glucose, bicarbonate, and potassium. Serum creatinine, bicarbonate, potassium, urinary pH, protein, and glucose should be monitored closely in patients receiving these agents. Because the reversibility of the lesions varies among clinical reports and a significant number of patients who develop renal toxicity with these agents require dialysis,²²⁴ patients should discontinue treatment with these agents if they show any changes in serum creatinine or electrolytes.

METHOTREXATE

37. J.R., a 15-year-old boy with osteogenic sarcoma of the right knee, was treated with amputation of his right leg. His leg is now healed and chemotherapy consisting of high-dose methotrexate, leucovorin rescue, doxorubicin, dactinomycin, bleomycin, cisplatin, and ifosfamide is planned. The dose of methotrexate is 15 g/m² administered over 3 hours. What precautions are necessary to prevent the renal and other toxicities associated with high-dose methotrexate therapy in J.R.?

Methotrexate normally is not nephrotoxic, although 90% of the agent is excreted unchanged in the urine; however, acute tubular obstruction can occur with high-dose methotrexate if appropriate precautions are not taken. Acute tubular obstruction is caused by tubular precipitation of methotrexate, which is poorly soluble at a pH <7.0. To prevent this occurrence, preventive measures should be planned for J.R., including hydration and brisk diuresis to produce urine output in the range of 100 to 200 mL/hour for at least 24 hours after the administration of high-dose methotrexate. A urine pH >7.0 usually can be ensured by administration of 25 to 50 mEq/L sodium bicarbonate within the hydration fluid. Acetazolamide, a carbonic anhydrase inhibitor, promotes urinary bicarbonate excretion and is used by some clinicians at doses of 500 mg two to four times daily to assist in maintaining a urinary pH >7.0. J.R.'s urine output and pH must be monitored closely to prevent acute tubular obstruction associated with high-dose methotrexate therapy.²¹⁴

If J.R. has any existing renal insufficiency, methotrexate excretion will be decreased significantly, and he may experience

Table 89-13 Chemotherapeutics and Targeted Agents Requiring Dosage Modifications or Dosage Omissions in Renal Insufficiency³²⁰⁻³²²

| | |
|--------------|--------------|
| Bleomycin | Ifosfamide |
| Capecitabine | Lomustine |
| Carboplatin | Melphalan |
| Carmustine | Methotrexate |
| Cisplatin | Mitomycin |
| Cytarabine | Pemetrexed |
| Dacarbazine | Pentostatin |
| Fludarabine | Topotecan |

greater bone marrow suppression and GI side effects because of prolonged exposure to high serum methotrexate levels. Leucovorin or folinic acid is a reduced form of folic acid. Leucovorin is given after methotrexate administration to selectively rescue normal cells from the adverse effects of methotrexate caused by inhibiting production of reduced folates. Because leucovorin does not require the action of dihydrofolate reductase for its conversion, it is unaffected by methotrexate's inhibition of this enzyme. Therefore, it is important to ensure that appropriate leucovorin rescue is initiated within 48 hours after the high-dose methotrexate infusion. In addition, intrapatient and interpatient variability in methotrexate clearance is considerable, particularly with high doses of methotrexate therapy. Renal excretion of methotrexate is a complex process involving glomerular filtration, tubular reabsorption, and secretion. Concentrations of methotrexate obtained within 24 hours after the infusion often are not predictive of concentrations at 48 hours. Therefore, methotrexate concentrations between 24 and 48 hours must be monitored in J.R. and in all patients receiving high-dose therapy. Methotrexate levels are necessary to optimize leucovorin rescue (see Chapter 91, Solid Tumors). Leucovorin rescue does not affect the renal toxicity of methotrexate, however. Acute tubular obstruction associated with high-dose methotrexate therapy can be prevented only by appropriate attention to optimal urinary output before and for at least 24 hours after high-dose methotrexate administration and urinary alkalinization.²²⁵

IFOSFAMIDE

38. J.R. also is receiving ifosfamide. What unique bladder toxicity occurs with ifosfamide that requires attention before its administration?

Pathogenesis

Ifosfamide is a structural analog of cyclophosphamide belonging to the oxazaphosphorine class of antitumor alkylating agents, which must be hydroxylated and activated by the cytochrome 3A4/5 and 2B6 in the liver. The 4-hydroxy metabolite spontaneously liberates acrolein, which is excreted in high concentrations in the urine. Acrolein is responsible for urotoxicity causing a direct irritation of the bladder mucosa. Both ifosfamide and cyclophosphamide can produce cystitis, which ranges from mild to severe bladder damage and hemorrhage. Cystitis is characterized by tissue edema and ulceration followed by sloughing of mucosal epithelial cells, necrosis of smooth muscle fibers and arteries, and culminating in focal hemorrhage. Because the metabolic activation of ifosfamide proceeds more slowly than the metabolic activation of cyclophosphamide, the dosages of ifosfamide are three to four times higher than the dosages of cyclophosphamide. This may explain the higher incidence of urotoxicity associated with ifosfamide.

Clinical Presentation

Patients with oxazaphosphorine-induced hemorrhagic cystitis initially go through an asymptomatic stage characterized by complaints of brief episodes of painful urination, frequency, and hematuria. The symptoms may subside over a period of several days or weeks after discontinuing the agent. The course of oxazaphosphorine-induced hemorrhagic cystitis usually is

relatively benign, although death from massive refractory hemorrhage has occurred. Factors that may predispose J.R. to hemorrhagic cystitis include IV administration and the high doses he is receiving.

Prevention

Historically, forced hydration was the primary method used to prevent hemorrhagic cystitis in patients treated with cyclophosphamide therapy. Theoretically, hydration flushes the toxic metabolites out of the bladder so that insufficient contact time is available to set up the tissue reaction. The more urotoxic agent ifosfamide was introduced to the market with a uroprotective agent, mesna. Mesna liberates free thiol groups in the bladder, which can neutralize the oxazaphosphorine metabolite. When administered in an appropriate dosing schedule, mesna can prevent the bladder toxicity completely.

The manufacturer and ASCO currently recommend a parenteral mesna dose of 20% of the ifosfamide dose ($<2.5 \text{ g/m}^2$) given IV at zero, 4, and 8 hours after ifosfamide (for a total mesna dose of 60% of the ifosfamide dose).⁴⁹ The goal is to maintain mesna levels within the urinary tract for some time after treatment with ifosfamide to provide adequate uroprotection. Repeated administration is required because mesna has a short elimination half-life (<1 hour), especially compared with the relatively long half-life of ifosfamide. If patients receive a continuous infusion of ifosfamide, clinicians fear that patients may not receive adequate uroprotection with this divided dose regimen. Therefore, for patients receiving a continuous infusion of ifosfamide, ASCO guidelines recommend an IV bolus mesna dose of 20% of the ifosfamide followed by a 40% mesna dose by continuous infusion given over 12 to 24 hours after the end of the ifosfamide infusion.⁴⁹ This regimen ensures that mesna remains in the bladder for an extensive amount of time following the end of the ifosfamide infusion.

Various other mesna dosing schedules are clinically used, but no trials have compared the different regimens. One author suggests that a total mesna dose equivalent to 17% w/w of the ifosfamide dose was just as effective in preventing urotoxicity as the 60% w/w dose.²²⁶ Many investigators use a 1:1 w/w dose of mesna to ifosfamide when administered by continuous infusion. The dosing guidelines become less well defined, however, when patients receive higher dosages of ifosfamide ($>2.5 \text{ g/m}^2$).

The lack of data and the unique pharmacokinetic properties of ifosfamide have caused some concerns about the current dosing guidelines. The pharmacokinetics of ifosfamide is dose dependent. The elimination half-life associated with doses of 2.5 g/m^2 is 6 to 8 hours, whereas the elimination half-life associated with doses of 3.5 to 5 g/m^2 is 14 to 16 hours. The current recommendations for mesna administration provide protection for ~ 12 hours after an IV bolus; thus, with higher dosages of ifosfamide, mesna should be infused beyond the recommended 8 hours after ifosfamide to maintain bladder protection. Based on pharmacokinetics of ifosfamide and mesna and the observation that hematuria can develop 1 to 2 days after combined ifosfamide and mesna infusions have been discontinued, mesna infusions should be continued for some time following discontinuation of ifosfamide.²²⁷ Also, concern exists that the 4-hour dosing interval may be inadequate to maintain sufficient mesna levels within the bladder. Although most of the mesna dose after IV administration is

eliminated within 4 to 6 hours, data demonstrate that elimination rates (mg/kg/hour) are highest in the first 2 hours after IV administration.^{228,229} To ensure maximal protection against urotoxicity, ASCO currently recommends more frequent or prolonged mesna dosage regimens.⁴⁹ Indeed, some centers administer mesna by continuous infusion to avoid the need for frequent bolus dosing. Because ifosfamide and mesna are compatible in solution, combining the ifosfamide and mesna in one IV bag and administering by continuous infusion allows patients to conveniently receive uroprotection.

Another question concerns the influence of urination on the efficacy of mesna uroprotection. Several authors have suggested that the frequency of mesna doses be adjusted based on frequency and amount of urination.^{230,231} Although forced hydration has been the mainstay for prevention of cyclophosphamide-induced hemorrhagic cystitis, it is unnecessary and potentially disadvantageous when mesna is used. This is because forced hydration can increase urination and increase the evacuation of mesna from the bladder.

Mesna is often given IV, but an oral formulation is available. The oral bioavailability of mesna is approximately one-half that of IV mesna. Therefore, patients should receive two times the standard IV dose if they receive mesna orally (e.g., oral mesna 40% of the ifosfamide dose) 2 hours before and 4 and 8 hours after ifosfamide.²³² Others have recommended that an oral dose also be given with the ifosfamide dose. Several centers administer the first dose of mesna IV followed by oral doses at 4 and 8 hours, particularly in the outpatient clinic setting.⁴⁹ All patients receiving cyclophosphamide should receive saline diuresis or forced saline diuresis to protect urothelial tissue. When patients receive cyclophosphamide for a BMT, they may receive mesna in conjunction with saline diuresis because the higher cyclophosphamide dosages produce more of the urotoxic metabolites than conventional dosing. Other practices to prevent this complication include hyperhydration and the use of continuous bladder irrigation. Data comparing these methods are controversial and report varying rates of hematuria and severe hemorrhagic cystitis. These recommendations are currently supported by the ASCO consensus guidelines⁴⁹ (see Chapter 92, Hematopoietic Cell Transplantation).

39. If J.R. develops hemorrhagic cystitis, how should it be treated?

Once hemorrhagic cystitis develops, the chemotherapy agent causing the disorder must be discontinued and vigorous hydration started. If gross hematuria occurs, a large-bore urinary catheter should be inserted to avoid obstruction of the urethra by clots. Some clinicians also use continuous silver nitrate irrigation, local instillation of formalin, or electrocauterization of bladder blood vessels to control bleeding. If these measures fail, surgical intervention may be necessary to divert urine flow away from the bladder.

Pulmonary Toxicities

40. J.A., a 67-year-old man with an 8-year history of chronic lymphocytic leukemia (CLL), was treated intermittently for 7 years with chlorambucil and prednisone. About 1 year ago, increasing lymphadenopathy was noted, and a biopsy revealed that his CLL had transformed to large-cell lymphoreticular lymphoma. (This transformation is called Richter's syndrome.) At that time, he was started on a chemotherapy regimen of cyclophosphamide, doxorubicin, vincristine, prednisone, and bleomycin (CHOP-Bleo), and his disease stabilized. Three weeks after his ninth course, he developed dyspnea, a nonproductive cough, and fever. Chest radiograph showed diffuse bilateral infiltrates; his respiratory rate (RR) was 36 breaths/minute; and his arterial blood gases (ABG) were pH, 7.50 (normal, 7.35–7.45); PO₂, 62 (normal, 80–100 mmHg); PCO₂, 28 (normal, 35–45 mmHg); and an O₂ saturation of 92% (normal, 95%–98%). What are the possible causes of his new pulmonary findings?

41. A bronchoscopy with bronchoalveolar lavage and a biopsy with pathologic and microbiologic evaluations were performed. Bacterial, fungal, and viral cultures were negative, and the biopsy revealed inflammation and fibrosis with no evidence of lymphoma. These results are highly suggestive of chemotherapy-induced pulmonary damage. (Note: If the results of the bronchoscopy had not been helpful in establishing a diagnosis, an open-lung biopsy would have been recommended.) Which of the agents that J.A. received are associated with pulmonary toxicity, and what other factors may have increased his risk of pulmonary toxicity?

J.A. is at risk for several processes that could produce diffuse pulmonary infiltrates and dyspnea. He undoubtedly is immunosuppressed secondary to both his lymphoma and the chemotherapy; therefore, J.A. has an increased risk for infection (e.g., *Pneumocystis carinii* or cytomegalovirus [CMV]). In addition, his lymphoma now may be resistant to the therapy, and the infiltrates may represent progression of the disease. Pulmonary infiltrates also may represent toxicity resulting from one or more of the chemotherapy agents he has received. Further diagnostic workup is necessary to establish the cause.

41. A bronchoscopy with bronchoalveolar lavage and a biopsy with pathologic and microbiologic evaluations were performed. Bacterial, fungal, and viral cultures were negative, and the biopsy revealed inflammation and fibrosis with no evidence of lymphoma. These results are highly suggestive of chemotherapy-induced pulmonary damage. (Note: If the results of the bronchoscopy had not been helpful in establishing a diagnosis, an open-lung biopsy would have been recommended.) Which of the agents that J.A. received are associated with pulmonary toxicity, and what other factors may have increased his risk of pulmonary toxicity?

Many chemotherapy agents have been associated with pulmonary toxicity and the varying types of mechanisms and clinical presentations have been reviewed²³³ (Table 89-14). J.A. has received three agents with potential pulmonary toxicity, including chlorambucil, cyclophosphamide, and bleomycin. Because J.A. has received three potentially pulmonary toxic agents and because of his advanced age, he is at increased risk for pulmonary toxicity.

Among the chemotherapy agents, bleomycin most commonly causes pulmonary toxicity. Although several forms have been reported, the most frequent is interstitial pneumonitis followed by pulmonary fibrosis.^{233–235} Patients generally present with a nonproductive cough and dyspnea. Clinicians may detect only fine crackling bibasilar rales that often progress to coarse rales. The chest radiograph may be normal in the early stages, but patients can develop bilateral alveolar and interstitial infiltrates. ABG show hypoxia, and pulmonary function tests generally show a progressive fall in the diffusing capacity without a significant decrease in the forced vital capacity.²³⁴ The most significant factor associated with the development of pulmonary toxicity is the cumulative dose of bleomycin. At total doses <400 mg, <10% of patients may develop pulmonary toxicity. When the cumulative dose reaches 450 to 500 mg, the incidence is higher. The incidence may be lower when patients receive bleomycin by a continuous infusion.²³⁶ A rarer, hypersensitivity reaction produces fever, eosinophilia, and diffuse infiltrates, and this pulmonary toxicity is not dose related. The mortality associated with bleomycin pulmonary toxicity

Table 89-14 Chemotherapy-Induced Pulmonary Toxicity

| <i>Drug</i> | <i>Histopathology</i> | <i>Clinical Features</i> | <i>Treatment/Outcome</i> |
|--------------------------------------|---|---|--|
| Aldesleukin ³²³ | Capillary leak, pulmonary edema | <i>Clinical presentation:</i> ↓ BP, fever, SOB, anorexia, rash, mucositis | Stop infusion; provide supportive care to cause a quick resolution of symptoms. |
| Bleomycin ^{236,237,324,325} | Interstitial edema and hyaline membrane formation; mononuclear cell infiltration pneumonitis with progression to fibrosis; eosinophilic infiltrations seen in patients with suspected hypersensitivity-type reactions | Cumulative dose-related toxicity with risk increasing substantially with total dose >450 mg or 200 mg/m ² ; may occur during or after treatment <i>Clinical presentation:</i> cough, fever, dyspnea, tachypnea, rales, hypoxemia, bilateral infiltrates, dose-related ↓ in diffusing capacity | Recovery if bleomycin is discontinued while symptoms and radiologic changes still minimal; progressive and usually fatal if symptoms severe. Avoid cumulative doses >200 mg/m ² ; monitor serial pulmonary function tests. Discontinue therapy if diffusing capacity ≤40% of baseline, FVC <25% of baseline, or if any signs or symptoms suggestive of pulmonary toxicity occur. Steroids may be helpful if toxicity is result of hypersensitivity. |
| Busulfan ²³⁵ | Pneumocyte dysplasia; mononuclear cell infiltrations; fibrosis | Does not appear to be dose-related, but no cases reported with total doses <500 mg <i>Clinical presentation:</i> insidious onset of dyspnea, dry cough, fever, tachypnea, rales, hypoxemia diffuse linear infiltrate, ↓ in diffusing capacity | Fatal in most patients; progressive despite discontinuation of busulfan. High-dose steroids (50–100 mg prednisone daily) have been helpful in a few cases. |
| Carmustine ^{326–330} | | Dose-related; usually occurs with doses >1,400 mg/m ² <i>Clinical presentation:</i> dyspnea, tachypnea, dry hacking cough, bibasilar rales, hypoxemia, interstitial infiltrates; spontaneous pneumothorax has been reported | May continue to progress after carmustine discontinued. No evidence that steroids improve or alter incidence. High mortality rate if symptoms severe. Serial pulmonary function studies recommended. Total cumulative dose should not exceed 1,400 mg/m ² . |
| Chlorambucil ²³⁴ | Pneumocyte dysplasia; fibrosis | Usually occurs after at least 6 months of treatment with total cumulative doses of >2 g <i>Clinical presentation:</i> dyspnea, dry cough, anorexia, fatigue, fever, hypoxemia, bibasilar rales, localized infiltrates progressing to diffusing involvement of both lung fields | Fatal in most cases despite discontinuation of chlorambucil and treatment with high-dose steroids. |
| Cyclophosphamide ^{234,329} | Endothelial swelling, pneumocyte dysplasia, lymphocyte infiltration fibrosis | Does not appear to be schedule- or dose-related and may occur after discontinuation <i>Clinical presentation:</i> progressive dyspnea, fever, dry cough, tachypnea, fine rales, ↓ diffusing capacity and restrictive ventilatory defect, bilateral interstitial infiltrates | Clinical recovery reported in about 50% of patients within 1–8 wk if therapy stopped. Some of these patients received steroid therapy; however, others have died despite steroid therapy. Occasionally, therapy has been restarted without recurrence. |
| Cytarabine ³³¹ | Pulmonary edema, capillary leak | <i>Clinical presentation:</i> tachypnea, hypoxemia, interstitial or alveolar infiltrates | Not always fatal. |
| Gemcitabine ³³² | Pulmonary edema, rare interstitial pneumonitis | Dyspnea was reported in 23% of patients; severe dyspnea in 3%; dyspnea occasionally accompanied by bronchospasm (<2% of patients); rare reports of parenchymal lung toxicity consistent with drug-induced pneumonitis | Treatment is supportive care measures. Symptoms resolve and are usually not seen with rechallenge. |
| Fludarabine ³³³ | Interstitial infiltrates, alveolitis, centrilobular emphysema | <i>Clinical presentation:</i> fever, dyspnea, cough, hypoxia; onset 3–28 days after third or fourth course; bilateral infiltrates and effusions | Resolves spontaneously over several weeks with or without corticosteroids. |
| Melphalan ²³⁴ | Pneumocyte dysplasia | Not dose-related <i>Clinical presentation:</i> dyspnea, dry cough, fever, tachypnea, rales, pleuritic chest pain, hypoxemia | Most patients die because of progressive pulmonary disease. Most reported cases occurred while patients were receiving concomitant prednisone therapy. Usually progresses rapidly. |

Table 89-14 Chemotherapy-Induced Pulmonary Toxicity (Continued)

| Drug | Histopathology | Clinical Features | Treatment/Outcome |
|--|--|---|---|
| Methotrexate ^{334–337} <i>Delayed</i> | Nonspecific changes; occasional fibrosis | No evidence that dose-related; daily or weekly schedules more likely to cause toxicity than monthly dosing <i>Clinical presentation:</i> headache, malaise prodrome, dyspnea, dry cough, fever, hypoxemia, tachypnea, rales, eosinophilia, cyanosis in up to 50% of patients, interstitial infiltrates, ↓ diffusing capacity, restrictive ventilatory defect | Most patients recover within 1–6 wks (some may have persistent infiltrates or ↓ pulmonary function parameters). Steroids may produce more rapid resolution. May resolve despite continuation of methotrexate, but discontinuation may speed resolution. Rarely fatal. |
| <i>Noncardiac pulmonary edema</i> <i>Pleuritic chest pain</i> | Acute pulmonary edema | Occurs very rarely 6–12 hr after PO or IT methotrexate Not related to other methotrexate toxicities or serum levels; may not occur with each course of therapy <i>Clinical presentation:</i> right-sided chest pain, occasional pleural effusion or collapse of lung, thickened pleural densities | May be fatal. Usually resolves within 3–5 days. |
| Mitomycin ²³⁴ | Similar to bleomycin | <i>Clinical presentation:</i> dyspnea, dry cough, basilar rales, hypoxemia, bilateral interstitial or finely nodular infiltrates, ↓ diffusing capacity | Fatal in ≈50% of cases. Complete resolution reported in some patients, including some who received steroid therapy. |
| Procarbazine ^{338,339} | Hypersensitivity pneumonitis with eosinophilia and interstitial fibrosis | <i>Clinical presentation:</i> nausea, fever, dry cough, dyspnea within a few hours of ingestion, bilateral interstitial infiltrates, and pleural effusion | Rapid resolution after discontinuation. |
| Vinblastine ²³⁵ | Hyperplasia, dysplasia, interstitial edema, and fibrosis | Associated with concomitant treatment with mitomycin <i>Clinical presentation:</i> acute respiratory distress, bilateral infiltrates | Initial improvement with subsequent progression. |

BP, blood pressure; FVC, forced vital capacity; IT, intrathecal; SOB, shortness of breath.

is about 50%.^{233–235} If bleomycin is discontinued while symptoms are minimal and before pulmonary function has decompensated significantly, the damage may not progress. In contrast, patients with prominent physical and radiographic findings generally die because of pulmonary complications. Other chemotherapy agents can potentially exacerbate the pulmonary toxicity associated with bleomycin.

Less commonly, chlorambucil and cyclophosphamide induce pulmonary toxicities similar to bleomycin. Chlorambucil-induced lung damage appears to be dose related because most cases have occurred in patients who received a total dose >2 g over >6 months.²³⁴ In most instances, patients died of severe interstitial pulmonary fibrosis. Cyclophosphamide pulmonary toxicity does not appear to be related to the dosage regimen. Approximately 50% to 65% of patients improve clinically after discontinuing cyclophosphamide therapy. If a patient presents with signs or symptoms consistent with pulmonary toxicity, the patient should undergo a diagnostic workup after discontinuing therapy.

42. Why are routine pulmonary evaluations indicated in patients such as J.A. who receive bleomycin or other pulmonary toxic agents?

Because a dose-related decrease in diffusing capacity has been observed in patients receiving bleomycin before the on-

set of clinical symptoms, routine baseline and serial pulmonary function studies are recommended.²³⁷ Bleomycin therapy should be withheld if the diffusing capacity falls below 40% of the baseline value, if the forced vital capacity falls below 75% of the baseline value, or if patients develop any signs or symptoms of pulmonary damage.²³⁴ Some practitioners also recommend limiting the total cumulative dose to ≤450 mg. Specific screening is not routinely recommended for patients receiving other pulmonary toxic agents; however, if patients develop any symptoms or clinical findings, therapy should be withheld until the cause can be determined.

Management

43. How should J.A.'s agent-induced pulmonary toxicity be managed?

The most effective way to manage pulmonary toxicity is to prevent it. If pulmonary toxicity becomes evident, however, all responsible agents (in J.A.'s case: bleomycin, chlorambucil, and cyclophosphamide) should be discontinued and the patient should receive symptomatic support based on their physical condition (e.g., oxygen). As illustrated by J.A., other treatable causes of pulmonary infiltrates (e.g., infection) also should be ruled out. In many cases, however, pulmonary toxicity is irreversible and progressive, and effective treatments are unavailable. Corticosteroids often are administered but

probably are effective only in cases in which hypersensitivity caused the pulmonary damage. Nevertheless, because other effective treatments are lacking, a trial of steroids generally is indicated for all patients; if steroids are discontinued, they must be tapered carefully to avoid clinical deterioration.

Hepatotoxicity

44. J.D. has received two courses of chemotherapy with cytarabine and daunorubicin. Before chemotherapy was started, his liver function tests (LFT) and coagulation studies were within normal limits. His current laboratory values include the following: aspartate aminotransferase (AST), 204 U/L (normal, 8–46); alanine aminotransferase (ALT), 197 U/L (normal, 7–46); lactate dehydrogenase (LDH), 795 U/L (normal, 100–190); alkaline phosphatase, 285 U/L (normal, 25–100); bilirubin, 1.2 mg/dL (normal, <1.5); and PT, 13.1 seconds (normal, 11–16). Why could J.D.'s chemotherapy be responsible for these laboratory abnormalities?

[SI units: AST, 3.4 μ kat/L; ALT, 22.98 μ kat/L; LDH, 13.25 μ kat/L; alkaline phosphatase, 4.75 μ kat/L; bilirubin, 20.52 mmol/L]

Elevated LFT occur frequently in cancer patients and their causes are listed in Table 89-15. Other signs and symptoms include jaundice, nausea, vomiting, abdominal pain, and, rarely, encephalopathy. Patients should receive an extensive workup to determine whether they require any immediate attention for tumor involvement of the liver or possible infection. In addition, patients should discontinue any nonessential medications that can potentially cause hepatotoxicity. The clinician may also need to consider discontinuing chemotherapy because some agents may cause the hepatotoxicity observed.

Several chemotherapy agents, including cytarabine given to J.D., have been associated with hepatocellular damage and are reviewed in detail²³⁸ (Table 89-16). The agents most commonly associated with hepatotoxicity include asparaginase, carmustine, cytarabine, mercaptopurine, streptozocin, clofarabine, and gemtuzumab ozogamicin. Methotrexate has caused hepatotoxicity when given on a daily schedule; however, if it is given on an intermittent basis, the incidence of toxicity decreases significantly.^{239–240} All of these drugs come in contact with the liver by entering the liver's blood supply; the liver uniquely receives a dual blood supply from the portal and superior mesenteric veins. The liver can detoxify or inactivate noxious substances and metabolizes many chemotherapeutic agents as well. When chemotherapy agents undergo metabolism, they can damage the metabolic processes in the

Table 89-16 Hepatotoxicity From Select Antineoplastic Drugs

| Drug/Schedule | Prevalence | Type |

liver. The exact mechanisms by which chemotherapy agents cause hepatotoxicity are unknown, but most agents probably cause hepatic damage by (a) interfering with the mitochondrial function of the hepatocyte, (b) depleting hepatic glutathione stores, (c) eliciting hypersensitivity reactions, (d) decreasing bile flow, or (e) causing phlebitis of the central hepatic vein to produce veno-occlusive disease.²³⁸

Several laboratory tests can provide markers of liver structure and function. Serum transaminases, alkaline phosphatase, and bilirubin levels should be monitored routinely in patients receiving hepatotoxic chemotherapy. Although these laboratory indices are sensitive indicators of liver injury, they are nonspecific for the type of liver disease and do not necessarily correlate with hepatic function. Serum levels of proteins produced by the liver (e.g., ferritin, albumin, prealbumin, or retinol-binding protein) also may be helpful in assessing liver function. The decision to continue or discontinue chemotherapy in patients with apparent hepatic dysfunction can be difficult. If the chemotherapy is the suspected cause, therapy should be withheld until LFT are within normal ranges. The clinician should also consider alternative (nonhepatotoxic) chemotherapy for future treatment. In addition, agents that are cleared

predominantly via the liver may require dosage adjustments and should be administered cautiously (Table 89-17).

J.A.'s therapy is likely responsible for his elevated liver enzymes. Therefore, costly workup should be deferred to allow recovery of liver function. Recovery should occur within 2 weeks of chemotherapy. If full recovery does not occur, further therapy (agents, doses, or both) may require modifications.

LONG-TERM COMPLICATIONS OF CHEMOTHERAPY

Second Malignancies After Chemotherapy

Acute Myeloid Leukemia (AML)

45. T.D., a 55-year-old woman, was diagnosed with an early stage breast cancer and successfully treated with radical mastectomy followed by four cycles of adjuvant AC (doxorubicin 60 mg/m² IV on day 1, cyclophosphamide 600 mg/m² IV on day 1). Eighteen months after her breast cancer therapy was completed, T.D. presents to her primary care physician with complaints of fatigue, SOB, easy bruising, and sinusitis. A peripheral blood smear shows a WBC count of 120,000/mm³ with a differential of >90% leukemic blasts and a bone marrow biopsy confirms acute myeloid leukemia (AML). Subsequent cytogenetic analysis revealed abnormalities involving chromosome 11q23. What factors support the diagnosis of chemotherapy-associated acute leukemia in T.D.?

Acute leukemia has been associated with chemotherapy used to treat hematologic malignancies, solid tumors, and non-malignant diseases.²⁴¹ AML also has been reported after combination chemotherapy that involves topoisomerase inhibitors, including teniposide, etoposide, and anthracyclines.²⁴² These leukemias usually occur 1 to 3 years after the completion of chemotherapy and myelodysplasia does not usually occur before the leukemia. Other characteristics include FAB M4 or M5 classification and chromosomal abnormalities involving chromosome 11q23. This is an important area for research given the widespread use of these agents for many curable diseases.

Acute myeloid leukemia has also been reported in patients who have had previous exposure to alkylating agents. It usually occurs 5 to 7 years after the patient finishes chemotherapy.²⁴³ Myelodysplastic syndrome (preleukemia changes) commonly occurs in 50% of patients before overt acute leukemia.^{244,245} Although all alkylating agents can cause acute leukemia, melphalan appears to be the most potent leukemogenic agent in this class; other classes of chemotherapy agents do not appear to carry as significant a risk. Large doses, continuous daily dosing, prolonged treatment periods, age >40 years, and concomitant radiation therapy may increase the risk of developing acute leukemia. Several additional factors may increase a patient's risk of developing acute leukemia.^{241,246–248}

Evidence that chemotherapy can cause secondary lymphoid malignancies, particularly non-Hodgkin's lymphoma, is also strong. Immunosuppression from the disease and its treatment rather than the particular chemotherapy agent may be the primary cause of NHL. Other secondary malignancies can occur after chemotherapy as well. Solid tumors have been associated with superficial bladder cancer in patients treated with daily oral cyclophosphamide, and bone sarcoma has occurred after treatment with alkylating agents.²⁴⁹ The secondary solid tumors in patients treated with other chemotherapy agents are considered coincidental.^{249–251}

T.D.'s AML probably occurred secondary to her previous anthracycline therapy. The chemotherapy agent, as well as the time course for her acute leukemia, is consistent with topoisomerase-II agent-induced malignancies. In addition, cytogenetic abnormalities occur in >90% of those patients who have received chemotherapy or radiation therapy and have subsequently developed therapy-related myelodysplastic syndrome or AML.²⁴⁵ Abnormalities in chromosome 11q23 are involved in many of the cases with cytogenetic abnormalities from topoisomerase inhibitors.²⁵² The chromosomal abnormalities of 11q23 in T.D. strongly support the diagnosis of chemotherapy-associated acute leukemia rather than *de novo* leukemia.

46. Are the therapy and prognosis of T.D. with treatment-associated AML similar to those of patients with *de novo* AML?

Therapy for patients with treatment-associated AML compares poorly with that of patients with *de novo* leukemia. Complete remissions with standard cytarabine and daunorubicin regimens are obtained in less than half of patients with treatment-associated AML compared with a complete remission rate of 70% to 80% in patients with *de novo* leukemia^{253,254} (see Chapter 90 Hematologic Malignancies). High-dose cytarabine produced remissions in 10 of 11 patients with AML secondary to chemotherapy in one series.²⁵⁵ Most series, however, reported a lower response rate, with responses of short duration and a median survival of only 3 to 4 months. Isolated case reports suggest that BMT may benefit younger patients and those with human leukocyte antigen (HLA) identical donors.^{256–258}

The best “treatment” of therapy-associated AML is prevention. In patients such as T.D. receiving adjuvant chemotherapy for curable malignancies, avoiding the use of agents that cause treatment-related AML should be discussed in conjunction with other risks and benefits of therapy.

Fertility and Teratogenicity

Effects on Oogenesis

47. C.L., a 32-year-old woman with recently diagnosed stage II breast cancer, underwent a lumpectomy and external-beam radiation therapy and is scheduled to begin adjuvant chemotherapy with cyclophosphamide, doxorubicin, and fluorouracil (CAF). C.L. was married 12 months before her diagnosis and wishes to have children. What are C.L.’s prospects for fertility following adjuvant chemotherapy?

Chemotherapy is potentially gonadotoxic in humans. Ovarian biopsies taken from women treated for cancer demonstrate loss of ova and follicular elements.^{259,260} This injury is evident even in prepubertal female patients treated for cancer.²⁶¹ Ova die or become nonfunctional by direct injury to the ova or by indirect injury resulting from loss of supporting follicular cells. If the damage to the follicular elements is extensive and irreversible, fertility is impaired even if the ova are spared.

Agent-induced injury to ova and follicular elements reduces ovarian estrogen and progesterone secretion in menstruating women. This causes the hypothalamus and pituitary to secrete more follicle-stimulating hormone (FSH) and luteinizing hormone (LH), which in turn increase follicular recruitment and the number of follicles vulnerable to chemotherapy agents. If the gonadal toxicity is severe or prolonged, permanent ovarian failure can occur secondary to depletion of ova and follicles. Recovery of some of the affected follicles often occurs, however, and this may be manifested by irregular menses or delayed recovery of menses. If the ova are spared and follicular cells recover sufficiently, ovulation and pregnancy might occur, but premature ovarian failure is inevitable in most women treated with large doses of gonadotoxic agents given over long periods.

Prepubertal girls have a greater reserve of primary follicles and because their ovaries are not producing estrogen and progesterone, increases in FSH and LH with resultant recruitment of follicular elements do not occur. For this reason, prepubertal girls can tolerate large doses without apparent effects even if

the pathology previously described occurs. The gonadal effects of chemotherapy in women and girls have been described in several reviews.^{261,262}

C.L. is going to receive one of the alkylating agents, which are the most potent gonadotoxic agents. Cyclophosphamide is well known for producing infertility in men and women and gonadal failure even in children. The effect is influenced strongly by the total dose of cyclophosphamide and the patient’s age at the onset of chemotherapy. Nearly 100% of women over 20 years of age develop amenorrhea when the mean total dose is 20 to 50 g. The same consequence can be expected in women >35 years of age who receive >6 to 10 g and in women 40 years of age and older who receive more than 5 g.²⁶³ Depending on the exact dose of cyclophosphamide in the CAF regimen planned, C.L. may or may not fall into a dose range that would be expected to produce permanent amenorrhea.

The clinician also must consider that a synergistic gonadotoxic effect has been reported when doxorubicin is combined with cyclophosphamide. The onset of amenorrhea may occur at half the total dose of cyclophosphamide after therapy with doxorubicin and cyclophosphamide than after treatment with cyclophosphamide, methotrexate, and fluorouracil. Fluorouracil is unlikely to play any role in producing ovarian failure. Aside from the alkylating agents, the only chemotherapy agents with strong evidence of gonadal toxicity include vinblastine, etoposide, and cisplatin. Several excellent reviews discuss the doses of chemotherapy agents, used both alone and in combination, and specific incidences of associated gonadotoxicity, as well as the prevalence of temporary and permanent amenorrhea.^{264,265}

C.L. most likely will experience amenorrhea along with the signs and symptoms of menopause as both estrogen and progesterone production diminish during chemotherapy. C.L. may recover from chemotherapy-induced amenorrhea months to years after completion of her therapy. Recovery may be manifested as amenorrhea interspersed with normal menstrual periods. Pregnancy is possible during periods of normal menstruation because ovulation does occur in most instances. Premature menopause is inevitable, however. Because the greatest risk of pregnancy exists early in the course of chemotherapy, C.L. should be counseled to practice birth control while receiving chemotherapy. Because oral contraceptives are contraindicated in patients with breast cancer, barrier methods (i.e., diaphragm, condoms, spermicide) should be advised.

Effects on Spermatogenesis

48. J.K., a 25-year-old man with recently diagnosed stage IV Hodgkin’s lymphoma, will receive systemic chemotherapy. What effect does systemic chemotherapy have on male gonadal function?

The primary gonadal toxic effect of chemotherapy agents in male patients is a progressive dose-related depletion of the germinal epithelium lining the seminiferous tubule.²⁶⁶ The clinical manifestations of germinal depletion include a marked reduction in testicular volume and azoospermia. The Leydig cells responsible for testosterone production remain morphologically intact, although mild functional impairment occurs rarely. The major toxicity of chemotherapy in men is loss of reproductive capacity. During treatment, libido and sexual activity may decline, but most men report a return to pretreatment sexual function after chemotherapy.²⁶⁶

Of the chemotherapy agents, alkylating agents most commonly are associated with azoospermia. Progressive dose-related oligospermia occurs in men receiving chlorambucil,^{267,268} cyclophosphamide,^{269,270} nitrogen mustard, busulfan, procarbazine, and nitrosureas; procarbazine appears to be the most gonadotoxic alkylating agent in men. Doxorubicin, vinblastine, cytarabine, and cisplatin also have been associated with azoospermia,²⁷¹ and doxorubicin appears to have a synergistic toxic effect in men when given with cyclophosphamide similar to that previously described in women. Phase-specific agents, such as antimetabolites and plant alkaloids, seem unlikely to produce azoospermia when used alone but may play a minor role in combination chemotherapy regimens.

In contrast to oogenesis, in which women are born with a full complement of ova, spermatogenesis occurs in a continuous cycle of regeneration, differentiation, and maturation beginning in the second month of embryogenesis and continuing through old age. Although different chemotherapy agents appear to exert more damage to germ cells in specific phases of spermatogenesis in animal models, in humans, gonadotoxic agents generally are used in sufficiently large doses to affect varying proportions of maturing sperm cells in any stage of development. This has two realistic implications. The first is that because spermatogenesis must start at the beginning after agent-induced azoospermia occurs, the length of recovery is prolonged, usually lasting at least 2 to 3 years. The second is that the relationship of age to the development of azoospermia is far less clear than the relationship of age to ovarian suppression. Although conventional wisdom holds that prepubertal boys are less likely to be affected by chemotherapy agents than adult men, the reserve of primitive sperm cells in male children is far less than it is in adults. Therefore, the spermatogenesis potential in prepubertal testes may make them more vulnerable to cytotoxic damage than those of adults. A review of the literature regarding the effects of chemotherapy administered to male children concluded that agents and regimens known to be toxic in men should be considered toxic in young boys.²⁶⁴ Short of a testicular biopsy, the damage cannot be detected until puberty.

The two diseases most likely to affect young men who are concerned with their fertility are Hodgkin's disease and testicular cancer. The standard treatment for advanced Hodgkin's disease is doxorubicin, bleomycin, vinblastine, and dacarbazine (ABVD) (see Chapter 88, Neoplastic Disorders and Their Treatment). Azoospermia has been observed in 35% of patients receiving ABVD and spermatogenesis nearly always recovered in these patients.²⁷¹ A similar scenario exists in patients about to start on chemotherapy for testicular cancer. Evidence to date suggests that chemotherapy-induced azoospermia that follows treatment with vinblastine, bleomycin, and cisplatin for nonseminomatous testicular carcinoma is reversible within 2 to 3 years in approximately 50% of patients treated and that those who recover spermatogenesis are capable of impregnating their partners.^{272,273} In this particular patient population, it is important to recognize that retroperitoneal lymph node dissection, which results in retrograde ejaculation, as well as cryptorchidism, which predisposes to infertility, may contribute to the lack of full recovery of fertility potential.

49. Aside from the use of chemotherapy agents with less gonadal toxicity, are there means of circumventing infertility in young patients receiving chemotherapy?

Sperm or gamete cryopreservation should be considered in males. A major limitation of this approach has been the finding of diminished sperm counts, sperm volume, and sperm motility in young men affected with Hodgkin's disease and testicular cancer before combination chemotherapy is initiated.^{274,275} Although published studies suggest that the quantity and motility of sperm are important determinants of successful artificial insemination, pregnancies have been reported.^{276,277} Thus, sperm banking should be considered even in oligospermic men.

Oocyte and embryo cryopreservation now are feasible options for young women about to undergo cytotoxic chemotherapy. Even in the face of chemotherapy-induced ovarian failure, in vitro fertilization of an ovum, and implantation into the endometrium with proper hormonal support can successfully accommodate a term pregnancy.^{278,279} This may be an option for C.L. described in Question 47.

In both genders, it has been hypothesized that gonadal toxicity from chemotherapy could be decreased by inhibiting spermatogenesis or follicular development during chemotherapy. Methods used to suppress gonadal function have included administration of testosterone in men, oral contraceptives in women, and gonadotropin-releasing hormone analogs (LHRH analogs) in both men and women. A review describes approaches in detail²⁸⁰ and the ASCO provides recommendations on preserving fertility in cancer patients.²⁸¹

Teratogenicity

50. If C.L. or J.K. regain fertility after their planned combination chemotherapy regimens, are they at risk for producing offspring with congenital abnormalities or an excess risk of cancer?

Most of the agents used to treat cancer are designed specifically to interfere with DNA synthesis, cellular metabolism, and cell division. Thus, reason exists to suspect that they may cause mutation of ova or spermatocytes exposed to these effects. The actual outcomes of pregnancies in survivors of cancer are published as case reports, small series, and retrospective case series. Nearly 1,600 children have been born to 1,078 patients previously treated for malignancy in childhood or as adults. A review of the published information suggests no evidence that spontaneous abortion, genetic disease, or congenital anomalies occurs more frequently in the progeny of cancer survivors. Similarly, there does not appear to be an increased risk of malignancy in the offspring of patients treated for cancer.²⁶⁴ The likely explanation for this is that ova and sperm cells affected by chemotherapy usually are killed. The risk of producing an abnormal offspring thus would be highest at the time of ongoing germ cell exposure. Men and women should be explicitly discouraged from conception during chemotherapy. In general, adults surviving cancer should be advised to wait at least 2 years after completion of therapy before attempting to parent a child; this theoretically allows time for elimination of damaged germ cells. This also provides time to assess the likelihood of the necessity for further treatment that would have grave consequences on the fetus, particularly in the case of female patients.

ACKNOWLEDGMENTS

The authors and editors would like to acknowledge the contribution of Celeste Lindley of this topic in the previous edition.

HEMATOLOGIC MALIGNANCIES: ADULT DEFINITIONS AND CLASSIFICATION

Cancers arising from hematopoietic cells and lymphoid tissue are termed “hematologic malignancies,” and include leukemias, lymphomas, plasma cell disorders, and myeloproliferative disorders. Compared with other cancers, they are relatively uncommon (<10% of all newly diagnosed cancers) and will account for approximately 52,300 deaths in the United States in 2007.¹ Chemotherapy is the primary treatment for most cases of hematologic malignancies because they are usually disseminated at the time of diagnosis. Focal treatment with surgery and/or radiation therapy is not commonly used to manage these cancers. Compared with solid malignancies, the growth rate of most hematologic malignancies is rapid, and aggressive combination chemotherapy regimens can provide high response rates and cures. Complex supportive care regimens are often needed in conjunction with chemotherapy because of multiple disease symptoms and toxicities associated with chemotherapy. The hematologic malignancies also serve as the most common experimental laboratory models of cancer growth, biology, and treatment effects. In addition, advances in delineating molecular targets and improved disease detection continue to lead to changes in therapeutic approaches.

Leukemias

Leukemias are hematologic malignancies that are derived from cytogenetic alterations in hematopoietic cells. Biologically, they originate in the bone marrow before disseminating to systemic tissues. Leukemias are classified based on the cell of origin (myeloid or nonlymphocytic and lymphocytic) and clinical course. Myeloid leukemias include disorders of granulocytes, monocytes, erythrocytes, and platelets. Lymphocytic leukemias include disorders of B and T lymphocytes. Leukemias are further classified as acute or chronic.

Acute leukemia is characterized by the expansion and differentiation arrest of immature hematopoietic cells. This expansion causes large numbers of early progenitor cells (blasts) to appear in the bone marrow. Leukemic blasts develop a growth advantage that leads to failure of the bone marrow to produce adequate numbers of functional mature blood cells. The immature blast cells generally retain some features that indicate their origin from the hematopoietic lineage. If the blasts have lymphoid features, the leukemia is classified as *acute lymphocytic leukemia* (ALL). If the blasts have myeloid features, the leukemia is classified as *acute myeloid leukemia* (AML). Clinical and laboratory distinction of AML from ALL is illustrated in Table 90-1. AML and ALL can be distinguished based on morphologic examination of the bone marrow and peripheral blood, along with special cytochemical stains, surface membrane phenotyping, and chromosomal analysis. Acute leukemias appear suddenly and progress very rapidly. Death due to infection or bleeding occurs within weeks to months if the patient is not effectively treated.

Chronic leukemias follow a more insidious onset and course than acute leukemias and are associated with proliferation of more mature hematopoietic cells. Chronic lymphocytic leukemia (CLL) is characterized by overproduction of mature lymphocytes. Chronic myeloid (or granulocytic) leukemia (CML or CGL) is associated with overproduction of mature

AML, acute myelogenous leukemia; ALL, acute lymphocytic leukemia; CNS, central nervous system; CALLA, common acute lymphocytic leukemia antigen.

neutrophils or granulocytes. Deposition of these cells in various organs, as well as high numbers in vascular spaces, have profound and unique consequences that are discussed in subsequent cases. Other less common chronic leukemias include hairy cell leukemia and chronic myelomonocytic leukemia. Patients with chronic leukemias also often have decreased production of red blood cells (RBCs) and platelets. Although patients with chronic leukemias may survive for years with suppressive therapies, these disorders are curable in only a fraction of patients who are candidates for immune-based approaches using chemotherapy and progenitor cell replacement (see Chapter 92).

Lymphomas

The lymphomas are a heterogeneous group of hematologic malignancies that originate in lymphoid tissues. A lymphoma may arise within single or multiple lymph nodes or in extranodal sites commonly involving the lymphoid tissue of the gastrointestinal (GI) tract, central nervous system (CNS), or numerous other sites. The two major types of lymphomas are Hodgkin disease (HD) and non-Hodgkin lymphoma (NHL) (Table 90-2). It is estimated that these hematologic malignancies account for >60,000 new cases annually, with seven times as many patients affected by NHL compared with HD.¹ NHLs

Table 90-2 Comparison of Hodgkin Disease and Non-Hodgkin Lymphoma

| Characteristic | Hodgkin Disease | Non-Hodgkin Lymphomas | |
|--|---------------------|-----------------------|-------------------------|
| | | Low Grade | Intermediate-High Grade |
| Site(s) of origin | Nodal | Extranodal (10%) | Extranodal (35%) |
| Nodal distribution | Axial (centripetal) | Centrifugal | Centrifugal |
| Nodal spread | Contiguous | Noncontiguous | Noncontiguous |
| Central nervous system involvement | Rare (<1%) | Rare (<1%) | Uncommon (<10%) |
| Hepatic involvement | Uncommon | Common (>50%) | Uncommon |
| Bone marrow involvement | Uncommon (<10%) | Common (>50%) | Uncommon (<20%) |
| Marrow involvement adversely affects prognosis | Yes | No | Yes |
| Curable by chemotherapy | Yes | No | Yes |

represent a spectrum of diseases marked by different pathological features, natural history, response to treatment, and prognosis. NHLs have been divided into categories based on cell of origin (B or T), histology (low, intermediate, or high grade), immunophenotypic characteristics, cytogenetic abnormalities, and natural history. The main classification systems used for NHLs are the Working Formulation (WF) classification and the Revised European-American Lymphoma (REAL) classification. The WF classification is based on the morphology and clinical behavior of the disease; the REAL classification has been advocated because it also incorporates immunophenotypic and molecular characteristics. Further classification of all neoplastic diseases of myeloid and lymphoid tissues by the World Health Organization (WHO) beyond the 1994 REAL system is currently ongoing, with the goal of removing arbitrary clinical groupings of lymphoid neoplasms from clinical practice and relying on more complete information (including morphology, immunophenotype, cytogenetic features, and clinical features) to guide prognosis and therapy.² The additional information included with further classification will ideally provide insight into the biological diversity of each type of lymphoma and assist with therapeutic decisions.^{3,4}

Plasma Cell Disorders

Plasma cell disorders include a group of neoplasms that arise from antibody-secreting B cells that overproduce excessive amounts of a monoclonal immunoglobulin or part of a monoclonal immunoglobulin (light chains). If the monoclonal protein is in the IgM subclass, the disease is called “Waldenström macroglobulinemia,” and the malignant cells are called “plasmacytoid lymphocytes.” If the monoclonal protein is in the IgG (70% of cases) or IgA (20% of cases) subclass or if only monoclonal light chains are present in blood, the disease is called “multiple myeloma,” and the malignant cells are called “plasma cells.”⁵ High monoclonal immunoglobulin concentrations can be found in conditions other than multiple myeloma or Waldenström macroglobulinemia, such as monoclonal gammopathy of undetermined significance or amyloidosis. However, the amount of immunoglobulin produced with multiple myeloma or Waldenström macroglobulinemia generally exceeds the amount produced with other conditions. Excessive amounts of protein cause a number of clinical manifestations, including hyperviscosity and renal dysfunction. If plasma cells infiltrate the bone marrow, a decreased production of RBCs and platelets occurs. Multiple myeloma is the most common

plasma cell disorder, accounting for 14% of all hematologic malignancies.¹

ACUTE MYELOID LEUKEMIA

Signs and Symptoms

1. D.M., a 35-year-old woman, presented to the emergency department with increasing fatigue and fever. This past week, a peripheral blood smear (complete blood count [CBC]) revealed a white blood cell (WBC) count of 80,000/mm³ (normal, 4,000–11,000) with a differential of >90% leukemic blasts (normal, 0%), a hematocrit (Hct) of 31% (normal, 40%–44%), and a platelet count of 46,000/mm³ (normal, 150,000–400,000). A bone marrow aspirate and biopsy confirmed the diagnosis of AML (FAB-M2, myeloid with maturation; 60% blasts, myeloperoxidase positive; CD13 and CD33 positive). All serum chemistry values were within normal limits, with the exception of potassium (K), 3.2 mEq/L (normal, 3.5–5.5); phosphorus, 5.5 mg/dL (normal, 2.5–4.5); and lactate dehydrogenase (LDH), 3,000 mU/mL (normal, 30–120). Physical examination was unremarkable except for a perirectal cellulitis. Which signs and symptoms exhibited by D.M. are consistent with AML?

[SI units: WBC count, 80 × 10⁶/L (normal, 4–11) with differential >0.9 leukemic blasts (normal, 0); Hct, 0.31 (normal, 0.40–0.44); platelets 46 × 10⁹/L (normal, >150); K, 3.2 mmol/L (normal, 3.5–5.5); phosphorus, 5.5 mmol/L (normal, 2.5–4.5); LDH, 3,000 (normal, 30–120)]

D.M.’s symptoms of increasing fatigue and fever of 1 week’s duration are consistent with a rapid reduction in RBCs leading to anemia (Hct, 31%) and a low neutrophil count leading to infection (perirectal cellulitis). Although her WBC count is high, the differential reveals that >90% are “blasts,” which are immature, nonfunctional cells of myeloid or lymphoid origin. Circulating blast cells are typically not present in chronic leukemias or mild-to-moderate infection. However, blasts may also be observed on the peripheral smear in patients with anemia associated with primary bone marrow dysfunction (myelodysplastic syndromes). They are also present in patients with severe infection, stress, or trauma and in those with CML in “transformation” to acute leukemia. D.M.’s platelet count is also low, which may lead to bleeding or bruising. Collectively, these are often the presenting signs and symptoms of acute leukemia.

D.M.’s symptoms are consistent with either AML or ALL. However, patients with ALL also commonly present with

Table 90-3 Classification of Acute Myeloid Leukemia^a

| Designation | Name | Predominant Cell Type | Cytogenetics | Frequency (%) | Morphology |
|------------------------|-------------------------------|--|-------------------------------------|---------------|--|
| M ₀ | Undifferentiated myeloblastic | | | | No maturation of myeloblasts |
| M ₁ | Undifferentiated myelocytic | Myeloblasts | t(9;22) + 8 del(5), del(7) | 2–3 | Minimal maturation of myeloblasts |

^aFrench-American-British (FAB) classification system.

lymphadenopathy and hepatosplenomegaly. It is important to distinguish between these two disorders because treatment regimens differ significantly. AML is far more common in adults than in children. (For a complete discussion of ALL, see Acute Lymphoblastic Leukemia of Childhood section.)

Classification and Diagnosis

For a definitive diagnosis of AML to be made, the bone marrow aspirate must contain more than 20% leukemic blast cells. A normal bone marrow aspirate would typically contain less than 5% blasts. Eight major variants of AML are defined by the French-American-British (FAB) classification system based on morphologic characteristics (Table 90-3). More recently, the World Health Organization (WHO) has developed a classification system that expands the number of AML subtypes and better incorporates genotypic information, which is important in determining prognosis.² Cells of myeloid origin commonly contain myeloperoxidase enzymes and express surface markers CD13, CD33, CD14, and CD15. Specific clonal chromosomal abnormalities are associated with several AML subtypes. These aberrations include gains or losses of whole chromosomes on the long (q) or short (p) arms of chromosomes, as well as a variety of structural rearrangements (e.g., translocations, inversions, insertions). A number of cytogenetic abnormalities in AML have suggested molecular-clinical syndromes, which are now being analyzed at the genetic level. The translocation t(15;17)(q22;q12) is the cytogenetic hallmark of acute promyelocytic leukemia (AML-M3). This translocation splits the retinoic acid receptor gene on chromosome 17 and blocks expression of retinoic acid–controlled genes required for cell differentiation. Treating patients with acute promyelocytic leukemia with all-*trans* retinoic acid (ATRA, tretinoin) has caused complete morphologic responses. This example shows how defining cytogenetic or chromosomal abnormalities in acute leukemia can be critical to understanding its pathophysiology and identifying optimal treatments. Currently, three chromosomal abnormalities are recognized as being associated with a good prognosis^{6,7}: t(8;21), t(15;17), and inv 16. In con-

trast, several chromosomal abnormalities have been associated with a relatively poor prognosis, including inv 3, del 5, del 5q, del 7, and del 7q; trisomy 8; and complex (three or more unrelated cytogenetic abnormalities) cytogenetics. These chromosomal findings are increasingly being used to guide treatment decisions. For example, patients with cytogenetic findings associated with a poor prognosis may be considered for more aggressive postremission therapy such as high-dose chemotherapy with stem cell support (i.e., transplantation). Other poor prognostic signs in AML include age older than 60 years at the time of diagnosis, a pre-existing hematologic disorder (e.g., myelodysplastic syndrome), prior exposure to a chemotherapy agent (e.g., a secondary leukemia), and poor baseline performance status.

D.M. has FAB-M2 (myelomonocytic) AML. Approximately 10% to 20% of patients with FAB-M2 acute leukemia have a translocation of t(8;21)(q22;q22).⁶ This translocation is usually seen in young patients such as D.M. and is associated with a favorable response to therapy. D.M.'s bone marrow has been sent for cytogenetic analysis; however, results will not be available for several days. Although the cytogenetic analysis will not alter recommendations for induction therapy for D.M., these findings, in combination with other prognostic features, do influence postremission therapy recommendations.

Treatment

Goal of Therapy

2. What is the goal of treatment, and what type of therapy is indicated for D.M. at this time?

The leukemic cells populating D.M.'s blood are abnormal and incapable of fighting infection. Their rapid proliferation is also suppressing RBC and megakaryocyte production in the bone marrow. D.M. is at substantial risk for both life-threatening infections and bleeding complications. The goal of the initial chemotherapy is to clear the bone marrow and peripheral blood of all blast cells in the hope that normal blood cell components can regenerate.

Induction Therapy

Standard induction chemotherapy for AML includes an anthracycline (either daunorubicin or idarubicin) and cytarabine, an antimetabolite. One commonly used regimen includes idarubicin 12 mg/m²/day on days 1 to 3 as an intravenous (IV) bolus injection, plus cytarabine 100 mg/m²/day as a continuous IV infusion on days 1 to 7. This combination (7 + 3) is one of the most successful chemotherapy regimens used to treat AML, with complete response (CR) rates of 60% to 80%.⁶ Continuous infusions of cytarabine are preferred because these regimens produce higher response rates than bolus injections during induction therapy.^{8,9} Using higher doses of cytarabine by increasing the number of days of therapy to 10, doubling the daily dose to 200 mg/m², and using high dose cytarabine (HiDAC) (0.5–6.0 g/m²/day) has not shown consistent improvement in complete remission rates or survival.¹⁰ Adding etoposide for 7 days may increase the CR rate, response duration, and survival in patients younger than 55 years.¹¹ However, other investigators have not shown a benefit with the addition of etoposide to the standard 7 + 3 induction regimen.¹²

If a patient presents with a very high WBC count, he or she may experience complications associated with hyperviscosity of the blood (e.g., ringing ears, stroke, blindness, or headache as a result of impaired oxygen delivery to the CNS, pulmonary infarction). Because it may take several days for cytarabine and idarubicin to substantially decrease the WBC count, the patient may receive hydroxyurea 2 to 4 g orally (PO) or undergo leukapheresis to quickly reduce the WBC count.

TRETINOIN AND ARSENIC TRIOXIDE FOR ACUTE PROMYELOCYTIC LEUKEMIA

3. Would induction therapy for other subtypes of AML differ from that described previously?

Induction therapy is standard for all types of AML, with one exception: acute promyelocytic leukemia (APL) or FAB-M3. APL is uniquely characterized by the t(15;17) translocation that fuses the PML gene on chromosome 15 to the retinoic acid receptor-alpha (*RAR-α*) gene on chromosome 17. Severe coagulopathy is also common in patients with APL at the time of diagnosis or during induction therapy. Myeloperoxidase and procoagulant substances released from granules contained within the leukemia cells cause these complications. As discussed previously, tretinoin or ATRA induces promyelocyte differentiation and maturation.¹³ In clinical trials, ATRA has induced complete remissions in approximately 90% of patients with APL.¹⁴ Serial bone marrow aspirations after initiation of ATRA therapy demonstrate progressive differentiation without hypoplasia.^{14,15} Unfortunately, ATRA typically induces brief remissions. A number of trials have investigated combination treatment with chemotherapy and ATRA.^{16,17} Current evidence supports the use of concurrent ATRA plus conventional chemotherapy for induction, with ATRA starting 2 days before chemotherapy. In addition, postremission therapy should include at least two cycles of an anthracycline-based regimen.^{17,18} Maintenance therapy with intermittent ATRA has been shown to decrease the relapse rate.^{16,19}

ATRA therapy, although avoiding life-threatening myelosuppression, can produce significant toxicities, including the retinoic acid syndrome (RAS), which manifests as fever, weight gain, respiratory distress, lung infiltrates, pleural or pericardial effusion, hypotension, and acute renal failure.²⁰ If

RAS develops, corticosteroid therapy (dexamethasone 10 mg BID for at least 3 days) should be initiated.²¹ In patients receiving concurrent ATRA and chemotherapy, ATRA may be stopped if the patient has received ATRA for at least 20 days or if symptoms of RAS are life threatening or not improving with dexamethasone. Patients with leukocytosis seem to be more likely to experience RAS. Concurrent use of chemotherapy and ATRA has been reported to reduce the likelihood of RAS.²¹ ATRA also causes dryness of the lining of the mouth, rectum, and skin; hair loss; skin rash; blepharitis; conjunctivitis; corneal erosions; muscle weakness; nail changes; depression; elevated liver enzymes; and high cholesterol. Despite the risk of serious complications and death during induction therapy, the long-term disease-free survival (DFS) rate of patients with APL is superior compared with other AML subtypes. Approximately 75% of patients who receive ATRA-based induction and maintenance therapy are alive 3 to 5 years after diagnosis.¹⁹

Arsenic trioxide (ATO) has also been evaluated in the treatment of patients with APL. Clinical trials have confirmed that ATO is highly effective for the treatment of patients with relapsed APL, with complete remission rates up to 85%.²² Preliminary results suggest no benefit to adding ATRA to ATO in this setting; however, future studies will determine whether ATO in combination with other strategies will yield superior outcomes.²³ There are several clinically significant adverse effects associated with ATO use. QT interval prolongation and *torsades de pointes* have been reported in a small number of patients, and warrant careful monitoring and management. Signs and symptoms of RAS were also reported, suggesting that this syndrome is not specific to therapy with ATRA and may be more appropriately referred to as APL syndrome. The monitoring and management of APL syndrome with ATO are the same as with ATRA. Coagulopathy, leukocytosis, neuropathy, nausea and vomiting, cough, headache, rash, hypokalemia, and hyperglycemia have also been frequently reported with ATO therapy and should be monitored appropriately.

COMPLICATIONS OF INDUCTION THERAPY

Tumor Lysis Syndrome

4. Twenty-four hours after D.M.'s induction chemotherapy was initiated, the following laboratory values were obtained: WBC count, 28,000/mm³ (normal, 4–11); K, 5.3 mEq/L (normal, 3.5–5.5); phosphorus, 6.0 mg/dL (normal, 2.5–5.5); uric acid, 9.8 mg/dL (normal, 2.5–8); calcium, 6.0 mg/dL (normal, 9.0–11.5); and creatinine, 1.6 mg/dL (normal, 0.8–1.2). Why have these laboratory values changed so suddenly? Could they have been minimized or prevented? How should these metabolic disturbances be managed?

[SI units: WBC count, 58 × 10⁶/L; K, 5.3 mmol/L; phosphorus, 1.94 mmol/L; uric acid, 582.9 mmol/L (normal, 148.7–475.84); calcium, 1.5 mmol/L (normal, 2.25–2.875); creatinine, 141.44 mol/L (normal, 88.4–176.8)]

D.M. presented with a very high number of peripheral blasts. Consequently, chemotherapy resulted in rapid lysis of the blast cells and the release of their cellular contents into the blood. A hypercellular bone marrow with a very high number of blast cells can also lead to rapid lysis of the blast cells and the release of cellular contents. Typical metabolic abnormalities associated with tumor lysis syndrome (TLS) are hyperuricemia, hyperphosphatemia, hypocalcemia, and uremia. These

Table 90-4 Complications Associated With Acute Tumor Lysis Syndrome

| | |
|-------------------|---------------------------|
| Hypocalcemia | Renal failure |
| Hyperkalemia | Electrocardiogram changes |
| Hyperphosphatemia | Metabolic acidosis |
| Hyperuricemia | |

disturbances may lead to arrhythmias and acute renal failure (Table 90-4). Patients can present with TLS, but, most commonly, TLS occurs 12 to 24 hours after chemotherapy is initiated. TLS may occur after therapy for other malignancies, particularly in those with a high tumor burden, such as high-grade lymphomas and ALL. TLS rarely occurs after therapy for solid tumors.

Before chemotherapy is initiated, leukapheresis to reduce D.M.'s peripheral WBC count may minimize TLS. Leukapheresis is not routinely done unless the patient is experiencing symptoms of hyperviscosity. Patients should receive IV hydration (2–3 L/day) beginning 24 to 48 hours before chemotherapy to (a) maintain renal perfusion, (b) optimize the solubility of tumor lysis products, and (c) compensate for fluid losses due to fever or vomiting. Alkalinization of the urine may also reduce or prevent uric acid from precipitating in the renal tubules and collection ducts by maintaining the urate in its ionized state. However, increased pH may increase the risk of precipitating calcium phosphate in both soft tissue and kidney tubules, and it may aggravate hypocalcemia.²⁴

Allopurinol (a xanthine oxidase inhibitor that blocks the metabolism of uric acid) should be started before chemotherapy to minimize the complications of TLS. The recommended adult dosage is 300 to 600 mg/day. D.M.'s serum uric acid and electrolytes should be monitored at least two to three times a day for 24 to 48 hours after initiating chemotherapy. If severe abnormalities occur, more aggressive measures should be initiated. Allopurinol may be discontinued if the serum uric acid is within normal limits and the WBC count is low. Rasburicase, a recombinant urate oxidase product, can also be used as prophylaxis in patients who are at high risk of developing TLS or for the treatment of patients who present with or develop TLS. Rasburicase acts as a catalyst in the enzymatic oxidation of uric acid to allantoin, which is five to ten times more soluble than uric acid and undergoes rapid renal excretion. The recommended dose of rasburicase for both prevention and treatment of TLS is 0.2 mg/kg/dose. Rasburicase results in a rapid reduction in serum uric acid (within 4 hours of administration) and is generally well tolerated.²⁵ Most of the clinical data for rasburicase is in the pediatric population; however, data from compassionate use trials suggest that rasburicase is equally effective in adults.^{26,27} Although rasburicase has demonstrated excellent efficacy and tolerability, its optimal role in the prevention and management of hyperuricemia in adults remains to be defined because of its high cost and lack of a randomized trial comparing its effect with other interventions.

Although D.M.'s serum potassium was low on admission, it has increased significantly as a result of tumor cell lysis. For this reason, replacement potassium therapy is not recommended before chemotherapy in patients in whom TLS is highly likely. In extreme circumstances, dialysis may be required to correct

severe metabolic and electrolyte disturbances associated with TLS.

Myelosuppression

5. D.M. received allopurinol therapy and aggressive hydration throughout her induction chemotherapy. The metabolic abnormalities gradually resolved as her WBC count declined and tumor lysis diminished. What other complications may occur during induction therapy. Can they be treated?

Patients receiving cytarabine and idarubicin induction therapy develop profound anemia, granulocytopenia (e.g., WBC count $<100/\text{mm}^3$) and thrombocytopenia ($<20,000$ platelets/ mm^3) shortly after therapy is initiated that persists for 21 to 28 days. All infectious complications must be considered life threatening in severely immunocompromised patients such as D.M. (see Chapter 68).

Filgrastim (granulocyte colony-stimulating factor [G-CSF]) and sargramostim (granulocyte-macrophage colony-stimulating factor) stimulate leukemic cells as well as normal granulocyte precursors in vitro; however, several studies have demonstrated that these agents, when used as an adjunct to AML chemotherapy, are safe and do not adversely affect disease outcome.^{28,29} Most studies have demonstrated that CSFs can modestly decrease the length of profound neutropenia, and sometimes reduce the incidence of infection-related morbidity, the duration of systemic antibiotic and antifungal therapy, and the number of hospitalization days. Guidelines published by the American Society of Clinical Oncology recommend that patients older than 55 years are most likely to benefit from CSF administration after completion of induction chemotherapy.³⁰ Despite the reduction in short-term complications, administration of CSFs after induction chemotherapy does not appear to have an impact on the rate of complete remissions or the long-term outcomes of the disease.

Severe thrombocytopenia may result in bleeding episodes that range in severity from oozing gums to massive GI hemorrhage. Serious bleeding complications can usually be avoided if patients receive platelet transfusions when their platelet counts decrease to $<10,000/\text{mm}^3$ or when patients experience bleeding. Currently, there are no data to support the use of interleukin (IL)-11 (oprelvekin) or investigational thrombopoietic agents in this setting. Because D.M. is premenopausal, she has a significant risk of excessive vaginal bleeding if she begins menstruating while she is thrombocytopenic. The menstrual cycle can be suppressed with daily, uninterrupted oral contraceptives or progesterone (e.g., medroxyprogesterone 10–20 mg/day PO). If spotting occurs, dosages should be increased until bleeding stops. After D.M.'s platelet count returns to normal, suppressive therapy can be discontinued.

Other common drug-induced complications that may occur during induction therapy include nausea and vomiting, mucositis, fever, and skin rash (see Chapters 7 and 89).

Postremission Therapy

Rationale

6. After completion of her induction chemotherapy, D.M.'s WBC count fell to $<100/\text{mm}^3$, and her platelet count fell to $5,000/\text{mm}^3$. She received platelet transfusions approximately

every 2 to 3 days to prevent bleeding complications. On day 9, she developed a fever of 38.8°C. She was started immediately on empiric, broad-spectrum antibiotic therapy, which resolved her fever. On day 29, her WBC count was 5,600/mm³ with a normal differential, and her platelet count was 168,000/mm³. She received packed RBC transfusions on two separate occasions when her Hct fell to <30%. A repeat bone marrow aspirate showed no evidence of persistent leukemia, and D.M. was told that her leukemia was in remission. Nevertheless, her oncologist recommended additional chemotherapy, and D.M. questions why this is necessary. Is postremission therapy necessary, and if so, what therapeutic options are available to D.M.?

Although >60% of patients treated for AML achieve complete remission after induction therapy, the median duration of the remission is only about 12 to 18 months, and only 20% to 40% of patients have a DFS exceeding 5 years.¹⁰ Short remissions have been attributed to proliferation of clinically undetectable leukemic cells. Thus, the rationale for administering chemotherapy after remission is to eradicate these residual cells.

In AML, postremission therapy (also referred to as “consolidation therapy”) includes two to four cycles of chemotherapy. Clinical trials have shown that high-dose postremission therapy results in a higher percentage (30%–40%) of long-term (>2–5 years) disease-free survivors than either no or low-dose postremission chemotherapy.^{31,32} Postremission therapy regimens usually include HiDAC alone or in combination with one or more agents such as mitoxantrone, idarubicin, or etoposide. Patients 60 years of age and older or those with comorbid disease may not be able to tolerate this intensive postremission therapy. In these circumstances, the risk of life-threatening toxicity may outweigh the potential benefits of postremission chemotherapy. Allogeneic hematopoietic cell transplantation (HCT) has also been studied in the postremission treatment of AML and is addressed in Chapter 92.

Administration of chemotherapy (thioguanine, methotrexate) and biologicals (IL-2) for a prolonged period has been investigated to see if it can prolong survival. This is often referred to as maintenance therapy. With the exception of APL, maintenance chemotherapy has not been shown to improve survival in patients with AML.

High-Dose Cytarabine

7. D.M. does not have any siblings that would be a compatible donor for an allogeneic hematopoietic cell transplant. Consequently, her oncologist recommends three courses of high-dose cytarabine (HiDAC) as postremission therapy while an unrelated compatible donor is sought. One week after she was declared to be in remission, D.M. is readmitted to the hospital to receive cytarabine 3 g/m² Q 12 hr, over 3 hours, on days 1, 3, and 5. What are the potential acute and delayed toxicities associated with HiDAC, and how can these effects be prevented?

At conventional dosages of 100 to 200 mg/m²/day, adverse effects associated with cytarabine include myelosuppression, fever, and skin rashes. Occasionally, liver enzymes rise transiently. The side effect profile for HiDAC (>1 g/m²/day), however, is very different and can produce major cerebellar, ocular, and skin toxicities.^{33,34}

CEREBELLAR TOXICITY

Cerebellar toxicity is a significant problem in patients receiving HiDAC therapy. See Chapter 89 for details regarding cytarabine-induced cerebellar toxicity.

OCULAR TOXICITY

Ocular toxicity results from damage to corneal epithelium, when cytarabine penetrates the epithelium through the anterior chamber of the eye or tears. Symptoms include conjunctivitis, excessive lacrimation, “burning” ocular pain, photophobia, and blurred vision. Artificial tears (two drops every 4–6 hours) administered concurrently with HiDAC generally prevents these symptoms. Corticosteroid eyedrops should be used if symptoms of conjunctivitis occur.³⁵

DERMATOLOGIC TOXICITY

Dermatologic toxicity may be manifested as a rash covering most of the body (similar to that seen with conventional doses) or plantar-palmar erythema. Desquamation of the palms and soles can occur with plantar-palmar erythema, causing significant pain and allowing for pathogenic organisms to enter the body.

ACUTE LEUKEMIA IN THE ELDERLY

8. Would recommendations for induction and postremission therapy differ if D.M. were elderly (60 years of age or older)?

The incidence of AML gradually increases with age, with the median age of affected patients between 65 and 70 years. Several clinical trials have shown lower complete remission rates, as well as reduced DFS and overall survival (OS) in patients older than 55 years. The reason for this is most likely multifactorial, including a decreased tolerance to chemotherapy, comorbidities, and compromised organ function, as well as inherent biological differences between AML in the elderly and in younger patients.³⁶ Poor prognostic factors more common in the elderly include a history of preleukemic syndrome (myelodysplastic syndrome), poor cytogenetic abnormalities, high expression of multidrug-resistant glycoprotein MDR1, and prior radiation therapy or chemotherapy.³⁷ Whether the elderly should receive aggressive chemotherapy is often debated.³⁸ Two studies have evaluated a standard induction regimen versus alternatives of low-dose or palliative chemotherapy.^{39,40} Both studies demonstrated superior prolonged survival in the standard therapy arms at the cost of increased treatment-related mortality. It must be taken into consideration, though, that these studies were performed approximately 20 years ago and that improvements in supportive care may significantly improve the treatment-related mortality observed in these studies. Nevertheless, many oncologists believe aggressive therapy is warranted in most elderly patients given the rapid progression of the disease and certain death within weeks if the disease is not treated.

The decision of postremission therapy is a difficult decision in elderly patients because they have a higher risk of morbidity and mortality, and, more important, no clinical trials have demonstrated the benefit of postremission therapy specifically in the elderly. The intensity of the regimens must often be attenuated because there is risk of serious toxicities. This is particularly true with HiDAC therapy due to the increased risk of cerebellar toxicity in the elderly. Studies have shown that

postremission therapy with low-dose cytarabine (100 mg/m² by continuous infusion for 5 days) is as effective as HiDAC and better tolerated in elderly patients.³¹

Refractory or Resistant Acute Myeloid Leukemia

9. A.W., a 65-year-old man, is 30 days post induction therapy with 7 + 3. His neutrophil count has been <200/mm³ since day 12. Bone marrow biopsy reveals 60% blasts, confirming the diagnosis of refractory AML. What are treatment options for A.W. at this time?

Given the decreased efficacy and tolerability of myelosuppressive chemotherapy in the elderly, novel immunotherapeutic approaches are being developed. Gemtuzumab ozogamicin, a humanized anti-CD33 antibody coupled to calicheamicin, an anthracycline-like toxin, is approved for relapsed or refractory AML in patients 60 years and older who are not considered candidates for further cytotoxic chemotherapy.⁴¹ CD33 is a cluster differentiation antigen present on the majority of blast cells, but not on hematopoietic stem cells. The conjugation of an anthracycline to the anti-CD33 antibody targets the delivery of the toxin to the CD33-positive blast cells. A total of 142 patients participating in open-label trials were treated with gemtuzumab 9 mg/m² on days 1 and 15.⁴¹ Gemtuzumab provided an overall response (OR) rate of 30%. Myelosuppression and thrombocytopenia appear to be of longer duration compared to conventional chemotherapy regimens in this setting; however, it is associated with less nonhematologic side effects such as mucositis, nausea and vomiting, and alopecia. Infusion-related adverse events such as rigors, chills, and fever are common and are severe in approximately 30% of patients. This drug may be a reasonable alternative to additional chemotherapy for A.W.

CHRONIC MYELOID LEUKEMIA

Signs and Symptoms

10. S.E., a 66-year-old white female, recently had a routine CBC drawn during her annual checkup. Her CBC showed a WBC count of 60,000/mm³ with 90% neutrophils, Hct of 32%, and a platelet count of 300,000/mm³. The only pertinent physical finding was splenomegaly. A bone marrow aspirate revealed a hypercellular marrow with less than 10% blasts. Cytogenetic analysis confirmed a diagnosis of Philadelphia chromosome-positive CML. Explain S.E.'s high WBC counts. What are the possible clinical consequences of these abnormal values?

[SI units: WBC count, 60 × 10⁶/L with 0.9 neutrophils; Hct, 0.32, platelets 900 × 10⁶/L]

CML is a myeloproliferative disorder characterized by unregulated stem cell proliferation in the bone marrow and an increase in mature granulocytes in the peripheral blood. Common clinical symptoms on presentation include fatigue, fever, anorexia, and weight loss. Approximately 50% to 70% of patients present with a leukocyte count >100,000/mm³. Symptoms of hyperleukocytosis and hyperviscosity include priapism, headaches, tinnitus, and cerebrovascular accidents. On physical examination, the most common abnormal finding is splenomegaly, which results from increased activity of the reticuloendothelial system to remove increased numbers of

WBCs. Although these symptoms are common, approximately 30% to 40% of patients are asymptomatic at presentation, and the initial suspicion for CML is based solely on an abnormal CBC.⁴²

Clinical Course and Prognosis

11. What is the expected disease progression for S.E. and others with newly diagnosed CML?

The natural history of CML can be divided into three distinct phases: chronic phase, accelerated phase, and blastic phase. Early in the disease (chronic phase), patients exhibit leukocytosis and associated symptoms as described previously. Bone marrow examination and peripheral blood smear reveal <10% immature blast cells.⁴³ The duration of the chronic phase may range from a few months to many years. Because symptoms may be nonspecific and relatively minor, CML may remain undiagnosed until patients progress into more advanced stages. The annual transition rate from chronic phase to accelerated phase is 5% to 10% in the first 2 years and 20% in subsequent years. Common signs and symptoms suggestive of this transition include increased leukocytosis, anemia, increased splenomegaly, fever, and bone pain.

During the second phase of the disease, the accelerated phase, leukocytosis progresses (despite therapy), and an increased number of immature leukocytes (blasts) appear in the peripheral blood. Patients often report significant symptoms. The accelerated phase generally lasts <6 weeks. The final phase of the disease (blastic phase or blast crisis) is characterized by a predominance of immature cells. Bone marrow examination of the peripheral blood at this time reveals >20% blasts.⁴³ During this phase, CML is indistinguishable from AML with the exception of cytogenetics. In blast crisis, patients often experience bone pain, fatigue, worsening anemia, infections, and bleeding complications. The blast phase is often refractory to conventional induction regimens for AML, and median survival is approximately 5 months.⁴² Because less than 10% blast cells are present in S.E.'s bone marrow, she is in the chronic phase of the disease.

12. What is the significance of the finding of the Philadelphia chromosome?

The cytogenetic hallmark of CML is the Philadelphia chromosome, which is present in more than 90% of cases. Cytogenetic analysis reveals a translocation of chromosomes 9 and 22 t(9;22)(q34;q11).⁴⁴ This translocation creates a new protein (BCR-ABL) that has unregulated tyrosine kinase activity. The three major mechanisms that have been implicated in the malignant transformation by unregulated tyrosine kinase include abnormal cell cycling, inhibition of apoptosis, and increased proliferation of cells.⁴⁴ Identifying the Philadelphia chromosome helps confirm the diagnosis of CML and helps with monitoring the efficacy of treatment.

Treatment

13. What therapy is appropriate for S.E.?

In newly diagnosed patients who present with very high leukocyte counts (>100,000/mm³), the initial goal of therapy

is to reduce leukocytosis and its related symptoms.⁴³ Hydroxyurea is still the most common agent used for initial leukocyte reduction. Treatment is initiated with 2 g/day PO, and the dosage is titrated to a WBC count of <20,000/mm³. A small dosage decrease often permits a considerable rise in leukocyte count in 1 or 2 days. Hydroxyurea is well tolerated and is relatively free of nonhematologic side effects. Although effective for initial control of high leukocyte counts, hydroxyurea is inferior to other treatments for long-term control of CML.

The ultimate goal of therapy for CML is to cure patients of their disease. The only curative therapy for CML to date is allogeneic HCT. The best results are achieved with HLA-matched related donors; however, HLA-matched unrelated donor transplants in select patients can also yield favorable long-term DFS rates.⁴⁵ When patients are transplanted during the blast phase, only 10% to 20% survive >5 years. If patients are transplanted during the chronic phase, 50% to 60% are disease free at 5 years.⁴⁶ The highest rate of prolonged DFS occurs in younger patients who undergo transplantation within 1 year of initial diagnosis during the chronic phase.⁴⁷

Because most patients newly diagnosed with CML are not transplant candidates because of their age and lack of a suitable donor, alternative therapies must be considered. When cure is not an option, the primary goals of therapy are to prolong survival, prevent progression of disease, and attain a complete hematologic and/or cytogenetic remission. The definition of a complete hematologic response is a reduction in the leukocyte count to <10,000/mm³ and the platelet count to <450,000/mm³. A cytogenetic response is defined by the percentage of cells in metaphase that are positive for the Philadelphia chromosome in the bone marrow (Table 90-5).

Imatinib

In May 2001, the U.S. Food and Drug Administration (FDA) approved imatinib mesylate (Gleevec) for the treatment of patients with CML. Imatinib is a tyrosine kinase inhibitor that occupies the adenosine triphosphate binding site of several tyrosine kinase molecules and prevents phosphorylation of substrates that are involved in regulating the cell cycle. Imatinib was initially tested in patients with chronic phase CML who were refractory to or intolerant of interferon (IFN)-based therapy. Ninety-eight percent of patients receiving 300 mg or more per day of imatinib achieved a complete hematologic response, whereas 31% of patients at the same dose achieved a major cytogenetic response.⁴⁸ Imatinib has also shown efficacy in accelerated and blastic phase CML.^{49,50} These impressive results set the stage for the pivotal International Randomized Study of Interferon and STI571 (IRIS) trial, which compared imatinib

Table 90-6 Response Rates in International Randomized Study of Interferon and STI571 Trial

| Response | % Imatinib (N = 553) | % Interferon Plus Cytarabine (N = 553) |
|----------------------|-------------------------|---|
| Complete hematologic | 95.3 (93.2–96.9) | 55.5 (51.3–59.7) |
| Major cytogenetic | 85.2 (81.9–88.0) | 22.1 (18.7–25.8) |
| Complete cytogenetic | 73.8 (69.9–77.4) | 8.5 (6.3–11.1) |
| Partial cytogenetic | 11.4 (8.9–14.3) | 13.6 (10.8–16.7) |

with the combination of IFN- α plus low-dose cytarabine in patients with newly diagnosed CML in the chronic phase. A total of 1,106 patients were randomly assigned to either imatinib (400 mg PO daily) or IFN plus cytarabine.⁵¹ For patients on imatinib, the dose could be escalated to 400 mg BID if no hematologic response was seen within 3 months or if no cytogenetic response was seen within 12 months. All primary and secondary end points of the trial, including rates of complete hematologic remission, major and complete cytogenetic response, and freedom from progression to the accelerated phase or blast crisis, demonstrated superiority of imatinib over IFN plus cytarabine (Table 90-6). Estimated survival rates at 18 months between the two arms were not significantly different (97.2% vs. 95.1% for imatinib and IFN plus cytarabine, respectively; $p = 0.16$). The lack of survival difference is most likely due to a large percentage of patients (89%) in the IFN plus cytarabine arm who crossed over to the imatinib arm due to lack of efficacy or intolerance to therapy. In addition to superior efficacy, imatinib was very well tolerated. The most common toxicities reported with imatinib are superficial edema, nausea, muscle cramps, and rashes. Only 12% of patients in the imatinib arm discontinued therapy due to adverse events compared with 33% in the IFN plus cytarabine arm. More mature data from this trial, with a median follow-up of 60 months, demonstrated an 89% OS of patients who received imatinib as initial therapy.⁵² This landmark trial clearly showed the superiority of imatinib over IFN plus cytarabine in the treatment of patients with newly diagnosed CML in chronic phase. Based on these results, imatinib is now considered the front-line standard of care for patients with newly diagnosed CML in chronic phase. Practical management strategies for dosing, treatment and prevention of toxicities, and possible drug interactions have been reviewed extensively elsewhere.⁵³ The excellent results seen with imatinib challenge the role of allogeneic stem cell transplantation as front-line therapy. Clinicians and patients must carefully evaluate the potential risks and benefits of each treatment modality in order to make the best therapeutic decision for each individual situation.

Table 90-5 Definition of Cytogenetic Response in Chronic Myeloid Leukemia

| Cytogenetic Response ^a | Philadelphia (Ph) Chromosome-Positive Cells (%) |
|-----------------------------------|---|
| Complete | 0 |
| Partial | 1–35 |
| Minor | 36–65 |
| Absent | >65 |

^aMajor response is defined as complete or partial responses.

Relapsed and Refractory Disease

14. On routine follow-up, cytogenetics analysis of S.E.'s bone marrow demonstrates a rising percentage of Philadelphia chromosome-positive cells. S.E. has her imatinib dose increased to 400 mg BID. After 3 months at the higher dose, S.E. continues to demonstrate cytogenetic relapse. A bone marrow biopsy results in less than 10% leukemic blast cells, demonstrating chronic phase CML. What available options are there for S.E.?

Based on the most recent update of the IRIS trial, approximately 30% of patients initially treated with imatinib will have to discontinue therapy either due to lack of therapeutic benefit or intolerable side effects. Dasatinib, an orally available, multitargeted kinase inhibitor that is active against BCR-ABL and SRC family kinase, has recently been approved for the treatment of CML patients who are refractory to or intolerant of imatinib. Dasatinib 70 mg BID has demonstrated activity in all phases of CML.^{54,55} For patients in chronic phase after failure to imatinib, complete hematologic and cytogenetics responses were seen in 90% and 52% of patients, respectively.⁵⁶ Non-hematologic toxicities were mild to moderate, and cytopenias could effectively be managed with dosage reductions.

CHRONIC LYMPHOCYTIC LEUKEMIA

Signs and Symptoms

15. B.R., a 66-year-old male, presents to his physician with a persistent semiproductive cough and increased fatigue. A routine CBC revealed an Hgb of 13.0 g/dL, a WBC count of 34,000 mm³ (80% lymphocytes), and a platelet count of 175 × 10⁶/L. Blood pressure was 120/70 mmHg, heart rate 64 beats/minute, and respiratory rate 23 breaths/minute. He was afebrile. Physical examination was unremarkable. He was prescribed azithromycin for possible community-acquired pneumonia and scheduled for a return visit in 3 weeks. At that time, his CBC results were Hgb 13.2 g/dL, WBC count 32,000 mm³ (82% lymphocytes), and platelets 168 × 10⁶/L. Physical examination was unchanged, the chest radiograph was clear, and his cough had resolved. B.R. was referred to a hematologist for evaluation of his persistent lymphocytosis. What is the most likely cause of persistent lymphocytosis in B.R.?

[SI units: Hgb 130 g/L (normal, 135–175); WBC count, 34 × 10⁹/L with 0.8 lymphocytes and 32 × 10⁹/L with 0.82 lymphocytes, respectively (normal, WBC 4.5–10 with 0.15–0.5 lymphocytes); platelets, 175 × 10⁹/L and 168 × 10⁹/L (normal, >150)]

CLL is a chronic lymphoproliferative disorder characterized by an excess of functionally incompetent B-cell lymphocytes derived from a single stem cell clone. CLL should be included in the differential diagnosis of any adult with persistent lymphocytosis (>5,000 lymphocytes/mm³ in peripheral blood). Additional causes of lymphocytosis include transient reactions to acute infections and viruses such as influenza or mononucleosis, as well as other hematologic malignancies, including lymphoma and ALL.

To differentiate between benign and malignant lymphocytosis, examination of the peripheral blood or bone marrow morphology by a hematologist or pathologist may be required. Patients with CLL commonly have lymphocytosis in both the peripheral blood and bone marrow, whereas patients with other disorders have a high percentage of atypical lymphocytes in the peripheral blood alone. The absence of fever or additional signs of infection without significant diagnostic or physical exam findings, together with the presence of mature peripheral blood lymphocytes, make CLL the most likely diagnosis for B.R. Cell surface marker staining (immunophenotyping) is required, and bone marrow biopsy with aspirate may be useful to determine the definitive diagnosis.⁵⁷

Staging and Prognosis

16. Bone marrow examination reveals normal cellularity with >30% of nucleated cells lymphocytes. The immunophenotype indicates that peripheral blood lymphocytes are predominately B cells and are positive for CD5, CD19, and CD20. A diagnosis of CLL is confirmed. What is the usual presentation and prognosis of CLL? What treatment is indicated at this time? B.R.'s cells were sent for routine cytogenetic analysis, which revealed a chromosome abnormality (Deletion 11q-). How does this impact his management?

CLL is the most common type of leukemia in adults, with more than 15,000 estimated new cases annually.⁵⁸ CLL is characterized as a disease of the older population. Median age at diagnosis is 65 years with 90% of patients older than age 50 at diagnosis.^{59,60} Approximately 40% of patients are asymptomatic at presentation and are diagnosed by routine CBC.⁵⁹ Predicting the clinical course of CLL remains a challenge as some patients experience an indolent course with a maintained quality of life, whereas others experience more aggressive disease and debilitation. Therefore, survival is variable and depends on the stage of disease at diagnosis. CLL is staged based on peripheral lymphocyte counts; enlargement of lymph nodes, liver, and spleen; and the presence of anemia and/or thrombocytopenia. The two most commonly used staging systems in clinical practice are included in Tables 90-7 and 90-8. B.R. would be classified as having early stage disease, with a historical median survival of ≥10 years.^{59,61}

An accepted treatment modality for early stage disease includes a conservative watchful waiting approach. No clear advantage has been demonstrated in treating asymptomatic patients in early stage disease with alkylator-based chemotherapy

Table 90-7 Binet Classification

| | Lymphocytosis ^a | Anemia ^b | Thrombocytopenia ^c | Number of Involved Nodes (Max 5) ^d | Median Survival (Years) |
|---|----------------------------|---------------------|-------------------------------|---|-------------------------|
| A | + | – | – | <3 | 12 |
| B | + | – | – | ≥3 | 7 |
| C | + | ± | ± | Any | 2–4 |

^aLymphocytes >5 × 10⁹/L in peripheral blood and >30% of total cells in the bone marrow.

^bHemoglobin <11 g/dL in men and <10 g/dL in women excluding immune-mediated etiology.

^cPlatelets <100,000 × 10⁹/L.

^dMaximum of five—cervical, axillary, inguinal, spleen, and liver—are counted as one area.

Adapted from reference 61.

Table 90-8 Modified Rai Classification

| Risk | Stage | Lymphocytosis ^a | Anemia ^b | Thrombocytopenia ^c | Lymphadenopathy | Hepatomegaly or Splenomegaly | Median Survival (Years) |
|--------------|-------|----------------------------|---------------------|-------------------------------|-----------------|------------------------------|-------------------------|
| Low | 0 | + | – | – | – | – | 10 |
| Intermediate | I | + | – | – | + | – | 7 |
| | II | + | – | – | ± | + | |
| High | III | + | + | – | ± | ± | 1.5–4 |
| | IV | + | ± | + | ± | ± | |

^aLymphocytes $>5 \times 10^9/L$ in peripheral blood and $>30\%$ of total cells in the bone marrow.

^bHemoglobin <11 g/dL excluding immune-mediated etiology.

^cPlatelets $<100,000 \times 10^9/L$.

From reference 409.

as compared to deferred treatment.⁶² The survival of patients with smoldering CLL is similar to an age- and gender-matched normal population.^{63,64} B.R. decides to delay treatment until he becomes symptomatic.

Biological explanations for the heterogeneity in the clinical course of CLL are under investigation. Recent advances have led to the discovery of chromosomal abnormalities (Deletions 17p-, 11q-), gene mutations (unmutated immunoglobulin variable region and p53), and serum or cell surface markers (increased B₂-microglobulin, zeta-associated protein-70, and CD 38 expression) that may confer poor prognosis and resistance to treatment.^{65–68} Because the clinical practice of risk-adapted therapy is still evolving, survival estimation or treatment initiation based on prognostic markers alone cannot be recommended outside a clinical trial.

Treatment

17. B.R. returns to the hematologist every 3 months and does well for about 2 years. At that time, physical examination reveals enlargement of cervical, inguinal, and axillary lymph nodes; hepatomegaly; and splenomegaly. His lymphocyte count has increased from 32,000/mm³ 6 months ago to 68,000/mm³ today. His Hgb is 11.7 g/dL, and his platelet count is $140 \times 10^6/L$. Is treatment now indicated?

[SI units: lymphocyte count, $32 \times 10^9/L$ and $68 \times 10^9/L$, respectively; Hgb, 117 g/L; platelets, $140 \times 10^9/L$]

Indications for treatment initiation in CLL include significant anemia and/or thrombocytopenia, progressive disease demonstrated by lymphadenopathy, hepatomegaly, splenomegaly, a lymphocyte doubling time <6 months, persistent B symptoms (fever, night sweats, and weight loss), and recurrent infection. Patient performance status, comorbid conditions, pharmacoecomic variables, and social support should all be taken into consideration when selecting treatment. B.R. should initiate treatment at this time to prevent further deterioration of his hematologic and immune function.

Initial Therapy

CHLORAMBUCIL

Historical therapy for CLL included use of an alkylating agent, most often oral chlorambucil or cyclophosphamide, with or without prednisone. A variety of daily and intermittent dosing schedules have been reported. The OR rate to chlorambucil was approximately 40% to 60%, but only 3% to 5%

achieved CR.⁵⁹ Chlorambucil therapy requires dose titration and frequent monitoring of blood counts and physical findings to maximize its efficacy and prevent toxicity. Chlorambucil use has diminished, and the use of purine analogs, including fludarabine and cladribine, is more common in clinical practice; however, chlorambucil remains an option for elderly patients or those with contraindications to other therapies.

FLUDARABINE

Fludarabine is now considered the single most active agent in the treatment of CLL. Fludarabine monotherapy at a dose range of 25 to 30 mg/m²/dose IV \times 5 days has shown a 70% to 80% OR rate, and CR rates of 20% to 30% with increased progressionfree survival (PFS).^{69–71} The impact of fludarabine on OS has yet to be demonstrated. Toxicities associated with fludarabine are typically mild and include fever, myelosuppression, and immunosuppression. Increased incidence of infection and autoimmune hemolytic anemia is also associated with fludarabine therapy. Infectious prophylaxis should be considered in elderly patients and patients with advanced disease or renal dysfunction.

Fludarabine has been combined with chemotherapy and monoclonal antibodies, including cyclophosphamide, epirubicin, and rituximab, in an effort to prevent multidrug resistance (MDR) and increase response. Although combination regimens including fludarabine have demonstrated higher response rates and PFS, no difference in OS has been consistently demonstrated.^{72–74} Additional toxicities of the combination regimen include higher rates of leucopenia, thrombocytopenia, nausea, vomiting, and alopecia.

A Cancer and Leukemia Group B trial compared single-agent fludarabine, single-agent chlorambucil, and the combination of fludarabine and chlorambucil.⁷⁰ Fludarabine monotherapy achieved higher CR rates than single-agent chlorambucil (20% vs. 4%, $p = 0.001$). Patients in the combination arm experienced more life-threatening toxicities, including infectious complication warranting early termination of this study arm. Patients receiving single-agent fludarabine had a 29% major infection rate versus 17% in patients treated with chlorambucil.⁷⁵

CLADRIBINE

The response to cladribine, a synthetic purine nucleoside, is superior to chlorambucil with OR and CR rates comparable to single-agent fludarabine.⁷⁶ A typical dose and schedule is 10 mg/m²/dose PO on days 1 to 5 monthly or on days 1 to 3 at Q 3 weeks. The toxicity profile is similar to fludarabine.

Although cladribine in combination with cyclophosphamide with or without mitoxantrone achieved higher CR rates and less MDR clones, no significant improvement in OR, PFS, or OS has been demonstrated.⁷⁷ A higher percentage of grade 3/4 neutropenia was seen with the combination regimens.

RITUXIMAB

Rituximab is a chimeric human-murine anti-CD20 monoclonal antibody. The CD20 surface antigen is expressed on a high percentage of CLL cells. Rituximab monotherapy as initial therapy for untreated patients at a dose of 375 mg/m² yielded OR and CR rates lower than those seen with cytotoxic therapy with a disappointing duration of response.⁷⁸ Therefore, rituximab therapy is reserved for combination therapy with cytotoxic agents and/or monotherapy maintenance after a CR has been achieved. The optimal dose and schedule for maintenance rituximab therapy is yet to be determined. All patients should be pretreated with acetaminophen and diphenhydramine to prevent a cytokine release reaction associated with rituximab infusion. Rituximab should be omitted from the first cycle of therapy or administered in a split dosing schedule when the absolute lymphocyte count is >25,000.⁷⁹ The rate of infusion should be titrated as tolerated to a maximum of 400 mL/hour. In addition, allopurinol may be required to prevent TLS.

A regimen of particular interest for initial treatment is the combination of fludarabine, cyclophosphamide, and rituximab (FCR). In a study of 224 patients with various stage CLL, patients were treated with fludarabine 25 mg/m² IV × days 1 to 3, cyclophosphamide 250 mg/m² IV × days 1 to 3, and rituximab 375 mg/m² IV × day 1 of cycle 1 escalated to 500 mg/m² in subsequent cycles. All patients received prophylaxis against *Pneumocystis (carinii) jiroveci* pneumonia (PCP), herpes simplex, and herpes zoster. CR was attained by 70% of patients.⁷³ Toxicity of this regimen included infusion, related reactions, nausea, vomiting, and myelosuppression. Grade 3/4 neutropenia was noted in 52% of treatment courses, with a major infection rate of 2.6%.

ALEMTUZUMAB

Alemtuzumab is another humanized conjugated anti-CD52 monoclonal antibody that has been used in CLL. Initial doses of 3 mg, titrated to 10 mg, and, ultimately, 30 mg were administered either subcutaneously or intravenously three times weekly. Although the role of alemtuzumab in first-line therapy is still under investigation, CR rates of approximately 20% and OR rates of 80% to 87% have been reported.^{80,81} Toxicities associated with alemtuzumab include infusion-related reactions (rigors, fever, dyspnea), neutropenia, and infectious complications.^{82,83} The role of alemtuzumab maintenance following cytotoxic therapy is also under investigation.⁸⁴

18. B.R. receives FCR as initial CLL therapy. After the third cycle, he has complete regression of his lymphadenopathy and hepatosplenomegaly, and his lymphocyte count decreases to 8,000/mm³. B.R. comes to clinic 2 years after completion of therapy. A CBC is obtained that reveals WBC count 55,000 mm³ with 70% lymphocytes, Hgb of 10 g/dL, and platelet count of 90 × 10⁹/L. On physical examination, B.R. is found to have some cervical, inguinal, and axillary lymphadenopathy with no palpable splenomegaly. He complains of excessive fatigue and fever.

A 2-month trial of oral chlorambucil is tried with no change in WBC count, lymphadenopathy, or symptoms. What therapies may be helpful to B.R. at this point?

[SI units: WBC count, 55 × 10⁹/L; Hgb 100 g/L; platelets, 90 × 10⁹/L]

Salvage Therapy

Second-line therapy should be selected based on criteria similar to those used for initial management. Relapsed patients are classified as fludarabine naive, fludarabine sensitive (relapse more than 6 months post treatment), or fludarabine refractory.

Fludarabine Naive and Fludarabine Sensitive

In a follow-up of 91 patients receiving salvage therapy after relapse, approximately 20% of patients achieved CR with either fludarabine monotherapy or a fludarabine combination regimen. Four of the five CRs reported with a fludarabine combination regimen used the combination of fludarabine and cyclophosphamide. In contrast, only 1 of the 28 patients receiving nonfludarabine regimens achieved CR.⁶⁹ Patients who failed to respond to initial fludarabine treatment did not respond to salvage treatment with a fludarabine-based regimen. In a subsequent study, the combination of FCR achieved a CR in 25% (45/177) of patients who had received at least one prior regimen. The majority of patients, 82% (145/177), had received prior fludarabine therapy. The estimated median OS was longer than historical data, although this remains to be confirmed.⁸⁵

Fludarabine Refractory

Alemtuzumab has been FDA approved for the treatment of refractory CLL. The OR rate is approximately 30%, with a 0% to 2% CR rate and an OS of 16 to 27.5 months.^{86,87} Activity has been demonstrated in patients who relapsed after or were refractory to alkylator or purine analog therapy, including those with the 17p- cytogenetic mutation, which is associated with resistance to most cytotoxic agents.⁸⁸ Alemtuzumab is least effective in patients with bulky (>5 cm) disease.⁸⁹

Major toxicities of alemtuzumab include infusion-related events, infections, and cytopenias. The occurrence of opportunistic infections, including PCP and cytomegalovirus (CMV) in as many as 15% to 25% of patients treated with alemtuzumab, warrants the use of prophylactic therapy. An increased risk of infection occurs 3 to 8 weeks post treatment, which corresponds to the T cell nadir. Viral prophylaxis should be continued for at least 2 months after completion of therapy and bacterial prophylaxis until the CD4 count is at least ≥200 cells/μL.^{90,91}

Younger patients (age younger than 55 years) with relapsed disease or high-risk features may benefit from autologous or allogeneic HCT. Both clinical and molecular remissions have been reported following autologous HCT, although no plateau in the OS curves has been demonstrated.⁹² No prospective randomized trial comparing autologous HCT versus chemotherapy for poor prognosis patients has been conducted. Allogeneic HCT is the only curative treatment for CLL to date. However, the high risk of treatment-related morbidity and mortality must be considered. Patients with relapsed CLL after fludarabine therapy or with high-risk features should be referred for an HCT consultation to determine candidacy.

Infectious Complications

19. Six weeks after the initiation of alemtuzumab, B.R. complains of progressive shortness of breath and fever. On questioning, he reveals that he quit taking his trimethoprim/sulfamethoxazole and valacyclovir because “I felt fine.” X-ray of the chest reveals bilateral infiltrates. B.R. is admitted to the hospital for further evaluation and treatment. A CBC reveals a WBC count of $22,000/\text{mm}^3$ with 80% lymphocytes and an absolute neutrophil count of $800/\text{mm}^3$, Hgb of 11 g/dL, and platelet count of $70 \times 10^9/\text{L}$. Quantification of serum immunoglobulins reveals profound hypogammaglobulinemia. What are the possible causes of B.R.’s pneumonia, and what treatment is indicated?

[SI units: WBC count, $22 \times 10^9/\text{L}$; Hgb 110 g/L; platelets, $70 \times 10^9/\text{L}$]

Infections contribute significantly to morbidity and mortality in CLL. Immunoglobulin deficiency, abnormal T-cell function, and neutropenia contribute to the increased rate of both common and opportunistic infections.⁹³ Opportunistic infections (OIs) associated with alemtuzumab therapy include PCP, invasive fungal infections, viral infections, and listeria. The most commonly reported OI associated with alemtuzumab is CMV reactivation. The use of supplemental intravenous immune globulin (IVI_g) is controversial, particularly in the setting of acute infection due, in part, to high cost.⁹⁴ However, in patients with low immunoglobulin levels and recurrent infections requiring hospitalization, supplementation can be recommended.⁹³ Hospitalization for broad-spectrum antimicrobials for neutropenic fever and a thorough workup for opportunistic etiologies is warranted for B.R. Because B.R. has a significant pulmonary infection requiring hospitalization with a documented hypogammaglobulinemia, IVI_g therapy may be considered if his condition worsens.

NON-HODGKIN LYMPHOMA

Clinical Presentation

20. R.G., a 39-year-old female, presents with complaints of swollen lymph nodes and occasional fevers and night sweats over the past month. Physical examination reveals marked cervical, supraclavicular, and inguinal lymphadenopathy >2 cm. Laboratory values are normal with the exception of a mild anemia (Hgb, 11 g/dL) and a slightly elevated LDH. HIV and hepatitis B surface antibody and antigen are negative. Excisional biopsy of a supraclavicular lymph node and immunophenotyping confirms a diagnosis of diffuse large B-cell (DLBC) lymphoma. Flow cytometry is positive for CD20, CD22, CD38, and CD45 surface markers. How does this type of lymphoma differ from other types of NHL?

Lymphomas are a heterogeneous group of disorders that arise from malignant transformation of lymphocytes (B cells, T cells, or natural killer [NK] cells) in the lymphoid system. Approximately 63,000 new cases of NHL are diagnosed annually, making it the fifth most common new cancer in both men and women in the United States.⁵⁸ More than 80% of NHL are B-cell neoplasms, with follicular lymphoma and DLBC as the most common subtypes.³

Hundreds of lymph nodes designed to process antigens present in the lymphatic fluid can be found throughout the body. Lymph nodes consist of a capsule, cortex, medulla, and

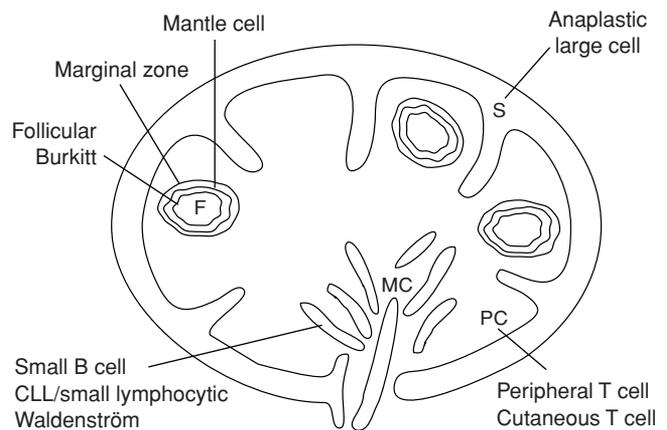

FIGURE 90-1 Sites of origin of malignant lymphomas in a lymph node according to anatomical and functional compartments of the immune system. CLL, chronic lymphocytic leukemia; F, follicles, or germinal centers; MC, medullary cords; PC, paracortex, or interfollicular areas; S, sinuses.

sinuses with anatomical and functional compartments, such as follicular (germinal) centers, follicular mantle, and interfollicular and medullary areas (Fig. 90-1). The growth pattern of lymphoma is described as follicular when malignant B cells take over normal germinal centers of lymph follicles. When the normal architecture of the lymph node is totally replaced by a uniform population of neoplastic lymphocytes, the growth pattern is described as diffuse. Other morphologic features, such as cell type, size, and appearance are determined to establish the specific subtype of NHL and are helpful in determining the best treatment.⁹⁵

Patients with slow-growing indolent lymphomas such as follicular or marginal zone lymphoma typically present with painless generalized lymphadenopathy that can be either transient or persistent. Presentation of fast-growing aggressive lymphomas, such as DLBC, is variable; most patients present with lymphadenopathy and extranodal involvement. The most common extranodal sites include the GI tract, skin, bone marrow, sinus, or central nervous system. Fever ($>38^\circ\text{C}$), night sweats, and weight loss ($>10\%$ of body weight over 6 months) are defined as B symptoms and may be associated with more advanced or aggressive disease. Approximately one-third of patients with aggressive lymphomas will report B symptoms.⁹⁶

Numerous classification systems have been used to categorize this diverse group of malignancies. One of the early classification systems was the WF, which classified NHLs into three broad groups (low, intermediate, and high grade) based on their morphology and clinical behavior. The REAL classification includes morphology, immunophenotype, cytogenetics, and clinical information. Clinical groupings—indolent, aggressive, and highly aggressive lymphomas—were added as part of the REAL classification (Table 90-9).^{97,98} The WHO updated the REAL classification, including additional disease categories and removing clinical groupings (Table 90-10).⁹⁸ For the purpose of this text, the grouping of indolent, aggressive, and highly aggressive will be used. R.G. has DLBC lymphoma, which can be classified as an intermediate-grade lymphoma (WF), aggressive (REAL), and mature B-cell neoplasm (WHO).

Table 90-9 Clinical Groupings Based on REAL Classification

| B-Cell Neoplasm | T-Cell and NK Cell Neoplasm |
|--|---|

Staging and Prognosis

Lymphoma is staged based on its distribution and the number of involved sites; presence or absence of extranodal involvement and constitutional symptoms using the Ann Arbor Staging Classification (Table 90-11).⁹⁹ In general, stage I or II is referred to as limited disease, whereas stage III or IV is considered advanced disease. The majority of patients with NHL present with advanced-stage disease. Due to the wide range of outcomes in patients with lymphoma, even within histologic subtypes, factors that predict both response to treatment and outcomes are used to determine overall prognosis and need for aggressive therapy. The International Prognostic Index (IPI) was designed to determine predictors of survival for aggressive lymphomas (Table 90-12). An age-adjusted model for patients younger than 60 years has also been developed (Table 90-13).¹⁰⁰ R.G. has advanced stage III_B disease, an aggressive lymphoma with a high/intermediate IPI; therefore, she will require treatment with systemic chemotherapy. Patients with a high-intermediate IPI have a 50% chance of being cured with standard therapy.⁹⁶

Treatment

Aggressive Lymphomas

21. R.G. had a consultation with a hematologist, and several treatment options were discussed. R.G. elected to receive combination chemotherapy consisting of cyclophosphamide, doxorubicin, vincristine, and prednisone with rituximab (R-CHOP)

every 21 days for six to eight cycles. She will then be referred to a radiation oncologist to determine whether she will receive additional benefit from radiation therapy. Is this considered standard therapy? What information should be included in her medication counseling?

Aggressive and highly aggressive lymphomas are potentially curable. Patients with nonbulky (<10 cm) localized stage I/II disease without B symptoms were typically treated with cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP) for three to eight cycles with or without radiotherapy. For patients with advanced disease; defined as bulky stage II or stage III/IV disease, CHOP for six to eight cycles had been established as the standard of care with a CR rate of 58%.¹⁰¹ Phase II trials comparing CHOP versus other regimens (m-BACOD, MACOP-B, ProMACE-CytaBOM) appeared promising; however, phase III data showed no difference in CR rate or 3-year survival. Increased toxicities, including fatal toxicity, was described in the non-CHOP arms.^{102,103}

The effect of dose intensity (reduction of treatment interval from 3 weeks to 2 weeks) on response was investigated in a study of patients ages 61 to 75 years comparing CHOP every 14 days with traditional CHOP every 21 days. A significant ($p < 0.05$) increase in CR, 5-year eventfree survival (EFS) and 5-year OS was observed in the every 14-day CHOP arm.¹⁰⁴ Growth factor support with G-CSF was required in the every 14-day arm to prevent treatment delay. These results were not reproducible in patients ages 18 to 60 years.¹⁰⁵

More recently, the Groups d'Étude des Lymphomas de l'Adult compared the 5-year follow-up of CHOP to R-CHOP in

newly diagnosed DLBC patients ages 60 to 80 years. Rituximab is a chimeric human monoclonal antibody to the B-cell surface antigen CD20. Although the exact mechanism is unknown, rituximab is believed to induce lysis through complement-mediated destruction, antibody-dependent cytotoxicity, and induction of apoptosis working in synergy with chemotherapy.¹⁰⁶ EFS, progression-free survival (PFS), DFS, and OS was higher in the R-CHOP arm. No additional significant long-term toxicity was apparent.¹⁰⁷ Because these results have been confirmed in both young and elderly patients, R-CHOP has become the standard of care in the United States.^{108,109}

The standard dose of rituximab is 375 mg/m² given intravenously in a variety of dosing schedules. The first infusion should be administered at a rate of 50 mg/hour and can be increased every 30 minutes to a maximum of 400 mg/hour. Subsequent infusions can be initiated at a rate of 100 mg/hour and increased to 400 mg/hour as tolerated. An infusion-related complex consisting of fever, chills, and rigors may occur during rituximab infusion, necessitating premedication. Other less common infusion-related symptoms include nausea, urticaria, pruritus, bronchospasm, angioedema, and hypotension. These reactions generally occur within 30 minutes to 2 hours from the start of the infusion (typically, the first dose) and resolve if the infusion is slowed or interrupted. Another less common side effect associated with rituximab is TLS, which occurs mostly in patients with a high number of circulating CD20-positive cells.¹¹⁰

Safety precautions prior to administration of the CHOP regimen include documentation of a normal cardiac ejection fraction (EF) and a baseline peripheral neuropathy assessment. Antiemetics should be given prior to administration to prevent nausea or vomiting, and a bowel regimen should be initiated to prevent constipation. Prophylaxis against febrile neutropenia with G-CSF post chemotherapy should be considered.

22. R.G. has a CR to R-CHOP therapy demonstrated by restaging studies performed after her third and sixth cycle of treatment. Every 3 months, she has a follow-up examination for disease recurrence. At her 15-month follow-up visit, she has radiographic evidence of disease recurrence in her abdomen. What treatment options are available to R.G. at this time?

High-dose chemotherapy immediately followed by autologous HCT should be considered for patients who relapse after conventional chemotherapy. Salvage chemotherapy regimens are administered prior to transplant to assure the disease is sensitive to additional cytotoxic therapy. Regimens use non cross-resistant agents such as ICE (ifosfamide, carboplatin, etoposide) ± rituximab, DHAP (dexamethasone, cytarabine, cisplatin) ± rituximab, and ESHAP (etoposide, methylprednisolone, cytarabine, cisplatin) ± rituximab. Patients who have responded to conventional therapy and demonstrated chemosensitive disease at relapse have the best outcome from HCT. Transplant is not recommended as initial therapy or for those with chemorefractory disease.¹¹¹ Allogeneic transplant should be reserved for those who have relapsed after autologous SCT, and the risk–benefit profile should be considered. R.G. received three cycles of R-ICE chemotherapy, and then her stem cells were collected for autologous HCT.

23. How does treatment differ for highly aggressive NHL?

Highly aggressive NHL, such as lymphoblastic or Burkitt lymphoma, progresses very rapidly and commonly metastasizes to the CNS.⁹⁵ The majority of adult patients can be cured with aggressive combination therapy. Regimens such as R-CHOP may not be intensive enough to prevent progression between cycles of therapy. Therefore, regimens similar to those for ALL are used because they provide more continuous exposure to more intensive chemotherapy. The hyper-CVAD regimen (hyperfractionated cyclophosphamide, vincristine, doxorubicin, and dexamethasone, alternating with high-dose methotrexate and cytarabine) has a CR rate of 91%.¹¹² These regimens must include CNS prophylaxis with intrathecal methotrexate or cytarabine.⁹⁵ These patients are at increased risk for TLS and should be treated with allopurinol, vigorous IV hydration, and electrolytes.

Indolent Lymphoma CLINICAL PRESENTATION

24. D.J. is a 64-year-old male who presents to his physician complaining of low-grade fevers and a constant “bloated feeling,” despite taking over-the-counter aluminum hydroxide and famotidine. He was otherwise asymptomatic, denying recent weight loss or night sweats. On physical examination, axillary adenopathy was found. An excisional biopsy and pathological examination revealed CD20-positive follicular B-cell lymphoma. CT scans of the chest, abdomen, and pelvis showed axillary and mediastinal lymphadenopathy. What are appropriate treatment options at this time?

The goal of therapy for indolent lymphomas is typically palliative because few patients will be cured of disease. However, the progression of the disease is typically very slow, and median survival is 8 to 12 years after diagnosis.⁹⁶ Treatment of localized disease, defined as nonbulky stage I or II, includes radiation with or without systemic therapy. Approximately half of the patients with localized disease will remain lymphoma free at 10 years with radiation therapy alone.⁹⁶ The addition of chemotherapy has not been shown to improve OS.⁸⁸

Treatment for advanced disease (bulky stage II, stage III, or IV) is individualized based on age, performance status, comorbid disease states, disease progression, and future transplant possibility. The choice for initial therapy is controversial because observation alone has been associated with a 5-year survival of more than 75%.¹¹³ Most experts advocate treating these patients only after they become symptomatic. Calculation of the Follicular Lymphoma International Prognostic Index (FLIPI) score may also guide treatment decisions (Table 90-14). D.J.’s disease is stage II with a low-intermediate FLIPI score for which he decides to pursue localized radiation therapy and to delay systemic therapy until he becomes symptomatic.

TREATMENT

25. D.J. remains asymptomatic for 3 years. At this time, he develops abdominal and splenic lymphadenopathy, night sweats, and weight loss over a 2-month period. What treatment options are available for D.J.?

Table 90-14 Follicular Lymphoma International Prognostic Index (FLIPI criteria)

| Risk Factors | Risk Group | Number of Risk Factors | 10-Year Overall Survival (%) |
|--|------------------|------------------------|------------------------------|
| All patients | Low | 0–1 | 70 |
| Age >60 years | Low-intermediate | 2 | 50 |
| LDH >normal | | | |
| Hemoglobin <12 g/dL | High | >3 | 35 |
| Ann Arbor stage III or IV | | | |
| Extranodal involvement >5 sites ^a | | | |

^aNodal sites include cervical, axillary, mesenteric, inguinal, mediastinal, and para-aortic.
Adapted from references 412 and 413.

Chemotherapy options include single-agent rituximab with a CR rate of 15% and OR rate of 64%, which may be extended by maintenance rituximab.¹¹⁴ No improvement in OS has been reported. Rituximab, in combination with chemotherapy regimens such as CHOP or cyclophosphamide, vincristine, and prednisone (CVP), achieve higher CR rates and extend the duration of response.^{115,116} Other options include purine analogs alone or in combination, such as FND (fludarabine, mitoxantrone, dexamethasone) with or without rituximab, or oral alkylating agents such as chlorambucil or cyclophosphamide.^{88,117} The National Comprehensive Cancer Network practice guideline recommends treatment with a rituximab-containing regimen unless contraindicated, although definitive evidence supporting a survival advantage is lacking.⁸⁸ A cardiac echocardiogram reports D.J.'s EF as 40%. Therefore, a nonanthracycline-containing regimen (R-CVP) was selected.

26. D.J. is 6 years out from his initial diagnosis. His disease was stable for 2 years after treatment with R-CVP. However, his most recent CT scan shows progression of his disease. The decision is made to administer single-agent rituximab to D.J. His daughter read on a lymphoma website that rituximab has been combined with radiation (radioimmunotherapy) and transplantation. She asks if these options would be appropriate for D.J.

Relapsed disease is treated with the same modalities as first-line treatment. Retreatment with rituximab has been found to be efficacious without additional toxicities.¹¹⁸ Radioimmunconjugates are monoclonal antibodies (rituximab) linked to radioisotopes that target CD20-positive lymphoma cells, which deliver local radiation therapy. Although radioimmunotherapy may be used first line, it is most often used in the setting of relapsed disease.^{119,120} Both iodine-131 (¹³¹I) tositumomab and yttrium-90 (⁹⁰Y) ibritumomab tiuxetan have been developed to treat follicular lymphomas. Both contain anti-CD20 antibodies with β -emitting radioisotopes. ¹³¹I tositumomab also emits gamma irradiation.

Patients are candidates if they have <25% bone marrow involvement and >100 × 10⁹/L platelets due to the significant hematologic toxicity associated with radioimmunotherapy. Response rates are higher than those seen with rituximab therapy alone. However, due to the complicated administration and high cost, this treatment has not been widely used clinically. ¹³¹I tositumomab patients should receive saturated solution of potassium iodide (two drops PO TID) at least 24 hours before the first dose is administered. This should be continued for 14 days after therapy to protect the thyroid gland. Because there are low-level radiation exposure is a concern, patients receiving either agent should be counseled to properly dispose of body fluids, carefully attend to personal hygiene, and limit their social contact for up to 7 days after administration. Hematologic toxicity can occur 7 to 9 weeks after administration, with a median duration of neutropenia and thrombocytopenia of approximately 3 weeks.¹¹⁹

High-dose chemotherapy followed by autologous HCT has a higher PFS and OS than standard therapy (RCHOP or other).¹²¹ Patients in second remission should be referred for transplant evaluation. Use of radioimmunconjugates as part of the preparative regimen prior to autologous HCT has also been explored.¹²² Allogeneic or reduced intensity allogeneic HCT are additional options but require careful patient selection due to high risk of morbidity and mortality.¹²³ D.J. is not a transplant candidate because of his advanced age and EF.

HODGKIN LYMPHOMA

Clinical Presentation and Prognosis

27. J.R. is a 55-year-old man with complaints of painless swelling around his collarbone, fever, night sweats, cough, and an unintentional 20-lb weight loss over the past 6 months. X-ray of the chest revealed a mediastinal mass, and a CT scan of the neck, chest, abdomen, and pelvis confirmed cervical and mediastinal lymph node enlargement, as well as multiple enlarged lymph nodes in the perisplenic and inguinal areas. A bone marrow biopsy was positive for lymphoma cells. Excisional biopsy of the cervical lymph node revealed nodular sclerosis Hodgkin lymphoma with Reed-Sternberg cells. Is this a typical presentation for Hodgkin lymphoma? What is J.R.'s prognosis?

Hodgkin lymphoma (or HD) can occur at any age and represents <1% of all cancers in the United States. Presentation can be limited to a single lymph node or to an extralymphatic organ or site, or it can involve multiple lymph nodes and extralymphatic organs. The WHO classification of Hodgkin lymphoma is shown in Table 90-10. Nodular sclerosis Hodgkin lymphoma is the most common subtype and represents about two-thirds of cases. The Ann Arbor staging system for lymphomas is shown in Table 90-11.⁹⁹ J.R. has lymphadenopathy above and below the diaphragm and bone marrow involvement; therefore, he has stage IV disease. He has also been experiencing constitutional B symptoms (i.e., fever, night sweats, weight loss), which are designated by the letter B in the staging system. Hodgkin lymphoma is one of the few malignancies that is typically curable, even in the advanced stages. An analysis of patients with up to seven prognostic factors showed 5-year disease-free progression of 42% to 82%.¹²⁴

Treatment

28. J.R. is scheduled to begin chemotherapy with the ABVD (doxorubicin [Adriamycin], bleomycin, vinblastine, and dacarbazine) regimen. Is this the optimal initial treatment?

Multiple combination chemotherapy regimens have been developed; however, none have demonstrated superiority to ABVD in patients with advanced Hodgkin lymphoma. Other regimens evaluated include MOPP (mechlorethamine, vincristine, procarbazine, and prednisone), BEACOPP (bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisone), and the Stanford V regimen (mechlorethamine, doxorubicin, etoposide, vincristine, vinblastine, bleomycin, and prednisone). In direct comparison with MOPP, ABVD has been shown to have an improved OS and a lower risk of both short- and long-term toxicities, including myelosuppression, infertility, and secondary leukemias.^{125–127} Although promising results have been obtained with BEACOPP and Stanford V, they have not been compared with ABVD in well-designed, long-term studies evaluating survival and toxicity.

Hodgkin lymphoma is a chemotherapy-sensitive disease, and administration of full doses given on schedule is critical. Cycles of ABVD are given every 28 days, and all patients should continue treatment for two cycles beyond documentation of complete remission for a total of six to eight cycles. A significant toxicity associated with ABVD use is bleomycin-induced lung injury. Patients should be monitored for pulmonary symptoms and/or abnormal pulmonary function tests or x-rays of the chest. If any of these occur, bleomycin should be discontinued from further treatment. The deletion of bleomycin from ABVD in patients who have pulmonary complications does not appear to reduce long-term survival.¹²⁸

Traditionally, all histologic subtypes of Hodgkin lymphoma have been treated in a similar fashion, and this remains the standard of care. One exception is nodular lymphocyte-predominant Hodgkin lymphoma (LNPH), which overexpresses CD20. Selected patients who are not candidates for standard chemotherapy may benefit from rituximab.¹²⁹ The future role of rituximab in combination treatment of LNPH remains to be determined, and these patients should be referred to ongoing clinical trials.

Relapsed Disease

29. J.R. achieved a complete remission and received a total of six courses of full-dose ABVD. Two years after completion of chemotherapy, a routine follow-up x-ray of the chest revealed enlarged lymph nodes, which were subsequently biopsied and found to be recurrent disease. What treatment should J.R. receive?

Patients with relapsed Hodgkin lymphoma have two main treatment options: salvage chemotherapy with or without radiation therapy, or high-dose chemotherapy with autologous stem cell support. Prognostic and patient-specific factors determine which avenue is optimal. Patients whose recurrence occurs in less than 1 year following initial therapy and have stage III or IV disease at relapse need more aggressive therapy if age and performance status permit.¹³⁰ Because it has been more than 1 year since he completed initial chemotherapy and

he does not have stage III or IV disease, J.R. should be offered salvage chemotherapy. Regimens such as ESHAP, DHAP, or ICE could be considered, along with others. DFS for patients who relapse 1 year or later after initial therapy and are treated with salvage chemotherapy is 45% at 20 years.¹³¹

MULTIPLE MYELOMA

Clinical Presentation

30. Z.C. is a 59-year-old man who presents with low back pain that has increased over the past month and fatigue. He has been self-medicating his back pain with over-the-counter nonsteroidal anti-inflammatory drugs (NSAIDs), but has achieved little relief. Plain films of the spine show a compression fracture at the L1 level. Further workup reveals hemoglobin (Hgb) of 9 g/dL, serum calcium of 11.5 mg/dL, and serum creatinine of 2.1 mg/dL. Serum and urine protein electrophoreses reveal a monoclonal protein typed as IgG lambda of 8.8 g/dL, IgA of 0.008 g/dL, and IgM of 0.025 g/dL. A 24-hour urine collection showed 5.2 g total protein, with 77% Bence Jones proteins. A serum β -2-microglobulin was 5.7 mg/L. Bone marrow biopsy reveals 47% plasma cells with normal cytogenetics. Skeletal survey shows additional lesions in the skull and ribs. A diagnosis of multiple myeloma (MM) stage III is made. Is this presentation consistent with the diagnosis of MM?

[SI units: Hgb, 90 g/L (normal, 135–165); calcium, 2.5 mmol/L (normal, 2.13–2.55); creatinine, 212.2 μ mol/L (normal, 70.7–123.8); IgG, 0.088 g/L (normal, 0.005–0.016); IgA, 0.00008 g/L (normal, 0.0004–0.004); IgM, 0.00025 g/L (normal, 0.0003–0.002); β -2-microglobulin, 0.0045 g/L (normal, 0.0011–0.0025)]

MM is a malignancy of fully differentiated B lymphocytes called “plasma cells.” Proliferation and accumulation of plasma cells leads to excessive antibody (immunoglobulin) production, typically IgG or IgA. A variety of clinical manifestations can be seen and are related to excessive immunoglobulin production, plasma cell infiltration, and immune deficiency. Of patients who develop MM, 55% are male, and 98% are 40 years or older.^{132,133} The disease occurs twice as often in blacks compared with whites and has increased in each decade since the 1970s.¹³² Z.C. presents with a number of the classic features of MM. Bone pain and skeletal disease are common and occur when plasma cells infiltrate the bone marrow and secrete osteoclast-activating factors (e.g., IL-6, tumor necrosis factor, parathyroid hormone–related peptide). Plain radiographic films will reveal osteopenia and/or multiple osteolytic bone lesions (punched-out areas on radiographs). Hypercalcemia and pathological fractures often accompany the osteolytic lesions associated with this disease. When plasma cells infiltrate the bone marrow, they can also lead to a normocytic normochromic anemia in up to 70% of patients. Comparatively, neutropenia and thrombocytopenia are rarely present at the time of diagnosis. Renal dysfunction is generally attributable to deposition of kappa or lambda light chains of immunoglobulin in the distal tubule, and up to 50% of patients have or will develop renal insufficiency with the disease.¹³⁴ In most patients with MM, only light chains are found in the urine. Myelomas that overproduce light chains are most commonly associated with renal dysfunction. Renal dysfunction can be further

complicated by dehydration secondary to hypercalcemia, the use of NSAIDs for pain relief, and the use of contrast dyes in radiographic evaluation. Z.C. should receive hydration with a sodium chloride-containing solution to restore euvolemia and reduce his calcium; he should avoid NSAIDs and other nephrotoxic therapies. Another feature that may accompany MM is hyperviscosity syndrome, more commonly seen with IgA subtype. Hyperviscosity causes CNS, renal, cardiac, and pulmonary symptoms and complications. Plasmapheresis may be used emergently to alleviate life-threatening cases. Patients may develop recurrent infections as a result of depressed production of other immunoglobulin classes, leading to an inability to opsonize bacteria.

Staging and Prognosis

Plasma cell disorders comprise a spectrum of disorders that range from monoclonal gammopathy of undetermined significance to MM.¹³⁵ Differential diagnoses for all plasma cell disorders are shown in Table 90-15. Z.C. clearly meets the criteria for MM. The prognosis for patients diagnosed with MM has traditionally been based on tumor mass and end-organ damage (hypercalcemia, renal dysfunction, anemia, and bone lesions), but recently a large international study demonstrated that staging and prognosis can be predicted reliably from serum β -2-microglobulin (a light chain protein expressed on all nucleated cells) and albumin (Table 90-16).¹³⁶ Median survival is 62 months for patients with stage I disease and 29 months

Table 90-16 International Staging System for Multiple Myeloma

Stage I— β -2-microglobulin <3.5 mg/L and serum albumin \geq 3.5 g/dL
 Stage II—neither stage I nor stage III
 Stage III— β -2-microglobulin \geq 5.5 mg/L

Adapted from reference 136.

for patients with stage III disease.¹³⁶ Evaluation of bone marrow cytogenetics also helps determine prognosis. Patients who have deletions of chromosome 13 or 17 and those with a 4;14 or 14;16 translocation have lower responses to initial therapy and shorter times to progression than those without the abnormalities.¹³⁷ Based on his serum β -2-microglobulin, Z.C. has stage III disease.

Treatment

Initial Therapy

31. The decision is made to begin Z.C. on thalidomide plus dexamethasone. What advantages and disadvantages does this regimen have compared with others?

Patients who meet the diagnostic criteria for MM and who are symptomatic are candidates for systemic chemotherapy (Table 90-17). Prior to treatment initiation, all patients should be evaluated for high-dose chemotherapy with autologous HCT. Those who are eligible for HCT should not be treated with alkylating agents (e.g., melphalan) before the stem cell collection because use of this class of agents may compromise the ability to collect a sufficient number of cells to perform the procedure. Agents such as thalidomide, dexamethasone, doxorubicin, and vincristine have been shown to be effective in induction regimens and do not reduce stem cell yield.

Thalidomide is an immunomodulatory agent with antiangiogenic properties, which are effective in patients with MM. Doses of thalidomide have ranged from 200 to 800 mg daily in the evening. Common adverse effects include sedation, constipation, thrombotic events, and neuropathies. Because of teratogenic effects, thalidomide is available only through a restricted distribution program, and patients must be thoroughly counseled about contraception. Dexamethasone is moderately effective as induction therapy alone and in combination, but has significant adverse effects, including hyperglycemia, insomnia, and increased infection risk.¹³⁸ The combination of thalidomide and dexamethasone was compared to dexamethasone alone in 207 previously untreated patients.¹³⁹ Response to the combination was 63% compared to 41% with single-agent dexamethasone; however, significant adverse events were also more common with the combination (34% vs. 18%, respectively). Combination therapy with vincristine, doxorubicin, and dexamethasone is another option for patients eligible for autologous HCT. The conventional VAD (vincristine, doxorubicin [Adriamycin], dexamethasone) regimen is a 4-day infusional treatment that was historically preferred over melphalan-based regimens because the response was more rapid and caused less myelosuppression. However, the requirement of a central

Table 90-15 Diagnostic Criteria for Plasma Cell Disorders^a

Multiple Myeloma

1. Presence of a serum or urinary monoclonal immunoglobulin protein
2. Presence of clonal plasma cells in the bone marrow or a plasmacytoma
3. Presence of end-organ damage related to plasma cell proliferation, including:
 - Elevated calcium (1 mg/dL above the upper limit of the normal range, or >11 mg/dL)
 - Renal insufficiency (creatinine >1.9 mg/dL)
 - Anemia (2 g/dL below the lower limit of the normal range, or <10 g/dL)
 - Bone lesions (lytic lesions or osteoporosis with compression fractures)

Asymptomatic (Smoldering) Multiple Myeloma

1. Serum monoclonal immunoglobulin >3 g/dL and/or bone marrow plasma cells >10%
2. No end-organ damage related to plasma cell proliferation

Monoclonal Gammopathy of Undetermined Significance

1. Serum monoclonal immunoglobulin <3 g/dL
2. Bone marrow plasma cells <10%
3. No end-organ damage related to plasma cell proliferation

^a All criteria must be met.

Adapted from reference 135.

Table 90-17 Multiple Myeloma Treatment Regimens

| Regimen | Agents | Comments |
|--|--|---|
| Induction Therapy | | |
| Eligible for High-Dose Chemotherapy With Autologous Stem Cell Support | | |
| Thalidomide + dexamethasone | Thalidomide 200 mg PO daily Dexamethasone 40 mg PO daily, days 1–4, 9–12, 17–20 Repeat cycle Q 28 days | Thalidomide should be given in the evening to minimize sedation. Antithrombotic prophylaxis is recommended. Thalidomide ± dexamethasone may also be used as salvage therapy. |
| DVD | Pegylated liposomal doxorubicin (Doxil) 40 mg/m ² mg IV once, day 1 Vincristine 1.4 mg/m ² (max 2 mg) IV once, day 1 Dexamethasone 40 mg PO daily, days 1–4 Repeat cycle Q 28 days | |
| VAD | Vincristine 0.4 mg/day CIV, days 1–4 Doxorubicin 9 mg/m ² /day CIV, days 1–4 Dexamethasone 40 mg PO daily, days 1–4, 9–12, 17–20 Repeat cycle Q 28 days | Should be administered through an indwelling central venous catheter to reduce extravasation risk. May also be used as salvage therapy. |
| Dexamethasone | Dexamethasone 40 mg PO daily, days 1–4, 9–12, 17–20 Repeat cycle Q 35 days | |
| Ineligible for High-Dose Chemotherapy With Autologous Stem Cell Support | | |
| MPT | Melphalan 4 mg/m ² PO daily, days 1–7 Prednisone 40 mg/m ² PO daily, days 1–7 Thalidomide 100 mg PO daily Repeat cycle Q 28 days | Melphalan should be given on an empty stomach due to variable absorption when administered with food. |
| MP | Melphalan 8–10 mg/m ² PO daily, days 1–4 Prednisone 60 mg/m ² PO daily, days 1–4 Repeat cycle Q 28–42 days | |
| Salvage Therapy | | |
| Bortezomib | Bortezomib 1.3 mg/m ² IV once, days 1, 4, 8, 11 Repeat cycle Q 21 days | Dose reduction to 1 mg/m ² may be necessary in patients with neuropathy and/or thrombocytopenia. Addition of dexamethasone may be required in patients who do not respond. |
| Lenalidomide + dexamethasone | Lenalidomide 25 mg PO daily, days 1–21 Dexamethasone 40 mg PO daily, days 1–4, 9–12, 17–20 for the first four cycles, then days 1–4 only in subsequent cycles | Consider prophylactic antithrombotics. |
| DT-PACE | Dexamethasone 40 mg PO daily, days 1–4 Thalidomide 400 mg PO daily at night Cisplatin 10 mg/m ² /day CIV days 1–4 Doxorubicin 10 mg/m ² /day CIV days 1–4 Cyclophosphamide 400 mg/m ² /day CIV days 1–4 Etoposide 40 mg/m ² /day CIV days 1–4 | Thromboembolic events with thalidomide are increased in combination with doxorubicin and require prophylactic antithrombotics. |

CIV, continuous intravenous infusion.

venous access device and the length of IV therapy make this a more cumbersome treatment. The substitution of pegylated liposomal doxorubicin (Doxil) for conventional doxorubicin and administration of vincristine on day 1 only with standard dexamethasone (DVD) makes this combination more convenient. A noninferiority comparison of VAD and DVD was conducted in 192 patients with untreated MM. The response was equivalent, and neutropenia, growth factor use, and alopecia were significantly lower in the DVD group, whereas hand-foot syndrome was more common.¹⁴⁰ To date, no comparison of induction with IV therapy and oral therapy has been made in patients eligible for autologous HCT.

In patients ineligible for autologous HCT, melphalan-based regimens are appropriate for induction therapy. Melphalan and

prednisone (MP) was the first regimen to show significant activity in myeloma, but it rarely produces a complete remission. The addition of thalidomide to MP (MPT) was compared to MP in patients ages 60 to 85 years.¹⁴¹ OR and CR rates were significantly improved with MPT (76%, 16%) compared to MP (48%, 2%). In addition, 2-year EFS was superior in patients receiving MPT compared to MP (54% vs. 27%). Thromboembolic events seen in the early part of the trial in patients receiving MPT led to the use of enoxaparin 40 mg SC daily, which reduced thromboembolism from 20% to 3%. Other toxicities seen more commonly with MPT included peripheral neuropathy, constipation, and infection, necessitating discontinuation of thalidomide in 33% of patients prior to completion of 2 months of therapy. Despite these toxicities, MPT is now

considered the optimal induction therapy in patients ineligible for HCT.

Because Z.C. is eligible for autologous HCT and oral therapy is more convenient than IV therapy, the combination of thalidomide and dexamethasone is appropriate induction therapy.

Hematopoietic Cell Transplantation

Efforts to improve the outcome of MM treatment have led to the investigation of high-dose chemotherapy (e.g., melphalan 200 mg/m²) with autologous stem cell support and nonmyeloablative regimens with allogeneic stem cell support. Randomized comparisons of autologous HCT and conventional chemotherapy in previously untreated patients younger than 65 years have been conducted.^{142–145} All patients received two to six cycles of conventional chemotherapy before randomization to autologous HCT or standard chemotherapy. Most trials have reported higher response rates and improved survival in patients randomized to receive autologous HCT. Younger age, chemosensitive disease, and fewer pretransplant therapies have emerged as important predictive factors for response to autologous HCT. Despite flaws in study design, autologous HCT is regarded as the current treatment of choice for eligible patients with MM who achieve CRs following induction therapy.¹⁴⁶ The use of allogeneic HCT transplantation in MM is a potentially curative option, but has been associated with excessive mortality. Nonmyeloablative allogeneic regimens are generally associated with fewer regimen-related toxicities than full allogeneic transplants, but allow for a graft-versus-tumor effect that eradicates residual disease (see Chapter 92). Initial trials have been encouraging, particularly in patients who are not heavily pretreated and those with chemotherapy-sensitive disease.^{147–149} Z.C. will receive four cycles of thalidomide and dexamethasone and will be evaluated for HCT.

Supportive Care

Bisphosphonates

32. Zoledronic acid 4 mg IV over 15 minutes every 28 days is ordered for Z.C. What is the rationale for bisphosphonate therapy in the presence of normal serum calcium? What benefits and toxicities are associated with bisphosphonate therapy?

The efficacy of IV pamidronate and zoledronic acid for the prevention of skeletal fractures in myeloma patients with osteolytic bone lesions or osteopenia has been established and guidelines for their use developed.¹⁵⁰ Equivalent efficacy with monthly infusion has been shown with pamidronate 90 mg and zoledronic acid 4 mg. Zoledronic acid can be given over 15 minutes, whereas pamidronate is given over 2 hours. Because bisphosphonates can negatively affect kidney function, serum creatinine should be monitored monthly and urine albumin measured every 3 months. Higher doses and shorter infusion times have been associated with renal damage; patients with creatinine clearances between 30 and 60 mL/minute should receive reduced doses of zoledronic acid. In patients with baseline creatinine values of >3 mg/dL, pamidronate 90 mg over 4 to 6 hours is recommended. Bisphosphonate therapy should be held in patients who have creatinine elevations above the normal baseline of 0.5 mg/dL or more until renal function re-

turns to baseline. Osteonecrosis of the jaw (ONJ) is a rare but serious complication of bisphosphonate therapy that appears to increase in likelihood with prolonged treatment. Baseline dental examinations and avoidance of invasive dental procedures during therapy are recommended. The use of zoledronic acid has been associated with a 9.5-fold increased risk of ONJ compared to pamidronate.¹⁵¹ All patients with responsive or stable disease should be strongly considered for bisphosphonate discontinuation after 2 years of treatment. Z.C. is a candidate for bisphosphonate therapy because he has lytic disease in the skull and ribs.

Relapsed and Refractory Disease

33. Z.C. receives four cycles of thalidomide and dexamethasone, followed by autologous HCT. Three years after HCT, he is found to have relapsed disease. What other therapies may offer benefit for his myeloma?

Treatment options for relapsed and refractory MM (salvage therapy) may include agents and regimens patients were not given in induction or other combinations (Table 90-17). Two newer agents for MM therapy are bortezomib and lenalidomide. Bortezomib acts by inhibiting the proteasome, a multienzyme complex responsible for regulation of proteins that promote cell survival, stimulate growth, and reduce susceptibility to programmed cell death. It is given for 2 weeks every 21 days for up to eight cycles. Dexamethasone 20 mg on the day of and after bortezomib may be added in patients who do not respond after two cycles. Common toxicities include sensory neuropathy, thrombocytopenia, and diarrhea; and dose reductions or omissions may be necessary for neuropathy and thrombocytopenia. In a comparison with dexamethasone, patients receiving bortezomib had a longer time to disease progression (6.2 months vs. 3.5 months) and better OS, leading to a recommendation to halt the dexamethasone arm and allow those patients to receive bortezomib.¹⁵² Lenalidomide is an analog of thalidomide that is more potent with a more favorable toxicity profile. Unlike thalidomide, sedation, constipation, and neuropathy are not seen, but dose-related side effects do include thrombocytopenia and neutropenia. Lenalidomide also causes thromboembolic events and is only available through a restricted access program. The combination of lenalidomide and dexamethasone was compared with dexamethasone alone in 353 patients with relapsed or refractory MM.¹⁵³ OR was greater with the combination (61.0% vs. 19.9%); neutropenia was the most common toxicity (41.2% vs. 4.6%).

Results with single-agent thalidomide and few overlapping toxicities led to interest in combination therapy with conventional chemotherapy earlier in the course of disease. A regimen of two cycles of high-dose dexamethasone, thalidomide, and a 4-day continuous infusion of cisplatin, doxorubicin, cyclophosphamide, and etoposide (DT-PACE) given 4 to 6 weeks apart was evaluated in relapsed patients treated with two prior regimens who also remained candidates for HCT.¹⁵⁴ Treatment was delayed or reduced for neutrophil counts <1,000/mm³ or platelet counts <100,000/mm³. An OR rate of 48% was seen in patients able to receive full doses of therapy for both cycles. Significant differences were seen in both complete and partial response rates for patients receiving <100% of scheduled

doses. Thromboembolic events necessitated anticoagulant prophylaxis during the study and neutropenia, thrombocytopenia, nausea, and sensory neuropathies were seen in 65%, 37%, 21%, and 13% of patients, respectively. DT-PACE represents an effective regimen in patients who can tolerate significant cytopenias and remain eligible for transplantation.

HEMATOLOGIC MALIGNANCIES: PEDIATRIC ACUTE LYMPHOBLASTIC LEUKEMIA OF CHILDHOOD

The two most common types of childhood leukemia are acute lymphoblastic leukemia (ALL) and acute myelogenous leukemia (AML), with the former accounting for 75% of cases and the latter for approximately 19%. ALL is the most common childhood cancer, accounting for approximately 30% of all malignancies in children.¹⁵⁵ Approximately 2,400 new cases of childhood ALL occur each year in the United States, with an estimated incidence of 34 cases per million in children younger than 15 years.¹⁵⁵

A distinct peak incidence occurs at ages 2 to 3 years for ALL (>80 cases/million), and then decreases substantially for 8 to 10 year olds (20 cases/million). A higher incidence of ALL is seen in white children than in black children. This racial difference is most apparent in the 2- to 3-year-old age group, with a nearly threefold greater incidence rate for white children. Over the past 20 years, the incidence rate of ALL in U.S. children has increased by approximately 0.9% per year. These incidence figures are derived from the Surveillance, Epidemiology and End Results Program (SEER), which collects data from nine tumor registries throughout the United States.¹⁵⁵ The nine registries account for approximately 13% of the U.S. population. Total U.S. incidence is then estimated by applying the SEER data to the total population size. It is unknown how reflective the SEER data are of the true U.S. incidence and/or if certain unmonitored regions may have significantly different rates of disease.

Before the early 1970s, ALL was a fatal illness; most children did not survive >2 to 3 months after diagnosis. Today, >80% of children will achieve prolonged survival with antileukemic therapy.^{155,156} New innovations in therapy for ALL are now focusing on additional refinements in therapy to further improve on survival and to decrease the long-term morbidity associated with the therapeutic components of current treatment regimens.

Etiology

The etiology of ALL is unknown; however, several interesting associations have been discovered. A high incidence of leukemia was found among survivors of the atom bomb explosion in Japan during World War II, and those closest to the epicenter of the blast were at greatest risk.^{157,158} Leukemia also occurs in children exposed to radiation in utero.¹⁵⁹ Other unproven factors that have been suggested to cause ALL include exposure to electromagnetic fields, pesticides, maternal use of alcohol, contraceptives, and cigarette smoking.¹⁶⁰⁻¹⁶³ Viruses have not been proved to cause childhood ALL.¹⁶⁴ Evidence supporting an association between ALL and electromagnetic field exposure is currently inadequate.^{155,165} In particular, the incidence of childhood ALL has not increased markedly over the past 40 years during a time when electricity use has seen

a large increase.¹⁶⁶ Clusters of leukemia cases that occur over certain time frames and around certain places may represent merely instances of statistic coincidence.¹⁶⁷ Also of interest, there is a significant correlation between the incidence of childhood ALL and type 1 diabetes around the world. This was found to be related to socioeconomic variables, such as national prosperity, with an apparent relationship to an affluent lifestyle. It is hypothesized that affluence may lower infectious disease prevalence and the childhood exposure pattern to pathogens. This suggests that the prevention of infection in infancy may increase vulnerability to later disease by inappropriate modulation of a naïve infant immune system.¹⁶⁸ Because the incidence of childhood ALL in the United States has increased moderately over the past 20 years and because the SEER program samples data only from a small portion of the U.S. population and excludes several geographic regions, it is unclear whether significant variations in childhood ALL incidences across the nation may be related to certain environmental factors. Recent examination of the relationship between childhood leukemia and environmental benzene exposure demonstrated an association between dwellings close to sources of benzene and the risk of childhood leukemia, particularly for AML.¹⁶⁹

Pathophysiology

The pathophysiology of ALL involves the replacement of normal bone marrow elements with a clone of immature lymphoid cells. The essential lesion in ALL is a stabilization of a malignant cell in the lymphocyte differentiation process. Many factors are involved in the control of normal cellular proliferation. Leukemia may represent a disruption in one or more of the normal relationships within the cell proliferation pathway, such as an abnormal response to lymphoid cell growth factors.¹⁷⁰

With the availability of classification systems of lymphoblasts based on morphology, immunology, and cytogenetics, it has become clear that ALL is a heterogeneous disease. This is especially true with regard to cytogenetic abnormalities. The immunologic heterogeneity results from leukemic transformation at various stages of lymphocyte differentiation. In addition, an emerging classification involving gene expression profiling may allow for further classification of ALL cytogenetic subtypes, potentially allowing for prediction of response and adverse events.¹⁷¹ As discussed later in this section, these classifications have important prognostic value.

Clinical Presentation

The signs and symptoms of ALL are nonspecific, and many are shared with other childhood diseases such as juvenile rheumatoid arthritis (JRA). This occasionally leads to a child with ALL being mistakenly treated with corticosteroids for JRA. As a general rule, children should not be treated with chronic corticosteroids without first performing a CBC and/or a bone marrow aspirate. These signs and symptoms reflect the uncontrolled growth and differentiation of the leukemic clone and the resulting deficiency in normal bone marrow elements, namely, neutrophils, RBCs, and platelets. Frequent clinical findings include fever (61%), bleeding (48%), and bone pain (23%).¹⁷² Bone pain is believed to be the result of hypercellular bone marrow and infiltration of leukemic lymphoblasts into pain-sensitive structures such as the periosteum. Although

bone pain may be severe, it quickly resolves once chemotherapy is initiated. On physical examination, many patients have lymphadenopathy (50%), splenomegaly (63%), and/or hepatosplenomegaly (68%).¹⁷²

A CBC will demonstrate that at least 59% of patients have a normal or low WBC count; the remainder have elevated counts.¹⁷² The WBC differential reveals a low percentage of neutrophils and bands and a marked lymphocytosis. Lymphoblasts may be present in the peripheral blood even with a low WBC count (e.g., 2,000–4,000/mm³), but they are more likely when the WBC count is elevated.¹⁷⁴ A normochromic, normocytic anemia, along with thrombocytopenia, is present in most patients.¹⁷²

A bone marrow aspirate and biopsy are usually necessary to confirm the diagnosis of ALL. Occasionally, in patients with elevated WBC counts, the diagnosis can be confirmed by studies of lymphoblasts in the peripheral blood. The diagnosis of ALL is made when at least 25% of lymphoid cells in the bone marrow are blasts.¹⁷³ Most ALL patients have far greater than 25% blasts, and many have complete replacement of bone marrow with lymphoblasts. Once a child is diagnosed with ALL, it is important to determine the various characteristics that influence treatment decisions and the prognosis.

Prognostic Variables

Clinical Variables

Certain clinical and laboratory findings that are present at diagnosis are important to predict a child's prognosis and to classify his or her risk stratification. Children with ALL are classified

by their risk of relapse into one of the following categories: low, intermediate, high, or very high risk. It is important to stress that much debate continues over which variables most strongly influence patient outcome. One agreed that the most important risk-defining features of childhood ALL are age and initial WBC count.¹⁷⁴ However, several ongoing investigations are likely to further refine what constitutes different ALL risk populations.

WHITE BLOOD CELL COUNT

The initial WBC count is considered to be among the most important predictors of outcome in childhood ALL. Its importance as a prognostic feature is often retained after the adjustment for other important prognostic criteria.¹⁷³ Children with the highest WBC counts at presentation have the shortest duration of complete remissions.^{175–177} There appears to be a linear relationship between the duration of remission and the WBC count at presentation (Fig. 90-2). Although exactly where the demarcation line is for predicting a good or a poor prognosis is unknown, an initial WBC count >50,000/mm³ is generally associated with a poor prognosis.¹⁷⁴

AGE

Patients younger than 1 year or older than 9.99 years of age at diagnosis tend to have worse prognoses.¹⁷⁴ At least one trial has demonstrated that more intensive therapy may overcome the adverse prognostic factor of adolescent age.¹⁷⁸ These investigators reported that young adults (16–21 years of age) with ALL have an EFS of approximately 60% at 6 years, which is similar to that of patients 10 to 15 years of age and superior to that achieved in most trials of older adults.¹⁷⁸ Age is

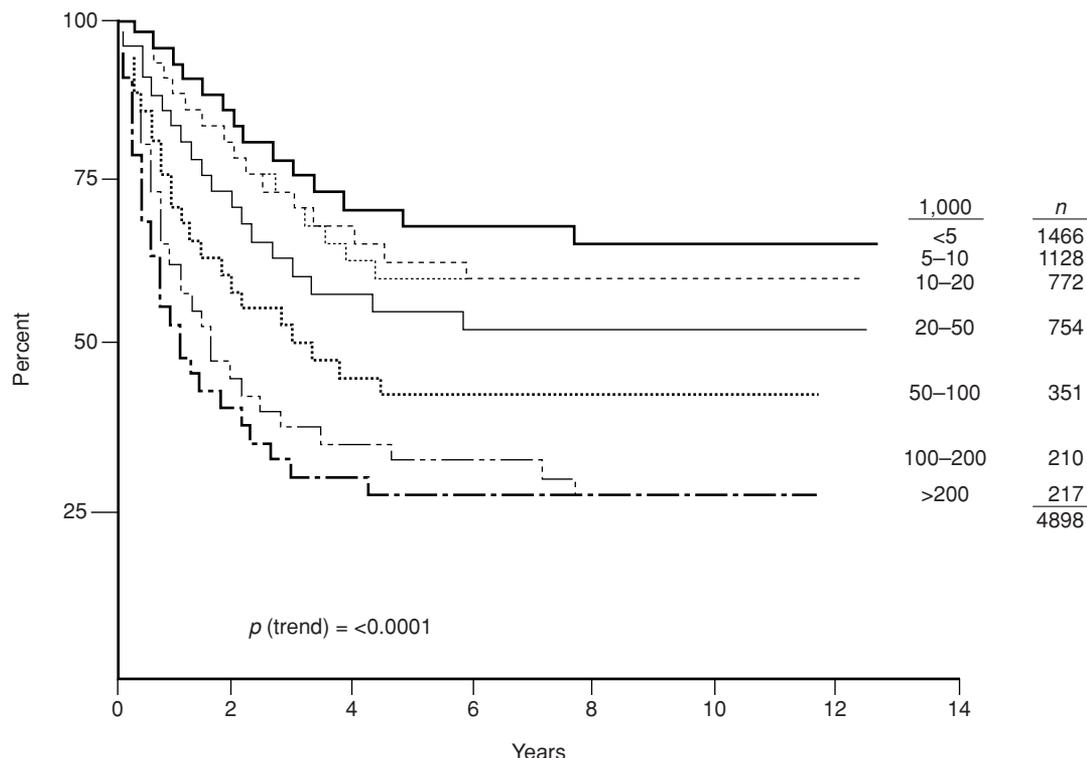

FIGURE 90-2 Percentage of children with acute lymphocytic leukemia in continuous complete remission stratified according to their white blood cell count at the time of diagnosis. Source: From reference 185. Reprinted with permission of Wiley-Liss, a subsidiary of John Wiley and Sons, Inc.

the strongest predictor of prognosis with regard to infants, a group in which survival is exceedingly poor compared with other age groups.^{179–181} For this group, even with intensified chemotherapy regimens, long-term, DFS is usually <50%, especially when associated with cytogenetic aberrations involving the mixed lineage leukemia (MLL) locus.¹⁸²

GENDER

Patient gender also has been shown to be an important prognostic factor in several studies.^{183,184} Testicular relapse is responsible for a somewhat worse prognosis in males, but it is not believed to completely account for the better prognosis of females. However, occult testicular disease is usually not ruled out when males experience relapse. Another factor that may be of importance is the inherent ability of males to tolerate higher doses of chemotherapy.¹⁸⁵ Greater therapy tolerance in males suggests the need to use the maximum tolerated dose intensity to produce the same therapeutic effect achieved in females at lower doses. This finding may be due to a gender difference in the metabolism of certain chemotherapy agents.¹⁸⁶ Whether current improvements in the treatment of childhood ALL have nullified the adverse prognostic association of male gender has recently been re-evaluated. A large series examined the outcome in >2,000 patients treated over >30 years. Females had significantly better outcomes than males in the early era, and although prognosis improved for both genders, an approximate 10% EFS advantage in females remained during the modern era (73.4% vs. 63.5%). After accounting for differences in immunophenotype and DNA index between genders, these differences were no longer present. It was noted that males were significantly more likely to have T-cell ALL, and there was a trend for them to have a less favorable DNA index, indicating that these factors may be responsible for the adverse prognostic factor of male gender.¹⁸⁷

RACE

Although blacks have a lower incidence of ALL, several studies have shown that black children appear to have a higher relapse rate than white children.^{155,188–190} Data from the SEER program demonstrate a 5-year survival rate of 64% versus 78% for black and white children, respectively. The differences in outcome for blacks appear to be the result of a more severe form of ALL in this patient population.¹⁸⁹ A trial with more intensive therapy failed to show a worse outcome in black children.¹⁹¹ It has also been demonstrated in a recent SEER update that the incidence rate for Hispanics was greater than for non-Hispanics and was the highest of all racial subgroups.¹⁹² A more recent analysis of racial and ethnic differences in outcome with contemporary therapy also demonstrated a difference in survival among groups, with the greatest survival for Asian children and lowest for blacks and Hispanics.¹⁹³

Immunologic Variables

ALL is classified into different immunologic subsets based on cell surface markers and/or antigens present on the leukemic lymphoblasts at diagnosis. These can be categorized as cells of B-cell and T-cell origin. The B-cell lineage is further classified into various subtypes through the use of monoclonal antibodies. These subtypes reflect the various stages of differentiation at which leukemia may develop. Approximately 15% to 20% of children with ALL have leukemia with a T-cell lineage,^{194,195}

and 1% to 2% of patients have leukemia with a mature B-cell origin.^{195,196} Using more sophisticated diagnostic techniques, the majority of patients who were previously classified as non-T, non-B-cell ALL (null cell ALL) are now known to have leukemia of a more immature B-cell lineage.^{197,198,199} Most patients with B-cell lineage ALL (80%) have cells that are positive for the common ALL antigen (CALLA, designated CD10) on their surface^{200,201}; this is referred to as common ALL. Additional markers, including CD19 and cytoplasmic immunoglobulin, have been used to further determine the level of differentiation of leukemic cells of the B-cell lineage. Intermediate cells of the B-cell lineage (pre-B cells) possess these markers, but more immature cells (early pre-B cells) do not.^{198,202} More than 60% of children with ALL have a leukemia of the early pre-B subtype, and approximately 20% have a leukemia of pre-B cells.

Mature B-cell ALL (or Burkitt ALL) has traditionally been associated with a poor prognosis,^{198,203,204} but prognosis has improved greatly with the advent of short-term, very intensive chemotherapy.^{205,206} Although differences in outcome have been noted among the B-cell subtypes,¹⁹⁸ when other prognostic factors are considered and when effective therapy is used, these differences may no longer be evident.¹⁸³ At present, immunologic features that differentiate B-cell precursor, T-cell, and mature B-cell ALL are believed to be clinically important because different types of chemotherapeutic strategies are employed for these three immunophenotypes.^{156,206}

Patients with T-cell ALL have several distinguishing features, including a greater likelihood of being older males with high initial WBC counts and the presence of a mediastinal mass and/or initial leukemic involvement of the CNS.^{207,208} Patients with T-cell ALL historically have had a decreased survival, although more intensive treatment is improving their outcomes.^{209,210} Studies with more intensified therapy also demonstrate no difference in relapse between T-cell and B-cell lineage ALL, although T-cell ALL patients tend to relapse much earlier.^{211,212} T-cell lymphoblasts are less efficient at polyglutamation methotrexate because these cells have lower concentrations of the methotrexate polyglutamate synthesizing enzyme, folylpolyglutamate synthetase.²¹³ This has been proposed as a possible explanation for the relative chemotherapy resistance and the need for increased methotrexate dose intensity in patients with T-cell ALL.¹⁵⁶

Patients with ALL may present with a mixed-cell lineage disease, containing lymphoblasts that also express myeloid antigens. Expression of myeloid antigens is not believed to be an important prognostic factor in predicting the risk of relapse.¹⁵⁶

Cytogenetic Variables

Advances in chromosomal analysis have improved the understanding of ALL biology. Abnormalities in either chromosome number (ploidy) or structure of the leukemic clone have been found in 60% to 75% of ALL cases.¹⁵⁶ Many of these abnormalities appear to have prognostic importance.^{156,214} Ploidy is represented by the DNA index. A value of 1.0 indicates a normal number of chromosomes, and a value >1.0 indicates an increased number of chromosomes by a multiplication factor of the normal chromosome number. Children with leukemia blasts containing >52 chromosomes (DNA index >1.16, hyperdiploid) appear to have an increased probability of continuous

complete remission versus patients with leukemia blasts containing a diploid chromosome complement or with a DNA index <1.16 .²¹⁴ Approximately 30% of ALL cases have a DNA index >1.16 . Patients whose ALL cells are hyperdiploid also tend to have other favorable prognostic features.²¹⁴ For example, children with hyperdiploid ALL may have a more favorable prognosis owing to their increased sensitivity to chemotherapy. An in vitro study of hyperdiploid versus nonhyperdiploid ALL revealed that those cells with a higher DNA index were more sensitive to antimetabolites (e.g., mercaptopurine) and asparaginase.²¹⁵ Also, B-precursor hyperdiploid ALL cells contain more reduced folate carriers than diploid B-precursor blasts. Hyperdiploid cells have elevated levels of gene expression for these carriers, which may account for the higher levels of methotrexate polyglutamates noted in these cells as compared to patients with B-precursor diploid ALL.^{216,217} In contrast, patients with hypodiploidy (<45 chromosomes and, in particular, those with 24–28 chromosomes) have a significantly worse outcome than nonhypodiploid patients.²¹⁸

Translocations are the most common structural abnormalities occurring in leukemic cells²¹⁹ and occur in approximately 75% of childhood ALL cases.²²⁰ Certain translocations are associated with treatment failure and relapse.¹⁵⁶ The translocations most commonly associated with treatment failure are the *MLL* rearrangements— $t(4;11)$, $t(11;19)$, and $t(1;11)$ —and the *BCR-ABL* fusion transcript— $t(9;22)$, Philadelphia chromosome. In particular, children with the Philadelphia chromosome appear to represent a population at very high risk of relapse. This translocation occurs in approximately 2% to 5% of childhood ALL cases. A published review compared the outcome of 30 patients with this translocation from a group of 1,322 children enrolled on ALL studies. This study demonstrated a 4-year EFS estimate of only 20% for children with the Philadelphia translocation versus 76% in those without it. This difference remained regardless of patient age, initial WBC count, or rapidity of response to therapy. Most patients with this translocation who were event-free survivors underwent bone marrow transplantation during their first remission.²²¹ A second case series of 61 children with Philadelphia chromosome-positive ALL identified early treatment response as a strong independent predictor of outcome. In this latter trial, 65% of these patients had a good initial response and a lower risk of treatment failure with either intensive chemotherapy or bone marrow transplantation when compared with the poor initial responders (EFS = 55% vs. 10%, respectively).²²²

Using more sensitive (polymerase chain reaction [PCR]-based) methods than available with classic cytogenetic techniques, the previously unrecognized *TEL/AML1* rearrangement— $t(12;21)$, *ETV6-CBFA2* fusion transcript—has now been identified as the most commonly occurring (approximately 18% of patients) translocation in childhood ALL. This translocation is associated with patients ages 1 to 10 years, and most are precursor B-cell type and nonhyperdiploid. The *TEL/AML1* translocation is an independent predictor of good prognosis; however, relapses tend to occur later in these patients, necessitating a long follow-up to determine the ultimate impact of this translocation.²²⁰ At present, reducing the intensity of chemotherapy for children with this translocation is not recommended.²²⁰ Also, a recent analysis has shown that this fusion transcript was not an independent predictor of outcome in multivariate analysis.²²³

The prognostic value of the main clinical variables can often be explained by cytogenetic abnormalities. For instance, most infants have rearrangements of the *MLL* gene. This abnormality, as well as the Philadelphia chromosome, occurs more often in adolescents and adults.¹⁵⁶ In addition, two cytogenetic abnormalities associated with improved outcome (hyperdiploidy and the *TEL-AML* translocation) are found mainly in the 1- to 9-year age group. In addition to the prognostic significance of the acquired genetic mutations, germ-line mutations may also predict outcomes. There are several polymorphisms that encode for proteins that can affect the pharmacodynamics of certain drugs used to treat ALL. Patients with high-risk ALL who had genotypes expressing greater glutathione S-transferase and thymidylate synthetase activity had a greater risk for relapse. These polymorphisms may be future targets for tailoring antileukemic therapy.²²⁴

Once a patient achieves complete remission, abnormalities of both ploidy and structure are not evident in the patient's recovered bone marrow by morphologic assessment, although a leukemic cell burden as large as 10^9 may remain.²²⁵ However, new techniques based on PCR assays can detect minimum residual disease (MRD) in many patients.²²⁵ If relapse does occur, the leukemic cell cytogenetic characteristics are usually identical to those observed at diagnosis.²¹⁹

Early Response

An additional factor of prognostic importance in childhood ALL is that of early response to therapy. Several investigations have noted that early response, as measured by either clearance of blasts from the peripheral blood or morphologic bone marrow remission (e.g., $<5\%$ bone marrow blasts) on day 7 or 14 of therapy, is predictive of long-term DFS. In a review of 15 trials, early response was an independent prognostic factor in each study.²²⁶ Response was most commonly measured based on morphologic evaluation of day 14 bone marrow results, and it appeared that assessment of early response was more sensitive with bone marrow studies. Children who were slow early responders were 2.7 times more likely to have an adverse event than those with more rapid clearance of blasts. Interestingly, the rapidity of response maintained its prognostic significance within different strata delineated by the initial WBC count, providing further evidence that this variable is an important independent marker of prognosis. The rapidity of response is an intuitive marker of treatment sensitivity. However, the use of morphologic criteria to assign responder status will still include many patients with a significant disease burden. It is important to note that such tests of bone marrow burden may represent a dilute sample or a decrease in marrow cellularity and may not reflect the total leukemia burden in the body. It is estimated that these measures of early response may detect up to 25% of children at risk for early relapse.²²⁶ At present, rapid early response is defined as clearance of bone marrow blasts by day 15 of induction, whereas slow early response refers to the converse. Whether patients are rapid or slow early responders is now being used to determine the type and intensity of further chemotherapy because slow earlier responders benefit from more intensive postinduction chemotherapy.²²⁷ Other groups have examined response to initial treatment with a 7-day course of prednisone (initiated prior to the start of systemic induction chemotherapy) in children with high-risk ALL. Prednisone-poor response, defined

as patients with $>1,000$ blast cells/ μL in peripheral blood after 7 days, was a predictor of poor outcome and was used to intensify induction therapy, with a consequent improvement in EFS.²²⁸

Minimum Residual Disease

Several investigators have examined the prognostic value of detecting MRD in bone marrow samples through the use of sophisticated PCR and flow cytometric-based assays. A variety of lymphoblast characteristics, including gene fusion transcripts, immunophenotype, and antigen receptor gene rearrangements, may be relied on for minimal disease detection in children with ALL. Although specific fusion transcripts can be relied on as PCR targets in only one-third of childhood ALL cases, clonal antigen receptor gene rearrangements occur in virtually all cases.²²⁵ Using various techniques, approximately 50% of children with ALL are MRD positive at the completion of induction therapy, and roughly 45% of these patients will experience a relapse. The association for a negative test for MRD at the completion of induction therapy appears stronger because it has a negative predictive value of 92.5% and a positive predictive value of 44.5% at this time point. In patients positive for MRD, there is a continuous decrease in MRD during the months of chemotherapy treatment. Persistence of MRD beyond 4 to 6 months or re-emergence of MRD is almost always predictive of future relapse.²²⁹ It is now established that the presence of MRD is an important prognostic factor, regardless of the patient's initial WBC count or age at presentation.²²⁵ At the time of this writing, monitoring of MRD has become important in the management of childhood ALL and is being used to risk stratify treatment in current front-line leukemia studies.

Additional Variables

Several additional variables may determine the prognosis of children with ALL. A complete discussion of these factors is beyond the scope of this text, but a few of these deserve brief mention. In addition to having an increased risk for developing ALL, children with Down syndrome are at a slightly greater risk for treatment failure. Their adverse outcome has been ascribed to an excess of therapy-related toxicities, especially associated with high-dose methotrexate.²³⁰ One variable that has not been traditionally listed as a prognostic factor is that of nutritional status. Although this is usually not an important variable in the United States and in developed nations, it may be a significant factor in Third World countries, which are home to the majority of the world's children. In several trials, the outcome in childhood ALL was significantly worse for malnourished patients, and in at least one trial, the most important predictor of relapse was malnutrition.²³¹ This may be related to a decrease in patient tolerance to chemotherapy. A malnutrition prevalence rate of up to 50% for children with ALL in Third World countries has been reported. When compared with socioeconomic status, malnutrition was more closely related to prognosis than was poverty. It appears that height for age is a more reliable predictor of prognosis than weight for age, suggesting that chronic stunting is more important than acute wasting in malnourished patients.²³¹

These prognostic variables can be used to assign patients to various categories based on their risk of relapse. These categories are important in determining the therapy that pa-

tients should receive. Although there is considerable agreement regarding the importance of certain variables in assigning patients to a defined risk group (e.g., age, initial WBC, DNA index, translocations), institutions that treat ALL differ in their definitions of what constitutes high-, intermediate-, and low-risk patients. This makes it difficult to compare treatment results from different institutions or treatment groups. Last, newer prognostic variables, especially rapidly evolving cytogenetic prognosticators, complicate the comparisons of treatment regimens over time.

Treatment

Remission Induction Therapy

ALLOPURINOL INTERACTION

34. J.B. is a 4-year-old Hispanic boy presenting with a 2-week history of an upper respiratory tract infection and a 1-week history of otitis media. His symptoms have worsened, and he now presents with a nosebleed and fatigue. Physical examination reveals appreciable pallor and hepatosplenomegaly. A CBC with differential reveals a normochromic, normocytic anemia with Hct of 15.7% (normal, 39%–49%), Hgb of 5.7 g/dL (normal, 14–18), WBC count of 4,300/ mm^3 (normal, 3,200–9,800), and platelet count of 13,000/ mm^3 (normal, 150,000–400,000). A differential on the WBC count reveals 82% lymphocytes (normal, 30%–40%), 7% neutrophils (normal, 50%–60%), and 11% lymphoblasts (normal, 0%). Based on these findings, a bone marrow biopsy is performed, which reveals 95% lymphoblasts. A diagnosis of ALL is made. The immunologic class is early pre-B cell based on CD10 and CD19 positivity. Analysis of the chromosomes reveals the TEL-AML1 translocation and a DNA index of 1.0. X-ray of the chest does not reveal a mediastinal mass, and a lumbar puncture shows that there are no leukemic lymphoblasts in the cerebrospinal fluid. J.B. is hydrated, alkalinized, and treated with oral allopurinol 200 mg/ m^2 /day, with a plan to institute induction therapy the next day. (For a discussion of the use of allopurinol in induction chemotherapy for the prevention of TLS, see *Complications of Induction Therapy* section.) Within a few days, J.B. will be treated with several drugs for his leukemia. Do any of the agents that are likely to be used in J.B. exhibit significant drug interactions with allopurinol?

[SI units: Hct, 0.157 (normal, 0.39–0.49); Hgb, 5.7 g/L (normal, 14–18); WBC count, $4.3 \times 10^6/\text{L}$ (normal, 3.2–9.8) with 0.82 lymphocytes (normal, 0.3–0.4), 0.07 neutrophils (normal, 0.5–0.6), and 0.11 lymphoblasts (normal, 0); and platelets, $13 \times 10^6/\text{L}$ (normal, 150–400)]

Xanthine oxidase, the enzyme inhibited by allopurinol, also converts mercaptopurine to 6-thiouric acid.²³² Thus, allopurinol may markedly increase the plasma concentrations of oral mercaptopurine by inhibiting first-pass metabolism, and this may lead to toxicity.²³³ This potentially serious drug interaction is usually irrelevant for most patients with ALL because these agents are rarely used together. Allopurinol is usually employed early in the first week of induction therapy, and patients do not receive mercaptopurine until they finish induction therapy in most contemporary childhood ALL protocols.

35. What is the goal of the induction therapy that J.B. will receive? Which agents should be used to achieve this goal?

Table 90-18 Systemic Induction Regimens for Childhood Acute Lymphocytic Leukemia

| Agent | Route | Dose/Schedule |
|--|-------|--|
| Three-Drug Induction Schema | | |
| Prednisone or Dexamethasone ^a | PO | 40 mg/m ² /day × 28 days |
| with Vincristine | IV | 1.5 mg/m ² /week (max 2 mg) × 4 |
| and Asparaginase | IM | 10,000 U/m ² 3 times weekly × 9 doses |
| or Pegaspargase | IM | 2,500 U/m ² × 1 dose |
| And (if Four-Drug Induction) | | |
| Daunorubicin | IV | 25 mg/m ² on days 2, 8, 15 |

^aDenotes that this agent is only employed in three-drug induction regimens (see text). PO, orally; IV, intravenously; IM, intramuscularly. Adapted from references 239–242 and 246–248, 252.

GOAL OF INDUCTION

The goal of induction therapy is complete remission (i.e., the inability to detect leukemic cells in the peripheral blood or the bone marrow by morphologic microscopic evaluation). J.B.'s peripheral blood values must be within the normal range, and the bone marrow must reveal <5% lymphoblasts. This definition also assumes the absence of lymphoblasts in the CSF. Although these findings indicate an adequate response to chemotherapy, they do not indicate a cure. Most patients have a total of 10¹² cells at diagnosis, and successful induction regimens reduce this cell load by 99% to 10⁹.^{234,235} Therefore, continuation of therapy will be required for J.B. to further reduce the leukemic cell population and to increase his chances of long-term survival. Without continuation of therapy, the majority of patients with ALL will relapse within 1 to 2 months.²³⁶

INDUCTION COMBINATION CHEMOTHERAPY

The agents most commonly used in remission induction therapy are vincristine (Oncovin), prednisone (Deltasone), dexamethasone (Decadron), asparaginase (Elspar), pegaspargase (Oncaspar), and daunorubicin (Cerubidine) (Table 90-18). The prednisone or dexamethasone dose is not routinely tapered at the end of induction treatment.^{237–240} More recently, dexamethasone has begun to supplant prednisone as the corticosteroid employed during induction therapy and/or throughout therapy. This is based on earlier work showing that dexamethasone has greater CSF penetration.²⁴¹ In patients with standard-risk ALL, a randomized comparison of dexamethasone to prednisone for induction therapy showed a lower CNS relapse rate in the dexamethasone group.²³⁹ However, the use of a 28-day course of dexamethasone during induction for patients with high-risk ALL was also associated with an increased risk of infectious complications, in particular, sepsis and toxic deaths.²⁴² This has led to removal or alteration of dexamethasone use during induction therapy in high-risk patients. It is plausible that the addition of dexamethasone to a more intensive chemotherapy backbone that is employed for induction

therapy of high-risk ALL may significantly increase the risk of infection in this more myelosuppressive milieu. In addition to the choice of corticosteroids, the efficacy of the long-acting polyethylene glycol (PEG) asparaginase has been compared with the short-acting native *Escherichia coli* asparaginase. One study demonstrated a comparable degree and duration of systemic asparagine depletion with PEG as compared to native asparaginase. However, unlike native asparaginase, PEG did not result in asparagines depletion within the CNS. It is unclear if this could have an impact on CNS relapse in children receiving contemporary chemotherapy regimens.²³⁸ With regard to immunogenicity, PEG asparaginase is less likely to induce high anti-asparaginase antibody titers, which are in turn associated with lower asparaginase activity. This resulted in an almost complete avoidance of the silent inactivation noted to occur in approximately 30% of patients receiving native asparaginase.²⁴³

No chemotherapy drug meets the criteria of an ideal agent (i.e., toxic to leukemic cells only and active in all phases of the cell cycle). Corticosteroids, vincristine, and various asparaginase products come closest to this ideal in terms of activity, primarily against lymphocytic leukemia, because none of these agents is myelosuppressive to normal marrow elements. To improve the success in attaining complete remission, additional agents have been added to vincristine, prednisone, and asparaginase (Table 90-18). The most frequently used additional agent is an anthracycline, such as daunorubicin or doxorubicin. Use of at least a three-drug induction regimen is the current standard of care for children at low or intermediate risk of relapse and results in improvements in both remission rate and duration versus less intensive therapy.^{244–246} Currently, a four-drug regimen, or an even more intensive induction regimen consisting of more than four drugs, and often for a duration of >4 weeks, is used for children at high risk of relapse and adult ALL patients.^{237,247–250}

If complete remission is not achieved with three agents by the end of induction, patients are treated with additional agents (e.g., an additional 2–4 weeks of daunorubicin and prednisone; initiation of cytarabine with additional asparaginase; vincristine and prednisone for 1–2 weeks). Because this occurs rarely, there is no consensus about the most effective agents or schedules to use in this situation. Most of these patients have a decreased survival and a higher relapse rate.

Intensive induction treatment has benefits for the majority of children with ALL. This treatment strategy supports the hypothesis of Goldie and Coldman,²⁵¹ that intensification of early treatment may decrease the chance that drug resistance will develop and may therefore potentially increase the proportion of long-term relapse-free survivors. Although J.B. has a DNA index of 1.0, based on his age, initial WBC count, and translocation, he is a patient with a low to intermediate risk of relapse. A three-drug induction regimen consisting of vincristine, dexamethasone, and pegaspargase is recommended to optimize his chances for long-term DFS.^{238,239,243}

Vincristine Toxicity

36. J.B. is discharged from the hospital during the second week of induction chemotherapy. Results of his CBC and differential indicate that he is responding well to his chemotherapy (i.e., WBC count 2,600/mm³, neutrophils 69%, lymphocytes 22%, platelets

229,000/m³, Hct 28.6%, blasts 0). However, during the third week of induction chemotherapy, J.B. develops severe abdominal pain. It is discovered that he has not had a bowel movement in 6 days. J.B. has also been exhibiting “acting out” behaviors in recent days. How might these symptoms be explained?

[SI units: WBC count, $2.6 \times 10^6/L$; neutrophils, 0.69; lymphocytes, 0.22; platelets, $229 \times 10^6/L$; Hct, 0.286; blasts, 0]

The use of vincristine is associated with an autonomic neuropathy, which may substantially reduce GI motility²⁵²; in severe cases, paralytic ileus may result. Constipation is often accompanied by colicky abdominal pain, which may be quite distressing.²⁵³ These symptoms usually become apparent 3 to 10 days after drug administration and resolve over several days. Prophylactic use of a stool softener (docusate [Colace]) and/or laxative (polyethylene glycol [Miralax]) may lessen the severity of J.B.’s constipation and facilitate defecation. This regimen should have been instituted soon after the first dose of vincristine.

J.B.’s emotional changes are likely the result of the dexamethasone he is receiving. Emotional lability, sleep disturbances, depressed mood, and listlessness have occurred during corticosteroid therapy in children with ALL.²⁵⁴ These behavioral changes can be quite disruptive, and parents should be prepared for them in advance. Behavioral disturbances typically resolve within 2 weeks after corticosteroid discontinuation.²⁵⁴

Central Nervous System Preventive Therapy

37. In addition to the aforementioned drugs, J.B. also receives intrathecal (IT) chemotherapy for CNS prophylaxis with methotrexate at the beginning (week 1) and end (week 4) of induction therapy. What is the purpose of IT chemotherapy? What are the various treatments available for CNS preventive therapy? What determines which one is chosen for J.B.?

PURPOSE

IT or CNS preventive therapy decreases the chance of relapse within the CNS and increase J.B.’s chance of long-term survival. Before CNS preventive therapy was routine, the CNS was the most common site of leukemic relapse and thus predicted bone marrow relapse.^{255,256} Patients at greatest risk for CNS relapse include those with very high initial WBC counts, T-cell ALL, and infants.^{257,258} However, because all patients with ALL are at risk for CNS relapse, one of the largest incremental improvements in DFS has been the routine use of CNS preventive therapy.¹⁵⁶ Because many antileukemic agents do not distribute well into the CSF, this area becomes a sanctuary site for leukemic lymphoblasts. The aim is to eradicate any CNS leukemic lymphoblasts present at diagnosis and to prevent the emergence of a relapse within the CNS.

CENTRAL NERVOUS SYSTEM PREVENTIVE THERAPY OPTIONS

All treatment protocols for childhood ALL use some form of CNS preventive therapy, although different regimens are used. The first successful CNS prophylaxis treatments were 2,400 cGy of craniospinal radiation with or without IT methotrexate, which markedly reduced the CNS relapse rate.²⁶⁰ To avoid the myelosuppression and reductions in spinal growth due to craniospinal irradiation, the standard CNS preventive therapy was modified to 2,400 cGy of cranial irradiation, along with IT methotrexate. However, the adverse effects of cranial irra-

diation remained problematic. These included decreased intellectual function, dysfunctions of the neuroendocrine system, and poorer psychosocial functioning.^{261–263} As a result, clinicians sought alternative, potentially safer forms of CNS preventive therapy. For example, lower doses (1,800 cGy) of cranial irradiation were combined with IT methotrexate to reduce the CNS effects, and this has proved to be equivalent to 2,400 cGy in preventing CNS relapse.^{258,264} The results of a long-term follow-up study indicate mild, but diffuse deficits in information processing in patients receiving 2,400 cGy of cranial irradiation but not in patients treated with 1,800 cGy, suggesting that the lower radiation dose reduces neuropsychological morbidity. Nevertheless, because concerns regarding the long-term toxicity of cranial radiation remain, especially for younger children, it is currently reserved for patients with detectable CNS disease on presentation, some patients with T-cell ALL and patients with CNS relapse. Currently, CNS preventative therapy includes IT methotrexate alone, triple IT chemotherapy (methotrexate, cytarabine, and hydrocortisone), or IT methotrexate combined with systemic dose-intensified methotrexate.^{265–268}

Because patients differ in their risk for developing CNS leukemia, CNS preventive therapy should be tailored accordingly. Children with low- and intermediate-risk ALL have equivalent CNS protection rates with either cranial radiation or IT chemotherapy, as long as adequate intensive systemic therapy is provided.^{266,269,270} Patients at low or intermediate risk of relapse may be treated with either triple IT chemotherapy or IT methotrexate, depending on the institutional protocol.^{266,269} Some high-risk children who are early responders to chemotherapy and who do not have CNS disease on presentation may also obtain adequate CNS protection with IT methotrexate alone.²⁷¹ Currently, most patients with T-cell disease still receive cranial radiation therapy as a component of their CNS preventive therapy, although with current intensive systemic therapy a radiation dose of 1,200 cGy appears to provide adequate CNS protection.¹⁵⁶

INTRATHECAL CHEMOTHERAPY: CHRONIC ADVERSE EFFECTS

The chronic toxicities of IT chemotherapy are now being determined. When examined for effects on growth, triple IT chemotherapy demonstrated no effect on the final height achieved by children in contrast to a reduced final height in patients receiving cranial irradiation.²⁷² Limited evidence suggests that IT chemotherapy may be associated with some neuropsychological deficits. At least one study of patients receiving IT chemotherapy without cranial irradiation has demonstrated deficits in higher-order cognitive function tasks and learning disabilities in mathematics.²⁷³ Another study has demonstrated that children who were treated with IT chemotherapy before age 5 years had deficits in the cerebellar-frontal brain subsystem and in neuropsychological performance.²⁷⁴ It is unclear whether these deficits will translate into significant long-term consequences for these children.

Dosage

38. J.B. is at a low risk for CNS relapse, and the decision is made to treat him with IT methotrexate. What dose of IT methotrexate should J.B. receive?

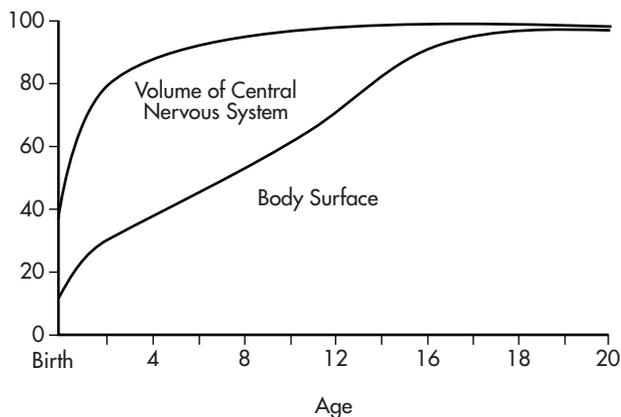

FIGURE 90-3 Relationship between body surface area and central nervous system (CNS) volume as a function of age. CNS volume increases at a more rapid rate than body surface area, reaching adult volume by 3 years of age. From Bleyer WA et al. Reduction in central nervous system leukemia with a pharmacokinetically derived intrathecal methotrexate dosage regimen. *J Clin Oncol* 1:1983:289. Reprinted with permission © 2008 American Society of Clinical Oncology. All rights reserved.

High chemotherapy concentrations can be attained within the CSF with relatively low doses because the CSF volume of distribution is small in contrast to the peripheral plasma volume (140 vs. 3,500 mL).^{275,276} Drug exposure is also maximized by the longer half-life of most drugs in the CSF.²⁷⁷ The approach used for IT dosing differs from systemic administration, the latter of which is based on body weight or body surface area. CSF methotrexate concentrations appear to correlate better with patient age than size.²⁷⁸ As seen in Figure 90-3, the CSF volume in children approaches that of an adult by the age of 3 years. Because CSF volume does not correlate with body surface area, IT doses based on body size result in subtherapeutic concentrations in young children and potentially toxic concentrations in older children and adults. The age-based dosing regimens shown in Table 90-19 are less neurotoxic and are associated with a lower rate of CNS relapse than doses based on size.²⁷⁹ Using this dosing regimen, J.B.'s dose of IT methotrexate should be 12 mg. If triple intrathecal therapy were employed, the doses of IT cytarabine and hydrocortisone would be 24 and 12 mg, respectively. These latter doses are also based on age, but no literature exists to support how they were derived. Nevertheless, empiric evidence supports their efficacy.²⁶⁶

Table 90-19 Dosage Regimen for Intrathecal Chemotherapy Based on Patient Age

| Patient Age (years) | Methotrexate (mg) | Hydrocortisone (mg) | Cytarabine (mg) |
|---------------------|-------------------|---------------------|-----------------|
| <1 | 6 | 6 | 12 |
| 1 | 8 | 8 | 16 |
| 2 | 10 | 10 | 20 |
| 3 | 12 | 12 | 24 |
| ≥9 | 15 | 15 | 30 |

Adapted from reference 280.

PRECAUTIONS

39. J.B.'s triple IT methotrexate is to be administered on the same day as his vincristine dose. Are there any special precautions that should be taken when these medications are administered in close proximity?

Inadvertent IT administration of vincristine is almost uniformly fatal,^{280–282} although there is at least one report of a patient in whom death was prevented.²⁸³ Despite widespread educational efforts and numerous precautionary measures used by the pharmaceutical industry in recent years, deaths from the inadvertent IT administration of vincristine continue to be reported.²⁸⁴ The clinical course in patients mistakenly given IT vincristine has typically progressed from backache and headache on day 1, muscle weakness (generalized) on day 2, apnea on day 5, loss of evidence of electroencephalographic activity by days 7 to 9, and death on day 12.²⁸⁰ To avoid the tragedy of IT vincristine administration, vincristine should be admixed separately from IT medications, specially labeled, and preferably delivered to the patient area for IV infusion after the administration of IT medications.

Acute Adverse Effects

40. J.B. develops severe nausea and vomiting following his IT methotrexate treatment. Is this common following IT chemotherapy? What can be done to decrease this toxicity for future IT chemotherapy treatments?

Several acute toxicities have been reported following IT chemotherapy. Acute arachnoiditis may occur 12 to 24 hours after injection, resulting in headaches, nausea, vomiting, and various other signs of increased intracranial pressure.²⁸⁵ Severe symptoms occurred in 4 of 91 children receiving combination IT chemotherapy.²⁸⁶ IT methotrexate alone produces these side effects in 38% of cases.²⁸⁷ Fortunately, these reactions are usually self-limiting and can be reduced by use of doses based on patient age.²⁷⁹

Nausea and vomiting due to IT chemotherapy is usually mild to moderate in severity.²⁸⁸ The emetogenic effect of IT chemotherapy is likely the result of direct contact between the chemotherapy and the chemoreceptor trigger zone. IV ondansetron (a 5-HT₃ antagonist) at a dose of 0.15 mg/kg before and 3 to 4 hours after IT chemotherapy or 0.3 mg IV × 1 dose prior to IT chemotherapy can significantly reduce the incidence and severity of nausea and vomiting secondary to triple IT chemotherapy.²⁸⁸ Without antiemetic protection, only 22% of children receiving IT chemotherapy had no vomiting. With the addition of ondansetron, complete protection from vomiting rose to 69%.²⁸⁸ The efficacy of ondansetron IV when chemotherapy is administered IT is consistent with animal data demonstrating that 5-HT₃ antagonists administered directly into the brainstem can block the emetic response of systemically administered chemotherapy.²⁸⁹ (Also see Chapter 7.)

Rarely, a form of methotrexate neurotoxicity resulting in either paraplegia or necrotizing leukoencephalopathy may occur.^{290–292} Leukoencephalopathy is associated with cranial irradiation given before or during IT therapy.²⁹² The preservatives in the chemotherapy diluents (methylhydroxybenzoate and benzyl alcohol) rather than the chemotherapy agents are believed to be responsible for the paraplegia. This

emphasizes the importance of diluting IT chemotherapy with a preservative-free diluent.²⁹⁰ In addition, acute seizures associated with IT methotrexate have been reported. It also has been shown that methotrexate can increase the CSF concentration of homocysteine, as a consequence of decreased CSF folate. It is known that homocysteine can be metabolized to excitatory neurotransmitters that are agonists of the *N*-methyl-d-aspartate (NMDA) receptor, leading to seizures.^{293,294} It is possible that known NMDA receptor antagonists (e.g., dextromethorphan) may decrease the risk of seizures in patients who develop this toxicity.²⁹⁴

Consolidation Therapy

41. J.B. had bone marrow aspirations performed at day 8 and at the completion of induction treatment on day 29; both indicated a complete morphologic remission, indicative of a rapid early response. After completion of the induction phase, J.B. was scheduled to receive an intensified phase of chemotherapy known as consolidation therapy. What is the purpose of consolidation treatment, and what are some examples of effective regimens for this phase of treatment?

Consolidation or intensification is a period of dose-intensive chemotherapy following induction therapy. This phase of treatment has proved to be an important strategy for the prevention of relapse in children with ALL and has helped produce EFS of greater than 80% in low-risk childhood ALL.^{156,295} To date, the optimum consolidation/intensification regimens have yet to be determined. However, a few interesting findings from investigations of consolidation therapy are briefly mentioned. A comparison between methotrexate 1 g/m² IV (intermediate-dose methotrexate) and low-dose (180 mg/m² divided into six doses) oral methotrexate revealed an approximate 4.4% increase in continuous complete remission with the higher-dose regimen.²⁹⁵ This study is considered to be one of the pivotal trials demonstrating the superiority of higher-dose methotrexate in childhood ALL.¹⁵⁶ Although this difference was statistically significant, it may not have been clinically significant because leukoencephalopathy also occurred in 4.5% of children treated with the higher-dose regimen, compared with 0.6% of those treated with low-dose methotrexate. Although this study was not designed to examine differences in gender, female patients failed to benefit from the higher-dose regimen. This study has also been criticized for using the same leucovorin dosage with both methotrexate regimens because it is known that a lower-dose oral regimen without leucovorin may produce similar RBC concentrations to that achievable with higher-dose methotrexate with leucovorin.²⁹⁶

It is not uncommon for newer consolidation regimens to lead to complications, given the baseline treatment intensity of many contemporary ALL treatments. For example, a trial evaluating the addition of either intensified asparaginase or cytarabine to intermediate-dose methotrexate in standard-risk ALL patients failed to show any incremental benefit in EFS over that achievable with methotrexate alone, although the cytarabine regimen did result in an increase in both infectious morbidity and hospitalizations.²⁹⁷ Some examples of state-of-the-art consolidation regimens are provided in Table 90-20.^{239,247,295,297,298}

Table 90-20 Consolidation/Intensification Regimen Components

| Week | Reference |
|--|-----------|
| Week 1 | |
| Methotrexate 1 g/m ² IV over 24 hours | |
| Mercaptopurine 1 g/m ² IV over 6 hours | |
| Week 2 | |
| Methotrexate 20 mg/m ² IM × one dose | 297 |
| Mercaptopurine 50 mg/m ² PO daily × 7 days | |
| Triple intrathecal therapy on weeks 1, 2, 3, 7, 12, 19, and 25 | |
| Repeat 2-week cycles for a total of 12 courses | |
| Cyclophosphamide 1 g/m ² IV on days 0 and 14 | |
| Cytarabine 75 mg/m ² SC or IV on days 1–4, 8–11, 15–18, and 22–25 | |
| Mercaptopurine 60 mg/m ² PO daily × 28 days | 300 |
| Methotrexate IT weekly × 4 weeks | |
| Mercaptopurine 25 mg/m ² PO daily on days 1–56 | 249 |
| Methotrexate 5 g/m ² IV over 24 hours on days 8, 22, 36, and 50 | |
| Methotrexate IT on days 8, 22, 36, and 50 | |
| Methotrexate 1 g/m ² IV over 24 hours, every 3 weeks × 6 doses | 299 |
| Vincristine 1.5 mg/m ² IV on weeks 8, 9, 17, and 18 | |
| Prednisone 40 mg/m ² PO daily × 7 days on weeks 8 and 17 | |
| Dexamethasone 10 mg/m ² PO daily × 21 days + 7-day taper | 241 |
| Vincristine 1.5 mg/m ² IV on days 0, 7, and 14 | |
| L-asparaginase 6,000 U/m ² IM × 6 doses on days 3–17 | |
| Doxorubicin 25 mg/m ² IV on days 0, 7, and 14 | |

IV, intravenously; IM, intramuscularly; PO, orally; SC, subcutaneously; IT, intrathecally.

METHOTREXATE CONCENTRATION MONITORING

42. J.B. receives consolidation therapy with intermediate-dose methotrexate. His methotrexate serum concentrations are monitored after the administration of each dose of methotrexate during this phase of therapy. Why is monitoring of serum concentrations important when giving this dose of methotrexate? Are methotrexate concentrations important in predicting the outcome of ALL therapy?

After dose-intensive methotrexate therapy, concentration monitoring is crucial to establish the dose of leucovorin and the duration of hydration and alkalinization needed to prevent systemic methotrexate toxicity.²⁹⁹ Before serum methotrexate concentrations were routinely monitored after high-dose methotrexate, severe GI desquamation and myelosuppression led to fatalities in as many as 6% of patients.³⁰⁰ Methotrexate concentrations are measured approximately 24 hours after completion of the methotrexate infusion and repeated daily until the concentration falls below the toxic threshold of 0.05 μmol/L. Patients who have unexpectedly high concentrations after high-dose methotrexate may require higher doses of leucovorin and prolonged hydration and alkalinization to circumvent methotrexate toxicity.²⁹⁹ (See Pediatric Tumors:

Osteosarcoma section of Chapter 91 for details on monitoring methotrexate concentrations and dosing leucovorin.)

Investigators have evaluated the influence of serum concentrations of methotrexate on the outcome of ALL patients.^{300,301} These studies have determined that children with higher methotrexate clearance values appear to be at higher risk of relapse and suggest that concentration monitoring may also play a role in enhancing the long-term survival of these patients.³⁰¹ However, when follow-up was extended, the survival advantage reported in one of these studies was lost.^{301,302} A subsequent investigation of individualized chemotherapy versus standard dosing based on body surface area also demonstrated that concentration monitoring and subsequent dose adjustment of methotrexate during consolidation was associated with a significant 10% improvement in continuous complete remission for children with B-cell lineage ALL.²⁴⁸ It also remains to be seen whether this difference will be lost with further patient follow-up. Given the somewhat conflicting data at present, dose adjustment of methotrexate for efficacy purposes based on serum concentrations should be considered investigational and should not be used for dose adjustments in J.B. Currently, dosage adjustment of intermediate- and high-dose methotrexate should be used only for patients experiencing excess toxicity.

Maintenance Therapy

43. After completion of his induction and consolidation/intensification treatments, J.B. is scheduled to receive maintenance (continuation) treatment for a total therapy duration of 2.5 years from the start of his induction therapy. His parents question why treatment will be of such a long duration and ask whether this is necessary because J.B. is already in remission. What is the purpose of J.B.'s maintenance or continuation treatment for ALL? Which agents should be used in J.B. for this phase of therapy?

PURPOSE

Maintenance or continuation treatment sustains the complete remission achieved from induction chemotherapy. Early trials have shown that without maintenance treatment, the majority of ALL patients will relapse.²³⁶ It must be stressed that patients who have successfully responded to induction and consolidation/intensification therapy may still have a high leukemic cell burden (although undetectable), which must be eradicated by additional treatment. This is supported by the results of bone marrow biopsies from patients who have experienced relapse after several months to years of treatment. The cytogenetic characteristics of the leukemic cells in relapsed patients are identical to those at the time of diagnosis.^{303,304} Maintenance therapy is also supported by the results of MRD studies, which demonstrate that some amount of measurable leukemic cells are still present months after the completion of induction therapy.²²⁵

CHEMOTHERAPY REGIMENS

Drugs that are effective during induction therapy cannot, by themselves, prolong remission during maintenance therapy.¹⁷³ However, other agents are effective in sustaining a complete remission. Two of the most effective drugs are mercaptopurine (Purinethol) and methotrexate.^{244,305,306} Methotrexate is most effective and least toxic when administered intermittently, usually on a weekly basis in oral doses of 20 mg/m²/week. Mer-

captopurine is effective and well tolerated orally when dosed daily, usually at a dose of 50 to 75 mg/m²/day.

Other agents have been added to standard maintenance therapy with mercaptopurine and methotrexate to improve remission duration and to increase a patient's chances for long-term survival. There is evidence that monthly pulses of vincristine and prednisone offer advantages (lower bone marrow and testicular relapse rates) in standard-risk patients as well.³⁰⁷ At present, most contemporary treatment regimens for childhood ALL have intensified induction and consolidation phases, and sometimes include a reinduction and/or a delayed intensification phase within the first 6 months.^{247,249,295,297,298} Following this early intensive treatment schema, these newer protocols use a less intensive maintenance therapy consisting of methotrexate and mercaptopurine in combination with periodic IT chemotherapy treatments, either with or without intermittent vincristine/prednisone pulses.^{247,249,295,297,298} It is unclear which of these regimens is best because risk criteria used to assign patients to various maintenance treatment arms within these protocols have varied among investigators.

The available evidence suggests that a patient like J.B. with standard-risk ALL will benefit from use of daily mercaptopurine 50 to 75 mg/m² PO and weekly methotrexate 20 mg/m² PO, IM, or IV, along with periodic pulse therapy with vincristine 1.5 mg/m² for 1 day and either prednisone 40 mg/m² or dexamethasone 6 mg/m² PO for 7 days every 4 weeks. In addition, IT methotrexate should be repeated every 8 to 12 weeks.

Potential Problems

44. After 6 weeks of maintenance therapy with the aforementioned regimen, J.B. has an absolute neutrophil count (ANC) that has ranged between 2,000 and 3,500 cells/mm³ for >6 weeks. Other CBC findings are also within normal limits. Should any changes in his maintenance therapy be considered at this time? Are there any potential problems with mercaptopurine and methotrexate that could explain his ANC values and that might increase his risk of treatment failure?

Diurnal variation of methotrexate concentration and marked interpatient variability in absorption and metabolism of mercaptopurine have been described, which may explain the varied response among patients to standard doses.³⁰⁸⁻³¹⁰ Most patients are able to tolerate full doses of mercaptopurine, which is inactivated by the enzyme thiopurine methyltransferase (TPMT). It is known that approximately 89% to 94% of patients have high TPMT activity, whereas 6% to 11% have intermediate activity, and 0.3% have deficient activity. Patients with deficient TPMT activity develop severe and even fatal toxicity with standard mercaptopurine doses and require very low doses (approximately 10 mg/m² three times per week) for avoidance of profound myelosuppression.^{311,312}

Patients receiving half doses of these agents have shorter remission durations³¹³; however, those who tolerate maximal protocol dosages may also be at greater risk of relapse.¹⁸⁵ Patients who are able to tolerate maximal doses without significant myelosuppression may require even higher doses than are recommended in some protocols. Investigations, including studies of intracellular concentrations of active metabolites, have not found the pharmacokinetics of mercaptopurine or methotrexate to be predictive of outcome in children with

ALL.^{314–316} However, one of these trials did demonstrate that dose intensity of mercaptopurine was a significant predictor of EFS.³¹⁴ Because bioavailability is a concern for both agents and because some patients, particularly males, may be able to tolerate high dosages without toxicity, doses are often adjusted upward based on the degree of leukopenia. Some protocols allow for dosage increases of methotrexate or mercaptopurine every 4 to 6 weeks to maintain a target ANC in the range of 300 to 2,000/mm³.^{314,315} This is usually accomplished by alternately increasing the doses of mercaptopurine and methotrexate by 25%.

For J.B., this means an increase in mercaptopurine from 50 mg/day to a daily schedule alternating 50 mg with 75 mg, or an increased methotrexate dose from 20 to 25 mg/week. Although parenteral administration of methotrexate is logical, it does not consistently improve the results of therapy.^{316,317} To assess whether J.B. is receiving an adequate dose, weekly WBC counts are essential. This allows one to accurately appraise the adequacy of his dose and to follow his disease status to ensure that remission is continuing. If an inadequate degree of myelosuppression is demonstrated, J.B.'s compliance should be investigated because decreased compliance is a frequent problem in the therapy of childhood ALL.^{318–320} At least one investigation has found improved compliance with evening administration of mercaptopurine.³¹⁸

Duration of Therapy

45. How long should J.B.'s maintenance therapy be continued?

Most centers treat children with ALL until a total therapy duration of approximately 2.5 years is reached.^{321,322} Extending maintenance treatment to 5 or 6 years adds no benefit.^{321,322} Other data suggest that a shorter duration of 18 months may be adequate for girls, but not for boys.³²³ Most patients who experience relapse do so during therapy or within the first year of completing therapy. After the second year of therapy and for every year thereafter, relapses become much less common, but are occasionally observed. Some centers are exploring whether more intensive treatment protocols could decrease the duration of maintenance treatment because the optimal duration is based on less aggressive protocols. Until there is more conclusive evidence regarding the duration of ALL maintenance therapy, patients with J.B.'s characteristics should receive chemotherapy for approximately 2.5 years.

High-Risk Acute Lymphoblastic Leukemia

LONG-TERM SEQUELAE

46. N.B. is a 12-year-old Hispanic boy with a 4- to 5-week history of an enlarging right-sided neck mass. On physical examination, he is found to have a 6 × 3-cm right neck mass with extension to the nape of the neck. X-ray of the chest indicates an anterior mediastinal mass. The CBC reveals a WBC count of 62,000/mm³ (43% lymphoblasts, 27% neutrophils, and 27% lymphocytes), Hct of 41.5%, and platelet count of 83,000/mm³. Other pertinent laboratory results are urate of 15.1 mg/dL and LDH of 1,636 U/L (normal, 280–540). A bone marrow biopsy confirms the diagnosis of ALL and shows that 85% of the bone marrow is replaced by leukemic lymphoblasts. The leukemic cells are T lymphoblasts, and their DNA index is 1.0. A lumbar puncture reveals a few cells

within the CSF that are terminal deoxynucleotid transferase (TdT) negative, but are rather suspicious.

N.B. is started on rasburicase 0.2 mg/kg/day for 1 to 3 days, instead of allopurinol and hydration and alkalinization. Because N.B. is known to have T-cell ALL, he is begun on an intensive protocol. The induction regimen consists of six drugs, including prednisone 40 mg/m²/day PO on days 1 to 29; vincristine 1.5 mg/m² IV weekly for 5 weeks; cyclophosphamide (Cytosan) 1 g/m² on day 1 and 600 mg/m² on day 22; doxorubicin (Adriamycin) 50 mg/m² on day 1; cytarabine 100 mg/m²/day via continuous infusion for 5 days starting on day 22; and asparaginase 10,000 U/m² IM on days 27, 29, and 31. Triple IT therapy consists of methotrexate 15 mg, cytarabine 30 mg, and hydrocortisone 15 mg administered weekly for 6 weeks. Why was rasburicase used instead of standard tumor lysis syndrome (TLS) preventive strategies?

Despite the standard prophylactic regimen for TLS, some high-risk patients may develop urate nephropathy. Patients with a significant elevation in uric acid and/or renal dysfunction may not derive significant early benefit from the standard regimen, which is designed to prevent the formation of additional uric acid and to aid in its excretion. Significant elevations in uric acid and/or renal dysfunction may even delay the initiation of chemotherapy. Rasburicase is a recombinant form of urate oxidase, the enzyme that catalyzes the conversion of uric acid to the more water-soluble allantoin. Rasburicase produces a dramatic reduction in uric acid within 4 hours of administration. Uric acid is often reduced below the normal range, and additional daily doses are not necessary if uric acid normalizes and remains within normal limits. Given N.B.'s significantly elevated uric acid, he is at significant risk for TLS and is a good candidate for initial management with rasburicase. Rasburicase obviates the need for allopurinol, hydration, and alkalinization.³²⁴

47. N.B. achieves a complete remission based on the results of a bone marrow specimen on day 29. His parents are concerned about the doxorubicin because they have heard about heart problems with this drug. His protocol includes significant doses of this agent throughout his treatment plan. They ask about the likelihood for cardiac toxicity, what might be done to screen for it, and whether any preventive strategies exist that might be of value. They also ask about other potential long-term sequelae from his treatment. What are the recommended screening tools and preventive strategies for anthracycline cardiotoxicity in children? What is the evidence for the relationship between osteonecrosis and corticosteroid used in the treatment of childhood ALL?

The relationship between cumulative anthracycline dose and cardiotoxicity is well established; a dramatic increase in congestive heart failure (CHF) is observed at cumulative doses >450 mg/m².^{156,325} However, because this is a median dose for cardiotoxicity, limiting the total dose to this threshold will not protect all patients. At least one study has demonstrated that both biochemical and echocardiographic abnormalities can be seen in childhood cancer survivors following low cumulative anthracycline doses.³²⁶ Although some early reports suggested reversibility in children, subsequent follow-up data confirm a worsening of CHF over time.^{327–330} Late-occurring cardiotoxicity (i.e., years following completion of chemotherapy) has been reported in children.^{330,331} One of these studies used a very sensitive echocardiography technique and reported that the majority of patients had either abnormal

contractility or afterload.³³¹ The other study used a less sensitive echocardiography technique and reported a lower prevalence of cardiotoxicity, although the rate of abnormalities was shown to increase substantially with longer patient follow-up.³³⁰ Recent prospective studies of long-term cardiac function following anthracycline therapy in children show a continual decrement in left ventricular function years after chemotherapy.³³² It is currently unclear what the long-term risk of CHF is in children. Close patient follow-up is important for early detection, although currently used screening tools such as echocardiography detect only functional damage and have not demonstrated value in preventing CHF. Newer nuclear medicine probes are showing some promise in the early detection of anthracycline-induced cardiotoxicity and may be used in the future for identifying children before the development of functional deficits.²⁵⁹ Dexrazoxane (Zinecard), an intracellular iron chelator, has been studied for its effectiveness in preventing anthracycline-induced CHF in adults.^{333,334} However, because there was a decreased antitumor response in dexrazoxane-treated patients in one of these trials, it was subsequently studied at a reduced dose. It has been approved for use only in women with breast cancer who have received a cumulative anthracycline dose of 300 mg/m². In one small trial in children with sarcoma, dexrazoxane decreased the risk of cardiotoxicity and improved tolerance of higher cumulative anthracycline doses.³³⁵ However, the left ventricular EF declined in both groups receiving higher cumulative anthracycline doses. A more recent study employing serum troponin T elevations as a surrogate marker for cardiac damage demonstrated that children with ALL randomized to receive dexrazoxane with each dose of doxorubicin were less likely to have elevations of troponin T levels, but EFS was not different between the group receiving dexrazoxane versus those receiving doxorubicin alone. Also, it is unclear whether these differences in serum troponin T will translate into differences in cardiotoxicity because the study did not report the results of echocardiography.³³⁶ In summary, whether dexrazoxane circumvents the long-term risk of anthracycline-induced CHF in children is unclear. Some degree of long-term cardiotoxicity or CHF risk in children may be unavoidable when an anthracycline is used, even if it is combined with dexrazoxane. Because anthracyclines are an important component of many ALL treatment protocols and have figured significantly into the improved survival rates achieved in high-risk patients in recent years, the benefits seem to outweigh the risks in these patients at present. Although N.B. will be monitored closely for the occurrence of cardiac deterioration, there is currently no proven way to completely eliminate the risk of cardiotoxicity, although restricting children to a cumulative dose of <300 mg/m² has resulted in a low frequency of late occurring cardiotoxicity.³³⁷

Many survivors of childhood ALL therapy are found to have decreased bone mineral density.^{338–342} This has been attributed to both corticosteroids and cranial radiation therapy. Studies of osteonecrosis in childhood ALL demonstrate an overall incidence of 1.1% to 1.8%.^{339,340} However, patient age at the time of treatment is an important risk factor with an incidence of 0.2% in children younger than 10 years, but 8.9% in patients 10 years and 16.7% in those 15 years. Most patients developed osteonecrosis in two or more joints. There is a fairly clear relationship between the cumulative dose of corticosteroid received and the incidence of osteonecrosis. An increased risk of

fractures during chemotherapy has also been reported in children with ALL.³⁴² These risks of bone pathology in survivors of childhood ALL argue in favor of close monitoring as well as optimization of mineral supplementation.

48. After completing induction therapy, N.B. is scheduled to receive a 25-week consolidation therapy consisting of vincristine/prednisone pulses, along with doxorubicin 30 mg/m² Q 3 weeks, in addition to oral mercaptopurine and three IV doses of methotrexate 5 g/m² on weeks 7, 10, and 13. Weekly asparaginase at a dose of 25,000 U/m² IM will also be given weekly for the first 20 weeks. Is this the usual dose of asparaginase? What is the value of asparaginase in patients with T-cell leukemia?

This dosage of asparaginase is higher than that usually used in the treatment of ALL (6,000–10,000 U/m²). This is based on a study of T-cell ALL, in which patients were randomized to receive asparaginase 25,000 U/m² IM every week or not for 20 doses. There was a significant improvement in continuous complete remission at 4 years for those who had received the additional high-dose asparaginase therapy (68% vs. 55%). This provided evidence that patients with T-cell ALL may achieve long-term remission rates similar to those of other ALL immunologic subtypes.²¹⁰ Furthermore, the addition of high-dose methotrexate has increased relapse-free survival rates to approximately 80% in patients with T-cell ALL.

49. Two weeks following his vincristine/doxorubicin/prednisone/mercaptopurine regimen and 5 days following his fifth dose of asparaginase, N.B. develops severe epigastric abdominal pain and hyperglycemia. N.B. has been having normal bowel movements and does not have abdominal distention. The serum amylase is markedly elevated to 450 IU/L (normal, 111–296). Which agent is likely responsible for N.B.'s abdominal pain? What other complications are associated with asparaginase?

Pancreatitis

Pancreatitis has been noted in children following the administration of asparaginase.³⁴³ As illustrated by N.B., this often presents as abdominal pain accompanied by an elevated serum amylase and hyperglycemia. Insulin may be required to control the hyperosmotic, nonketotic hyperglycemia that may result.^{344,345} The pancreatitis is occasionally severe, and fatalities have been reported.³⁴⁶ Unfortunately, the serum amylase may not predict whether patients will develop acute fatal pancreatitis.³⁴⁶ N.B.'s pancreatitis secondary to asparaginase makes further treatment with this agent inadvisable. Because this reaction is not a hypersensitivity reaction, further therapy with the *Erwinia* form of asparaginase is also not recommended. N.B. may be treated with supportive care and insulin therapy. He should recover fully and be able to receive further chemotherapy.

Hypersensitivity Reactions

Hypersensitivity reactions are common, occurring in 20% to 35% of patients, but they are usually mild, generally presenting as urticarial eruptions.³⁴⁴ Premedication does not appear to prevent subsequent reactions in most patients.³⁴⁷ Severe anaphylactoid reactions may occur and can be fatal.³⁴⁸ Clinical reactions correlate better with asparaginase-specific IgG rather than IgE antibodies, and severe hypersensitivity

reactions can be explained in most instances by complement activation.^{349,350}

Anaphylactoid reactions appear to be less common when asparaginase is administered intramuscularly.^{351,352} This is because the slow absorption of asparaginase after IM administration results in delayed, less severe acute reactions. Because these reactions can be delayed, prolonged monitoring is recommended after IM asparaginase.³⁵³ Most serious hypersensitivity reactions tend to occur after the patient has received several doses.

A significant number of patients receiving asparaginase as a component of ALL treatment test positive for anti-asparaginase antibodies, and antibody concentrations are significantly higher in patients who experience a hypersensitivity reaction.³⁴⁷ Patients who are receiving asparaginase may also develop “silent” immune clearance, resulting in rapid clearance of asparaginase from the plasma (similar to patients with hypersensitivity) but without an allergic reaction.^{354–356} These patients may not obtain benefit from asparaginase and may be at greater risk for treatment failure.³⁵⁷ More recently, the prevalence of antibodies to asparaginase has been investigated. It was demonstrated that asparaginase antibody titers were present in 61% of patients receiving native *E. coli* asparaginase during induction therapy (including 29% with silent hypersensitivity). It was also shown that the majority (73%) of these patients did not have measurable asparaginase activity in their serum. Preliminary analysis from this study also demonstrated a relationship between antibody titers and outcomes, with patients with silent hypersensitivity more likely to have an adverse outcome.³⁵⁸ Because premedication usually does not prevent future reactions and because of the possibility that patients who exhibit hypersensitivity may derive no benefit from asparaginase, it appears that the best course of action is to switch patients from the *E. coli* preparation to an alternate asparaginase preparation.

Preparations

Asparaginase is available from two natural sources, *E. coli* and *Erwinia*. These two preparations are not 100% cross-reactive, so the *Erwinia* product may be substituted for the *E. coli* product when hypersensitivity reactions occur.³⁵⁹ However, one should be aware that cross-reactions occur in 17% to 26% of patients.^{240,360} Because of the shorter half-life of the *Erwinia* product, a dosage increase of *Erwinia* asparaginase is necessary to mimic the activity of the *E. coli* product.³⁶¹ Of note, patients receiving equivalent doses of *Erwinia* asparaginase have a poorer remission rate and survival than those patients receiving the *E. coli* asparaginase.³⁶² In contemporary protocols, the dose of *Erwinia* asparaginase is typically about 2.5 times greater than the *E. coli* asparaginase dose. The incidences of hypersensitivity reactions are equivalent for these two preparations.³⁵⁹

Asparaginase is also available as an altered form known as pegaspargase (Oncaspar). This agent is formed by covalently linking monomethoxy PEG to *E. coli* asparaginase. Pegaspargase has a prolonged half-life of 5.8 days compared with 1.2 days for *E. coli* asparaginase and appears to be safe and effective, even in patients with prior reactions to *E. coli* and *Erwinia* asparaginase.³⁶³ The prolonged half-life allows for less frequent (i.e., every 2 week) dosing of PEG asparaginase than for the natural source asparaginase products (i.e., three times a week).³⁵⁵ Asparaginase compounds derived from different *E.*

coli strains may differ in both enzyme activity and half-life. At least one study has reported an unexpected mortality rate in childhood ALL associated with an assumption of equivalence among different *E. coli* asparaginase preparations.³⁶⁴

Asparaginase-Induced Coagulation Disorders

Asparaginase is known to cause decreases in albumin, fibrinogen, and α and β globulins, owing to its effects on general protein synthesis, which can result in inhibition of the synthesis of various clotting factors.^{365,366} Asparaginase may also produce abnormalities in the coagulation-inhibiting and fibrinolytic system, along with deficiencies in antithrombin III and plasminogen.^{365,366} This complex series of events can result in coagulopathies, occasionally leading to cerebral hemorrhage or infarction.^{240,365–367} Some have suggested monitoring markers of the coagulation-inhibiting and fibrinolytic system to identify patients at risk for severe coagulation disturbances,³⁶⁵ but no prospective studies have documented this practice. A higher risk of thrombotic events has been observed among children with central venous catheters and/or a genetic predisposition.^{368,369} There is also a greater risk of thromboembolism in children receiving native asparaginase in combination with prednisone versus dexamethasone, perhaps due to greater inhibition of prostaglandin and thromboxane synthesis by the latter agent.³⁷⁰

Relapsed Acute Lymphoblastic Leukemia

50. After 1 year of continuation therapy, N.B. undergoes a routine lumbar puncture. Analysis of the CSF indicates the presence of numerous lymphoblasts. A CBC reveals Hct of 29.5%, platelet count of 120,000/mm³, and WBC count of 5,300/mm³, with 45% lymphocytes, 50% neutrophils, and 5% bands. A bone marrow biopsy confirms relapsed ALL, with 53% lymphoblasts. Would routine bone marrow biopsies of N.B. have allowed for early detection of N.B.’s relapse and an increased chance for long-term survival? What are N.B.’s chances of achieving a second remission and long-term survival? Which treatments could be used in N.B. in an attempt to attain a complete remission and improve his chances of long-term survival?

[SI units: Hct, 0.295; platelets, 120 × 10⁶/L; WBC count, 5.3 × 10⁶/L with 0.45 lymphocytes, 0.50 neutrophils, and 0.05 bands]

N.B. is asymptomatic at the time of relapse, as are most patients experiencing a relapse of ALL. Most of these patients are diagnosed by routine CBCs and/or lumbar punctures.³⁷¹ Routine bone marrow biopsies identify some bone marrow relapses before they become evident on a CBC, but it has not been demonstrated that earlier identification of bone marrow relapse by morphologic criteria makes an impact on long-term survival. In the future, recognition of MRD with molecular probes may change the prognostic value of routine bone marrow examination.

N.B.’s chances of achieving a second remission with salvage chemotherapy are good. Approximately 80% to 85% of relapsed patients attain a second complete remission with further chemotherapy.^{371–374} Unfortunately, however, bone marrow relapse in childhood ALL is associated with poor long-term survival.^{371–377} Only 6% to 29% of patients with bone marrow relapse may be rendered disease free for 2 years after relapse.^{375–377} Allogeneic HCT for ALL in relapse results in

a 10% to 20% long-term leukemia-free survival.³⁷⁸ However, better results with HCT are possible after a second remission has been achieved. Studies of children with ALL receiving allogeneic HCT in second remission report 5-year DFS rates of 40% and 64%.³⁷⁹⁻³⁸¹ These results are superior to those of chemotherapy in patients such as N.B.³⁸¹⁻³⁸³ However, no randomized trials have established that bone marrow transplantation is superior to chemotherapy for children with ALL in second remission, and some of the reported advantages with transplantation may be due to selection bias.³⁸¹ Autologous HCT does not appear to be superior to chemotherapy for children with ALL in second remission.^{381,384} N.B.'s family should be offered the option of an HCT if testing determines that he has an acceptable bone marrow donor match.

Agents used in salvage regimens are similar to those used in high-risk ALL regimens. In general, treatment usually consists of an intensive three- or four-agent induction regimen of vincristine, prednisone, and daunorubicin with or without asparaginase. This is accompanied by radiation therapy to sites of local relapse (e.g., testis, CNS) and IT chemotherapy.^{374,376,377} After this regimen has been completed, the patient may continue with courses of intensification therapy, continuation therapy, and IT therapy.^{376,377} N.B. already has been treated with many different chemotherapeutic agents. Therefore, the regimen selected should include agents to which N.B. has had little or no exposure. This theoretically increases his chances of maintaining a second remission. For example, a regimen that includes doxorubicin, asparaginase, and cyclophosphamide appears most appropriate for N.B. If N.B. fails to respond to the initial reinduction attempt, HiDAC (3 g/m² Q 12 hr for four doses) in conjunction with standard-dose asparaginase may be used to induce a remission. This approach has been successful in approximately 40% of patients. However, the median duration of second remission was only 3 months.³⁸⁵

PEDIATRIC NON-HODGKIN LYMPHOMA

Lymphomas account for approximately 10% of all childhood malignancies, and they are less common in children than in adults. Children younger than 16 years account for only 3% of all lymphoma cases. The malignancy can occur in any lymphoid cell at any level of differentiation and appears to be a consequence of a genetic alteration. Considerable progress has been made in the treatment of children with NHL, and currently, approximately 80% are cured.³⁸⁶

Classification

Numerous classification systems for NHL exist, and there is considerable variation in terminology among these systems.³⁸⁷⁻³⁹⁰ Pediatric NHLs are best classified using histopathology, which divides them into three different categories: B-cell lymphomas, lymphoblastic lymphomas, and anaplastic large cell lymphomas.³⁸⁶ This is a narrower range of histologic types than in adults.

Lymphoblastic lymphomas account for approximately 30% of childhood NHLs, B cell for about 50%, and large cell for the remainder.³⁸⁶ The lymphoblastic lymphomas are usually immature T cells that are histologically identical to the cells of ALL. The distinction between lymphoblastic lymphoma and ALL is made on the basis of bone marrow involvement, with

ALL being diagnosed if there is >25% bone marrow infiltration. This distinction is made by the amount of bone marrow infiltration that is present at the time of diagnosis. B-cell lymphomas may be further divided into Burkitt, Burkitt-like, and large B-cell lymphomas. Anaplastic large cell lymphomas may be T cell or null cell in origin.

Clinical Presentation

Pediatric patients with NHL may present with a number of different symptoms, many of which are related to the cell type of NHL. In general, these symptoms differ from those in adults because of the propensity of pediatric NHLs to be extranodal in origin in contrast to the common nodal presentation of adult NHL.³⁸⁶ Patients with lymphoblastic lymphoma commonly present with a mediastinal mass or pleural effusions.³⁸⁶ They also may have pain, dyspnea, or swelling of the face and upper arms if superior vena cava obstruction is present. Lymphoblastic lymphoma also has a predilection for the bone marrow and the CNS.^{391,392} Lymphadenopathy in patients with lymphoblastic lymphoma tends to be supradiaphragmatic. Patients with B-cell NHL typically present with an abdominal tumor, abdominal pain, an alteration in bowel function, and possibly nausea and vomiting.³⁹³ In addition, many patients with B-cell NHL present with bone marrow involvement.³⁷⁸ Lymphadenopathy in these patients typically occurs below the diaphragm in the inguinal or iliac area. Anaplastic large cell lymphomas may involve the gut or unusual sites such as the lung, skin, face, or CNS.³⁸⁶

Staging

Several staging systems for pediatric NHLs are used.³⁹³ Today the most commonly used staging system for pediatric NHL is the St. Jude Staging system.³⁸⁶ This staging system includes four stages, with stage I being a single tumor or a single nodal area, and higher stages including cases with regional involvement or more than one anatomical site involved. The highest stage (stage IV) refers to patients with bone marrow or CNS involvement. The main predictor of outcome in pediatric patients with NHL has historically been determined by tumor burden at presentation.³⁹⁴ However, with modern chemotherapy regimens that are tailored to the extent of disease, patients with higher-stage disease may achieve a similar EFS to that achieved in patients with lower-stage disease.^{386,395} Serum concentrations of several different molecules, particularly serum LDH, help clinicians estimate tumor burden. It has also been demonstrated that serum LDH ≥ 500 to 1,000 U/L was a significant predictor of adverse outcome.³⁸⁶

Treatment

Lymphoblastic (T Cell)

The primary treatment for all stages and histologic types of pediatric NHL is combination chemotherapy because it is a generalized disease at the time of diagnosis.³⁸⁶ A wide variety of chemotherapy agents have activity in childhood NHL. At present, the best results to date are reported by the BFM group, with an estimated 5-year EFS of approximately 92%³⁹⁵ (Table 90-21). This regimen employs an intensive scheme of multiagent chemotherapy administered for a treatment duration of

Table 90-21 BFM Group Treatment Protocol for T-Cell Lymphoblastic Lymphoma

| <i>Drug</i> | <i>Dose</i> | <i>Days of Administration</i> |
|---|----------------------------------|----------------------------------|
| Induction Protocol I (All Stages) | | |
| Prednisone (PO) | 60 mg/m ² | 1–28, then taper |
| Vincristine (IV) | 1.5 mg/m ² (max 2 mg) | 8, 15, 22, 29 |
| Daunorubicin (IV over 1 hour) | 30 mg/m ² | 8, 15, 22, 29 |
| L-asparaginase (IV ^a over 1 hour) | 10,000 IU/m ² | 12, 15, 18, 21, 24, 27, 30, 33 |
| Cyclophosphamide ^b (IV over 1 hour) | 1,000 mg/m ² | 36, 64 |
| Cytarabine (IV) | 75 mg/m ² | 38–41, 45–48, 52–55, 59–62 |
| 6-Mercaptopurine (PO) | 60 mg/m ² | 36–63 |
| Methotrexate (IT) | 12 mg | 1, 15, 29, 45, 59 |
| Protocol M | | |
| Mercaptopurine (PO) | 25 mg/m ² | 1–56 |
| Methotrexate (IV) | 5 g/m ² | 8, 22, 36, 50 |
| Methotrexate (IT) | 12 mg | 8, 22, 36, 50 |
| Reinduction Protocol II (Stages III and IV Only) | | |
| Dexamethasone (PO) | 10 mg/m ² | 1–21, then taper |
| Vincristine (IV) | 1.5 mg/m ² (max 2 mg) | 8, 15, 22, 29 |
| Doxorubicin (IV over 1 hour) | 30 mg/m ² | 8, 15, 22, 29 |
| L-asparaginase (IV ^a over 1 hour) | 10,000 IU/m ² | 8, 11, 15, 18 |
| Cyclophosphamide ^b (IV over 1 hour) | 1,000 mg/m ² | 36 |
| Cytarabine (IV) | 75 mg/m ² | 38–41, 45–48 |
| Thioguanine (PO) | 60 mg/m ² | 36–49 |
| Methotrexate (IT) | 12 mg | 38, 45 |
| Maintenance (All Stages) | | |
| Mercaptopurine (PO) | 50 mg/m ² | Daily until month 24 of therapy |
| Methotrexate (PO) | 20 mg/m ² | Weekly until month 24 of therapy |

^aThis agent is typically administered intramuscularly in most treatment protocols in the United States.

^bWith mesna.

Note. Doses were adjusted for children younger than 3 years. Ten percent of the dose was given over 30 minutes, and 90% was given as a 23.5-hour continuous IV infusion. Leucovorin rescue: 30 mg/m² IV at hour 42; 15 mg/m² IV at hours 48 and 54.

Additional doses are given on days 8 and 22 for CNS-positive patients.

IV, intravenously; IT, intrathecally.

Adapted from reference 395.

24 months. Patients with lymphoblastic lymphoma require longer treatment duration than patients with B-cell or anaplastic large cell lymphoma. This chemotherapy plan is similar to that employed in the treatment of ALL and is designed to deliver continuous or weekly therapy. All patients with lymphoblastic lymphoma are given CNS preventive therapy, regardless of stage. Few patients with lymphoblastic lymphoma present with limited disease (stages I and II), thus making it difficult to conduct adequate studies in this patient population. Attempts to shorten the duration of therapy for patients with limited-stage disease have been unsuccessful, although less intensive therapy is administered to patients with early-stage disease on some protocols.³⁸⁶

B Cell

The main differences between the treatment of lymphoblastic and B-cell lymphoma are the use of more agents and a longer treatment duration in the former. The trend in the treatment of B-cell lymphomas has been toward using short duration, intensive therapy with alkylating agents in conjunction with high-dose antimetabolite therapy (e.g., methotrexate, cytarabine). Chemotherapy is administered in rapid succession with limited recovery from neutropenia (i.e., ANC 500) between

cycles. Patients with localized B-cell lymphomas respond as adequately to a four-drug regimen (consisting of cyclophosphamide, vincristine, methotrexate, and prednisone) as they do to more aggressive regimens.³⁸⁶

Evidence suggests that a 6-month course is as efficacious as the previously used 18-month course for patients with localized B-cell lymphomas.³⁸⁶ Studies indicate that even 6 months of chemotherapy may be unnecessary for patients with limited-stage disease because it has been demonstrated that maintenance treatment offered no additional benefit after 9 weeks of combination chemotherapy.³⁸⁶ Contemporary chemotherapy regimens include varying degrees of treatment intensity from three to seven cycles, depending on whether the tumor is completely resected, and on bone marrow and CNS involvement, and the serum LDH.³⁹⁶

With the addition of high-dose methotrexate, ifosfamide, etoposide, and HiDAC to the standard regimen, patients with stage III disease are now achieving survival rates comparable to those of patients with limited-stage disease.³⁹⁶ Patients with bone marrow disease also benefit from these intensive therapeutic strategies and have achieved impressive survival rates of approximately 80%.³⁸⁶ Currently, patients with advanced-stage disease are treated with a total of six to eight cycles of

chemotherapy, and these treatment protocols achieve superior results to those of a much longer duration (e.g., 1–2 years) used previously.^{386,396,397} Although rituximab is now a standard therapy component for B-cell lymphomas in adults, it has yet to be routinely employed in front-line treatment in the pediatric arena. Case reports demonstrate the utility of this agent when added onto a standard chemotherapy backbone for children with relapsed disease.^{398,399}

Large Cell

Large cell lymphomas have responded well to both types of regimens.^{386,400,401} Thus, the use of shorter, less complicated, B-cell protocols is appropriate. Patients who fail to respond may be treated with additional courses of their prescribed protocol in hopes of eventually inducing a response. Patients who relapse may be reinduced with intensive chemotherapy, but their prognosis for long-term survival is unfavorable.

Lymphoblastic Lymphoma

Treatment

ACUTE TREATMENT

51. D.B., a 16-year-old girl, presents with a history of shortness of breath and chest pain for 3 weeks before admission. A mediastinal mass is found, and a biopsy confirms a lymphoblastic (T-cell) lymphoma. X-ray of the chest reveals a right pleural effusion. Laboratory values show erythrocyte sedimentation rate, 35 (normal, 0–20); WBC count, 22,000/mm³ (normal, 4,500–11,000); uric acid, 7 mg/dL; and LDH, 1,259 U/L (normal, 280–540). The bone marrow, CNS, and abdomen are negative for lymphoma. How should D.B. be managed acutely? Besides chemotherapy, what types of adjunctive therapies should be initiated to minimize the acute effects of treatment?

Given D.B.'s shortness of breath and chest pain, it is likely that her mediastinal mass may be obstructing the superior vena cava. To alleviate this obstruction, the most appropriate course of action is to decrease the tumor mass by initiating chemotherapy as soon as possible. Radiation therapy offers no additional benefit in patients such as D.B., with a tumor such as NHL, which is highly responsive to chemotherapy.^{386,402} Because of the high cell kill that will result from the initial chemotherapy treatment, uric acid nephropathy is also possible. However, the risk of this complication is probably greater in patients with B-cell NHL in whom the fraction of cells in S phase is higher.^{403,404}

Alkaline diuresis and allopurinol should be instituted before chemotherapy to prevent this complication (see question 4). Because D.B. has a pleural effusion, fluids may collect in this third space, resulting in weight gain and decreased urine output. Thus, in addition to placement of a chest tube with suction, D.B. should be given diuretics to maintain an adequate urine output. To minimize intravascular volume depletion and maintain electrolyte balances, fluid input and output, body weight, and electrolyte panels should be monitored daily. These values should be used to make appropriate adjustments in D.B.'s electrolyte and fluid balance.

ADVERSE EFFECTS

52. D.B. is treated with the BFM combination chemotherapy regimen. Due to her intrathoracic mass, her disease is character-

ized as stage III. She is to receive induction therapy for 8 weeks, as outlined in Table 90-21. Which acute adverse effects is D.B. likely to experience with these agents? How can they be monitored, minimized, and treated?

Several toxicities are expected with these chemotherapy agents. For vincristine, both constipation and neuropathy are likely to appear during or following the 4 weeks of therapy.²⁵² Constipation can be prevented or minimized by use of stool softeners with or without a laxative.⁴⁰⁵ Neuropathy may be painful (especially when jaw pain occurs) but can be managed with mild analgesic regimens consisting of NSAIDs and/or acetaminophen with codeine. Both toxicities are self-limiting and are not reasons to discontinue or decrease the dosage of vincristine unless neuromuscular toxicity, as evidenced by motor weakness, develops. As outlined previously, asparaginase can cause several types of toxicities, most of which cannot be prevented.

Prednisone is likely to increase D.B.'s appetite and may cause gastritis, although divided doses will help decrease stomach upset. In addition, prednisone-induced behavioral disturbances are not uncommon.²⁵⁴

Unlike prednisone and vincristine, daunorubicin, cyclophosphamide, cytarabine, and mercaptopurine produce significant myelosuppression. Leukopenia is the primary sign, with the nadir occurring in approximately 8 to 14 days and recovery occurring by approximately day 21 after administration. Because the goal of induction therapy is achievement of remission, doses of daunorubicin will not be held for uncomplicated myelosuppression during the first 4 weeks of induction therapy, although during the latter 4 weeks, the combination of cyclophosphamide, cytarabine, and mercaptopurine are typically held until hematologic recovery occurs.

Hemorrhagic cystitis may occur with cyclophosphamide, but it is usually associated with high-dose therapy or with prolonged administration, which D.B. is not receiving. Vigorous IV hydration to maintain urine output of approximately 50 to 100 mL/m²/hour should reduce the risk of this toxicity at this dose. In addition, this chemotherapy protocol also includes mesna, which will bind to urotoxic metabolites of cyclophosphamide and also reduce the risk of hemorrhagic cystitis. Because most of the induction regimen will be administered on an outpatient basis, patients and/or parents should be instructed to report signs or symptoms of infection (e.g., febrile episodes) immediately so that proper treatment may be instituted as soon as possible. To decrease the risk of hemorrhagic cystitis, parents should be instructed to report whether patients are urinating regularly after cyclophosphamide.

Nausea and vomiting are likely to be induced by both daunorubicin and cyclophosphamide/cytarabine.⁴⁰⁶ D.B.'s chemotherapy regimen includes a corticosteroid (prednisone), which may provide some antiemetic activity during the initial 4 weeks.⁴⁰⁷ However, to maximize tolerance to her chemotherapy, D.B. should receive a 5-HT₃ serotonin antagonist. Ondansetron may be used in this setting and is more effective than metoclopramide when either is combined with a corticosteroid.⁴⁰⁸ D.B. is unlikely to require corticosteroids during the first 4 weeks of induction therapy. However, during the second portion of induction, D.B. will benefit from a few doses of dexamethasone at 10 mg/m² PO or IV at the time of cyclophosphamide administration.⁴⁰⁶

Central Nervous System Prophylaxis

53. What is the importance of CNS prophylaxis for D.B., and what type of treatment regimen is typically used?

All pediatric patients with lymphoblastic lymphoma should receive some form of CNS prophylaxis. Although lymphoblastic lymphoma rarely presents with CNS involvement, as illustrated by D.B., it was a common site of relapse before CNS prophylaxis was included as a routine part of the chemotherapy regimen.^{391,392} Recurrence of NHL within the CNS is rare when intrathecal methotrexate and/or cytarabine are given.³⁸⁶ D.B. will be treated with intrathecal methotrexate periodically, as outlined in Table 90-21.

Myelosuppression and Hematopoietic Recovery

54. After completion of initial therapy, the chemotherapy plan for D.B. consists of protocol M and reinduction protocol II, as outlined in Table 90-21. How should D.B.'s hematopoietic recovery be managed, and what guidelines may be used to determine when it is appropriate for her to receive the next sequence of the treatment cycle? Would D.B. benefit from a colony-stimulating factor (CSF) to aid with hematopoietic recovery?

Protocol M will likely not produce significant myelosuppression because leucovorin rescue will tend to minimize the myelosuppression from the high-dose methotrexate. The most

challenging problems with this phase of treatment will be to confirm that the methotrexate has been properly eliminated and to continue aggressive hydration, alkalization, and leucovorin dosing until the methotrexate level is nontoxic. Due to D.B.'s pleural effusion at the time of diagnosis, it should be confirmed that this has resolved prior to administration of high-dose methotrexate in order to avoid significantly delayed clearance because the pleural effusion could allow for third spacing of high doses of methotrexate. Pleural effusions are a relative contraindication to high-dose methotrexate. Methotrexate elimination has high inter- and intrapatient variability, and necessitates close monitoring of methotrexate concentrations and renal function after each dose.

Protocol II will result in significant myelosuppression. However, as with protocol I, dosing of doxorubicin will not be held for uncomplicated myelosuppression. Similarly, during the second phase of this protocol, dosing of cytarabine and thioguanine will also not be held for uncomplicated myelosuppression. However, prior to the start of this second phase on cycle day 36, clinicians will assure adequate hematologic recovery, typically defined as an ANC > 750/mm³ and platelets > 100,000/mm³. It is unlikely that D.B. will benefit from a CSF during these phases of therapy. When myelosuppressive chemotherapy is given fairly continuously, as is the case with protocol II, there is little room for inserting doses of CSFs on days where myelosuppressive chemotherapy is not being administered.

Solid tumors include the malignancies that initially present as discrete masses. They arise from malignant transformations of cells within virtually any organ system except the hematopoietic system. Solid tumors are far more common than hematologic malignancies and represent the major causes of cancer-related morbidity and mortality. Depending on the specific type

of cancer and its stage, surgery, radiation, chemotherapy, biologic therapy, immunotherapy, and hormonal manipulation all play important roles in patient treatment. The types of solid tumors that occur in adult versus pediatric populations are distinctively different. Specific tumors commonly treated with drug therapy are included in this chapter.

ADULT TUMORS BREAST CANCER

Risk Factors

1. B.W., a 41-year-old woman, is found to have a 2.2-cm mass in the upper, outer quadrant of her left breast during routine screening mammography. Biopsy of the mass reveals infiltrating ductal carcinoma. Physical examination is unremarkable, and she has no complaints. All laboratory values, including the complete blood count (CBC) and liver function tests (LFT), are within normal limits and a chest radiograph is negative. Her family history is significant in that her mother died of breast cancer at age 42, and her 44-year-old sister had a breast tumor removed about 5 years ago. B.W. reports that she had her first menstrual cycle at age 10 and has had regular periods since that time. She is married but has never been pregnant. What is the incidence of breast cancer in premenopausal women? Did any factors place B.W. at an increased risk of developing breast cancer?

Overall, breast cancer is the most common cancer in women in the United States and accounts for 26% of their cancer occurrences and 15% of their cancer deaths; however, the incidence rates as well as the death rates have been declining since 1990.¹ The lifetime risk of developing breast cancer is approximately one in eight women with the greatest risk occurring after age 65.¹ For women 39 years of age or younger, the chance of developing breast cancer is <1%; however, a strong family history of breast cancer increases the relative risk.¹

Some cases of familial breast cancer, especially those occurring in premenopausal women, have been linked to specific breast cancer susceptibility genes, BRCA-1 and BRCA-2. Carriers of these genes have an increased risk of breast and ovarian cancer in women, and prostate cancers in men. Women such as B.W. who have a positive family history and who are carriers of the gene have an 85% chance of developing breast cancer and a 60% chance of developing ovarian cancer by age 70.² The risk is not as significant in women who are carriers and who do not have a positive family history. Genetic testing is available; however, if a woman chooses to have such testing, appropriate genetic counseling and psychological support should be made available.

Despite the strong relationship with breast cancer development, it is also important to realize that BRCA gene mutations account for only 5% to 10% of all cases. Several additional factors have been associated with an increased risk of developing breast cancer (Table 91-1). Nulliparous women such as B.W. have a higher incidence of breast cancer than women who have had one or more pregnancies, but age at first pregnancy appears to be an even more important determinant. One study indicated that the risk of developing breast cancer was substantially higher in women whose first pregnancy was after age 30, compared with those whose first pregnancy was before age 18. Early menarche also has been associated with an increased risk of breast cancer.³

Screening

2. Is routine screening mammography recommended for B.W. because of her increased risk of breast cancer? Is it recommended for all women?

Table 91-1 Risk Factors Associated With Development of Breast Cancer

Strong Risk Factors

- History of breast cancer in the contralateral breast
- Family history of breast cancer, especially in first-degree relatives
- Benign breast “cancer” (i.e., atypical hyperplasia)
- Early menarche, late menopause
- Late first pregnancy greater than no pregnancy
- Advancing age

Possible Risk Factors

- Obesity
- High-fat diet
- Long-term use of exogenous estrogens
- Alcohol

Women with a positive family history often are instructed to begin screening at an early age. Several different guidelines for breast cancer screening are available. Although strong evidence of benefit is lacking, it generally is agreed that women should perform monthly breast self-examinations. Annual examination for breast cancer performed by a health care provider is recommended for all women >40 years of age.

Nearly 75% of breast cancers occur in women >50 years of age. Currently, all screening guidelines recommend that women in this age group have annual mammography but disagree over the value of mammography screening in women age 40 to 49 years; therefore, the guidelines differ for this group of patients. Meta-analyses reveal the risk reduction from mammography screening does not differ substantially by age, although absolute benefits are lower in women <50 years compared with women aged 50 years and older.⁴ More recently, data have supported the role of magnetic resonance imaging (MRI) in women at higher risk, defined as those with a lifetime risk of approximately 20% to 25%, which includes women with a family history (especially early onset), genetic mutations including BRCA, and certain clinical factors that increase risk. For this reason, the American Cancer Society (ACS) updated their recommendations to include MRI, depending on the presence of risk factors, as an adjunct to annual mammography screening, which should be initiated at age 40.⁵

It is not clear how long screening should be continued. Women >70 years of age are at increased risk for developing breast cancer; however, no randomized trials have evaluated the merits of annual mammography in this group. The ACS states there is no chronologic age at which screening should stop, emphasizing that as long as a woman is in good health she is likely to benefit from annual mammography.

Surgery

3. After receiving the results of the biopsy, B.W. has a partial mastectomy and full axillary lymph node dissection because of a positive sentinel lymph node biopsy. The tumor is estrogen- and progesterone-receptor negative; human epidermal growth factor receptor-2 (erB-2 or HER-2) positive; and 4 of 20 lymph nodes are positive for tumor involvement. Is partial mastectomy as effective as more extensive surgical procedures such as modified radical mastectomy? Is radiation indicated following surgery?

Historically, radical mastectomy (removal of the breast, axillary lymph nodes, and pectoralis muscles) and modified radical mastectomy (radical mastectomy with preservation of the pectoralis muscles) have been the standard surgical procedures used for primary breast cancer. The psychological and cosmetic effects of breast loss can be substantial, however. This has led to the use of more conservative surgical procedures, such as lumpectomy, partial mastectomy, and evaluation of axillary lymph nodes using lymph node mapping with sentinel lymph node biopsy. Lumpectomy consists of gross removal of the tumor without attention to margins; a partial mastectomy includes excision of the tumor with clean surgical margins. It is now standard to evaluate the axilla through the use of the sentinel lymph node by the injection of radioactive colloid or blue dye into the breast to identify the lymph nodes that first receive drainage for the tumor. Use of the sentinel lymph node to assess spread of disease has reduced the number of patients who require axillary lymph node dissection.⁶ Early trials evaluating conservative procedures without treatment of the remaining breast tissue or axillary lymph nodes reported high failure rates. Failures presented primarily as cancer recurrences in the remaining breast tissue or axilla.⁷ Therefore, postoperative radiation therapy is indicated after conservative breast surgery because it reduces the risk of local recurrence. Additionally, no difference in survival is seen between patients having conservative surgery (e.g., lumpectomy or partial mastectomy) followed by local radiation therapy and those treated with a radical mastectomy.^{7,8}

Adjuvant Therapy

4. B.W. recalls that her sister received chemotherapy after her surgery for breast cancer. She now questions whether she should receive any additional therapy and wonders what her chances are that her cancer has been cured. What factors determine the need for adjuvant systemic therapy following surgery, and what are the indications for administering adjuvant chemotherapy, biologic therapy, or hormonal therapy?

A significant portion of women who have early-stage disease experience relapse at distant sites and ultimately die of recurrence-related complications. Distant treatment failures indicate that some women have clinically undetectable micrometastatic disease at the time of diagnosis, therefore locoregional (surgery and radiation) therapy is insufficient. Adjuvant therapy is given to kill any cells that may have spread from the primary site and that are not detectable by radiographic measures. Adjuvant systemic therapy can include chemotherapy, hormonal approaches, biologic therapy, or experimental agents.

Recommendations regarding adjuvant chemotherapy are generally made by estimating the risk of recurrence and the expected benefit of therapy balanced with the anticipated toxicity. The benefit of systemic adjuvant therapy is directly related to the likelihood of disease recurrence. A number of factors determine the likelihood of recurrence and the role of adjuvant therapy for early stage breast cancer. Size of the primary tumor, presence and number of involved axillary lymph nodes, HER-2 oncogene amplification, nuclear or histologic grade of the tumor, and the presence of hormone receptors on the tumor (estrogen, progesterone, or both) appear to be the most

important factors that predict prognosis.^{9,10} More recently, the enhanced use of molecular markers has improved prognostic profiling to determine risk of recurrence.

Currently, the single most important factor that predicts recurrence of breast cancer in patients such as B.W., whose tumor is initially small and localized, is the presence and extent of lymph nodes positive for cancer. Women with positive lymph nodes (stage II disease) have a 40% to 60% chance of cure with surgery alone. Women with negative lymph nodes (stage I disease) have a 70% to 90% chance of cure with surgery alone. Because B.W., who has four positive nodes, negative hormone receptors, and positive HER-2, is at high risk for recurrence, she should receive adjuvant therapy.

Patients with node-negative, estrogen-receptor positive (ER+) breast cancers have a better prognosis. They may not require adjuvant chemotherapy, and many only need 5 years of hormonal therapy. Genomic tools evaluating the tumor specimen from tissue blocks, utilizing *oncoType* DX^{®11}, and from fresh tissue, utilizing MammaPrint,¹² are being tested in clinical trials to identify patients with node-negative, ER+ tumors at high risk of recurrence that would benefit from adjuvant chemotherapy. The *oncoType* DX[®], commercially available in the United States, utilizes a 21-gene recurrence score, based on monitoring of messenger RNA (mRNA) levels of 16 cancer-related genes in relation to five reference genes.¹¹ These recurrence scores have identified patients at low-, intermediate-, or high-risk of recurrence in a retrospective analysis. This analysis revealed that women in the low-risk group (recurrence score <18) need only hormonal therapy, whereas the high-risk group (recurrence score ≥31) require both chemotherapy and hormonal therapy.¹¹ It is not clear from the retrospective analysis which patients in the intermediate-risk group require adjuvant chemotherapy in addition to hormonal therapy. Although *oncoType* DX[®] is not widely used in clinical practice, the prospective study TAILORx (Trial Assigning Individualized Options for Treatment), which is accruing 10,000 women in North America, will further define whether chemotherapy is required in addition to hormonal therapy for the intermediate-risk group defined by the recurrence score of 12 to 25.

Trials of systemic adjuvant therapy in women with breast cancer began in the 1960s. These trials originally focused on patients with stage II disease; however, recognizing the significant rate of disease recurrence in patients with stage I disease, later trials included patients with stage I disease as well. Many trials evaluating the effects of systemic adjuvant chemotherapy, endocrine therapy, and combined chemoendocrine therapy have been conducted over the past 45 years. Because many of the individual trials have included relatively small numbers of patients, multiple patient subsets, or different therapeutic strategies, a series of meta-analyses have been performed by the Early Breast Cancer Trialists' Collaborative Group. The most recent meta-analysis reviewed data from 194 randomized clinical trials conducted worldwide, which included 110,000 women with stages I and II breast cancer. The overview concluded that appropriate use of adjuvant cytotoxic chemotherapy can reduce the rate of death by as much as 10% in women <50 years of age and by 3% for those age 50 to 69 years.¹³ Irrespective of age or chemotherapy, for ER+ disease, adjuvant tamoxifen reduces the annual breast cancer death rate by 31%.¹³ Anthracycline-containing regimens were associated with a 38% decrease in the annual death rate in women <50 years

of age and by 20% in women 50 to 69 years of age.¹³ Additionally, the use of anthracycline-based adjuvant regimens led, on average, to improved treatment results compared with non-anthracycline-based regimens in node-positive breast cancer. The proportional reduction in risk of death in stages I and II is approximately equivalent; however, the absolute survival difference is greater in patients with stage II disease who have a higher risk of recurrence. Because B.W.'s risk of recurrence is high and her age is <50 years, systemic adjuvant chemotherapy would be recommended. Common regimens for the adjuvant setting (outlined in Chapter 88, Neoplastic Disorders and Their Treatment) include FAC (fluorouracil, doxorubicin, cyclophosphamide), FEC (fluorouracil, epirubicin, cyclophosphamide), AC (doxorubicin, cyclophosphamide), EC (epirubicin, cyclophosphamide), TAC (docetaxel, doxorubicin, cyclophosphamide), and CMF (cyclophosphamide, methotrexate, fluorouracil), among others.

Biologic therapy targeting HER-2 has become a standard in the adjuvant setting in patients whose tumors overexpress HER-2. A number of trials evaluating trastuzumab in the adjuvant setting with various combination chemotherapies have shown that adjuvant trastuzumab significantly reduces the risk of recurrence and may prolong overall survival with acceptable toxicity.^{14,15} Additionally, concurrent administration of trastuzumab with chemotherapy appears to be superior to sequential administration.

Treatment recommendations for patients with stages I and II breast cancer continue to evolve.^{16,17} Early guidelines were based on menopausal status (if unknown, based on age older than or younger than 50 years) and the presence of involved axillary lymph nodes at the time of the initial surgery. The results of these early studies demonstrated conclusively that premenopausal women, particularly those with four or more positive lymph nodes who received chemotherapy, had significant prolongation in disease-free and overall survival compared with untreated controls. These trials also demonstrated that postmenopausal women treated with adjuvant endocrine therapy, such as tamoxifen or an aromatase inhibitor, had significant improvement in disease-free and overall survival compared with untreated controls. Thus, chemotherapy was recommended for premenopausal women and endocrine therapy for postmenopausal women.

The significance of menopausal status for adjuvant therapy is related to hormone receptors in the primary tumor. Whereas most premenopausal women are hormone receptor negative, most postmenopausal women are hormone receptor positive. Endocrine therapy is most likely to benefit women with positive hormone receptors. In early studies, hormone receptor assays were not available and menopausal status served as a surrogate marker of hormone receptor positivity. Although current adjuvant treatment guidelines retain the categories of premenopause and postmenopause, they also incorporate hormone receptor status.

RECOMMENDED REGIMENS

5. Based on current guidelines and the estrogen receptor status of her tumor, B.W.'s physician recommends that she receive adjuvant chemotherapy. What regimens are currently recommended?

B.W. has several poor prognostic characteristics associated with her disease, including the presence of positive lymph

nodes, negative hormone receptors, and HER-2 overexpression. The HER-2 oncogene has undergone extensive study as both a prognostic and a predictive factor in early stage breast cancer.^{10,18,19} The gene encodes for a growth factor receptor, and its overexpression correlates with a poor prognosis and predicts a stronger likelihood of response to an anthracycline-containing regimen. For this reason, B.W. could receive a doxorubicin-containing regimen with trastuzumab.

It was hypothesized that owing to the importance of doxorubicin in the treatment of breast cancer, increasing the dose would be beneficial. Although trials reveal that increasing the dose of doxorubicin does not appear to influence treatment outcomes, the addition of a taxane results in a significant reduction of the rate of both recurrence and death.^{20,21} Dose density has also been shown to be important in the adjuvant setting.²² Dose density refers to the administration of drugs with a shortened intertreatment interval (e.g., every 2 weeks). Therefore, it is recommended that B.W. receive four cycles of dose-dense doxorubicin and cyclophosphamide followed by 12 weekly doses of paclitaxel with concurrent weekly trastuzumab, which is continued for a total of 52 weeks.

ENDOCRINE THERAPY

6. Should B.W. receive adjuvant endocrine therapy in addition to chemotherapy?

Because B.W.'s tumor was negative for hormone receptors, endocrine therapy is not indicated as it is ineffective against ER- tumors in the adjuvant setting. In premenopausal women with ER+ tumors, however, combined chemoendocrine therapy may be beneficial. Results of the meta-analysis found that ovarian ablation, by surgery or radiation or ovarian suppression by treatment with luteinizing hormone-releasing hormone (LHRH) analogs, in patients <50 years of age was as effective as chemotherapy in reducing recurrence and mortality.²³ This, however, is an indirect comparison of results of trials employing ovarian ablation with those using combination chemotherapy. The report of this meta-analysis has stimulated renewed interest in the value of endocrine therapy (ovarian ablation, tamoxifen, or LHRH analogs) in premenopausal women. Combination chemotherapy often produces permanent ovarian failure in premenopausal women and evidence exists that this is associated with a favorable prognosis.

If B.W.'s tumor had been ER+, both chemotherapy and endocrine therapy would have been indicated. Typically, radiation and adjuvant chemotherapy are completed before the initiation of hormonal therapy. In the meta-analysis, chemoendocrine therapy was associated with the greatest reduction in risk of death in women ages 50 to 69 years.¹³ Consequently, chemoendocrine therapy is now recommended for patients with ER+ tumors.

For the last 20 years, interest in adjuvant endocrine therapy for pre- and postmenopausal women with ER+ tumors has concentrated on the optimal use of tamoxifen.¹³ Although it is clear from these studies that adjuvant tamoxifen therapy in patients with ER+ tumors for 5 years is superior to 2 years, no evidence indicates that extending tamoxifen beyond 5 years provides any advantage, and benefits are seen independent of age and menopausal status.²⁴ Whereas adjuvant tamoxifen was considered the classic standard care for the endocrine therapy of ER+ breast cancer, successful trials involving aromatase

inhibitors (anastrozole, letrozole, and exemestane) for postmenopausal women in the adjuvant setting have challenged the gold standard, tamoxifen.

Trials of the aromatase inhibitors, used only in postmenopausal women with ER+ tumors, have revealed that both anastrozole and letrozole reduce the recurrence risk when compared with tamoxifen.^{24,25} Additionally, use of exemestane for 2 to 3 years following 2 to 3 years of tamoxifen (for a total of 5 years of therapy) was associated with an improvement in relapse-free survival.²⁴ Although each of the studies involving aromatase inhibitors compared with tamoxifen used different study designs (head-to-head, sequential, extended), aromatase inhibitors are now the standard in the adjuvant setting for postmenopausal women. Finally, letrozole for 5 years after completion of first-line tamoxifen therapy has also been shown to be effective. Currently, no comparative trials exist to document enhanced efficacy of one aromatase inhibitor over another. Concerns with the use of aromatase inhibitors are the reported increased cardiovascular complications versus tamoxifen, which did not reach statistical significance. Increased bone fractures were also observed; a number of studies with new data to be presented over the next few years should clarify this association.

For premenopausal women such as B.W., combining different endocrine modalities such as tamoxifen with ovarian ablation has been investigated. The rationale for these studies is based on data from patients with metastatic disease in whom an improvement in outcomes was noted in those receiving an LHRH agonist in combination with tamoxifen compared with either therapy alone.²⁴ Ongoing studies evaluating the role of LHRH agonists in combination with tamoxifen or an aromatase inhibitor will better define the role of estrogen suppression in premenopausal women.

Metastatic Disease

Prognosis

7. Approximately 2 years after completing adjuvant chemotherapy and trastuzumab therapy, B.W. begins experiencing back pain that is partially relieved by ibuprofen 400 mg as needed (PRN). Because the pain was temporally related to moving some furniture in her living room, she did not seek medical attention. Five days after the onset of the back pain, her husband noted that she was mildly confused. He contacted her physician who suggested she come to the clinic immediately. Physical examination was negative for lymphadenopathy or breast masses, and chest and abdominal examinations were unremarkable. Pertinent laboratory values were as follows: calcium (Ca), 15 mg/dL (normal, 9.0–11.5 mg/dL); phosphorus, 4.2 mg/dL (normal, 2.5–4.5 mg/dL); sodium (Na), 138 mEq/L (normal, 136–145 mEq/L); potassium (K), 4.3 mEq/L (normal, 3.5–5.5 mEq/L); albumin, 3.0 g/dL (normal, 3.5–5.5 g/dL); alkaline phosphatase, 580 mU/mL (normal, 15–70 mU/mL); aspartate aminotransferase (AST), 258 mU/mL (normal, 5–20 mU/mL); and alanine aminotransferase (ALT), 96 mU/mL (normal, 5–24 mU/mL). The CBC was within normal limits. Spinal cord radiographs revealed several lytic vertebral lesions consistent with metastatic carcinoma, but a myelogram did not show any evidence of spinal cord compression.

B.W. is admitted to the hospital for acute management of hypercalcemia and restaging of her breast cancer to determine the

extent of tumor spread. A bone scan shows positive uptake in the spine and right scapula and a liver scan reveals two small nodules consistent with metastatic disease. A computed tomography (CT) scan of the brain is positive. Is any further assessment of the disease stage necessary at this time? What is the prognosis now that B.W.'s disease has metastasized?

[SI units: Ca, 3.75 mmol/L (normal, 2.25–2.88); phosphorus, 1.36 mmol/L (normal, 0.81–1.45); Na, 138 mmol/L (normal, 136–145); K, 4.3 mmol/L (normal, 3.5–5.5); albumin, 30 g/L (normal, 35–55); alkaline phosphatase, 580 U/L (normal, 15–70); AST, 258 U/L (normal, 5–20); ALT, 96 U/L (normal, 5–24)]

The purpose of documenting all sites of disease involvement is to provide a means by which treatment efficacy can be assessed and to identify any disease sites that may require immediate therapy to avoid life-threatening complications (e.g., brain metastases). B.W. has documented disease in the liver, bones, and brain. Other common sites of disease are the remaining breast tissue, bone marrow, and the lungs. Because her CBC is normal, further examination of the bone marrow is not necessary at this time; however, a chest radiograph should be ordered to rule out involvement of the lungs.

Metastatic breast cancer is rarely curable. After metastatic disease is documented, survival may range from a few months to several years, depending on the site(s) and number of metastases as well as the rate of tumor growth (which may be assessed by the disease-free interval). The median duration of survival after recurrence is approximately 2 years. Multiple sites of metastatic disease, a relatively short disease-free interval (<1 year), liver involvement, negative estrogen and progesterone receptors at the time of diagnosis, and premenopausal status all confer a poor prognosis for B.W.

Chemotherapy and Targeted Therapy

8. What treatment options are available for B.W. at this time?

The goals of therapy for metastatic disease are to prolong survival, alleviate or prevent tumor-related symptoms or complications, and maintain or improve quality of life. Currently, patients such as B.W. with metastatic disease have a 5-year survival rate of 26%.¹ B.W. has tumor in both the liver and bones, and systemic therapy is necessary to treat both disease sites simultaneously. Bone and soft tissue metastases tend to have a better prognosis and are more likely to respond to endocrine therapy. B.W. is unlikely to respond to endocrine manipulations such as hormonal therapy or oophorectomy, however, because her tumor is ER– and she is premenopausal. Liver metastases do not respond well to hormonal therapy. Patients such as B.W. who are symptomatic and unlikely to benefit from hormonal therapy should receive chemotherapy.

Cytotoxic chemotherapy is the mainstay of treatment for advanced breast cancer in patients whose tumors are refractory to endocrine therapy or not sensitive to hormone therapy. With the increased use of adjuvant chemotherapy, however, the choice of first-line treatment for metastatic breast cancer is increasingly complicated and is determined by a complex interaction of tumor, patient tolerability, and oncologist preferences. Many antitumor agents have some degree of activity against breast cancer (Table 91-2).²⁶ Several combination regimens that have been widely used in advanced breast

Table 91-2 Single-agent Response Rates of Chemotherapy Used as First-line Therapy in the Treatment of Metastatic Breast Cancer²⁶

| Agent | Dose/Frequency | Response Rates (%) |
|---------------------------------------|---|--------------------|
| Doxorubicin | 60–75 mg/m ² every 3 wk | 36–41 |
| Pegylated liposomal doxorubicin | 40–50 mg/m ² every 28 days | 36–41 ^a |
| Epirubicin | 75–90 mg/m ² every 3 wk | 36–41 ^a |
| Paclitaxel | 20–30 mg/m ² every wk | |
| | 135–175 mg/m ² every 3 wk | 22–29 ^b |
| | 80–100 mg/m ² weekly | 50–55 ^c |
| Docetaxel | 100 mg/m ² every 3 wk | 48 |
| Capecitabine | 1,250 mg/m ² twice a day for 14 days of a 21-day cycle | 30–37 |
| Nanoparticle albumin bound paclitaxel | 260 mg/m ² every 3 wk | 33 |
| Vinorelbine | 25 mg/m ² every wk | 25–40 |
| Gemcitabine | 1,200–1,500 mg/m ² every wk for 3 of 4 wk | 15–37 |

^aStudies report equivalence to doxorubicin in response rate and time to progression.

^bResponse rates include those patients that were anthracycline pretreated.

^cBoth first- and second-line response rates.

cancer are listed in Chapter 88, Neoplastic Disorders and Their Treatment. Currently, sequential therapy with one agent at a time over concurrent therapy with combination therapy is more common; however, this concept is changing with the targeted therapies. Chemotherapy is commonly continued as long as the patient is achieving a response or has stable disease and is tolerating treatment. Because adjuvant chemotherapy is increasingly common, many patients in the metastatic setting have received many of the active agents utilized in the metastatic setting. Response rates to combination chemotherapy regimens in metastatic disease in patients who have not received prior chemotherapy are high. The response rates to chemotherapy in patients who have had prior exposure to chemotherapy are low, however.

One of the most important factors in determining the choice of first-line metastatic chemotherapy is the type of treatment given in the adjuvant setting. Anthracyclines are considered the most active agents against breast cancer; however, overall response rates in patients who have had prior anthracyclines are only 20% to 30%. In patients who have not received adjuvant anthracyclines, first-line anthracycline therapy should be considered, particularly in patients who have had disease-free intervals >12 months and in whom the maximal lifetime dose of anthracycline has not been achieved; however, data conclusively supporting this approach are lacking. Consideration of a different dose, a different anthracycline, or altered schedule should be given. Taxane-based therapy is considered the standard of care after anthracycline therapy. In patients who have received adjuvant taxane therapy and have had a long disease-free interval, treatment with a different taxane is a reasonable option. Finally, the recent approval of ixabepilone as monotherapy or in combination with capecitabine has been shown to be effective in patients who have previously been treated with an anthracycline and a taxane.

In patients with HER-2 positive tumors, trastuzumab in combination with chemotherapy has been shown to improve response rates and survival. In the largest trial of trastuzumab in patients with HER-2 positive, untreated metastatic breast cancer, trastuzumab plus chemotherapy prolonged the median time to disease progression and median response duration, increased the overall response rate, and improved overall survival time.²⁷ The greatest improvement was seen in patients re-

ceiving the combination of trastuzumab and paclitaxel. Other regimens consisting of other active agents with trastuzumab have been investigated. Weekly trastuzumab and vinorelbine resulted in an 84% response rate in patients receiving this regimen as first-line therapy for metastatic disease.²⁸ In patients who had previously received paclitaxel, the use of docetaxel in combination with trastuzumab reported a response rate of 20%. As with B.W., however, the use of trastuzumab in a patient who has already been treated with the drug in the adjuvant setting is unclear because the recurrent cancer is likely to be HER-2 positive, further targeting may provide some benefit. B.W.'s cancer recurred 2 years following chemotherapy, so other chemotherapy alternatives should be investigated. Importantly, she has central nervous system (CNS) involvement. Trastuzumab, a large protein, would not be expected to cross the blood–brain barrier to treat the metastases. The oral dual tyrosine kinase inhibitor lapatinib, with specificity for both the epidermal growth factor receptor (EGFR) and HER-2 would be an option for the management of B.W.'s disease at this time. One of the advantages of lapatinib over trastuzumab is that lapatinib does cross the blood–brain barrier. Additionally, lapatinib in combination with capecitabine is active in women with HER-2 positive advanced breast cancer that has progressed after treatment with regimens that include an anthracycline, a taxane, and trastuzumab.²⁹

Another novel biologic agent used to treat metastatic breast cancer, bevacizumab, targets tumor angiogenesis through targeting the vascular endothelial growth factor (VEGF). Two randomized phase III trials evaluating single-agent chemotherapy with or without bevacizumab have been reported. The first trial enrolled patients with anthracycline- and taxane-resistant disease who had received one prior therapy for metastatic disease and evaluated bevacizumab in combination with capecitabine. The other trial evaluated bevacizumab with paclitaxel as first-line therapy for locally recurrent or metastatic breast cancer.³⁰ The bevacizumab and capecitabine therapy in the second-line trial resulted in improved response rates with no significant differences in survival, whereas the first-line treatment resulted in significant improvements in response rates and progression free survival, but no improvement in overall survival. This data, however, are still immature. Recently, bevacizumab was approved for treatment of HER-2 negative metastatic breast

cancer as first-line therapy in combination with paclitaxel, but follow-up data from these trials and ongoing studies will better define its role in patients with metastatic breast cancer.

B.W. had received an anthracycline-containing regimen followed by paclitaxel and trastuzumab in the adjuvant setting. In patients treated with anthracyclines, taxanes, or both in the adjuvant setting, first-line treatment options for metastatic disease include re-exposure to the same agent or introduction of a different treatment. Studies evaluating retreatment with anthracyclines and taxanes after prior exposure in the adjuvant setting have yielded conflicting results. B.W.'s oncologist decides to use capecitabine in combination with lapatinib because she now has metastatic disease in multiple locations, including the CNS, and has previously received paclitaxel and trastuzumab.

Hormonal Therapy

ESTROGEN AND PROGESTERONE RECEPTORS

9. M.L., a 68-year-old woman with a history of breast cancer, had a lumpectomy followed by radiation therapy 7 years ago. At the time of initial diagnosis, she had been postmenopausal for approximately 10 years, and her tumor was documented to have high concentrations of both estrogen and progesterone receptors. She received 5 years of tamoxifen, which she completed approximately 2 years ago. She remained disease-free until recently, when she was found to have bone metastases in her left scapula and several ribs. No other sites of disease involvement were identified. Her only symptom is shoulder pain. What would be the appropriate treatment for M.L. at this time?

Breast cancer is one of the few human tumors that can be very sensitive to hormonal manipulations; however, it is also well recognized that only a subset of patients with breast cancer respond to the various endocrine therapies. Patients with tumors that are potentially endocrine-sensitive can be identified by measuring estrogen and progesterone receptors in the tumor tissue. Patients whose tumors are both ER+ and progesterone receptor positive (PR+) have a much higher response rate to endocrine therapy than patients without either receptor (~70% vs. 10%). Patients with ER+, PR- tumors have an intermediate response rate (30%).³¹ Patients with endocrine-responsive tumors also are reported to have longer disease-free intervals after initial surgery, such as M.L. experienced.^{31,32} In addition, they may have a longer survival after the documentation of metastatic disease. M.L.'s tumor was strongly ER+ and PR+ and she had a long disease-free interval (7 years); therefore, she is likely to respond to endocrine therapy.

Bisphosphonates

10. M.L. starts oral letrozole 2.5 mg every day and intravenous (IV) zoledronic acid 4 mg monthly. Is this a reasonable approach?

Hormonal agents, including antiestrogen (e.g., tamoxifen) and aromatase inhibitors (anastrozole, letrozole, exemestane), are equally effective for the initial treatment of endocrine-responsive breast cancer. As reviewed above, the aromatase inhibitors have dramatically changed the treatment of women with ER+ breast cancer. Because M.L. received adjuvant tamoxifen for 5 years and has ER+ disease, the use of an aromatase inhibitor would be appropriate. Multiple studies with anastrozole, letrozole, and exemestane have shown that they

produce equivalent or superior response rates or time to disease progression compared with tamoxifen when used as first-line treatment for advanced disease.³³ Therefore, the use of letrozole is reasonable. Other treatment options for patients with ER+ disease include fulvestrant, an ER antagonist without agonist effects, which has also been shown to be equivalent to tamoxifen with respect to time to disease progression, overall response rate, and median duration of response.

Following the initiation of endocrine therapy, it usually takes 3 months before the therapeutic response can be assessed. In patients such as M.L. with only bone metastases, assessment may be difficult because it may take 4 to 6 months to reossify the involved bones. In such cases, the decision to continue therapy may be based on the lessening of bone pain and disease stabilization (i.e., no new metastatic sites).

Bone metastases occur in approximately 70% of patients with metastatic breast cancer and are associated with a median survival of 24 months with 20% of patients alive at 5 years.³⁴ Skeletal-related complications caused by the bone metastases are common, including significant bone pain, spinal cord complications, hypercalcemia, and pathologic fractures. An integrated approach to treating these patients includes pain medications, antineoplastic therapy or endocrine therapy (depending on the ER status), radiation therapy for palliation, and bisphosphonates. The bisphosphonates have been shown to decrease the risk for skeletal-related events by approximately one-third.³⁴ Current guidelines support the use of bisphosphonates in women with radiographic evidence of bony metastases.³⁵ More recently, zoledronic acid 4 mg was shown to be as effective and as well tolerated as pamidronate 90 mg in the treatment of osteolytic and mixed bony metastases in patients with advanced breast cancer.³⁶ The advantage of zoledronic acid over pamidronate is that therapy can be administered as a 15-minute infusion versus a 2-hour infusion. Therefore, M.L. should begin zoledronic acid therapy.³⁵

11. Over the next 18 months, M.L. continues letrozole therapy and has a complete resolution of her shoulder pain with considerable improvement of the radiographs and no appearance of new lesions. She is now experiencing left hip pain and a bone scan has documented new metastatic disease. What therapy should be considered at this time?

M.L. had a good initial response to letrozole, so she is likely to respond again to another type of endocrine therapy. Exemestane is an irreversible, nonsteroidal aromatase inhibitor that has been shown to be effective as second-line therapy, as has fulvestrant.^{33,37} Megestrol also can be considered as a third-line hormonal therapy. Radiation therapy may provide M.L. with palliative relief of pain. If M.L. had rapidly worsening disease involving a visceral organ, such as the liver, or if she had not responded well to prior endocrine therapy, cytotoxic chemotherapy may have been more appropriate.

COLON CANCER

Screening

12. E.R., a 55-year-old man, is having his first physical examination in >10 years because he has noted a change in his bowel habits recently. His father died of colorectal cancer 2 years ago.

E.R. questions whether his risk is increased and if there is anything that he can do to prevent colon cancer or decrease his risk of dying from it.

Colorectal cancer is the third leading cause of cancer deaths in the U.S. adult population.¹ Approximately 70% of these cancers will arise in the colon, whereas 30% will occur in the rectum. Multiple risk factors are well recognized: family history; age >50 years; high-fat, low-fiber diet; obesity; chronic inflammatory bowel disease; and a personal history of colorectal polyps or cancer. Several hereditary syndromes are recognized that place persons at an extremely high risk, such as hereditary nonpolyposis colorectal cancer (HNPCC or Lynch syndrome) and familial adenomatous polyposis (FAP).³⁸ The American Society of Clinical Oncology currently recommends genetic testing for HNPCC or Lynch syndrome for those at high risk.³⁹

Evidence suggests that continuous aspirin or other nonsteroidal anti-inflammatory drug (NSAID) use may prevent the development of colorectal cancer by inhibiting cyclooxygenase (COX-2) expression.³⁸ Presumably, COX-2 acts as a tumor promoter in the intestine. In fact, celecoxib, a COX-2 inhibitor, is approved as an oral adjunct to usual care in patients with FAP because it was shown to reduce the number and size of colorectal polyps in these patients. Large-scale, prospective clinical trials evaluating aspirin and classic NSAIDs have revealed promising results, and trials with the newer selective COX-2 inhibitors are ongoing.³⁸ Other potential preventive measures include calcium supplementation and a high-fiber diet.³⁸ Chemoprevention trials for colorectal cancer are discussed in Chapter 88, Neoplastic Disorders and Their Treatment.

Because E.R. is >50 years of age and has a family history of colorectal cancer, he should undergo screening. He also has symptoms (i.e., change in bowel habits) that heighten suspicion. Current screening recommendations for colorectal cancer include fecal occult blood testing and, depending on age and risk, sigmoidoscopy or total colonic examination.⁴⁰

Fecal Occult Blood Testing (FOBT)

13. What methods to detect FOBT are available, and are there any advantages of one method over another?

A FOBT increases the chance of diagnosing colorectal cancer at an early stage of disease and is associated with a 30% reduction in colorectal cancer mortality.⁴⁰ Of the three FOBT methods used, the guaiac test is the most common, simple, and inexpensive, although newer methods may be more sensitive and specific. The guaiac test is a colorimetric test in which guaiac dye is oxidized to a bluish quinone compound in the presence of a peroxidase (e.g., hemoglobin). Foods, other substances, and medical conditions that contain or produce peroxidase activity may yield false-positive readings (Table 91-3). Conversely, large amounts of ascorbic acid can produce false-negative guaiac test results. A second method is a quantitative test based on fluorometry of heme-derived porphyrin. During intestinal transit, hemoglobin is broken down to porphyrin. The third method is an immunochemical test (e.g., Heme-Select) that uses antiserum to human hemoglobin to detect blood in the feces. This test is very sensitive and specific; however, it loses sensitivity if the bleeding is from the proximal colon because bacteria alter the globin. The immunochemical test eliminates the need for dietary restrictions; however, there

is a 24-hour delay in reading the results because an extract needs to be prepared from the stool sample. Red meat should be eliminated from the diet for 3 days before occult blood is tested using the guaiac methods and for 4 days before testing using methods based on heme-derived porphyrins.⁴¹ Approximately 2% of persons >50 years of age will have a positive FOBT. Of these, 10% will be diagnosed with cancer, 30% with polyps, and the remaining 60% will have false-positive results.

Staging and Prognosis

14. E.R.'s fecal occult blood tests are positive on specimens obtained on two consecutive days. Colonoscopy revealed a 2.5-cm mass, and a biopsy of the lesion is interpreted as adenocarcinoma of the colon. Surgical resection of the mass and regional lymph nodes is performed. The tumor is confined to the bowel wall, although four regional lymph nodes show evidence of tumor involvement. Distant metastases of the tumor are not evident at this time, and his colon cancer is stage III. E.R.'s physical examination is otherwise unremarkable and all laboratory values are within normal limits except for an elevated lactate dehydrogenase (LDH) and a carcinoembryonic antigen (CEA) level of 647 ng/mL (normal, <5 ng/mL). What is the prognosis for stage III colon cancer? Could earlier detection have improved the prognosis?

When colorectal cancer is diagnosed in the early stages, it is curable with surgical intervention and >90% of patients survive 5 years. The 5-year survival rate declines to 55% to 60% in patients such as E.R. with stage III disease. Overall 5-year survival rates have increased during the past two decades from 50% to 63%.⁴² The tumor node metastasis (TNM) staging system is most commonly used for colon cancer. Stage I indicates penetration into (but not through) the bowel wall. Stage II generally indicates penetration through the bowel wall; stage III indicates lymph node involvement; and stage IV indicates metastatic disease. Optimal node sampling at the time of

surgery is critical to staging and should include the evaluation of 12 to 17 lymph nodes. Patients with early-stage colorectal cancer often are asymptomatic; therefore, intensive screening programs as just described are advocated to reduce the mortality of this disease. Of patients with metastatic and recurrent colorectal cancer, 60% to 90% have elevated CEA or CA-19-9 levels. Levels are elevated in relation to the stage and extent of disease, the degree of tumor differentiation, and the site of metastases. If the CEA level is elevated at the time of initial diagnosis, as in E.R., it can be monitored after surgical resection of the tumor for evidence of recurrent disease.⁴³

Treatment

Adjuvant Therapy

15. All evidence of tumor is removed, and E.R.'s CEA level declines. Therefore, the surgery may be considered potentially curable. Should E.R. receive any additional therapy at this time?

Tumor recurrence is a significant problem associated with stage III colon and rectal cancers, with up to 60% of all surgically treated patients eventually developing local recurrences. Causes of these relapses may include peritoneal seeding caused by exfoliation of tumor cells in the colonic lumen and spillage during surgery. Most tumor recurrences are secondary to either disease spread to the regional lymph nodes or extension of the tumor into the bowel wall, with subsequent hematogenous dissemination. Metastasis to the liver via hematogenous spread (through the portal circulation) is the most common site of disease spread beyond the regional lymph nodes and occurs in 50% of patients with invasive disease.⁴⁴ Lung metastases (without liver metastases) occur rarely and generally are associated with lesions in the lower rectum.

Because of the significant relapse rate in patients with stage III and high-risk stage II colon cancer, adjuvant chemotherapy has been extensively studied. Chemotherapy improves disease-free survival (DFS) and overall survival in patients, such as E.R., who have had "potentially curative surgery."⁴⁵ The first definitive adjuvant chemotherapy regimens contained fluorouracil and leucovorin. Currently, agents used in combination chemotherapy for the adjuvant treatment of colorectal cancer (Chapter 88) include fluorouracil, leucovorin, oxaliplatin, and capecitabine in various combinations and doses. Patients such as E.R. who have stage III disease should receive adjuvant therapy consisting of 6 months of FOLFOX (fluorouracil, leucovorin, oxaliplatin). Three clinical trials support the use of FOLFOX or XELOX (capecitabine and oxaliplatin) in the adjuvant setting.⁴⁶⁻⁴⁸ These trials have shown improved DFS compared with adjuvant fluorouracil and leucovorin, but an overall survival benefit has not been observed.^{46,48} The trade-off for this improved DFS has been increased toxicity caused by the oxaliplatin, including neutropenia and neurotoxicity, which interferes with the activities of daily living. In the X-ACT trial, capecitabine was equivalent to the combination of fluorouracil and leucovorin in the adjuvant setting.⁴⁹

Ongoing trials are evaluating the role of the monoclonal antibodies bevacizumab (targeting VEGF) and cetuximab (targeting EGFR) in combination with FOLFOX in the adjuvant setting. Until the results of these trials are available, the use of monoclonal antibodies in the adjuvant setting is limited to participation in a clinical trial.

Follow-Up Care

16. Within 6 months after surgery, E.R.'s CEA level has fallen to <2.5 ng/mL and he completes the adjuvant therapy without serious sequelae. What follow-up care is recommended at this time?

E.R. continues to be at significant risk for developing recurrent disease. If recurrences are detected early, it is possible to cure them with additional surgery. In most cases, patients with early recurrences are asymptomatic; therefore, an active follow-up program is necessary to detect them, including a medical history, physical examination, and CEA levels every 3 months for the first 3 years, then every 6 months for the next 2 years, and then annually.⁴³ Colonoscopy is repeated annually for several years and then every 3 to 5 years. He should receive a chest radiograph annually or when prompted by an elevated CEA or symptoms. Additional tests, such as abdominal and pelvic CT scans and liver function chemistries, should be done if routine test findings are abnormal or if symptoms suggest recurrent disease.⁴³

Recurrent Disease

Rising Carcinoembryonic Antigen Level

17. Eighteen months after completing adjuvant chemotherapy, E.R. returns for routine follow-up; his CEA levels are elevated. What is the significance of a rising CEA level?

Although widespread serum CEA level monitoring is not an efficient way to screen for colorectal cancer in the general population, a rising CEA level in a patient with a history of colorectal cancer may be the first indication of recurrent disease if the patient had an elevated CEA level at the time of original diagnosis. Generally, the CEA level is measured every 3 months for 3 years and then every 6 months for 2 years.⁴³ More than 50% of patients who have recurrent disease also have elevated CEA levels.

Chemotherapy for Metastatic Disease

18. On a routine follow-up visit several months later, a CT scan of E.R.'s abdomen shows that the disease in his colon has recurred and the liver CT shows two discrete nodules along with a nodule in the left lung that are consistent with metastatic disease; however, E.R. is feeling well and has no symptoms suggestive of metastases. What is the role of further chemotherapy now that E.R. has recurrent disease?

Of those patients such as E.R. who present initially with localized, resectable disease, 30% will subsequently develop metastatic disease. Among patients with newly diagnosed colorectal cancer, 25% will present with metastatic disease. Significant treatment advances have been made in the last 5 years to manage cases of advanced colorectal cancer such that the median survival is now up to 2 years in treated patients.⁵⁰ These include single-agent therapy (irinotecan, oxaliplatin, capecitabine), combination chemotherapy, and the use of monoclonal antibodies (bevacizumab, cetuximab, and panitumumab). Comparisons of irinotecan, fluorouracil, and leucovorin regimens (IFL, FOLFIRI) with oxaliplatin, fluorouracil, and leucovorin (FOLFOX) combinations for the initial treatment of metastatic colorectal cancer have been

reported. Patients treated with FOLFOX had a response rate, time to disease progression, and overall survival rate that were superior to those observed with IFL or IROX (irinotecan, oxaliplatin). The overall survival results did not account, however, for second-line therapy, which was not controlled for and could affect survival.⁵¹ Nevertheless, this established FOLFOX as the first-line chemotherapy choice for patients with metastatic disease. Other regimens used first-line therapy for metastatic disease (outlined in Chapter 88) include FOLFIRI (fluorouracil, irinotecan, leucovorin), CAPOX (capecitabine, oxaliplatin), XELOX (capecitabine, oxaliplatin), and XELIRI (capecitabine, irinotecan); however, the optimal sequence of any of these regimens and the effect of sequence on survival are unclear. Often, the decision regarding the choice of combination therapy for first- or second-line therapy is based on prior therapy, quality of life, pre-existing toxicities, and comorbid conditions.

Biologic therapies targeting VEGF (bevacizumab) and EGFR (cetuximab and panitumumab), play a significant role in the metastatic setting. The addition of bevacizumab to IFL significantly improved response and overall survival.⁵² As second-line therapy, the combination of FOLFOX and bevacizumab has also demonstrated significant improvement both in response and overall survival.⁵³ Cetuximab, a chimeric monoclonal antibody against the extracellular domain of EGFR, has shown efficacy, but has not improved survival as a single agent or in combination with irinotecan in patients with irinotecan-refractory malignancies in the metastatic setting.⁵⁴ Despite the lack of improvement in survival, cetuximab is approved for second- and subsequent-line therapy in patients with EGFR-positive, irinotecan-refractory metastatic colorectal cancer. A recent trial evaluated the combination of cetuximab plus bevacizumab with or without irinotecan in previously treated patients with advanced colorectal cancer and reported a response rate for the three-drug combination of 37% and a time to disease progression of 7.9 months.⁵⁵ These response rates are impressive for an otherwise chemotherapy-refractory population. Finally, panitumumab, a fully human monoclonal antibody also targeting the extracellular domain of EGFR, has shown activity as monotherapy in the treatment of refractory metastatic disease when compared with best supportive care. Ongoing trials are evaluating the efficacy and safety of panitumumab in combination with chemotherapy.

Now that E.R. has metastatic disease in both the liver and the lung, he should receive combination chemotherapy. The choice of regimen depends on prior therapy, and because E.R. has received adjuvant FOLFOX, the use of FOLFIRI in combination with bevacizumab would be a reasonable approach.

Hepatic Metastases

Colorectal-related metastases mainly affect the liver. In one-third of the cases, the metastases are synchronous and in two-thirds, metachronous. Surgical resection, if possible, is the most effective treatment modality for potential long-term survival in colorectal patients with isolated liver metastases. Many patients, however, could potentially benefit from regional therapy. Because liver tumors derive most of their blood supply from the hepatic artery, direct administration of effective anticancer drugs into the artery provides high drug concentrations to the area of tumor involvement.⁵⁶ Hepatic intra-arterial administration of fluorouracil, floxuridine, or other chemother-

apeutic agents has been extensively studied in patients with metastases confined to the liver. More recently, the intra-arterial use of oxaliplatin- and irinotecan-based chemotherapies has yielded encouraging results. Because E.R. has disease that also involves the lung, he should receive systemic chemotherapy for his disease.

Genomic Markers

19. What is the role of genomic markers in the treatment of colon cancer?

The identification of appropriate patients for treatment could be improved in both the metastatic and adjuvant setting by molecular profiling. This would allow the clinician to individualize therapy based on risk of toxicity and potential for response. Although not standard in today's practice, a number of predictive markers have been identified, including the evaluation of microsatellite instability, protooncogenes such as *K-ras*, and DNA microarray profiling.⁵⁷ Microsatellite instability is found in almost two-thirds of colon cancers and these tumors exhibit improved survival from recurrence. Mutations in *K-ras* occur in approximately 30% of colon cancer cases and in early stage disease. These tumors are associated with recurrence and poorer long-term survival, so patients should receive adjuvant chemotherapy. Finally, DNA microarray profiling may allow identification of patients who respond to specific chemotherapies, such as fluorouracil, irinotecan, or oxaliplatin. Although all these markers are currently under investigation in clinical trials, they will allow clinicians to tailor therapy according to an individual patient and tumor profile.

A genetic diagnostic test (Invader UGT1A1 Molecular Assay), which assesses the status of an individual's UGT1A1 enzyme, is available for clinical use. The test allows clinicians to individualize irinotecan therapy by identifying patients at risk for toxicity. Irinotecan is metabolized by enzymes exhibiting polymorphic activity, specifically uridine 5' diphosphate glucuronosyltransferase (UGT). UGT1A1 is responsible for glucuronidating SN38, an irinotecan metabolite that produces severe toxicity. Individuals with the UGT1A1*28 variant have reduced activity of UGT1A1 and may suffer severe neutropenia. Despite the tremendous advance in using UGT1A1*28 to predict neutropenia risk, more research is needed to identify patients at risk for irinotecan-induced diarrhea. The commercially available test is designed to predict which patients are at risk for enhanced toxicity. In clinical practice, however, genotyping is performed once the patient has severe neutropenia to determine if the patient has reduced enzyme activity.

LUNG CANCER

Clinical Presentation

20. H.H., a 57-year-old, white woman with a 6-month history of weight loss and increasing fatigue, recently noted shortness of breath (SOB) and fever. She also complains of joint pain in her knees and elbows and has noted a change in her fingers and nails over the past several months. Physical examination is significant for swelling and tenderness over her knees and elbows as well as hypertrophy and clubbing of the distal joints of both hands. A chest radiograph and CT scan reveals a central mass causing

obstruction of the middle right lobe as well as mediastinal lymphadenopathy. Bronchoscopy washings and cytology were positive for small-cell lung carcinoma. H.H. denied exposure to any environmental or occupational carcinogens but did admit to a 40-pack/year history of cigarette smoking. Are H.H.'s symptoms typical of those associated with lung cancer?

Signs and symptoms associated with lung cancer depend on the size and location of the tumor and degree of spread outside of the lungs. The most common symptoms at presentation are those associated with the primary tumor and include cough, wheezing, chest pain, hemoptysis, and dyspnea.⁵⁸ Because many patients have other medical problems, such as chronic obstructive airway disease related to cigarette smoking, the worsening of these symptoms may go unnoticed for a period or may be attributed to other smoking-related illnesses. A large tumor can result in obstruction, leading to fever and other evidence of pneumonia.

Regional spread to lymph nodes and other structures within the thorax can result in dysphagia, superior vena cava obstruction, pleural effusion, and hoarseness. Patients with distant metastatic spread may have findings associated with the site of disease involvement. For example, if the tumor has spread to the liver, patients are likely to have elevated LFT, or if they have brain metastases, severe headache, neurologic impairment, or seizures may be present.

Almost one-third of patients with lung cancer present with nonspecific symptoms such as anorexia and weight loss.⁵⁸ In addition, a few patients will present with paraneoplastic syndromes. Hypertrophic osteoarthropathy, with inflammation of the outer covering of bones and clubbing, can cause pain, tenderness, and swelling over the affected bones such as that experienced by H.H. This often mimics bone metastases (bone scans also may be positive); however, further studies will reveal no evidence of direct tumor involvement of the bones. Other paraneoplastic syndromes commonly seen in patients with lung cancer include ectopic Cushing's syndrome and the syndrome of inappropriate antidiuretic hormone secretion (SIADH). Characteristically, successful treatment of the tumor will reduce the effects of paraneoplastic syndromes.

Prevalence and Risk Factors

21. How common is lung cancer and what factors place H.H. at risk?

Over 160,390 deaths will occur from lung cancer in 2007. Although the World Health Organization recognizes that there are >10 types of primary pleuropulmonary malignancies, four major types of carcinomas account for up to 95% of all lung cancers.⁵⁸ The four major types are adenocarcinoma, squamous cell, small-cell, and large-cell carcinoma (Table 91-4).⁵⁸ Adenocarcinoma, squamous cell, and large-cell carcinoma are grouped together and referred to as non-small-cell lung cancers (NSCLC) because they are similar in prognosis and response to therapy.

Cigarette smoking is the predominant cause of lung cancer worldwide, and the risk appears to increase with the number of cigarettes smoked each day.⁵⁹ Approximately 75% to 80% of lung cancer cases are attributable to smoking.⁵⁹ Second-hand smoke exposure is also a risk factor, with approximately 3,000 deaths attributable to this factor. Although the risk of develop-

Table 91-4 Histologic Classification of Lung Cancer⁵⁸

| Classification | Prevalence (%) |
|---|----------------|
| Adenocarcinoma | 40 |
| Squamous cell carcinoma | 25 |
| Small-cell carcinoma | 20 |
| Large-cell carcinoma | 10 |
| Adenosquamous carcinoma, carcinoid, bronchial gland carcinoma | <5 |

ing any type of lung cancer increases with cigarette smoking, the relative risk of small-cell lung cancer (SCLC) is among the highest. Therefore, patients such as H.H. who have a long history of cigarette smoking have the highest risk of developing lung cancer relative to any other population. Other risk factors for lung cancer include exposure to passive smoke (i.e., non-smokers who live with smokers); pipe and cigar smoking; and exposure to asbestos, radon, or other occupational carcinogens such as heavy metals, chloromethyl ether, and arsenic.⁵⁹

Prevention and Screening

22. What are the current recommendations for prevention and screening for early detection of lung cancer in patients like H.H.?

By far, the most important intervention for preventing lung cancer is to avoid or cease smoking and to avoid secondary smoke whenever possible. Antioxidants and β -carotene have no protective effect and, in at least two large trials, an increase in lung cancer was found in persons receiving β -carotene.^{60,61} Secondary analysis in a trial of selenium for the prevention of skin cancer revealed a significant reduction in the occurrence of lung cancer,⁶² but definitive trials are still in progress.

Lung cancer screening has not affected overall mortality. In the early 1970s, the National Cancer Institute (NCI) launched three studies evaluating sputum cytology and chest radiography as lung cancer screening tests. Although cancers were detected earlier, the overall mortality rates in the two groups did not differ significantly.^{63,64} Since the time of these studies, the quality of diagnostic testing has been substantially enhanced and many new tests have become available; therefore, new screening studies, especially for high-risk populations are underway. Presently, no medical or scientific organization recommends testing for early lung cancer detection in asymptomatic individuals. Growing evidence suggests spiral CT may be effective for detecting early lung cancer, but prospective trials confirming a benefit have not been completed.⁶⁵ Ongoing trials will better determine its role in the evaluation of patients at high-risk for lung cancer.

Small-Cell Lung Cancer Versus Non-Small-Cell Lung Cancer

23. How do treatment and prognoses for SCLC and NSCLC differ?

The natural history and response to treatment of patients with SCLC and NSCLC differ significantly. Therefore, it is extremely important to establish a histologic diagnosis before contemplating treatment (Table 91-4). In general, the NSCLC

are less likely to metastasize early in the course of the disease and are less sensitive to chemotherapy than SCLC. In contrast, SCLC progresses rapidly, but is sensitive to many chemotherapeutic agents.

Surgery is curative only in early stages of NSCLC and is the treatment of choice for patients with stage I through IIIA NSCLC.^{58,66} Radiation therapy may be considered an alternative for patients who are poor surgical risks. Radiotherapy also is used as an adjuvant therapy to surgery to treat NSCLC characterized by large tumors or extensive lymph node involvement; however, no survival advantage has been observed with the addition of radiation therapy.⁶⁷ In advanced stages of NSCLC, overall response rates to combination chemotherapy are 20% to 40%, with fewer than 5% of patients achieving a complete response.^{68,69} The highest response rates for chemotherapy in NSCLC have been achieved with regimens using cisplatin or carboplatin combined with etoposide, paclitaxel, docetaxel, vinorelbine, and gemcitabine. Even with the best therapy, median survival is approximately 12 months.

Small-cell lung cancer is staged as “limited” or “extensive.” Limited-stage disease is confined to one hemithorax and the regional lymph nodes and can be encompassed within one radiation port. Extensive disease is that which extends beyond the thorax. Because SCLC disseminates early in the disease, surgery is almost never indicated. The only exception is the rare patient who presents with very early stage disease. Such patients may benefit by resection of the tumor followed by combination chemotherapy. Overall, the use of combination chemotherapy regimens for SCLC has increased median survival by four- to fivefold. In disease limited to the thoracic cavity, optimal chemotherapy regimens produce response rates of 85% to 95%, with 50% to 60% of patients achieving a complete response. Although many patients initially respond to therapy, most eventually relapse and die from their SCLC. The median duration of survival is 12 to 16 months and the 2-year DFS rate is usually 15% to 20% for patients with limited disease. Response rates are somewhat lower for patients with disease outside the thoracic cavity, and the median survival is only 7 to 11 months. The 2-year DFS for these patients is <2%.

Small-Cell Lung Cancer

Staging

24. What information, in addition to the histologic type, is necessary before H.H.’s treatment can be initiated?

Before initiating therapy, the stage of H.H.’s disease should be evaluated. This will help establish a prognosis and identify tumor lesions that can be monitored to evaluate the response to therapy. Staging also will assist in determining if H.H. will benefit from radiation therapy in addition to chemotherapy. Because the TNM staging factors do not appear to correlate with survival, a simple two-stage system is used for SCLC. Staging procedures should include a thorough workup of any areas that are suspicious for tumor involvement, a chest radiograph and CT scans, a CBC, LFT, physical examination of the liver, and a neurologic examination. In addition, H.H.’s physiologic and performance status should be assessed to determine her ability to tolerate the aggressive chemotherapy and possible radiation therapy. This includes evaluation of her nutritional,

cardiac, and pulmonary status, as well as her renal and hepatic function.

Combination Chemotherapy

25. H.H. is to start a chemotherapeutic regimen of cisplatin 100 mg/m² IV on day 1 and etoposide 100 mg/m² IV on days 1 through 3. The chemotherapy is to be repeated every 28 days. She also will receive radiation therapy to the area of tumor involvement. Is H.H. likely to benefit from the addition of prophylactic radiation or other cytotoxic agents to her regimen?

Although combination chemotherapy is clearly superior to single-agent therapy in the treatment of SCLC, no major differences exist between several combination chemotherapy regimens that have been widely studied when compared for response rate or survival. Most current first-line regimens include cisplatin or carboplatin in combination with etoposide. Other active agents for SCLC include topotecan, paclitaxel, docetaxel, ifosfamide, cyclophosphamide, teniposide, doxorubicin, vincristine, and methotrexate.

26. How should H.H. be monitored during therapy?

Approximately 80% of patients respond to initial chemotherapy for SCLC. Because this is a chemosensitive disease, patients typically show evidence of response within days. Follow-up care of a patient receiving chemotherapy should include the following: (a) assessment of chemotherapy-associated toxicities (e.g., mucositis, myelosuppression, renal dysfunction, electrolyte disorders) so that appropriate interventions can be initiated; (b) regular re-evaluation of renal, hepatic, and bone marrow function to assess the patient’s ability to tolerate further treatment; and (c) assessment of the antitumor effects of the treatment.

Myelosuppression (i.e., granulocytopenia, thrombocytopenia) is generally only moderate with cisplatin-etoposide regimens; however, the addition of radiation therapy is likely to increase its severity. Therefore, H.H. should have her CBC monitored weekly once therapy begins. Because nephrotoxicity is the usual dose-limiting toxicity of cisplatin, renal function must be evaluated.

Chest radiographs and CT scans should be repeated after every two to three courses of therapy to assess antitumor effects. Therapy should be continued if the tumor is responding to treatment and discontinued or changed with evidence of tumor progression.

Duration of Therapy and Prophylactic Irradiation

27. After six courses of this regimen, repeat chest radiographs and CT scans reveal no evidence of residual tumor in H.H. A repeat bronchoscopy is also negative. Is additional treatment indicated?

Despite the high recurrence rate for patients with SCLC who achieve a complete response, no current evidence supports prolonged administration of chemotherapy after complete response is achieved. Long-term survival rates appear to be similar for patients who receive 4 to 6 months of treatment and those who receive 12 to 24 months. In addition, patients who receive a shorter duration of chemotherapy exposure are less likely to suffer major toxicities. After disease recurrence, however, response rates to second-line therapy are only 20% to

40% with few complete responses; the median survival is only a few months. Today, the topoisomerase inhibitors (topotecan or irinotecan), taxanes, paclitaxel or docetaxel, gemcitabine or vinorelbine are the most widely used second-line agents.

At least 20% to 25% of patients with SCLC eventually develop brain metastases, which produce significant morbidity. Clinical trials have demonstrated that prophylactic cranial irradiation significantly reduces the incidence of symptomatic brain metastases and prolongs disease-free and overall survival.⁷⁰ Therefore, prophylactic cranial irradiation is recommended for patients such as H.H. who attain a response to chemotherapy.

Non-Small-Cell Lung Cancer

Metastatic Disease

28. M.D., a 62-year-old man, was recently diagnosed with stage IV adenocarcinoma of the lung. His medical history is not significant, and he is otherwise in good health. What are the current treatment recommendations?

Although NSCLC is less chemosensitive than SCLC, evidence gathered over the past decade substantiates that combination chemotherapy improves median survival from 16 to 26 weeks and enhances 1-year survival rates by 10% over the best supportive care. The American Society of Clinical Oncology now recommends two to eight cycles of platinum-based combination chemotherapy for patients with stage IV disease and good performance status (Eastern Cooperative Oncology Group [ECOG] 0, 1, and possibly, 2).⁶⁹ The most widely used first-line regimens include carboplatin or cisplatin plus either paclitaxel, docetaxel, vinorelbine, or gemcitabine. Some newer regimens also incorporate three of these agents. Response is generally re-evaluated after two cycles of chemotherapy and, if a response or stable disease is noted, treatment is continued for up to eight cycles. If disease progression is evident, second-line therapy with agents not previously received or palliative radiation therapy is recommended. One-year survival rates range from 25% to 40% using these newer regimens.

The role of targeted therapies, specifically the antivascular endothelial growth factor agent bevacizumab, has been evaluated in patients with advanced (stage IIIB and IV) NSCLC and it is now U.S. Food and Drug Administration (FDA)-approved for use as first-line treatment of advanced or metastatic NSCLC in combination with standard chemotherapy. The pivotal study utilized paclitaxel 200 mg/m² and carboplatin area-under-the-curve (AUC) of 6 (mg/mL × minute) every 3 weeks for six

cycles with or without bevacizumab 15 mg/kg continued until disease progression. The regimen containing bevacizumab resulted in significant improvements in median survival (12.5 vs. 10.5 months, respectively) as well as significantly improved response rates and progression-free survival.⁷¹ Women, however, did not experience a survival benefit (13.3 vs. 13.1 months, respectively).

The novel tyrosine kinase inhibitors that act on EGFR, gefitinib and erlotinib, were fast-tracked to the market pending phase III confirmatory trials as single-agent treatment for patients with NSCLC who failed platinum and docetaxel regimens. Use of gefitinib is now limited, however, to those cancer patients who, in the opinion of their treating physician, are currently benefiting, or have previously benefited, from gefitinib treatment because it did not significantly improve overall survival in the randomized phase III setting.⁷² The response rates to these agents were highly variable in certain subgroups, with women, those with adenocarcinoma, and nonsmokers having higher response rates. Importantly, clinical trials adding these agents to platinum-based chemotherapy have shown no advantage except in the subset of patients who have never smoked. In them, erlotinib in combination with chemotherapy significantly improved overall survival.⁷² Currently, the use of erlotinib is limited to single-agent therapy in the metastatic setting, although ongoing trials are evaluating its use sequentially with chemotherapy.

For patients with unresectable stage III disease, there have now been at least 10 major multi-institutional trials in which patients were randomized to treatment with thoracic radiation with or without platinum-based chemotherapy. A statistically significant survival advantage was seen for the combined modality therapy.⁷³

Adjuvant Chemotherapy

29. If M.D. had been diagnosed with stage II disease, what would be the role of chemotherapy after surgical resection?

Surgical resection is the cornerstone of therapy for early stage disease, but relapse is high with 30% to 60% of patients with resected NSCLC still dying of their disease. Until recently, no additional treatment beyond surgery was known to be beneficial. Three randomized trials, however, validated the role of adjuvant chemotherapy for completely resected NSCLC with survival advantages at 5 years ranging from 5% to 15% (Table 91-5).⁷⁴⁻⁷⁶ The role of surgery in stage IB remains controversial, however, but beneficial trends exist, especially when tumors are large (at least 4 cm in size).⁷⁴ Recently, absence of the ERCC1 (excision repair cross-complementation group 1)

Table 91-5 Adjuvant Lung Cancer Trials

| Study/Reference | Patients (N) | Stage | 5-yr Survival (%) | | p-Value |
|-----------------------|--------------|----------|-------------------|------------------|---------|
| | | | Control | Chemotherapy Arm | |
| IALT/ ⁷⁵ | 1,867 | I-III A | 40 | 45 | <0.03 |
| NCICTG/ ⁷⁶ | 482 | IB-II | 54 | 69 | 0.03 |
| ANITA/ ⁷⁴ | 840 | IB-III A | 43 | 51 | 0.013 |

ANITA, Adjuvant Navelbine International Trialists Association; IALT, International Adjuvant Lung Trial; NCICTG, National Cancer Institute of Canada Trials Group.

protein in operative tumor specimens of patients with NSCLC has been used to identify tumors that appear to benefit most from adjuvant cisplatin-based chemotherapy.⁷⁷ Each of the positive adjuvant trials utilized cisplatin-based chemotherapy regimens in combination with etoposide or a vinca alkaloid, with two of the trials utilizing cisplatin and vinorelbine. Therefore, if M.D. was diagnosed with stage II disease, he should receive six cycles of a cisplatin-based regimen.

OVARIAN CANCER

Risk Factors and Clinical Presentation

30. C.R., a 50-year-old woman, presents to her family physician complaining of vague abdominal pain over the last several weeks. A detailed history revealed that she had experienced increasing abdominal girth without significant weight gain and a change in her usual bowel habits. The abdominal and pelvic ultrasound studies reveal a 6- to 10-cm mass, and her serum CA-125 antigen is significantly elevated. C.R. is referred to a gynecologic oncologist who performs a total abdominal hysterectomy and bilateral salpingo-oophorectomy. Pathologic examination of the mass determined it to be epithelial carcinoma of the ovary. The large intra-abdominal mass and numerous peritoneal tumor implants were resected during surgery; however, several small (<0.5 cm) tumor implants were not resectable. What factors are associated with an increased risk of ovarian cancer? Are C.R.'s symptoms consistent with ovarian cancer?

Ovarian cancer is the fifth most common cause of cancer and cancer deaths in women.¹ The three categories of ovarian cancer are named for their cell of origin. Greater than 90% are epithelial cancers, arising from the epithelial layer that covers the surface of the ovaries, whereas the remainder are either germ cell or stromal tumors. Postmenopausal women (median age, 63 years) are most likely to develop epithelial ovarian cancer. Factors that appear to increase the risk of ovarian cancer include positive family history, nulliparity or a low number of pregnancies, first child after age 35, prolonged use of ovulation-inducing drugs, and increasing age.⁷⁸ A genetic predisposition may also exist to ovarian cancer, which can be related to hereditary breast cancer. Genetic mutations in the *BRCA1* and *BRCA2* genes may play a role in the development of ovarian cancer.³⁹

Ovarian cancer is known as the silent killer because 70% of patients present with advanced disease. As in C.R.'s case, patients with early stages of ovarian cancer may be relatively asymptomatic. The patient's only complaint may be vague abdominal symptoms, and she may not seek medical attention until symptoms become significantly worse. Ovarian carcinoma, however, usually has extended beyond the pelvis at the time of diagnosis. Pain, abdominal distention, and vaginal bleeding are the most common symptoms in patients with advanced disease.⁷⁸ Other symptoms may include weight loss, nausea, or a change in bowel or bladder habits if the tumor mass is compressing adjacent structures.

Screening and CA-125

31. C.R. is surprised by the diagnosis and questions why the cancer was not diagnosed earlier. She has always had routine annual

physical and gynecologic examinations that included the Papanicolaou (Pap) test.

The diagnosis of ovarian cancer typically does not occur early in the disease. This is because the ovaries are suspended by ligaments in a large spacious pelvic cavity where masses are not easily detectable until they become large. At the time of diagnosis, 75% of women with ovarian cancer have evidence of spread beyond the ovaries and, in 60%, the cancer has spread beyond the pelvis. Although the Pap test is the single most successful screening test used in gynecology, it is not useful for detecting ovarian cancer. The dramatic decrease in invasive cervical cancers along with a 70% reduction in mortality, however, confirms the efficacy of the Pap test as a screening tool for uterine cervical cancer.⁷⁹ The pelvic examination is the most common method of screening for ovarian cancer, but it has a low sensitivity; for every 10,000 examinations, approximately one tumor is detected.⁸⁰ The presence of a pelvic mass at physical examination is the most important sign of ovarian cancer. Abdominal ultrasounds have been investigated, but produce a high number of false-positive findings, even in high-risk populations.⁷⁸ Transvaginal ultrasonography produces clearer images than abdominal scanning and more accurately identifies intrapelvic disease. A CT of the abdominal-pelvic area may aid in the evaluation of a pelvic mass. Currently, none of these tests are recommended for screening women in the general population. The serum CA-125 level has been evaluated as a screening tool for ovarian cancer, but there is a high false-positive rate because a number of gynecologic and nongynecologic conditions can also elevate CA-125 levels. Currently, the primary role of CA-125 is to monitor disease status in patients diagnosed with ovarian cancer. Other candidate biomarkers are under investigation for the early detection of ovarian cancer.⁷⁸ Although no data indicate their value as screening tests, annual rectovaginal pelvic examinations, CA-125 levels, and transvaginal ultrasonography are often performed in high-risk women.

Chemotherapy

32. Following surgery, C.R. is advised that she should receive chemotherapy to eradicate the remaining tumor cells. Which antineoplastic drugs are effective in advanced ovarian carcinoma?

The first goal in the treatment of patients with epithelial ovarian cancer is optimal surgical cytoreduction of metastatic disease. Optimal debulking is defined as removal of all disease 1 cm or larger in diameter. The amount of residual disease after primary surgery is generally considered the most important modifiable prognostic factor that influences survival of patients with advanced disease.⁸¹ After surgery, postoperative chemotherapy is administered to patients such as C.R. with a significant risk of recurrence. Single agents that have exhibited activity in the treatment of advanced ovarian cancer include cisplatin, paclitaxel, docetaxel, topotecan, gemcitabine, and altretamine. Several studies have shown that carboplatin and cisplatin have equivalent benefits when used with paclitaxel.⁷⁸ Currently, the standard first-line chemotherapy for epithelial ovarian cancer is the combination of carboplatin plus paclitaxel resulting in a 75% complete response rate; however, the relapse rate is 50% within 2 years.

Recurrent Disease

33. After six courses of paclitaxel and carboplatin, C.R. has no remaining evidence of ovarian cancer. Planned follow-up includes repeat serum CA-125 levels and CT scans at 3-month intervals. Six months after completing chemotherapy, the CA-125 level was increased and a CT scan of the abdomen revealed several new masses. Should C.R. receive more paclitaxel and carboplatin therapy at this time?

Although ovarian cancer is initially sensitive to chemotherapy, most women will experience a relapse of their disease. At the time of recurrence, the median survival is 2 years; therefore, the primary goal of therapy is management of symptoms. The relapse-free interval after completion of platinum-based therapy (the platinum-free interval) has been recognized as a predictor of the likelihood of subsequent response to chemotherapy. Patients with disease that recurs within 6 months after treatment are unlikely to benefit from additional therapy with the first-line agents. Therefore, it is most appropriate to treat C.R.'s cancer with a drug that has a different mechanism of action and, it is hoped, a different pattern of resistance. Several agents have shown activity in the second-line setting, including topotecan, liposomal doxorubicin, taxanes, gemcitabine, oral etoposide, altretamine, and ifosfamide. Response rates range from 16% to 30% when these agents are administered as single agents; combination therapy has not been shown to be more effective than any single agent evaluated to date.⁷⁸ A number of trials are evaluating the role of novel agents in the setting of recurrent ovarian cancer and, owing to the low response rates from currently available agents, patients should be encouraged to participate in these trials. Bevacizumab has shown promising activity, but its use has been limited by the occurrence of bowel perforation.⁸² Ongoing trials will better define the occurrence of this serious adverse effect and the role of bevacizumab in recurrent ovarian cancer.

Intraperitoneal Chemotherapy

34. What is the role of intraperitoneal chemotherapy in ovarian cancer?

Ovarian carcinoma is usually limited to the peritoneal cavity. Commonly, tumor plaques are attached to the underside of the diaphragm as well as to the exterior of other organs within the abdominal cavity. Even following meticulous surgical removal of the tumor, some residual disease nearly always remains. Thus, intraperitoneal (IP) instillation of chemotherapeutic agents allows drug delivery directly to the site of the tumor and produces higher concentrations of drug at the tumor than could be attained by systemic administration. The ideal agent for IP administration is water soluble with a high molecular weight, which will slow its removal from the peritoneal cavity. Although drug delivery to the tumor is primarily by surface diffusion, agents that are then absorbed systemically from the peritoneum also reach the tumor via capillary flow. Intraperitoneal cisplatin has been the most widely studied IP drug in both the adjuvant and metastatic setting. A randomized trial in previously untreated stage III ovarian cancer with minimal disease following surgery compared cisplatin 100 mg/m² IV with the same IP dose in conjunction with IP cyclophosphamide 600 mg/m².⁸³ Median survival was significantly longer (41

vs. 49 months) and moderate to severe toxicities were fewer in the IP treatment group. A similar trial compared standard IV cisplatin and paclitaxel with IV carboplatin followed by IV paclitaxel and IP cisplatin; again, the IP arm was associated with significantly improved overall survival.⁸⁴ Although these studies were associated with improved outcomes, it was not considered the standard of care until an NCI clinical announcement was made based on results of a recent study.⁸⁵ In the most recent study, IV paclitaxel and cisplatin were compared with IV paclitaxel followed by IP cisplatin and IP paclitaxel in patients with stage III disease who had undergone optimal surgical cytoreduction. Although <50% of the patients in the IP arm completed therapy, similar to earlier studies, the progression-free survival and overall survival again favored IP administration.⁸⁵ Neutropenia, gastrointestinal (GI) toxicity, fatigue, pain, and metabolic events were more common in the IP group and quality of life was significantly worse. The NCI, however, now recommends a regimen containing IP cisplatin and a taxane administered IV or IV and IP for women with optimally debulked stage III ovarian cancer.⁸⁶ Ongoing studies are evaluating the optimal dose and schedule of IP chemotherapy administration.

BLADDER CANCER

Risk Factors and Clinical Presentation

35. B.B., a 65-year-old man, presented with complaints consistent with cystitis, including burning and pain on urination. Urinalysis reveals no white blood cells (WBC) or bacteria and 10 red blood cells (RBC)/high-power field (HPF). B.B. is a textile worker who smokes cigarettes but does not drink alcohol. He is referred to a urologist for cystoscopy, and the biopsy is consistent with multifocal, transitional cell carcinoma of the bladder, grade 3. What factors placed B.B. at risk for bladder cancer?

Risk factors for bladder cancer include age >60 years, male gender, occupational exposure to chemical carcinogens (aryl amines, including organic chemical, aniline dye, rubber, and paint industries), cigarette smoking, drugs (oral cyclophosphamide and phenacetin), and chronic urinary tract infections.⁸⁷ Because the whole uroepithelium is chronically exposed to carcinogens excreted in the urine, these cancers tend to recur in multiple sites even after surgical resection. B.B.'s male gender, long career as a textile worker, coupled with his significant history of cigarette smoking, place him at increased risk of bladder cancer.

The only symptom many patients experience before diagnosis is bladder irritation; in women, this may be mistaken for interstitial cystitis. Microscopic or gross hematuria is often the finding that prompts the patient to seek medical intervention. Patients with more extensive tumors may experience flank pain, constipation, or lower extremity edema.

Treatment

Intravesical Therapy

36. Further workup establishes that B.B. has superficial disease. He undergoes transurethral resection (TUR) and

fulguration (tumor is charred and then scraped with a curet). Is further therapy indicated at this time?

Approximately 70% of the newly diagnosed cases of bladder cancer will present with superficial disease. Optimal management of these cases can range from TUR alone to adjuvant intravesical (instillation directly into the urinary bladder) therapy to very aggressive approaches utilizing radical cystectomy. Although resection is highly effective in eradicating existing lesions, 30% to 85% of patients eventually develop new lesions.⁸⁸ B.B.'s tumor is grade 3 (poorly differentiated) and multifocal, which further increases his risk for recurrence. Adjuvant intravesical therapy is recommended for high-risk patients to reduce the risk of recurrence. This route places high concentrations of the drug into direct contact with the bladder mucosa and can delay or prevent progression of disease (which could require cystectomy or systemic chemotherapy). The limited systemic absorption of intravesicular therapy also minimizes the risk of serious systemic toxicities.

Drugs that have been used intravesicularly include thiotepa, doxorubicin, valrubicin, mitomycin, and bacillus Calmette-Guerin (BCG).⁸⁹ The choice of intravesical therapy is individualized; however, BCG is accepted as the standard therapeutic intervention for carcinoma inside of the bladder and for prophylaxis of tumor recurrence in superficial bladder cancer.⁹⁰ Specifically, evidence shows that patients who receive BCG for both the induction and maintenance regimen, have better outcomes than those receiving intravesical chemotherapy. A number of novel agents are currently under investigation, with considerable interest in intravesicular gemcitabine and early trials of intravesicular docetaxel.

Neoadjuvant and Adjuvant Chemotherapy

37. What role does chemotherapy play in the treatment of B.B.'s cancer?

Combining radical cystectomy with chemotherapy is an attractive approach to managing bladder cancer. Whether all patients or only high-risk patients should be treated this way and optimal timing of this approach is an ongoing debate. A small, but significant improvement is seen in survival in patients who receive neoadjuvant MVAC (methotrexate, vinblastine, doxorubicin, cisplatin).⁹¹ The small benefit must be balanced with the potential toxicities associated with this regimen. Alternatively, adjuvant chemotherapy following cystectomy may be offered to patients at high-risk. Currently, no data confirm a survival benefit from adjuvant chemotherapy, although the available trials have had significant flaws in their design.⁹² Recent meta-analyses have concluded that adjuvant therapy modestly, but significantly, improved survival over surgery alone.^{93,94} An ongoing European trial will better define the impact of adjuvant chemotherapy on overall survival. Because B.B. has high-grade disease, he should receive neoadjuvant chemotherapy with MVAC.

Metastatic Disease

38. Six months after receiving neoadjuvant chemotherapy and surgery, B.B. is found to have recurrent, metastatic disease (stage IV) involving his lungs and liver. What is the incidence of disease dissemination and what type of treatment should B.B. receive?

Approximately 40% of patients with bladder cancer develop metastatic disease during their clinical course. The most common sites of disease spread are the lymph nodes, liver, lung, and bone. Follow-up histories, physical examinations, and assessments should focus on these areas. Once the disease disseminates to a distant site, the prognosis is poor and the objective of treatment is to reduce symptoms and prolong survival. The standard therapy for metastatic disease is systemic chemotherapy with multidrug regimens that contain cisplatin. The classic regimen is MVAC, but more recently the commonly used doublet of gemcitabine and cisplatin has been utilized. In chemotherapy naïve patients, the combination of gemcitabine and cisplatin was associated with a higher response rate and less toxicity, including significantly less neutropenic sepsis and grade III/IV mucositis, compared with MVAC.⁹⁵ The taxanes are active agents for bladder cancer, along with pemetrexed in combination with gemcitabine.⁹² Because bladder cancer with distant metastases is considered an incurable disease, patients should be encouraged to participate in clinical trials whenever feasible. B.B.'s cancer has recurred within 6 months of treatment with MVAC; therefore, a single-agent taxane could be useful. If he responds, he could be offered treatment with the doublet of gemcitabine and cisplatin, if and when the cancer progresses.

MELANOMA

Risk Factors and Clinical Presentation

39. B.C., a 35-year-old white man, has worked for the past 12 years as a landscaper in south Florida. Two years before this recent admission he had undergone surgical resection of a stage IB malignant melanoma. What risk factors placed B.C. at an increased risk for melanoma?

Melanoma can occur in adults of all age groups and predominantly affects whites. The precise cause of melanoma is unknown; however, epidemiologic studies suggest that sunlight, especially exposure to ultraviolet (UV) rays, is the most important factor in its pathogenesis.^{96,97} Individuals with light complexions, an inability to tan, blond or red hair, or blue eyes have a higher risk of melanoma than the general population. Sunburns, especially during childhood, along with sun exposure, and use of tanning beds at an early age have been associated with an increased risk of melanoma.^{96,97} Finally, the total number of benign nevi on the body has been directly correlated to the risk of melanoma.⁹⁷ For B.C., constant exposure to sun is the most important risk factor for melanoma.

Screening high-risk individuals is extremely important because the initial presentation is often a melanoma lesion. Early recognition involves the ABCD evaluation of lesions (A, asymmetric; B, irregular borders; C, color variegation; D, diameter >6 mm). Commonly, these lesions are located on the back and trunk of men and the lower extremities of women. Cutaneous melanoma can arise on any surface of the skin and is perhaps the most visible of malignancies; therefore, it can be detected in asymptomatic persons. Early detection and recognition of melanoma are essential for possible cure. Occasionally, melanomas develop in noncutaneous tissues (e.g., the retina). The most critical factor in determining the prognosis following surgical removal of a melanoma is the vertical extension of the

lesion into the skin and subcutaneous tissue; those that extend into the subcutaneous fat have a high rate of tumor recurrence and a grave prognosis.

Treatment

Adjuvant Therapy

40. At the time of diagnosis, B.C. underwent a wide excision of the area, but because he did not have lymphadenopathy, the regional lymph nodes were not dissected. Should B.C. receive adjuvant therapy?

A number of agents have been evaluated in the adjuvant setting in high-risk patients with cutaneous melanoma. Chemotherapy has been largely unsuccessful, and the significance of adjuvant interferon- α -2b treatment is difficult to evaluate because different doses and schedules were utilized. A meta-analysis of high and low dose adjuvant interferon- α -2b, however, showed a trend toward a reduction in the risk of melanoma recurrence and melanoma-related deaths.⁹⁸ Although no clear differences in high-dose versus low-dose regimens for responses were seen, the high-dose regimen was associated with more severe toxicity. Because of the lack of consistent benefit, the use of interferon- α -2b has not been widely adopted. The effectiveness of tumor-specific vaccines in the adjuvant setting is being evaluated for patients with high-risk melanoma.

Accurate staging is necessary to identify patients whose risk of recurrence is high and who may benefit from systemic adjuvant treatment. Staging involves the assessment of lymph node status at the time of surgical removal of the primary lesion. The need to understand lymph node status has led to the emergence of lymph node dissection and sentinel-lymph-node biopsy at the time of surgery. Because B.C. did not have lymph node dissection, information is insufficient to assign an accurate stage to his melanoma.

Metastatic Disease

41. B.C. now presents with complaints of enlarged, painful lymph nodes in his groin; physical examination reveals several enlarged inguinal nodes and hepatomegaly as well. A lymph node biopsy confirms recurrence of malignant melanoma and his LFTs as follows: AST, 190 IU/L (normal, 5–35 IU/L); ALT, 165 IU/L (5–45 IU/L); and bilirubin, 2.2 mg/dL (2–18 mg/dL). Is chemotherapy indicated for B.C., who has metastatic malignant melanoma?

[SI units: AST, 190 U/L; ALT, 165 U/L; bilirubin, 37.62 mmol/L]

To date, the prognosis of patients with stage IV disease is poor because the results of chemotherapy in the treatment of melanoma have been disappointing. Only two agents, dacarbazine and interleukin-2 (IL-2), are FDA approved for the treatment of metastatic melanoma. Other agents that have demonstrated modest activity include carboplatin, carmustine, temozolomide, and cisplatin. Most responses are only partial, however, and the duration of response is generally only 3 to 6 months. Over the past 30 years numerous combination chemotherapy regimens utilizing dacarbazine as the primary active agent have been used but have not consistently demonstrated differences in response or survival. No combination

regimen has yet been proved to be superior to dacarbazine alone.⁹⁶

For several reasons, melanoma has been one of the most widely studied tumors in the area of immunotherapy. Commonly, melanoma cells express surface antigens that can be targeted by specific immunotherapy (e.g., monoclonal antibodies) and these surface antigens enhance recognition by the host's own immune system. The latter is supported by the lymphocytic infiltrates commonly observed in tumor biopsies. In addition, melanoma and its normal precursor cells, melanocytes, require growth factors for proliferation. Although melanocytes require exogenous growth factors, melanoma cells (at least sometimes) produce their own. This may explain, in part, the progressive nature of malignant melanomas. The interferons, IL-2, and vaccines are biologic therapies that have been most widely studied in the treatment of melanoma. Other biologic therapies that have been added to IL-2, but have not improved response rates or durable remissions, include monoclonal antibodies, active immunotherapy by vaccination, and adoptive immunotherapy using tumor-infiltrating lymphocytes or lymphokine-activated killer (LAK) cells. Initial studies using high-dose IL-2, either alone or in combination with LAK cells, produced overall response rates of only 10% to 20%. Importantly, about 5% of patients responded completely, most of whom have maintained responses without therapy for many years. Pooled analyses of patients treated with high-dose IL-2 supported the benefit of therapy, with overall objective response rates of 16% and a 6% complete response.⁹⁹

Several different preparations of IL-2 have been used in clinical trials. Variations in dose determination (on a per meter squared or per kilogram of body weight basis) as well as the use of different unit standards has caused dosing confusion. The World Health Organization (WHO) has defined international units (IU).¹⁰⁰ In the case of the commercially available aldesleukin (Proleukin, Chiron Therapeutics, Inc.), a milligram, which had previously been defined as equivalent to 3 million Cetus units, is now defined as equivalent to 18 million IU. Attention to the formulation and units is crucial to ensure the use of appropriate dosages.

Regimens using high doses of IL-2 (e.g., 600,000 IU/kg every 8 hours for 15 days) have been associated with considerable dose-related toxicities.¹⁰¹ Most of these can be included in a "diffuse capillary leak syndrome" characterized by intravascular volume depletion, oliguria, and edema of all major organs resulting in multiorgan dysfunction. Once therapy is discontinued, the capillary leak and related toxicities resolve quickly. During therapy, fluid balance must be carefully and frequently evaluated and IV hydration administered cautiously. Early administration of vasopressors is usually necessary when patients receive high-dose therapy to maintain systemic perfusion and enhance urinary output. Patients also require H₂-receptor antagonists to prevent gastritis, and premedication with acetaminophen and an NSAID (e.g., indomethacin) to prevent fever and chills associated with IL-2 administration. Meperidine is usually effective in attenuating chills when they occur. Concurrent with resolution of widespread edema, desquamation and intense pruritus often are observed, which can be managed with emollients. Corticosteroids should not be given because they may attenuate the immunomodulatory effects of IL-2. Although patients receiving single-agent IL-2 do not become neutropenic,

a high incidence of staphylococcal bacteremia has been observed.

Recent approaches have focused on combining chemotherapy with immunotherapy, a concept labelled “biochemotherapy.” Early trials were promising; however, recent phase III studies reveal no survival benefit with biochemotherapy when compared with either chemotherapy or immunotherapy alone.⁹⁶

Active specific immunotherapy (vaccination) uses tumor-associated antigens to induce an immune response against melanoma. Both autologous and allogeneic vaccines have been studied.⁹⁹ Therapeutic cancer vaccines, angiogenesis inhibitors, and novel cytotoxic agents are under investigation for the treatment of metastatic melanoma. Because no standard therapy exists, B.C. should be encouraged to participate in a clinical trial.

PROSTATE CANCER

Etiology and Risk Factors

42. J.D., a 65-year-old black man, was diagnosed with prostate carcinoma 18 months ago. At that time, he underwent a radical prostatectomy and was found to have stage II disease (confined to the prostate) with a Gleason score of 7. What are J.D.’s risk factors for prostate cancer?

Although adenocarcinoma of the prostate is the most common malignancy in adult males in the United States, specific risk factors (other than male gender and increasing age) have not been identified. The median age at diagnosis is 66 years and the disease is rare before the age of 40 years. Ethnicity is a well known risk factor, with the highest incidence worldwide in black men. Asian men have the lowest risk.¹ The mortality rate in black men is 2.4 times that of white men. Family history is a risk, most notably if it occurs in a first-degree relative.

The cause of prostate cancer is unknown. Regional variation in incidence worldwide suggests that environmental factors may have a role. Nationalized males have incidence rates that are intermediate between those born in the United States and those who have remained in their native country, which also suggests that environmental factors contribute. Increased risk also has been linked to high-fat diets. High levels of testosterone also have been implicated in prostate cancer development. Support for a hormonal etiology includes the hormone dependence of prostate cancer, the absence of prostate cancer in eunuchs, and the increased incidence in male populations with higher testosterone levels. An increased risk of prostate cancer in patients with benign prostatic hyperplasia has been suggested, although others have not observed this association. Conclusive evidence that widespread screening and early detection of prostate cancer improves survival is lacking. Before the advent of prostate specific antigen (PSA) screening, most prostate cancers were detected by digital rectal examination. Screening leads to earlier diagnosis and most agree that screening for prostate cancer has led to the recent declines in prostate cancer mortality. Because PSA is specific to the prostate and not specific for cancer, it is not a sensitive screening tool when used alone. Furthermore, several situations can falsely elevate PSA. Finasteride reportedly doubles the PSA, and prostate ma-

nipulation, biopsy, and the digital rectal examination increase the PSA as well. Nevertheless, the routine evaluation of PSA in men >50 years of age has become the standard of care.

Staging

43. Before surgery, J.D.’s PSA was 25 ng/mL (normal, <4.0 ng/mL). At a regular follow-up examination, his only complaint is mild backache, which he attributes to strain. Now, his PSA is 100 ng/mL and a CT scan of the pelvis shows several enlarged lymph nodes consistent with metastatic prostate cancer. Bone scan reveals blastic lesions in the lumbar region of the spine. J.D. is otherwise asymptomatic. His only other medical problems are a 20-year history of essential hypertension and evidence of early congestive heart failure. Is J.D.’s disease still considered stage II?

Following radical prostatectomy, serum PSA should be undetectable. Lifelong follow-up should occur in these patients. Stage I disease is typically found incidentally when prostate tissue is removed for other reasons, such as benign prostatic hypertrophy. The cells closely resemble normal cells and the gland feels normal to the examining finger. In stage II, which was J.D.’s initial diagnosis, more of the prostate is involved and a lump can be felt within the gland. In stage III, the tumor has spread through the prostatic capsule and the lump can be felt on the surface of the gland. In stage IV disease, the tumor has invaded nearby structures, or has spread to lymph nodes or other organs. Grading is based on cellular content and tissue architecture from biopsies (Gleason), which provides an estimate of the destructive potential and ultimate prognosis of the disease. From the CT scan, J.D. now has obvious spread to the pelvic lymph nodes and bone, indicating stage IV disease. The stage of the disease determines the most appropriate therapy.

Treatment

44. Does J.D.’s disease require therapy at this time? Is there a role for intermittent androgen blockade?

J.D. has advanced disease and is experiencing symptoms that could progress, causing him considerable pain and loss of neurologic function if left untreated. Hormonal manipulation that reduces testosterone to levels consistent with castration is the mainstay of pharmacotherapy for advanced symptomatic prostate cancer. Testosterone deprivation is effective against prostate cancer cells because the growth of both normal and malignant prostate tissue depends on it. Multiple hormonal manipulations can be employed alone or in combination, including (a) ablation of androgen sources, (b) inhibition of testosterone production, and (c) interference of testosterone binding at its receptor site.

Testosterone is produced by the testicles in response to pituitary follicle-stimulating hormone (FSH) and luteinizing hormone (LH) and also by metabolic conversion of androgens produced by the adrenal glands. Testosterone is converted by α -reductase enzymes to dihydrotestosterone, the major intracellular androgen, which then binds to a specific cytoplasmic receptor protein. The receptor–dihydrotestosterone complex is then translocated into the prostatic nucleus where it binds to and activates DNA to induce the production of mRNA. Messenger RNA then codes for proteins essential for the

metabolic functions of the prostate cells, including prostate cancer cells.

Therapeutic options for J.D. at this time include (a) orchiectomy; (b) LHRH agonists (e.g., leuprolide, goserelin), which decrease FSH and LH synthesis and production, which in turn decrease testosterone production; (c) a nonsteroidal antiandrogen (e.g., flutamide, bicalutamide, nilutamide), which inhibits dihydrotestosterone binding to its receptor; or (d) combined androgen blockade, using both an LHRH agonist and an antiandrogen.¹⁰²

Bilateral Orchiectomy

Bilateral orchiectomy is considered by many to be the therapy of choice because it permanently removes the primary source of testosterone production (95%) with few surgical complications.¹⁰² Orchiectomy does cause impotence (as do all forms of testosterone ablation) and patients may suffer from hot flashes; however, the need for regular long-term administration of drugs that have potential side effects is avoided.¹⁰³ Nevertheless, some patients find this procedure unacceptable.

LHRH Agonists

Medical castration with an LHRH agonist, or bilateral orchiectomy, is recommended as an initial treatment for metastatic prostate cancer.¹⁰² Leuprolide (Lupron) and goserelin (Zoladex) are LHRH agonists. The efficacy of leuprolide and goserelin appears to be similar, although large-scale comparative trials have not been completed. As with LHRH itself, these drugs stimulate the release of FSH and LH by the pituitary, which increases the production of testosterone. Thus, when therapy is initiated, an initial testosterone surge occurs (during the first 10–14 days), which can transiently worsen symptoms such as pain (i.e., flare reactions). Some clinicians choose to initiate short-term antiandrogen therapy before or together with the LHRH agonist and to continue the antiandrogen for about a month. This method is intended to reduce the possibility for the flare reaction. Over several weeks, the LHRH receptors in the pituitary are downregulated by the continuous onslaught of synthetic LHRH, followed by a decline in the release of LH. Ultimately, the levels of FSH, LH, and testosterone become profoundly suppressed.

Long-term use of LHRH agonists is associated with anemia, fatigue, and osteoporosis. Therapy is continued until the disease progresses (i.e., new metastatic sites). Many experts advocate continuing androgen deprivation with these agents for the duration of the patient's life, even after disease progression and the addition of chemotherapy.

Antiandrogens

Monotherapy with antiandrogens such as flutamide, bicalutamide, and nilutamide has been evaluated in previously untreated patients in a small number of trials.¹⁰⁴ The most studied antiandrogen for monotherapy in the metastatic setting is bicalutamide.¹⁰⁴ Although monotherapy with an antiandrogen may be discussed as an alternative, it should not be offered.¹⁰² When compared with castration, bicalutamide was associated with a decreased time to treatment failure, time to objective progression, and increased risk for death, but no statistical difference in survival.¹⁰⁵ The most common antiandrogen-related adverse effects include gynecomastia, hot flashes, GI disturbances, breast tenderness, and liver function abnormalities.

Because antiandrogens do not directly reduce testosterone levels, patients often can maintain sexual potency.

Combined Hormonal Blockade

The rationale for combination hormonal therapy is to interfere with multiple hormonal pathways to completely eliminate androgen action. In clinical trials, combination hormonal therapy, sometimes also referred to as *maximal androgen deprivation* or *total androgen blockade*, has been used. The combination of LHRH agonists or orchiectomy with antiandrogens is the most extensively studied combined androgen deprivation approach. Combined hormonal blockade with conventional medical or surgical castration and the addition of a nonsteroidal antiandrogen improves overall survival but increases adverse effects.¹⁰² Combined androgen blockade (e.g., LHRH agonist or orchiectomy plus nonsteroidal antiandrogen) would be an appropriate choice given J.D.'s minimal disease and good performance status.

Intermittent Androgen Blockade

The efficacy of intermittent versus total continuous complete androgen blockade in patients who have never received pharmacologic treatment whose prostate cancer has relapsed has been evaluated in a few studies. This approach involves hormonal therapy (LHRH agonists) for 6 to 9 months until the PSA level is <4 ng/mL followed by a break in therapy until the PSA reaches a predetermined level, such as 10 ng/mL or half of the PSA level when the treatment was initiated.¹⁰⁶ The value of such an approach is to allow periods during which testosterone production resumes and adverse effects are abated. Unknown are the effects on prostate cancer when testosterone levels are allowed to rebound. This approach remains investigational.

Immediate versus Delayed Androgen Ablation

Deferring androgen ablation therapy with active surveillance may be an option in men who have an increasing PSA level, who are asymptomatic or have no clinical or radiographic evidence of metastatic disease after local therapy.¹⁰⁶ Early initiation of androgen ablation for an increasing PSA level only exposes patients to risks of adverse events and provides only temporary benefit. Early therapy is associated with higher costs and greater frequency of treatment-related adverse effects, whereas deferred treatment may increase the risk for the development of hormone independence in the tumor. Patients who opt for active surveillance require close follow-up and ongoing discussions regarding the risks and benefits of deferred therapy. Because J.D. has evidence of metastatic disease, he requires immediate therapy.

Monitoring Therapy

45. J.D. started intramuscular (IM) leuprolide 22.5 mg every 3 months and flutamide 250 mg three times daily (TID). How should his response to therapy be monitored?

Blastic bone lesions heal slowly and have been shown to persist even when biopsy documents absence of disease. Therefore, a repeat bone scan would not be a useful indicator of response; however, it may be used to rule out new lesions or progressive disease. If bony lesions improve, it may take up to

6 months for resolution on the bone scan because of the slow rate of bone remodeling in elderly men.

Measurement of PSA is the most useful tool to follow response to therapy. Because the serum half-life of PSA is only 2 to 4 days, serial measurements provide a rapid indication of tumor status. It also is less expensive and more sensitive than imaging techniques (e.g., CT scans, bone scans). Control of symptoms, such as pain, and maintenance of quality of life are important outcome indicators in this disease and should be monitored frequently.

Androgen-Independent Disease

46. Following initiation of treatment, J.D.'s PSA level fell to 8 ng/mL and remained stable for the next 18 months. During this time, he had no clinical evidence of disease progression. His most recent clinic visit, however, revealed an increase in his PSA level to 75 ng/mL and a repeat bone scan and pelvic CT showed some disease progression. Is a change in therapy warranted at this time?

Various second-line hormonal therapies have been studied. If J.D. had been receiving an LHRH agonist alone, a testosterone level could be checked to ensure castrate levels have been achieved. If castrate testosterone levels (<20 ng/dL) are not achieved, then an orchiectomy or the addition of an antiandrogen is an option.¹⁰⁷ Because J.D. was receiving combined androgen blockade, a trial of antiandrogen withdrawal should be initiated. This approach produces symptomatic improvement and objective signs of tumor regression or a decrease in PSA in up to 35% of patients.¹⁰⁸ This is likely because of a mutation in the androgen receptor and a change in the selectivity or activation of the receptor that allows antagonists to act as agonists. Therefore, J.D.'s flutamide should be discontinued. The addition of an aromatase inhibitor, such as aminoglutethimide, or ketoconazole, is also a reasonable choice. Because J.D. is not experiencing progressive symptoms at this time, the benefits of additional therapy with either aminoglutethimide or ketoconazole probably do not outweigh the potential risks and complications of treatment and its associated costs.

Chemotherapy

47. J.D.'s metastatic disease continues to progress. Would cytotoxic chemotherapy be beneficial at this time?

Almost all patients with metastatic prostate cancer initially treated with androgen deprivation will develop progressive disease within 2 to 3 years. The term *androgen independent prostate cancer* describes the situation in which a patient has a documented castrate testosterone level and progressive disease. These patients typically have a median survival of 6 months.

Chemotherapy is now a standard for men with androgen-independent disease who have metastatic disease. Mitoxantrone with prednisone was the standard of care for a number of years, with approval based on clinically meaningful benefits, such as PSA reduction, pain relief, and a delay in bone scan evidence of disease progression.¹⁰⁶ Docetaxel is now the standard of care for the management of cases of metastatic androgen-independent prostate cancer after a small, but significant, survival benefit was observed in two separate trials

when compared with the combination of mitoxantrone and prednisone.^{109,110} Therefore, J.D. should receive single agent docetaxel for the management of his disease.

TESTICULAR CANCER

Clinical Presentation

48. M.W., a 26-year-old man, noted painless swelling of his left testicle approximately 2 or 3 weeks before seeing his family physician. Physical examination reveals an indurated mass located in the lower pole of the left testicle. Epididymitis is ruled out because of the location. Laboratory evaluation reveals the following: α -fetoprotein (AFP) is 300 ng/mL (normal, <40), β -human chorionic gonadotropin (β -hCG) (<5 IU/L) is negative, and LDH is 43 U/L. He is referred to a urologist who performs a radical inguinal orchiectomy and a nerve-sparing retroperitoneal lymph node dissection. M.W. has two positive nodes and the pathology report reveals embryonal carcinoma. Following orchiectomy, the AFP declines exponentially; a metastatic workup, including chest radiograph and CT scan of the abdomen and pelvis, reveals no evidence of disease. Is this a typical presentation of testicular cancer?

[SI units: AFP, 300, respectively (normal, <40); LDH, 43 U/L]

Testicular cancer is the most common malignancy in men between ages 15 and 35 years. M.W.'s presentation is typical in that the cancer presents as a painless swelling in one gonad. The cause of testicular cancer is unknown, but approximately 10% of patients have a history of cryptorchidism.¹¹¹ Other possible risk factors include race (the incidence is much lower among black male patients) and family history.¹¹²

Histologic Classification

49. Does histologic classification provide a clinical basis for therapeutic decisions?

Germinal neoplasms are divided into seminomas and various other types known collectively as nonseminomatous germ cell tumors (Table 91-6). Seminomas arise from malignant transformations of spermatocytes, whereas nonseminomas arise from transformation of germ cells of placental origin. Although treatment of advanced disease is similar, seminoma is exquisitely sensitive to radiation and, therefore, early stages of the disease are more frequently treated with radiotherapy.¹¹²

Table 91-6 Histologic Classification of Primary Tumors of the Testes

Germinal Neoplasms

Seminoma
Embryonal carcinoma
Teratoma
Choriocarcinoma
Yolk sac tumor

Nongerminial Neoplasms

Specialized gonadal stromal neoplasms (e.g., Leydig cell tumor)
Gonadoblastoma
Miscellaneous (e.g., adenocarcinoma, carcinoid, mesenchymal)

Determining the most appropriate therapy depends on both the histology and stage of the disease. Because M.W. has a non-seminoma (i.e., embryonal carcinoma), initial radiation is not indicated.

Staging

50. What is the stage of M.W.'s disease?

Stage I disease is limited to the testes; stage II disease involves the testes and lymph nodes; and stage III disease includes all metastatic tumors. Following orchiectomy, a metastatic workup was completed to rule out spread of the disease. Such a workup should include chest radiograph, CT evaluation of retroperitoneal lymph nodes, and assessment of decline in the tumor markers following orchiectomy. Because M.W. has two positive lymph nodes, his disease is classified as stage II.

Treatment

Adjuvant Chemotherapy

51. M.W. is diagnosed with stage II disease. Following surgery, the AFP declined exponentially. Is adjuvant chemotherapy indicated at this time?

Approximately 30% of patients such as M.W. (less than six positive nodes) whose disease is apparently completely resected (AFP declined following lymph node dissection) ultimately experience relapse, and adjuvant chemotherapy (two cycles of a platinum-based regimen) dramatically reduces this risk.¹¹³ If patients do not receive adjuvant chemotherapy and are monitored closely for early detection of relapse, the chance of cure following aggressive induction of chemotherapy remains high (>80%).¹¹³

Metastatic Disease

52. The decision is that M.W. will not receive adjuvant therapy at this time. Instead, he will be followed by a monthly history, physical examination, and AFP for the first year, every 2 months during the second year, and every 6 months thereafter. After 4 months, M.W. is lost to follow-up. He returns to his urologist 1 year later with complaints of abdominal discomfort and shortness of breath. A chest radiograph reveals multiple nodules in the lung, and an abdominal CT reveals a 6- to 10-cm mass. His AFP is 360 ng/mL and the β -hCG is 290 ng/mL. Is chemotherapy indicated at this time?

[SI unit: AFP, 360 mg/L]

M.W. now has metastatic testicular cancer and should receive systemic chemotherapy. For many years the combinations of either (a) cisplatin, vinblastine, and bleomycin or (b) cisplatin, etoposide, and bleomycin have produced responses in almost all men and complete responses in 60% to 80% of patients.^{114–116} A randomized trial demonstrated a higher long-term survival rate for patients who had received the regimen containing etoposide in a subset of patients at high risk; therefore, this combination is most widely used today.¹¹⁶

Before initiating chemotherapy, pulmonary function tests, an audiogram, and a 24-hour urinary creatinine clearance are

obtained. M.W. is hydrated with IV D5/0.45% sodium chloride and chemotherapy is initiated with cisplatin 20 mg/m²/day for 5 days; etoposide 100 mg/m² on days 1 to 5; and bleomycin 30 units on days 2, 9, and 16. Courses are repeated every 21 days. Because M.W. disease places him at high risk (i.e., nonseminomatous, extragonadal disease) he should receive a minimum of four courses of chemotherapy.

Monitoring Therapy

53. How should M.W. be monitored for therapeutic and toxic responses to chemotherapy?

Response to chemotherapy would be demonstrated by a reduction in the size of the abdominal mass, a reduction in the size and number of pulmonary nodules, and a steady decrease in the AFP and β -hCG without any other evidence of disease progression. CT scans, chest radiographs, and tumor markers are typically re-evaluated after every second course of therapy.

The most significant toxicities associated with this regimen include myelosuppression and the nephrotoxicity and neurotoxicity associated with cisplatin. A CBC with differential and platelet count should be performed once weekly until the myelosuppression has resolved and just before the next course. Serum creatinine, blood urea nitrogen (BUN), and electrolytes (including potassium and magnesium) should be monitored daily during chemotherapy and weekly thereafter. If evidence of toxicity appears, more intense monitoring may be recommended. Weekly symptom analysis and physical examination should include assessment for cisplatin neurotoxicity and other chemotherapy-associated toxicities. To assess bleomycin lung toxicity, baseline pulmonary function tests should be performed before the first course and after every second or third course.

54. M.W.'s AFP and β -hCG drop dramatically after his first course of chemotherapy and less so after his second course; however, they appear to plateau at an AFP of 170 ng/mL and β -hCG of 200 ng/mL after the third course. No evidence is found of tumor on the abdominal CT scan or chest radiograph. Should the fourth and fifth cycles of chemotherapy be administered?

[SI unit: AFP, 170 mg/L]

The plateau of the tumor markers confirms that M.W.'s disease is not continuing to regress after chemotherapy. First-line, cisplatin-based combination chemotherapy cures 70% of patients with disseminated germ cell tumors.¹¹¹ The remaining 30% of patients are candidates for salvage chemotherapy at the time of relapse or disease progression. Additional cycles of chemotherapy with the same regimen are unlikely to produce further tumor regression and normalization of the tumor markers. Because he had an initial good response to cisplatin therapy, it is reasonable to continue cisplatin in this circumstance. M.W. could receive salvage chemotherapy with cisplatin 20 mg/m²/day for 5 days, vinblastine 0.11 mg/kg on days 1 and 2, and ifosfamide 1.2 g/m²/day for 5 days. More recently, paclitaxel has replaced the vinblastine in this regimen.¹¹⁷ As a single agent, ifosfamide produces responses in approximately 22% of patients with refractory germ cell tumors.¹¹⁸ In patients such as M.W., the combination of ifosfamide with cisplatin and vinblastine has produced a 36% complete response rate with a

median duration of remission of 34 months. Mesna should be administered concurrently with ifosfamide to prevent hemorrhagic cystitis.

The response and long-term survival rates reported with both first-line and salvage chemotherapy for testicular cancer are considerably higher than for most solid tumors. Because of the likelihood of long-term survival, efforts are now focused on minimizing the long-term sequelae of chemotherapy (e.g., secondary malignancies, sterility).

Alternatively, at the time it was recognized that M.W.'s AFP and β -hCG plateaued, high-dose chemotherapy and autologous stem cell support could have been considered. Testicular cancer is potentially curable by means of high-dose chemotherapy plus hematopoietic stem-cell rescue, even in the third-line setting.¹¹⁹

PEDIATRIC SOLID TUMORS

Statistics

In the United States, more children between 1 and 14 years of age die of cancer than any other disease.¹²⁰ Yet, many common pediatric cancers that had low cure rates before the advent of chemotherapy now have 5-year survivals >70%. Acute leukemias are the most common malignancies of childhood (Table 91-7), whereas the solid tumors discussed in this chapter each represent 2.7% to 6.5% of all childhood malignancies.¹²⁰ Many common pediatric solid tumors are uncommon in adults. Likewise, many tumors common in adults occur infrequently in children. In general, sarcomas and embryonal tumors are common in children, whereas carcinomas predominate in adults.

Small Round Cell Tumors

Several pediatric malignancies present as small round cell tumors, making morphologic diagnosis by traditional light microscopy more difficult. The most challenging diagnostic problems are the less typical forms of these diseases. The list commonly includes peripheral primitive neuroectodermal tumors, extraosseous Ewing's sarcoma, extranodal lymphoma,

rhabdomyosarcoma, metastatic neuroblastoma, and some bone sarcomas.¹²¹ Problems involved with diagnosing these tumors have stimulated the development of newer techniques aimed at detecting tumor-specific antigens or chromosomal aberrations. This information may prove useful in identifying prognostic subgroups as well as tumor types in children and adults with cancer. Identification of the t(11;22) chromosomal translocation in both peripheral primitive neuroectodermal tumors and Ewing's sarcomas has resulted in the classification of both into the Ewing's sarcoma family of tumors.¹²²

Genetics

Similar to adult cancers, the association of many pediatric cancers with chromosomal aberrations or genetic defects is well confirmed. Examples include the association of Wilms' tumor with congenital malformations, acute lymphoblastic leukemia with Down syndrome, and the association of some pediatric cancers with loss of the p53 or retinoblastoma tumor suppressor genes^{121,123}.

Carcinogens

The role of carcinogens in pediatric cancer is probably less prominent than in adults because of the long latency periods required. Carcinogens, however, are implicated in the etiology of some childhood cancers.¹²⁴ Postnatal exposure to ionizing radiation is associated with acute leukemias, chronic myelogenous leukemia, and solid tumors, such as brain, thyroid, bone, and other sarcomas.¹²⁴ Treatment of pediatric malignancies with alkylators is associated with an increased risk of leukemias.¹²⁵ Etoposide and teniposide are associated with an increased risk of secondary acute myelogenous leukemia.¹²⁶ Treatment of childhood acute lymphoblastic leukemia, especially in those <5 years of age who received irradiation, results in an increased risk of CNS neoplasms, leukemia, lymphoma, and other neoplasms later in life.¹²⁷ The only well-documented prenatal carcinogen is diethylstilbestrol (DES), which is associated with an increased risk of vaginal or cervical cancer in offspring.¹²⁸

Patient Age

Patient age can be a factor in pediatric cancers and their treatment. Neuroblastoma is the most common malignancy in infants; however, an infant's prognosis is typically better than a child's, which is attributed to the biology of the disease in this age group.¹²⁹ In contrast, infants with acute lymphoblastic leukemia tend to have a worse prognosis than older children.¹³⁰ The biology and location of rhabdomyosarcoma are often different in younger and older children, with younger children having the better overall survival.¹³¹

Similarly, age may be a consideration with regard to the toxicity of treatments. Children may have increased susceptibility to toxicity from irradiation relative to adults. Normal organ development may be disrupted; the skeletal system and, in children <4 years of age, the brain are particularly susceptible.^{124,129} Prepubertal girls may have a decreased risk of fertility problems from chemotherapy, and conversely, children appear to have a greater risk for anthracycline cardiovascular toxicity than adults.¹³²

Table 91-7 Relative Incidence of Malignancies in Children 0 to 14 Years of Age

| Malignancy | Relative Incidence (%) |
|------------------------------|------------------------|
| Acute lymphoblastic leukemia | 25.7 |
| Central nervous system | 24.8 |
| Neuroblastoma | 6.5 |
| Non-Hodgkin's lymphoma | 5.6 |
| Wilms' tumor | 4.7 |
| Hodgkin's lymphoma | 3.5 |
| Acute myeloid leukemia | 5.2 |
| Rhabdomyosarcoma | 3.5 |
| Retinoblastoma | 2.7 |
| Osteosarcoma | 2.7 |
| Ewing's sarcoma | 1.4 |
| Other histologic types | 13.7 |

Multi-Institutional Research Groups

With the exception of a few pediatric oncology centers, most treatment centers do not have sufficient patients with specific diagnoses to scientifically establish the efficacy of therapeutic regimens within a reasonable time frame. Thus, most centers join the Children's Oncology Group (COG), the largest pediatric multi-institutional research group in the United States, Canada, Australia, and New Zealand. Through this mechanism, clinical trials often can be finished in 3 to 4 years, allowing for more rapid progress in the treatment of pediatric cancers. With the number of childhood cancer survivors increasing, research is focusing on reducing the long-term risks and complications of treatment modalities. It is important to determine which patients are at greatest risk from their cancer and to stratify treatments such that the minimal treatment needed to produce cure is given when the prognoses are good, and maximal treatment is given when the potential benefits outweigh the risks. Progress is already being made in this direction, and the future holds promise, especially with rapid gains in our understanding of the biology of cancers.

NEUROBLASTOMA

Neuroblastoma develops in immature cells of sympathetic nervous system origin.¹³³ It is the most common extracranial tumor of childhood, representing 6.5% of all childhood cancers. The median age at diagnosis is 19 months; 36% occur in children <1 year of age, and 89% before 5 years of age.¹³³ Of neuroblastomas, 65% are abdominal (half of these adrenal) and 20% are thoracic.¹³³ Neuroblastoma often presents as a fixed, hard, abdominal mass noted on physical examination by the family or physician without any other signs or symptoms, although other findings may be present depending on the location of the primary tumor and metastases. For example, GI fullness, discomfort, or dysfunction can occur. Other less common but characteristic signs include proptosis with periorbital ecchymoses, increased-renin hypertension, secretory diarrhea with increased vasoactive intestinal peptide, respiratory distress, nerve root compression, opsomyoclonus, and unilateral ptosis.¹³⁴ The most common sites of metastases are the bone marrow, bone, liver, and skin.¹³³

The catecholamine metabolites vanillylmandelic acid (VMA) and homovanillic acid (HVA) are elevated in the urine of 90% of patients with neuroblastoma.¹³⁵ Because infants have a better prognosis than older children with neuroblastoma, efforts have been made to screen infants using urinary concentrations of VMA and HVA.^{136,137} To date, these efforts have resulted in the diagnosis of more infants with good-risk disease, but have not reduced the number of older children diagnosed with poor-risk disease.

A simplified description of the international staging system is shown in Table 91-8. Twenty percent of infants (<1 yr), and 59% of children have stage IV disease at the time of diagnosis. A large number of prognostic factors have been identified and are discussed elsewhere.^{133,138} Patients are stratified for treatment based on age, stage, *N-myc* amplification, histology, and diploidy. The COG guidelines divide patients into three risk levels (Table 91-9).¹³⁸ Three-year, DFS for patients at high risk is approximately 30% and for those at low risk it is 90%. Infants have better outcomes for the same stage of disease and

Table 91-8 International Neuroblastoma Staging System (Abbreviated)

| | |
|-----------|---|
| Stage I | Local tumor with complete gross excision |
| Stage IIA | Unilateral localized tumor with incomplete gross excision |
| Stage IIB | Unilateral localized tumor, complete or incomplete excision, with ipsilateral nonadherent lymph node spread |
| Stage III | Involves both sides of the midline |
| Stage IV | Distant lymph node or organ involvement |
| Stage IVS | Infants <1 yr of age with localized primary tumor (stage I or II) with dissemination limited to liver, skin, or <10% of bone marrow |

Adapted from reference 138, with permission.

stage IVS has a significant incidence of spontaneous regression or regression with minimal treatment.^{134,139}

In current U.S. clinical trials, patients with low-risk disease are typically treated with surgery. Progression or recurrence may be treated with surgery again, unless disease is unresectable, in which case chemotherapy is used. Two to four courses of chemotherapy may be used with initial surgery if organ or life-threatening symptoms are present. Intermediate-risk disease is treated with surgery and four or eight courses of chemotherapy (Table 91-10) for favorable or unfavorable histology disease.¹³⁹ Chemotherapy for patients with low- or intermediate-risk disease avoids cisplatin to reduce nephrotoxicity and ototoxicity, limits the total doxorubicin dose to avoid cardiac toxicity, limits the total etoposide dose to reduce the risk of secondary acute myelogenous leukemia, and avoids ifosfamide to eliminate Fanconi renal syndrome. Radiation therapy is used only for poor responders.

Table 91-9 Children's Oncology Group Neuroblastoma Risk Groups

Low Risk

All stage 1 patients
 Patients >1 year of age with stages IIA or IIB, and *N-myc* not amplified, or amplified but with favorable histology
 Infants <1 year of age with stages IIA, IIB, or IVS with *N-myc* not amplified, favorable histology and hyperdiploidy

Intermediate Risk

Patients >1 year of age at diagnosis with stage III, *N-myc* not amplified, and favorable histology
 Infants with stages IVS and *N-myc* not amplified, and either diploidy or unfavorable histology
 Infants with stage III or IV and *N-myc* not amplified

High Risk

Infants with stage III, or stage IV <18 months of age, and *N-myc* amplified
 Patients >1 year of age with stage IIA or IIB, *N-myc* amplified, and unfavorable histology
 Patients >18 months of age with stage IV, or >1 year of age with stage III and *N-myc* amplified, or stage III and *N-myc* not amplified but unfavorable histology

Adapted from reference 138, with permission.

| Cyclophosphamide, etoposide |
| Carboplatin, cyclophosphamide, doxorubicin |
| Carboplatin, etoposide |
| Cyclophosphamide, doxorubicin |

^aEach line represents a single course of therapy. Generally the first four cycles are used in patients at intermediate risk with favorable histology disease, and all eight for patients with unfavorable histology. Patients at low risk whose disease is potentially organ- or life-threatening may receive the first two to four cycles of these drugs plus their surgery, rather than surgery alone.

Therapy for high-risk disease generally involves a first surgery for biopsy, aggressive chemotherapy (Table 91-11), second-look surgery for residual tumor resection, either additional aggressive chemotherapy or high-dose chemotherapy with autologous progenitor cell rescue, and then radiation to the tumor bed.¹³⁸ An alternative regimen of chemotherapy with equivalent short-term results would be four courses of cyclophosphamide, doxorubicin, and vincristine with two courses of cisplatin and etoposide, followed by the transplant.¹⁴⁰ High-dose chemotherapy with progenitor cell rescue has raised 2-year, disease progression-free survival to 49% from historic values of 10% to 20%; however, relapses can occur later, with 7-year disease progression-free survival of only 26%.¹⁴¹ Evidence suggests that survival can be improved (46% vs. 29% 3-year postchemotherapy disease-free survival) for patients with higher-risk disease if standard-dose or high-dose chemotherapy is followed by six cycles of isotretinoin 80 mg/m² given orally twice daily for 14 days of each 28-day cycle.¹⁴² Typical conditioning regimens preceding progenitor cell rescue include carboplatin and etoposide with either cyclophosphamide or melphalan, or thiotepa and cyclophosphamide. Total body irradiation may also be used.

| Carboplatin, etoposide |

^aThe second five cycles may be skipped if the patient is ready to proceed to high-dose chemotherapy with progenitor cell rescue after the first five combinations. Patients who are not candidates for autologous progenitor cell rescue receive all ten cycles of chemotherapy. Primary tumor removal or debulking is performed before progenitor cell rescue. Radiation to the site of the primary tumor occurs after all chemotherapy and progenitor cell rescue. Patients who are in complete response after this therapy will receive six cycles of isotretinoin (14 of every 28 days).

Clinical Presentation and Diagnosis

55. H.K. is a 2-year-old girl with a 3-month history of constipation and progressive abdominal distention. She has a decreased appetite, 1-week history of vomiting, and is pale and tired. She has a large retroperitoneal mass and multiple bilateral enlarged inguinal lymph nodes. Her hemoglobin is 5.1 g/dL (normal, 11–14 g/dL); the WBC count, differential, and platelets are within normal limits. Serum sodium, potassium, chloride, creatinine, and glucose are within normal limits. LDH is 6,144 U/L (normal, 322–644 U/L), and albumin is 2.3 g/dL (normal, 3.5–5.0 g/dL). Urine HVA is 570 g/mg creatinine (normal, <26 g/mg); VMA, 31 g/mg creatinine (normal, <11 g/mg). Biopsies of the abdominal mass and bone marrow are positive for neuroblastoma. The lymph nodes are negative for neuroblastoma. Scans are negative for other sites of disease. Which of these signs, symptoms, and laboratory results are consistent with a diagnosis of neuroblastoma?

[SI units: hemoglobin (Hgb), 51 g/L (normal, 110–140); LDH, 6,144 U/L (normal, 322–644)]

Virtually all of H.K.'s findings are consistent with neuroblastoma. The low hemoglobin and albumin and high LDH, however, are not specific for this cancer. In addition to the biopsy, the elevated urine VMA and HVA (catecholamine metabolites) are most helpful in confirming the diagnosis of neuroblastoma. Neuroblastomas can contain malignant (neuroblastoma) and benign (ganglioneuroma) cells within the same tumor, which is referred to as *ganglioneuroblastoma*.¹³³ In H.K., biopsies of the bone marrow, lymph nodes, and primary tumor are necessary to demonstrate the presence or absence of neuroblastoma at more than one site for staging purposes.

Treatment

56. What stage of disease does H.K. have? What treatment will she receive?

H.K.'s abdominal disease with distant bone marrow involvement indicates stage IV disease. Considering her age and disease stage, H.K. has a high risk of dying from her disease. Therefore, she is started on chemotherapy consisting of cisplatin (40 mg/m²/day on days 1 through 5) and etoposide (100 mg/m²/dose every 12 hours on days 1 through 3). Subsequent courses will contain vincristine, cyclophosphamide, and doxorubicin; ifosfamide and etoposide; carboplatin and etoposide; and a repeat of the cisplatin and etoposide.

57. H.K. is 81.5 cm tall, weighs 11.65 kg, and has a body surface area of 0.5 m². She starts cisplatin and etoposide with hydration fluids of 5% dextrose with 0.45% sodium chloride at 62.5 mL/hour. Urine output is 4 mL/kg/hour. How does monitoring of H.K.'s chemotherapy differ from that of an adult?

Monitoring Vital Signs for Etoposide

Although prevention and monitoring of toxicities from chemotherapy agents in children follow the same basic rules as in adults, there are some differences. When monitoring vital signs for hypotensive reactions to etoposide, normal blood pressure will be lower (90th percentile 104/60 mmHg for a 2-year-old girl) and the pulse higher (mean, 119 beats/minute for

a 2-year-old) than in adults.¹⁴³ It is important to have baseline vital signs so that hypotension or tachycardia will be recognized.

Monitoring Hydration for Cisplatin

In adults receiving cisplatin, hydration is often standardized with 1 to 2 L of IV fluids given before the drug, 1 to 2 L with the drug, and then continuous hydration for at least 24 hours after the dose.¹⁴⁴ In children, hydration volumes should be calculated based on the child's size. To decrease the risk of cisplatin nephrotoxicity, most pediatric protocols recommend IV fluids at twice maintenance rates to maintain urine outputs of at least 2 mL/kg/hour. The COG calculates maintenance fluids as 1,500 mL/m²/24 hours, so H.K. should receive 3,000 mL/0.5 m² = 1,500 mL over 24 hours (62.5 mL/hour). H.K.'s measured urine output is 4 mL/kg/hour, which should be adequate to prevent nephrotoxicity. Weight should also be monitored throughout cisplatin administration to assure fluid balance. Acute weight gain may require diuretics to prevent overhydration, and weight loss may indicate dehydration with impending reduction of urine output that could lead to acute nephrotoxicity. Increased IV fluids would help prevent the latter.

Adjustment of Creatinine Clearance to Adult Size

58. H.K.'s measured creatinine clearance (ClCr) is 39 mL/minute. Should her cisplatin be withheld or the dose adjusted because of low creatinine clearance?

[SI unit: ClCr, 0.65 mL/second]

Cisplatin is either not administered or administered at a reduced dosage when the creatinine clearance is <50 to 60 mL/minute/1.73 m².¹⁴⁵ Although H.K.'s creatinine clearance of 39 mL/minute appears to be low, it is not relative to the patient's size (i.e., 39 mL/minute/0.5 m²). Guidelines for dosing drugs cleared by glomerular filtration are based on creatinine clearance for normal adult body size, 1.73 m². Therefore, it is important to correct H.K.'s creatinine clearance to adult body size.¹⁴⁶ Multiplying by 1.73/0.5, her creatinine clearance is 135 mL/minute/1.73 m², so this is not a reason to withhold cisplatin. One precaution is that the accuracy of serum creatinine and creatinine clearance in assessing renal function during cisplatin therapy in children has been questioned.¹⁴⁷

Partial Response

59. H.K. obtains a partial response to the aforementioned initial chemotherapy regimen with reduction of urine VMA and HVA concentrations and a 50% decrease in the size of the primary tumor in the abdomen. Second-look surgery is performed to debulk the tumor, and pathology results indicate that the residual tumor contains 95% mature (benign) ganglioneuroma cells, but neuroblastoma cells are still present. What further treatment has the most potential benefit for H.K.?

Stem Cell Transplant

The best chance for prolonged DFS for H.K. is dose-intensive chemotherapy combined with autologous peripheral blood progenitor cell rescue. Although improvement in long-term DFS has not been shown in all trials, the 2- to 3-year DFS is better with intensive chemotherapy followed by autologous progen-

itor cell rescue.^{133,138,140–142} The plan for H.K. is to proceed to high-dose chemotherapy with an autologous progenitor cell rescue. If a complete response is achieved, she would then receive 6 months of isotretinoin (cis-retinoic acid) therapy following cell rescue.

Treatments Based on Disease Biology

With rapid advances in neuroblastoma biology being made, future alternatives may include biologic treatments. One agent in clinical trials is iodine-131-metaiodobenzylguanidine (I-MIBG), a compound that delivers radiation directly to catecholamine-secreting cells such as neuroblastoma. Pilot studies have used I-MIBG as part of the conditioning regimen before progenitor cell rescue in patients with neuroblastoma.¹⁴⁸ A published trial has demonstrated improved survival for high-risk patients in complete response who are postchemotherapy and receive isotretinoin.¹⁴²

WILMS' TUMOR

Wilms' tumor, also known as nephroblastoma, is a kidney tumor composed of various kidney cell types at different stages of maturation.¹⁴⁹ Approximately 5% of all childhood cancers are Wilms' tumor, making it the most common intra-abdominal tumor of childhood.¹²⁰ The peak incidence occurs at 3 years of age.¹⁵⁰ Wilms' tumor frequently presents as an asymptomatic abdominal mass, although malaise and pain may be reported.¹⁴⁹ Hematuria and high renin hypertension each occur in approximately 25% of patients. Metastases, when present at diagnosis, most commonly involve the lung (80%) or the liver (15%).

The relationship of genetic factors to Wilms' tumor is demonstrated by the approximately 1.5% of patients with Wilms' who have family members with the disease, and the approximately 10% who have aniridia, hemihypertrophy, or genitourinary anomalies.¹⁴⁹ Chromosomal aberrations at 11p13 and 11p15, known respectively as WT1 and WT2, are thought to be losses of tumor suppressor genes that occur in nonfamilial Wilms' tumor. The familial syndrome is probably related to unidentified genes.¹⁴⁹

Overall, Wilms' tumor has an excellent prognosis. Treatment is based on disease stage following surgical resection or debulking, and favorable histology versus focal or diffuse anaplasia. A simplified description of the staging is as follows: stage I is limited to the kidney and can be completely removed surgically; stage II is extended beyond the kidney but can be completely excised; stage III is characterized by residual tumor confined to the abdomen; stage IV is distant metastases; and stage V is bilateral disease.¹⁵¹ Metastases are present in only 15% of patients at diagnosis, and even these patients have relatively good prognoses. Four-year, relapse-free survival rates from the fourth National Wilms' Tumor Study (NWTS-4) range from 79% for stage IV with favorable histology to as low as 17% for patients with stage IV and diffuse anaplasia.¹⁵¹ Survival is approximately 90% for patients with stage I regardless of histology.

Clinical Presentation and Treatment

60. B.N. is a 34-month-old boy who is pale and irritable. He has had abdominal complaints with decreased bowel movements and

reduced oral intake for 2 weeks. He has played less than normal for the last 4 weeks. B.N.'s blood pressure has intermittently been as high as 146/87 mmHg (normal, 90th percentile, 106/69). His Hgb is 7.9 g/dL (normal, 11.5–13.5) and his erythrocyte sedimentation rate is 139 mm/hour (normal, <10). B.N. has a history of hypospadias and left hydronephrosis. Scans show a right kidney mass extending through the capsule plus two distant metastases in the peritoneum. Chest radiography shows one nodule in the lung as well. Pathology from a biopsy sample shows favorable histology Wilms' tumor. What is the current treatment for Wilms' tumor?

The series of five National Wilms' Tumor studies have sought to progressively minimize toxicities from radiation and chemotherapy while maintaining the excellent cure rate. The fourth National Wilms' Tumor Study Group (NWTS-4) study demonstrated that intermittent, higher doses of dactinomycin allowed higher dose intensity with less myelosuppression than lower doses given daily for 5 days. Using greater dose intensity and dose density, 6 months of therapy was shown to be as effective as 15 months of therapy given the traditional way.¹⁵² Also, fewer clinic visits were made and estimated costs were reduced by 50%.^{152,153} The fifth NWTS study used surgery followed by 18 to 24 weeks of chemotherapy. The drugs were determined by the stage and histology (Table 91-12). Abdominal radiation therapy is used for stage II disease with unfavorable histology (focal or diffuse anaplasia) or stages III or IV with any histology; pulmonary radiation is used for stage IV disease if the chest radiograph is positive for metastases. For patients with stage V, or those with inoperable tumors, surgery can be delayed until chemotherapy reduces the tumor size.

Table 91-12 National Wilms' Tumor Study V Treatment Regimens by Stage and Histology

Stages I and II, Favorable Histology; Stage I, Focal or Diffuse Unfavorable Histology:

Surgery followed by 18 wk of vincristine and dactinomycin

Stage III, Favorable Histology; Stages II and III, Focal Anaplasia:

Surgery followed by 24 wk of vincristine, dactinomycin, and doxorubicin, with abdominal radiation. *Stage IV, Favorable Histology or Focal Anaplasia:* add pulmonary radiation if chest radiograph shows metastases

Stage II or III, Diffuse Anaplasia; Stages I to III Clear Cell Sarcoma of the Kidney (Unfavorable Histology):

Surgery followed by 24 wk of vincristine, doxorubicin, etoposide, and cyclophosphamide with mesna, abdominal radiation. *Stage IV, Diffuse Anaplasia or Clear Cell Sarcoma of the Kidney:* add pulmonary radiation if chest radiograph is positive for metastases

Stage V:

Biopsy followed by neoadjuvant vincristine, dactinomycin, and doxorubicin, then complete resection or debulking followed by more chemotherapy and, if a poor response, radiation therapy; more aggressive treatment if unfavorable histology (10%)

Stages I–IV, Rhabdoid Tumor (Unfavorable Histology):

Surgery followed by 24 wk of carboplatin, etoposide, and cyclophosphamide with mesna, abdominal radiation

Dosing Chemotherapy in Infants

61. Are there any special precautions for dosing chemotherapy in B.N.?

The NWTS-2 noted an excessive number of toxic deaths in infants with good prognosis, and this resulted in a dosing change.¹⁵⁴ After chemotherapy doses were decreased by 50%, severe hematologic toxicity, toxic deaths, and pulmonary and hepatic complications were reduced.¹⁵⁵ Importantly, no decrease in therapeutic effect was noted. Reduction of chemotherapy doses in infants may be a consideration for other pediatric cancers as well.^{156–158} Reasons for increased toxicity may include altered pharmacokinetics or organ sensitivity as well as the larger body surface area per kilogram relative to older children and adults.¹⁵⁴ In NWTS-5, dosages of chemotherapy agents for children <30 kg were converted from mg/m² to mg/kg. By assuming the average 1-m² child weighs 30 kg, the dose/m² can be divided by 30 to arrive at a dose per kilogram, which can be used in dosing calculations. This adjustment lowers the dose by 20% to 50% in children who weigh <15 kg. In NWTS-5, infants <12 months of age received doses that were further reduced by halving the milligram per kilogram dose.

Interaction of Chemotherapy With Radiation

62. Are there any dosing precautions required because of potential interactions between B.N.'s treatments?

Another drug-related problem that may arise in B.N. is the interaction of dactinomycin and doxorubicin with radiation therapy.^{159–163} Two effects have been reported. One is acute enhancement of radiation effects, and the other is recurrence (recall) of radiation effects up to several weeks later, especially to skin and mucous membranes. Because B.N. is to receive abdominal and lung irradiation during his chemotherapy treatment, concurrent doses of dactinomycin and doxorubicin will need to be reduced by 50% or held if wet desquamation of the skin occurs. In many of the Ewing's sarcoma and rhabdomyosarcoma protocols, dactinomycin or doxorubicin is stopped during concurrent radiation treatments.

Doxorubicin Cardiotoxicity in Pediatrics

63. When B.N. receives lung irradiation for his metastases, how will it affect the doxorubicin he is scheduled to receive?

Although it is well known that mediastinal irradiation can increase the risk of anthracycline-induced cardiac toxicity,¹⁶⁴ the only adjustment for B.N. would be temporary reduction of doxorubicin doses as described in Question 62. The total doxorubicin dose should be limited to no more than 5 mg/kg (150 mg/m² in larger children). In earlier Wilms' tumor studies, the risk of congestive heart failure was 4.4% at 20 years, or up to 17.4% in patients who relapsed and received more doxorubicin.¹⁶⁵ Thus, cardiovascular toxicity can develop as long as 20 years after therapy is completed, with an apparent decrease in left ventricular wall thickness and increased ventricular afterload, probably related to inadequate numbers of myocytes.¹⁶⁶ These reports emphasize the need to minimize chemotherapy in patients with good prognosis, as the Wilms' tumor studies are doing. New recommendations include better standardization of cardiac monitoring and continuation of

monitoring for life in survivors of childhood cancer who receive cardiotoxic agents.

Dactinomycin Hepatotoxicity

64. B.N. is to receive vincristine 0.05 mg/kg weekly for 10 weeks; doxorubicin 1.5 mg/kg on weeks 3 and 9; 1 mg/kg on weeks 15 and 21; and dactinomycin 0.045 mg/kg on weeks 0, 6, 12, 18, and 24. During the third week of treatment, his ALT is elevated to 78 U/dL (normal, 7–56). Is this related to his drug therapy?

Early in the NWTs-4, an increased incidence (14.3%) of severe hepatotoxicity (elevation of AST or ALT 10 times normal with or without ascites) was reported with the pulse-intensive dactinomycin doses (0.060 mg/kg per single dose) in patients receiving no abdominal radiation.¹⁶⁷ Subsequently, dactinomycin doses were reduced. Still, the incidence of hepatotoxicity in patients receiving the newer 0.045-mg/kg pulse doses (3.7%), as well as those receiving the standard 0.015 mg/kg/day for 5 days (2.8%), remained elevated relative to the NWTs-3 results (0.4%), which used 0.015 mg/kg/day for 5 days.¹⁶⁸ The reasons for the increased hepatotoxicity are not known. Liver function usually returns to baseline within 1 to 2 weeks after discontinuation of chemotherapy, although more severe problems with veno-occlusive disease (hepatopathy) have also been reported.¹⁵¹ Chemotherapy was restarted in some patients, although frequently at lower doses or without dactinomycin. B.N. should be monitored closely in case his liver enzymes continue to rise, especially because he will receive abdominal radiation treatments. If his ALT rises to two to five times normal, or his total bilirubin is 3 to 5 mg/dL, doses of all three of his drugs should be reduced by 50%. If his ALT or bilirubin rises above two to five times normal, the drugs should be withheld until laboratory values return to the aforementioned range.

OSTEOSARCOMA

Osteosarcoma is a malignant bone tumor that occurs most commonly in adolescents or young adults in the second or third decade of life.¹⁶⁹ It occurs most frequently in the metaphyseal ends of the distal femur, proximal tibia, or proximal humerus, but it can occur in the flat bones as well.¹⁷⁰ The age range and bones involved suggest a malignant response associated with the normal childhood growth spurts.¹⁶⁹ The most common manifestation at diagnosis is pain at the site, which can sometimes be present for several weeks to months.¹⁶⁹ Clinically detectable metastases are present in 15% to 20% of patients, usually in the lungs but occasionally in bone.

If surgery alone is used for treatment, 80% of patients will die within 5 years of recurrent metastatic disease, indicating the presence of subclinical micrometastases at the time of diagnosis.^{170,171} Although surgery is the main treatment of the primary tumor, chemotherapy is used to prevent development of metastases. Drugs frequently used for osteosarcoma include high-dose methotrexate, cisplatin, doxorubicin, and ifosfamide.¹⁶⁹ Regimens have changed minimally in the last 25 years, with the current standard treatment in the COG being cisplatin and doxorubicin alternating with two courses of high-dose methotrexate. The tumor is relatively resistant to radiation therapy, which is usually reserved for cases in which local control cannot be achieved surgically.^{169,172} When

chemotherapy is used with surgery, long-term (2–5 years) DFS estimates typically range from 50% to 75%.^{169–171,173,174}

65. G.C. is an 18-year-old man with a 2- to 3-month history of left shoulder pain. A tumor is found on radiograph, and biopsy confirms a high-grade conventional osteosarcoma of the left proximal humerus. No apparent metastases are found with CT and bone scans. G.C. begins neoadjuvant chemotherapy consisting of high-dose methotrexate alternating with cisplatin and doxorubicin. Two cycles of this chemotherapy will be given before his surgery, after which he will receive two additional cycles with all three drugs and two more without the cisplatin. What is the goal of chemotherapy? What is the role of presurgical (neoadjuvant) chemotherapy in G.C.?

Because G.C.'s osteosarcoma is in his proximal humerus, the surgeon can remove the primary tumor using one of the various operations that have been described elsewhere.¹⁶⁹ Limb salvages typically work well in the upper extremities, with fewer complications than when they are used for lower extremities. Because patients with osteosarcoma usually die from metastases, the goal of the chemotherapy is to eradicate micrometastases. Neoadjuvant chemotherapy of osteosarcoma was developed to treat micrometastases while waiting for limb salvage surgeries to be arranged, performed, and healed. Neoadjuvant therapy may also facilitate limb-sparing surgery by shrinking the tumor; it also allows histologic grading of the response to initial chemotherapy at surgery, a prognostic factor for risk of relapse. No convincing evidence to date indicates that DFS is better for patients who receive neoadjuvant chemotherapy relative to those who receive only adjuvant therapy.^{172,174}

Prognostic Factors

66. At surgery, G.C.'s tumor shows excellent histologic response, with 99% necrosis. At diagnosis, his LDH was 684 U/L (normal, 322–644 U/L). Both of these factors indicate that G.C. is a good-risk patient. How do prognostic factors affect the choice of therapy in osteosarcoma?

Conventional staging systems do not correlate well with prognosis for most bone cancers. Clinically apparent metastases or a location that does not allow complete surgical removal of the primary tumor are associated with a poor prognosis.¹⁷² Newer surgical techniques and treatments have improved the outlook, with 20% to 30% of these patients cured using neoadjuvant chemotherapy and surgery of the primary tumor and metastases.¹⁷⁵ Patients with poor prognostic factors continue to be less likely to benefit from conventional surgery and chemotherapy. Other potential prognostic factors have been identified; however, few of these factors have been used to stratify patients to different treatment regimens.¹⁷² One exception is the histologic grade of the tumor at surgery. In current studies, patients with >90% tumor necrosis after two cycles of neoadjuvant chemotherapy are considered good risk and are treated with standard chemotherapy such as G.C. is receiving. Patients whose tumors have less necrosis at surgery are considered to be standard risk, and efforts are being made to increase their response rates by adding courses of ifosfamide and extending the duration of the standard regimen.

Delayed Clearance After High-Dose Methotrexate

67. After reconstructive surgery using a vascularized fibula graft, G.C. restarts his chemotherapy. During his fourth cycle of chemotherapy, after high-dose methotrexate is given, G.C.'s peak methotrexate concentration is 1,300 micromolar/L and the 72-hour concentration is 0.22 micromolar/L (normal, <0.1 micromolar/L at 72 hours). Recorded urine-specific gravities are <1.015, urine pHs are >6.5, and urine output is >2 mL/kg/hour, all meeting the guidelines to reduce the risk of methotrexate-induced nephrotoxicity. His creatinine has increased from 0.9–1.1 mg/dL (normal, 0.5–1.2 mg/dL), however. Leucovorin rescue (15 mg IV every 6 hours) is continued. What potential problems could be causing his retention of methotrexate?

Accumulations of protein-containing “third-space” fluids, such as pleural effusion and ascites, or GI obstruction, may retain methotrexate and cause slow terminal excretion.^{176–178} Slow terminal excretion of methotrexate allows more proliferating cells to be exposed to methotrexate during the S phase of the cell cycle, increasing the cytotoxicity and resulting in more mucositis and myelosuppression. Many drugs interact with methotrexate, which can also slow its terminal excretion. Cisplatin reportedly reduces the excretion of methotrexate, especially at cumulative doses >300 mg/m².¹⁷⁹ G.C. has received four doses of 120 mg/m² of cisplatin, which may have contributed to the reduced methotrexate excretion. He has not received concomitant nephrotoxins, such as aminoglycosides or amphotericin B. Weak organic acids, such as salicylates, ketoprofen, or trimethoprim-sulfamethoxazole (TMP-SMX), can compete with methotrexate for renal tubular secretion.^{180,181}

Although G.C.'s serum creatinine appears to be the same that it was at diagnosis (1.1 mg/dL), serum creatinine is not always a good indicator of renal function, so it is possible that G.C. has had some renal damage that is not apparent from his serum creatinine concentrations.¹⁴⁷ A measured creatinine clearance was 176 mL/minute/1.73 m² at diagnosis, and a repeat at this point is 106 mL/minute/1.73 m². Even measured creatinine clearance may not always be accurate when compared with Cr-EDTA measurement of glomerular filtration rate.¹⁴⁷ Although the reduced renal clearance may be contributing, it is not clear why G.C. is retaining methotrexate; future courses of methotrexate will need close monitoring.

Leucovorin Rescue

68. How long should leucovorin be administered to G.C.?

Cytotoxic effects of methotrexate depend on concentration and duration of exposure.¹⁸² Many high-dose methotrexate protocols continue leucovorin rescue until serum methotrexate concentrations are 0.1 micromolar/L, which would be expected to occur approximately 72 hours after a 12-g/m² dose infused over 4 hours. Because G.C. has delayed clearance with persistence of low methotrexate levels past 72 hours, prevention of GI and bone marrow cytotoxicity may require continuation of leucovorin rescue until methotrexate concentrations are <0.01 to 0.05 micromolar/L.¹⁷⁸ For G.C., methotrexate concentrations did not fall below 0.1 micromolar/L until 108 hours after his dose; thus, leucovorin was continued 24 hours past that

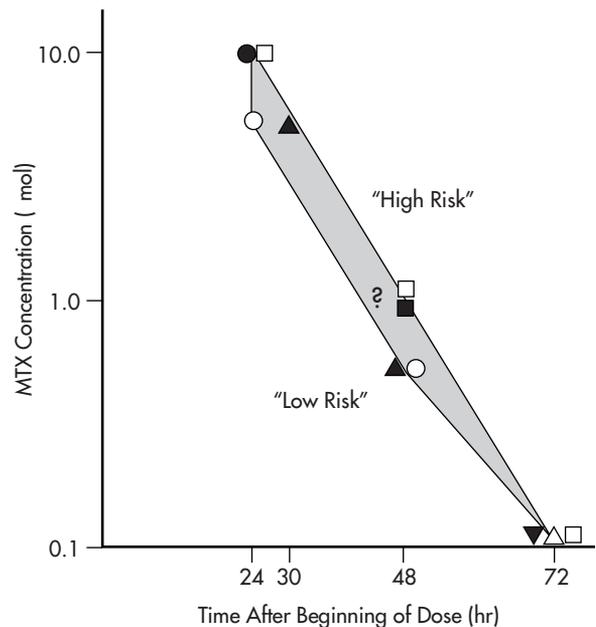

FIGURE 91-1 Composite semilogarithmic plot of serum methotrexate (MTX) concentrations that have been proposed to identify patients at “high risk” to develop toxicity from high-dose MTX if conventional low-dose leucovorin is administered. From Petros WP, Evans WE. Anticancer agents. In: Burton ME, et al., eds. Applied Pharmacokinetics & Pharmacodynamics. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2006:617.¹⁷⁷ Data for the figure were obtained from reports of: (▲) Evans,¹⁸³ (△) Tattersal,¹⁸⁴ (●) Isacoff,¹⁸⁵ (○) Isacoff,¹⁸⁶ (□) Nirenberg,¹⁸⁷ (■) Stoller,¹⁸⁸ and (▼) Rechnitzer.¹⁸⁹

time. Other considerations may also be important in patients receiving leucovorin rescue. Because of the competitive nature of leucovorin rescue, higher leucovorin doses may be needed for patients with excessively high methotrexate concentrations.

Petros and Evans¹⁷⁷ have published a figure that helps identify patients who are at high risk for methotrexate toxicity if given the usual low doses of leucovorin rescue^{177,183–189} (Fig. 91-1). Using their guidelines, if G.C.'s methotrexate concentrations had remained between 1 and 5 micromolar/L 42 hours after the beginning of the infusion, recommendations would include increasing the dose of the leucovorin to 30 mg/m² every 6 hours until methotrexate concentrations fall below 1 micromolar/L. A rough guideline for normal methotrexate concentrations after a 12-g/m² dose is infused over 4 hours would be as follows: 1,000 micromolar/L for the peak, 10 micromolar/L at 24 hours, 1 micromolar/L at 48 hours, and 0.1 micromolar/L at 72 hours. If concentrations exceed 1 micromolar/L 42 hours or more after the methotrexate dose, higher doses of leucovorin may be needed. Oral leucovorin administration should not be used when the patient has emesis or requires larger doses (>50 mg), which are often poorly absorbed.¹⁷⁷

RHABDOMYOSARCOMA

Rhabdomyosarcoma is the most common soft tissue sarcoma of childhood, occurring in 3.5% of all children with cancer.¹²⁰ The two most common histologic types are embryonal and alveolar. Embryonal rhabdomyosarcoma cells resemble

striated muscle and occur most frequently in young children with involvement in the head and neck or genitourinary tract. Alveolar rhabdomyosarcoma cells resemble lung parenchymal cells and occur more frequently in older children or adolescents with involvement of the trunk or extremities. Generally, patients with alveolar rhabdomyosarcoma have a poorer prognosis than patients with the embryonal type. The clinical presentation of rhabdomyosarcoma varies with its location.

Treatment combines surgery, radiation, and chemotherapy. Complete surgical removal is often difficult, given the locations and infiltrative characteristics of rhabdomyosarcoma. Because good local control improves the prognosis,¹³¹ radiation is generally added to the surgery to achieve this. Combination chemotherapy is necessary because the 5-year survival with local control alone is 10% to 30%. Vincristine, dactinomycin, and cyclophosphamide (VAC regimen) have been used extensively to treat rhabdomyosarcoma.¹³¹ Other agents producing responses include combinations of vincristine, doxorubicin, and cyclophosphamide; ifosfamide and etoposide; and vincristine and irinotecan.^{190–192} Results of the fourth Intergroup Rhabdomyosarcoma Study (IRS) indicate a 76% failure-free survival for patients with nonmetastatic disease.¹⁹³

Clinical Presentation and Prognostic Factors

69. F.J. is a 2-year-old girl with a rapidly enlarging mass on the lateral head of the gastrocnemius muscle in the right calf. F.J. has no other complaints. Bone marrow and scans are negative for metastatic disease. The diagnosis is embryonal rhabdomyosarcoma, stage III (unfavorable site and >5 cm mass). Initial expectations were that gross residual tumor would remain after the surgery, making it clinical group III. Chemotherapy consists of 3-week cycles of vincristine 0.05 mg/kg (days 1, 8, and 15 of some cycles, but day 1 only of some cycles); dactinomycin 0.045 mg/kg on day 1 of each cycle; and cyclophosphamide 73 mg/kg on day 1 of each cycle with mesna to reduce the risk of hemorrhagic cystitis. Because of reports of hepatotoxicity during a prior study, especially in patients <3 years of age, the protocol recommends all three drugs be dosed in milligram per kilogram for children <3 years of age. TMP-SMX is begun at 150 mg/m²/day (TMP) divided twice daily for 3 consecutive days per week. After each course of chemotherapy, F.J. is to receive filgrastim 5 mcg/kg/day subcutaneously for 14 days or until the absolute neutrophil count (ANC) is >1,000. What factors in F.J. are associated with a good prognosis? What are the chemotherapy treatment options for rhabdomyosarcoma?

The embryonal histopathologic classification has a better prognosis than the alveolar one, although evidence indicates that the primary tumor site is more important than the histology.^{131,194,195} The primary site affects resectability, route of spread, and how early the diagnosis is made. Additionally, age between 1 and 9 years is associated with a better prognosis. The Intergroup Rhabdomyosarcoma Studies (IRS) have used a clinical grouping system (groups I to IV), which is based on spread of the disease and extent of resection. This system has been useful because of its correlation with prognosis where complete surgical removal and lack of metastases both correlate with good prognosis.¹³¹ The fourth and fifth IRS studies compared the clinical grouping system with a TNM staging

system similar to that used in adult cancers. Although the two systems may result in different disease stages for a specific patient, both are considered valuable and current protocols use both systems.

In rhabdomyosarcoma, the tumor site is one important part of the T rating in the staging system. F.J.'s tumor involves an unfavorable site, and is >5 cm, making it stage III. Although her tumor was expected to be clinical group III, after a good response to neoadjuvant chemotherapy, a complete resection was performed, making it clinical group I. This suggests that she has an 80% to 90% chance of 3-year survival based on the IRS-II, IRS-III, and IRS-IV results.^{131,193,196} The IRS-V classified patients as having low-, intermediate-, or high-risk disease. Low-risk includes patients with embryonal rhabdomyosarcoma at favorable sites, or at unfavorable sites with no more than microscopic residual tumor.¹⁹² Patients at intermediate risk have the embryonal subtype with gross residual tumor or the alveolar subtype without metastatic disease. Patients at high risk include those with metastatic alveolar or embryonal disease.

Chemotherapy for many patients at low risk is limited to vincristine and dactinomycin.¹⁹² Most at intermediate risk are treated with vincristine, dactinomycin, and cyclophosphamide. New studies are adding courses of vincristine and irinotecan (COG ARST0531). Patients at high risk have not responded well in the past and are candidates for trials with newer drugs added to the vincristine, dactinomycin, and cyclophosphamide. A current study adds courses of vincristine and irinotecan, ifosfamide and etoposide and vincristine, doxorubicin, and cyclophosphamide (COG ARST0431).¹⁹² F.J. would be in the low-risk group; however, her large tumor justifies adding cyclophosphamide to the vincristine and dactinomycin as in the intermediate-risk regimen. Because radiation to her leg would stop bone growth, and her surgical margins were tumor-free, no radiation is being administered.

TMP-SMX Prophylaxis and Filgrastim for Myelosuppression

70. What are the reasons for treating F.J. with TMP-SMX and filgrastim?

F.J.'s VAC regimen (vincristine, dactinomycin, and cyclophosphamide) was associated with a high incidence of neutropenic fevers even during the pilot studies. Because of the frequency of severe myelosuppression, TMP-SMX is used until 6 months after chemotherapy for prophylaxis against *Pneumocystis jirovecii* (*carinii*), an opportunistic pathogen. Filgrastim is used to minimize neutropenia so that the chemotherapy dose intensity can be maintained.

Renal Fanconi Syndrome With Ifosfamide

71. F.J.'s mother read on the internet about a patient with rhabdomyosarcoma who had received vincristine, ifosfamide, and etoposide and was cured. She wants to know why that regimen is not being used for her daughter.

The IRS-IV results for local or regional disease (intermediate risk) demonstrated no advantages of vincristine, ifosfamide, and etoposide or vincristine, dactinomycin, and

ifosfamide over the standard vincristine, dactinomycin, and cyclophosphamide treatment.¹⁹³ Additionally, the ifosfamide-containing regimens caused more toxicity. Ifosfamide has been associated with renal Fanconi syndrome, a proximal tubular defect that is characterized by wasting of electrolytes, glucose, and amino acids, as well as renal tubular acidosis and an increased serum creatinine. Data suggest that the risk of Fanconi syndrome is increased in children <3 years of age; have

received total ifosfamide doses >72 to 100 g/m²; have hydronephrosis, a single kidney, or an elevated serum creatinine; or have received previous platinum therapy.¹⁹⁷⁻²⁰⁰ During each course of her chemotherapy, F.J. develops ketonuria; however, this is not a toxicity of her chemotherapy. Ketonuria is caused by her mesna therapy, which has been reported to routinely cause false-positive ketone tests.²⁰¹

ISSUES OF SURVIVORSHIP AFTER HEMATOPOIETIC STEM CELL TRANSPLANTATION 92-27

OVERVIEW

Worldwide, more than 30,000 autologous and 15,000 allogeneic hematopoietic stem cell transplantations (HCTs) are performed annually.¹ HCT is a medical procedure involving the infusion of hematopoietic stem cells into a patient, or the HCT recipient, to treat disease and/or restore normal hematopoiesis and lymphopoiesis. Originally, HCT developed from allogeneic bone marrow transplantation (BMT).¹ These early allogeneic BMTs involved administration of a myeloablative preparative regimen, which was followed by true “transplantation” of bone marrow from one individual to another. Bone marrow contains pluripotent stem cells and postthymic lymphocytes, which are responsible, respectively, for long-term hematopoietic reconstitution, immune recovery, and graft-versus-host disease (GVHD).¹ Subsequently, the “dose intensity” concept for cancer treatment was expanded to using myeloablative preparative regimens followed by au-

tologous HCT. *Autologous HCT*, or infusion of a patient’s own hematopoietic stem cells, allows for the administration of higher doses of chemotherapy, radiation, or both to treat cancer.^{1,2} In the setting of autologous HCT, the hematopoietic stem cells “rescue” the patient from otherwise dose-limiting hematopoietic toxicity. During the 1990s, there was an improved understanding of the graft-versus-tumor (GVT) effect, where the donor’s cytotoxic T lymphocytes suppress the recipient’s malignancy. This led to investigations with reduced intensity or nonmyeloablative preparative regimens. These less toxic preparative regimens are used with the hope of expanding the availability of HCT to those patients whose pre-existing medical condition(s) or age prohibits use of myeloablative regimens.^{3–5}

HCT is the only treatment available to many patients; however, it is associated with considerable morbidity and mortality with approximately 40% of advanced cancer patients

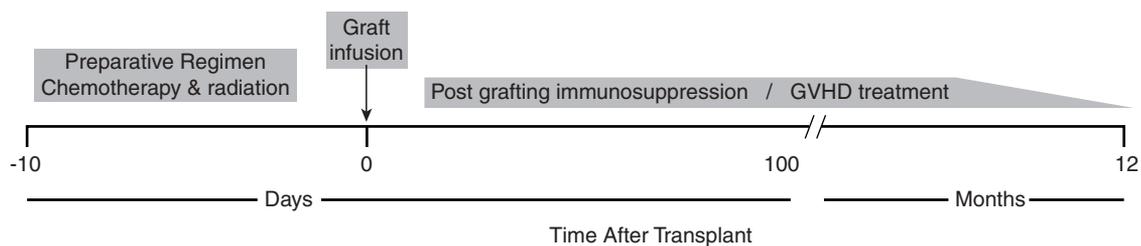

FIGURE 92-1 Basic schema for hematopoietic stem cell transplantation. Day 0 = bone marrow, peripheral blood progenitor cell, or umbilical cord blood infusion. Postgraft immunosuppression or graft-versus-host disease prophylaxis for allogeneic grafts only.

who undergo an HCT dying from complications due to this procedure.¹ The basic schema for HCT is illustrated in Figure 92-1. The combination of chemotherapy and/or radiation administered before infusion of hematopoietic stem cells is referred to as the *preparative* or conditioning regimen.¹ Its purpose is to eradicate the residual malignancy and, in the setting of an allogeneic HCT, to suppress the recipient's immunity.¹ Only myeloablative preparative regimens are used for autologous HCT, whereas myeloablative, reduced intensity, or nonmyeloablative preparative regimen may be used with allogeneic HCT. Myeloablative preparative regimens involve administration of near-lethal doses of chemotherapy and/or radiation, which are generally followed by a 1- to 2-day rest and then infusion of hematopoietic stem cells. Myeloablative preparative regimens have significant regimen-related toxicity and morbidity, and thus, are usually limited to healthy, younger (i.e., usually younger than 55 years) patients.⁶ Alternatively, reduced intensity or nonmyeloablative transplantations (Fig. 92-2) are being performed with the hope of curing more cancer patients with less preparative regimen-related toxicity and by using the GVT effect. For most chemotherapy-based preparative regi-

mens, the rest period is necessary to allow for elimination of toxic metabolites from the chemotherapy that could damage infused cells. After chemotherapy and radiation, a period of pancytopenia lasts until the infused hematopoietic stem cells reestablish functional hematopoiesis. This process is called *engraftment* and is commonly defined as the point at which a patient can maintain a sustained absolute neutrophil count (ANC) of >500 cells/mm³ and a sustained platelet count of at least 20,000/mm³ lasting 3 consecutive days without transfusions.⁷ Graft rejection occurs when the patient cannot maintain functional hematopoiesis. Graft rejection can occur after either autologous or allogeneic HCT.

There are various sources of hematopoietic stem cells that can be used for HCT. The key properties of the hematopoietic stem cells are their ability to engraft, the speed of engraftment, and the durability of engraftment.⁸ Peripheral blood progenitor cell transplant (PBPCT) has essentially replaced BMT for autologous HCT and is being increasingly used in the allogeneic setting.⁹ Cord blood transplant (CBT) has increased the availability of allogeneic HCT to those in need of an urgent HCT or to those for whom suitable donors are not found.¹ Umbilical

^aRisk varies depending on underlying disease, patient characteristics, and previous medical history.

^bRisk of infection increases with prolonged immunosuppression and/or chronic GVHD.

cord blood is rich in hematopoietic stem cells but has a limited volume; thus, both hematologic and immunologic reconstitution is delayed in CBT.¹

The type of HCT performed depends on a number of factors, including type and status of disease, availability of a compatible donor, patient age, performance status, and organ function. Characteristics of autologous and allogeneic transplantation, with either myeloablative or nonmyeloablative preparative regimens, are compared in Table 92-1.¹ Many diseases are treated with autologous or allogeneic HCT and are listed in Table 92-2.¹ Modifications to the basic schema for HCT are necessary based on the immunologic source (i.e., allogeneic or autologous) and the anatomical source (i.e., bone marrow, peripheral blood progenitor cells [PBPCs], or umbilical cord blood) of the hematopoietic stem cells infused. The number of allogeneic HCTs has plateaued, most likely because of the limited availability of suitable donors, the limited success to date with HLA-disparate donors, and the increasing availability of targeted therapies for diseases that were traditionally treated with HCT (e.g., the replacement of HCT with imatinib as first-line therapy for chronic phase chronic myeloid leukemia [CML]).¹⁰

AUTOLOGOUS HEMATOPOIETIC STEM CELL TRANSPLANTATION

The defining characteristic of autologous HCT is that the donor and the recipient are the same individual. Consequently, pretransplantation and posttransplantation immunosuppression is unnecessary. Autologous hematopoietic stem cells must be obtained (i.e., harvested) before the myeloablative preparative regimen is administered and subsequently stored for administration after the preparative regimen. Essentially, these hematopoietic stem cells are administered as a rescue intervention to re-establish bone marrow function and avoid long-lasting, life-threatening marrow aplasia that results from the myeloablative preparative regimen.¹¹

Indications for Autologous Hematopoietic Stem Cell Transplantation

1. P.J., a 46-year-old man, has diffuse large-cell B-cell non-Hodgkin lymphoma (NHL) in first relapse after a complete remission of 1 year duration. An 80% reduction in measurable

disease is noted after two cycles of dexamethasone, high-dose cytarabine, and cisplatin [DHAP] salvage chemotherapy. P.J.'s bone marrow biopsy and lumbar puncture are negative for malignant cells. Is a myeloablative preparative regimen with autologous HCT indicated for P.J.?

Autologous HCT is used to treat a variety of malignancies (Table 92-2). NHL and multiple myeloma are the most common indications for this procedure and represent more than two-thirds of all autologous HCT.¹ Patients with NHL are more frequently treated with an autologous HCT than with

^aTiming relative to diagnosis and other therapies may vary. From reference 1.

an allogeneic HCT because autologous HCT has equivalent or superior survival to allogeneic HCT.^{12,13} The usefulness of reduced intensity preparative regimens with allogeneic HCT is currently being evaluated for the treatment of NHL because of the potential advantages of a graft-versus-lymphoma effect and of using hematopoietic stem cells unexposed to prior cytotoxic chemotherapy.³⁻⁵

The most appropriate patient population and timing for autologous HCT in the treatment of NHL are being defined. A significant percentage of patients with aggressive NHL are cured with conventional chemotherapy alone. Adding autologous HCT to initial combination chemotherapy does not improve outcomes in patients with aggressive NHL.¹⁴⁻¹⁶ The primary eligibility criterion for autologous HCT is relapsed disease that is chemotherapy sensitive or refractory.¹⁷ In a randomized, controlled trial,¹⁸ autologous BMT, compared with conventional chemotherapy with DHAP, resulted in a 5-year event-free survival of 46% and 12%, respectively ($p = 0.001$). Overall 5-year survival was 53% in the BMT group and 32% in the conventional chemotherapy patients ($p = 0.038$).¹⁸ Prospective studies comparing preparative regimens, stem cell mobilization techniques, and stem cell source (i.e., BMT vs. PBPC) are not available; however, autologous PBPC has become the standard of care, most likely owing to the improved outcomes with PBPC in other disease settings.¹⁴

P.J. has minimal residual disease that has demonstrated chemotherapy sensitivity (i.e., he had a partial response to chemotherapy). Long-term prognosis will be improved with autologous PBPC rather than further conventional chemotherapy, as described previously.¹⁸ Thus, autologous PBPC is indicated.

Harvesting Autologous Hematopoietic Stem Cells

2. What is the best way to harvest and preserve harvested hematopoietic stem cells?

Autologous PBPCs have essentially replaced bone marrow at many HCT centers because PBPCs result in earlier engraftment than bone marrow.⁹ Because the harvest occurs before administering the preparative regimen, autologous hematopoietic stem cells must be cryopreserved.¹ Hematopoietic stem cells are usually frozen below -120°C and used within a few weeks, although, when frozen, they are viable for years.¹ Dimethylsulfoxide (DMSO) is the cryopreservative commonly used to protect hematopoietic stem cells from damage during freezing and thawing. Infusion of hematopoietic stem cells stored in DMSO can be associated with toxicities due to the DMSO itself. During infusion, DMSO is associated with skin flushing, nausea, diarrhea, dyspnea, hypotension, arrhythmias, and, rarely, anaphylactic reactions.¹⁹ Although contamination of grafts with tumor cells contributes to relapse of hematologic cancers, purging the grafts of tumor cells does not appear to improve survival.¹

Relative to a bone marrow graft, a PBPC graft results in a higher number of hematopoietic stem cells that are harvested and thus infused. This results in a PBPC graft having more rapid neutrophil and platelet recovery (i.e., a shorter duration of neutropenia or thrombocytopenia), fewer platelet transfusions, fewer days of intravenous (IV) antibiotics, and a shorter duration of hospitalization compared to a bone marrow graft.

Thus, the shift to the use of PBPCs over bone marrow for autologous HCT is primarily because of the more rapid engraftment and less invasive collection methods.⁹

Mobilization and Collection of Autologous Peripheral Blood Progenitor Cells

3. For PBPC mobilization, P.J. received one dose of cyclophosphamide 4 g/m^2 IV on day 1, followed by filgrastim 10 mcg/kg/day subcutaneously (SC) beginning on day 2 and continuing through completion of pheresis. Twelve days after receiving cyclophosphamide, P.J.'s white blood cell (WBC) count recovered to $3,000/\text{mm}^3$ and pheresis was begun. An adequate number of PBPCs is collected after two pheresis sessions are processed and then stored. What was the rationale for administering filgrastim and cyclophosphamide? What determines the duration of pheresis?

[SI units WBC $3,000 \times 10^6$ cells/L]

There is a low frequency of PBPCs in the peripheral circulation. Thus, mobilizing PBPC from the marrow compartment and increasing their numbers in the peripheral circulation is necessary to collect sufficient numbers of PBPCs for clinical use. Mobilization will lead to collection of sufficient numbers of autologous PBPCs in most patients, although a significant minority of patients has poor mobilization.⁹

PBPCs are obtained by administering a mobilizing agent(s) followed by leukapheresis, which is an outpatient procedure similar to dialysis.⁹ Hematopoietic growth factors (HGFs) alone or in combination with myelosuppressive chemotherapy are used to mobilize of PBPCs.⁹ The HGF granulocyte-macrophage colony-stimulating factor (sargramostim, Leukine) and granulocyte colony-stimulating factor (filgrastim, Neupogen) are used as mobilizing agents for PBPC collection.^{9,20} Both HGFs reliably mobilize PBPCs, with filgrastim providing a higher PBPC yield.⁹ The most frequently used filgrastim doses for autologous PBPC mobilization are in the range of 10 to 24 mcg/kg/day SC .^{9,20} PBPC yield is higher when pheresis is started at day 5 (vs. day 6), with the optimal yield being 3 to 7 hours after filgrastim administration.⁹

Myelosuppressive chemotherapy stimulates stem cell and progenitor cell proliferation. The combination of chemotherapy with filgrastim enhances PBPC mobilization relative to filgrastim alone.⁹ The chemotherapy also treats the underlying malignancy, but increases the risk of neutropenia.⁹ No mobilization chemotherapy regimen is clearly superior, which has led to incorporating PBPC mobilization into a cycle of disease-specific chemotherapy. Examples of PBPC mobilization chemotherapy regimens are single-agent cyclophosphamide or ifosfamide, carboplatin, and etoposide.⁹ Stem cell toxic agents, such as melphalan and carmustine, should be avoided because they lower the quantity and quality of PBPCs.⁹ The HGF is initiated 24 hours after completion of chemotherapy. Pheresis begins when the peripheral WBC count begins to recover to >1 to 3×10^9 cells/L.⁹

Pheresis is continued daily until the target number of PBPCs per kilogram of the recipients' weight is obtained.⁹ For adult recipients, the number of cells infused that expresses the CD34 antigen (i.e., CD34^+ cells) is the most reliable

Table 92-3 Representative Myeloablative Preparative Regimens Used in Hematopoietic Stem Cell Transplantation (HCT)

| Type of HCT | Disease State | Regimen | Dose/Schedule |
|---|---------------------------------------|---|--|
| Allogeneic ¹⁰² | Hematologic malignancies ^a | Cyclophosphamide (CY)/total body irradiation (TBI) | CY 60 mg/kg/day IV on 2 consecutive days before TBI 1,000–1,575 rads fractionated over 1–7 days |
| Allogeneic Autologous ^{62,81,84} | Acute and chronic leukemias | Busulfan (BU)/CY | BU adult 1 mg/kg/dose PO or 0.8 mg/kg/dose IV Q 6 hr for 16 doses Children <12 kg 1.1 mg/kg/dose IV Q 6 hr for 16 doses CY 50 mg/kg/day IV QD for 4 days after BU or 60 mg/kg/day IV QD for 2 days after BU |
| Autologous ¹⁸ | Non-Hodgkin lymphoma | BEAC (carmustine/etoposide/cytarabine/cyclophosphamide) | Carmustine 300 mg/m ² /day IV, day –6 Etoposide 200 mg/m ² /day BID IV for 4 days, days –5 to –2 Cytarabine 200 mg/m ² /day IV BID for 4 days, days –5 to –2 CY 35 mg/kg/day IV for 4 days, days –5 to –2 Mesna 50 mg/kg/day IV for 4 days, days –5 to –2 |

^aIncludes acute myelogenous leukemia, acute lymphocytic leukemia, chronic myelogenous leukemia, non-Hodgkin lymphoma, and Hodgkin disease.

indicator of an adequate PBPC population and predictor of durable engraftment.⁹ The CD34 antigen is expressed on 1% to 4% of human marrow cells. It is expressed on virtually all unipotent and multipotent colony-forming cells and on precursors of colony-forming cells, but not on mature peripheral blood cells.²¹ A variety of different thresholds have been identified regarding the minimal number of CD34⁺ cells needed for an autologous PBPC to produce rapid and complete (i.e., WBC, red blood cell [RBC], platelet) engraftment in adults. The threshold range has varied from 1 to 3 × 10⁶ CD34⁺ cells/kg of recipient weight, with more rapid platelet and neutrophil engraftment occurring with ≥5 to 8 × 10⁶ CD34⁺ cells/kg of recipient weight.

More intensive prior chemotherapy or radiation therapy is associated with a lower yield of CD34⁺ cells. There is a paucity of information regarding the parameters associated with engraftment in children undergoing an autologous PBPC.²² After pheresis, the cells are cryopreserved, stored, thawed, and infused into the patient as described in the “Harvesting Autologous Hematopoietic Stem Cells” section.

Myeloablative Preparative Regimens

4. What are the goals and characteristics of agents used for myeloablative preparative regimens in patients like P.J.?

The primary goal of P.J.’s high-dose, myeloablative preparative regimen is to eradicate residual malignancy. With autologous HCT, there is no need to induce immunosuppression because the donor and recipient are genetically identical.¹ Combination chemotherapy with multiple alkylating agents comprises the most common high-dose regimen before autologous HCT. Alkylating agents are used because they exhibit a steep dose–response curve for various malignancies and are characterized by dose-limiting bone marrow suppression.² Ideally, if combinations of antineoplastics are used, they should have nonhematologic toxicities that do not overlap and are not life threatening. Examples of common myeloablative regimens used with hematopoietic stem cell support are illustrated in Table 92-3. The early and late toxicities to myeloablative conditioning are listed in Table 92-4.

Complications of Autologous Hematopoietic Stem Cell Transplantation

5. What complications must be anticipated as a consequence of autologous HCT? How can these be minimized? How can treatment be provided in an outpatient setting?

The most common cause of death after autologous HCT is the primary disease. The more concerning toxicities of the preparative regimen are infection and organ failure, each occurring in less than 5% of the patients. Because autologous HCT is not complicated by profound immunosuppression or GVHD, supportive care strategies vary from allogeneic HCT in the early and later recovery periods. Isolation and use of laminar air flow rooms are unnecessary, although many centers continue to provide care for patients undergoing autologous HCT in high-efficiency particulate air (HEPA)-filtered rooms. The use of autologous PBPC is associated with shorter periods of neutropenia and less need for clinical resources. Thus, some HCT centers have developed programs that incorporate outpatient care into the initial recovery; these programs also offer cost savings to the payer for health services.^{23,24} Successful outpatient care during administration of a myeloablative preparative regimen and the neutropenic period requires careful development and implementation of the necessary supportive care

Table 92-4 Common Toxicities Associated With Myeloablative Allogeneic Hematopoietic Stem Cell Transplantation

| Early | Late |
|--|---|
| Febrile neutropenia | Increased susceptibility to infections |
| Nausea, vomiting, diarrhea | Endocrine disorders (hypothyroidism, hemorrhagic cystitis, infertility, growth retardation) |
| Mucositis | |
| Veno-occlusive disease | Neurocognitive changes |
| Renal dysfunction | Secondary malignant neoplasms |
| Cardiotoxicity | Chronic GVHD |
| Pneumonitis | Cataracts |
| Graft rejection | |
| Acute graft-versus-host disease (GVHD) | |

strategies to prevent or minimize infection, chemotherapy-induced nausea and vomiting (CINV), pain, and bleeding, along with admission criteria for more severe complications. Use of prophylactic oral antibiotics and once-daily IV antibiotics to prevent or treat uncomplicated febrile neutropenia have facilitated outpatient care and prevented many patients from being hospitalized.²⁵ In addition, outpatient care during autologous HCT demands that HCT centers have appropriate resources, facilities, and staff to provide 24-hour patient care coverage. Patients undergoing outpatient care must meet eligibility criteria, including the availability of caregivers 24 hours a day and housing within close proximity to the HCT center.

Hematopoietic Growth Factors After Autologous Peripheral Blood Progenitor Cell Infusion

6. After 10 days of rest, P.J. is admitted for his autologous BMT. He receives a myeloablative preparative regimen with cyclophosphamide, carmustine, and etoposide with an autologous PBPC graft. An order is written to begin filgrastim 5 mcg/kg/day SC, beginning on day 0 and continuing until the ANC has recovered to 500/mm³ for 2 consecutive days. What is the rationale for filgrastim in P.J. following the transplant procedure?

[SI units: ANC 500 × 10⁶ cells/L]

Autologous HCTs, regardless of the stem cell source, are associated with profound aplasia due to the myeloablative preparative regimen. Aplasia typically lasts 20 to 30 days after an autologous BMT and 7 to 14 days after an autologous PBPC. During this period of aplasia, patients are at high risk for complications such as bleeding and infection. Filgrastim and sargramostim exert their effects by stimulating the proliferation of committed progenitor cells, and, once engraftment occurs, hematopoietic recovery may be accelerated.

Several factors need to be considered when discussing the role of HGF in accelerating engraftment after HCT. First, the anatomical source of hematopoietic stem cells predicts the degree of benefit. The greatest benefit is enhanced neutrophil recovery and decreased use of associated resources in the setting of autologous BMT. The benefits of the HGF have been shown in several large multicenter, randomized, double-blind, placebo-controlled trials.^{26–28} The majority of the trials suggest HGF administration is associated with a shorter time to neutrophil engraftment (by 4–7 days), less infectious complications, and shorter hospitalization after autologous BMT.^{26,27,29} Survival is equivalent in those who received an HGF or a placebo.^{26,28}

Although some studies in the autologous PBPC setting note more rapid neutrophil recovery after HGF use, others report no difference in infection rates and minimal decreases in associated resource use such as the duration of hospitalization.^{27,29–31} In addition, sargramostim administration had no benefit (i.e., neutrophil and platelet engraftment) over placebo after autologous PBPC in one trial.³² Although clinical practice guidelines for HGF support their use after both autologous BMT and PBPC, pharmacoeconomic analyses are needed to further evaluate the true benefit of HGFs after autologous PBPC.

Filgrastim is preferred for this indication in clinical practice. The reason most commonly cited, is the desire to avoid febrile reactions associated with sargramostim, which complicate interpretation of febrile neutropenia. Although sargramostim or filgrastim theoretically may stimulate proliferation of leukemia myeloblasts, no evidence to date suggests that the incidence of leukemia relapse is higher in patients who receive these HGFs after autologous or allogeneic HCT.^{32,33} This may be due to the fact that patients with leukemia are usually in remission at the time of HCT. Thus, the population of residual leukemia cells is probably minimal.

Although both filgrastim and sargramostim successfully hasten neutrophil recovery, neither agent stimulates platelet production or augments platelet recovery.^{26,27} This is an important consideration because thrombocytopenia is often a cause of prolonged hospitalization in the HCT patient. Successful engraftment of all hematopoietic stem cell lines will likely require combinations of growth factors that work in concert to augment hematopoiesis. However, erythropoietin (Epoen, Procrit) and interleukin (IL)-11 (Neumega) have only been used experimentally in the HCT patient. At this time, there is no established role for either agent in the care of these patients.

In summary, P.J. is undergoing autologous PBPC for the treatment of a lymphoid malignancy. Thus, either sargramostim or filgrastim is an acceptable option for accelerating engraftment. Whether the addition of either agent will reduce infection and improve other clinically relevant outcomes is debatable.²⁰ A complete blood cell (CBC) count with differential should be obtained daily. Filgrastim should be continued until neutrophil recovery is achieved.

ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION

Allogeneic HCT involves the transplantation of hematopoietic stem cells obtained from a donor's bone marrow, PBPCs, or umbilical cord blood to a patient. Thus, to understand the application of and complications after allogeneic HCT, a working knowledge of immunology and the MHC and HLA in humans is necessary.³⁴

Eligibility criteria for allogeneic HCT vary between institutions. Having a matched sibling donor is no longer a requirement for allogeneic HCT, because improved immunosuppressive regimens and the National Marrow Donor Program have allowed an increase in the use of unrelated or related matched or mismatched HCT.³⁵ Potential donors also include haploidentical donors, who are a parent, sibling, or child of a parent with only one identical HLA haplotype. HCT with a haploidentical donor was initially associated with high rates of graft failure and GVHD, but recent technological advances have improved outcomes. Haploidentical HCT involves another alloreactive mechanism involving NK cells, which may be associated with reduced relapse rates in acute myelogenous leukemia (AML) patients.¹

Normal renal, hepatic, pulmonary, and cardiac functions are necessary for eligibility at most centers. Historically, patients older than 55 years were excluded from allogeneic HCT because they were more likely to succumb to transplantation-related complications. However, many centers are now

considering patients up to 65 years old and basing their selection criteria on physiological rather than biological age.

Indications for Allogeneic Hematopoietic Stem Cell Transplantation

7. B.S., a 22-year-old man, has AML in first remission after induction chemotherapy with standard doses of cytarabine and daunorubicin and consolidation with high-dose cytarabine. B.S. has poor risk cytogenetics, with abnormalities of 11q23 and inversion 3. Thus he will receive an allogeneic HCT as part of postremission therapy. HLA typing performed on family members has identified a fully HLA-matched sibling donor. B.S. returns to clinic today for a pretransplantation workup. At this time, his physical examination is noncontributory. All laboratory values are within normal limits. A bone marrow biopsy reveals <5% blasts. B.S. has a normal electrocardiogram and cardiac wall motion study. His renal and hepatic, and pulmonary function tests are normal. Is an allogeneic HCT indicated for B.S.?

B.S. has a diagnosis of AML, which is one of the most common indications for allogeneic HCT.¹ The primary indications for allogeneic HCT include treatment of otherwise fatal diseases of the bone marrow or immune system (Table 92-2). The optimal role and timing of allogeneic HCT, in contrast to other therapies, remains controversial,³⁶ especially because treatment options for AML have increased. The National Comprehensive Cancer Network Guidelines for AML patients include the use of allogeneic HCT. A matching sibling or alternative donor (e.g., matched unrelated donor) HCT is recommended as part of postremission therapy in patients with preceding hematologic disease (e.g., myelodysplasia, secondary AML) or poor risk cytogenetics, such as B.S.³⁷ Current research efforts focus on the use of reduced intensity preparative regimens and the utility of HCT relative to novel targeted agents in the hope of improving the outcome of allogeneic HCT.³⁷ B.S. is eligible for allogeneic HCT by virtue of his cytogenetics and the availability of a histocompatible donor. In addition, he meets age and organ function eligibility requirements and is in complete remission with minimal residual disease. The decision regarding timing of allogeneic HCT compared with other therapies must be made, weighing the aforementioned risks and benefits. B.S. can either undergo allogeneic HCT now or receive consolidation chemotherapy and delay HCT until early in his first relapse.

Histocompatibility

8. How does histocompatibility influence the risks for graft rejection and graft-versus-host reactions in patients like B.S. who undergo an allogeneic HCT?

Because the tissue transplanted in allogeneic HCT is immunologically active, there is potential for bidirectional graft rejection.¹ In the first scenario, cytotoxic T cells and NK cells belonging to the host (recipient) recognize MHC antigens of the graft (donor hematopoietic stem cells) and elicit a rejection response. In the second scenario, immunologically active cells in the graft recognize host MHC antigens and elicit an immune response. The former is referred to as host-versus-

graft disease and the latter as GVHD. Host-versus-graft effects are more common in solid organ transplantation. When host-versus-graft effects occur in allogeneic HCT, they are referred to as graft rejection, which results in ineffective hematopoiesis (i.e., adequate ANC and/or platelet counts were not obtained). Therefore, an essential first step for patients eligible for HCT is finding an HLA-compatible graft with an acceptable risk of rejection and GVHD.

Graft rejection is least likely to occur with a syngeneic donor, meaning that the recipient and host are identical (monozygotic) twins. Identical twins occur spontaneously in nature in approximately 1 in 100 births; thus, it is unlikely that a patient would have a syngeneic donor. In those patients without a syngeneic donor, initial HLA typing is conducted on family members because the likelihood of complete histocompatibility between unrelated individuals is remote. Siblings are the most likely individuals to be histocompatible within a family. However, <30% of potential HCT recipients have an HLA-identical sibling.¹

Determination of histocompatibility between potential donors and the patient is completed before allogeneic HCT.³⁴ Initially, HLA typing performed using blood samples and compatibility for class I MHC antigens (HLA-A, HLA-B, and HLA-C) is determined through serologic and DNA-based testing methods.³⁸ In vitro reactivity between donor and recipient can also be assessed in mixed lymphocyte culture, a test used to measure compatibility of the MHC class II antigens (HLA-DR, HLA-DP, HLA-DQ).³⁸ Currently, most clinical and research laboratories are also performing molecular DNA typing using polymerase chain reaction (PCR) methodology to determine the HLA allele sequence.³⁸ A donor-recipient pair with different HLA antigens (i.e., “antigen mismatched”) always has different alleles, whereas pairs with the same allele always have the same antigen and are termed “matched.” However, some pairs have the same HLA antigen but different alleles and are thus “allele mismatched.”³⁹ (See Chapter 34 for full discussion of histocompatibility.)

Lack of an HLA-matched sibling donor can be a barrier to allogeneic HCT. The use of alternative sources of allogeneic hematopoietic stem cells, such as related donors mismatched at one or more HLA loci, or phenotypically (i.e., serologically) matched unrelated donors has been evaluated.³⁵ Establishment of the National Marrow Donor Program has helped increase the pool of potential donors for allogeneic HCT.³⁵ Through this program, an HLA-matched unrelated volunteer donor might be identified. Recipients of an unrelated graft are more likely to experience graft failure and acute GVHD relative to recipients of a matched-sibling donor.⁴⁰ Thus, work is ongoing to identify factors that predict graft failure or GVHD to improve the availability and safety of unrelated donor transplants⁴¹ (see “Graft Rejection” section).

The preparative regimen or GVHD prophylaxis may be altered based on the mismatch between the donor and the recipient. The risk of graft failure decreases with better matches, such that those with a class I (i.e., HLA-A, -B, or -C) antigen mismatch have the highest risk of rejection compared with those with just one class I allele mismatch who have a minimal risk. Graft failure does not appear to be associated with mismatch at a single class II antigen or allele.³⁸ GVHD, both acute and chronic, and survival have also been

associated with disparity for class I and II antigens and alleles.^{42,43}

Harvesting, Preparing, and Transplanting Allogeneic Hematopoietic Stem Cells

9. What methods can be used to harvest hematopoietic stem cells from B.S.'s histocompatible sibling and prepare them for transplant? Are there any advantages to the use of bone marrow, PBPCs, or umbilical cord blood as a source for hematopoietic stem cells?

The method of harvesting allogeneic hematopoietic stem cells varies according to the site of harvest (i.e., bone marrow, peripheral blood, or umbilical cord blood).

ABO incompatibility increases the complexity of HCT, but is not an obstacle to HCT. The hematopoietic stem cells may need additional processing if the donor and recipient are ABO incompatible, which occurs in 30% to 40% of sibling donor HCTs and is higher in unrelated donor HCT.⁴⁴ Various strategies used to manage blood support for ABO-incompatible HCT recipients include removing RBC from the HCT product, as well as transfusing type O RBCs to minimize the risk of immune-mediated hemolytic anemia and thrombotic microangiopathic syndromes.⁴⁴

Bone Marrow

Harvesting bone marrow entails a surgical procedure in which marrow is obtained from the iliac crests. Allogeneic bone marrow is obtained from the donor under local or general anesthesia on day 0 of BMT.¹ Multiple aspirations of marrow are obtained from the posterior iliac crests until a volume with a sufficient number of hematopoietic stem cells is collected (e.g., 600–1,200 mL of bone marrow). The bone marrow is then processed to remove fat or marrow emboli and is usually immediately infused intravenously into the patient like a blood transfusion. Bone marrow is the primary graft source for allogeneic transplant in children, accounting for 60% of HCT in this population with PBPCs and cord blood accounting for the remainder.⁴⁵

Peripheral Blood Progenitor Cells

Peripheral blood has replaced marrow for allogeneic HCT in adults.^{1,45} Marrow stem cells continuously detach, enter the circulation, and return to the marrow; thus, the peripheral blood is a convenient source of hematopoietic stem cells. The number of PBPCs is estimated by using the cell surface molecule CD34 as a surrogate marker. The number of circulating CD34⁺ cells in blood is increased by mobilizing them from the marrow. The most commonly used regimen to mobilize allogeneic (healthy) donors is a 4- to 5-day course of filgrastim, 10 to 16 mcg/kg/day SC, followed by leukapheresis on the fourth or fifth day when peripheral blood levels of CD34⁺ cells peak.⁴⁶ An adequate number of hematopoietic stem cells is usually obtained with one to two pheresis collections, with the optimal number of CD34⁺ collected being 5 to 8 × 10⁶ cells/kg of recipient body weight.^{47,48} Higher cell doses have been associated with not only more rapid engraftment, but also fewer fungal infections and improved overall survival.⁴⁹ Hematopoietic stem cells obtained from the peripheral blood are processed like bone marrow–derived stem cells and may be infused im-

mediately into the recipient or frozen for future use. Allogeneic donation of PBPC has a similar level of physical discomfort to bone marrow donation; however, PBPC donation leads to quicker recovery.⁴⁸ The donor may experience musculoskeletal pain, headache, mild increases in hepatic enzyme or lactate dehydrogenase levels due to filgrastim administration, and hypocalcemia due to citrate accumulation, which decreases ionized calcium concentrations during pheresis.⁵⁰

Compared to bone marrow, PBPC infusions are associated with quicker neutrophil and platelet engraftment.¹ In patients with a hematologic malignancy and a matched sibling donor, PBPC is also associated with lower relapse rates and increased disease-free survival rates.⁵¹ However, PBPC grafts contain more T cells than bone marrow grafts.¹ PBPC has a similar incidence of acute GVHD, but an approximately 20% higher incidence of extensive stage and overall chronic GVHD.⁵¹

Umbilical Cord Blood

Blood from the umbilical cord and the placenta is rich in hematopoietic stem cells but limited in volume.¹ Thus, CBT offers an alternative stem cell source to those patients who do not have an acceptable matched related or unrelated donor. After consent is obtained, the cord blood cells are obtained in the delivery room after birth and delivery of the placenta.⁵² The cord blood is then processed, and a sample is sent for HLA typing and frozen for future use. At least 2,000 HCTs with cord blood donors have been performed, with more than 70,000 cord blood units banked for future HCT.⁵² It is unclear how long cord blood can be viably cryopreserved.⁵²

HCT with an unrelated cord blood donor has several potential advantages over unrelated marrow or PBPC donors.⁵² Specifically, cord blood is readily available, which leads to a more rapid time to HCT and the ability to tolerate greater degrees of HLA disparity.⁵² CBT has less stringent HLA matching requirements than bone marrow or PBPC grafts, because mismatched cord blood cells are less likely to cause GVHD while still maintaining GVT activity.¹ The less stringent HLA requirements increase the likelihood of identifying a suitable allogeneic donor, which is particularly beneficial for minority populations who are underrepresented in adult registries and often lack matched stem cell sources.¹ Outcomes in umbilical cord blood recipients are improved, with fewer HLA mismatches and greater numbers of CD34⁺ cells.¹ However, the limited number and quality of hematopoietic stem cells in cord blood are potential disadvantages. To improve engraftment, research is ongoing with two cord blood grafts each from different donors, with a cord blood and HLA-matched haploidentical PBPC grafts, and ex vivo expansion of cord blood cells.¹

Most CBT clinical data are derived from retrospective case series. These data have shown that CBT from a related or unrelated donor is effective in children with cancer and nonmalignant conditions.⁵² Platelet and neutrophil engraftment is slower in CBT, with a lower risk of acute and chronic GVHD and similar survival rates relative to a BMT.⁵² In children, engraftment is related to the dose of nucleated cells with an optimal dose of approximately 2 × 10⁷ nucleated cells per kilogram of recipient body weight.⁵³ This raises the question as to whether a CBT can provide enough nucleated cells to adequately engraft within an adult. In adults who do not have a related or unrelated

donor for bone marrow or PBPC donation, a CBT is feasible when at least 1×10^7 nucleated cells per kilogram of recipient body weight are administered.⁵⁴

In summary, it is most reasonable to harvest PBPCs from B.S.'s sibling to use for his myeloablative HCT.

Graft-versus-Tumor Effect

10. What is the GVT effect? Which tumors are most responsive to this effect?

Initial clinical evidence of a GVT effect came from the observation that patients with GVHD had lower relapse rates compared with those who did not.^{55,56} This suggests a GVT effect due to the donor lymphocytes. Further support for a GVT effect is the higher rate of leukemia relapse after T-cell-depleted BMT, in part due to the reduction in GVHD and concomitant loss of GVT effect.^{57,58} The effectiveness of donor lymphocyte infusions in patients who experienced relapse after allogeneic HCT also suggests a GVT effect. Lymphocytes are collected from the peripheral blood of the donor and administered to the recipient. Eradication of the recurrent malignancy is due to either specific targeting of the tumor antigens or to GVHD, which may affect cancer cells preferentially. Different illnesses vary in their responsiveness to donor lymphocyte infusions, with CML and acute leukemias being the most and least responsive, respectively.⁵⁹ Patients with certain solid tumors (e.g., renal cell carcinoma) also appear to benefit from a GVT effect.⁶⁰ These data gave rise to the use of reduced intensity and nonmyeloablative preparative regimens, which rely on the GVT effect.

Preparative Regimens for Allogeneic Hematopoietic Stem Cell Transplantation

Myeloablative Preparative Regimens

11. What is the rationale for using myeloablative preparative regimens for patients like B.S. who are to receive an allogeneic HCT? What types of regimens are used, and what is recommended for B.S.?

The combination of chemotherapy and/or radiation used in allogeneic HCT is referred to as the preparative or conditioning regimen. The rationale for high-dose myeloablative preparative regimens was similar to that discussed in the "Autologous Hematopoietic Stem Cell Transplantation" section of this chapter. Specifically, infusion of hematopoietic stem cells circumvents dose-limiting myelosuppression, maximizing the potential value of the steep dose-response curve to alkylating agents and radiation,² and suppressing the host immune system. The preparative regimen is designed to eradicate immunologically active host tissues (lymphoid tissue and macrophages) and to prevent or minimize the development of host-versus-graft reactions. In contrast, a myeloablative preparative regimen may not be necessary if a histocompatible allogeneic HCT is performed on a patient with a poorly functioning immune system (e.g., severe combined immunodeficiency disease).⁶¹ In the absence of a functioning immune system, the likelihood of a host-versus-graft reaction to histocompatible donor hematopoietic stem cells is small. Similarly, patients undergoing syngeneic transplantation do not require immunosuppres-

sive preparative regimens before HCT because the donor and the patient are genetically identical. Thus, the preparative regimen is tailored to the primary disease and to HLA compatibility between the recipient-donor pair.

Examples of common preparative regimens for allogeneic HCT are shown in Table 92-3.^{18,62,63} Table 92-4 lists the common toxicities associated with myeloablative allogeneic HCT. Most allogeneic preparative regimens for the treatment of hematologic malignancies contain cyclophosphamide, radiation, or both. The combination of cyclophosphamide and total body irradiation (TBI) was one of the first preparative regimens used, and it is still used widely today. This regimen is immunosuppressive and has inherent activity against hematologic malignancies (e.g., leukemias, lymphomas). TBI is myeloablative and immunosuppressive, does not have cross-resistance to chemotherapy, and also reaches sites not affected by chemotherapy (e.g., the central nervous system).¹ Toxicity to TBI is considerable and although fractionating its dose reduces toxicity, research is ongoing to identify newer methods of selective radiation with increased specificity.¹ The toxicity of TBI and the scarcity of facilities for its delivery have led to the development of radiation-free preparative regimens. Modifications of the cyclophosphamide-TBI preparative regimen include replacing TBI with other agents (e.g., busulfan) and adding other chemotherapeutic or monoclonal agents to the existing regimen. These measures are designed to minimize the long-term toxicities associated with TBI (e.g., growth retardation in children, cataracts) or to provide additional antitumor activity, respectively. In the case of a mismatched allogeneic HCT with a substantially increased chance of graft rejection, antithymocyte globulin (ATG) may also be added to the preparative regimen to further immunosuppress the recipient.

The optimal myeloablative preparative regimen for allogeneic HCT is challenging to study because several indications for HCT (e.g., thalassemia) are rare enough that it is not feasible or is too cost-prohibitive to conduct clinical trials adequately powered to detect clinically relevant differences. However, the long-term outcomes of busulfan/cyclophosphamide (BU/CY) and CY/TBI in patients with AML and CML have been compared in a meta-analysis of four clinical trials.⁶⁴ Equivalent rates of long-term complications were present between the two preparative regimens, except for a greater risk of cataracts with CY/TBI and alopecia with BU/CY. Overall and disease-free survival rates were similar in patients with CML, whereas there was a trend for improved disease-free survival with CY/TBI in AML patients. Thus, the preparative regimen can be tailored to the primary disease and HLA compatibility.

Based on these data, the CY/TBI preparative regimen is preferred for B.S. because he has AML in first remission.

Reduced Intensity or Nonmyeloablative Preparative Regimens

12. Describe the rationale for nonmyeloablative preparative regimens. Is B.S. a candidate for such a regimen?

The regimen-related toxicity of a myeloablative preparative regimen (Table 92-4) limits the use of allogeneic HCT to younger patients who have minimal comorbidities. Since most cancer patients are elderly myeloablative HCT cannot be offered to a substantial portion of these patients.⁶⁵ An improved understanding of the GVT effect led to the development of a strongly immunosuppressive but not myeloablative (i.e.,

a reduced intensity) preparative regimens.¹ Now reduced intensity preparative regimens account for 30% of allogeneic transplants.⁴⁵ More than 60% of patients receiving reduced intensity preparative regimens are older than 50 years.⁴⁵

There is a wide spectrum of reduced intensity preparative regimens (Fig. 92-2), with the nonmyeloablative regimens causing the least amount of myelosuppression. More intensive myeloablation is required for engraftment in the setting of unrelated donor or HLA-mismatched related HCT.⁶⁶ Reduced intensity regimens do not completely eliminate the host's normal and malignant cells and depend on the graft to eradicate remaining cancer. Thus, these preparative regimens may be preferable in those malignancies in which immunologic elimination of the malignant stem cells is possible.¹ The donor cells eradicate residual host hematopoiesis, and the GVT effects generally occur after the development of full donor T-cell chimerism.⁶⁰ After engraftment, mixed chimerism should be present as evidenced by the ability to detect both donor- and recipient-derived cells. Thus, if the graft is rejected, autologous recovery should promptly occur. Following a reduced intensity preparative regimen, mixed chimerism (defined as 5%–95% peripheral donor T cells) between the host and recipient develops, which allows for a GVT effect as the primary form of therapy. Chimerism is evaluated to monitor disease response and engraftment at varying time points. Chimerism is assessed within peripheral blood T cells and granulocytes and bone marrow using conventional (e.g., using sex chromosomes for opposite sex donors) and molecular (e.g., variable number of tandem repeats for same sex donors) methods. The methods used to characterize chimerism after HCT are reviewed elsewhere.^{67–69} A few months after HCT, donor lymphocytes can be infused (called a “donor lymphocyte infusion”) to augment the GVT activity.¹ The challenge is to maximize the GVT effect while minimizing the risk of GVHD. Therefore, GVHD prophylaxis, although different from that used with myeloablative regimens, is still necessary as is follow-up for infectious complications.

The safety and efficacy of these regimens have led to their wider application to nonmalignant conditions.¹ Reduced intensity preparative regimens lead to lower treatment-related mortality rates, but, they may be offset by higher relapse rates.⁷⁰ They are most effective in treating slow-growing cancers (e.g., chronic lymphocytic leukemia).¹ Because most of the data for reduced intensity preparative regimens are derived from older patients or those with comorbid conditions, they cannot be compared with data for myeloablative preparative regimens.⁷⁰ It is unclear if reduced intensity preparative regimens improve long-term survival of patients with malignant or nonmalignant diseases who are younger or without comorbid conditions. Prospective controlled trials are needed with stratification based on comorbidities, disease characteristics, pretransplant therapy, and hematopoietic stem cell source.⁷⁰

There are a paucity of data regarding the optimal source of hematopoietic stem cells following reduced intensity preparative regimens. Most case series have combined data from PBPC and marrow grafts. But some data suggest that, compared to bone marrow grafts, PBPC is associated with quicker engraftment, earlier T-cell chimerism, longer progression-free survival, and a lower risk of graft rejection.^{71,72}

B.S. is young and healthy enough to receive a myeloablative allogeneic HCT. Presently, reduced intensity HCT is not indi-

cated as first-line therapy for any malignant or nonmalignant conditions. It is not an option for B.S.

Posttransplantation Immunosuppressive Therapy

13. What is the rationale for immunosuppressive therapy after an allogeneic HCT? What is recommended for B.S.?

After infusion of hematopoietic stem cells, immunosuppressive therapy is administered to prevent or minimize GVHD. Patients receiving syngeneic transplants or a T-cell–depleted histocompatible allogeneic transplant generally do not receive posttransplantation immunosuppressive therapy. In syngeneic transplantation, the donor and the patient are genetically identical, and GVHD should not be elicited. In T-cell depleted transplantation, the volume of donor T cells infused into the patient is usually insufficient to elicit a significant graft-versus-host reaction.^{57,73} Numerous immunosuppressive agents given alone or in combination have been evaluated for the prevention of GVHD. Commonly used regimens after myeloablative HCT include cyclosporine or tacrolimus administered with a short course of low-dose methotrexate.⁷⁴ GVHD prophylaxis varies between a myeloablative and reduced intensity HCT (Table 92-5). Corticosteroids may also be used to prevent GVHD, but they are more commonly used to treat GVHD. In allogeneic HCT recipients without GVHD, immunosuppressive therapy is slowly tapered and discontinued over 6 months to 1 year because of immunologic tolerance. Over time, the immunologically active tissue between host and recipient become tolerant of one another and cease recognizing the other as foreign. In contrast, solid organ transplant recipients usually continue immunosuppressive therapy for the duration of the recipient's life.

Thus, B.S. should receive cyclosporine or tacrolimus administered with a short course of methotrexate for posttransplantation immunotherapy. This combination regimen will lower the risk of GVHD after his allogeneic HCT with a myeloablative preparative regimen.

Table 92-5 Common Reduced Intensity Preparative Regimens and Post Grafting Immunosuppression²³⁰

| Preparative Regimens | Postgrafting Immunosuppression |
|---|---|
| Fludarabine 30 mg/m ² /day IV on 3 consecutive days (–4, –3, –2), TBI 2 Gy as single fraction on day 0 | Cyclosporine 6.25 mg/kg PO BID, days –3 to day + 100 with taper from day + 100 to + 180 Mycophenolate mofetil 15 mg/kg PO BID or TID, day + 0 to + 40 with taper from day + 40 to + 90 |
| Fludarabine 25 mg/m ² /day IV for 5 days and melphalan 90 mg/m ² /day IV for 2 days | Tacrolimus to maintain trough blood concentration of 5–10 ng/mL with methotrexate 5 mg/m ² /day IV days + 1, + 3, + 6, + 11 |
| Fludarabine 25–30 mg/m ² /day IV for 3–5 days, busulfan ≤9 mg/kg/total | |

COMPARISON OF SUPPORTIVE CARE STRATEGIES BETWEEN AUTOLOGOUS AND ALLOGENEIC MYELOABLATIVE HEMATOPOIETIC STEM CELL TRANSPLANTATION

14. How do supportive care strategies used for myeloablative preparative regimens with an autologous graft differ from those described for an allogeneic graft?

Supportive care strategies common to patients receiving a myeloablative preparative regimen, regardless of whether they have received an autologous or allogeneic HCT, include use of indwelling central venous catheters; blood product support; and pharmacologic management of chemotherapy-induced nausea and vomiting (CINV), mucositis, and pain. These similarities are a function of the side effects of a myeloablative preparative regimen.

Because of the different needs for immunosuppression with an autologous and allogeneic HCT the supportive care differs. Allogeneic HCT patients experience an initial period of pancytopenia followed by a more prolonged period of immunosuppression, which substantially increases the risk of bacterial infections, but more importantly, fungal, viral, and other opportunistic infections.⁷ The risk of infection increases as additional immunosuppressive therapy is incorporated to prevent or treat GVHD. Supportive strategies designed to minimize infection during immunosuppression are essential after allogeneic HCT (see “Infectious Complications” section).

COMPARISON OF SUPPORTIVE CARE STRATEGIES BETWEEN ALLOGENEIC MYELOABLATIVE AND NONMYELOABLATIVE HEMATOPOIETIC STEM CELL TRANSPLANTATION

15. How do supportive care strategies used for myeloablative and nonmyeloablative preparative regimens with an allogeneic graft differ?

Nonmyeloablative HCT is the least myelosuppressive reduced intensity regimen (Fig. 92-2). A direct comparison of the toxicities with a myeloablative and nonmyeloablative preparative regimen is difficult because the latter is offered only to patients who are not candidates for myeloablative allogeneic HCT. These preparative regimens differ substantially in terms of the chemotherapy agents used (Tables 92-3 and 92-5) and the degree of myelosuppression. Nonmyeloablative HCT may have a different time pattern for infectious complications but there is a similar incidence and severity of acute GVHD. Nevertheless, comparisons between the preparative regimens are challenging because of the differences in the pre-HCT health of the recipients.⁶⁶ Clinical research is focusing on designing optimal preparative regimens with acceptable efficacy and toxicity (i.e., mixed chimerism, disease response). Thus, relative to myeloablative HCT, the preparative regimens and immunosuppression used after graft infusion are more variable for reduced intensity or nonmyeloablative HCT (Table 92-5).

DOSE CALCULATIONS IN OBESITY

16. K.M. is a 36-year-old woman with CML in accelerated phase. After her initial diagnosis, a successful search for an unre-

lated 6/6 HLA-matched allogeneic donor was conducted. K.M. is being admitted for myeloablative allogeneic PBPCT. Orders for K.M.’s preparative regimen are written as follows: height, 162 cm; actual body weight (ABW), 80 kg; ideal body weight (IBW), 54 kg; body surface area (BSA), 1.85 m²; body mass index (BMI), 30.5 kg/m²; and busulfan, 16 mg/kg total dose to be administered over 4 days (1 mg/kg per dose PO Q 6 hr for 16 doses, days -7, -6, -5, and -4). Cyclophosphamide 60 mg/kg/day IV to be administered on days -3 and -2. Day -1 is a “rest” day, followed by infusion of PBPC on day 0. Which weight should be used to calculate doses for K.M.’s preparative regimen?

K.M.’s ABW is 48% over her IBW. She is considered obese because her ABW is 30% greater than her IBW and her BMI is between 27 and 35 kg/m². Obesity has numerous effects on the pharmacokinetic disposition of medications; unfortunately, there is a paucity of data regarding the effects of obesity on the clinical outcomes of anticancer agents. The risk associated with inaccurate dosing of the preparative regimen for a myeloablative HCT is particularly challenging, because using a weight that is too high can cause lethal toxicity, while one that is too low could result in inadequate marrow ablation or disease eradication.

Few studies have evaluated the association of body weight and outcome to preparative regimens for myeloablative HCT.⁷⁵⁻⁷⁷ Routine dosing of oral or IV busulfan based on adjusted IBW or BSA does not require a specific dose adjustment for obesity.^{77,78} K.M.’s busulfan dose should not be based on her ABW because it does not accurately correct for her obesity and may predispose her to hepatic veno-occlusive disease (VOD). Her initial busulfan doses should be based on adjusted IBW.

COMPLICATIONS ASSOCIATED WITH HEMATOPOIETIC STEM CELL TRANSPLANTATION

17. What toxicities associated with myeloablative preparative regimen should be anticipated in K.M.? Are they similar to those anticipated after standard-dose chemotherapy?

Myelosuppression is a frequent dose-limiting toxicity for antineoplastics when administered in conventional doses used to treat cancer. However, because myelosuppression is circumvented with hematopoietic rescue in the case of patients receiving HCT, the dose-limiting toxicities of these myeloablative preparative regimens are nonhematologic (i.e., extramedullary) in nature. The toxicities vary with the preparative regimen used. Most patients undergoing HCT experience toxicities commonly associated with chemotherapy, such as alopecia, mucositis, CINV, infertility, and pulmonary toxicity (see Chapter 89). However, these toxicities are magnified in the HCT population.

Table 92-4 depicts a range of toxicities that can occur after myeloablative preparative regimen for HCT, and Figure 92-3 depicts the time course for complications after HCT. Selected toxicities are discussed in the following sections.

Busulfan Seizures

18. In addition to her preparative regimen, the following supportive care agents and monitoring parameters are prescribed

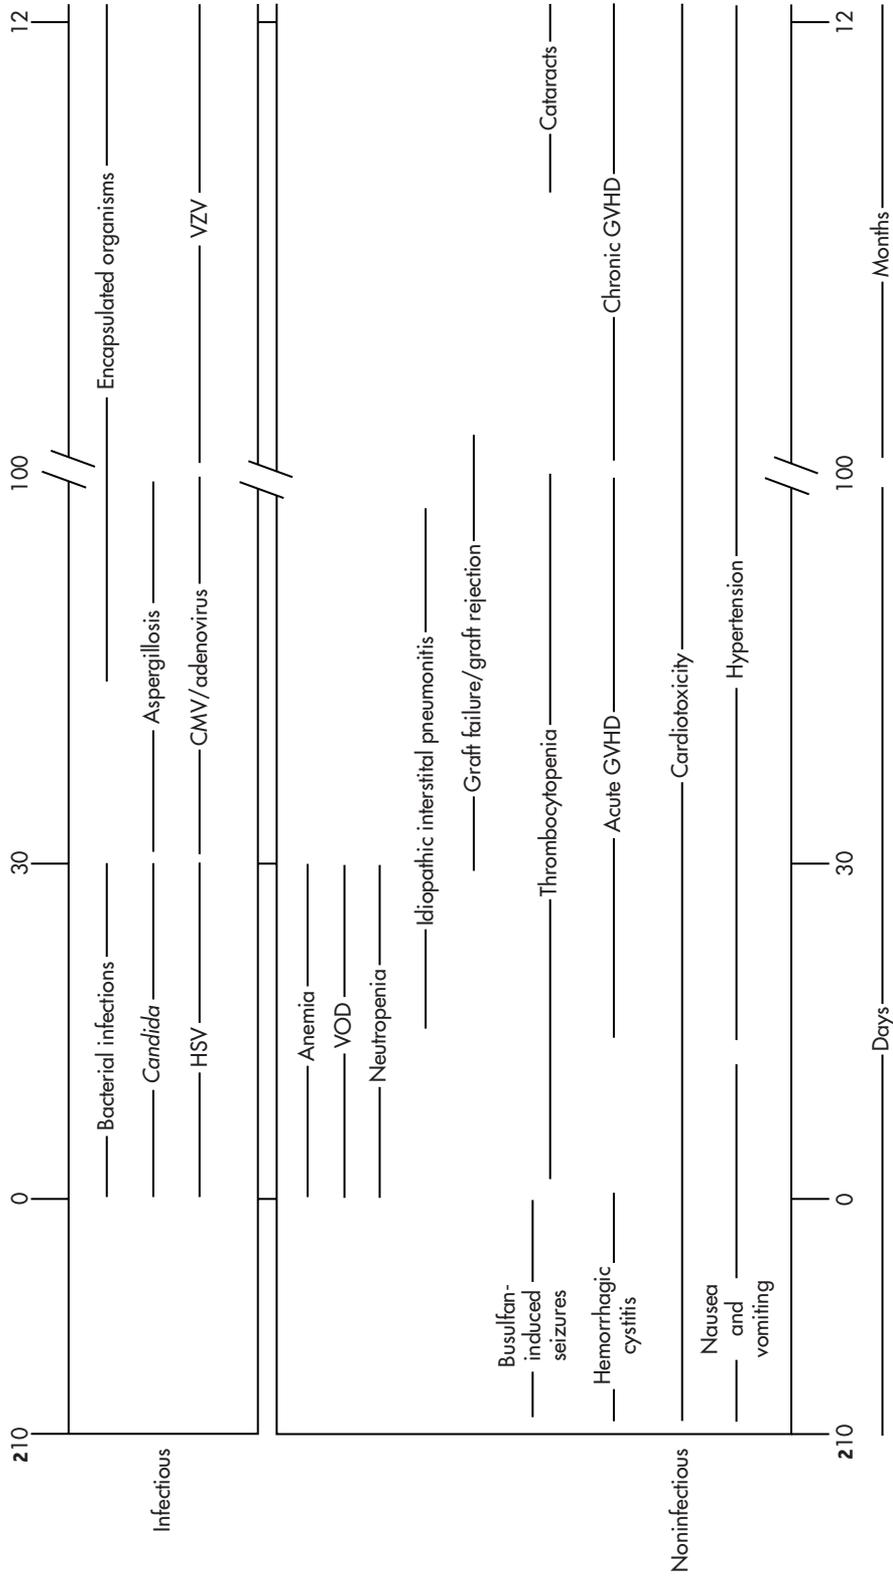

FIGURE 92-3 Complications after hematopoietic stem cell transplantation (HCT) by time for patients undergoing myeloablative allogeneic HCT only. CMV, cytomegalovirus; GVHD, graft-versus-host disease; HSV, herpes simplex virus; VOD, veno-occlusive disease; VZV, varicella-zoster virus.

for K.M.: on the day of admission (day -8), administer a phenytoin loading dose (10–15 mg/kg) orally in divided doses (300, 300, and 400 mg Q 3 hr). Continue 300 mg PO daily from days -8 to -3. Busulfan pharmacokinetic blood sampling is to occur after dose 1 to a target busulfan concentration at steady state (C_{SS}) >900 ng/mL. Begin normal saline hydration 3,000 mL/m²/day 4 hours before cyclophosphamide and continue for 24 hours after the last cyclophosphamide dose. Mesna is to be given concurrently with cyclophosphamide as 10% of the cyclophosphamide dose administered intravenously 30 minutes before starting the cyclophosphamide dose, then as 100% of cyclophosphamide dose administered as a continuous IV infusion over 24 hours after each dose of cyclophosphamide. Beginning on day -5, weigh patient twice daily, check fluid input and urinary output every 4 hours, and monitor urine for RBCs daily until 24 hours after the last cyclophosphamide dose. If urine output drops below 300 mL over 2 hours, administer an IV bolus of 250 mL normal saline and give furosemide 10 mg/m², not to exceed 20 mg IV. What is the rationale for these supportive care therapies and monitoring parameters prescribed for K.M. as they relate to busulfan therapy?

Seizures occur in approximately 10% of patients receiving high-dose busulfan for HCT preparative regimens. Busulfan is highly lipophilic and readily crosses the blood–brain barrier with an average CSF: plasma ratio of 1 or higher. Seizures are probably a direct neurotoxic effect,⁷⁹ so, seizure prophylaxis is used. Many HCT centers use phenytoin for seizure prophylaxis, although benzodiazepines (e.g., lorazepam or clonazepam) also have been used.⁸⁰ Seizure prophylaxis is started at least 24 hours before the first busulfan dose and is usually discontinued 24 to 48 hours after administering the last busulfan dose. Seizures can occur despite the use of seizure prophylaxis, but they usually do not result in permanent neurologic deficits.

Adaptive Dosing of Busulfan

19. What dosing strategies can be used to minimize busulfan toxicities?

Wide interpatient variability in the clearance of both oral and IV busulfan, along with the identified concentration–effect relationships, has led to adaptive dosing of busulfan. The clearance of Busulfex (IV busulfan) adjusted for weight exhibited interpatient variability with a coefficient of variation (CV, standard deviation/mean) of 25% in 59 patients.⁸¹ Oral busulfan exhibited a similar CV of 21% in 279 adult patients.⁷⁷ Weight, disease, and age are factors that may influence the clearance of oral busulfan.⁷⁷

In patients receiving BU/CY, adaptive dosing of busulfan to achieve a target plasma level minimizes veno-occlusive disease (VOD), while improving engraftment and relapse rates.^{82–84} The pharmacodynamic relationships are briefly reviewed here; however, more complete reviews of these relationships after oral busulfan administration are available elsewhere.^{85,86} When reviewing pharmacodynamic data for busulfan, close attention should be paid to their interpretation because of the potential changes in the concentration–effect relationships between busulfan C_{SS} and outcome in each patient population and for each preparative regimen. Most studies have shown a pharmacodynamic relationship in patients receiving the BU/CY preparative regimens. One must also pay close attention to the units used in these studies. Data are also represented as area un-

der the plasma concentration time curve (AUC) or C_{SS} . AUC data are easily converted to C_{SS} ($C_{SS} = \text{AUC}/\text{dosing interval}$). Results are expressed as μM -minute or ng/mL; an AUC of 1,500 μM -minute is roughly equivalent to a C_{SS} of 1,025 ng/mL based on busulfan's molecular weight of 246.

Hepatic VOD was observed more frequently in patients receiving BU/CY with a busulfan C_{SS} >925 to 1,025 ng/mL. In BU/CY regimens, busulfan C_{SS} >600 ng/mL favors engraftment, although contradictory data exist. Higher busulfan concentrations (C_{SS} >900 ng/mL) were associated with lower relapse rates in adult CML patients receiving BU/CY before HLA-matched grafts, with acceptable rates of VOD. Thus, a busulfan C_{SS} >900 ng/mL is targeted for K.M. because she has CML.

IV busulfan (Busulfex) was approved by the U.S. Food and Drug Administration (FDA) for use in combination with cyclophosphamide as a preparative regimen before allogeneic HCT for CML. The FDA-approved dose is 0.8 mg/kg IV Q 6 hr for 16 doses, which is similar to the oral busulfan dose of 1 mg/kg with a mean fraction absorbed (F) of 90%.⁸⁷ Busulfex, at 0.8 mg/kg of ABW or 29 mg/m² of BSA produces an average AUC of 1,200 μM -minute, within a wide range of 900 to 1,500 μM -minute in 80% of patients.⁷⁸ The product labeling states “high busulfan AUC values (>1,500 μM -minute) may be associated with an increased risk of developing hepatic VOD,” which has caused many HCT centers to institute adaptive dosing of IV busulfan. See Questions 23–25.

Hemorrhagic Cystitis

20. What is the rationale for these supportive care therapies and monitoring parameters prescribed for K.M. as they relate to cyclophosphamide therapy?

In HCT patients receiving cyclophosphamide, moderate to severe hemorrhagic cystitis occurs in 4% to 20% of patients receiving hydration alone.⁸⁸ The putative bladder toxin is acrolein, a metabolite of cyclophosphamide.⁸⁹ Mesna donates free thiol groups to bind acrolein. American Society of Clinical Oncology (ASCO) Guidelines for the Use of Chemotherapy and Radiotherapy Protectants recommends the use of mesna plus saline diuresis or forced saline diuresis to lower the incidence of urothelial toxicity with high-dose cyclophosphamide in the setting of HCT.⁹⁰ It is important to note that hematuria or hemorrhagic cystitis can occur despite the use of any of these methods.

The optimal mesna dose with high-dose cyclophosphamide in preparation for myeloablative HCT is unknown. A variety of different regimens have been used, including intermittent bolus dosing (mesna dose 20%–40% of cyclophosphamide dose, administered for three or four doses) or continuous infusion regimens (mesna dose 80%–160% of cyclophosphamide dose).^{88,91,92} Mesna should be continued for 24 to 48 hours after the last cyclophosphamide dose, such that mesna is present within the bladder to donate free thiol groups at the same time as the urotoxic metabolite acrolein. After IV administration of mesna, most of it (i.e., 60%–100%) is excreted within the urine over 4 hours.⁹³ Cyclophosphamide has an average half-life of 7 hours after administration of 60 mg/kg,⁹⁴ and acrolein may be present within the urine for 24 to 48 hours after cyclophosphamide administration.⁹⁵

Thus, K.M. is receiving hydration with normal saline and mesna, administered as a continuous infusion, to minimize her risk of hemorrhagic cystitis due to cyclophosphamide. K.M. should also be monitored for any RBCs present in the urine, along with her urinary output, to allow for rapid intervention if hemorrhagic cystitis occurs.

Chemotherapy-Induced Gastrointestinal Effects

21. What other end-organ toxicities must be watched for? Should any medications be ordered for K.M. to prevent and treat the gastrointestinal (GI) effects associated with myeloablative therapy?

Preparative regimens for myeloablative HCT result in other end-organ toxicities, such as renal failure⁹⁶ and idiopathic pneumonia syndrome.⁹⁷ Lung injury post HCT has a mortality rate greater than 60%. Risk factors include total body irradiation (TBI), allogeneic HCT, and acute GVHD, which suggest that donor lymphocytes target the lung.⁹⁸ Tumor necrosis factor, induced by GVHD and damage to the intestinal mucosa, contributes to lung injury. Lung injury may be decreased by prompt treatment with etanercept, which inhibits tumor necrosis factor, and corticosteroids.¹

The preparative regimen causes most patients to be nauseated and anorexic until day +10 to +15. CINV in HCT recipients can be due to highly emetogenic chemotherapy agents, TBI administration, and poor control of CINV prior to HCT. Thus, patients such as K.M. who are undergoing a myeloablative HCT should be treated with a serotonin antagonist plus a corticosteroid.⁹⁹ ASCO guidelines state that the use of the neurokinin receptor 1 antagonist, aprepitant, should be considered, although evidence to support its use in HCT patients is lacking.⁹⁹ Because aprepitant is a moderate inhibitor of cytochrome P450 3A4, it can theoretically interact with the preparative regimen; thus, well-controlled studies evaluating its efficacy, along with its potential for causing drug interactions, are needed.⁹⁹ The serotonin antagonist ondansetron may increase cyclophosphamide clearance in breast cancer patients undergoing a myeloablative HCT^{100,101}; however, further work is needed to identify the clinical implications of this finding because, to date, cyclophosphamide concentrations have not been consistently associated with clinical outcomes in patients undergoing a myeloablative HCT.^{87,102}

Most patients receiving a myeloablative preparative regimen experience mucositis due to its effects on rapidly dividing cells of the oral epithelium. The use of methotrexate, as GVHD prophylaxis, also contribute to mucositis.¹⁰³ Oral mucositis causes nausea and anorexia. In severe cases, parenteral opioid analgesics for pain relief¹⁰⁴ and total parenteral nutrition to prevent the development of nutritional deficits may be needed. Because mucositis can be worsened by superinfection, good oral hygiene should be practiced. Soft toothbrushes should be used and replaced often¹⁰⁵ The FDA recently approved recombinant human keratinocyte growth factor palifermin (Kepivance). The Multinational Association of Supportive Care in Cancer (MASCC) and International Society for Oral Oncology (ISOO) Guidelines recommend palifermin to prevent mucositis for patients with hematologic malignancies receiving myeloablative chemotherapy and TBI with autologous HCT. Palifermin 60 mcg/kg/day should be given for 3

days immediately prior to administering the preparative regimen and for 3 days after infusion of the hematopoietic stem cell graft (i.e., days 0, +1, +2).¹⁰⁵ In these patients, palifermin lowered the incidence and average duration of clinically meaningful oral mucositis. The incidence of bloodborne infections and the use of parenteral opioids also diminished outcomes.¹⁰⁶

Myelosuppression and Growth Factor Use

22. An order is written to begin filgrastim on day 0 and to continue administration until the ANC has recovered to 500/mm³ for 2 consecutive days. Is this therapy appropriate for K.M.?

[SI units: ANC 500 × 10⁶ cells/L]

The use of hematopoietic growth factors (HGFs) after infusion of allogeneic PBPC is controversial and is not recommended by ASCO Guidelines.²⁰ Administration of HGFs after allogeneic graft infusion decreases the duration of neutropenia, but does not decrease cost, length of hospitalization, or antibiotic use. HGF administration increases the incidence of severe GVHD and lowers survival. K.M. is receiving an allogeneic PBPC graft and, thus, should not receive filgrastim starting on day 0.

Veno-Occlusive Disease of the Liver

23. K.M.'s pretransplantation admission laboratory values are within normal limits. Her weight on admission is 80 kg. During the first 5 days after marrow infusion, K.M.'s weight begins to increase by approximately 0.5 kg/day, her inputs exceed her outputs by about 500 to 1,000 mL/day, and she is mildly febrile with an axillary temperature of 38°C. Blood and urine cultures are all negative. On day +6, her weight is 85 kg. Laboratory values drawn on day +7 are significant for a total bilirubin of 1.5 mg/dL, an aspartate aminotransferase (AST) of 40 U/L (normal, 0–45), and an alkaline phosphatase of 120 U/L (normal, 30–120). By day +10, K.M. is complaining of midepigastric, right upper quadrant pain, and a liver that is tender to palpation. Over the next few days, K.M. begins to look icteric. Her liver function tests continue to rise slowly, until day +18 when they reach the following peak values: total bilirubin 5.0 mg/dL (normal, 0.1–1), AST 150 U/L, and alkaline phosphatase 180 U/L. On day +18, K.M.'s weight is 90 kg. “Rule out VOD of the liver” is included on her problem list in the medical record. What is VOD?

[SI units: total bilirubin 25.6 and 85.5 μmol/L respectively; AST, alkaline phosphatase, same as previously]

Hepatic VOD is a life-threatening complication of HCT.¹⁰³ The incidence of VOD varies considerably, ranging from 5.3% to 54%, mainly due to differences in the preparative regimens.¹⁰³ Preparative regimens including busulfan, cyclophosphamide, and/or TBI >13.2 Gy have been associated with higher VOD rates.^{102,107} Although the pathogenesis is not understood completely, the key event is toxic injury to the sinusoidal endothelial cells. Involvement of the hepatic venules is not essential to developing the clinical signs and symptoms; thus, the term “sinusoidal obstruction syndrome” has been proposed in place of VOD.¹⁰⁸ The endothelial damage initiates the coagulation cascade, induces thrombosis of

the hepatic venules, and eventually leads to fibrous obliteration of the affected venules.¹⁰³ The cardinal histologic features are marked sinusoidal fibrosis, necrosis of pericentral hepatocytes, and narrowing and eventual fibrosis of central veins.¹⁰⁸ In patients with VOD, early microscopic changes include subendothelial swelling, leading to several physiological changes, including narrowing of hepatic venules and necrosis of centrilobular hepatocytes.¹⁰³

Clinical Presentation

24. What signs and symptoms in K.M. are consistent with a diagnosis of VOD?

The signs and symptoms associated with VOD are hyperbilirubinemia (≥ 2 mg/dL), weight gain ($> 5\%$ above baseline), hepatomegaly, azotemia, elevated alkaline phosphatase, ascites, elevated AST, and encephalopathy.¹⁰⁹ Insidious weight gain exceeding 5% of baseline is usually the first manifestation of impending VOD, occurring in more than 90% of patients within 3 to 6 days after marrow infusion.¹¹⁰ Weight gain is caused by sodium and water retention, as evidenced by decreased renal sodium excretion. This is usually distinguished from cyclophosphamide-induced syndrome of inappropriate secretion of antidiuretic hormone by the time course relative to administration of the preparative regimen. Hyperbilirubinemia, which also occurs in virtually all patients, follows the onset of weight gain and usually appears within 10 days after hematopoietic stem cell infusion. In more than half of the patients, the peak bilirubin concentration is > 6 mg/dL. Other liver function test abnormalities usually occur after hyperbilirubinemia and include elevations in AST and alkaline phosphatase. Ascites, right upper quadrant pain, and encephalopathy lag behind changes in liver function tests and develop within 10 to 15 days after infusion of hematopoietic stem cells.¹¹⁰

A clinical diagnosis of VOD is made when two of the following features occur within the first 20 days of HCT: (a) hyperbilirubinemia (total serum bilirubin > 2 mg/dL), (b) hepatomegaly or right upper quadrant pain, and (c) sudden weight gain.¹¹⁰ To make a clinical diagnosis of VOD, the features listed previously must occur without other causes of post-HCT liver damage, including GVHD, viral hepatitis, fungal abscesses, and drug reactions. A clinical diagnosis can be confirmed histologically via liver biopsy.

In summary, the signs and symptoms consistent with VOD in K.M. include insidious weight gain, hyperbilirubinemia, and right upper quadrant pain. The onset and timing of these signs and symptoms are consistent with VOD and occurred without other causes of hepatic toxicity.

Prevention and Treatment

25. What is the likelihood that K.M. will recover from her VOD? How should she be treated?

The overall mortality for patients who develop VOD varies considerably (i.e., 0%–67%) due to the variable definitions of VOD and fatal VOD.¹⁰³ Patients with greater weight gain and elevations in total bilirubin are more likely to die of VOD when compared to patients with less severe weight gain and elevations in total bilirubin.¹⁰³ Severe VOD is usually accompanied by multiorgan system failure, and these patients rarely

die from liver failure itself but from renal and cardiopulmonary failure.¹⁰³

Risk factors for severe and/or fatal VOD have been identified in the hope of preventing this condition or its progression through early treatment. Although various risk factors have been identified, their association is variable, and conflicting reports of their association can be found. The most important risk factors are the preparative regimen, TBI dose, the pharmacokinetics of busulfan and/or cyclophosphamide, and liver inflammation and fibrosis pre-HCT.¹⁰³ In patients with AML, gemtuzumab ozogamicin (Mylotarg) has been associated with VOD when used prior to and after HCT.¹⁰³

Various pharmacologic methods to prevent VOD have been evaluated. One such method is altering the preparative regimen. The substitution of fludarabine for cyclophosphamide in combination with busulfan (i.e., BU/FLU) and the use of reduced intensity regimens that contain no liver toxins appear to lower VOD risk.^{1,103,111,112} When busulfan is dosed based on body weight, VOD rates are lower with IV busulfan compared to oral busulfan.^{113,114} Individualizing chemotherapy doses for busulfan or cyclophosphamide may also lower VOD rates. There is interpatient variability in their metabolism and clearance, along with pharmacodynamic relationships, although the relationships vary within the various preparative regimens.^{85,115} The association of VOD with busulfan concentrations is discussed in the “Adaptive Dosing of Busulfan” section. Although the data from clinical trials are mixed, some HCT centers routinely use heparin infusions or low-molecular-weight heparin subcutaneously. Single-agent ursodiol (600 mg/day PO) has been associated with a lower incidence of VOD^{116,117} or with a lower frequency of total serum bilirubin > 3 mg/dL.¹¹⁸ Ursodiol, which is a bile acid, most likely lowers cholestasis but not toxic liver injury.¹⁰³ Prostaglandin E1 and anticytokine strategies, specifically pentoxifylline, have been ineffective in preventing VOD in clinical trials.¹⁰³

Most patients with VOD (70%–85%) spontaneously recover; thus, the mainstay of treatment is managing sodium and water balance and repeated paracentesis for ascites that is associated with pain for pulmonary compromise.¹⁰³ Volume expanders such as albumin and colloids may be used to maintain intravascular volume, spironolactone may be used to minimize extravascular fluid accumulation, and protein restriction and lactulose may be used if encephalopathy develops. Unfortunately, improved outcomes with these measures have not been confirmed. In patients with severe VOD and multiorgan failure, available treatment options are limited. Thrombolytic therapy with recombinant human tissue plasminogen activator (rh-TPA) and heparin have had mixed results in terms of efficacy, and can cause fatal intracerebral or pulmonary bleeding.¹⁰³ Defibrotide, an investigational new drug, has shown promising results in the treatment of VOD.^{119–121} Defibrotide, a ribonucleotide, has antithrombotic, anti-ischemic, and thrombolytic activity without producing significant systemic anticoagulation. In a compassionate use trial of 88 patients with severe VOD and associated organ dysfunction, 36% of patients had complete resolution of VOD and 35% survived past day 100 after HCT.¹²¹

Because K.M. does not meet the criteria for severe VOD, she should be managed conservatively with fluid restriction and spironolactone. Her signs and symptoms should resolve

over the next 2 weeks. Because she has mild VOD, she is likely to recover completely without sequelae.

Graft Rejection

26. E.R. is a 65-year-old woman diagnosed with myelodysplastic syndrome. Past medical history is significant for type I diabetes and renal dysfunction. After her initial diagnosis, a successful search for a completely HLA-matched unrelated donor was conducted. E.R. will receive a nonmyeloablative allogeneic HCT using bone marrow. E.R.'s preparative regimen orders are written as follows: fludarabine, 30 mg/m²/day on days -4, -3 and -2 and 2 Gy TBI on the day of marrow infusion with postgrafting cyclosporine and mycophenolate mofetil. It now is day +28, and E.R.'s CBC reveals the following: WBC count, 500 cells/mm³ (normal, 3,200–9,800); no granulocytes or monocytes detected on differential; platelets, 100,000/mm³ (normal, 130,000–400,000); and hematocrit (Hct), 30% (normal, 33%–43%). Donor T-cell chimerism is <5%. What is E.R. experiencing, and how should she be treated?

[SI units: WBC, <0.1 cells/L platelets, 100 × 10⁹ cells/L Hct, 0.22]

Reduced intensity regimens typically consist of fludarabine in combination with an alkylating agent or low-dose TBI (Fig. 92-2). With the nonmyeloablative fludarabine/TBI regimen, there is minimal neutropenia, thrombocytopenia, and nonhematologic toxicity, thus making HCT an outpatient procedure.¹ Engraftment is usually evident within the first 30 days in patients receiving a nonmyeloablative preparative regimen; however, rejection can occur after initial engraftment.⁴ Because E.R. has low donor T-cell chimerism on day +28, she is at higher risk of experiencing graft rejection.

In myeloablative allogeneic HCT, graft rejection is less common because the donor PBPC or marrow is unmanipulated and free from the toxic effects of prior chemotherapy. A delicate balance between host and donor effector cells is necessary since residual host-versus-graft effects may lead to graft rejection. The incidence of graft rejection is higher in patients with aplastic anemia and in patients undergoing HCT with histoincompatible marrow or T-cell-depleted marrow. Graft rejection is uncommon in leukemia patients receiving myeloablative preparative regimen with a histocompatible allogeneic donor. After myeloablative HCT, there are limited therapeutic options for the treatment of graft rejection. A second HCT is the most definitive therapy, although the toxicities are formidable.¹²² In patients receiving myeloablative allogeneic HCT, graft rejection is best managed with immunosuppressants such as antithymocyte globulin.

E.R. received nonmyeloablative conditioning, and thus, she should have mixed chimerism posttransplant. However, because she is <5% donor she will not benefit from the GVT effect due to the lack of the donor's cytotoxic T lymphocytes that suppress the recipient's malignancy. Current research is focusing on quantitative chimerism monitoring, specifically evaluating the percent donor chimerism, which may be a tool on which to base clinical interventions.⁶⁸ Donor chimerism is evaluated in different cell types (e.g., T cells, NK cells, granulocytes). The longitudinal changes in the percent donor chimerism, termed "engraftment kinetics," are influenced by several factors such as, type of HCT conditioning, stem cell

source, intensity of postgrafting immunosuppression.^{68,123} A balance between the recipient and donor's cells is needed to maximize the GVT effect, which lowers the risk of relapse while minimizing the risk of GVHD. Some HCT centers are evaluating the benefit of clinical interventions to tip this balance.^{68,123}

E.R. is at high risk of graft rejection. A trial of discontinuing cyclosporine and mycophenolate mofetil is an option. E.R.'s T-cell chimerism should be monitored periodically, and hematopoietic function should be monitored with daily CBCs and a bone marrow biopsy every 2 weeks.

GRAFT-VERSUS-HOST DISEASE

GVHD is caused by activation of donor lymphocytes leading to immune damage to the recipient. Histocompatibility differences between donor and recipient necessitate posttransplantation immunosuppression after allogeneic HCT because considerable morbidity and mortality are associated with graft rejection and GVHD. Therefore, postgrafting immunosuppression or GVHD prophylaxis is used after allogeneic HCT. However, because allogeneic transplantation offers the potential for a GVT effect in which immune effector cells from the donor recognize and eliminate residual tumor in the recipient, research is focusing on being able to improve GVT effects while lowering the risk of graft rejection and GVHD.³

GVHD is the most important complication of allogeneic HCT.¹ GVHD can occur after allogeneic HCT, regardless of the preparative regimen used. The pathophysiology of GVHD is not completely understood, but the current view of its development is described by a three-step process. The pathophysiology for acute GVHD is a multistep phenomenon, including (a) the preparative regimen results in tissue damage and release of inflammatory cytokines into the circulation; (b) both recipient and donor antigen presenting cells and inflammatory cytokines trigger activation of donor-derived T cells; and (c) the activated donor T cells mediate cytotoxicity through a variety of mechanisms, which leads to tissue damage characteristic of acute GVHD.¹²⁴

GVHD is divided into two forms (i.e., acute or chronic) based on clinical manifestations. Acute GVHD damages the skin, GI tract, and liver and usually occurs in the first 100 days after allogeneic HCT.¹ In contrast, chronic GVHD can affect almost any organ system, closely resembles several autoimmune diseases, and usually occurs after day 100.

The vast majority of the data regarding the prevention and treatment of GVHD have been obtained after myeloablative preparative regimens. Therefore, this section refers only to trials conducted in recipients of a myeloablative allogeneic HCT.

Acute Graft-versus-Host Disease

Risk Factors

27. M.P., a 22-year-old, 70-kg man, undergoes a one-antigen mismatched allogeneic HCT from his sister for the diagnosis of Philadelphia chromosome-positive AML. After a preparative regimen of CY/TBI, the following immunosuppressive regimen is ordered: tacrolimus 0.3 mg/kg/day as a continuous infusion from days -1 until tolerating oral medications, then switch to tacrolimus 1.2 mg/kg PO Q 12 hr until day +50. Methotrexate 15 mg/m² IV

Table 92-6 Clinical Staging of Acute Graft-versus-Host Disease (GVHD) According to Organ System

| Stage | Skin ^a | Liver | Intestinal Tract ^b |
|-------|--|------------------------|---|
| + | Maculopapular rash <25% of body surface | Bilirubin 2–3 mg/dL | 500–1,000 mL/day diarrhea or persistent nausea ^c |
| ++ | Maculopapular rash 25%–50% body surface | Bilirubin 3.1–6 mg/dL | 1,000–1,500 mL/day diarrhea |
| +++ | Generalized erythroderma | Bilirubin 6.1–15 mg/dL | >1,500 mL/day diarrhea |
| ++++ | Generalized erythroderma with bullous formation and desquamation | Bilirubin >15 mg/dL | Severe abdominal pain with or without ileus |

^aExtent of rash determined by burn chart or “rule of nines.”

^bDiarrhea volume applies to adults.

^cPersistent nausea requires endoscopic biopsy to show evidence of GVHD histology in stomach or duodenum.

Adapted from Sullivan KM. Graft-versus-host disease. In: Blume KG et al, eds. *Thomas' Hematopoietic Cell Transplantation*. 3rd ed. Malden, MA: Blackwell; 2004:635.

on day +1, then 10 mg/m² day +3, +6, and +11. What factors are associated with an increased risk of acute GVHD?

The single most important factor associated with the development of GVHD is the degree of histocompatibility between donor and recipient.¹ Clinically relevant grade II–IV acute GVHD occurs in 20% to 50% of HLA-matched sibling grafts and 50% to 80% of HLA-mismatched sibling or HLA-identical unrelated donors.¹²⁵ The onset of acute GVHD is earlier and severity is increased in mismatched grafts relative to matched grafts, and also in matched unrelated donors relative to matched sibling donors.^{40,126} Other factors that increase the risk of developing acute GVHD include increasing recipient (and possibly donor) age, greater intensity of the preparative regimen, use of PBPC rather than bone marrow, and donor/recipient sex mismatch.¹²⁴ CBT have a lower risk of acute GVHD.^{127–129}

M.P. is receiving allogeneic bone marrow from a female sibling donor that is mismatched at one HLA antigen. These two factors increase his risk of developing acute GVHD.

Clinical Presentation

28. On day +14, the time at which engraftment occurred, M.P. is noted to have a diffuse macular papular rash on his arms, hands, and front trunk. He does not have diarrhea, and his liver function tests are within normal limits. At the onset of his rash, M.P.'s empiric antibiotics are changed from cefepime to imipenem. Despite the change in antibiotics, M.P.'s rash persists. How is M.P.'s presentation consistent with acute GVHD?

The primary targets of immune-mediated destruction of host tissue by donor lymphocytes in acute GVHD are the skin, liver, and GI tract.¹²⁵ Acute GVHD of the skin usually manifests as a diffuse maculopapular rash that starts on the palms of the hands or soles of the feet or face. In more severe cases, skin GVHD can progress to a generalized total body erythroderma, bullous formation, and skin desquamation. The earliest symptoms of acute GVHD of the GI tract are usually loss of appetite followed by nausea and vomiting.¹⁰³ Abdominal pain and watery or bloody diarrhea also occur, which can result in electrolyte abnormalities, dehydration, or ileus in severe cases. Liver GVHD usually follows skin and/or GI GVHD. Clinical symptoms of liver GVHD include a gradual rise in total bilirubin, alkaline phosphatase, and hepatic transaminases.¹⁰³ Acute GVHD is usually not evident until the time of engraftment, when donor lymphoid elements begin to proliferate. The skin is usually the first organ to be involved. The onset of liver or GI GVHD usually lags behind the onset of skin GVHD by

approximately 1 week and infrequently occurs without skin GVHD.

Acute GVHD must be distinguished accurately from other causes of skin, liver, or GI toxicity in the HCT patient. For example, a maculopapular rash, which may occur as a manifestation of an allergic reaction to antibiotics, usually begins on the trunk or upper extremities and rarely presents on the palms of the hands or soles of the feet. Diarrhea can be caused by chemotherapy, radiation, infection, or antibiotic therapy.¹⁰³ However, diarrhea caused by the preparative regimen is rarely bloody and usually resolves within 3 to 7 days after discontinuation of drugs and radiation. Diarrhea caused by infectious agents such as *Clostridium difficile* or cytomegalovirus (CMV) should be distinguished from GVHD. Liver GVHD must be distinguished primarily from VOD and, to a lesser extent, hepatitis induced by drugs, blood products, or parenteral nutrition.¹⁰³ Although liver function test abnormalities between these syndromes are similar, liver GVHD is rarely associated with insidious weight gain or right upper quadrant pain.¹⁰³ A tissue biopsy of the affected organ in conjunction with clinical evidence is the only way to definitively diagnose acute GVHD. Acute GVHD is associated with characteristic histologic changes to affected organs. A staging system based on clinical criteria is used to grade acute GVHD. The severity of organ involvement is determined first (Table 92-6), and then an overall grade is established based on number and extent of involved organs (Table 92-7).

Table 92-7 Overall Clinical Grading of Severity of Acute Graft-versus-Host Disease

| Grade | Degree of Organ Involvement |
|---------------------|---|
| I—Mild | + to ++ skin rash; no liver involvement; no gastrointestinal (GI) involvement; no functional impairment |
| II—Moderate | + to +++ skin rash; + liver involvement; + GI involvement; mild functional impairment |
| III—Severe | ++ to ++++ skin rash; ++ to ++++ liver involvement, ++ to ++++ GI involvement (or both); moderate functional impairment |
| IV—Life threatening | Any skin involvement, ++ to ++++ liver involvement, ++ to ++++ GI involvement and extreme functional impairment |

Adapted from Sullivan KM. Graft-versus-host disease. In: Blume KG et al, eds. *Thomas' Hematopoietic Cell Transplantation*. 3rd ed. Malden, MA: Blackwell; 2004:635.

M.P. developed a rash at the time of engraftment that could have been consistent with either an antibiotic-induced rash or acute GVHD. Although it was appropriate to change antibiotics, the fact that M.P.'s rash did not improve is suggestive of acute GVHD. M.P.'s rash is present on 36% of his body, but because there are no signs of GI or liver involvement at this time, M.P. is likely to have grade I GVHD (Tables 92-6 and Table 92-7).

Immunosuppressive Prophylaxis

29. Why did M.P. receive prophylactic immunosuppressive therapy with tacrolimus and methotrexate?

GVHD is a leading cause of morbidity and mortality after allogeneic HCT. Without post-HCT immunosuppression, serious acute GVHD would occur in almost every allogeneic HCT recipient.¹ The most common method used to minimize GVHD risk is to administer postgrafting immunosuppression. However, these immunosuppressive regimens are associated with significant toxicity and a higher risk of relapse in patients with acute leukemia who are at high risk of relapse.¹³⁰ The latter is most likely due to the GVT effect mediated in conjunction with acute GVHD because an inverse relationship between acute GVHD and leukemic relapse has been observed.³ Patients with acute leukemias at high risk for relapse may receive single-agent prophylaxis for acute GVHD because the development of some acute GVHD may facilitate a GVT effect.

Initially, acute GVHD was prevented with single-drug therapy using ATG, cyclophosphamide, methotrexate, or cyclosporine.^{131–133} ATG binds nonspecifically to mononuclear cells and depletes hematopoietic progenitor cells in addition to lymphocytes. Consequently, ATG is rarely used for fear of a high incidence of graft failure.¹³¹ The risk of GVHD is greatly reduced by two-drug combination immunosuppression (Table 92-8). Methotrexate, cyclosporine or tacrolimus, and corticosteroids are the agents most commonly incorporated into combination immunosuppressive regimens. Although the most widely published regimen is short-course methotrexate plus cyclosporine (Seattle regimen),¹³³ there is no national consensus with regard to the most effective regimen. Methotrexate is administered up to day +11. Several randomized clinical trials have compared tacrolimus and short-course methotrexate with cyclosporine plus short-course methotrexate in patients undergoing allogeneic HCT using HLA-matched siblings^{134,135}

and unrelated donors.⁷⁴ Recipients of matched-sibling grafts treated with tacrolimus had a lower incidence of grade II to IV acute GVHD, but a similar incidence of chronic GVHD.¹³⁴ Overall survival was lower in the tacrolimus group as a result of more toxic deaths in patients with advanced stage disease; however, a higher number of advanced stage disease patients in the tacrolimus/methotrexate group make the results of this trial somewhat difficult to determine.¹³⁴

Subsequently, the IBMTR conducted a matched control study, which suggested that the survival difference between the two arms was in fact due to the imbalance in the underlying risk factors.¹³⁵ In patients receiving HLA-matched or slightly mismatched unrelated grafts, those given tacrolimus had a lower incidence of grade II to IV acute GVHD, a similar incidence of chronic GVHD and similar disease-free and overall survival rates.⁷⁴ Patients with advanced hematologic malignancies were excluded from this study. Both regimens are currently used in allogeneic HCT after myeloablative preparative regimens.

Several studies have compared triple-drug with two-drug immunosuppression. The incidence of acute GVHD has been similar or lower with triple-drug regimens, but infectious complications are higher, and overall survival is similar to two-drug regimens.^{136,137} Three-drug immunosuppression regimens are still being evaluated and are used mainly in mismatched or unrelated allogeneic HCT, where the risk of acute GVHD is increased.

M.P. received acute GVHD prophylaxis with a two-drug regimen of short-course methotrexate and tacrolimus.

30. What principles are used in dosing medications used for acute GVHD prophylaxis?

Although the various combination immunosuppressive regimens vary slightly by drug, dose, and combination, several guidelines are consistent throughout all regimens. First, cytotoxic agents used in combination for prophylaxis of acute GVHD (e.g., methotrexate) are withheld or given in reduced doses if mucositis or myelosuppression is severe.^{133,136} Methotrexate for GVHD prophylaxis can delay engraftment, increase the incidence and severity of mucositis and cause liver function test elevations. The methotrexate dose is reduced in the setting of renal or liver impairment.¹³⁸

The calcineurin inhibitors (i.e., cyclosporine, tacrolimus) should be initiated before or immediately after donor cell infusion (day –1 or 0) when used for GVHD prophylaxis. This schedule is recommended because of the known mechanism of

Table 92-8 Combination Regimens of Prophylaxis of Acute Graft-versus-Host Disease

| Drug | Dosing Examples |
|---|--|
| Cyclosporine/short-term methotrexate ¹³³ | 1.5 mg/kg IV or 6.25 mg/kg (Sandimmune) PO Q 12 hr, days –1 to + 50, then taper 5% per week and discontinue by day + 180 Methotrexate 10 mg/m ² IV, days + 3, + 6, + 11 |
| Tacrolimus/short-term methotrexate ⁷⁴ | Tacrolimus 0.03 mg/kg/day continuous IV infusion or 0.12 mg/kg/day PO BID Methotrexate 15 mg/m ² IV day + 1, 10 mg/m ² IV, days + 3, + 6, + 11 |
| Cyclosporine/methotrexate/prednisone ¹³⁶ | Cyclosporine 5 mg/kg/day IV continuous infusion, day –2 to + 3, then 3–3.75 mg/kg IV until day + 35; then 10 mg/kg/day (Sandimmune) PO, dose adjusted to cyclosporine concentrations (via radioimmunoassay) of 200–600 ng/mL. Taper by 20% Q 2 wk; then discontinue by day + 180 Methotrexate 15 mg/m ² IV day + 1, 10 mg/m ² IV day + 3, + 6 Methylprednisolone 0.5 mg/kg/day IV, day + 7 until day + 14, then 1 mg/kg/day IV until day + 28, then prednisone 0.8 mg/kg/day PO until day + 42, then taper slowly and discontinue by day + 180 |

action of cyclosporine, which entails blocking the proliferation of cytotoxic T cells by inhibiting production of helper T-cell–derived IL-2. Administering cyclosporine before the donor cell infusion allows inhibition of IL-2 secretion to occur before a rejection response has been initiated.

Cyclosporine is usually administered intravenously until the GI toxicity from a myeloablative preparative regimen has resolved (e.g., for 7–21 days).¹³³ This is because GI effects of the preparative regimen (e.g., CINV, diarrhea) and GVHD affect the oral absorption of microemulsion cyclosporine and may result in inconsistent blood concentrations.¹³⁹ Most centers use the microemulsion oral formulation (Neoral) or other new generic microemulsion formulations that have improved bioavailability. With the Neoral formulation, a ratio of 1:2 or 1:3 is used. The most common ratio used when converting tacrolimus from IV to oral is 1:4. Different conversion ratios for IV to oral regimens may be used when patients are receiving concomitant medications that affect cytochrome P450 3A or P-glycoprotein, which are involved in the metabolism and transport of the calcineurin inhibitors (e.g., itraconazole). Thus, careful monitoring for drug interactions with the calcineurin inhibitors is warranted.¹⁴⁰

The dose of cyclosporine or tacrolimus is adjusted based on serum drug levels and the serum creatinine (SrCr) concentration. Doses are usually reduced by 50% if the SrCr concentration doubles above baseline and is withheld for SrCr concentrations >2 mg/dL.^{133,141} Although the calcineurin inhibitors do not contribute to myelosuppression, common adverse effects to these agents include neurotoxicity, hypertension, and/or nephrotoxicity (which may lead to an impaired clearance of methotrexate).⁷⁹

When corticosteroids are added to combination immunosuppressive regimens, they are usually withheld until engraftment is expected (7–14 days after marrow infusion). Administering corticosteroids earlier in the posttransplantation period (e.g., day 0) paradoxically increases the incidence of GVHD when used in combination with methotrexate and cyclosporine.¹⁴² Corticosteroids are associated with several adverse effects, including infectious complications, hyperglycemia, and an increased incidence of hypertension when used in combination with a calcineurin inhibitor.

Tapering schedules for cyclosporine or tacrolimus and corticosteroids vary widely among institutions. The general goal is to keep calcineurin inhibitor doses stable to day +50, and then slowly taper with the intent of discontinuing all immunosuppressive agents by 6 months after HCT. By this time, immunologic tolerance has developed, and patients no longer require immunosuppressive therapy.

Adaptive Dosing of Calcineurin Inhibitors

31. On day +18, a tacrolimus level is drawn right before the morning dose and is reported to be 15 ng/mL. Why are tacrolimus levels being obtained for M.P.?

The role of pharmacokinetic monitoring of the calcineurin inhibitors in HCT patients is not well defined but is commonly performed because of the established pharmacodynamic associations within solid organ transplant recipients. In general, desired tacrolimus trough concentrations are 5 to 15 ng/mL. Tacrolimus concentrations >20 ng/mL have been associated with increased risk of toxicity, primarily nephrotoxicity.^{143,144}

Adjustments in tacrolimus dosing for increased SrCr should be made in a manner similar to that described for cyclosporine.

It is standard practice for HCT centers to adjust cyclosporine or tacrolimus doses based on trough blood concentrations.¹⁴⁴ An association between cyclosporine concentrations and acute GVHD was not found in early studies; however, other studies have suggested that cyclosporine trough concentrations less than 200 ng/mL are associated with an increased risk of acute GVHD.^{145,146} Pharmacokinetic monitoring may play a more important role in minimizing the risk of cyclosporine-induced nephrotoxicity. Cyclosporine trough concentrations >400 ng/mL (via radioimmunoassay and high-pressure liquid chromatography assay) are associated with a higher incidence of nephrotoxicity in some series.¹⁴⁷ However, it is important to note that cyclosporine-induced nephrotoxicity can occur despite low or normal concentrations of cyclosporine and may be a consequence of other drug- or disease-related factors known to influence the development of nephrotoxicity (e.g., concurrent use of other nephrotoxic agents, sepsis).

It is reasonable to adjust doses to maintain tacrolimus trough concentrations between 5 to 15 ng/mL in patients undergoing allogeneic HCT with a myeloablative preparative regimen. Recommendations for dose adjustments should be based on tacrolimus concentrations and SrCr concentration. Dosage adjustments should be made for SrCr, regardless of tacrolimus concentration, as recommended previously. No standard dosage adjustment schedule exists, but most centers adopt their own standardized approach. M.P. has a normal SrCr, and his tacrolimus level is 15 ng/mL. Therefore, his tacrolimus dose should be maintained.

Treatment of Established Acute Graft-versus-Host Disease

32. On day +19, the suspicion of acute skin GVHD is confirmed by biopsy. On the same day, M.P. experiences 1,000 mL of diarrhea over the next 24 hours and is noted to have a bilirubin of 2.8 mg/dL. He is started on methylprednisolone 35 mg IV Q 6 hr. What is the rationale for methylprednisolone therapy in M.P.?

[SI units: total bilirubin = 48 μ mol/L]

Preventing the development of GVHD is the most effective way to treat this HCT complication. Corticosteroids, often in combination with calcineurin inhibitors, are first-line treatment for GVHD. For this reason GVHD and its treatment cause profound immunodeficiency.^{1,148} The combination of GVHD and infectious complications are leading causes of mortality for allogeneic HCT patients.

Corticosteroids are the first-line treatment for established GVHD.¹²⁴ A complete response occurs in 25% to 40% of patients, with a lower likelihood of response in more severe cases of acute GVHD.¹²⁴ Patients with mild to moderate (grades I–III) acute GVHD who respond to initial therapy have a significantly better survival advantage than patients with severe acute GVHD who do not respond to initial therapy. Patients who do not respond to therapy or have ongoing severe GVHD usually die from a combination of GVHD and infectious complications.¹⁴⁹

When treating acute GVHD, corticosteroids are generally tapered based on response. There is no consensus on the optimal method for tapering the corticosteroids¹⁴⁸ and the tapering rate depends on the patient. Patients who develop acute GVHD

or who experience flares of existing GVHD during a tapering trial will have their dosages increased or tapered more slowly as tolerated.

Because M.P. had objective evidence of established acute GVHD, he was given systemic corticosteroids at the first sign of progressive disease. This was appropriate because single-agent corticosteroids are considered the therapy of choice for established acute GVHD.¹⁵⁰ Corticosteroids indirectly halt the progression of immune-mediated destruction of host tissues by blocking macrophage-derived IL-1 secretion. IL-1 is a primary stimulus for helper T-cell–induced secretion of IL-2, which in turn is responsible for stimulating proliferation of cytotoxic T lymphocytes. The recommended dosage of methylprednisolone for the treatment of established acute GVHD is 1 to 2 mg/kg/day, given intravenously or orally in four divided doses for a minimum of 14 days, followed by a tapering schedule that is determined by response.¹⁴⁹ The dosage of methylprednisolone in M.P., approximately 2 mg/kg/day, is consistent with these recommendations. Trials that compared higher doses of corticosteroids (i.e., 10 mg/kg/day) to 2 mg/kg/day as initial treatment of acute GVHD showed no advantage.¹⁵¹ Monitoring for acute GVHD response should occur every 3 to 5 days.¹²⁴

A significant portion of patients do not respond to corticosteroids, and they are said to have steroid-refractory GVHD.¹²⁴ The timing of treatment response varies among the organs affected by GVHD and patients. If GVHD symptoms worsen over 3 days of treatment and if the skin does not improve by 5 days, it is unlikely that a response will be achieved in a timely manner, and secondary therapy should be considered.¹²⁴ Patients with steroid-refractory acute GVHD have a poor prognosis. A variety of medications are being studied for “salvage” or secondary therapy. The salvage therapy depends on the organs affected. For example, phototherapy is used as salvage therapy for skin GVHD and nonabsorbable corticosteroids are used for GI GVHD. Other options for salvage therapy include ATG, denileukin diftitox, TNF- α blockers (e.g., infliximab, etanercept).¹²⁴ The most effective dose, timing, or combination of these salvage therapies is still unknown.

M.P. should be evaluated for response to methylprednisolone after 4 to 7 days. If his acute GVHD has improved or stabilized, he should be continued on therapy at this dose for a total of 14 days. If M.P. responds to therapy, his methylprednisolone dose should be tapered slowly over a minimum of 1 month, and he should be monitored for any evidence of recurrent GVHD. If the GVHD flares during his steroid taper as evidenced by worsening skin reactions, increased bilirubin, or increased diarrhea volume, the dose should be increased again until his disease is stable; the subsequent taper should be initiated at a slower rate. If M.P. fails to respond to first-line therapy with methylprednisolone, he should receive salvage therapy.

Chronic Graft-versus-Host Disease

Clinical Presentation

33. M.P. was successfully treated for his acute GVHD, is no longer taking corticosteroids, and is currently tapering his cyclosporine. On day +200, M.P. comes to clinic for follow up after a 2-week vacation in Florida. On examination, M.P. is found to have a mild skin rash on his arms and legs, hyperpigmentation of the tissue surrounding the eyes, and white plaquelike lesions in

his mouth. He is also complaining of dry eyes. Laboratory tests reveal an increased alkaline phosphatase and total bilirubin concentration. What is the most likely cause of M.P.’s findings?

Chronic GVHD, the most common late complication of allogeneic HCT, occurs in 20% to 70% of patients surviving more than 100 days.¹⁵² Chronic GVHD is a major cause of nonrelapse morbidity and mortality.¹ Risk factors for chronic GVHD include recipient, donor, and transplant factors. Non-modifiable recipient risk factors include older age, certain diagnoses (e.g., CML), and lack of an HLA-matched donor. Modifiable factors that may lower the risk of chronic GVHD include selecting a younger donor, avoiding a multiparous female donor, using umbilical cord blood or a bone marrow graft rather than PBPC, and limiting the CD34⁺ and T-cell dose infused.¹⁵² Development of acute GVHD is a major predictor of chronic GVHD; 70% to 80% of those with grade II to IV acute GVHD develop chronic GVHD.¹⁵²

Chronic GVHD is not a continuation of acute GVHD.¹⁵² Traditionally, the boundary between the two was based on time, but now they are classified based on different clinical symptoms.¹⁵² Signs and symptoms of chronic GVHD in various organ systems are listed in Table 92-9. A consensus guideline for the diagnosis and scoring of chronic GVHD has been published.¹⁵³ The diagnosis of chronic GVHD requires (a) being distinct from acute GVHD, (b) having at least one diagnostic clinical sign of chronic GVHD or at least one distinctive manifestation confirmed by pertinent biopsy or other relevant tests, and (c) exclusion of other possible diagnoses. The clinical scoring system uses a numerical value of 0 to 3, with more severe symptoms having a higher, number. A global score is calculated by including the number of organs involved and the severity within each affected organ. The global score reflects the effect of chronic GVHD on the patient’s performance status and can be used to evaluate whether treatment with systemic immunosuppression is required.

The signs and symptoms of chronic GVHD in M.P. include a rash in sun-exposed areas of the skin, hyperpigmentation of tissues surrounding his eyes, white plaque-like lesions in the mouth, dry mucous membranes, and increased alkaline phosphatase and total bilirubin levels. These symptoms appeared after a period of complete resolution of acute GVHD. Thus, M.P. has limited involvement, quiescent chronic GVHD.

Pharmacologic Management

34. M.P. is started on prednisone 1 mg/kg PO daily for the treatment of his chronic GVHD. His cyclosporine taper is stopped, and the dosage is raised to therapeutic concentrations. Is this therapy rational? What other agents are available to treat chronic GVHD?

There is no specific prophylactic therapy for chronic GVHD. The mainstay of therapy for chronic GVHD is long-term immunosuppressive therapy. Survival for patients with chronic GVHD is improved by extended corticosteroid therapy, although there are multiple long-term adverse effects associated with the corticosteroids.^{152,154} The prednisone dose is 1 mg/kg/day, administered orally in divided doses for 14 days and then converted slowly to alternate-day therapy by increasing the “on-day” and decreasing the “off-day” dose until a total of 1 mg/kg/day on alternate days is administered.¹⁵⁴ Alternate-day therapy is preferred to minimize adrenocortical suppression. Once therapy is initiated, 1 to 2 months may pass before an improvement in clinical symptoms is noted. Therapy is

Table 92-9 Abbreviated Table of Signs and Symptoms of Chronic Graft-versus-Host Disease (GVHD)^a

| Affected Organ | Diagnostic | Distinctive | Other Features ^b | Seen With Both Acute and Chronic GVHD |
|------------------------|---|---|--|--|
| Eyes | | New-onset drug, gritty or painful eyes ^c Cicatricial conjunctivitis Keratoconjunctivitis sicca ^c Confluent areas of punctate keratopathy, tear formation, dry eyes, burning, photophobia | Photophobia Periorbital hyperpigmentation Erythema of the eyelids with edema | |
| Gastrointestinal tract | Esophageal web Stricture or stenosis in the upper to mid third of the esophagus ^d | | Pancreatic insufficiency | Anorexia Nausea Vomiting Diarrhea Weight loss Failure to thrive (infants and children) |
| Liver | | | | Total bilirubin, alkaline phosphatase >2 × upper limit of normal ^d Bronchiolitis obliterans organizing pneumonia |
| Lung | Bronchiolitis obliterans diagnosis with lung biopsy | Bronchiolitis obliterans diagnosed with pulmonary function tests and radiology ^c | | |

^aSigns and symptoms for nails; scalp and body hair; mouth; genitalia; muscles, fascia, and joints; hematopoietic and immune; and other organs are also described by Filipovich et al.¹⁵³

^bCan be acknowledged as part of chronic GVHD symptomatology if the diagnosis is confirmed.

^cDiagnosis of chronic GVHD requires biopsy or radiology confirmation (or Schirmer's test for eyes).

^dInfection, drug effects, malignancy, or other causes must be excluded.

usually continued for 9 to 12 months and then slowly tapered after signs and symptoms of chronic GVHD have resolved. If chronic GVHD worsens during the tapering or after discontinuation of prednisone, immunosuppressive therapy is restarted. Other potential approaches for patients with refractory chronic GVHD include mycophenolate mofetil, daclizumab, sirolimus, pentostatin, and extracorporeal photochemotherapy.¹⁵⁴

When immunosuppressive therapy is administered for long periods, the patient must be monitored closely for chronic toxicity. Cushingoid effects, aseptic necrosis of the joints, and diabetes can develop with long-term corticosteroid use. Other severe complications include a high incidence of infection with encapsulated organisms and atypical pathogens such as *Pneumocystis jiroveci* (*P. Jiroveci*) pneumonia, CMV, and herpes zoster.

Thus, it is reasonable to start M.P. on single-agent prednisone for chronic GVHD treatment.

Adjuvant Therapies

35. Suggest some adjuvant therapies that should be instituted in a patient like M.P. with chronic GVHD.

Patients who are being treated for chronic GVHD should receive trimethoprim-sulfamethoxazole for prophylaxis of *P. jiroveci* and encapsulated organisms, such as *Streptococcus pneumoniae* and *Haemophilus influenzae*. Ensuring optimal prophylactic antibiotics in chronic GVHD patients is critical because infection is the primary cause of death during treatment.¹⁵⁵ Artificial tears and saliva may im-

prove lubrication and decrease the occurrence of cracking and fissures in mucous membranes. If nutritional intake is poor, consultation with a clinical nutritionist and use of oral nutritional supplementation may be advisable. Patients should be instructed to apply sunscreens to exposed areas whenever prolonged sun exposure is anticipated. Liver function abnormalities have been improved by up to 30% with the use of ursodiol as bile acid displacement therapy.^{116–118} Calcium supplements, estrogen replacement, or other antioestrogen agents should be considered in women or other patients at risk for fracture or bone loss while receiving prolonged regimens with immunosuppressant therapy.¹⁵⁶ Patient education regarding the delay in improvement of symptoms, anticipated duration of therapy, and importance of compliance with oral immunosuppressive therapy is essential.

INFECTIOUS COMPLICATIONS

Opportunistic infections are a major cause of morbidity and mortality after myeloablative and nonmyeloablative HCT. There are three general periods of infectious risk (Fig. 92-3). During the early period pre-engraftment, particularly for patients undergoing myeloablative HCT, the primary pathogens are aerobic bacteria, *Candida* spp., and herpes simplex virus (HSV). Chemotherapy-induced mucosal damage creates a portal of entry into the bloodstream for many organisms, such as viridans group *Streptococcus*, *Candida*, and aerobic gram-negative bacteria. *Staphylococcus* is also common because patients undergoing HCT have indwelling IV central catheters.

The routine use of antiviral prophylaxis has decreased the incidence of HSV. Respiratory viruses such as respiratory syncytial virus (RSV), influenza, adenovirus, and parainfluenza are increasingly recognized as pathogens causing pneumonia, particularly during community outbreaks of infection.¹⁵⁷ To reduce potential exposure of HCT recipients to these pathogens, visitors and staff members with signs and symptoms of a viral respiratory illness may not be allowed direct contact with patients.

A potential advantage of reduced intensity or nonmyeloablative preparative regimens is reduced toxicity of the preparative regimen compared to myeloablative HCT. Reduced intensity or nonmyeloablative preparative regimens frequently do not result in true neutropenia,⁴ and the incidence of mucositis during the early period is reduced.¹⁵⁸ In a matched controlled study comparing the incidence of infection following nonmyeloablative and myeloablative HCT, the incidence of bacteremia during the first 30 days post-HCT in the nonmyeloablative group was significantly reduced.¹⁵⁸ Moreover, nonmyeloablative HCT recipients experienced significantly fewer infections attributable to mucositis during the early period.

The second or middle period of infectious risk includes the time from engraftment to posttransplantation day +100. Pathogens such as CMV, adenovirus, and *Aspergillus* are common. CMV, adenovirus, *Aspergillus*, and *P. jiroveci* frequently cause interstitial pneumonitis. Patients undergoing reduced intensity or nonmyeloablative preparative regimens that experience acute GVHD and are treated with corticosteroids have a similar risk of infection during this time period as those undergoing myeloablative HCT.¹⁵⁸

During the late period (after day +100), the predominant pathogens are the encapsulated bacteria (e.g. *S. pneumoniae*, *H. influenzae*, *Neisseria meningitidis*), fungi, and varicella-zoster virus (VZV). The encapsulated bacteria commonly cause sinopulmonary infections. The risk of infection during this late period is increased in patients with chronic GVHD as a result of prolonged immunosuppression.

Because of the morbidity associated with opportunistic infection in HCT recipients, optimal pharmacotherapy for prevention and treatment is critical. In 2000, the Centers for Disease Control and Prevention (CDC) published guidelines for prevention of opportunistic infection in HCT recipients.⁷ These guidelines were constructed from available data by an expert panel from CDC, the Infectious Disease Society of America (IDSA), and the American Society for Blood and Marrow Transplantation. The following discussion incorporates recommendations from the CDC guidelines and also provides information on the pharmacotherapy of opportunistic infections in all types of HCT.

Prevention and Treatment of Bacterial and Fungal Infections

36. S.D. is a 26-year-old woman with Ph⁺ acute lymphocytic leukemia (ALL) in first complete remission who is admitted for allogeneic myeloablative HCT. The following orders are written: admit to a room with a positive-pressure HEPA filter. Flush double-lumen Hickman catheter per protocol. Immunosuppressed patient diet as tolerated. Begin fluconazole 400 mg PO Q 24 hr on admission. Begin ceftazidime 2 g IV Q 8 hr with

first fever when ANC <500/mm³. Transfuse 2 units of packed RBCs for hematocrit <25% and 1 unit of single-donor platelets for platelet count <20,000/mm³. What is the rationale for these supportive measures?

As a result of disease-related immunosuppression, intensive preparative regimens, and posttransplantation immunosuppressive therapy, patients undergoing allogeneic HCT require careful vigilance for regimen-related toxicities and intensive supportive care directed at maintaining adequate blood counts, preventing or treating infection, and providing optimum nutrition.

Placement of a double-lumen or triple-lumen central venous catheter (e.g., Hickman, Groshong, Broviac, Neostar) is mandatory in all patients. The need for prolonged administration of chemotherapy, blood products, antibiotics, parenteral nutrition, and adjunctive medications precludes the use of peripheral access sites. The use of a central venous catheter allows delivery of maximum concentrations of all medications into a high-flow blood vessel. Administration time is reduced and daily fluid infusion is minimized.

After administration of the preparative regimen and before successful engraftment, allogeneic myeloablative HCT patients undergo a period of pancytopenia lasting from 2 to 6 weeks. During this time, patients may require multiple RBC and platelet transfusions. Packed RBCs and platelets are usually given for a hematocrit <25% and a platelet count less than 10,000/mm³ or 20,000/mm³. Transfusions with multiple blood products put patients at risk for blood product-derived infection (e.g., CMV, hepatitis). In addition, sensitization to foreign leukocyte HLA antigens (alloimmunization) may cause immune-mediated thrombocytopenia. Thus, blood product support in the myeloablative allogeneic HCT patient must incorporate strategies that reduce the risk of viral infection and alloimmunization. Effective methods include minimizing the number of pretransplant infusions, use of single-donor rather than pooled-donor blood products, irradiating blood products, and filtering blood products with leukocyte reduction filters.

Patients receiving reduced intensity or nonmyeloablative preparative regimens may or may not experience neutropenia and generally have reduced requirements for blood products. In fact, many centers perform reduced intensity or nonmyeloablative HCT in the outpatient setting and admit patients to the hospital only for complications requiring more aggressive management.

Several measures are recommended to minimize the risk of infection in autologous and allogeneic myeloablative HCT patients. Private reverse isolation rooms equipped with positive-pressure HEPA filters and adherence to strict handwashing techniques reduce the incidence of bacterial and fungal infections.⁷ To reduce exposure to exogenous sources of bacteria in immunosuppressed patients, low microbial diets are instituted on hospital admission, and visitors are prohibited from bringing plants or flowers into the patient's room. Patients are encouraged to maintain good oral hygiene because the mouth can be a source of bacterial or fungal infection. Frequent (four to six times daily) mouth rinses with sterile water, normal saline, or sodium bicarbonate are effective.⁷ Brushing or flossing teeth is avoided during periods of thrombocytopenia and neutropenia.

Aggressive use of antibacterial, antifungal, and antiviral therapy, both prophylactically and for documented infection, is an important aspect of patient management. Antibiotics with a broad gram-negative spectrum may be instituted prophylactically once the patient becomes neutropenic, or empirically after the patient is neutropenic and experiences fever. S.D. will receive ceftazidime empirically. Some transplant centers administer a prophylactic fluoroquinolone such as levofloxacin on admission for HCT and then switch to a broad-spectrum IV antibiotic such as ceftazidime, cefepime, or imipenem when the patient becomes neutropenic and febrile. Fluoroquinolone prophylaxis significantly reduces the incidence of gram-negative bacteremia but generally does not affect mortality.⁷ Concerns regarding prophylactic fluoroquinolone use include the emergence of resistant organisms and an increased risk of streptococcal infection.^{7,159} The incidence of infection during HCT due primarily to members of the viridans group of streptococci is increasing, and prompt, aggressive treatment is warranted.^{7,160} Prophylactic antibiotics (e.g., penicillin, vancomycin) are not recommended due to their lack of proven efficacy in preventing streptococcal infections and the concern about antibiotic-resistant bacteria.⁷ At a minimum, broad-spectrum IV antibiotics should be initiated or added at the time of the first neutropenic fever according to treatment guidelines endorsed by the IDSA.^{7,161}

S.D. is prescribed fluconazole 400 mg/day because prophylactic use of this agent until day +75 posttransplantation decreases the incidence of systemic fungal infection and fungal death in patients undergoing transplantation.^{162,163} The use of prophylactic fluconazole by most HCT centers has been linked to reports of breakthrough infections with resistant fungi such as *C. glabrata* and *Aspergillus*.^{164,165} Itraconazole has improved activity *in vitro* against fluconazole-resistant fungi. In a randomized clinical trial, allogeneic HCT patients treated with prophylactic itraconazole (200 mg IV Q 24 hr or oral solution 200 mg BID) developed significantly fewer invasive fungal infections than those treated with fluconazole (400 mg Q 24 hr). Although there was a trend toward fewer fungal deaths in the itraconazole-treated patients, overall mortality was similar. Itraconazole was associated with more frequent GI side effects (e.g., nausea, vomiting).¹⁶⁶

Published data supporting the use of newer mold-active agents for antifungal prophylaxis are limited. Van Burik et al. compared micafungin (50 mg IV Q 24 hr) to fluconazole (400 mg IV Q 24 hr) in a randomized, double-blind study of patients undergoing HCT. Overall success was defined as the absence of suspected, proven, or probable systemic fungal infection through the end of therapy and as the absence of proven or probable systemic fungal infection through the end of the 4-week posttreatment period. The overall efficacy was greater in the patients who received micafungin (80.0% vs. 73.5% in patients treated with fluconazole, $p = 0.03$). Fewer episodes of aspergillosis occurred in patients treated with micafungin. Patient tolerability of the regimens was similar.¹⁶⁷

Prevention of Herpes Simplex Virus and Varicella-Zoster Virus

37. On routine screening before transplantation, S.D. is found to be HSV and VZV seropositive. How will this affect her management?

Forty-three to 70% of HSV-seropositive patients undergoing myeloablative allogeneic HCT experience reactivation of HSV.^{168,169} Prophylactic acyclovir is commonly used in HSV-seropositive patients undergoing allogeneic or autologous HCT to prevent viral reactivation.⁷ Dosing regimens for prophylactic acyclovir vary widely; the dose of IV acyclovir is typically 250 mg/m² IV Q 12 hr, whereas oral doses of acyclovir range from 600 mg/day to 1,600 mg/day.⁷ The recommended duration of acyclovir prophylaxis for HSV varies from day +30 to day +365 posttransplantation or longer, depending on the specific type of HCT and other factors. Valacyclovir, a prodrug of acyclovir with improved bioavailability, may allow for adequate serum concentrations to prevent HSV in patients with mucositis or GI GVHD.¹⁷⁰ Prophylactic valacyclovir is commonly used at a dose of 500 mg PO Q 12 hr.^{171,172}

VZV-seropositive patients are at risk for developing herpes zoster, particularly after day +100 posttransplantation.¹⁷⁰ Prophylactic acyclovir reduces the risk of VZV reactivation.¹⁷³ As with prophylaxis for HSV reactivation, the optimum duration of VZV prophylaxis is controversial, often extending to day +365 posttransplantation or longer.

Patients who are HSV or VZV seronegative rarely develop primary HSV or VZV infection and are therefore not administered prophylactic acyclovir. If HSV does occur, lesions usually appear on the oral mucosa, nasolabial mucous membranes, or genital mucocutaneous area and can be managed with acyclovir at appropriate treatment doses.

Because S.D. is HSV and VZV seropositive, she is at risk for viral reactivation and should receive prophylactic acyclovir.

Prevention of Cytomegalovirus Disease

38. S.D. is also CMV seropositive. What is the significance of this finding, and what measures can be taken to prevent reactivation of CMV?

CMV has the ability to establish lifelong latent infection following primary exposure. In immunocompromised patients, the virus may reactivate, resulting in asymptomatic shedding or the development of CMV disease. The incidence of CMV infection (defined as isolation of the virus or detection of viral proteins or nucleic acid in any body fluid) and CMV disease in HCT recipients is 15% to 60% and 20% to 35%, respectively. The most common manifestations of CMV disease after allogeneic HCT are pneumonitis, fever, and GI infection.¹⁷⁴

In the CMV-seronegative HCT recipient, primary CMV can be prevented by transplanting PBPCs or bone marrow from CMV-seronegative donors and using only blood products from CMV-seronegative donors. In patients who are CMV-seropositive or who have received a CMV-seropositive graft, antiviral drugs are essential to minimize morbidity associated with CMV reactivation or secondary infection. Two general strategies are possible. Universal prophylaxis involves the administration of ganciclovir from the time of engraftment until approximately day +100 posttransplantation. This strategy significantly decreases the incidence of CMV infection and disease compared with placebo.¹⁷⁵ However, prophylactic ganciclovir therapy is associated with neutropenia in 30% of patients, which contributes to an increased risk of invasive bacterial and fungal infections.^{175,176} Neutropenia secondary to ganciclovir may lead to interruptions in antiviral therapy or necessitate

administration of filgrastim daily or several times per week to maintain adequate neutrophil counts.

Pre-emptive therapy, or risk-adjusted therapy, is the most commonly used strategy for preventing CMV disease after allogeneic HCT.^{170,177} This strategy, based on detection of early reactivation of CMV using shell vial cultures, assay of blood for CMV antigens (e.g., pp65), or viral nucleic acid using the PCR results in the selective administration of ganciclovir to those HCT patients at greatest risk for development of CMV disease.^{178–180} Antigenemia-based pre-emptive therapy is as effective as universal ganciclovir prophylaxis for prevention of CMV disease and has also been associated with reduced CMV mortality.^{176,181–184} The induction dose of ganciclovir is typically 5 mg/kg IV Q 12 hr for 7 to 14 days, followed by a maintenance dose of 5 mg/kg IV daily until 2 to 3 weeks after the last occurrence of antigenemia or until day +100 posttransplantation.⁷ Pre-emptive therapy limits patient exposure to the potential toxicity of ganciclovir and thus reduces overall cost.¹⁷³ Recent data suggest that oral valganciclovir is a safe and effective alternative to ganciclovir for pre-emptive therapy.^{185,186} Foscarnet may be administered in lieu of ganciclovir, but its use is complicated by nephrotoxicity and electrolyte wasting.^{184,187}

Autologous HCT recipients who are CMV-seropositive pretransplant should receive antiviral treatment pre-emptively as described previously.^{7,188} Because host T cells may persist in the peripheral blood for up to 6 months following reduced intensity or nonmyeloablative preparative regimens, their presence may provide protection against early CMV disease. A matched controlled study comparing the incidence and outcome of CMV infection in myeloablative and nonmyeloablative HCT demonstrated that although the time to onset of CMV antigenemia was similar in the two groups, fewer nonmyeloablative HCT recipients developed CMV disease in the early period.¹⁸⁹ The overall 1-year incidence of CMV disease was also similar, suggesting that nonmyeloablative HCT recipients are at increased risk for developing late CMV disease (> 100 days after transplantation) compared to their myeloablative counterparts.¹⁸⁹ It is therefore recommended that nonmyeloablative HCT patients receive pre-emptive antiviral therapy and be monitored for development of CMV antigenemia for 1 year after HCT.^{189,190}

S.D.'s absolute neutrophil count recovers to >1,000 cells/ μ L on day +20, and on day +32, her weekly surveillance blood sample is positive for CMV by PCR. Pre-emptive ganciclovir therapy is initiated at 5 mg/kg IV Q 12 hr. After 3 weeks of therapy, S.D.'s surveillance samples are negative and ganciclovir is discontinued. Weekly surveillance sampling continues until day +100. If surveillance samples again become positive for CMV, ganciclovir therapy should be reinstated.

Diagnosis and Treatment of *Aspergillus* Infection

Risk Factors

39. A.W., a 60-kg, 165-cm, 15-year-old boy, is day +79 after a matched, unrelated, nonmyeloablative PBPC transplant for ALL in third complete remission. He presents to the clinic for evaluation of a temperature of 102.3°F and a 3-day history of non-productive cough. Significant medical history includes skin and GI GVHD (stable on his current regimen of cyclosporine, my-

cophenolate mofetil, and prednisone) and congestive heart failure believed to be secondary to anthracycline exposure. A.W. has chronic low-grade nausea and hypomagnesemia necessitating daily IV hydration with magnesium supplementation. Relevant laboratory values are as follows: Na, 138 mEq/L (normal, 135–147); K, 4.2 mEq/L (normal, 3.5–5.0); Cl, 100 mEq/L (normal, 95–105); CO₂, 23 mEq/L (normal, 22–28); blood urea nitrogen (BUN), 18 mg/dL (normal, 8–18); SrCr, 0.8 mg/dL (normal, 0.6–1.2); total bilirubin, 0.6 mg/dL (normal, 0.1–1); Mg, 1.5 mg/dL (normal, 1.6–2.4); WBC count, 3,500/mm³ (normal, 3,200–9,800); platelets, 78,000/mm³ (normal, 130,000–400,000); ANC, 1,810 cells/L (normal, >1,700); and Hgb, 10.8 g/dL (normal, 12–15). He was CMV and HSV seropositive before HCT. Oral medications include cyclosporine 275 mg Q 12 hr, mycophenolate mofetil 900 mg Q 12 hr, prednisone 60 mg Q am and 12.5 mg Q pm (tapering), trimethoprim-sulfamethoxazole (TMP/SMX) 160 mg/800 mg BID on Monday and Tuesday, fluconazole 400 mg Q am, valganciclovir 500 mg BID, digoxin 0.125 mg Q 12 hr, enalapril 10 mg Q 12 hr, and One-a-Day Plus vitamin Q am.

On physical examination, A.W. is a chronically ill-appearing child with moon facies, dry skin with thickened areas, a pleural friction rub, and thinning hair. Blood cultures, urinalysis, and chest x-ray are obtained. Chest x-ray reveals several small cavitary lesions worrisome for fungal disease. A.W. is admitted for further workup and management of presumed *Aspergillus* infection. What risk factors does A.W. have for developing infection with *Aspergillus*?

[SI units: Na, 138 mmol/L; K, 4.2 mmol/L; Cl, 100 mmol/L; CO₂, 23 mmol/L; BUN, 6.43 mmol/L; SrCr, 71 μ mol/L; total bilirubin, 10.26 μ mol/L; Mg, 0.61 mmol/L; WBC count, 3,500 \times 10⁶ cells/L; platelets, 78 \times 10⁹ cells/L; ANC, 1,810 \times 10⁶ cells/L; Hgb, 108 g/L]

Invasive molds (most commonly *Aspergillus* spp., but also *Fusarium* spp., *Scedosporium*, and *Zygomycetes*) are an increasing cause of morbidity and mortality after allogeneic and autologous HCT.¹⁶⁴ Factors contributing to this trend include (a) more effective prevention of bacterial and viral infection, as described previously; and (b) the use of fluconazole prophylaxis, which has reduced the incidence of candidemia and *Candida*-related mortality.^{162–164,191,192} *Aspergillus* infection is reported in up to 26% of HCT recipients, and the mortality rate of invasive aspergillosis (IA) is 74% to 92%.¹⁹³

Several risk factors for development of invasive fungal infection have been identified.^{191,192} Given that neutrophils are critical for host defense, prolonged neutropenia is considered the single most important predictor of infection at all time points after HCT.^{165,191} GVHD (acute and chronic) and treatment with corticosteroids are also important risk factors, particularly for aspergillosis occurring between day +40 and day +100 posttransplantation, presumably as a result of neutrophil dysfunction.^{191,192,194} In addition, the widespread use of fluconazole prophylaxis (400 mg/day) for prevention of invasive candidiasis in transplant patients since the early 1990s has led to a substantial increase in the incidence of IA and also fluconazole-resistant *Candida* species such as *Candida krusei* and *Candida glabrata*.^{191,194,195}

A.W. is receiving corticosteroid treatment for GVHD and fluconazole prophylaxis. These therapies increase his risk for developing IA.

Treatment

40. A.W. undergoes bronchoalveolar lavage in an attempt to identify the organism responsible for his infection. Pathological examination of the fluid obtained reveals septate, branching hyphae, and culture results confirm the diagnosis of *Aspergillus fumigatus* infection. CT scans are negative for extrapulmonary involvement. A.W. is started on amphotericin B lipid complex (ABLC) at a dose of 300 mg IV daily. How is aspergillosis usually diagnosed, and what are the acceptable alternatives for treating this infection?

Early diagnosis and treatment of IA, which rely on tissue or fluid obtained from the infected site followed by aggressive antifungal therapy, may improve patient survival.¹⁹⁶ Although the lower respiratory tract is frequently the primary focus of infection, *Aspergillus* may invade blood vessels and spread hematogenously to other organs, including the brain, liver, kidneys, spleen, and skin.¹⁹⁷ Head, chest, abdomen, and pelvic CT scans assist in assessing the extent of disease, treatment options, and overall prognosis. Cultures of respiratory tract secretions lack sensitivity for detecting *Aspergillus*, and the medical condition of the patient may preclude invasive diagnostic procedures altogether. Many clinicians have adopted the European Organization for Research and Treatment of Cancer criteria for diagnosis of proven, probable, and possible IA.¹⁹⁸

Newer diagnostic tests based on the detection of fungal antigens or metabolites, such as galactomannan, 1,3- β -D-glucan, and fungal DNA detection by PCR, are being developed. Galactomannan is a polysaccharide component of the *Aspergillus* cell wall that is released during fungal cell growth. Galactomannan detection by enzyme-linked immunoassay (GM-EIA) has proved to be a sensitive and specific tool for early detection of *Aspergillus* infection. The test is useful not only for serum samples, but also for bronchoalveolar lavage and cerebrospinal fluid. Concomitant antifungal therapy may cause false-negative GM-EIA results, whereas antibiotics of fungal origin (e.g., piperacillin/tazobactam) have been associated with false positives.^{193,199}

Antifungals

Outcomes for patients with IA after HCT are often poor, with approximately 20% of patients alive after 1 year.¹⁹¹ Treatment success depends not only on the use of intensive antifungal agents, but also on recovery of the host immune system and/or reduction of immunosuppression.^{196,200} Conventional amphotericin B (c-AmB) at a dose of at least 1 mg/kg/day has traditionally been the gold standard antifungal therapy for IA. Response rates with c-AmB monotherapy range from 28% to 51%, depending on the severity of the underlying immunosuppression; however, 65% of responders eventually die of their infection.¹⁹⁶ Moreover, toxicity associated with c-AmB frequently limits the dose and duration of therapy. Fortunately, the lipid derivatives of amphotericin B, broad-spectrum triazoles, and echinocandins are available as alternatives to c-AmB.

Three lipid formulations of amphotericin B have been marketed: ABLC (Abelcet), liposomal amphotericin B (L-AmB; AmBisome) and amphotericin B colloidal dispersion (ABCD; Amphotec). Practice guidelines delineating use of these agents for fungal infections in HCT patients have been published.²⁰¹ Studies of lipid amphotericin B formulations as monotherapy for patients with IA who have failed or are intolerant to c-AmB

therapy demonstrate response rates of 23% to 71%, regardless of which formulation is used. No randomized trials show superiority of lipid amphotericin B products over c-AmB for IA.²⁰⁰ Doses most commonly used in the studies are 5 mg/kg/day for ABLC and L-AmB and 4 to 6 mg/kg/day for ABCD. The lipid formulations of amphotericin B are clearly less toxic than c-AmB, with L-AmB being the least toxic.²⁰²

The cost of the amphotericin B lipid formulations, which is 15- to 30-fold higher than c-AmB, is a limiting factor. Drug acquisition cost should be balanced against the potential expense of managing c-AmB nephrotoxicity. A recent pharmacoeconomic evaluation comparing hospital costs for neutropenic patients with persistent fever treated with L-AmB or c-AmB demonstrated significantly higher overall costs for patients receiving L-AmB, principally due to higher acquisition cost.²⁰³ Thus, establishing cost-effective strategies for the appropriate use of the lipid amphotericin b formulations is imperative. Most HCT centers have developed criteria for appropriate use based on risk for nephrotoxicity and severity of the infection being treated.

Three broad-spectrum triazole agents are available for patients who are refractory to or intolerant of amphotericin B therapy. Oral itraconazole capsules (Sporanox) were approved in 1992, followed later by the oral solution and an IV formulation. In an early compassionate use trial of IA unresponsive to amphotericin B, 27% of patients had a complete response to itraconazole, and another 35% experienced improvement in their infection.²⁰⁴ Patients who had undergone HCT had response rates similar to patients who were less immunocompromised. Unfortunately, oral itraconazole capsules exhibit erratic absorption, and the IV form is complicated by the risk of drug precipitation in the IV line.²⁰⁰ In addition, itraconazole is a potent inhibitor of common CYP isoforms and also has negative inotropic properties.^{205,206}

Voriconazole (Vfend) was approved in 2002. An advantage of voriconazole is excellent (96%) oral bioavailability; however, like itraconazole, the drug is a potent inhibitor of cytochrome P450 enzymes. Voriconazole has been compared to c-AmB in a randomized, unblinded trial as primary therapy for established IA in an immunocompromised host.²⁰⁷ The primary study objective was to demonstrate the noninferiority of voriconazole compared with c-AmB after 12 weeks of therapy in patients with definite or probable IA. Patients received voriconazole 6 mg/kg IV Q 12 hr \times two doses followed by 4 mg/kg IV Q 12 hr for at least 7 days, followed by oral voriconazole 200 mg Q 12 hr or c-AmB at a dose of 1 to 1.5 mg/kg/day. Patients refractory to or intolerant of initial therapy could receive other antifungal drugs. Of 144 evaluable patients who received voriconazole, 76 (52.8%) had a partial or complete response compared to 42 of 133 (31.6%) patients treated with c-AmB. The median duration of therapy for patients treated with voriconazole was 77 days, and 52 of 144 patients switched to an alternative agent. In contrast, the median duration of therapy for patients receiving c-AmB was 10 days, and 107 of 133 patients switched to another agent (most commonly, a lipid formulation of amphotericin B). The survival rate at 12 weeks in the voriconazole group was 70.8% compared to 57.9% in the c-AmB group ($p = 0.02$). These results of initial therapy with voriconazole indicate superior response and improved survival compared to c-AmB in immunocompromised patients, such as allogeneic HCT

recipients, with IA. Voriconazole-treated patients also experienced fewer drug-related adverse effects.

Posaconazole (Noxafil) was approved in 2006. This broad-spectrum triazole is available only as a variably absorbed oral suspension, and like itraconazole and voriconazole, it is a cytochrome P4503A4 inhibitor. Posaconazole has the lowest MICs of any available triazole against *Aspergillus* spp., including *Aspergillus terreus*, and it is the only triazole with useful activity against the *Zygomycetes*. Published clinical experience with posaconazole is limited; however, in an open-label externally controlled trial in patients with IA refractory to or intolerant of other therapies, the overall success rate was 42% in posaconazole-treated patients compared to 26% for controls ($p = 0.006$).²⁰⁸

Echinocandin antifungal agents (caspofungin, micafungin, and anidulafungin) inhibit the synthesis of β -(1,3)-glucan, an important component of the fungal cell wall. No prospective randomized trials document the efficacy of any echinocandin for primary therapy of IA, and only caspofungin is approved for salvage therapy. An open-label, noncomparative trial evaluated the efficacy of caspofungin in 69 patients with IA who had failed or were intolerant of at least 7 days of standard antifungal therapy.²⁰⁹ Patients received 70 mg IV of caspofungin on day 1 followed by 50 mg IV daily. Of the 63 evaluable patients, 26 (43%) responded favorably to treatment. Twenty-six of 52 patients (50%) who had received at least 7 days of therapy had a favorable response. In another open-label, noncomparative trial, Denning et al. evaluated the safety and efficacy of micafungin (alone or in combination) in patients with proven or probable IA. Eighty of 225 patients (35.6%) had a favorable response. Most patients received combination therapy; the 34 patients treated with monotherapy had a similar response rate.²¹⁰

In summary, the number of agents available to manage IA has expanded greatly in the past few years. Although some experts believe that voriconazole is the drug of first choice, considerable controversy still exists. Therapy should be tailored to the individual patient based on response, tolerability, and cost.

Antifungal Toxicities

41. Despite premedication with acetaminophen and diphenhydramine, A.W. experiences significant chills and rigors with his ABLC infusions. In addition, he is having daily temperatures exceeding 39°C. On day 5 of therapy, morning laboratory tests reveal a SrCr of 1.4 mg/dL, K of 2.7 mEq/L, and Mg of 1.4 mg/dL. What expected adverse reactions of conventional amphotericin B–based therapy does A.W. demonstrate?

[SI units: SrCr, 123.8 μ mol/L; K, 2.7 mmol/L; Mg, 0.57 mmol/L]

The most troublesome side effect of c-AmB therapy is nephrotoxicity. Up to 80% of patients treated with c-AmB will experience an episode of altered renal function.²¹¹ The mechanism of amphotericin B nephrotoxicity is complex and poorly understood. It most likely results from afferent vasoconstriction leading to cortical ischemia and a subsequent decrease in glomerular filtration rate, as well as defective acid secretion by the renal tubule. Risk factors for nephrotoxicity include concomitant administration of other nephrotoxic drugs such as aminoglycosides, cyclosporine, cisplatin, and radiocontrast

dye; prolonged duration of therapy; history of chronic renal disease; male gender; and a mean daily dose ≥ 35 mg.²¹²

The lipid derivatives of amphotericin B were developed with the goal of reducing nephrotoxicity, and each is significantly less nephrotoxic compared to c-AmB.^{201,213–216} Furthermore, patients treated with c-AmB who experience nephrotoxicity and are then switched to a lipid formulation frequently show improvement in renal function. It is difficult to determine the true incidence of nephrotoxicity associated with the lipid products because most trials evaluate their use in patients who have received prior c-AmB therapy. In addition, many trials do not control for other factors known to reduce the risk of nephrotoxicity, including sodium loading and IV fluid boluses administered before c-AmB infusion. Nonetheless, clinical experience confirms the reduced incidence of nephrotoxicity with these products, and they are recommended as first-line therapy for patients at high risk for nephrotoxicity or in whom baseline renal function is impaired.

Other toxicities of c-AmB include infusion-related reactions (fever, chills, rigors, hypotension, hypoxia), hypokalemia, hypomagnesemia, nausea, and anemia. Premedications such as acetaminophen, diphenhydramine, meperidine, and/or hydrocortisone are typically administered before each dose to lessen or prevent the infusion-related reactions, with mixed results. Patients may also develop tolerance. Fortunately, there appears to be a reduced incidence of infusion-related reactions when the lipid products are used. Significant hypokalemia and hypomagnesemia may persist well beyond discontinuation of c-AmB. Most patients require daily potassium and magnesium supplementation, particularly if they require prolonged antifungal treatment.

Length of Antifungal Therapy and Combination Antifungal Therapy

42. In response to A.W.'s rise in SrCr, his physician elects to discontinue ABLC and begin voriconazole 6 mg/kg IV Q 12 hr \times two doses, followed by 4 mg/kg IV Q 12 hr plus caspofungin 70 mg IV on day 1 and 50 mg IV QD thereafter. What is the rationale for combination therapy, and how should the patient be monitored? How long should A.W. receive antifungal therapy for his IA?

Common toxicities reported with voriconazole include reversible visual disturbances (blurred vision, altered color perception, photophobia, visual hallucinations), skin reactions (rash, pruritus, photosensitivity), elevations in hepatic transaminase enzymes and alkaline phosphatase, nausea, and headache.^{207,217,218} Caspofungin has fewer adverse effects. Vein irritation and headache are most common; dermatologic reactions related to histamine release (flushing, erythema, wheals) have also been reported. Increased hepatic transaminase enzymes occur in approximately 6% of patients treated with caspofungin.²⁰⁹ A.W. should be monitored for changes in liver function and counseled regarding the potential visual side effects of voriconazole.

Data supporting improved outcomes with two-drug combinations of triazoles, echinocandins, and polyenes in patients with IA are sparse. However, *in vitro* and animal data suggest that an echinocandin plus voriconazole or a polyene may be synergistic.^{219–222} Given the overall poor prognosis of IA in severely immunocompromised patients, many practitioners are choosing to treat patients with two-drug combination therapy. Voriconazole in combination with caspofungin is thus a

reasonable alternative for A.W., particularly in view of the ABLC toxicity he is experiencing.

The optimum duration of antifungal therapy for treatment of IA is unestablished.²⁰⁰ Important considerations include the status of the patient's immune system and the extent of response to treatment. Many clinicians continue aggressive antifungal therapy until the infection has stabilized radiographically and then proceed with less aggressive "maintenance" therapy (e.g., single-agent oral voriconazole) until restoration of the immune system has taken place. It is not uncommon for a patient to require several months of antifungal therapy for effective management of IA.

Prevention of *Pneumocystis jiroveci* pneumonia

43. A.W. is receiving TMP/SMX, one double-strength tablet PO BID on Monday and Tuesday. What is the rationale for its use?

P. jiroveci (formerly *Pneumocystis carinii*) is a common pathogen in patients who have undergone allogeneic HCT. *Pneumocystis pneumonia* (PCP) is a potentially lethal infection, and therefore, prophylaxis is routinely administered. The optimum prophylactic regimen is unestablished, but most centers administer TMP/SMX for PCP prophylaxis.⁷ Dapsone or aerosolized pentamidine are alternatives for patients who are allergic to sulfonamides or do not tolerate TMP/SMX for other reasons.

PCP prophylaxis is usually begun following neutrophil recovery because (a) PCP most commonly occurs after engraftment, and (b) TMP/SMX is potentially myelosuppressing. Patients should be closely monitored for unexplained neutropenia or thrombocytopenia. Rash secondary to the sulfonamide component of TMP/SMX may force its discontinuation. TMP/SMX is usually avoided on days of methotrexate administration because of increased systemic methotrexate exposure resulting from increased methotrexate free fraction and decreased renal clearance of free methotrexate.²²³ Prophylaxis is typically continued for 6 to 12 months posttransplantation.

The risk of PCP is lower in autologous HCT patients because posttransplant immunosuppression is not used. However, TMP/SMX prophylaxis may be administered after autologous HCT for non-Hodgkin lymphoma, Hodgkin disease, multiple myeloma, and lymphocytic leukemia because of the immunosuppressive nature of the underlying disease.

ISSUES OF SURVIVORSHIP AFTER HEMATOPOIETIC STEM CELL TRANSPLANTATION

44. H.O. is a 32-year-old woman who received a BU/CY preparative regimen and an HLA-matched sibling BMT for treatment of chronic phase CML at age 21. H.O. received her BMT more than 10 years ago, is disease free, and has not had chronic GVHD for 9 years. Her only medication is one multivitamin tablet PO QD. What issues of cancer survivorship are of concern to H.O.?

A greater proportion of HCT recipients are surviving their cancer diagnosis without evidence of their primary malignancy, but they are at risk for long-term physical and emotional sequelae of their cancer treatments.¹ Since most long-term HCT survivors are no longer under the care of an HCT center, their health care providers may be unfamiliar with the

complications of HCT. To facilitate the clinical care of long-term HCT recipients, recommendations for screening and preventative practices have been created for adult and pediatric HCT survivors.^{224,225} These guidelines should facilitate the provision of health care to HCT recipients. The following paragraphs describe various concerns associated with the morbidity of long-term HCT survivors.^{224–226} Long-term HCT survivors should be regularly screened, or take preventative steps regarding immunity, secondary malignant neoplasm, oral complications, and liver, respiratory, endocrine, ocular, skeletal, nervous system, kidney, vascular, and psychosocial function.

Immune function can take more than 2 years to recover, even without immunosuppressants.²²⁷ Treatment of GVHD exacerbates immune system defects, necessitating prophylaxis and vigilant monitoring for infectious complications. Fevers should be rapidly assessed and treated to prevent a fatal infection. Recipients of HCT also lose protective antibodies to vaccine-preventable diseases. Therefore, HCT survivors need to be revaccinated for selected infectious diseases with due consideration for the risk of vaccination.

HCT survivors have a greater risk of secondary malignant neoplasms.¹ An increased incidence of cancer of the skin, oral mucosa, brain, thyroid, and bone is observed after allogeneic HCT, while an increased incidence of myelodysplasia and acute leukemia can occur after autologous HCT for NHL.¹ HCT survivors should avoid carcinogens (e.g., tobacco) and be screened for secondary malignant neoplasms indefinitely.¹ Long-term impairment of end-organ function may be due to the preparative regimen, infectious complications (either autologous or allogeneic grafts), and posttransplantation immunosuppression (allogeneic grafts only).^{224,225} Endocrine dysfunction, specifically of the thyroid, gonads, and growth velocity, is common.^{224,225} Adrenal insufficiency can result from long-term corticosteroids therapy used to treat GVHD. Infertility is commonly observed after myeloablative HCT secondary to the high doses of alkylating agents and radiation administered. Frequently, men become azoospermic, and chemically induced menopause develops in women.¹ However, pregnancies have occurred after HCT.¹ Up to 60% of HCT recipients have osteopenia, most likely resulting from gonadal dysfunction and corticosteroid administration; avascular necrosis due to corticosteroids can also occur.²²⁸ A significant portion (15%–40%) of HCT survivors develop pulmonary dysfunction with variable symptoms (e.g., restrictive, chronic obstructive lung disease) from multiple causes.²²⁸ Hepatic infections can occur in HCT recipients, with the prevalence of chronic hepatitis C ranging from 5% to 70% in long-term HCT survivors.²²⁹ Because of this, cirrhosis and its complications may become an important late complication of HCT.²²⁹ Hepatic dysfunction can also result from iron overload, which may occur secondary to multiple PRBC transfusions administered during aplasia after myeloablative preparative regimens and before HCT. Alopecia is a common late effect with BU/CY, as are cataracts with CY/TBI.⁶⁴

H.O. should be routinely monitored for signs of relapse and chronic GVHD. To lower the risk of infectious complications, she should be counseled to obtain prompt medical care for fevers or signs of an infection, and she should be revaccinated if she has not done so since receiving her myeloablative HCT. Thorough evaluation of end-organ function, including renal, hepatic, thyroid, and ovarian function, should

be assessed at regular intervals. In addition, her bone mineral density should be determined, and H.O. should be counseled on preventive measures for osteopenia (e.g., calcium sup-

plementation). In addition to standard cancer screening tests, H.O. should be closely monitored for secondary malignant neoplasms.¹

MEDICATION ADMINISTRATION ISSUES IN CHILDREN

Children represent more than 25% of the population and receive an average of three prescription medications before 5 years of age. The safe and effective use of medications in children, nevertheless, is challenging because of the lack of U.S. Food and Drug Administration (FDA)-approved indications and dosing guidelines for children, limited evidence-based medicine, and paucity of appropriate dosage formulations. About 60% of drugs have not been approved by the FDA for use in children, and even fewer have been approved for use

in infants. Most current laws governing FDA approval of drugs are the result of pediatric tragedies (e.g., thalidomide, sulfanilamide), but legislation to encourage research in pediatrics did not occur until the 1990s. The FDA Modernization Act of 1997, Best Pharmaceuticals for Children Act (BPCA), and the Pediatric Research Equity Act are attempts to encourage manufacturers to focus on pediatric indications for medications. As a result, knowledge of pediatric drug therapy has grown significantly; however, information on which to base drug therapy decisions remains inadequate. This chapter focuses on general principles guiding pediatric pharmacotherapy, and reviews the

pharmacotherapy of common pediatric disorders by integrating best-evidence medicine and the practical considerations unique to pediatric patients.

Medication Error Prevention

Children are at threefold greater risk for medication errors than adults, and up to 19% of these errors are deemed preventable.¹ The lack of appropriate information or guidelines for use of medications in children, the miscalculation of doses, and the need to either compound oral dosage forms or to dilute commercially available formulations contribute to this disproportionate rate of medication errors in children. In the last decade, efforts have increased to improve medication ordering processes, to standardize medication concentrations, and to educate practitioners about medication error prevention. The Pediatric Pharmacy Advocacy Group and other pediatric organizations have developed guidelines to reduce the potential for medication errors in children and these guidelines and strategies are becoming the focus for many health care systems and health care accrediting organizations.²

Drug Administration

Oral Medications

The administration of oral medications to a young child or infant often requires two adults: one to gently restrain the child while the other rapidly and accurately administers the medication. If only one adult is available, one can restrain the arms and legs of the child in a swaddling blanket or large towel as depicted in Figure 93-1.

The administration device (cup, syringe, or dropper) that generally accompanies a liquid medication product provides the most accurate measurement of the desired dose. For infants, liquid medications are most easily administered to the

FIGURE 93-1 Administration of oral liquid medication to a young child. (1) Premeasure the medication and have it within reach. (2) Hold the child in your lap, placing one of the child's arms behind your back and both of the child's legs between your legs. Restrain the child's other arm securely with your nondominant arm. (3) Tilt the child's head back slightly, pressing gently on the child's cheeks to open the mouth. Using your dominant hand, aim the dropper or syringe between the rear gum and cheek. Administer small amounts of medication (1–2 mL) at a time, making sure the baby swallows.

back cheek in 1- to 2-mL amounts with an oral syringe. Household teaspoons should not be used to measure medications because teaspoons are of variable sizes and hold 3 to 8 mL of a liquid. Crushed tablets or capsule contents mixed in small amounts (1–2 teaspoons) of food (e.g., chocolate pudding, applesauce, ice cream, jelly, chocolate syrup) offer an alternative to liquid formulations. The taste of liquid dosage formulations generally is improved by refrigeration and flavoring agents, and “chasers” (i.e., popsicle or flavored drink after a dose) also are helpful. Although medications can be delivered in small amounts (10–15 mL) of liquid in a bottle (juice, milk, formula), doses should not be diluted into an entire scheduled feeding or prepared ahead of time in batches in anticipation of future administration. Limiting the volume more likely facilitates delivery of the entire dose and adding the medication to a feeding bottle immediately before delivery minimizes the potential of drug instability. Drug interactions with foods also should be considered before drugs are added to feeding formulas. Most children are able to swallow tablets at 5 to 8 years of age. Duplicate supplies of medication should be provided to the caregiver when mid-day doses are required for children who attend school or childcare in the event a dose is dropped. Children of all ages should be encouraged and praised for their cooperation in taking their medicine. Rewards, gold stars, or stickers can be useful to gain cooperation in an older child.

Ear, Nose, and Eye Drops

Otic, ophthalmic, and nasal medications usually need to be administered to infants and young children in a different manner than adults. Otic medications should be instilled by pulling the auricle down and out in infants and young children, whereas older children should have the auricle of the ear held up and back to straighten the ear canal. During the instillation of nose and eye drops, position infants and toddlers with their head lower than the rest of the body because gravity assists in dispersing the medication. This can be achieved by laying the infant across a bed with the shoulders projecting over the edge of the bed. Restraining the infant often is required during the administration of ophthalmic formulations. When administering the eye medication (Fig. 93-2), the caregiver must be

FIGURE 93-2 Administering eye drops to a young child. (1) Place the child on a flat surface. Enlist the help of a second adult to restrain the child or swaddle the child as described in Figure 93-1. (2) Holding the child's head steady, gently pull the eyelids apart. The hand that is holding the medication dropper can rest on the child's head while administering the medication to minimize the potential for injury to the eye if the child's head moves abruptly. Administer the medication as directed.

cautious to avoid injury to the eye caused by sudden movements of the infant. The technique of placing the hand, which holds the eye medication, on the forehead of the infant during administration can help to minimize eye injury because the hand holding the eye dropper will move when the infant's head moves.

To minimize fear and improve cooperation during instillation of eye, nose, or ear drops, the procedure should be explained to the child as simply as possible. It is best to warm the medication in your hand for a few minutes before administration because medications can feel very cold inside the ears or nose even when stored at room temperature.

INFANT CARE

Teething

The growth and development of teeth begin as early as the sixth week of embryonic life. Calcification of the enamel and dentin begins at 4 months of gestation. Normal eruption of primary or deciduous teeth rarely begins before 4 to 5 months of age and usually is completed by 36 months of age.³ Although premature infants usually experience delayed eruption of their deciduous teeth, their first tooth appears (based on postconceptual age) at about the same time as term infants.⁴ In many full-term infants, however, teeth do not erupt until the end of the first year: delayed eruption of all teeth can reflect systemic or nutritional disturbances (e.g., hypothyroidism, hypopituitarism, rickets).³ Early eruption is less common and also can be associated with medical conditions (e.g., hyperthyroidism, precocious puberty, long-term steroid therapy).

Normal Eruption of Primary Teeth

Signs and Symptoms

1. C.J., a 6-month old, has become increasingly irritable and has been waking up four to five times a night. She is drooling excessively and biting on hard objects constantly. A brief examination of C.J.'s mouth shows red and tender gums. No teeth are present, and C.J. is afebrile. Her mother is concerned that C.J.'s teething has caused a secondary illness. What would be a likely explanation for these symptoms?

C.J.'s regular sleeping pattern has been disturbed by symptomatic teething. As the teeth penetrate the gums, the site can become tender: this process generally is associated with increased salivation. Bacterial invasion through a break in the tissue or under a gingival flap covering the teeth can cause inflammation and edema, but "teething" does not cause systemic disturbances.⁵ Restlessness, increased salivation, thumb-sucking, gum-rubbing, and decreased appetite commonly accompany teething.

Treatment

2. What course of treatment can be suggested for C.J.?

GENERAL MANAGEMENT

Gentle irrigation with water often relieves the inflammation around a gum flap. A topical anesthetic can be rubbed gently on the mucous membranes overlying the erupting tooth with a cotton-tipped applicator. Local anesthetics, however, should not be used long-term, and topical products containing lidocaine should not be used for symptomatic relief of teething

because absorption of lidocaine can lead to systemic toxicity. Alcohol-free products containing 7.5% benzocaine (e.g., Ora-jel Baby Gel, Orabase Baby Analgesic Teething Gel) can be used for infants more than 4 months of age.⁶ Giving the child a blunt, firm object to chew is helpful; and wrapping cracked ice in a soft cloth also can hasten tooth eruption and relieve pain. Rubber teething rings of various shapes can be beneficial, but trauma from the teething ring might lead to angular cheilitis.⁷ Water-containing rings can become contaminated with bacteria and should be avoided.

Ibuprofen and acetaminophen are commonly prescribed for younger children to relieve pain associated with the eruption of primary dentition. Ibuprofen's anti-inflammatory effects last for about 6 to 8 hours and might be especially helpful at bedtime. Pediatric dosage recommendations must be strictly followed. Topical aspirin should never be used because it can cause oral chemical burns. Oral aspirin is not used because of its association with Reye's syndrome, a condition consisting of encephalopathy and fatty degeneration of the liver.

Diaper Rash

Etiology

Diaper dermatitis is commonly encountered in pediatric practice, occurring in up to 35% of infants at any given time. Although the pathogenesis of diaper dermatitis is not well defined, a number of factors (e.g., chemical irritants, friction, bacteria) have been associated with skin inflammation in the diaper area. In particular, skin wetness and pH have been implicated in diaper dermatitis, and wetness appears to have greater influence than that of pH. Overhydration of the skin increases the permeability of low molecular weight compounds and exacerbates the effects of friction.⁸ Cloth diapers covered with plastic pants or disposable diapers with plastic outer linings decrease air circulation and increase moisture in the diaper area.⁹ Residual chemicals or laundry detergents in the diaper (cloth or disposable), as well as soaps, medications, or lotions that have been applied directly to the infant's skin also have roles in the development of diaper rash. A persistent diaper rash could represent a localized fungal or bacterial infection.⁹

Clinical Presentation

Four clinical presentations of dermatitis are associated with diaper wear:

1. A mild, scaling rash in the perianal area
2. A sharply demarcated confluent erythema
3. Ulceration distributed through the diaper area
4. A beefy red confluent erythema with satellite lesions, vesiculopustular lesions, and diffuse involvement of the genitalia

Treatment

3. K.G., a 3-month-old infant, has had a severe "diaper rash" for the past 4 days. The very inflamed and tender area is confined to the diaper area, and vesicular satellite lesions are present on the periphery of the erythematous area. K.G.'s mother uses only cloth diapers and has not changed soap or her normal pattern of diaper care since K.G. was born. Based on the clinical appearance of the rash and its duration, the clinician prescribed clotrimazole 1% cream and gave K.G.'s mother instructions for treatment. Why

was clotrimazole prescribed? What are some general measures for the prevention and treatment of diaper rash?

K.G.'s rash is consistent with a candidal infection, which typically is beefy red and associated with vesicular satellite lesions. Presence of a rash for >3 days and diffuse involvement of the genitalia and inguinal folds also are characteristic of this form of diaper rash. K.G.'s rash can be treated with clotrimazole or miconazole cream applied to the inflamed area four times daily until it has resolved. Nystatin ointment can be applied, but often is not as effective as the imidazole antifungals because of increasing resistance of candida species to nystatin.

Removal of stool and urine from the diaper area by gentle rinsing with plain water and more frequent diaper changes often help to alleviate diaper rashes. Wiping the baby with diaper wipes that contain alcohol can sting, further irritate the involved area, and should be avoided until the rash has resolved. A good protective agent containing zinc oxide or petrolatum (e.g., Desitin) can be applied with each diaper change to create a barrier to irritants and seal out moisture. Powdered protective agents (e.g., cornstarch, talc) can minimize friction caused by diapers, but should be used cautiously because the infant can aspirate powder particles and develop a chemical pneumonia.¹⁰ When used, powders should be shaken into the diaper or applied close to the body, away from the baby's face. The concern that cornstarch might serve as a culture medium for *Candida albicans* has not been substantiated.¹¹

Other prevention and treatment measures should include the following:

1. Change the diaper as soon as it is wet or at least every 2 to 4 hours during the day.
2. Keep the diaper area clean (e.g., nightly baths until resolved).
3. Use super absorbent disposable diapers at night.
4. Expose the diaper area to air as often as possible.
5. Dry the diaper area completely before a new diaper is put on.
6. For cotton diapers, use a bacteriostatic agent in the diaper pail and rinse water or employ a diaper service to ensure that diapers are sterile.
7. Apply a low-potency topical corticosteroid, such as 0.5% to 1% hydrocortisone, twice daily for up to 1 week when severe inflammation is present.¹²

Fever

Normal body temperature varies throughout the day, peaking in late afternoon or early evening. Body temperature can be measured rectally, orally, axillary (under the arm), and tympanically. Rectal temperatures are most reliable in infants <3 months of age. Oral measurements of temperature are not appropriate in children <3 years of age because it is difficult for young children to maintain a tight seal around the thermometer.

Fever is defined as an oral temperature >37.8°C (100°F), an axillary temperature >37.2°C (99.0°F), or in children <5 years of age, a rectal temperature >38°C (100.4°F). (*Fahrenheit temperatures can be converted to or from centigrade temperatures by the formula: °F = 1.8°C + 32.*)

Children with fevers might not have other signs or symptoms of an illness. *Any child <2 months of age* who develops a fever (e.g., rectal temperature >100°F) requires a

complete evaluation (e.g., blood culture, urinalysis) because clinical manifestations of a serious infection often are subtle, nonspecific, and not predictive of the extent or severity of illness. In this situation, antibiotic therapy usually is initiated while awaiting laboratory results. *Children 6 to 24 months of age* with a temperature >38.9°C (102°F) and white blood cell (WBC) counts <5,000/mm³ or >15,000/mm³ are at increased risk for bacteremia. *Children of any age* with fever >41°C should be evaluated not only for bacteremia, but also for possible meningitis. Blood cultures, lumbar puncture, urinalysis, and chest radiograph should be considered on an individual basis to help determine the etiology of infection. *Febrile immunocompromised children* and *febrile children with functional or anatomic asplenia* are at increased risk for sepsis or fulminant infections (e.g., *Streptococcus pneumoniae*, *Salmonella* species, *Escherichia coli*) and should receive prompt antibiotic therapy.¹³

4. R.B., a 12-month-old, 10-kg baby boy was well yesterday until his mother noticed that he felt warm to her touch later in the afternoon. For the past 24 hours, he has remained warm, is fussy and less active. A rectal temperature 15 minutes ago was 39°C. His mother is concerned R.B.'s temperature will continue to rise. When do fevers progress into febrile seizures? How should R.B.'s febrile illness be treated?

Risk of Febrile Seizures

Febrile seizures occur in approximately 2% to 4% of children 6 months to 5 years of age who have temperature elevations >38°C.¹⁴ The etiology and pathogenesis are unknown, but the temperature and the rate of temperature increase appear to be important factors.¹⁵ Genetic predisposition also appears to be a factor because febrile seizures occur with greater frequency among family members.¹⁴ Febrile seizures are of two types: simple and complex. Simple febrile seizures last <15 minutes and do not have significant focal features. Complex febrile seizures have a longer duration, occur in series, and are associated with focal changes. Typically, febrile seizures occur within the first 24 hours of a febrile episode.¹⁴ Although R.B. is in the age group at greatest risk for having a febrile seizure, he has been febrile for more than 24 hours and a seizure is unlikely during this illness.

Treatment

ANTIPYRETIC THERAPY

Acetaminophen is the most common antipyretic agent used in children. The usual dose, oral or rectal, is 10 to 15 mg/kg/dose administered every 4 to 6 hours as needed to a maximum of 65 mg/kg/day.

Ibuprofen is administered as 5 to 10 mg/kg/dose orally every 6 to 8 hours as needed to a maximum of 40 mg/kg/day. Ibuprofen is as effective as acetaminophen as an antipyretic and is associated with a low incidence of adverse effects.^{16,17} Although renal failure has been reported after ibuprofen use in children,^{18,19} the risk of renal impairment is small with short-term use and not greater than that with acetaminophen.^{17,19}

Acetaminophen or ibuprofen should be effective in lowering R.B.'s fever. Acetaminophen typically is considered to be a first-line drug in children. Dosing errors have occurred when teaspoonful quantities of acetaminophen infant drops (80 mg/0.8 mL) were given instead of the liquid formulation

(160 mg/5 mL) or when regular strength tablets (325 mg) have been substituted for chewable children's tablets (160 mg). Caretakers should be questioned about the dosage form of acetaminophen they have at home, concurrent use of any other products containing acetaminophen, and whether cumulative doses are within the recommended range. Ibuprofen, an alternative to acetaminophen for R.B., is available in two liquid formulations (infant drops, 50 mg/1.25 mL; children's suspension, 100 mg/5 mL) and two chewable tablet dosage formulations (50 mg, 100 mg). Adverse effects are limited when ibuprofen is used in recommended doses for short-term antipyresis. Although some practitioners may alternate acetaminophen and ibuprofen during the day, no data are available to support the efficacy or safety of combination therapy. Aspirin therapy is not recommended for treatment of fever in children or adolescents with chickenpox, gastroenteritis, or respiratory viral infections because of its association with Reye's syndrome.²⁰

Cough and Cold

Another common diagnosis in children is viral upper respiratory infection or the common cold.²¹ Preschool children have between three and nine colds each year.²¹ Children with a cold often present with sore throat, nasal congestion, rhinorrhea, sneezing, cough, and irritability.

Clinical Presentation and Treatment

5. J.K. is a 3-month-old infant who began having nasal congestion, rhinorrhea, and cough yesterday. She has had no fever and is eating well, but did not sleep well last evening. J.K.'s mother called her pediatrician and was told that J.K. most likely has a cold caused by a virus. How can J.K.'s symptoms be treated?

A cool mist humidifier can increase the amount of moisture in room air and decrease irritation in the upper airway when humidity is low. Saline nose drops followed by bulb suctioning can help to clear the nasal passages in J.K. who is <6 months of age.²¹ It is especially important to do this before feedings. If a topical nasal decongestant is needed, phenylephrine would be preferred over oxymetazoline and xylometazoline, because of its lesser association with toxicity (e.g., sedation, convulsions, insomnia, coma) in children <6 years of age.^{22,23} A decongestant, however, should not be prescribed for J.K. because of her age and the potential for adverse effects.

Several hundred over-the-counter medications for upper respiratory symptoms are available and about 95 million units of these products are sold each year in the United States. Nevertheless, the safety and effectiveness of these cough and cold medications in children have yet to be proved.^{24a} The Centers for Disease Control and Prevention (CDC) reported that 1,519 children <2 years of age were admitted to Emergency Departments in 2004 to 2005 because of overdoses and other problems associated with cough and cold medicines. Furthermore, according to the FDA, 54 deaths in children were linked to the use of decongestants (e.g., pseudoephedrine, phenylephrine, ephedrine) and 69 deaths to antihistamines (e.g., diphenhydramine, brompheniramine, chlorpheniramine) from 1969 to September 13, 2006. Most of these deaths occurred in children <2 years of age, and some of the fatalities occurred in children who received overdoses that might have been the re-

sult of inadvertent administration of multiple medications containing the same ingredient. Antihistamines are not effective for rhinorrhea caused by the common cold and should not be recommended. Antitussives also should not be used if the child's cough is productive, but might be helpful if a cough is dry and interferes with activities or sleep.²¹ Nevertheless, cough suppressant formulations for children, including dextromethorphan or diphenhydramine, have not been proven to be beneficial when compared with placebo. An FDA advisory committee in 2007 voted 13 to 9 to recommend that over-the-counter cold and cough medications not be used in children <6 years of age.^{24a} Expectorants, such as guaifenesin, also are not effective and evidence is insufficient to support the use of vitamin C, zinc, or echinacea in children for treatment or prevention of the common cold.

Owing to reports of toxicity and death related to over-the-counter cough and cold products, the CDC has recommended that caregivers avoid giving these products to children <2 years of age unless advised by a clinician.²⁴ In 2007, pharmaceutical manufacturers already had begun preemptively to stop selling versions of these medications (i.e., over-the-counter decongestants, antihistamines, and cough suppressants) aimed at infants <2 years of age. If deemed necessary by a physician for older children, nonprescription cough and cold medications containing single ingredients should be selected to minimize the potential for adverse effects and administration of multiple products with similar ingredients.

Constipation

Constipation, accounting for approximately 3% of general pediatric office visits,²⁵ can be defined as a stool frequency of less than 3 per week or occurrence of pain on defecation (signifying hard stools).²⁵ Beyond the neonatal period, constipation is most commonly idiopathic or functional and may be due to a diet low in fiber, lack of time or routine for toileting, or passage of a painful stool resulting in a fear of defecating. Stool retention over time may result in soiling or encopresis.

Clinical Presentation and Treatment

6. R.J., a 2-year-old boy, has had abdominal pain for several weeks. On average he has one stool weekly and he cries each time because of pain. After obtaining a thorough history and performing a physical examination, the physician determines that R.J. has functional constipation. What treatment measures should be taken to relieve and prevent R.J.'s constipation?

Before maintenance therapy can be initiated, disimpaction of the patient is necessary first. Although no controlled studies compare efficacy of the oral and rectal routes, oral therapy (mineral oil, polyethylene glycol, bisacodyl) is preferred because it is less invasive and might achieve better adherence than rectal therapy (phosphate soda enemas, mineral oil enemas, glycerin suppositories in infants, bisacodyl suppositories in older children).²⁶ After disimpaction, a combination of behavioral, dietary, and medication therapies should be initiated to promote regular stool production and prevent reimpaction. Dietary interventions include adequate fluid and fiber intake. Medications (e.g., polyethylene glycol 3350, mineral oil, lactulose, sorbitol) should be titrated to produce one to two soft stools daily; and stimulant laxatives might be needed

Table 93-1 Medications for the Treatment of Constipation^{25,26}

| Medication | Initial Dosage | Comments |
|------------------------|--|---|
| Osmotic Agents | | |
| Lactulose | 1–3 mL/kg/day QD-BID | |
| Sorbitol | 1–3 mL/kg/day QD-BID | Less expensive than lactulose |
| Barley malt extract | 2–10 mL/240 mL of milk or juice daily | Useful for infants drinking from a bottle |
| Magnesium hydroxide | 1–3 mL/kg/day using 400 mg/5 mL | Infants are at risk for hypermagnesemia. |
| Phosphate enema | ≥2 yr of age: 6 mL/kg up to 135 mL | Electrolyte abnormalities more common in children with renal failure or Hirschprung disease. Avoid in children <2 yr. |
| Lubricant | | |
| Mineral oil | >1 yr of age: Disimpaction: 15–30 mL/yr of age up to 240 mL daily Maintenance: 1–3 mL/kg/day | Better tolerated if chilled. Avoid in children <1 yr. Lipoid pneumonia may occur if aspirated. |
| Stimulants | | |
| Senna | 2–6 yr of age: 2.5–7.5 mL/day 6–12 yr of age: 5–15 mL/day | Not recommended for chronic use |
| Bisacodyl | ≥2 yr old: 0.5–1 suppository or 1–3 tablets per dose | Not recommended for chronic use |
| Glycerin suppositories | 1 suppository per dose | Preferred stimulant for children <2 yr of age |

BID, twice daily; QD, every day.

intermittently. The recommended dosing of medications for treatment of constipation is listed in Table 93-1.

Vomiting and Diarrhea

Vomiting and diarrhea, two commonly encountered complaints in pediatric practice, usually are self-limiting, but severe cases can result in serious complications (e.g., dehydration, metabolic disturbances, and even death). Infants and young children are particularly susceptible to more severe complications.

Pathogenesis and Presentation of Vomiting

Vomiting or emesis is defined as forceful expulsion of gastrointestinal (GI) contents through the mouth or nose; non-forceful expulsion of GI contents is considered regurgitation. In newborns, regurgitation of small amounts of breast milk or formula after feeding, especially when burping, is common. In most cases, regurgitation usually resolves by 1 year of age and rarely causes a problem.²⁷ Extensive evaluation of regurgitation is not needed in a child who is growing well. Other causes of vomiting during the newborn period include pyloric stenosis, gastroesophageal reflux, overfeeding, food intolerance, and GI obstruction. Beyond the neonatal period, the most common cause of vomiting is infection. Vomiting in infants and children also can be caused by central nervous system (CNS) disease (e.g., intracranial tumors), metabolic disease (e.g., urea cycle disorder), inflammatory bowel disease, and ulcers. Conditions causing emesis in older infants and children range from viral gastroenteritis to more severe illnesses, such as bowel obstruction or head injury, that require immediate medical attention (Table 93-2).²⁷ Acute vomiting also can result from medication or toxic ingestions. In teenagers, migraine, pregnancy, and psychological disorders (e.g., bulimia) have been associated with vomiting.

Pathogenesis and Presentation of Diarrhea

Diarrhea refers to an increase in frequency, volume, or liquidity of stool when compared with normal bowel movements. In developing countries, diarrhea is a common cause of death. In the United States, approximately 38 million cases of diarrhea will occur annually, resulting in approximately 2 to 4 million physician visits, 220,000 hospitalizations, and about 400 deaths.²⁸

Acute diarrhea in infants and children generally is abrupt in onset, lasts a few days, and usually is caused by viruses. (See Chapter 62, Infectious Diarrhea for infectious diarrhea of other etiologies.) Diarrhea is considered chronic if it is longer than 2 weeks in duration and can be caused by malabsorption, inflammatory disease, alteration of intestinal flora, milk or protein intolerance, and drugs.²⁹

Infants and children are at high risk for morbidity and mortality secondary to diarrhea for several reasons. Dehydration can occur easily as acute net intestinal fluid losses are relatively much greater in young children than in adults. This may result from inefficient transport systems in the developing intestine. In addition, the percent of total body water in children is higher than in adults; thus, they are more susceptible to body fluid shifts. Total body water changes from 80% of total body weight in premature infants to 70% in term infants and 60% in adults. Finally, the renal capacity to compensate for fluid and electrolyte imbalances in the infant is limited compared with an adult's.³⁰

VIRAL GASTROENTERITIS

7. J.R., a 15-month-old male infant, had one loose stool and began vomiting this morning but has not had a fever. On questioning, you discover that many children attending day care with J.R. are experiencing vomiting, diarrhea, and low-grade temperatures. How should J.R.'s vomiting be treated?

Table 93-2 Causes of Vomiting in Infants and Children²⁷

| <i>Causes</i> | <i>Other Signs and Symptoms</i> |
|---|---|
| Drug Induced | |
| Cancer chemotherapy | Nausea |
| Narcotics | |
| Theophylline/Aminophylline | |
| Antibiotics | |
| Alcohol | |
| Anesthetics | |
| Metabolic or Endocrine Disorders | |
| | Alteration in behavior |
| Infectious Diseases | |
| | Fever |
| Otitis media | Symptoms of otitis media |
| Meningitis | Stiff neck, toxic appearance |
| Appendicitis | Abdominal pain |
| Urinary tract infection or pyelonephritis | Dysuria, frequency and urgency in older children |
| Viral or bacterial gastroenteritis | Diarrhea |
| Mechanical Obstruction | |
| Bowel obstruction | Abdominal distention, green emesis |
| Pyloric stenosis | Projectile nonbilious vomiting Abdominal pain |
| Inflammatory | |
| Pancreatitis | |
| Inflammatory bowel | Diarrhea |
| Peptic ulcer disease | Black or red vomitus |
| Psychologic | |
| Chemotherapy | |
| Bulimia | |
| Miscellaneous | |
| Gastroesophageal reflux | Usually self-limited; indications for evaluation include recurrent pneumonia, poor growth, gastrointestinal blood loss, dysphagia, or heartburn |
| Increased intracranial pressure | Mental status alternation |
| Head injury or trauma | History of trauma, mental status changes |
| Food or milk intolerance | Irritability, loose stool, blood in stool or allergy |

Routine use of antiemetics for acute vomiting in children is not recommended because masking of symptoms may delay diagnosis of a treatable illness. In addition, the safety and efficacy of the antiemetics, metoclopramide, promethazine, trimethobenzamide, and dimenhydrinate have not been demonstrated.^{31,32} Ondansetron does decrease vomiting, and it increases oral intake and decreases the need for intravenous rehydration; however, the cost effectiveness of ondansetron for use in gastroenteritis needs consideration because this drug does not significantly decrease hospital admission.^{32,33}

Parents should be taught the signs and symptoms of gastroenteritis and vomiting that are sufficiently serious to warrant medical attention. A pediatrician should be contacted if a child is toxic appearing, exhibits unusual behavior or signs of an ear infection, experiences abdominal pain or distention, or has red or black vomitus or stool. In addition, a pediatrician should be

called if there is a history or suspicion of toxic ingestion or head trauma. Medical evaluation also is necessary for infants <6 months of age; when persistent vomiting or high volume diarrhea is present; or when chronic medical conditions or prematurity are involved. Because fever can accompany vomiting in viral gastroenteritis, any fever occurring in a neonate warrants medical attention, as well as in older infants and children when fever becomes prolonged or changes in pattern.

When communicating with a health care provider about a vomiting child, it is helpful if the parents have knowledge of the child's fluid intake, and the frequency and volume of vomiting and urination. The amount of vomitus can be estimated by the following rule of thumb: one tablespoon makes a spot four inches wide and a quarter-cup makes a spot approximately 8 inches wide.

Vomiting associated with gastroenteritis usually resolves in 24 to 48 hours. Infants are particularly susceptible to the development of fluid and electrolyte abnormalities; therefore, fluid and electrolyte replacements are critically important (see Question 9).

J.R., who is early in the course of gastroenteritis, must receive sufficient fluids to prevent dehydration. Oral hydration therapy can be successful when given in small volumes, even if J.R. is still vomiting. For example, 5 to 10 mL can be administered every 5–10 minutes, and the volume can be gradually increased as tolerated. Volumes equal to estimated fluid deficit (usually 50–100 mL/kg) should be given over 2 to 4 hours. For each diarrheal stool, an additional 10 mL/kg of oral electrolyte solution should be given. If diarrhea or vomiting recurs, 10 mL/kg and 2 mL/kg of an oral rehydration solution (ORS) can be administered for each stool or emesis, respectively.³¹ J.R.'s clinical condition should continue to be monitored by his caregiver. If stool output exceeds 10 mL/kg/hour, ORS might not be sufficient, and the health care provider should again be contacted. ORS should only be abandoned in children with intractable vomiting, loss of consciousness, bowel obstruction, or if the child is in shock. Most infants will tolerate oral hydration when small amounts are given frequently. Using a spoon or oral syringe to administer the fluid may be more effective than using a nipple or cup. As dehydration is corrected, the frequency of vomiting typically decreases. Once rehydration has been achieved, fluids other than ORS and a diet appropriate for age may be started.³¹ Breast milk or formula should be given as tolerated.

Assessment of Dehydration

8. On the second day of illness, J.R. develops a mild fever and diarrhea that has increased in frequency and water content. How can the severity of J.R.'s diarrhea be assessed? Should he be hospitalized for intravenous (IV) fluid replacement, or can he be treated on an outpatient basis?

To determine whether IV fluid replacement is needed, consider the following questions:

1. Does the child have any of the following signs and symptoms of severe dehydration? Deeply sunken eyes, parched mucous membranes, significantly prolonged capillary refill; cool, mottled extremities; crying without tears; oliguria or anuria; weak or thready pulses; lethargy; poor oral intake;

deep respirations; history of seizures or convulsions; a fever without perspiration, or thirst?

2. Are a large number of copious stools still being produced (>10 mL/kg/hour)? Is bowel obstruction a possibility?
3. Is there a risk of dehydration from inadequate monitoring, or is the parent unable to care for the child? Specific inquiries should be made about the number and consistency of stools in children with diarrhea.

Estimating the degree of dehydration is particularly valuable in assessing the patient with diarrhea: weight loss is a good criterion. A 3% to 9% weight loss is considered mild to moderate dehydration, whereas >9% is considered severe dehydration.³¹ (See Chapter 97, Pediatric Nutrition, for information about IV replacement therapy in children with 10% or more dehydration.)

Oral Replacement Therapy

9. On questioning, J.R. was not considered to be sufficiently dehydrated to warrant hospitalization. How might J.R.'s fluids and electrolytes be managed on an outpatient basis?

The goal of J.R.'s treatment should be focused on the prevention of dehydration and the restoration and maintenance of adequate fluid and electrolyte balance. Mild to moderate diarrhea without dehydration generally is managed at home by continued age-appropriate feeding. Fluid losses in stools can be replaced with a glucose-containing ORS. Glucose provides calories and enhances salt and water absorption in the small intestine through mechanisms that usually are unimpaired in many toxin-induced diarrheas. Parents formerly were instructed to prepare salt and sugar solutions at home; however, frequent errors in the preparation of these solutions resulted in exacerbation of problems with fluid and electrolyte balance. Oral glucose–electrolyte formulations (e.g., Pedialyte), designed to enhance glucose and sodium absorption, are commercially available and should be used in infants and young children. Gatorade is an alternative for older children, but carbonated beverages and fruit juices do not contain sufficient sodium to replace diarrheal losses. Rehydration and maintenance solutions can be made more palatable with sugar-free flavorings (e.g., Kool-Aid, Crystal Lite).

The World Health Organization (WHO) formerly promoted use of an oral replacement solution (WHO formula) containing sodium (90 mEq/L), potassium (20 mEq/L), bicarbonate (30 mEq/L), chloride (80 mEq/L), and 2% glucose for the widespread management of acute diarrhea in third-world countries. The WHO formula, which had a 90% successful rehydration rate for the management of diarrhea, contained a high concentration of sodium because secretory diarrhea (e.g., cholera) is associated with substantial loss of sodium. Malabsorptive diarrheas, such as those associated with rotavirus infections, are associated with much lower loss of sodium (<40 mEq/L). Although commercially available ORS contain less sodium than the WHO formulation, these preparations were equally effective as the WHO formula, even when used to treat the high-sodium losses associated with cholera. Furthermore, these lower sodium-containing formulations were associated with less vomiting, lower stool output, and reduced need for IV infusions in non–cholera-associated gastroenteritis. As a

Table 93-3 Oral Electrolyte Solutions³¹

| Solution | Compositions | | | Osmolarity |
|----------------------|-----------------|--------------------|-----------------------|------------|
| | Sodium (mmol/L) | Potassium (mmol/L) | Carbohydrate (mmol/L) | |
| Rehydration | | | | |
| Rehydralyte | 75 | 20 | 140 | 305 |
| WHO formula (1975) | 90 | 20 | 111 | 311 |
| WHO formula (2002) | 75 | 20 | 75 | 245 |
| Maintenance | | | | |
| Enfalyte | 50 | 25 | 167 | 200 |
| Pedialyte | 45 | 20 | 139 | 250 |
| Home Remedies | | | | |
| Apple juice | 0.4 | 44 | 667 | 730 |
| Gatorade | 20 | 3 | 255 | 330 |
| Ginger ale | 3 | 1 | 500 | 540 |
| Chicken broth | 250 | 8 | | 500 |
| Cola | 1.6 | | 622 | 730 |

WHO, World Health Organization.

result, the WHO, in 2002, promoted a new formulation that consists of 75 mEq/L sodium and a total osmolarity of 245 mOsm/L.³¹ Glucose is added to oral electrolyte solutions to enhance glucose-coupled sodium transport; however, concentrations >3% can impair sodium absorption because the glucose-coupled sodium transport system becomes saturated at this concentration and any additional glucose acts as an osmotically active solute in the bowel lumen. The electrolyte content of commonly used ORS is provided in Table 93-3.

Reinstitution of Oral Feedings

Previously, feeding during an episode of viral gastroenteritis has been delayed because of the malabsorption that typically occurs during and after these bouts. The malabsorption, however, is self-limiting and substantial amounts of carbohydrate, protein, and fat can still be absorbed. The reinstitution of a regular diet, therefore, should not adversely affect mild diarrhea and can be beneficial.³⁴ Parents are encouraged to continue feeding their children using age-appropriate diet while avoiding simple sugars, which can increase osmotic load and worsen diarrhea. Continuation of oral feeding, despite diarrheal episodes, minimizes the development of protein and energy deficits; facilitates the maintenance and repair of intestinal mucosa; promotes recovery of brush border membrane disaccharidases; decreases the duration of illness; and improves nutritional status.^{31,34} Although lactose intolerance can occur with viral gastroenteritis, most children with mild diarrhea can tolerate full-strength animal milk, animal milk-based formula, and breast milk. If the child becomes lactose intolerant during this illness, a lactose-free formula may be substituted for 2 to 6 weeks until GI lactase production returns to normal. Specific diets are often recommended during diarrhea (e.g., BRAT [bananas, rice, applesauce, toast]). Although these diets occasionally can be useful, the nutritional value of these foods is relatively low, and they do not provide optimal nutrition compared with complete diets with fats and proteins.³¹

Drug Therapy

10. What medications can be recommended for the treatment of diarrhea in children?

Medications play a minor role in the treatment of acute infantile diarrhea because most episodes are self-limiting. Antibiotics should be used only when systemic bacteremia is suspected; when immune defenses are compromised; or when a persistent enteric infection is sensitive to antibiotics.³⁵ In general, antidiarrheal preparations are not recommended for infants or children because they have little effect on acute diarrhea, are associated with side effects, and direct attention away from the use of oral hydration therapy.^{31,34} Drugs that alter GI motility should be avoided, especially in children with high fever, toxemia, or bloody mucoid stools, because they may worsen the clinical course of the bacterial infection. Adsorbents, such as Kaopectate, adsorb bacterial toxins and water and lessen the symptoms of diarrhea by producing more formed stools, but they do not decrease the duration of diarrhea or fluid and electrolyte losses. Kaopectate also can adsorb nutrients, enzymes, and antibiotics (especially with prolonged use).³⁴

Probiotics, live microbial foods containing species of lactobacillus, bifidobacterium, saccharomyces, and streptococcus, can improve the balance of intestinal flora and diminish the effect of enteric pathogens. These microbes are thought to exert their beneficial effects through various mechanisms (e.g., producing antibacterial chemicals, competing with enteric pathogens, inhibiting the adhesive capabilities of pathogens, altering toxins or toxin receptors).³⁶ Probiotics are most useful in infectious viral gastroenteritis (but not in bacterial infections) when used early in the course of disease. Lactobacillus GG, in doses of at least 10^6 to 10^9 colony-forming units per day, has been the most consistently beneficial in clinical trials. The manufacture of probiotics is not regulated; therefore, the organism count per dose might be based on the number present at the time of production and not at time of expiration, and the labeling might incorrectly identify the species of organism. As a result, the efficacy of probiotics is difficult to ascertain reliably. Probiotics are not recommended for use in immunocompromised individuals because systemic infections after use have been reported.^{31,36} Zinc supplementation holds promise for the treatment and prevention of diarrheal disease; however, its mechanism of action, best method of administration, and its efficacy in different populations are unclear.³¹

GASTROESOPHAGEAL REFLUX

Gastroesophageal reflux (GER) is a common disorder, with 50% to 67% of infants experiencing recurrent vomiting and regurgitation during the first 4 months of life.³⁷ Most reflux in infants is believed to be caused by transient relaxations of the lower esophageal sphincter (LES). Infants also might be predisposed to reflux because of their body positioning (e.g., slumped over in a car seat or lying supine); their consumption of a liquid feeding that exceeds the volume capacity of the stomach; and in premature infants, a decrease in peristaltic activity.³⁸ Infants and young children also might have undiagnosed underlying conditions that predisposes them to reflux (e.g., neurologic disorders, hiatal hernia, hypertrophic pyloric

stenosis, cow's milk protein allergy).⁴⁰ Of cases of reflux in infants, 80% are benign and resolve by 18 months of age,³⁹ and reflux in older children resolves in a timeframe similar to that of adults. If untreated, GER can result in esophageal strictures; GI hemorrhage; or chronic respiratory disease from the aspiration of GI contents. Children with asthma are noted to have an increased incidence of GER.⁴¹

Clinical Presentation

In infants, the vomiting and regurgitation of GER occur frequently and other symptoms often are nonspecific (e.g., failure to thrive [FTT], recurrent pneumonia, apnea, dysphagia, reactive airway disease, apparent life-threatening events [ALTE], hematemesis, anemia).⁴⁰⁻⁴² A thorough diagnostic workup generally is not necessary in a healthy infant with functional GER presenting as recurrent vomiting; empiric drug therapy can be initiated after the diagnosis is made based on clinical findings and after other causes of vomiting have been eliminated.^{40,43} Further diagnostic evaluations, however, are indicated for infants and children presenting with additional symptoms (e.g., FTT, irritability, ALTE, respiratory difficulties).⁴³ Currently, esophageal pH monitoring is considered the standard of practice for diagnosis of GER and endoscopic biopsy when mucosal abnormalities are noted.^{41,43} Multichannel intraluminal impedance measurements could replace these techniques.⁴⁴ Further evaluations (e.g., barium contrast radiography) might be necessary if anatomic abnormalities (e.g., strictures, pyloric stenosis) are suspected.⁴³

Treatment

Because uncomplicated GER usually resolves spontaneously in infants, therapy should focus on providing symptom relief and maintaining normal growth.⁴³ The goals of therapy are to heal esophagitis and prevent complications in infants and children with pathologic GER so that surgery can be avoided.⁴³ Infants and young children with underlying neurologic problems (e.g., cerebral palsy) are unlikely to have spontaneous resolutions of GER and frequently require aggressive antireflux therapies and surgical intervention.

Positional and Dietary Measures

11. S.B., a 3-month-old, 6-kg, 60-cm male infant, has a 2-week history of regurgitation after each feeding. The pediatrician noted that S.B. had not gained weight since his last visit 1 month earlier. The presumptive diagnosis is FTT secondary to GER, and S.B. was referred to a pediatric gastroenterologist. The gastroenterologist admitted S.B. to the hospital and confirmed the diagnosis using 24-hour pH monitoring. How should S.B. be treated initially?

S.B. can be treated conservatively because he does not present with life-threatening complications.⁴³ First, caregiver feedings should be observed to rule out regurgitation caused either by overfeeding or by inappropriate feeding techniques. Sometimes infants with milk protein allergies can have a similar clinical presentation; therefore, a change to a soy protein formula or hypoallergenic formula should be tried.⁴¹ Interventions to modify an infant's body positioning or to modify infant feedings with milk thickeners are not proved to be effective,

Table 93-4 Oral Drugs Used to Treat GER in Infants^{42,43,46,49,52-57,60,134,135-137,138,139-141}

| <i>Agent</i> | <i>Mode of Action</i> | <i>Oral Dosage</i> |
|---|--|--|
| Acid Suppressing Agents | | |
| Antacids (aluminum or magnesium hydroxide) | Neutralizes acid; | 0.5–1.0 mL/kg/dose before and after feeding (maximum, 15 mL/dose) |
| Proton Pump Inhibitors | ↓ acid secretion via inhibition of gastric hydrogen-potassium adenosine triphosphatase | 1 mg/kg/day divided daily–BID 5–10 mg daily (1–5 yr) 10–20 mg daily (6–11 yr) 15 mg daily (weight <30 kg) 30 mg daily (weight >30 kg) 20 mg daily (0.5–1 mg/kg/day) |
| Omeprazole | | |
| Esomeprazole | | |
| Lansoprazole | | |
| Pantoprazole | | |
| H₂ Receptor Antagonists | | |
| | Blocks H ₂ -receptors; ↓ acid secretion | |
| Cimetidine | | 40 mg/kg/day divided QID |
| Famotidine | | 0.5–1 mg/kg/day div daily–BID |
| Nizatidine | | 5–10 mg/kg/day divided BID |
| Ranitidine | | 5–10 mg/kg/day divided TID–QID |
| Prokinetic Agents | | |
| Bethanechol | Cholinergic agent; stimulates peristalsis ↑ ↑ LES pressure; ↑ gastric emptying; ↑ colonic motility ↑ gastric emptying; ↑ LES pressure; augments esophageal clearance | 0.1–0.2 mg/kg/dose QID given 30–60 min before feeding and HS |
| Cisapride | | 0.8 mg/kg/day divided QID |
| Metoclopramide | | 0.1–0.2 mg/kg/dose QID given 30 min before feeding and HS |
| Erythromycin | Motilin agonist stimulates smooth muscle contraction | 1–3 mg/kg/dose QID |
| Surface Active Agents | | |
| Sucralfate | Forms paste and adheres to damaged esophageal mucosa | 40–80 mg/kg/day divided QID |

BID, twice daily; GER, gastroesophageal reflux; HS, at bedtime; LES, lower esophageal sphincter; QID, four times daily; TID, three times daily.

but are reasonable to undertake.^{40–45} Maintaining S.B. at a 60-degree angle during the day while sitting and at a 30-degree position at night should be implemented in an effort to promote clearance of acid from the esophagus and to minimize reflux after meals. Milk thickeners (most commonly rice cereal in the United States) and more frequent, smaller feedings also are worthwhile interventions. Mild cases of GER often can be treated successfully by dietary measures alone, as well as by propping infants in an upright position during, and 1 hour after, feedings. Although the placement of infants in a face-down prone position during sleep can reduce reflux, the greater risk of sudden infant death syndrome (SIDS) in infants <12 months of age outweighs the benefits of such positioning.⁴¹ Older children and adolescents should follow the recommended dietary guidelines (i.e., avoidance of caffeine, chocolate, spicy foods) for adults.

Drug Therapy

The efficacy of pharmacologic therapy in altering the course of uncomplicated GER in infants has not been proved⁴³; however, a therapeutic trial of a prokinetic agent to manage recurrent vomiting in an infant with uncomplicated GER seems reasonable. In infants or children who present with nonspecific symptoms or complications, such as S.B., acid suppression therapy or prokinetic therapy is warranted even in the absence of documented esophagitis.⁴³ When esophagitis is present, acid suppression is always recommended to aid in the healing process; however, these agents alone do not rectify the causes of

the GER.⁴³ The various agents to treat infant GER are listed in Table 93-4.

ACID-SUPPRESSANT AGENTS

Antacids

Antacid therapy is not recommended for the treatment of GER in infants and young children because infants treated with aluminum-containing antacids can accumulate sufficient aluminum to cause osteopenia and neurotoxicity.^{41–43,46,47} In addition, information on other antacids in infants is limited; nevertheless, antacids can provide short-term relief of symptoms in older children and adults.

Proton-Pump Inhibitors

Proton-pump inhibitors (PPI) are superior to histamine₂-receptor antagonists (H₂RA) in relieving symptoms and in promoting healing of significant esophagitis from GER in infants, young children, and adults.^{43,48,49} PPI control both basal and meal-stimulated acid secretion, which may in part explain their superior efficacy. The incidence of adverse effects in children from PPI is similar to that reported in adults.⁴⁹ Despite concerns about the long-term use of PPI, untoward effects have not been observed from their use for up to 11 years.⁵⁰ In children, increased metabolism and decreased bioavailability necessitate larger milligram per kilogram doses to maintain acid suppression than adults; thus, titration of dose to response is necessary, particularly for treatment of esophageal erosions.^{44,51} Although most clinicians dose PPI once a day, multiple,

divided daily doses can prevent acid breakthrough and better promote healing.⁴⁸ Omeprazole and lansoprazole are available in extended-release capsules, which can be separated, opened, and sprinkled on soft foods. Lansoprazole also is available as granules for an oral suspension. Suspension formulations for both omeprazole and lansoprazole have been extemporaneously compounded and evaluated for stability.

Histamine₂-Receptor Antagonists

Histamine₂-receptor antagonists (H₂RA) reduce histamine-stimulated acid secretion, but have limited effects on acid secretion by other chemical mediators and other stimuli. In randomized, controlled trials, H₂RA in infants and children relieved symptoms and facilitated the healing of esophageal tissue.^{52,53} Tolerance to the acid suppressant activity of H₂RA over a relatively short time (<30 days), however,^{54,55} can limit their use for long-term treatment of esophagitis. Oral liquid formulations are available for most H₂RA. Ranitidine also is available in an effervescent tablet to facilitate compliance.

PROKINETIC AGENTS

Metoclopramide, a dopamine antagonist with cholinergic and serotonergic effects, accelerates gastric emptying, increases LES pressure, enhances esophageal clearance, and accelerates transit time in the small bowel; however, its effects on vomiting and esophageal pH in children with GER has been equivocal.^{56,57} Additionally, metoclopramide has been associated with significant CNS (i.e., restlessness, drowsiness, extrapyramidal) effects and rare reports of gynecomastia and galactorrhea. The prokinetic drug, *cisapride*, is not available in the United States; however, it can be obtained via a limited access protocol for children in whom conventional therapy has failed.⁴³ *Domperidone*, another prokinetic agent, also has been associated with limited benefits for the treatment of GER in infants.⁵⁸ *Erythromycin* increases GI motility by increasing smooth muscle contractions through its motilin agonistic activity, and has been used as a prokinetic agent for GER in children when acid suppression therapy alone was ineffective.⁵⁹ Erythromycin-induced development of infantile hypertrophic pyloric stenosis, arrhythmias, and potential changes in bacterial resistance patterns, however, limit its use for GER. The cholinergic agonist, *bethanechol*, reportedly reduces vomiting episodes in infants with GER;^{43,60} however, its role in treating GER in infants is limited because of its potential to induce bronchospasm and to stimulate gastric acid secretion. The lack of a suitable commercially available formulation of bethanechol for young infants necessitates its extemporaneous compounding. *Baclofen*, which decreases transient LES relaxations through its γ -aminobutyric acid (GABA) agonist actions, could be a future therapeutic option for GER, pending further study.⁶¹ Generally, prokinetic agents only are marginally effective in the management of GER.

SURFACE ACTIVE AGENTS

Sucralfate (Chapter 26, Upper Gastrointestinal Disorders) was equally effective as cimetidine for use in esophagitis⁶²; however, its use for GER is more limiting because of concern about the adverse effects of aluminum-containing products in infants.

12. Four weeks after instituting positional and dietary measures, S.B. continues to vomit and still has not been gaining weight.

On physical examination, the gastroenterologist notes bilateral wheezes; endoscopy rules out esophagitis. What would be the next step of therapy?

The treatment of S.B. can include acid suppression therapy and a prokinetic agent. Acid suppression therapy in children who have complications from GER can be implemented by a “step up” approach in which treatment is initiated with a H₂RA followed by a PPI if no improvement is noted, or through a “step down” approach involving a PPI followed by an H₂RA for maintenance therapy.⁴³ No evidence supports the preferential use of one H₂RA or PPI versus another; however, most pediatric gastroenterologists prefer to use PPI.

The effectiveness of acid suppression for managing symptoms of GER in children is not as well documented as it is for healing esophagitis; however, acid suppression is believed to play a useful role for symptom control, particularly for managing the respiratory symptoms.⁴³ If additional symptom control is desired, metoclopramide 0.6 mg (0.1 mg/kg/dose) four times daily, 30 minutes before meals and at bedtime can be initiated for S.B. This dose can be adjusted based on his response, with close observation for adverse effects. Treatment should be continued for at least 3 to 4 months, although the optimal duration of therapy is unknown. If S.B. requires additional drug therapy to control symptoms of GER beyond 18 months to 2 years of age, surgery should be considered because GER is unlikely to resolve spontaneously after this age.³⁹ Surgery might be considered earlier if S.B. fails medical therapy or if he develops an esophageal stricture, apnea, or recurrent respiratory disease.^{39,43}

SEDATION AND ANALGESIA

Sedation

Conscious Sedation

Sedation often is needed for children who must undergo diagnostic or therapeutic procedures or when placed in an intensive care setting. Table 93-5 lists characteristics of drugs commonly used to produce conscious sedation. In general, the IV administration of drugs provides the most rapid onset of action. The absorption of intramuscularly (IM), rectally, or orally administered sedatives can be variable, especially in infants and young children.⁶³

13. A.J., a 3-year-old, 15-kg girl, is admitted for evaluation of abdominal mass. A computed tomography scan is ordered. What regimen should be used to sedate A.J.?

The ideal sedative should be easy to administer, and have (a) a rapid and predictable onset, (b) minimal adverse effects, and (c) a duration of action that approximates the duration of many common medical procedures. Chloral hydrate, barbiturates (e.g., pentobarbital), narcotic analgesics (e.g., morphine, fentanyl), benzodiazepines (e.g., midazolam, lorazepam), and anesthetic agents (e.g., propofol, ketamine) can be used in pediatric patients for short-duration diagnostic procedures.

Although *chloral hydrate* had been used for sedation for many years without evidence of problems, it has not been tested extensively for toxicity or efficacy.⁶⁴ Several years ago, the potential carcinogenicity and genotoxicity of chloral hydrate became of concern because it is a metabolite of trichloroethylene, an industrial solvent and cleaning fluid, which has induced can-

Table 93-5 Drugs Commonly Used for Conscious Sedation^{67,71}

| Drug | Dosage ^a | Onset of Action | Duration | Comments |
|--|--|---|---|---|
| Chloral hydrate | 25–75 mg/kg (maximum, 1 g/dose to a total of 2 g) Route: PO, PR | 20–30 min | Unpredictable | Rapidly metabolized to active metabolite trichloroethanol; paradoxical excitation may occur; hyperbilirubinemia has been associated with chloral hydrate (repeated doses) in premature infants and neonates; absorption erratic when given PR |
| Diazepam (Valium) | IV: 0.04–0.3 mg/kg (maximum: 10 mg) PO: 0.2–0.3 (maximum: 10 mg) | IV: 2–3 min PO: 30–45 min | 2–6 hr | May burn when given IV (lipid soluble); do not use small veins; infuse IV over 3 min and at most 5 mg/min; potentiates the effect of narcotics and barbiturates |
| Fentanyl (Sublimaze) | IV: 1–2 mcg/kg (up to 100 mcg/dose) PO: 5–15 mcg/kg (maximum: 400 mcg) | IV: 1–1.5 min IM: 7–8 min PO: 5–15 min | IV: 30–60 min IM: 1–2 hr PO: 1–2 hr | Infuse IV over 3–5 min; effects potentiated by benzodiazepines; Oralet available in 200-, 300-, and 400-mcg doses Maximal dose is 400 mcg. Only about 25% of dose of Actiq is absorbed from the oral mucosa |
| Lorazepam (Ativan) | IV: 0.05 mg/kg PO: 0.02–0.1 mg/kg | IV: 2–5 min IM: 15–30 min PO: 30–60 min | 6–24 hr | Infuse IV over 2–3 min, not to exceed 2 mg/min; potentiates the effect of narcotics and barbiturates |
| Meperidine (Demerol) | IV: 0.5–1.5 mg/kg SC/IM: 1–2 mg/kg (maximum, 100 mg/dose) See combination drugs below for Demerol/Phenergan/Thorazine dosage | IV: 1–5 min SC/IM: 10 min | IV: 1–2 SC/IM: 2–4 hr | Metabolite (normeperidine) has neurotoxic effect; accumulation of normeperidine may result in central nervous system manifestation; caution in patients with renal impairment after high or repeated doses; infuse IV dose over 3–5 min |
| Midazolam (Versed) | IV: 0.05–0.1 mg/kg Intranasal: 0.2–0.3 mg/kg PO: 0.25–0.5 (maximum: 20 mg) | IV: 1–3 min IM: 10–15 min Intranasal: 5 min PO: 5–10 min | IV: 30–60 min IM: 2–6 hr Intranasal: 40–75 min PO: 30–90 min | 3–4 times potency of diazepam; potentiates the effect of narcotics; infuse IV dose over 1–2 min |
| Morphine | IV: 0.05–0.1 mg/kg | IV: 1.0–2.5 min | 1–2 hr | Maximal respiratory depression occurs within 7 min; effect potentiated by benzodiazepines; infuse IV dose over 3–5 min |
| Pentobarbital (Nembutal) | PO/PR/IM: 2–6 mg/kg (maximum, 100 mg/dose) IV: 1–3 mg/kg in increments of 1 mg/kg (maximum: 100 mg/dose) | PO/PR: 15–60 min IM: 10–25 min IV: 1–2 min | PO/PR: 1–4 hr IM: 30–60 min IV: 15–20 min | IV administration over at least 1 min or not to exceed 50 mg/min |
| Propofol (Diprivan) | IV: ≥ 2.5 mg/kg \times 1 7.5–15 mg/kg/hr | IV: 30 sec after bolus | 3–10 min, longer with prolonged use | Titrate to desired effect; lower dosages required when used with narcotics; metabolic acidosis with fatal cardiac failure has been reported in children |
| Combination drugs Demerol/ Phenergan/ Thorazine | IM: Demerol: 2 mg/kg (up to 50 mg) Phenergan: 1 mg/kg (up to 12.5 mg) Thorazine: 1 mg/kg (up to 12.5 mg) IV: 1/2 of IM dose | IM: 10–15 min IV: 5–10 min | 2–5 hr | Infuse IV dose over 5 min; hypotension can occur with rapid IV infusion; may be mixed in the same syringe |
| Ketamine | IV: 0.5–2 mg/kg IM: 3–7 mg/kg PO: 6–10 mg/kg | IV: 30 sec IM: 10–15 min PO: 30 min | IV: 1–2 hr IM: 3–4 hr | Can result in hallucinogenic emergence reactions; less common in younger patients, can be managed in part with benzodiazepines; can cause bronchial secretions |
| Etomidate | IV: 0.1–0.3 mg/kg | IV: 30–60 sec | IV: 2–10 min; dose dependent | Blocks cortisol production; avoid in critically ill patients and prolonged infusions; myoclonus seen in up to 33% of patients; no analgesic activity, use with opioid |
| Dexmedetomidine | IV: 0.5–1 mcg/kg loading dose, then 0.2–0.7 mcg/kg/hr infusion | IV: analgesia, ~30 min | IV: 2–3 hr | Sedative and analgesic properties; hypotension common |

^aUse low end of the dose if combined with another agent(s).

IM, intramuscular; IV, intravenous; PO, orally; PR, as needed; SC, subcutaneously.

cer in rodents.⁶⁵ Because the extrapolation of animal data to humans is only theoretical, the American Academy of Pediatrics (AAP) continues to support chloral hydrate use because many practitioners are familiar with the use of this drug and because it is associated with a low incidence of toxicity. A sudden switch by practitioners from chloral hydrate to a less familiar agent might pose a greater risk than a theoretic risk of carcinogenesis.⁶⁶ Practitioners, nevertheless, should become increasingly familiar with sedating agents other than chloral hydrate, especially for situations when chloral hydrate fails to produce the desired effect. The risks of chloral hydrate in pediatric patients needs further study. Chloral hydrate 25 to 75 mg/kg can be repeated in 30 minutes if needed to a maximal total dose of 120 mg/kg, or 1 g for infants and 2 g for older children.⁶⁷ Most children respond to 50 to 75 mg/kg; however, dose requirements can vary.^{66,68-70} Repetitive dosing of chloral hydrate to maintain prolonged sedation in infants and children during mechanical ventilation is not recommended because its pharmacologically active metabolites can accumulate and cause excessive CNS depression and other complications.^{64,66} Chloral hydrate can be particularly useful for sedating infants and children in preparation for electroencephalogram and pulmonary function tests.⁷¹

Pentobarbital induces sedation in children more rapidly than chloral hydrate and has shorter duration of action. A lower milligram per kilogram dose of pentobarbital is needed in older patients than younger infants and children. Intravenous pentobarbital should be given in 1 mg/kg increments to minimize risk of respiratory depression. In clinical trials, pentobarbital has compared favorably with chloral hydrate for sedation before imaging studies.^{72,73} Paradoxical reactions (e.g., excitation and hyperactivity) can occur with barbiturates; however, the administration of a narcotic (e.g., morphine) to the excited child can convert the reaction to a peaceful sedation.

Morphine and *fentanyl* can provide both sedation and analgesia in patients undergoing painful procedures (e.g., bone marrow biopsy). Narcotics, however, rarely are used alone for sedation because analgesia occurs at lower doses than those required for sedation. Fentanyl oral lozenge (Actiq) is available in 200, 400, 600, 800, 1200, and 1600 mcg strengths for the child to suck on the flavored lozenge until he or she falls asleep. Some clinicians, however, are uncomfortable with the psychological association of candylike preparations with drugs. Comparisons of oral transmucosal fentanyl with oral midazolam as premedication sedatives have shown mixed results.^{74,75} Narcotic analgesics can induce respiratory depression (especially when combined with benzodiazepines), however, the respiratory depression can be reversed by naloxone.⁷⁶ Fentanyl is usually the preferred agent because of its shorter duration of action, shorter recovery time, and relative lack of tendency to cause histamine-release related side effects.⁷¹

Benzodiazepines (i.e., lorazepam, diazepam, and midazolam) can induce sedation, hypnosis, muscle relaxation, and amnesia, and can decrease anxiety in patients undergoing procedures.⁷⁶ These benzodiazepines usually are administered IV before the procedure, although midazolam also has successfully induced sedation when administered orally, rectally, or intranasally.⁷¹ Flumazenil, a specific benzodiazepine antagonist, can reverse the sedative effects of benzodiazepines.⁷⁷

Propofol, an anesthetic agent, appears safe as a sedative for elective pediatric procedures. It is as effective as other

sedatives, and is associated with shorter recovery times and hospital stays.^{71,78,80} Transient hypotension and severe respiratory depression can occur, however, and the patient should be closely monitored.⁷¹ Because propofol administration generally requires anesthesiology support and because opioid-benzodiazepine combinations often result in prolonged sedation, the dissociative anesthetic, *ketamine* has been used as an adjunct to benzodiazepines for procedures in children and compares favorably with opioid-benzodiazepine combinations.^{79,81,82} Adverse effects associated with ketamine include increased bronchial secretions, hypertension, and increased muscle tone; older children have experienced hallucinations or vivid and disturbing dreams. *Etomidate*, an ultrashort-acting hypnotic is effective for procedural sedation in children, however, it has been associated with respiratory depression, clonus, and adrenal suppression.⁷¹ As a result, propofol remains as the ultrashort-acting agent of choice in most situations.⁷¹ *Dexmedetomidine*, a centrally acting α_2 -receptor agonist, has compared favorably with other agents used for conscious sedation in noninvasive procedures, but it might not be as effective as propofol or other agents for invasive procedures.⁸³ Dexmedetomidine does not affect respiratory or circulatory function to the same extent as propofol,⁷¹ but unlike propofol, a maintenance infusion is needed to supplement the bolus dose.

Any one particular sedative combination has not been shown to be superior to any another. The medication(s) of choice for conscious sedation in children, therefore, usually depend on the type of procedure, degree of sedation required, age of the patient, clinical status of the patient, anatomic location of the procedure, and the expertise of the staff administering the agents. For A.J., any of the above regimens could be appropriate. If anesthesiology support is available, propofol would be a good choice given its safety profile during short-term procedures and the rapid recovery time associated with its use. Nevertheless, chloral hydrate, pentobarbital, an opioid-benzodiazepine combination (e.g., fentanyl-midazolam), ketamine alone or in combination with benzodiazepines, and possibly etomidate and dexmedetomidine, would be appropriate choices as well. Serious adverse events do not appear to be related to medication class or route of administration, although an association exists with adverse outcome when three or more medications are used.⁸⁴ Any previous history of successful sedation also can be helpful in the selection of sedation for a patient. The patient should be monitored closely during and after the procedure, and adequate personnel and resuscitation equipment should be readily available.⁸⁵

Intensive Care Unit Sedation

14. M.P., a 5-year-old boy, is admitted to the pediatric intensive care unit (ICU) for sepsis. He currently is intubated and receiving a neuromuscular blocking agent. What are the considerations when sedating critically ill patients such as M.P.?

Children who require mechanical ventilation commonly receive medication to induce sedation to obviate resistance from the patient during ventilator manipulations. Children who receive drugs to induce paralysis also generally need adequate sedation to minimize the fear associated with being aware but unable to move. Critically ill children often require constant sedation; therefore, medication should be

administered on a set schedule or as a continuous IV infusion rather than on an as needed (PRN) basis. Intermittent administration results in peak and trough effects, whereas continuous infusions provide a more constant serum concentration and more constant sedation. Incompatibility with other IV medications, however, often can be a problem with continuous IV infusions. IM administration of sedation medications should be avoided because of injection pain and erratic absorption in critically ill patients. The oral administration of medications to induce sedation usually is impractical. Clinicians must be diligent in ensuring that sedation for critically ill children is adequate. In one study, 66% of children receiving morphine and midazolam remembered the pediatric intensive care unit (PICU), many recalled pain, and some stated that they were scared and could not sleep.⁸⁶

Propofol, with its a rapid onset of action and quick recovery from sedation on discontinuation, is commonly utilized in the ICU. This drug does not provide analgesia and should be combined with a narcotic when used after a painful procedure. Adequate sedation is usually achieved with a bolus dose followed by a continuous infusion titrated to effect.⁸⁷ Adverse effects of propofol include hypotension, dose-dependent respiratory depression, myoclonus, and seizure activity. Prolonged propofol infusions have been associated with a “propofol-related infusion syndrome” characterized by persistent and worsening metabolic acidosis, cardiovascular instability, arrhythmias often resistant to aggressive management, and fatalities.^{88–92} If propofol is to be used as a continuous infusion in the PICU, the acid base and overall clinical status of the patient needs to be carefully monitored. If prolonged mechanical ventilation is required, agents, such as opioids and benzodiazepines, might be more appropriate.

Children who receive repeated doses of agents for sedation may develop tolerance and require larger doses to achieve the desired effect. In addition, pediatric patients who receive narcotics or benzodiazepines for several days to weeks are at risk for developing symptoms of drug withdrawal.^{93,94}

15. S.C., a 7-year-old boy, is admitted to the hospital after being hit by a car while riding his bicycle. He sustained multiple fractures and has just returned from surgery after an open reduction and internal fixation of his left femur and left humerus. He is tearful and states that he is in a lot of pain. What classes of pain medication are available for use in children? What problems can be anticipated after the use of analgesics in children?

Analgesia

Inadequate pain control in children usually is the result of inaccurate pain assessment or misconceptions about pain. The pain experienced by infants and children often has been treated less aggressively than pain in adults⁹⁵; however, as the effects of pain on psychological, physiologic, and endocrine systems have become better understood, there has been an increased emphasis on ensuring adequate pain control in pediatric patients.⁹⁶

NARCOTIC ANALGESICS

Morphine is one of the most commonly used agents to treat moderate and severe pain in children and the pharmacokinetic parameters of this drug are well established. The elimination

and clearance of morphine in children >5 months of age is similar to that in adults. Neonates demonstrate decreased clearance of morphine and a longer elimination half-life when compared with older infants and children.⁹⁶ In neonates, the prolonged half-life may allow for adequate pain control when using intermittent bolus doses. When morphine is administered intermittently, however, older infants and children will require a shorter dosing interval (e.g., every 2–3 hours). This frequent dosing schedule has led to an increased use of continuous IV morphine infusion, patient-controlled analgesia (PCA), and epidural infusion.

Fentanyl, a popular analgesic because of its rapid onset and short duration of action, is most often administered as a continuous or epidural infusion for the management of postoperative pain. It also is administered as an intermittent bolus for short procedures. Fentanyl is highly lipophilic and rapidly penetrates the blood–brain barrier. Because it has a larger volume of distribution in neonates, infants, and toddlers, higher dosages may be needed to achieve a desired effect. Repeated fentanyl dosing or continuous infusion can lead to the accumulation of this drug.⁹⁶

Codeine often is administered orally in combination with acetaminophen to treat mild to moderate pain. It should not, however, be administered parenterally because parenteral administration offers no advantage over the IM administration of morphine or meperidine and is potentially dangerous. Serious adverse events after IV or IM administration of codeine have occurred in both children and adults.

Adverse Effects of Narcotic Analgesics. At equipotent doses, all narcotic analgesic agents cause a similar degree of respiratory depression and constipation. The side effects of nausea and vomiting from these analgesics often occur secondary to stimulation of the chemoreceptor trigger zone in the brain. Fentanyl produces less sedation than meperidine and morphine. Morphine can produce peripheral vasodilation, which can lead to significant hypotension in hypovolemic patients. Meperidine should be avoided in patients with renal failure because accumulation of its metabolite, normeperidine, has been associated with seizures. The most serious adverse effect after administration of opioid analgesics is respiratory depression. Infants <3 months of age are particularly susceptible because of their immature blood–brain barrier and decreased clearance of narcotics.⁹⁶ Patients receiving concomitant therapy with benzodiazepines or barbiturates may be at increased risk for cardiorespiratory side effects.

Adverse effects associated with epidural administration of morphine include nausea, pruritus, urinary retention, and late respiratory depression. Although late respiratory depression appears to be less common in children than adults, respiratory status should still be monitored carefully for up to 12 hours after administration of morphine.

NON-NARCOTIC ANALGESICS

Acetaminophen, salicylates, or nonsteroidal anti-inflammatory drugs (NSAID) commonly are used for treatment of mild to moderate pain (Table 93-6.) Salicylates and NSAID can have an opioid-sparing effect and are useful in the management of bone pain and pain associated with inflammation. Aspirin is not used routinely in children because of its association with Reye’s syndrome. Ketorolac (Toradol) is the only NSAID available parenterally.^{96,97} Side effects associated with

Table 93-6 Analgesic Agents Used in Children⁶⁷

| Product | Initial Dose | Comments |
|------------------|--|---|
| Nonopioid | | |
| Acetaminophen | 10–15 mg/kg/dose Q 4–6 hr | No anti-inflammatory effect |
| Salicylates | 10–15 mg/kg/dose Q 4–6 hr | Associated with Reye's syndrome; has anti-inflammatory effect |
| NSAIDs | | |
| Ibuprofen | 5–10 mg/kg/dose Q 6–8 hr | Gastritis with prolonged use |
| Naprosyn | 5–7 mg/kg/dose Q 8–12 hr | |
| Ketorolac | Adults: 15–30 mg IM/IV Q 6 hr Children: Not well established; 0.4–1 mg/kg IM/IV Q 6 hr; do not exceed adult dose | Increased risk of bleeding if high doses are used for >5 day |
| Opioids | | |
| Codeine | 0.5–1.0 mg/kg/dose Q 4–6 hr (Adults: 30–60 mg/dose) | Frequently combined with acetaminophen |
| Fentanyl | 1–2 mcg/kg/dose IV/IM (Adults: 50–100 mcg/dose) Infusion: 3–10 mcg/kg/hr | Chest wall rigidity, especially after rapid IV administration |
| Meperidine | IV/IM: 1.0–1.5 mg/kg Q 2–4 hr PO: 1–2 mg/kg Q 3–4 hr (Adults: 50–100 mg/dose) | Active metabolite has neurotoxic effect; avoid in renal failure |
| Morphine | IV: 0.05–0.1 mg/kg/dose Q 2–4 hr IM: 0.1–0.2 mg/kg Q 2–4 hr PO: 0.2–0.5 mg/kg Q 4–6 hr IV infusion: 0.05–0.1 mg/kg/hr | When changing to sustained release formulation, give daily dose as two to three divided doses |

IM, intramuscular; IV, intravenous; NSAID, nonsteroidal anti-inflammatory drug; PO, oral.

salicylates and NSAID are minimal, although gastritis may occur, especially after prolonged use. NSAID also have been associated with renal toxicity.

TOLERANCE AND DRUG WITHDRAWAL

Tolerance can occur in some children receiving several days of narcotic therapy resulting in the need for an increased dose to produce the same pain relief. If the patient continues to have reason for pain, doses should be adjusted accordingly. If narcotics are being used for sedation, an alternative agent should be considered.

Administration Schedules

The choice of drug, dose, frequency, and route of administration must be individualized. As-needed (PRN) dosing schedules are less desirable than scheduled dosing times (around the clock) because patients must endure or complain about pain before receiving analgesia. Generally, less medication is needed to prevent the return of pain than to control it. Continuous IV infusion and scheduled administration of pain medication maintain more constant blood levels and minimizes peak (sedation) and trough (return of pain) effects.

Patient-controlled analgesia (PCA) is an alternative to continuous IV infusion and scheduled administration regimens. PCA allows the patient to administer small bolus doses of analgesia, eliminates the time between pain perception and relief, and gives the patient control over pain therapy. PCA, even in children and adolescents, is safe and effective.⁹⁶ Children as young as 6 years of age can be taught to use PCA devices, although the age of children capable of understanding the concept of PCA will vary. In some instances, nurses or parents (especially when providing palliative care) are allowed to activate analgesia for the patients who are too young or unable to

activate the pump themselves.⁹⁷ If parents are to be allowed to participate, however, education on the appropriate and safe activation of the PCA pump should be provided to them and their actions should be closely supervised by nursing personnel. A low-dose, continuous infusion of a narcotic drug, when combined with PCA, has the benefit of providing baseline pain relief, especially while the patient is sleeping. This combined use, however, can contribute to increased side effects (e.g., hypoxia).⁹⁶

Routes of Administration

Typically, pain medication is administered IV, IM, or orally. The IV route provides the most rapid onset of action. When medication is administered IM, children may deny pain to avoid injections. When changing from parenteral to oral routes of administration, bioavailability and absorption need to be considered. Sustained-release oral formulations may be useful in children with chronic pain, but use of such products often is limited by the ability of the patient to swallow whole tablets and because of “fixed” tablet strengths.

Epidural administration of analgesics can provide pain relief for long periods of time with minimal sedation in children of all ages.⁹⁶ The transdermal fentanyl patch also offers a unique approach to pain control, and may be useful in children with severe cancer pain.⁹⁶ Patches have limited use in young patients because they cannot be cut to deliver smaller doses. Anesthesia also can be achieved through the administration of local anesthetics (e.g., bupivacaine, lidocaine) or narcotics (e.g., morphine, fentanyl).

16. Z.Z., a 15-month-old, 10-kg boy, has been receiving fentanyl continuous infusion for 3 weeks for pain and sedation during mechanical ventilation. The infusion has been decreased from 10 mcg/kg/hour to 1 mcg/kg/hour over the past 5 days. Because

Z.Z. has been successfully extubated and will be transferred to the ward in the morning, the fentanyl drip must be discontinued. Why is Z.Z. at risk for narcotic withdrawal? If Z.Z. develops signs and symptoms of withdrawal, how should these symptoms be managed?

The risk of fentanyl withdrawal is associated with the total dose and duration of the infusion. When the total fentanyl dose is >1.5 mg/kg or the duration of infusion has >5 days, approximately 50% of patients could experience opioid withdrawal symptoms. When the total fentanyl dose is >2.5 mg/kg or the duration of infusion is >9 days, almost all patients will experience withdrawal.⁹⁴ Z.Z. has been receiving fentanyl for 3 weeks; therefore, his risk of withdrawal symptoms is very high.

The fentanyl infusion for Z.Z. should be decreased by 10% every 6 hours, and then converted to an oral narcotic. Once Z.Z. is established on an oral regimen, it can be decreased by 10% to 20% a day. Z.Z. should be monitored for withdrawal symptoms, which usually occur within 24 hours of abrupt discontinuation or dosage reduction. Symptoms of opioid withdrawal include neurologic excitation (irritability, insomnia, tremors, seizures), GI dysfunction (nausea, vomiting, diarrhea), and autonomic dysfunction (sweating, fever, chills, tachypnea, nasal congestion, and rhinitis).⁹⁴ If Z.Z. develops withdrawal symptoms, the narcotic agent should be increased to the previously tolerated dose. Clonidine may be a useful adjunct to help prevent symptoms of withdrawal.⁹⁵

UNIQUE PEDIATRIC DISORDERS

Hemolytic Uremic Syndrome

Hemolytic uremic syndrome (HUS) is the most common cause of renal failure in children. It is characterized by microangiopathic hemolytic anemia, thrombocytopenia, and acute renal failure. HUS typically occurs several days to 2 weeks after an episode of gastroenteritis, upper respiratory tract infection, or acute flulike illness. HUS is classified into diarrhea-associated (D+) and non-diarrhea-associated (atypical or D-) illness. Diarrhea-associated HUS is more frequent, has seasonal variation, and occurs primarily between 6 months and 4 years of age. It most often is associated with *E. coli* (usually subtype O157:H7) that produces a vero-cytotoxin similar to the shiga-toxin produced by *Shigella* species. Pathologically, WBC activation and endothelial cell injury in the kidney lead to fibrin deposition and platelet adherence to vessel walls. Glomerular lumens are swollen and occluded resulting in renal insufficiency. Red blood cells (RBC) and platelets are damaged by the fibrin strands as they pass through the narrowed vessels. Abnormalities in coagulation involving prostacyclin-thromboxane axis and von Willebrand factor have been implicated in the pathogenesis of thrombocytopenia.^{98,99}

The shiga-toxin-producing *E. coli* (STEC) can be spread by contaminated or undercooked food and through person-to-person contact. In 1993, a single outbreak of STEC (subtype O157:H7) associated with hamburgers from a fast food chain caused over 600 cases of diarrhea, 151 hospitalization, 45 cases of HUS, most in children, and 3 deaths.¹⁰⁰ As a result, all ground beef should be well cooked until juices run clear and are no longer pink. *E. coli* O157:H7 outbreaks also have been associated with unpasteurized milk and juices, fresh produce, alfalfa sprouts, home made beer, venison, lettuce, and

contaminated swimming and drinking water.^{98,101} Although *E. coli* O157:H7 is by far the most common etiology, other bacteria and viruses have been implicated in D+ HUS, including *Shigella dysenteriae* type 1, *Salmonella*, *Campylobacter*, *Yersinia*, *Pseudomonas*, *Bacteroides*, *Aeromonas*, *Coxsackie*, influenza, and Epstein-Barr.¹⁰¹ Atypical HUS can be inherited, caused by drugs (e.g., oral contraceptives, cyclosporine, cancer chemotherapeutic agents), or associated with other conditions (e.g., pneumococcal infections, Kawasaki's disease, postpregnancy, bone-marrow transplant). The estimated prevalence of D+ HUS in the United States ranges from 0.2 to 7 per 100,000 children.^{99,102} Children with D- HUS appear to have a worse prognosis.¹⁰²

17. How can STEC infection be prevented?

The risk of STEC infection can be minimized by using the following guidelines.

1. Wash all fresh food thoroughly.
2. Remove the outer leaves of lettuce and greens.
3. Cook chicken and ground meats until all pink is gone and juices run clear.
4. Cook fish until it is opaque and flakes easily.
5. Do not drink unpasteurized milk, milk products, or juices.
6. Do not eat raw eggs.
7. Wash hands with soap and water after using the bathroom, changing diapers, before eating, and after handling raw meat, poultry, or seafood.

Clinical Presentation

18. R.H., a 14-month-old, 9.4-kg girl, has been increasingly irritable and lethargic over the past 24 hours. The sudden appearance of dark urine 24 hours ago and significantly decreased urine output in the past 12 hours caused her mother to bring her in for evaluation. Her recent medical history is significant for 3 days of gastroenteritis with blood, which resolved 2 days before the onset of her present symptoms. R.H.'s diet includes breast milk and table food; her mother states that she fed R.H. hamburger earlier in the week.

On physical examination, R.H. is pale, somnolent, and has small purple bruises over her arms and legs. Significant laboratory results reveal the following: partial thromboplastin time (PTT) 26 seconds (normal, 25–35 seconds); hemoglobin (Hgb) 7.6 g/dL (normal, 11.8 g/dL); hematocrit (Hct) 22.5% (normal, 36%); WBC 15,100 cells/mm³ (normal, 6,000–17,500 cells/mm³); platelet count 44,000 cells/mm³ (normal, 150,000–400,000 cells/mm³); reticulocytes 4.7% (normal, 0.5%–1.5%); blood urea nitrogen (BUN) 60 mg/dL (normal, 5–18 mg/dL); serum creatinine (SrCr) 3.9 mg/dL (normal, 0.3–0.7 mg/dL); potassium (K) 5.4 mEq/L (normal, 3.5–5.5 mEq/L); urinalysis 3+ protein and 3+ blood; blood smear, schistocytes (fragmented RBC); factor V and VIII within normal limits; fibrinogen within normal limits; and fibrin split within normal limits. R.H. is admitted to the hospital with a diagnosis of HUS. Which signs, symptoms, and laboratory tests are consistent with HUS in R.H.?

[SI units: Hgb 1.178 mmol/L (normal, 1.829); Hct, 0.225 (normal, 0.36); platelet count, $44 \times 10^{10}/L$ (normal, 150–400); WBC, $15.1 \times 10^{10}/L$ (normal, 6–17.5); reticulocytes, 0.047 (normal, 0.005–0.015); BUN, 21.42 mmol/L (normal, 1.8–6.4); SrCr, 344.8, mcgmol/L (normal, 26.5–61.9); K, 5.4 mmol/L (normal, 3.5–5.5)]

R.H. exhibits many signs and symptoms associated with HUS. Her lethargy, irritability, change in mental status, and pale color are symptoms of anemia. The dark color of her urine is indicative of hemolysis and renal damage; other signs of renal damage include anuria and hypertension. The purpura (i.e., bruises) on her arms and legs are evidence for thrombocytopenia.

R.H.'s laboratory abnormalities also help confirm a diagnosis of HUS. The low hemoglobin and hematocrit are consistent with anemia, whereas the high reticulocyte count and presence of schistocytes indicate hemolysis. Nephropathy in R.H. is manifested by proteinuria and elevations in BUN and creatinine. The hyperkalemia is a sign of both nephropathy and hemolysis. Finally, normal coagulation studies, absence of fibrin split products, and normal levels of clotting factors and fibrinogen indicate that R.H., as with many children with HUS, does not have active disseminated intravascular coagulation (DIC) at initial presentation.

Treatment

19. On admission, R.H. is given IV fluids without potassium at half maintenance and oral nifedipine 2 mg (0.2 mg/kg) Q 4 to 6 hr PRN for hypertension. Her urine output decreased significantly and peritoneal dialysis was initiated within 24 hours. How should R.H. be treated? What is the role of antibiotic therapy?

Therapeutic approaches aimed at modifying the acute phase of HUS have been unsuccessful, and supportive care is the only widely accepted form of treatment. Therapy for R.H. should be directed at managing the complications (e.g., fluid and electrolyte imbalance, anemia, thrombocytopenia, renal failure, hypertension, seizures) that are associated with HUS. Antimotility agents should be avoided because, in addition to having little if any clinical benefit, they may increase morbidity.⁹⁸ The value of using antibiotics to treat *E. coli* O157:H7 infections is questionable and may increase the rate of progression to HUS. The rate of HUS was increased in children with diarrhea caused by *E. coli* O157:H7 who were treated with either trimethoprim-sulfamethoxazole or β -lactam antibiotics.¹⁰³ As a result, until conclusive data indicate otherwise, antibiotics should be avoided.⁹⁸

Correction of Hemostatic and Electrolyte Imbalances

R.H.'s hemostatic and electrolyte imbalances need to be corrected first. Packed RBC are needed when anemia is significant (Hct <15%) or when the patient is symptomatic from the anemia. Infusion of platelets should be limited to those patients with active bleeding and those requiring surgery or central line placement because platelets can exacerbate platelet aggregation and thrombus formation. R.H. should not receive potassium in IV fluids, and her electrolytes should be monitored frequently. If peritoneal dialysis is not initiated, R.H. might require potassium-lowering therapy. Blood pressure elevations should be treated with nifedipine, and seizures should be treated initially with benzodiazepines, followed by phenobarbital or phenytoin if they cannot be controlled.^{98,102}

20. What other modes of therapy have been used to treat HUS in children?

Many treatments (e.g., aspirin, dipyridamole, heparin, streptokinase, urokinase, corticosteroids) have been evaluated in cases of HUS, but few have improved outcomes.^{98,99} Plasmapheresis and plasma infusion, exchange transfusions, and fresh frozen plasma administration also have been ineffective. Although a vaccine for *E. coli* O157:H7 has been studied, it is not yet approved for clinical use: a toxin binding agent has been clinically evaluated and found ineffective.^{104,105}

IDIOPATHIC THROMBOCYTOPENIC PURPURA

Idiopathic thrombocytopenic purpura (ITP) in children generally is an acute, self-limited, benign disease with spontaneous remission occurring in approximately 80% of cases within 6 months of diagnosis whether treated or not.¹⁰⁶ Chronic ITP evolves from the acute form in approximately 25% of cases, although <10% of these are clinically significant.^{107,108} Mortality rates are low, and most deaths can be attributed to intracranial hemorrhage, which occurs in <1% of children with platelet counts <10,000/mm³.^{106,109} The social and psychological effects that occur secondarily to restriction of normal childhood physical activity is the primary morbidity.

The etiology of ITP in children is unknown. ITP is thought to primarily be triggered by a viral infection that induces formation of antigen-antibody complexes. These complexes adhere to platelets resulting in increased platelet consumption by the reticuloendothelial system (RES). The chronic form, which is similar to adult ITP, may be caused by production of autoantibodies to platelet antigens.^{106,110}

Clinical Presentation

21. J.T., a 3-year-old, 15-kg, previously healthy girl, presents with a 3-week history of increased bruising and repeated nosebleeds after an episode of gastroenteritis. Physical examination is remarkable for generalized petechiae and scattered bruising. Her Hgb, Hct, WBC count and differential, and peripheral smear are within normal limits, but the platelet count is 10,000/mm³ (normal, 250,000–350,000/mm³). She is admitted to the hospital with a diagnosis of acute ITP. Which signs, symptoms, and laboratory tests in J.T. are consistent with ITP?

[SI unit: platelet count, $10 \times 10^{10}/L$ (normal, 250–350)]

Diagnosis of ITP is based on clinical presentation, complete blood count (CBC), and examination of peripheral smear.¹⁰⁷ As illustrated by J.T., children with acute ITP classically present with a sudden appearance of purpura or petechiae within 6 weeks of the onset of a viral infection. Approximately 25% of children with acute ITP have epistaxis (nosebleeds), 5% have hematuria, and <4% have massive purpura or retinal hemorrhages. Diagnosis of ITP is confirmed by the presence of thrombocytopenia with no apparent cause. The marked decrease in J.T.'s platelet count to <25,000 cells/mm³ with a normal CBC is indicative of ITP.

Treatment

22. How should J.T. be treated initially?

Hospitalization is indicated for children with life-threatening bleeding, regardless of the platelet count. J.T. can

be treated conservatively because she is not massively hemorrhaging. Medical treatment is indicated in the two groups of children thought to be at highest risk for intracranial hemorrhage: (a) children with platelet counts $<20,000$ cells/mm³ who have moderate mucous membrane bleeding and (b) children with platelet counts $<10,000$ cells/mm³ with minor purpura.¹⁰⁷ If J.T.'s platelet count were higher, some clinicians would delay treatment because the risk of spontaneous, severe bleeding is low if platelet counts remain $>30,000$ /mm³. Also, clinicians may not treat children such as J.T. who are not massively hemorrhaging or bleeding internally, regardless of the platelet count, because the incidence of catastrophic hemorrhage is very low.¹⁰⁹

Splenectomy

The treatment of choice is controversial because the mortality rate is low, the rate of spontaneous remission is high, and data for different therapies are inconsistent.¹⁰⁷ The only therapeutic modality with undisputed efficacy is splenectomy because the major site of platelet phagocytosis and antibody formation is removed. Because splenectomy is a major surgical procedure leaving a child at risk for serious infection and treatment with IV γ -globulin (IVIG) therapy or high-dose steroids is associated with good results, many clinicians reserve splenectomy for children with resistant cases of ITP.^{107,108}

23. What treatments are available for acute ITP?

Observation, splenectomy, glucocorticoids, IVIG, and anti-D immune globulin have been used to treat acute ITP. Platelet transfusions are ineffective because infused platelets are removed rapidly by the reticuloendothelial system.

Glucocorticoids

Glucocorticoids have been used as treatment for acute ITP for many years, but their benefits and indications are controversial.¹⁰⁶ Glucocorticoids might decrease the duration of thrombocytopenia by inhibiting platelet phagocytosis and they also might lower the risk of hemorrhage by increasing capillary integrity. Further study is needed to determine whether steroids induce a more rapid rise in platelet levels than would occur spontaneously and whether steroids increase capillary integrity. The indications for the use of steroids vary; however, most clinicians would consider steroids when the patient's platelet count is $<50,000$ /mm³ in the presence of severe bleeding, $<20,000$ /mm³ with mucous membrane bleeding, or $<10,000$ /mm³ with minor purpura.¹⁰⁷

Prednisone 4 mg/kg for 7 days followed by decreasing tapered doses until day 21, and methylprednisolone 30 to 50 mg/kg/day for 7 days, reportedly facilitate platelet recovery similar to IVIG. A short course of prednisone 4 mg/kg/day for 4 days also was able to increase platelet counts $>20,000$ /mm³.¹¹⁰ In a meta-analysis, however, steroids were less likely than IVIG to increase platelet counts to $>20,000$ /mm³ after 48 hours.¹¹¹ Although the optimal steroid regimen for acute ITP has not been determined, the risks of steroids are relatively low because they are used for a short period. Modest adverse effects (e.g., behavioral abnormalities, weight gain, acne, GI upset), however, have been reported in children receiving high-dose glucocorticoid therapy.

Intravenous γ -Globulin and Anti-D Immune Globulin

IVIG has been commonly used for management of acute ITP to induce a rapid rise in platelet counts to minimize the risk of hemorrhaging. IVIG purportedly blocks phagocytosis of antibody-coated platelets by the reticuloendothelial system or eliminates circulating immune complexes and microbial antigens.¹⁰⁶ Adverse reactions (e.g., flushing, chills, fever, headache, dizziness, diaphoresis, nausea) to IVIG usually are mild and related to the rate of administration. These can be minimized by stopping the infusion or decreasing the infusion rate. Anaphylactic reactions have been reported in patients with IgA deficiency, as have other serious adverse effects (e.g., hypotension, dyspnea, myalgias, joint pain, abdominal pain). Another consideration is the relatively high cost of IVIG therapy.

Anti-D immune globulin (anti-D), a polyclonal antiserum against the Rh(D) antigen of RBC that was first licensed to prevent hemolytic disease of newborns caused by Rh isoimmunization, is a treatment option for ITP because it has a lower cost and shorter infusion time (15 minutes) compared with IVIG. It has the greatest efficacy in patients who are D antigen positive and is thought to increase platelet counts in ITP by binding to Rh-positive erythrocytes. This leads to removal of the sensitized RBC by the spleen, allowing the antibody-coated platelets to survive.¹¹⁰ Most patients experience a mild, transient hemolysis.

Both IVIG and anti-D immune globulin appear to be equally effective, particularly when the anti-D is dosed at 50 mcg/kg.¹¹⁰ Little exists to guide the clinician in choosing IVIG or anti-D for ITP treatment. Survey data suggest a slight preference for anti-D over IVIG.¹¹⁰ In a randomized trial in Rh+ children, IVIG at 0.8 g/kg and anti-D at 75 mcg/kg (compared with anti-D at 50 mcg/kg) were equally effective, and adverse effect profiles were acceptable in both groups.¹¹²

Either IVIG, anti-D, or high-dose glucocorticoids are reasonable treatments for J.T. because she is at high risk for bleeding. On the other hand, some clinicians might elect to withhold therapy and monitor J.T. closely.

Goals of Therapy

24. What are the goals of therapy?

The ultimate goal of therapy for ITP is induction of remission. If remission does not occur, therapy is aimed at maintenance of hemostatic platelet levels and prevention of catastrophic hemorrhage. Severe internal bleeding has occurred in patients, however, despite treatment with steroids or IVIG. Another goal of therapy is to avoid performing a splenectomy, which would put the child at an increased risk for infections.¹⁰⁷

Prognosis

25. What is J.T.'s prognosis?

J.T.'s prognosis is good, much better than the prognosis of adults with ITP. Only 10% to 20% of children will fail to achieve remission within 6 months of diagnosis.¹¹³ Children with chronic ITP will enter remission slowly over a period of years or after a splenectomy. Although early institution of nonsurgical treatments for acute ITP can decrease morbidity and mortality, they probably cannot prevent the development of chronic ITP.¹⁰⁷

Chronic Idiopathic Thrombocytopenic Purpura

26. J.T.'s platelet count rose to 260,000/mm³ after she received the IVIG, and her counts have remained within normal limits for the past year. J.T. appears to be in remission. If she had developed chronic ITP, how would she have been treated?

[SI unit: platelet count, 260 × 10¹⁰/L]

Chronic ITP is defined as thrombocytopenia lasting >6 months. Different approaches exist for the treatment of chronic ITP, but all agree that splenectomy should be delayed to allow for spontaneous remission as long as hemostatic platelet counts are maintained and the child remains asymptomatic.¹⁰⁷

To maintain adequate platelet counts or to control symptoms before splenectomy is needed, IVIG, anti-D, or glucocorticoids have been prescribed.¹⁰⁷ IVIG sometimes is cited as the treatment of choice for chronic ITP because it has relatively few side effects. Doses of IVIG (0.8–1 g/kg) or anti-D (50–75 mcg/kg) might need to be repeated to maintain hemostatic platelet counts.¹⁰⁸ Long-term steroid use is discouraged because steroids have not been consistently effective, and because of adverse events (e.g., exacerbation of thrombocytopenia, delayed bone growth). Other modalities (e.g., plasmapheresis, danazol, α -interferon, azathioprine [Imuran], cyclophosphamide [Cytosan], vincristine [Oncovin], vinblastine [Velban], 6-mercaptopurine) have been attempted for children with steroid or IVIG-resistant chronic ITP, but data are insufficient to support their routine use.¹⁰⁷ Splenectomy is effective in 70% of children with chronic ITP and is indicated in symptomatic children with platelet counts that have remained <30,000/mm³ for 12 months.^{107,108} A good response to IVIG could be predictive of good response to splenectomy.^{114,115} Steroids or IVIG can be given before splenectomy to obtain platelet counts that will maintain hemostasis during surgery.¹⁰⁷ Children should be immunized with *Haemophilus influenzae* type b (Hib), pneumococcal, and meningococcal vaccines at least 2 weeks before an elective splenectomy. Therefore, if J.T. develops chronic ITP, she could receive a repeat course of IVIG with booster doses to maintain hemostasis; a second line of therapy would be steroids or anti-D. Splenectomy and immunosuppressive drugs would be considered last resorts.

Finally, parents should be educated to avoid medications with antiplatelet effects (e.g., aspirin, dipyridamole, NSAID) in children with ITP. Parents also should be instructed to monitor their child's physical activity in an effort to minimize trauma that could precipitate life-threatening hemorrhage.

NEPHROTIC SYNDROME

Nephrotic syndrome in children typically is characterized by proteinuria, hypoalbuminemia, edema, and hypercholesterolemia.^{116,117} Overall, it is a relatively rare pediatric disorder with an incidence of 2 to 7 cases per 100,000 children under 18 years of age.^{116,117} This idiopathic nephrotic state can present as minimal change nephrotic syndrome or focal segmental glomerular sclerosis. Minimal change disease is in part characterized by normal glomeruli on microscopic analysis.^{118,119} It is by far the more common manifestation in children, with >75% of those <12 years of age having this type of nephritic syndrome.^{117,119}

In minimal change disease, a loss occurs in charge selectivity of the glomerular membrane barrier, which allows large plasma proteins such as albumin and immunoglobulins to be filtered into the urine that would otherwise be reabsorbed.¹¹⁹ The etiology is complex, and has not been fully characterized, but T-lymphocyte dysfunction may play a role in the pathogenesis of nephrotic syndrome.¹²⁰

Clinical Presentation

27. G.G., a previously healthy 4-year-old, 21-kg boy, has been noted by his mother to have swelling in his face, (especially of his eyes) the past several mornings. The facial swelling disappears during the day, but at night his feet and lower legs are swollen. Physical examination reveals normal vital signs, mild facial puffiness, 2+ to 3+ pitting edema of the lower extremities. Urinalysis shows 4+ protein (normal, negative or trace) and a specific gravity of 1.029 (normal, 1.002–1.030). His serum albumin is 1.6 g/dL (normal, 3.9–5 g/dL), serum cholesterol is 296 mg/dL (normal, 109–189 mg/dL), and the other chemistry results are within normal limits. What subjective and objective data in this patient are consistent with nephrotic syndrome?

[SI units: albumin, 16 g/L (normal, 39–50), serum cholesterol, 7.7 mmol/L (normal, 2.8–4.8)]

G.G. presents with typical findings of nephrotic syndrome. Edema of the face early in the day, and lower extremities at night is a result of the loss of oncotic pressure caused by hypoalbuminemia. Other manifestations of this complication can include swelling of the scrotum, which can lead to testicular torsion. Decreased oncotic pressure can also result in abdominal pain owing to decreased perfusion to the splanchnic capillary bed.

The main laboratory finding in nephrotic syndrome is proteinuria. Levels of proteinuria associated with nephrotic syndromes generally are >50 mg/kg/24 hours or >3.5 g/1.73 m²/day. Sometimes, the proteinuria merely is described as “heavy proteinuria” or proteinuria that is sufficiently significant to result in the four major clinical findings in nephrotic syndrome.^{116,117,119} G.G. has 4+ protein in his “dipstick” urinalysis. If the dipstick protein is persistently elevated (>1+), the first morning urine should be “spot tested” to assess the protein:creatinine ratio (Pr:Cr). If the Pr:Cr is abnormal (normal for children <2 years of age is <0.2 mg Pr/1 mg Cr), a complete workup is warranted.¹¹⁶

Serum albumin levels of <2 g/dL will likely result in visible edema. Serum cholesterol and triglyceride concentrations often are increased, perhaps attributable to decreased catabolic capacity of the liver or increased production.¹¹⁷ Other laboratory abnormalities can include hypocalcemia, hyperkalemia, and hyponatremia. Patients with idiopathic minimal change disease do not usually present with gross hematuria, hypertension, or renal dysfunction.

Treatment

28. G.G. is eventually diagnosed with nephrotic syndrome. How should he be treated initially? What nonpharmacologic interventions can be considered?

Patients with nephrotic syndrome have an increased total body sodium owing to increased retention, even in the presence of low serum levels and decreased intravascular volume.^{116,117,119} Therefore, sodium restriction is important. Although it is not practical to set a sodium limit in children, a “no-added salt” diet is usually recommended in which family support and participation is crucial. Many institutions will provide patients with examples of foods that are low in sodium (e.g., fresh beef or chicken, fresh vegetables). Patients may eat the normal recommended daily allowance of protein, because protein restriction does not consistently decrease proteinuria or have an impact on the progression of renal disease.^{116,117}

A regimen of prednisone 2 mg/kg/day or 60 mg/m²/day (80 mg/day maximum) for 4 weeks, followed by 2 mg/kg/day or 40 mg/m²/day every other day, and subsequently tapered over another 4 weeks generally constitutes the first line of therapy. Single daily dosing is as effective as daily divided dosing. Some data support a longer regimen of 6 weeks of every day therapy followed by 6 weeks of every other day therapy. Longer treatment courses (i.e., 5–7 months, including daily therapy for 4 to 8 weeks followed by every other day therapy) might prove to be more effective in preventing relapse. Adverse effects are not significantly different with the longer regimens.¹²¹

29. How is G.G.’s response to steroid therapy determined?

Most children with minimal change disease respond within weeks of initiating corticosteroids.¹²⁰ Remission is defined as negative or trace protein for at least 3 consecutive days on dipstick urinalysis.¹¹⁶ Of patients who respond, 60% to 80% will have multiple relapses, defined as 2+ proteinuria for 3 consecutive days or 3+ to 4+ proteinuria with edema. Relapses are treated with high-dose prednisone until the urine is protein free for 3 days. Prednisone is then tapered over 4 to 6 weeks using alternate day therapy.¹¹⁶

30. What options are available for patients with frequent relapses or for those who are steroid dependent or resistant?

Many children with nephrotic syndrome will experience frequent relapses (i.e., ≥ 2 relapses in the first 6 months after initial response or ≥ 4 relapses in any 1-year period). A patient is deemed to be “steroid dependent” when experiencing two consecutive relapses either during steroid tapering or within 14 days of steroid discontinuation. Steroid resistance is described as a failure to achieve remission after 4 weeks of every day high-dose therapy followed by 4 weeks of alternate day therapy.¹¹⁶ Several studies have investigated patient characteristics that predict relapses in those with nephrotic syndrome. In one study, patients who responded within 1 week of therapy and did not present with hematuria were less likely to have frequent relapses in the first year.¹²² In another, children who relapsed within 1 year or who had short remissions before relapse were more likely to have subsequent relapses.¹²³ An initial remission time of 9 or more days and concurrent upper respiratory tract infections were predictive of steroid dependency.¹²⁴ Age at onset of disease, gender, and race were not associated with risk in any of the studies.

In difficult to manage cases, high-dose alternate day regimens are tapered to monthly IV pulse doses of methylprednisolone at 30 mg/kg (maximum, 1 g).^{116,117,120} Such patients

should be under the care of a pediatric nephrologist and should be monitored for infusion reactions (e.g., hypertension). Cytotoxics (e.g., cyclophosphamide, chlorambucil), are reserved for patients who do not respond to steroids after multiple courses or for those in whom side effects have become intolerable. Anytime cytotoxic agents are utilized, patients must be monitored for bone marrow suppression. Other potential problems that must be discussed with the family before initiation of these agents include the possibility of malignancy, infertility, alopecia, increased infection risk, and hemorrhagic cystitis with cyclophosphamide. Cyclosporine has become the most popular second-line agent in many institutions.¹²⁰

31. What other complications are possible in children with nephrotic syndrome?

Nephrotic syndrome can lead to a hypercoagulable state, which has been attributable to increased factor V and VIII, increased fibrinogen, decreased coagulation inhibitors (e.g., antithrombin III), and increased platelet activity.¹¹⁹ This alteration in hemostasis can lead to life-threatening events in children.^{125,126} Antiplatelet or anticoagulant agents are recommended for patients who have a history of a thromboembolic event.¹¹⁶ In addition, diuretics must be used more cautiously in patients with a history of hypercoagulability.

Children with nephrotic syndrome have an increased risk of infection secondary to alterations in circulating immune globulins, cellular immunity, and chemotaxis. Cellulitis and spontaneous bacterial peritonitis occur at higher rates in this population; children with albumin < 1.5 g/dL are thought to be at greatest risk.¹²⁷ Encapsulated organisms such as *Streptococcus pneumoniae* and gram-negative rods, such as *E. coli*, are the most frequent causes of bacterial infection. Prophylactic antibiotics have been used during active relapse, but no consensus exists among pediatric nephrologists on the management of infection risks in these patients.^{116,128} Patients should receive standard vaccination using the childhood immunization schedule. The pneumococcal conjugate vaccine (Prevnar) or the pneumococcal polysaccharide vaccine (Pneumovax) should be administered to children with nephrotic syndrome if they were not immunized as infants.^{116,129} Live viral vaccines are appropriate for these patients, but must not be given while receiving high-dose corticosteroids or other immunosuppressive therapy. Varicella vaccine has been studied in cases of nephrotic syndrome and is safe and effective.^{116,130}

Hyperlipidemia is a common complication of nephrotic syndrome, but it usually resolves spontaneously in steroid-responsive patients. Lipid levels may remain elevated in steroid-resistant patients and, if diet intervention is insufficient, bile acid sequestrants are FDA approved for use in pediatric patients.^{131,132} Therapy with statins appears to significantly reduce total cholesterol and low-density lipoprotein (LDL) and triglycerides, but has no documented impact on disease progression. Statin therapy might have beneficial effects on arterial endothelium.¹³³

Renal protein excretion may be decreased by angiotensin-converting enzyme inhibitors (ACE-I). Long-term benefit in children with nephrotic syndrome is not known. ACE-I should be given with caution, especially during initial steroid therapy because of the risk of hypotension, resulting in an increased risk of thrombosis.¹¹⁶

32. What is the prognosis of children with nephrotic syndrome?

In minimal change disease, mortality is approximately 2%, mostly caused by peritonitis or thrombotic complications. Most patients will be steroid responsive, but will likely have multiple relapses over several years. Considering all categories of

nephrotic syndrome in children, 20% will sustain remission, 50% will have relapses in any 5-year follow-up period, and the remaining 30% will develop nephrosis. Half of this last group can attain remission with combination therapy of prednisone and cytotoxic drugs if they have minimal change disease.¹¹⁷
