Cardiovascular disease is the leading cause of death among women, accounting for more deaths than all cancer types.³⁷ Some, but not all, studies report a non-age-related increase in coronary heart disease (CHD) in postmenopausal women.¹⁰ Estrogens have beneficial effects on lipids and endothelial function, suggesting a pharmacologic basis for a heart-protective effect.³⁸ However, the cardiovascular effects of ET remain controversial despite numerous studies addressing this issue. Case-control and cohort studies, such as the Nurses' Health Study (NHS), found that, compared with never users, postmenopausal women who used ET or EPT had a lower risk of CHD-related death.³⁹ However, the HERS trial, a prospective study of EPT in postmenopausal women with pre-existing heart disease, showed an increased risk of CHD during the first year of the study and no overall benefit on CHD after 4.1 years of follow-up.⁴⁰ The ERA Trial, which compared the effects of ET and placebo on the angiographic progression of pre-existing CHD, showed no benefit of ET.⁴¹ In the WHI, which was specifically designed to answer questions about ET/EPT and primary prevention of cardiovascular disease, increased cardiovascular events in the EPT group led to early termination of that arm of the study. The estrogen-only arm was also stopped early due to an increased risk of stroke without evidence of cardiovascular protection.^{29,42} A major criticism of the WHI was that the average age of the study participants, 63 years, did not reflect the typical age at which symptomatic menopausal women were most likely to use ET/EPT. Further analysis of the WHI data found a trend towards reduced CHD risk and lower total mortality in women aged 50 to 59 years

Table 48-4 Agents Used in ET/EPT Therapy

| <i>Drug (Brand Name)</i> | <i>Initial Daily Dosage</i> |
|---|---|
| Estrogens | |
| Conjugated equine estrogens (CEE) ^a (Premarin) | 0.3 mg |
| Synthetic conjugated estrogens (Cenestin, Enjuvia) | 0.3 mg |
| Estropipate ^a (piperazine estrone sulfate) (Ogen, Ortho-Est) | 0.625 mg |
| Micronized estradiol ^a (Estrace, Gynodiol) | 0.5 mg |
| Estradiol transdermal system ^a (various brand name products) | 0.014–0.025 mg/24-hr patch applied weekly or twice weekly |
| Esterified estrogen ^a (Estratab, Menest) | 0.3 mg |
| Estradiol acetate tablet (Femtrace) | 0.45 mg |
| Estradiol acetate vaginal ring (Femring) | 0.05 mg/24-hr ring inserted vaginally every 90 days |
| Estradiol topical emulsion/gel (Elestrin, Estrogel, Estrasorb) | 1 packet daily |
| Progestins | |
| Medroxyprogesterone acetate (Provera and generic products) | 5 mg for cyclic regimens/2.5 mg for continuous regimens |
| Norethindrone acetate (various brand name products) | 2.5 mg for cyclic regimens/0.5 mg for continuous regimens |
| Progesterone (Prometrium) | 200 mg for cyclic regimens/100 mg for continuous regimens |
| Progesterone vaginal gel (Prochieve, Crinone) | 1 full applicator of 4% gel every other day |
| Levonorgestrel-releasing IUD (Mirena) | 20 mcg/day |
| Estrogen and Progestin Combinations | |
| Prempro ^a | 0.3 mg CEE and 1.5 mg MPA |
| Premphase ^a | 0.625 mg CEE for 28 days with 5 mg MPA for last 14 days |
| CombiPatch | 0.05 mg estradiol with either 0.14 or 0.25 mg norethindrone |
| Femhrt ^a | 2.5 mcg EE ^b and 0.1 mg norethindrone acetate |
| Activella ^a | 0.5 mg estradiol and 0.5 mg norethindrone acetate |
| Prefest ^a | 1 mg estradiol and 0.09 mg norgestimate |
| Climara Pro ^a | 0.045 mg estradiol/0.015 mg levonorgestrel/24 hr patch once weekly |
| Estrogen and Androgen Combinations^c | |
| Esterified estradiol and Methyltestosterone (Estratest, Covaryx) | 0.625 mg esterified estrogens and 1.25 mg MT |
| Vaginal Estrogens (localized effect only) | |
| Conjugated Equine Estrogen cream (Premarin) | Initial: 1 gm cream (0.625 mg CEE) daily Maintenance: 1 gm cream once/twice weekly |
| Estradiol cream (Estrace) | Initial: 2–4 gm cream (0.2–0.4 mg estradiol) daily Maintenance: 1 gm cream (0.1 mg estradiol) twice weekly |
| Estradiol ring (Estring) | 2 mg ring (0.0075 mg/day) every 90 days |
| Estradiol hemihydrate tablets (Vagifem) | 1 tablet (0.025 mg) daily for 2 wk, then one tablet twice weekly |
| ^a Approved by the FDA for prevention of osteoporosis. | |
| ^b EE: ethinyl estradiol. | |
| ^c Requires addition of progestin in women with uterus. | |

who began therapy within 10 years of menopause.⁴³ The WHI-Coronary Artery Calcium Study, a WHI substudy, also found a lower calcified plaque burden in 50- to 59-year-old women who took ET as compared to placebo, suggestive of a protective effect of estrogen on CHD when used early after the onset of menopause.⁴⁴ The NHS analyzed CHD risk based on age at initial hormone use and found a 65% to 72% reduction in risk for women who began use within 10 years of menopause compared with no change in CHD risk for women who initiated first use more than 10 years after menopause.⁴⁵

Although there are still unanswered questions regarding the cardiovascular effects of ET/EPT, it appears to be safer than previously thought when used for symptom control soon after menopause. However, there is no clear indication that ET/EPT should be used for the prevention of CHD in asymptomatic women.⁴⁶

Gallbladder Disease

Estrogen, with or without progestin, increases the risk of gallbladder disease by approximately 60%.⁴⁷ In the WHI and HERS studies, use of ET/EPT was associated with a significant increase in the risk for gallbladder surgery.^{47,48}

Other Risks and Benefits

Oral estrogen therapy has beneficial effects on lipids, increasing HDL while decreasing total cholesterol, LDL and lipoprotein(a). However, it can also significantly increase triglyceride levels.^{49,50} Transdermal estrogen has similar but less pronounced effects on cholesterol levels.⁵⁰ Addition of a progestin attenuates the beneficial changes of ET on HDL but may also ameliorate ET's triglyceride-elevating effects. Of the commonly used progestins, micronized progesterone appears to have the least deleterious effect on the lipid profile.¹⁷

Observational studies have suggested that postmenopausal hormone use reduced the risk colorectal cancer during the time of use.⁵¹ In the WHI study, EPT was associated with a significantly decreased risk of colorectal cancer; however, this decreased risk was not seen with use of ET alone.^{29,52}

The effects of postmenopausal hormone therapy on cognitive function are unclear. While observational trials indicated that ET/EPT protects against mental decline, the WHI Memory Study (WHIMS), a substudy of the WHI, found that, in women aged 65 years or older at time of hormone initiation, ET and EPT increased the risk of dementia and mild cognitive impairment.^{53–56} Other studies suggest that when therapy is begun in recently postmenopausal women, ET/EPT may provide a protective effect on mental status.^{57,58} More data are needed on the effects of various regimens and time of use before a definitive answer about the effects of ET/EPT on cognitive function can be made.

The WHI study found a decreased incidence of new-onset diabetes mellitus in both the ET and EPT treatment groups and the HERS trial documented a similar reduction in risk.²³ Additional data are needed before hormone therapy can be recommended for the prevention of diabetes.

Dosing Regimens

4. What is an appropriate regimen of estrogen for the management of D.R.'s hot flashes?

There are a number of estrogen and estrogen/progestin products currently available for the management of vasomotor

symptoms (Table 48-4). Conjugated equine estrogens (CEE) have traditionally been the products most frequently used in the United States; however, use of alternate agents, including oral and transdermal estradiol, is increasing. Oral and transdermal estrogen appear to be equally efficacious in treating hot flashes.¹³ Transdermal estrogen is associated with a decreased risk for TED and hypertension but has less of a beneficial effect on the lipid profile compared to oral estrogen. The effect of transdermal estrogen on cardiovascular and gallbladder disease has not been well studied. Current recommendations are to initiate estrogen at a low dose (e.g., 0.3 mg of CEE or 0.025 mg of transdermal estradiol) with titration as needed for symptom control.

In women with an intact uterus, such as D.R., a progestin must also be added to the regimen to minimize the risk of endometrial cancer.²³ Currently, there is no indication for adding a progestin to ET in women without a uterus. Oral progestins used in the United States to antagonize the endometrial effects of estrogen are listed in Table 48-4. For medroxyprogesterone acetate (MPA), the most commonly used EPT progestin, 5 mg/day for at least 12 days/month is needed to prevent endometrial hyperplasia when used in cyclic regimens (Table 48-5). For continuous regimens, 2.5 mg/day may be adequate. Oral micronized progesterone 100 to 300 mg/day for 12 days/month or the progestin-releasing IUD also appear to protect against endometrial hyperplasia from ET.¹⁷

EPT may result in resumption of uterine withdrawal bleeding. The pattern and frequency of bleeding is dependent on the EPT regimen used (Table 48-5). For women using cyclic

Table 48-5 ET/EPT Regimens and Expected Vaginal Bleeding Patterns

| Estrogen/Progestin Dosing | Hormone Free Interval | Typical Bleeding Pattern |
|--|-----------------------|---|
| Combined Regimens (EPT) for Patient with intact uterus | | |
| CYCLIC REGIMEN | | |
| Estrogen (PO or TD): days 1–25 of each month Progestin: days 10–25 or 14–25 of each month | 3–6 days | Withdrawal bleeding 1–2 days after progestin dosing ended ^a 80% experience regular bleeding |
| CYCLIC COMBINED | | |
| Estrogen (PO or TD) and Progestin: days 1–25 of each month | 3–6 days | Withdrawal bleeding 1–2 days after progestin dosing ended ^a Lower incidence than cyclic regimen |
| CONTINUOUS CYCLIC | | |
| Estrogen (PO or TD): daily Progestin: 10–14 days every month | none | Withdrawal bleeding 1–2 days after progestin dosing ended ^a 80% experience regular bleeding |
| LONG-CYCLE CYCLIC | | |
| Estrogen (PO or TD): daily Progestin: 14 days every third month | none | Withdrawal bleeding 1–2 days after progestin dosing ended ^a ~70% experience regular bleeding |
| CONTINUOUS COMBINED | | |
| Estrogen (PO or TD) and Progestin: daily | none | 40% have irregular bleeding for first 6–12 months ^b 75%–89% become amenorrheic within 12 months |
| CONTINUOUS PULSED | | |
| Estrogen PO × 3 days then Estrogen + Progestin PO × 3 days Repeat continuously | none | ~70% experience spotting early during treatment 80% are amenorrheic at the end of 12 months ^b |
| Estrogen only Regimens (ET) for Patients without uterus | | |
| CONTINUOUS REGIMEN | | |
| Estrogen (PO or TD): daily | none | none |

^aBleeding earlier than 11 days after beginning progestin suggests need for endometrial evaluation.

^bBleeding after 6 months of therapy requires endometrial evaluation.

regimens, studies suggest that the use of progestin every 3 months rather than monthly is protective of the endometrium and may improve patient acceptance.⁵⁹ Patient preference regarding bleeding patterns should be considered when selecting an EPT regimen.

There is increasing consumer interest in “natural” (“bio-identical”) hormone therapy as a safer alternative to conventional estrogen products. “Natural hormone therapy” is extemporaneously compounded and does not carry the standardized FDA-approved warnings. However, there is no good clinical evidence to support claims of greater safety with these products.^{60,61}

Because hot flashes are self-limiting, discontinuation of ET/EPT should be attempted every 6 to 12 months. Abrupt discontinuation of ET/EPT may trigger recurrence of hot flashes; therefore, tapering is recommended. However, there are no specific guidelines; a taper regimen should be developed for each patient individually.⁶²

Adverse Effects

5. How should D.R. be counselled about possible side effects of ET/EPT?

In addition to being counselled about the serious risks of ET/EPT, D.R. should be advised regarding “nuisance” side effects from hormone therapy. These most commonly include resumption of vaginal bleeding (see Question 3) and breast tenderness.¹³ Nausea, weight gain, edema, headache, PMS-like symptoms, and increased vaginal discharge have also been reported. Skin irritation may occur with the use of transdermal products. Frequently, these side effects diminish with time or may respond to a change in dosage or product. Although ET/EPT has not been shown to consistently induce or worsen hypertension, patients should be monitored for increases in blood pressure.⁶³

6. D.R. has decided that she does not wish to take EPT for her hot flashes. What alternate therapy would be appropriate to try?

PROGESTINS

Progestins, given alone, appear to be similar to ET in relieving the symptoms of hot flashes. Regimens that have been shown to be effective include megestrol acetate, 40 mg/day PO, and medroxyprogesterone acetate, 10 mg/day PO or 150 mg IM Q 3 months or 500 mg IM on days 1, 14, and 28.^{64,65} Adverse effects of progestins include vaginal bleeding, fluid retention, increased appetite, breast tenderness, acne, hirsutism, headaches, mood swings, fatigue, and depression. In the absence of ET, progestins do not appear to increase the risk of thromboembolic disease.¹⁷ Progestins are a reasonable alternative for women who cannot take estrogen but need highly effective therapy for hot flashes.

ANDROGENS

Androgens do not relieve vasomotor symptoms in postmenopausal women. However, some clinical trials have shown that testosterone therapy in postmenopausal women can improve sexual function and may also improve energy levels and sense of wellbeing.^{66,67} Only methyltestosterone, in combination with estrogen, is FDA-approved for the management of menopausal symptoms (Table 48-4). Currently available gels and patches deliver an inappropriately high dose of androgen for women; however, use of smaller quantities of gel may provide adequate therapy (e.g., 5 mg of testosterone) while minimizing the risk of undesired side effects, such as acne, hirsutism, and masculinization. Products specifically designed for use in women are under development. A short-term trial of androgen therapy can be given to women taking ET/EPT who experience low libido. If improvement is not seen after several months of testosterone, it should be discontinued.

NONHORMONAL AGENTS

Nonhormonal agents are modestly effective in reducing hot flush frequency and severity. These agents include some serotonergic antidepressants, antiseizure, and antihypertensive drugs. Table 48-6 lists the agents and doses which have been

Table 48-6 Nonhormonal Agents for the Management of Vasomotor Symptoms⁷¹⁻⁷³

| Drug | Daily Dose Used in Clinical Trials | Placebo Controlled Trial? | Adverse Reactions Reported |
|-------------------------------------|--------------------------------------|---------------------------|---|
| Serotonergic Antidepressants | | | |
| Citalopram (Celexa) | 20 mg | Yes | Dry mouth, ↓ libido, rash/hives, insomnia, somnolence, bladder spasm, palpitations, arthralgias |
| Fluoxetine (Prozac) | 20–30 mg | Yes | Nausea, dry mouth, |
| Mirtazapine (Remeron) | 15–30 mg | No | ↑ appetite, dry mouth |
| Paroxetine (Paxil) | 10–25 mg | Yes | Headache, nausea, insomnia, drowsiness |
| Sertraline (Zoloft) | 50 mg | Yes | Nausea, fatigue/malaise, diarrhea, anxiety/nervousness |
| Venlafaxine (Effexor) | 37.5–150 mgXR | Yes | Dry mouth, ↓ appetite, nausea, constipation |
| Antiseizure Agents | | | |
| Gabapentin (Neurontin) | 900 mg | Yes | Somnolence, fatigue, dizziness, rash, palpitations, peripheral edema |
| Antihypertensive Agents | | | |
| Clonidine | PO: 0.05–0.15 mg TD: 0.1 mg/24 hr | Yes | Headache, dry mouth, drowsiness, skin reaction/itching (patch) |

shown to be effective along with adverse effects most commonly seen.^{68–70,71–73}

PHYTOESTROGENS

Phytoestrogens, including isoflavones and lignans, are plant-based substances that exert mild estrogenic effects. Epidemiologic studies have found an association between higher dietary soy intake and fewer menopausal symptoms.⁷⁴ However, the results of clinical trials of isoflavones, including soy and red clover extracts, are mixed. Several meta-analyses concluded that phytoestrogens have minor, if any, benefits^{70,74,75} on menopausal symptoms. This apparent lack of benefit may be related to the source and dose of isoflavones being evaluated. In general, isoflavones are well tolerated. The most commonly reported side effect is gastrointestinal intolerance. A 5-year study documented an increased risk of endometrial hyperplasia with phytoestrogen use.⁷⁶ Due to their estrogenic effects, phytoestrogens should be avoided or used cautiously in women with a history of estrogen-dependent disease.

BLACK COHOSH

Black cohosh (*cimicifuga racemosa*) is one of the most popular herbs for the management of menopausal symptoms. It does not appear to have estrogenic effects, but may exert a serotonergic effect.⁷⁷ Clinical studies of black cohosh for hot flashes have shown mixed results.^{78–81} Several trials have suggested that black cohosh may have a beneficial effect on mood symptoms associated with menopause.⁷⁷ The typical dose of black cohosh is 20 mg BID.⁸² It is generally well tolerated, but use beyond 6 months has not been evaluated. The most common adverse effects are gastrointestinal in nature. For women who do not wish to use hormonal agents, black cohosh would be a reasonable alternate treatment.

OTHER THERAPY

Studies on the use of wild yam extract, DHEA, ginseng, evening primrose oil, and dong quai do not support a beneficial effect of these agents in the management of hot flashes.^{82–84}

Genitourinary Atrophy

Signs and Symptoms

7. R.J., a 60-year-old woman who has remarried recently, complains of pain associated with intercourse. She also complains of vaginal dryness and pain during intercourse. Upon physical examination, she is noted to have sparse, gray pubic hair. Her labia minora have a pale, dry appearance, whereas the labia majora appear flattened. Her vagina is small with a pale, dry epithelium. How would you assess R.J.'s problem?

R.J. appears to be experiencing symptoms associated with genitourinary atrophy. Estrogen is the dominant hormone of vaginal physiology. With the postmenopausal loss of estrogen production, the vagina decreases in size and loses its rugal pattern: its mucosa becomes pale, thin, and dry and vaginal blood flow decreases. A decrease in lactobacillus production of lactic acid leads to an increase in vaginal pH to 5.0 or greater (compared to a premenopausal pH of 3.5–4.5).^{85,86} These changes make the vagina more susceptible to infection from bacterial colonization and localized trauma secondary to intercourse.

Unlike hot flashes, vaginal atrophy does not abate with time since menopause.

Symptoms of atrophic vaginitis include dryness, itching, pain and dyspareunia. About 10% to 40% of postmenopausal women experience symptoms, however, only 25% of those affected seek medical attention.⁸⁵ Postmenopausal women who engage in regular coital activity have less atrophic vaginal changes compared with those of similar age and estrogen levels who do not have regular intercourse. Also, postmenopausal women who have breaks in their sexual intercourse patterns, such as that experienced by R.J. between the death of her first husband and remarriage, tend to experience dyspareunia (painful coitus) with the resumption of intercourse.

Treatment

VAGINALLY ADMINISTERED ESTROGENS

8. What would be an appropriate regimen for R.J. to decrease her vaginal symptoms?

Estrogen therapy reverses vaginal epithelial thinning, decreases the vaginal pH and improves the symptoms of vaginal atrophy. If hot flashes are also present, oral or transdermal estrogen may be used. For treatment of vaginal symptoms alone, low-dose vaginal administration is the preferred route of administration.^{85,87} Absorption of estrogen through the vaginal mucosa is efficient and can produce estrogen levels adequate to relieve systemic symptoms such as hot flashes (e.g. 50–100 mcg/day estradiol acetate vaginal ring.) Limited data suggest that low-dose vaginal administration of estrogen does not significantly alter serum estradiol levels.⁸⁷ Low-dose vaginal estrogen is available in several dosage formulations (see Table 48-4). The various products appear to be equivalent in restoring vaginal cytology and pH and relieving symptoms of vaginal dryness, pruritus, and dyspareunia; product selection should be based on patient preference.⁸⁵ Vaginal creams and tablets are initiated with once daily dosing; after symptoms have resolved, the patient should be switched to maintenance dosing of once or twice weekly administration. The low-dose vaginal ring releases a constant dose of estrogen over 90 days.

The most common adverse effects of vaginal estrogens are vaginal irritation and bleeding and breast tenderness. Studies of limited duration suggest that the risk of endometrial hyperplasia from low-dose vaginal estrogen is small and the addition of a progestin is generally considered unnecessary.^{85,87} Women at high risk for endometrial cancer, using higher than usual doses of vaginal estrogen, or experiencing vaginal bleeding during intravaginal ET should be evaluated for endometrial hyperplasia.⁸⁵

OTHER TREATMENT

If a woman with vaginal atrophy is unwilling or unable to use estrogen, a vaginal bioadhesive (Replens) has been shown to significantly improve vaginal pH and atrophy symptoms, although to a lesser degree than vaginal ET.⁸⁸ Nonhormonal treatments, such as SSRIs and orally consumed herbal treatments (e.g., black cohosh, isoflavones), do not appear to improve vaginal atrophy symptoms.⁸⁶

Urinary Incontinence

9. Would ET/EPT be an appropriate choice of therapy if R.J. were experiencing urinary incontinence?

Estrogen has multiple effects on the urinary tract, including maintaining urethral pressure and collagen synthesis and controlling micturition. While the incidence of incontinence and urinary tract infections (UTI) increase with age, it is not clear that loss of estrogen production contributes to these problems.⁸⁹ Despite their theoretic benefits on the urinary tract, multiple studies have failed to show a benefit of ET/EPT on the symptoms of urinary incontinence.⁹⁰ In the WHI and NHS studies, ET and EPT increased the risk of developing urinary incontinence and worsened symptoms in women with pre-existing urinary incontinence.^{91,92} For women with recur-

rent UTI, 3 of 5 controlled trials showed a benefit of oral or vaginal estrogen in decreasing the frequency of infections.⁹³ Estrogens should not be used for management of urinary incontinence but could be given a trial in women with recurrent UTIs.

ACKNOWLEDGMENT

I would like to thank Dr. Rosalie Sagraves, Professor, University of Illinois at Chicago College of Pharmacy, Dr. Jennifer Hardman, Clinical Assistant Professor, University of Illinois at Chicago College of Pharmacy, and Dr. Nancy Letassy, Clinical Associate Professor, College of Pharmacy, University of Oklahoma Health Sciences Center, for their outstanding work on previous editions of this chapter.

Thyrotropin- α and Thyroid Suppression Therapy for Thyroid Cancer 49-36

OVERVIEW

Thyroid disease is common, affecting approximately 5% to 15% of the general population. Females are three to four times more likely than males to develop any type of thyroid disease. The typical thyroid disorders emphasized in this chapter are hypothyroidism, hyperthyroidism, and nodular disease. Thyroid cancer is discussed briefly. The reader is referred to standard medical textbooks for more detailed medical and diagnostic information.

Triiodothyronine (T_3) and thyroxine (T_4) are the two biologically active thyroid hormones produced by the thyroid gland in response to hormones released by the pituitary and hypothalamus. The hypothalamic thyrotropin-releasing hormone (TRH) stimulates release of thyrotropin (i.e., thyroid-stimulating hormone [TSH]) from the pituitary in response to low circulating levels of thyroid hormone. TSH in turn promotes hormone synthesis and release by increasing thyroid activity. When sufficient synthesis has occurred, high circulating thyroid hormone levels block further production by inhibiting TSH release. The intrapituitary deiodination of T_4 to T_3 also plays a critical role in the inhibition of TSH secretion. As the serum concentrations of thyroid hormone decrease, the hypothalamic-pituitary centers again become responsive by releasing TRH and TSH.

T_3 is four times more potent than T_4 , but its serum concentration is lower. T_4 is the major circulating hormone secreted by the thyroid. In contrast, about 80% of the total daily T_3 production results from the peripheral conversion of T_4 to T_3 through deiodination of T_4 . T_4 has intrinsic biological activity and does not function solely as a prohormone. Approximately 35% to 40% of secreted T_4 is converted peripherally to T_3 ; another 45% of secreted T_4 undergoes peripheral conversion to inactive reverse T_3 (rT_3). Certain drugs and diseases can modify the conversion rate of T_4 to T_3 and decrease the serum T_3 levels (Table 49-1; see question 2).

T_3 and T_4 exist in the circulation in free (active) and protein-bound (inactive) forms. About 99.97% of circulating T_4 is bound: 70% to thyroxine-binding globulin (TBG), 15% to thyroxine-binding prealbumin (TBPA), and the rest to albumin. Only 0.03% exists as the free form. This affinity for plasma proteins accounts for T_4 's slow metabolic degradation and long half-life ($t_{1/2}$) of 7 days. In contrast, T_3 is considerably less strongly bound to plasma proteins (99.7%); about 0.3% exists as free hormone. The lower protein-binding affinity of T_3 accounts for its threefold greater metabolic potency and its shorter half-life of 1.5 days.

Hypothyroidism is a clinical syndrome that results from a deficiency of thyroid hormone. The prevalence of hypothyroidism is 1.4% to 2% in females and 0.1% to 0.2% in males. The incidence increases in persons older than 60 years to 6% of women and 2.5% of men. Hypothyroidism can be caused by either primary (thyroid gland) or secondary (hypothalamic-pituitary) malfunction. Primary hypothyroidism is more common than secondary causes.

Hashimoto's thyroiditis, an autoimmune disorder, is the most common cause of primary hypothyroidism and appears to have a strong genetic predisposition. The pathogenesis of Hashimoto's thyroiditis results from an impaired immune surveillance, causing dysfunction of normal "suppressor" T lymphocytes and excessive production of thyroid antibodies by plasma cells (differentiated B lymphocytes). The destruc-

Table 49-1 Factors That Can Significantly Alter Thyroid Function Tests in Euthyroid Patients

| ↑ TBG Binding Capacity | |
|--|---|

| ↑ TSH Secretion | |
| | Metoclopramide ^{1,3,7} |
| | Domperidone ^{1,3,7} |

^aCan also cause hypothyroidism in patients receiving levothyroxine therapy.

FT₃, free triiodothyronine; FT₄, free thyroxine; FT₃I, free triiodothyronine index; FT₄I, free thyroxine index; PTU, propylthiouracil; T₃, triiodothyronine; T₄, thyroxine; TBG, thyroxine-binding globulin; TSH, thyroid-stimulating hormone; TT₃, total triiodothyronine; TT₄, total thyroxine.

tion of thyroid cells by circulating thyroid antibodies produces an underlying defect or block in the intrathyroidal, organo-binding of iodide. As a result, inactive hormones or insufficient amounts of active hormones are synthesized, and this eventually produces hypothyroidism. However, the clinical presentation of Hashimoto's thyroiditis can be variable, depending on the time of diagnosis. Although the typical presentation is hypothyroidism and goiter (thyroid gland enlargement),

patients can present with hypothyroidism and no goiter, with euthyroidism and goiter, or rarely (<5%) with hyperthyroidism (Hashi-toxicosis).

Hashimoto's thyroiditis might be related to Graves' disease, a common cause of hyperthyroidism. Both diseases share similar clinical features: positive antibody titers, goiter with lymphocytic infiltration of the gland, familial tendency, and predilection for women. Both diseases can coexist in the same gland. Thyrotoxicosis can precede the onset of Hashimoto's hypothyroidism, and the end result of Graves' hyperthyroidism is often hypothyroidism. These common clinical features suggest that Graves' disease and Hashimoto's thyroiditis might be the same disease manifesting in different ways.

Other common causes of hypothyroidism are presented in Table 49-2 and include iatrogenic destruction of the gland after radioiodine therapy or surgery and hypothyroidism secondary to nontoxic multinodular goiter. Drug-induced hypothyroidism (e.g., iodides, amiodarone, lithium, interferon- α) occurs in susceptible persons (i.e., Hashimoto's thyroiditis) with a pre-existing thyroid abnormality.

The typical symptoms of hypothyroidism include weight gain, fatigue, sluggishness, cold intolerance, constipation, heavy menstrual periods, and muscle aches. A goiter might or might not be present. Patients with end-stage hypothyroidism, or myxedema coma, can also present with hypothermia, confusion, stupor or coma, carbon dioxide retention, hypoglycemia, hyponatremia, and ileus. Symptoms of "slowing down" would be expected because thyroid hormone is essential for the function and maintenance of all body systems and metabolic processes. In general, the more severe the degree of hypothyroidism, the greater the number of clinical findings. The exception is the older patient with hypothyroidism, who often presents with minimal or atypical symptoms (e.g., weight loss, deafness, tinnitus, carpal tunnel syndrome). Patients with mild and subclinical hypothyroidism might also have few or no symptoms. Laboratory findings that are diagnostic for overt hypothyroidism include elevated TSH and low free thyroxine (FT₄) levels; those for subclinical or early hypothyroidism are elevated TSH and normal FT₄ levels. The common clinical symptoms, physical findings, and labora-

TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone.

tory abnormalities of overt hypothyroidism are summarized in Table 49-3.

Levothyroxine (L-thyroxine) is the preferred thyroid replacement preparation. Several brand name and less costly generic preparations are available, and they are interchangeable in most patients. The signs and symptoms of

Table 49-3 Clinical and Laboratory Findings of Primary Hypothyroidism

| <i>Symptoms</i> | <i>Physical Findings</i> | <i>Laboratory</i> |
|---|--|--------------------------------------|
| General: weakness, tiredness, lethargy, fatigue | Thin brittle nails | ↓ TT ₄ |
| Cold intolerance | Thinning of skin | ↓ FT ₄ I |
| Headache | Pallor | ↓ FT ₄ |
| Loss of taste/smell | Puffiness of face, eyelids | ↓ TT ₃ |
| Deafness | Yellowing of skin | ↓ FT ₃ I |
| Hoarseness | Thinning of outer eyebrows | ↑ TSH |
| No sweating | Thickening of tongue | Positive antibodies (in Hashimoto's) |
| Modest weight gain | Peripheral edema | ↑ Cholesterol |
| Muscle cramps, aches, pains | Pleural/peritoneal/pericardial effusions | ↑ CPK |
| Dyspnea | ↓ DTRs | ↓ Na |
| Slow speech | "Myxedema heart" | ↑ LDH |
| Constipation | Bradycardia (↓ HR) | ↑ AST |
| Menorrhagia | Hypertension | ↓ Hct/Hgb |
| Galactorrhea | Goiter (primary hypothyroidism) | |

Table 49-4 Treatment of Hypothyroidism

| Patient Type/Complications | Dose (L-thyroxine) | Comment |
|--------------------------------------|---|---|
| Uncomplicated adult | 1.6–1.7 mcg/kg/day; 100–125 mcg/day average replacement dose; usual increment 25 mcg q6–8wk | <i>Onset of action:</i> 2–3 wk; <i>max effect:</i> 4–6 wk. Reversal of skin and hair changes may take several months. An FT ₄ or FT ₄ I and TSH should be checked 6–8 wk after initiation of therapy because T ₄ has a half-life of 7 days and three to four half-lives are needed to achieve steady state. Levels obtained before steady state can be very misleading. Because 80% is bioavailable, adjust IV doses downward. Small changes can be made by varying dose schedule (e.g., 150 mcg daily except Sunday). |
| Elderly | ≤1.6 mcg/kg/day (50–100 mcg/day) | Initiate T ₄ cautiously. Elderly may require less than younger patients. Sensitive to small dose changes. A few patients older than 60 yr require ≤50 mcg/day. |
| Cardiovascular disease (angina, CAD) | Start with 12.5–25 mcg/day. ↑ by 12.5–25 mcg/day q2–6wk as tolerated | These patients are very sensitive to cardiovascular effects of T ₄ . Even subtherapeutic doses can precipitate severe angina, MI, or death. Replace thyroid deficit slowly, cautiously, and sometimes even suboptimally. |
| Long-standing hypothyroidism (>1 yr) | Dose slowly. Start with 25 mcg/day. ↑ by 25 mcg/day q4–6wk as tolerated | Sensitive to cardiovascular effects of T ₄ . Steady state may be delayed because of ↓ clearance of T ₄ . ^a Correct replacement dose is a compromise between prevention of myxedema and avoidance of cardiac toxicity. |
| Pregnant | Most will require 45% ↑ in dose to ensure euthyroidism | Evaluate TSH, TT ₄ , and FT ₄ I. <i>Goal:</i> normal TSH and TT ₄ /FT ₄ I in upper normal range to prevent fetal hypothyroidism. |
| Pediatric (0–3 mo) | 10–15 mcg/kg/day | Hypothyroid infants can exhibit skin mottling, lethargy, hoarseness, poor feeding, delayed development, constipation, large tongue, neonatal jaundice, piglike facies, choking, respiratory difficulties, and delayed skeletal maturation (epiphyseal dysgenesis). The serum T ₄ should be increased rapidly to minimize impaired cognitive function. In the healthy term infant, 37.5–50 mcg/day of T ₄ is appropriate. Dose decreases with age (Table 49-9). |

^aIn severely myxedematous patients, steady state may require ≥6 months. In patients who are clinically euthyroid but have ↑ TT₄ and FTI, use TT₃ and TSH as guide to dose adjustments.
CAD, coronary artery disease; FT₄, free thyroxine; FT₄I, free thyroxine index; IV, intravenous; MI, myocardial infarction; q, every; QD, every day; T₄, thyroxine; TSH, thyroid-stimulating hormone; TT₄, total thyroxine.

hypothyroidism can be reversed easily in most patients by the administration of L-thyroxine on an empty stomach at average oral replacement dosages of 1.6 to 1.7 mcg/kg/day. Exceptions include older patients, patients with severe and long-standing hypothyroidism, and patients with cardiac disease, in whom administration of full replacement doses might cause cardiac toxicity (Table 49-4). In such patients, minute T₄ doses should be started initially and the dosage titrated upward as tolerated; complete reversal of hypothyroidism might not be indicated or possible. In myxedema coma, intravenous (IV) therapy with large initial doses of L-thyroxine (e.g., 400 mcg) is necessary to increase the active free hormone level by saturating the empty thyroid-binding sites and to prevent the 60% to 70% mortality rate. In subclinical hypothyroidism, it is controversial whether T₄ replacement therapy is beneficial. There is no justification for treating patients with hypothyroid symptoms and normal laboratory findings with T₄.

The goal of therapy is to reverse the signs and symptoms of hypothyroidism and normalize the TSH and FT₄ levels. Some improvement of hypothyroid symptoms is often evident within 2 to 3 weeks of starting T₄ therapy. Overreplacement of L-thyroxine (manifested by below-normal or suppressed serum concentrations of TSH) is associated with osteoporosis and cardiac changes. The optimal T₄ replacement dosage must be administered for ~6 to 8 weeks before steady-state levels are reached. Evaluation of thyroid function tests before this time is misleading. Once a euthyroid state is attained, laboratory tests can be monitored every 3 to 6 months for the first year and then yearly thereafter. Medications that interfere with T₄

absorption (e.g., iron, aluminum-containing products, some calcium preparations, cholesterol resin and phosphate binders, raloxifene) should not be coadministered with T₄.

Hyperthyroidism or thyrotoxicosis is the hypermetabolic syndrome that occurs when the production of thyroid hormone is excessive. Hyperthyroidism affects about 2% of females and about 0.1% of males. The prevalence of hyperthyroidism in older patients varies between 0.5% and 2.3% but accounts for 10% to 15% of all thyrotoxic patients, depending on the population studied.

Graves' disease is the most common cause of hyperthyroidism. Toxic autonomous nodular goiters, both multi- and uninodular, account for a large proportion of the remaining

Table 49-5 Causes of Hyperthyroidism

| |

Table 49-6 Clinical and Laboratory Findings of Hyperthyroidism**Symptoms**

Heat intolerance
 Weight loss common, or weight gain caused by ↑ appetite
 Palpitations
 Pedal edema
 Diarrhea/frequent bowel movements
 Amenorrhea/light menses
 Tremor
 Weakness, fatigue
 Nervousness, irritability, insomnia

Physical Findings

Thinning of hair (fine)
 Proptosis, lid lag, lid retraction, stare, chemosis, conjunctivitis, periorbital edema, loss of extraocular movements
 Diffusely enlarged goiter, bruits, thrills
 Wide pulse pressure
 Pretibial myxedema
 Plummer's nails^a
 Flushed, moist skin
 Palmar erythema
 Brisk DTRs

Laboratory Findings

↑ TT₄
 ↑ TT₃
 ↑ FT₄I/FT₄
 ↑ FT₃I/FT₃
 Suppressed TSH
 ⊕ TRAb
 ⊕ ATgA
 ⊕ TPO
 RAIU >50%
 ↓ Cholesterol
 ↑ Alkaline phosphatase
 ↑ Calcium
 ↑ AST

^aThe fingernail separates from its matrix, but only one or two nails are generally affected.

AST, aspartate aminotransferase; ATgA, antihydroglobulin antibody; DTRs, deep tendon reflexes; FT₃, free triiodothyronine; FT₄, free thyroxine; FT₃I, free triiodothyronine index; FT₄I, free thyroxine index; RAIU, radioactive iodine uptake; TPO, thyroperoxidase antibody; TRAb, thyroid-receptor antibodies; TSH, thyroid-stimulating hormone; TT₃, total triiodothyronine; TT₄, total thyroxine.

causes. Other causes of hyperthyroidism, including iatrogenic ones, are outlined in Table 49-5. Graves' disease is an autoimmune disorder characterized by one or more of the following features: hyperthyroidism, diffuse goiter, ophthalmopathy (exophthalmos), dermatopathy (pretibial myxedema), and acropachy (thickening of fingers or toes). The production of excessive quantities of thyroid hormone is attributed to a circulating IgG or thyroid receptor antibody (TRAb), which has a TSH-like ability to stimulate hormone synthesis. The abnormal production of TRAb by plasma cells (differentiated B lymphocytes) results from a deficiency of suppressor T-cell lymphocytes. The peak incidence of Graves' disease occurs in the third or fourth decade of life, the duration of the disease is unknown, and its clinical course is characterized by remission and relapse.

The classic symptoms of hyperthyroidism, summarized in Table 49-6, mimic a hypermetabolic state and include nervousness, heat intolerance, palpitations, weight loss despite in-

creased appetite, insomnia, proximal muscle weakness, frequent bowel movements, amenorrhea, and emotional lability. Hyperthyroid symptoms can be present for 3 to 12 months before the diagnosis is made. The typical symptoms are often absent in the older patient, producing a masked or "apathetic" picture. Because the clinical presentation of hyperthyroidism in the older patient is atypical, occult hyperthyroidism always must be considered, especially in patients with new or worsening cardiac findings (e.g., atrial fibrillation). Untreated hyperthyroidism can progress to thyroid storm, a life-threatening form of hyperthyroidism characterized by "exaggerated" symptoms of thyrotoxicosis and the acute onset of high fever (sine qua non). The diagnosis of hyperthyroidism is confirmed by high serum concentrations of FT₄ and/or an undetectable TSH level. Positive thyroid antibodies confirm an autoimmune origin for the hyperthyroidism (e.g., Graves' disease).

The primary treatment options for hyperthyroidism are antithyroid drugs (thioamides), radioiodine, and surgery. All three modalities are effective, and the treatment of choice is influenced by the etiology of the hyperthyroidism, the size of the goiter, the presence of ophthalmopathy, comorbid conditions (e.g., angina), likelihood of pregnancy, patient age, patient preference, and physician bias. Older patients and those with co-existing cardiac disease, ophthalmopathy, and hyperthyroidism secondary to a toxic multinodular goiter are treated best with radioactive iodine (RAI). Surgery is preferable if obstructive symptoms are present or concomitant malignancy is suspected. Pregnant patients can be managed with thioamides or surgery in the second trimester; RAI is absolutely contraindicated.

The thioamides are used as primary therapy for hyperthyroidism and as adjunctive short-term therapy to produce euthyroidism before surgery or RAI. The thioamides (e.g., methimazole [Tapazole], propylthiouracil [PTU]) primarily prevent hormone synthesis but do not affect existing stores of thyroid hormone. Therefore, hyperthyroid symptoms will continue for 4 to 6 weeks after beginning thioamide therapy, and initial treatment with β -blockers or iodides is often required for symptomatic relief. The onset of action of PTU is more rapid than methimazole because PTU has an additional mechanism of action, which is to inhibit the peripheral conversion of T₄ to T₃. Therefore, PTU is the thioamide of choice for thyroid storm. PTU is also preferred during pregnancy because congenital defects have been reported with methimazole. Although both drugs are secreted in breast milk, no adverse effects have been reported in the exposed infants. Otherwise, methimazole is preferred over PTU to enhance adherence; it can be administered once daily, whereas PTU must be given two or three times daily. The duration of treatment is empiric, and thioamides typically are prescribed for 12 to 18 months in hopes of long-term spontaneous remission once the drug is discontinued. Although thioamides maintain euthyroidism, they do not change the natural course of the disease, and the likelihood of spontaneous remission, once treatment is discontinued, is about 50%. The expectation that the combination of thioamide and T₄ therapy might increase the likelihood of remission has been disappointing. The major adverse effects from thioamides include skin rash, gastrointestinal (GI) complaints, agranulocytosis, and hepatitis. Cross-sensitivity between the thioamides is not complete, and the alternative drug can be used if rash or GI complaints do not resolve. This is not true for agranulocytosis, and the alternative agent is not recommended.

Nodular goiters, both multi- and uninodular, are common thyroid problems. The estimated prevalence is 4% to 5% of the adult population. The origin of thyroid nodules is unknown, although TSH stimulation, iodine deficiency, goitrogens (e.g., iodides, lithium, amiodarone), and radiation exposure are contributory. The nodular goiter is usually found on routine physical examination in asymptomatic and euthyroid patients. However, patients can present with hyperthyroidism caused by autonomous functioning “hot” nodules, overt hypothyroidism, or obstructive symptoms of dysphagia and respiratory difficulty. Thyroid function tests, including TSH and FT₄ levels, and antibodies should be obtained. Additional information can be obtained from radioactive iodine uptake (RAIU), ultrasound, fine-needle aspiration (FNA), or magnetic resonance imaging.

Treatment options include surgery, RAI, or thyroid replacement therapy if necessary to correct the hypothyroidism. All goitrogens should be removed if possible. L-thyroxine suppression therapy is no longer recommended since the dangers from supraphysiologic dosages of T₄ (e.g., osteoporosis and the potential for cardiac arrhythmias) exceed the benefits of therapy.

Malignancy must be considered if there is recent growth in a “cold” single or dominant nodule, a firm nodule clinically suspicious for cancer on a physical examination, a history of thyroid irradiation, or a strong family history of medullary thyroid carcinoma. A FNA of the thyroid nodule can document an underlying malignancy. The risk of malignancy in a toxic multinodular goiter is small, and definitive treatment with RAI is usually required to manage any hyperthyroid symptoms. Surgery is indicated if malignancy is highly suspected or if any obstructive or respiratory symptoms are present.

Following a total thyroidectomy for thyroid cancer, RAI ablation is usually given to remove any remaining thyroid tissue. This dosage is higher than the dosage required for treatment of Graves’ disease. A yearly evaluation for detection of recurrence of some thyroid cancers requires the patient to be off T₄ for 4 to 6 weeks so that a repeat radioactive uptake and scan can be completed. An elevated TSH level is also necessary to allow thyroglobulin levels, a tumor marker, to rise if any malignant tissue is present. Recurrence of the thyroid cancer is likely if there are positive findings on the scan or an elevation in thyroglobulin levels. The administration of recombinant human TSH (Thyrogen) may improve quality of life because comparable elevations in TSH occur without stopping L-thyroxine therapy, reducing the duration of hypothyroidism.

THYROID FUNCTION TESTS

The principal laboratory tests recommended in the initial evaluation of thyroid disorders are the TSH and the FT₄ levels.¹⁻³ Positive thyroid antibodies indicate an autoimmune thyroid etiology. Adjuncts to the previous tests include the total T₃ (TT₃), free T₃ (FT₃) or FT₃ index (FT₃I), RAIU and scan, TRAb, ultrasound, and FNA biopsy (Table 49-7).

Measurements of Free and Total Serum Hormone Levels

Free Thyroxine, Free Thyroxine Index, Free Triiodothyronine, and Free Triiodothyronine Index

The FT₄ and FT₃ are the most reliable tests for the evaluation of hormone concentrations, especially when thyroid hormone

binding abnormalities exist. The FT₃ is most useful in hyperthyroidism but can be normal or low in hypothyroidism. If a direct measure of the free hormone levels are not available, the estimated free hormone indices (FT₄I, FT₃I) can provide comparable information. However, these indices do not correct for changes observed in patients with “euthyroid sick” nonthyroidal illnesses whose TBG binding affinity is altered. In these circumstances, the FT₄ and FT₃ are preferable.

Total Thyroxine and Total Triiodothyronine

The total thyroxine (TT₄) and total triiodothyronine (TT₃) measure both free and bound (total) serum T₄ and T₃. Because the bound fraction is the major fraction measured, situations that change the hormone’s affinity for TBG or the TBG level will influence the results. For example, falsely elevated levels of TT₄ and TT₃ are common in the euthyroid pregnant woman (see question 4). In addition, the TT₃ is often low in older patients and in many acute and chronic nonthyroidal illnesses because the peripheral conversion of T₄ to T₃ is decreased (see questions 2 and 3). Therefore, careful interpretation of these tests is necessary in situations that alter thyroid hormone binding, TBG levels, or T₄ to T₃ conversion (Table 49-1). The TT₃ is particularly helpful in detecting early relapse of Graves’ disease and in confirming the diagnosis of hyperthyroidism despite normal TT₄ levels. The TT₃ is not a good indicator of hypothyroidism because TT₃ can be normal. Measurement of only the total hormone levels is less reliable than either the free or estimated free hormone levels when alterations in thyroid-binding globulin or nonthyroidal illnesses exist.

Tests of the Hypothalamic-Pituitary-Thyroid Axis

Thyroid-Stimulating Hormone

The serum TSH or thyrotropin is the most sensitive test to evaluate thyroid function.¹⁻³ TSH, secreted by the pituitary, is elevated in early or subclinical hypothyroidism (when thyroid hormone levels appear normal) and when thyroid hormone replacement therapy is inadequate. TSH can be abnormal even if the FT₄ remains within the normal range because the TSH is specific for each person’s physiological set point. Polymorphisms in the TSH receptor contribute to this interindividual variability.⁴ Consequently, low normal free hormone levels can stimulate the pituitary to synthesize increased amounts of TSH. This test cannot be used to differentiate between primary hypothyroidism (thyroid failure), which is characterized by elevated TSH levels and secondary (pituitary or hypothalamus failure) hypothyroidism. In the latter instance, TSH levels may be low or normal. However, the TSH assay can quantitate the upper and lower limits of normal so that a suppressed TSH level is highly suggestive of hyperthyroidism or exogenous thyroid overreplacement. Of note, TSH is not entirely specific for thyroid disease because abnormal levels are observed in euthyroid patients with nonthyroidal illnesses and in patients receiving drugs that can interfere with TSH secretion. TSH secretion is increased at bedtime and is affected by lack of sleep and exercise.⁵ TSH secretion is suppressed physiologically by dopamine, which antagonizes the stimulatory effects of TRH. Therefore, both dopaminergic agonists and antagonists can alter TSH secretion (see Question 5). Whether the upper

Table 49-7 Common Thyroid Function Tests

| Tests | Measures | Normals^a | Assay Interference | Comments |
|--|---|---|--|---|
| Measurement of Circulating Hormone Levels | | | | |
| FT ₄ | Direct measurement of free thyroxine | 0.7–1.9 ng/dL (9–24 pmol/L) | No interference by alterations in TBG | Most accurate determination of FT ₄ levels; might be higher than normal in patients on thyroxine replacement |
| FT ₄ I | Calculated free thyroxine index | <i>T₄ uptake method:</i> 6.5–12.5 <i>TT₄ × RT₃U method:</i> 1.3–4.2 | Euthyroid sick syndrome (see question 2) | Estimates direct FT ₄ measurement; compensates for alterations in TBG |
| TT ₄ | Total free and bound T ₄ | 5–12 mcg/dL (64–154 mmol/L) | Alterations in TBG (Table 49-1) | Specific and sensitive test if no alterations in TBG |
| TT ₃ | Total free and bound T ₃ | 70–132 ng/dL (1.1–2 nmol/L) | Alterations in TBG levels; T ₄ to T ₃ (Table 49-1). Euthyroid sick syndrome (see question 2) | Useful in detecting early, relapsing, and T ₃ toxicosis. Not useful in evaluation of hypothyroidism |
| FT ₃ | Direct measurement of free T ₃ | 0.2–0.42 ng/dL (3.5–6.5 pmol/L) | No interference by alterations in TBG | Most accurate determination of FT ₃ levels; might be lower than normal in patients on thyroxine replacement |
| FT ₃ I | Calculated free T ₃ index | 17.5–46 | Euthyroid sick syndrome (see question 2) | Estimates direct FT ₃ measurement; compensates for alterations in TBG |
| Tests of Thyroid Gland Function | | | | |
| RAIU | Gland's use of iodine after trace dose of either ¹²³ I or ¹³¹ I | 5%–35% | False decrease with excess iodide intake; false elevation with iodide deficiency | Useful in hyperthyroidism to determine RAI dose in Graves'; does not provide information regarding hormone synthesis |
| Scan | Gland size, shape, and tissue activity after ¹²³ I or ^{99m} Tc | — | ¹⁵⁴ I scan blocked by antithyroid/thyroid medications | Useful in nodular disease to detect “cold” or “hot” areas |
| Test of Hypothalamic-Pituitary-Thyroid Axis | | | | |
| TSH | Pituitary TSH level | 0.5–5 μU/mL | Dopamine, glucocorticoids, metoclopramide, thyroid hormone, amiodarone, metformin (Table 49-1) | Most sensitive index for hyperthyroidism, hypothyroidism, and replacement therapy |
| Tests of Autoimmunity | | | | |
| ATgA | Antibodies to thyroglobulin | <1 IU/mL | Nonthyroidal autoimmune disorders | Present in autoimmune thyroid disease; undetectable during remission |
| TPO | Thyroperoxidase antibodies | <1 IU/mL | Nonthyroidal autoimmune disorders | More sensitive of the two antibodies; titers detectable even after remission |
| TRAb | Thyroid receptor stimulating antibody | <125% | — | Confirms Graves' disease; detects risk of neonatal Graves' |
| Miscellaneous | | | | |
| Thyroglobulin | Colloid protein of normal thyroid gland | <56 ng/mL | Goiters; inflammatory thyroid disease | Marker for recurrent thyroid cancer or metastases in thyroidectomized patients |

^a At University of California laboratories.

 ATgA, antibodies to thyroglobulin; FT₃, free triiodothyronine; FT₄, free thyroxine; FT₃I, free triiodothyronine index; FT₄I, free thyroxine index; RAI, radioactive iodine; RAIU, radioactive iodine uptake; T₃, triiodothyronine; T₄, thyroxine; TBG, thyroxine-binding globulin; TPO, thyroperoxidase antibodies; TRAb, thyroid-receptor antibodies; TSH, thyroid-stimulating hormone; TT₃, total triiodothyronine; TT₄, total thyroxine.

limits of normal for TSH should be lowered to 2.5 $\mu\text{U}/\text{mL}$ is controversial.^{4,5}

Tests of Gland Function

Radioactive Iodine Uptake

RAIU, a measure of iodine utilization by the gland, is an indirect measure of hormone synthesis. It is elevated in hyperthyroidism and in early hypothyroidism when the failing gland is trying to increase hormone synthesis. A low or undetectable RAIU occurs in hypothyroidism, thyrotoxicosis factitia, and subacute thyroiditis. Typically, RAIU is used to calculate the dose of RAI therapy for treatment of Graves' disease and to determine the activity of one or several nodules in a gland. The RAIU is not necessary to diagnose classic Graves' disease or hypothyroidism.

A tracer dose of ^{131}I is administered, and the radioactivity of the gland is measured at 5 and 24 hours after ingestion. It is necessary to measure both the 5- and 24-hour RAIU so that patients with rapid turnover of iodine will not be missed. In some hyperthyroid patients, the 5-hour uptake is elevated, but the 24-hour uptake can fall to normal or subnormal levels.

The normal range of the RAIU (Table 49-7) is affected by any condition that alters iodine intake. Iodine depletion caused by rigorous diuretic therapy or an iodine-deficient diet increases uptake because of replenishment of depleted total iodide pools. Conversely, dilution of ^{131}I with exogenous iodide sources (e.g., contrast dyes) decreases RAIU.

Imaging Studies

THYROID SCAN

A scan of the gland is performed simultaneously with the RAIU or after ingestion of technetium ($^{99\text{m}}\text{Tc}$) pertechnetate. The scan provides information concerning gland size and shape, and identifies hypermetabolic ("hot") and hypometabolic ("cold") areas. The possibility of carcinoma must be considered if cold areas are present. A scan should be considered in the patient with nodular thyroid disease.

Thyroid Ultrasound

A thyroid ultrasound can provide information about gland size and number of clinically palpable or nonpalpable nodules or cysts in the thyroid gland.

Tests of Autoimmunity

Thyroperoxidase and Antithyroglobulin Antibodies

Thyroperoxidase (TPO) and antithyroglobulin (ATgA) antibodies to the thyroid gland indicate an autoimmune process, although the nature of the problem is undetermined.^{1,3} About 60% to 70% of patients with Graves' disease and 95% of patients with Hashimoto's thyroiditis have positive antibodies to both thyroid antigens. Positive antibodies alone do not indicate thyroid disease because 5% to 10% of asymptomatic patients, as well as patients with other nonthyroidal autoimmune disorders, have positive antibodies.

Clinically, the TPO is more specific than ATgA in assessing disease activity. Although both antibodies are elevated during acute flares of the disease, lower titers of TPO remain positive

during quiescent periods of the disease, while ATgA levels revert to negative.

Thyroid Receptor Antibodies

TRAbs are IgG immunoglobulins that are present in virtually all patients with Graves' disease.^{1,3} Like TSH, these immunoglobulins can stimulate the thyroid gland to produce thyroid hormones. High titers of TRAb are useful in diagnosing otherwise asymptomatic Graves' disease (i.e., ophthalmopathy), in predicting the risk of relapse of Graves' disease after discontinuing medication, and in predicting the risk of neonatal hyperthyroidism in utero through transplacental passage of TRAb from the pregnant mother. Otherwise, TRAb measurement is expensive and offers no additional information in the patient with a typical Graves' disease presentation.

Clinical Application and Interpretation

Euthyroidism and Nonthyroidal Illness Syndrome

1. R.K., an obese 42-year-old woman, is admitted to the hospital because of increasing fatigue, sluggishness, shortness of breath (SOB), and pitting edema of the legs during the past 3 weeks. Bilateral pleural effusions found on her chest radiograph indicate a worsening of her congestive heart failure (CHF). Her other medical problems include cirrhosis of the liver, diabetes, and chronic bronchitis, for which she takes glipizide 10 mg every day (QD) and Lugol's solution three times a day (TID).

Pertinent physical findings include a palpable but normal-size thyroid, bibasilar rales, cardiomegaly, hepatomegaly, 4+ pitting edema, and normal deep tendon reflexes (DTRs). A diagnosis of worsening CHF secondary to hypothyroidism is suspected based on the following laboratory findings: cholesterol, 385 mg/dL (normal, <200); RAIU at 24 hours, 13% (normal, 5%–35%); scan, normal-size gland with homogenous uptake; TT₄, 1.4 mcg/dL (normal, 5–12); TT₃, 22 ng/dL (normal, 70–132); TSH, 4 $\mu\text{units}/\text{mL}$ (normal, 0.5–4.7); FT₄I, 3.5 (normal, 6.5–12.5); TPO, 30 IU/mL (normal, <1); and ATgA, 3 IU/mL (normal, <1). Evaluate and explain R.K.'s thyroid status based on her clinical and laboratory findings.

[SI units: cholesterol, 9.96 mmol/L (normal, <5.2); TT₄, 18 nmol/L (normal, 64–154); FT₄I, 45 (normal, 84–161); TT₃, 0.3 nmol/L (normal, 1.1–2); TSH, 4 mIU/L (normal, 0.5–4.7)]

Although low-output failure can be a presenting sign of hypothyroidism, the normal TSH definitely indicates that R.K. is euthyroid, despite the confusing results of her other thyroid function tests. The depressed RAIU is consistent with her history of iodide ingestion and dilution of the ^{131}I . The low TT₄, TT₃, and FT₄I may be explained by her cirrhosis and nonthyroidal illness syndrome (see question 2). The negative thyroid antibodies, the normal scan, and normal DTRs further substantiate the diagnosis of euthyroidism. In hypothyroidism, a lower rate of cholesterol degradation can produce an elevated serum cholesterol level. However, because many extrathyroidal factors influence the serum concentration of cholesterol, this test is an imprecise reflection of thyroid status. In this case, the elevated cholesterol level is not related to hypothyroidism.

2. Assess the results and explain the significance of R.K.'s TT₄, FT₄I, and TT₃ values.

R.K.'s thyroid function test results are consistent with non-thyroidal illness syndrome. Abnormal thyroid function tests are commonly found in euthyroid patients with various serious systemic diseases, including starvation, infections, sepsis, acute psychiatric disorders, HIV infection, myocardial infarction (MI), bone marrow transplantation, and severe chronic cardiac, pulmonary, renal, hepatic, and neoplastic diseases.^{1,3,7-14} This "euthyroid sick" syndrome occurs in 37% to 70% of chronically ill or hospitalized patients and must be recognized. In general, the sicker the patient, the greater the degree of abnormal thyroid function findings, even though the patient has no thyroid disease.

The extent of laboratory changes varies with the severity of the illness. Typical changes include a low TT₃ (e.g., 15–20 ng/dL), a high rT₃, a normal or low TT₄ and FT₄I, and a suppressed (uncommon), normal or borderline-high compensatory TSH as patients recover from illness. In more serious illness, the TT₄ and FT₄I are often low. Free hormone levels (e.g., FT₄, FT₃) are often normal or low, which might be related to variations in the assays used. However, these inconsistent findings fuel the controversy over whether thyroid hormone therapy is beneficial or detrimental. These findings are believed to be explained by alterations in the peripheral conversion of T₄ to T₃ and by complex changes in the hypothalamic-pituitary-thyroid relationships. The low serum T₃ levels and high inactive rT₃ levels are caused by decreased activity of 5'-deiodinase, an enzyme that is necessary for the peripheral conversion of T₄ to T₃. Impaired protein synthesis of thyroid-binding prealbumin and an increase in the proportion of a lower-binding-capacity form of TBG might account for the lower bound hormone levels, but the concomitant increase in the free hormone concentrations would maintain a euthyroid state. Furthermore, circulating substances that inhibit the binding of T₄ and T₃ to the serum-binding proteins might also be present.

Less common changes include a modestly elevated TT₄ and FT₄I in patients with acute viral hepatitis, psychiatric disorders, renal failure, and advanced HIV infection. The TT₃ is usually normal but can be low in critically ill patients. Modest elevations in hormonal binding affinity and increased synthesis of TBG explain these findings.

Several studies have shown a strong inverse correlation between mortality and total serum T₄, T₃, and rT₃ levels.¹⁰⁻¹² Of 86 hospitalized, intensive care patients, 84% of those with a serum T₄ of <3 mcg/dL died, whereas 85% of those with a serum T₄ of >5 mcg/dL survived. In 331 patients with acute MI, rT₃ levels >0.41 nmol/L were significantly associated with a greater risk of death at 1 year. During recovery, TSH levels increase and hormone levels start to normalize. Therefore, a favorable outcome is associated with reversal of the hormone indices.

Thyroid experts are divided about whether patients with euthyroid sick syndrome should be treated, and few randomized studies are available to guide therapeutic decisions.^{8,9-17} The few available studies found no survival benefits or favorable clinical outcomes following hormone therapy, although cardiac hemodynamics improved. The benefits of hormone replacement are unproven, and might be detrimental. In one trial,

the mortality of patients with acute renal failure treated with T₄ was 43% versus 13% in the control group.¹⁴ Opponents argue that T₄ therapy, by inhibiting TSH, may interfere with normal thyroid recovery, whereas proponents argue that there is no clear evidence that therapy is toxic.

In summary, T₄ and T₃ measurements are of limited value in the diagnosis of thyroid dysfunction in patients with significant nonthyroidal illness. A normal or near-normal TSH is necessary to establish euthyroidism in sick patients with nonthyroidal illness. The available data are not supportive of starting thyroid hormone treatment now. The abnormal laboratory findings should reverse when R.K.'s nonthyroidal illness is corrected. To confirm euthyroidism, the slightly elevated TSH should be repeated once R.K.'s medical condition improves.

Drug Interference With Thyroid Function Tests

3. J.R., a 45-year-old man, complains of fatigue, dry skin, and constipation. His other medical problems include alcoholism for 10 years, cirrhosis, grand mal seizures treated with phenytoin (Dilantin) 300 mg/day and phenobarbital 90 mg at night, and rheumatoid arthritis for which he takes aspirin 325 mg, 20 tablets/day.

The results of his thyroid function tests are TT₄, 4.2 mcg/dL (normal, 5–12); FT₄, 0.6 ng/dL (normal, 0.7–1.9); and TSH, 2.5 μunits/mL (normal, 0.5–4.7). How should these laboratory findings be interpreted? What factors are responsible for the observed changes?

[SI units: TT₄, 54 nmol/L (normal, 64–154); FT₄, 8 pmol/L (normal, 9–24); TSH, 2.5 mIU/L (normal, 0.5–4.7)]

Despite complaints that could be consistent with hypothyroidism (e.g., fatigue, dry skin, constipation) and findings of low serum hormone values, J.R. is euthyroid, as evidenced by the normal TSH level. Secondary hypothyroidism is unlikely at this age without a history of central nervous system (CNS) trauma or tumor. Some nonthyroidal factors could account for J.R.'s low TT₄ and FT₄ values.⁷ Anti-inflammatory doses of salicylates >2 g/day and salicylate derivatives (i.e., Disalcid, salsalate) can displace T₄ from both TBG and TBPA, causing these abnormal findings.^{7,18,19} Elevation in free T₄ levels and suppression of TSH below normal occur transiently (i.e., no longer than first 3 weeks of administration) but normalize with chronic administration. Cirrhosis, stress, severe infections, and hereditary factors can also decrease TBG and TBPA synthesis to produce similar TT₄ findings. A medication history for drugs such as androgens or glucocorticoids that can lower TBG levels, and therefore TT₄ levels, should be elicited (Table 49-1).⁷

Enzyme inducers, such as rifampin and anticonvulsants, (phenytoin [Dilantin], phenobarbital, valproic acid [Depakene], carbamazepine [Tegretol]), can alter serum thyroid hormone levels.^{7,20-25} A 40% to 60% reduction in total T₄ serum concentrations results from an increase in the metabolism (nondeiodination) of T₄ and from hormone displacement in patients receiving chronic anticonvulsant therapy. Serum T₃ levels are normal or slightly decreased. In addition, therapeutic levels of phenytoin and carbamazepine interfere with the FT₄ assay, causing a 20% to 40% lower FT₄ than would be expected in euthyroid persons.²¹ TSH levels remain

normal and patients are euthyroid; however, those who previously required T₄ therapy may need a dosage increment to maintain euthyroidism.^{24,25} Valproic acid is reported to have similar but less potent effects on thyroid function.^{20,22} Phenobarbital can increase T₄ uptake by the liver and increase the fecal excretion of T₄. Serum binding of thyroid hormones is unaffected by phenobarbital.

In summary, J.R. is taking several drugs that can further compromise the already low serum T₄ levels resulting from his liver disease. FT₄ remains subnormal in euthyroid persons receiving phenytoin, but normal TSH confirms euthyroidism.

4. S.T., a 23-year-old, sexually active woman whose only medication is birth control pills comes to the clinic complaining of extreme nervousness, diaphoresis, and scanty menstrual periods. Although she appears healthy, the possibility of hyperthyroidism is considered on the basis of the following laboratory values: TT₄, 16 mcg/dL (normal, 5–12); FT₄, 1.2 ng/dL (normal, 0.7–1.9); and TSH, 1.2 μ units/mL (normal, 0.5–4.7). Based on this information, what would be a reasonable assessment of S.T.’s thyroid status?

[SI units: TT₄, 206 nmol/L (normal, 64–154); FT₄, 16 pmol/L (normal, 9–24); TSH, 1.2 mIU/L (normal, 0.5–4.7)]

The normal FT₄, TSH, and calculated FT₄I confirm that S.T. is not hyperthyroid. The elevated TT₄ is consistent with increased TBG levels observed in patients with acute hepatitis; in pregnancy; and in persons taking estrogen, oral contraceptives, tamoxifen, raloxifene, heroin, or methadone.^{7,26–30} Because TBG and therefore bound T₄ levels are increased by estrogens in S.T., total serum T₄ measurements are falsely elevated. In patients requiring L-thyroxine, the use of estrogens can increase requirements of hormone replacement because the increased pituitary secretion of TSH cannot increase thyroid production needed to offset the increased binding of T₄.²⁷ Thyroid function tests should return to normal within 4 weeks after oral contraceptives are discontinued. Progesterone-only oral contraceptives do not affect protein binding and therefore do not alter thyroid function tests.

5. J.P., a 55-year-old woman, complains of 3 months of progressive tremors, dizziness, and ataxia. Two months ago, she had a silent MI complicated by malignant ventricular ectopy that was responsive only to amiodarone (Cordarone) therapy. Her other medical problems include Parkinsonism, insulin-dependent diabetes, and diabetic gastroparesis. Her current medications include amiodarone, insulin, metformin, metoclopramide (Reglan), bromocriptine (Parlodel), and levodopa/carbidopa (Sinemet). Physical examination of the thyroid was unremarkable. Thyroid function tests show TT₄, 14.5 mcg/dL (normal, 5–12); FT₄, 2.3 ng/dL (normal, 0.7–1.9); TSH, 3.8 μ units/mL (normal, 0.5–4.7); TT₃, 40 ng/dL (normal, 70–132); and TPO antibodies, 40 IU/L (normal, <1). How should J.P.’s laboratory values be interpreted?

[SI units: TT₄, 187 nmol/L (normal, 64–154); FT₄, 30 pmol/L (normal, 9–24); TSH, 3.8 mIU/L (normal, 0.5–4.7); TT₃, 0.63 nmol/L (normal, 1.1–2)]

Although the symptoms of tremors, dizziness, and weight loss are suggestive of hyperthyroidism, the low TT₃, negative antibodies, normal TSH, and normal thyroid examination make

this diagnosis unlikely. Side effects of amiodarone could be responsible for J.P.’s symptoms. Her drug therapy could also explain her laboratory findings.

Amiodarone produces complex changes in thyroid function tests that are confusing if not properly interpreted.^{31–33} Because amiodarone inhibits both the peripheral and pituitary conversion of T₄ to T₃, FT₄ levels are elevated above normal, and TT₃ levels are subnormal in euthyroid patients. Transient elevations in TSH levels occur (usually <20 μ U/mL) during the first few weeks of therapy but return to normal in approximately 3 months. If TSH levels do not normalize, then amiodarone-induced thyroid disease should be considered. Amiodarone can cause either hypothyroidism or hyperthyroidism in susceptible patients (see question 54).

The other drugs J.P. is taking—bromocriptine, levodopa, metformin, and metoclopramide—also add to the diagnostic confusion. Although these drugs do not affect the actual circulating hormone levels, they affect the dopaminergic system that controls both TSH and TRH secretion.^{2,3,7} Infusions of dopamine and dobutamine can decrease both TSH secretion and the TSH response to TRH in euthyroid and hypothyroid patients.^{2,3,7,34} Therefore, dopamine agonists such as bromocriptine, cabergoline, and levodopa can blunt the normal TSH response.^{2,7,35} In addition, metformin suppresses TSH levels by as yet an unknown mechanism of action.³⁶ Conversely, dopamine antagonists such as metoclopramide or domperidone can elevate TSH levels.^{2,7} Fortunately, the alterations in TSH caused by these agents are usually not substantial enough to completely obscure the true thyroid abnormality.

HYPOTHYROIDISM

Clinical Presentation

6. M.W., a 70-kg, 23-year-old voice student, thinks that her neck has become “fatter” over the past 3 to 4 months. She has gained 10 kg, feels mentally sluggish, tires easily, and finds that she can no longer hit high notes. Physical examination reveals puffy facies, yellowish skin, delayed DTRs, and a firm, enlarged thyroid gland. Laboratory data include FT₄, 0.6 ng/dL (normal, 0.7–1.9); TSH, 60 μ units/mL (normal, 0.5–4.7); and TPO antibodies, 136 IU/L (normal, <1). Assess M.W.’s thyroid status based on her clinical and laboratory findings.

[SI units: FT₄, 8 pmol/L (normal, 9–24); TSH, 60 mIU/L (normal, 0.5–4.7)]

M.W. presents with many of the clinical features of hypothyroidism as presented in Table 49-3. These include weight gain, mental sluggishness, easy fatigability, lowering of the voice pitch, puffy facies, yellowish tint of the skin, delayed DTRs, and enlarged thyroid.³⁷ The diagnosis of hypothyroidism is confirmed by her laboratory findings of a low FT₄, an elevated TSH value, and positive TPO antibodies.

A firm goiter, thyroid antibodies, and clinical symptoms of hypothyroidism strongly suggest Hashimoto’s thyroiditis. She has no history of prior antithyroid drug use, surgery, or RAI treatment, which are common causes of iatrogenic hypothyroidism. She is also not taking any goitrogens or drugs known to cause hypothyroidism (Table 49-2).

Table 49-8 Thyroid Preparations

| Drug/Dosage Forms | Composition | Dosage Equivalent | Comments |
|--|--|--------------------------|---|
| Thyroid USP (Armour) <i>Tab:</i> 0.25, 0.5, 1, 1.5, 2, 3, 4, and 5 gr | Desiccated hog, beef, or sheep thyroid gland Standardized iodine content | 1 gr ^a — | Unpredictable T ₄ :T ₃ ratio; suprathysiologic elevations in T ₃ levels might produce toxic symptoms; Armour brand preferred |
| L-thyroxine (Levoxyl, Levothroid, Synthroid, Unithroid, various) <i>Tab:</i> 0.025, 0.050, 0.075, 0.088, 0.112, 0.125, 0.137, 0.15, 0.175, 0.2, and 0.3 mg <i>Inj:</i> 200 and 500 mcg | Synthetic T ₄ — | 60 mcg ^a — | Stable, predictable potency; well absorbed; more potent than desiccated thyroid. When changing from >2 gr desiccated thyroid to L-T ₄ , a lower dosage of L-T ₄ might be needed to avoid toxicity. Weight should be considered in dosing (1.6– 1.7 mcg/kg/day). L-T ₄ absorption can be impaired by iron, aluminum-containing products (e.g., antacids, sucralfate), Kayexalate, calcium preparations, proton pump inhibitors, cholesterol resin and phosphate binders, raloxifene, soy, bran, fiber enriched foods. L-T ₄ metabolism increased by anticonvulsants, rifampin, imatinib, bexarotene, and pregnancy |
| l-Triiodothyronine (Cytomel) <i>Tab:</i> 5, 25, and 50 mcg <i>Inj:</i> 10 mcg/mL (Triostat) | Synthetic T ₃ — — | 25–37.5 mcg — — | Complete absorption; requires multiple daily dosing; toxicity similar to all T ₃ -containing products; see desiccated thyroid comments |
| Liatrix (Thyrolar) <i>Tab:</i> 0.25, 0.5, 1, 2, and 3 gr | 60 mcg T ₄ :15 mcg T ₃ 50 mcg T ₄ :12.5 mcg T ₃ | Thyrolar-1 — | No need for liatrix because T ₄ is converted to T ₃ peripherally; expensive, stable, and predictable content |

^a60 mg (1 gr) of desiccated thyroid = 60 mcg of T₄.⁴²

gr, grain; Inj, injection; L-T₄, levothyroxine; T₃, triiodothyronine; T₄, thyroxine; Tab, tablet; USP, United States Pharmacopeia.

Treatment With Thyroid Hormones

Thyroid Hormone Products

7. What thyroid preparation should be used to treat M.W.'s hypothyroidism? Are differences, advantages, or disadvantages significant among the various generic and brand name formulations of thyroid hormones?

The principal goals of thyroid hormone therapy are to attain and maintain a euthyroid state. Thyroid preparations (Table 49-8) are synthetic (L-thyroxine [various], L-triiodothyronine [Cytomel], liatrix [Thyrolar]) or natural (desiccated thyroid). The latter come from animal tissues.

DESICCATED THYROID

Desiccated thyroid (U.S. Pharmacopoeia [USP]) is derived from pork thyroid glands, although beef and sheep also are used. Today, starting patients on desiccated thyroid is not justified. The USP requires only that desiccated thyroid contain 0.17% to 0.23% organic iodine by weight. These requirements do not seem stringent enough because potency may vary with changes in the proportion of the two active hormones (T₃ and T₄) or with changes in the amount of organic iodine present.^{38,39} This variable potency seems to be particularly true of generic formulations compared with the biologically standardized Armour brand of desiccated thyroid. Inactive desiccated thyroid preparations that contain negligible amounts of T₃ and T₄ or even iodinated casein instead of active hormone have been identified in various brands sold in retail pharmacies and in over-the-counter products found in health food

stores.³⁹⁻⁴¹ Likewise, preparations with greater-than-expected activity caused by an abnormally high T₃ content have resulted in thyrotoxicosis.

Allergic reactions to the animal protein are another concern. In addition, desiccated thyroid suffers from two problems inherent to all T₃-containing preparations. Because T₃ is absorbed more rapidly than T₄, suprathysiologic elevations in plasma T₃ levels occur after oral ingestion, which can produce mild thyrotoxic symptoms in some patients. FT₄ levels are low during T₃ administration and, if misinterpreted, can result in the erroneous administration of more hormone. These problems with T₃ are easily missed unless T₃ levels are routinely monitored. Because significant amounts of T₄ are converted to T₃ peripherally, oral administration of T₃ offers no advantage and is not usually needed. (See Triiodothyronine section.)

Loss of tablet potency can occur from prolonged storage of desiccated thyroid preparations, but this instability is not as important as once believed. Because the only apparent advantage of desiccated thyroid is its low cost, it should not be considered the drug of choice for replacement therapy. Patients maintained on desiccated thyroid should be encouraged to change to L-thyroxine (T₄). Although 60 mg (1 gr) of desiccated thyroid is theoretically equal in potency to 75 to 100 mcg of T₄,⁴² this equivalency may not hold true if the desiccated thyroid preparation is less active than its labeled content. The patient's weight also should be considered when switching therapy (see Question 8).

The synthetic thyroid preparations differ from one another in their relative potency, onset of action, and biological half-life.

LEVOTHYROXINE OR L-THYROXINE

L-thyroxine is the thyroid replacement of choice.⁴³ Its advantages include stability, uniform potency, relatively low cost, and lack of allergenic foreign protein content. The long half-life of 7 days permits once-a-day dosing and, if necessary, the creation of special convenience schedules, such as the omission of medication on weekends. The mean absorption of a commonly used branded preparation is 81%.⁴⁴ Spuriously low absorption values noted in earlier studies resulted from an overestimation of L-thyroxine tablet content. Absorption is optimal on an empty stomach, at least 60 minutes before or 2 hours after meals or at bedtime.⁴⁵ Several medications can also impair L-thyroxine absorption (see Question 15).

Concerns about generic and branded L-thyroxine tablet stability and potency, bioavailability, and product interchangeability existed because L-thyroxine preparations were grandfathered in by the 1938 Food, Drug, and Cosmetic Act. To address these concerns, the U.S. Food and Drug Administration (FDA) required that all manufacturers of L-thyroxine products submit a New Drug Application (NDA) by August 2001 or cease production by 2003 if the NDA was not filed.⁴⁶ Several FDA-approved brand (e.g., Levoxyl, Levotheroid, Synthroid, Unithroid) and generic (e.g., Genpharm, Mylan Pharmaceuticals, Sandoz, Vintage) formulations approved under the NDA received AB or BX ratings, indicating interchangeability for some generic and brand preparations (e.g., Synthroid, Sandoz, Mylan). Raising concerns about the methodology the FDA used to determine bioequivalence, the American Thyroid Association, The Endocrine Society, and the American Association of Clinical Endocrinologists issued joint position statements expressing their displeasure with the FDA's conclusions of interchangeability.⁴⁷ Abbot Laboratories, the manufacturer of Synthroid, and others also disagreed with the FDA's findings.⁴⁸ Although this issue remains controversial, the preponderance of the evidence supports the FDA ratings and suggests that these preparations are likely to be interchangeable in the majority of patients.^{49–52}

TRIHODOTHYRONINE

T₃ (Cytomel) is not recommended for routine thyroid hormone replacement because of the problems identified earlier with T₃ administration (see Desiccated Thyroid section).⁴³ Numerous randomized studies now conclude that replacement with combination T₄ and small dosages of T₃ offer no advantage to T₄ alone, despite an initial study showing improved cognitive performance and mood changes.^{53,54} Its use in coronary bypass surgery is controversial.

Although T₃ is well absorbed, it has a relatively short half-life (1.5 days), necessitating multiple daily dosing to ensure a uniform response. Other disadvantages include higher expense and a greater potential for cardiotoxicity. Its primary use is for patients who require short-term hormone replacement therapy and those in whom T₄ conversion to T₃ might be impaired. Proponents favoring thyroid treatment of the “euthyroid sick” syndrome identify T₃ as the hormone replacement of choice. T₃ therapy should be monitored using the TSH and TT₃ or FT₃ levels.

LIOTRIX

Liotrix (Thyrolar) is a combination of synthetic T₄ and T₃ in a physiological ratio of 4:1. This preparation is subject to the

same disadvantages common to all T₃-containing preparations. It is also stable and potent, but it is more expensive than other thyroid preparations. Because oral administration of T₃ is not needed and there is no advantage of adding T₃ to T₄ therapy, this expensive preparation is not recommended.^{53,54} Patients should be changed to an equivalent dosage of L-thyroxine.

Thyroxine DOSAGE

8. What would you recommend as appropriate starting and maintenance dosages of T₄ for M.W.?

The maintenance dosage for M.W. can be estimated from her weight. Average replacement doses of 1.6 to 1.7 mcg/kg/day (e.g., 100–125 mcg) are sufficient in most patients to normalize the TSH.^{37,43} L-thyroxine dosages that suppress TSH levels to below normal or undetectable levels (subclinical hyperthyroidism) should be avoided to prevent osteoporosis and cardiac toxicity.^{43,55–59} Excessive L-thyroxine can cause tachycardia, atrial arrhythmias, impaired ventricular relaxation, reduced exercise performance, and increased risk of cardiac mortality.⁵⁵ These considerations are especially important in older patients, who might require less T₄ than their younger counterparts and who are particularly sensitive to minute changes in T₄ doses (see Question 11). As patients age, the dosage should be evaluated yearly and decreased if necessary to maintain a normal TSH level.

How rapidly T₄ replacement can proceed depends on the likelihood of invoking cardiac toxicity in susceptible patients. Minute doses of T₄ (e.g., <75 mcg) can increase heart rate, stroke volume, oxygen consumption, and cardiac workload before euthyroidism occurs. One double-blind study compared the clinical outcome between starting full replacement doses versus gradual 25-mcg incremental doses in relatively young hypothyroid subjects with asymptomatic cardiac disease and concluded that those receiving full doses normalized thyroid function tests more rapidly (4 weeks) and without any toxicity.⁶⁰ Although this strategy may improve symptoms more quickly, further confirmation is needed to eliminate concerns about potential cardiac toxicity. Because M.W. has no identifiable risk factors (see Question 21) for cardiotoxicity that require careful dosage titration (e.g., old age, cardiac disease, long duration of hypothyroidism), she can be started on an estimated full replacement dose of 125 mcg daily of L-thyroxine (70 kg × 1.7 mcg/kg/day = 120 mcg). An alternative conservative approach would be to start with 100 or 112 mcg/day, check the FT₄ or FT₄I and TSH tests after 6 to 8 weeks of therapy, and if the TSH is still elevated without any symptoms of toxicity, increase the dosage to 125 mcg/day. The appropriate replacement dose will produce a TSH of 1 to 2 μ units/mL, normalize FT₄ or FT₄ I levels, and reverse clinical symptoms of hypothyroidism. Generally, dosing adjustments should not exceed monthly increments of 12.5 to 25 mcg/day.

MONITORING THERAPY

9. Ten days after starting L-thyroxine therapy, M.W. continues to complain of tiredness, fatigue, and difficulty singing despite excellent adherence. Thyroid function tests show a TT₄ of 4 mcg/dL (normal, 5–12), an FT₄ of 0.5 ng/dL (normal, 0.7–1.9), and a TSH of 40 μ units/mL (normal, 0.5–4.7). What therapeutic

options are available? How should M.W.'s thyroid function tests be interpreted?

[SI units: TT₄, 52 nmol/L (normal, 64–154); FT₄, 6 pmol/L (normal, 9–24); TSH, 40 mIU/L (normal, 0.5–4.7)]

Clinical improvement in the signs and symptoms of hypothyroidism and normalization of laboratory parameters are appropriate therapeutic end points. If the replacement dose is sufficient, some correction of her symptoms should occur after 2 to 3 weeks, but maximal effects will not be evident for 4 to 6 weeks. Typically, improvement of anemia and hair and skin changes is delayed and requires several months of treatment before resolution.^{36,42}

In patients with severe myxedema, a transiently elevated T₄ level might occur at 6 weeks because the metabolic clearance of T₄ is decreased by the hypometabolic state associated with hypothyroidism.

FT₄ or FT₄I and TSH should be checked about 6 to 8 weeks after the initiation of therapy because T₄ has a half-life of 7 days, and three to four half-lives are needed to reach steady-state levels. Levels obtained before this time (as in M.W.) may be misleading and should be interpreted cautiously. No change in her L-thyroxine dosage should be attempted at this time.

10. Eight weeks later, on a routine follow-up visit, M.W. still feels tired and not back to her normal self. She denies any symptoms of hyperthyroidism. Her thyroid function tests show a TT₄ of 14 mcg/dL (normal, 5–12), a TT₃ of 50 ng/dL (normal, 70–132), FT₄ of 1.9 ng/dL (normal, 0.7–1.9), and a TSH of 3.5 μ units/mL (normal, 0.5–4.7). How should M.W.'s thyroid function tests be interpreted? What changes, if any, should be recommended in her therapeutic regimen?

[SI units: TT₄, 180 nmol/L (normal, 64–154); FT₄, 24 pmol/L (normal, 9–24); TT₃, 0.7 nmol/L (normal, 1.1–2); TSH, 3.5 mIU/L (normal, 0.5–4.7)]

Patients treated with L-thyroxine may develop an elevated TT₄ concentration and FT₄ without overt clinical signs of hyperthyroidism.^{61,62} Despite these elevated levels, patients are euthyroid, as evidenced by a normal TSH. Because T₃ is not being released from the nonfunctioning thyroid gland, a higher concentration of T₄ is necessary to increase the amount of T₃ obtained from peripheral conversion. Woeber reported that the mean FT₄ was significantly higher (16 pmol/L) and the mean FT₃ lower (4 pmol/L) in patients receiving L-thyroxine than in those with thyroid disease not on L-thyroxine (FT₄, 14 pmol/L; FT₃, 4.2 pmol/L).⁶¹ As expected, patients receiving L-thyroxine who had an elevated TT₄, an elevated TT₃, and an elevated T₃:T₄ ratio also had symptoms of hyperthyroidism. Thus, the TSH appears to be the best indicator of euthyroidism in patients treated with L-thyroxine.

Another possibility is that the elevated thyroid levels may only be an artifact of the laboratory collection time. Before any changes in her dosing regimen are made, M.W. should be asked about the time she takes the drug and its relationship to the time of her blood draw. Random sampling of FT₄ and TSH levels can be significantly different when compared with trough levels.^{63,64} In one study, the FT₄ level was 12% higher and the TSH level 19% lower when obtained from random samples compared with trough samples.⁶⁴ Transient elevations in FT₄ levels were detected for 9 hours after ingestion of the oral L-thyroxine.

The symptoms of fatigue that M.W., is experiencing is likely not due to her hypothyroidism. Patients may continue to have symptoms of hypothyroidism despite normalization of the TSH value. Although some have suggested that the goal TSH be titrated to 1 to 2 μ units/mL for replacement therapy, this is controversial. One study found that changes in T₄ dosing to achieve TSH concentrations of 2 to 4.8 μ units/mL, 0.3 to 1.9 μ units/mL, or <0.3 μ units/mL in hypothyroid patients did not result in improvements in well-being, psychological, or hypothyroid symptoms, or quality of life.⁶⁵

In conclusion, if an elevated TT₄ and FT₄ are noted without any symptoms of thyrotoxicosis (as in M.W.), the dosage should not be decreased; rather, a trough TT₄, TT₃, and TSH should be obtained to evaluate excessive dosing. The repeat values should be in the normal range with the correct dosing. An excessively suppressed TSH confirms a dosage that is too high. In M.W., the lack of hyperthyroid symptoms suggests euthyroidism, and no changes in her therapeutic regimen should be attempted until the trough levels are available. Evaluation for other causes of fatigue should be explored.

Triiodothyronine

11. C.B., a 65-year-old woman, complains of fatigue and vague muscle aches and pains, which she attributes to insufficient thyroid medication. On physical examination, the thyroid gland is palpable but not enlarged, and DTRs are 2 plus and brisk. Her dose of T₃ (Cytomel) was increased from 25 mcg TID to 50 mcg TID about 2 weeks ago based on the results of a recent FT₄ of 0.5 ng/dL (normal, 0.7–1.9). She denies taking any other medications. Is C.B.'s thyroid hormone replacement appropriate?

[SI units: FT₄, 6 pmol/L (normal, 9–24)]

As noted previously, Cytomel is not the drug of choice for thyroid replacement. The use of L-thyroxine would simplify her dosing regimen and facilitate monitoring.

The low FT₄ did not justify increasing C.B.'s dose of Cytomel. Because she is receiving T₃, the FT₄, which is a measure of free T₄, will always be low and will never reach normal levels. In fact, her vague complaints may be related to hyperthyroidism because she is receiving the equivalent of 0.2 to 0.3 mg of L-thyroxine daily. TSH and FT₃ levels are most useful in monitoring patients receiving T₃ therapy. A TSH level should be obtained to evaluate her thyroid function. A suppressed TSH and an elevated FT₃ would indicate hyperthyroidism. It is important to remember that in an older patient, hyperthyroidism might not always produce symptoms because of an "apathetic" sympathetic system.

L-thyroxine should be initiated cautiously in older patients to avoid exacerbating any pre-existing arteriosclerotic heart disease that might be masked by the hypothyroidism (see Questions 20 and 21). In general, older patients require smaller replacement dosages (approximately ≤ 1.6 mcg/kg/day of T₄) than their younger counterparts.^{66–68} Dosages of <50 mcg/day of T₄ are common in patients older than 60 years. However, this lower T₄ dosage is not universal for all older subjects.⁶⁸ The reason that older patients need lower dosages is unclear, but it has been suggested that the lower requirements result from an age-related decrease in T₄ degradation rates. Because dosage requirements change with age, patients should be reassessed annually to determine whether the original dosage prescribed is still appropriate.

In C.B., who had been on T₃ without any evidence of cardiac toxicity, a less cautious approach in changing to T₄ can be attempted. An empiric L-thyroxine dosage of 68 mcg/day (40 kg × 1.6 mcg/kg/day) is an approximate dosing end point for C.B. The Cytomel should be discontinued and T₄ initiated in a dosage of 50 mcg/day; this dosage can be adjusted as needed based on C.B.'s symptoms and thyroid function tests. After T₃ therapy is discontinued, its effects will disappear over 3 to 5 days. In contrast, T₄ levels rise slowly over 4 to 5 days, so no overlap in T₃ administration is necessary to prevent hypothyroidism.

PARENTERAL DOSING

12. G.F., a 70-year-old man with long-standing hypothyroidism, has been receiving L-thyroxine 0.2 mg/day. Currently, he is in the hospital with a stroke and paralysis that prohibits him from swallowing oral medications. His last thyroid function tests were normal. What is a reasonable method of administering thyroid hormone to G.F.?

Because L-thyroxine has a half-life of 7 days, administration can be delayed for up to 1 week, assuming G.F. can resume oral intake at that time. However, if parenteral administration is required, L-thyroxine is available as an intramuscular (IM) or IV injection. The IV route is preferred because IM absorption may be slow and unpredictable, particularly if the circulation is compromised. Because the oral absorption of T₄ is approximately 80%,⁴⁴ parenteral doses should be decreased. Once IV L-thyroxine replacement is successful, maintenance with a once-weekly IM injection is successful if oral ingestion is not feasible.⁶⁹

IN PREGNANCY

13. P.K. is a 35-year-old woman with Hashimoto's thyroiditis who is 6 weeks pregnant. Laboratory test results showed TT₄, 5 mcg/dL (normal, 5–12) and FT₄, 0.7 ng/dL (normal, 0.7–1.9). She takes her medications in the morning, which include L-thyroxine 0.1 mg/day and a prenatal vitamin enriched with iron and calcium. What dosing adjustments are required because of P.K.'s pregnancy?

[SI units: TT₄, 64 nmol/L (normal, 64–154); FT₄, 9 pmol/L (normal, 9–24)]

Inadequately treated or undiagnosed maternal hypothyroidism can be detrimental to the mother and the developing fetus.^{70–74} Miscarriage, spontaneous abortion, hypertension, pre-eclampsia, and higher rates of cesarean sections and stillbirths have been reported with maternal hypothyroidism. Congenital defects, congenital hypothyroidism (see Question 14), abnormal fetal development, and impaired cognitive development in the newborn have been attributed to maternal hypothyroidism. The IQ scores of children born to mothers with undiagnosed hypothyroidism during pregnancy averaged 7 points lower than children born to euthyroid mothers.⁷¹ A delay in both mental and motor development was observed in children ages 1 to 2 years old who were born to mothers with hypothyroxinemia but normal TSH levels during the first trimester of pregnancy.⁷⁴ Because thyroid hormone does not cross the placenta in significant amounts, the effect of maternal hypothyroidism on the fetus (if it occurs) must be indirect. The risk of congenital hypothyroidism is small if maternal antibodies from Hashimoto's thyroiditis cross the fetal circulation.

The infant's cord blood should be assayed at birth to ensure that TSH is normal and that the child is euthyroid.

The majority of women with primary hypothyroidism will require a 30% to 50% increase in the prepregnancy T₄ dosage to maintain euthyroidism during the first trimester of pregnancy.^{75,76} The only evidence of increased T₄ demands is an elevated TSH level (e.g., subclinical hypothyroidism) that occurs between weeks 5 (but can be as early as 3) and 16 of gestation. Often, no clinical symptoms of hypothyroidism are evident, and the FT₄ and the index are normal. Because of the adverse consequences associated with maternal hypothyroidism, some have advocated universal TSH screening of all pregnant women⁷⁷ as well as empirically increasing the prepregnancy T₄ dosage by 30% (extra two pills/week) as soon as pregnancy is confirmed.⁷⁶

Some authors have challenged the dogma that pregnancy per se increases T₄ demands. Rather, they propose that these increments were recommended before it was recognized that coadministration of iron- and calcium-containing prenatal vitamins reduced T₄ absorption (see question 15) and that these drug interactions may be primarily responsible for these increased needs. When prenatal vitamins with iron and calcium were separated by 4 hours from T₄ administration, only 31% of women required an increase in T₄ dose.⁷⁸ Nevertheless, women should be followed closely during pregnancy and the FT₄ and TSH levels evaluated monthly during the first trimester. If necessary, the T₄ dosage should be adjusted to maintain a normal TSH and an FT₄ or FT₄I in the upper limits of normal. Because TBG is elevated, the TT₄ should be kept above the normal range; it is not the best indicator of adequate replacement.

P.K.'s low TT₄ and FT₄ are concerning. The TT₄ should be much higher because of pregnancy-associated increases in TBG. The TSH level should be obtained, and the daily dosage of T₄ should be increased to 125 mcg after eliminating the possibility of patient nonadherence and drug interactions. Ingestion of the prenatal vitamins with iron and calcium should be separated by at least 4 hours from T₄. PK could also be instructed to take the T₄ at night for better absorption.⁴⁵ The TSH should be repeated in 6 weeks, and the dosage should be adjusted as needed to keep the TSH in the normal range. After delivery, the dosage should be reduced to prepregnancy levels and the FT₄ and TSH rechecked to ensure euthyroidism.

Congenital Hypothyroidism

14. P.K. delivered a healthy baby, T.K., at term without difficulty. T.K.'s postpartum screening serum T₄ level was 5 mcg/dL (normal, 5–12), and TSH was 35 μunits/mL (normal, 0.5–4.7). At home, T.K. became lethargic, had a weak cry, sucked poorly, and failed to thrive. Assess the situation (including a treatment plan and prognosis). How is mental development affected?

[SI units: T₄, 64 nmol/L (normal, 64–154); TSH, 15 mIU/L (normal, 0.5–4.7)]

T.K.'s symptoms are suggestive of congenital hypothyroidism, although in most infants the clinical signs and symptoms are so subtle and nonspecific that they are easily missed until the child is several months old. The early clinical findings include prolonged jaundice, skin mottling (cutis marmorata), lethargy, poor feeding, constipation, hypothermia, hoarse cry, large fontanelles, distended abdomen, hypotonia, slow reflexes, and piglike facies. Respiratory difficulties, delayed skeletal

maturation, and choking (but not palpable goiter) may be present. These infants are also at risk for additional congenital defects or complications.⁷⁹ Mass neonatal screening programs have been successful in detecting congenital hypothyroidism within the first few weeks of life before clinical manifestations are apparent and before irreversible changes occur.

The postpartum low serum T₄ concentration and elevated TSH level (>20 μunits/mL) in T.K. are of concern and should be verified. Transient hypothyroidism can result from intrauterine exposure to thioamides or excess iodides, or from transplacental passage of TRAb from the mother. Thyroid function tests often normalize without treatment in 3 to 6 months as the TRAb is cleared by the infant.⁷⁹ The diagnosis of hypothyroidism should be confirmed by a low serum T₄, a low FT₄, and an elevated TSH concentration during the next few weeks. Serum T₃ concentrations are often in the normal range and are not helpful. Normal serum T₄ concentrations are higher in the first few weeks of life and gradually return to normal by 2 to 4 months of life. The FT₄I may also be elevated. Because of these confusing changes, thyroid serum levels should be compared with the normal range for the approximate postnatal age.

Thyroid hormones play a critical role in normal growth and development, particularly of the CNS, during the first 3 years of life. If untreated, dwarfism and irreversible mental retardation occur. T.K.'s normal mental (IQ) and physical development will be determined by the age at which treatment is started, the initial dosage of T₄, the serum T₄ level attained during therapy, the adequacy with which treatment is maintained, and the cause and severity of the initial deficiency.⁸⁰⁻⁸⁶

Sodium L-thyroxine is the preparation of choice for replacement. T₄ tablets can be crushed and mixed with breast milk or formula; suspensions are not stable and should not be used. T₃ also can be used, but this form is less desirable because its short half-life causes a greater fluctuation in plasma levels (Table 49-8). The initial replacement dose of T₄ should raise the serum T₄ as rapidly as possible to minimize the consequences of hypothyroidism on cognitive function. A delay in starting therapy of even a few days has resulted in a poorer IQ outcome.^{81,82,86} A minimum T₄ dosage of 10 to 15 mcg/kg/day is recommended to raise the serum T₄ to >10 mcg/dL (129 nmol/L) by 7 days.⁸⁰ However, some suggest that higher than previously recommended dosages of 12 to 17 mcg/kg/day might be more effective, but concern about negative neurologic outcomes exists.^{79,81,82} In the full-term healthy infant, full initial replacement T₄ doses are appropriate unless the infant has underlying heart disease or is extremely sensitive to the effects of thyroid hormones. In these infants, reduced doses of T₄ (approximately 25%–33% of the recommended dose) can be started and increased gradually by similar increments until the

therapeutic dose is achieved. The recommended replacement dose decreases with age and is shown in Tables 49-4 and 49-9.

Mental development and attainment of normal growth are not severely impaired if adequate T₄ treatment is initiated before 3 months of age to achieve a serum T₄ level >10 mcg/dL (129 nmol/L).^{79-82,84} Nevertheless, children with the most severe congenital hypothyroidism (i.e., athyreosis) scored 8 IQ points lower than their siblings.⁸³ Young adults 20 years after congenital hypothyroidism showed impaired motor and intellectual outcomes after suboptimal T₄ (<7.8 mcg/kg/day) therapy compared to sibling controls.⁸⁴ However, those receiving optimal therapy still had some deficits in memory, attention, and behavior versus the siblings.⁸⁷ Newborns detected by screening programs who start therapy within the first 4 to 6 weeks of life have mean IQs of 100 to 109, similar to the control populations. The mean IQ drops if treatment is delayed until 6 weeks and 3 months (mean IQ, 95), or until 3 and 6 months (mean IQ, 75). When treatment is not started until 6 months to 1 year of age, normal mental development is impaired despite subsequent treatment (mean IQ, 55). Higher IQs also were found in children who received dosages of T₄ >10 mcg/kg/day compared to lower dosages and achieved a mean serum T₄ level >14 mcg/dL (181 nmol/L) in the first month of therapy.^{81,82,86,88} Neurologic deficits are also more likely to occur in infants whose thyroid replacement is delayed or inadequate (as evidenced by a serum T₄ <8 mcg/dL [103 nmol/L] within 30 days of therapy and delayed suppression [18–24 months] of the TSH into the normal range). Additional risk factors for a low IQ and poor motor and speech skills despite adequate therapy include clinical signs of hypothyroidism during fetal life, more marked chemical hypothyroidism at birth (T₄ <2 mcg/dL), thyroid aplasia, and retarded bone age.^{79,80,82}

The goal of therapy is a T₄ in the upper normal range (e.g., 10–18 mcg/dL [129–232 nmol/L]) and/or an FT₄ of 2 to 5 ng/dL (27–64 pmol/L) during the first 2 weeks of therapy, and then a lower target thereafter: a T₄ of 10 to 16 mcg/dL (129–206 nmol/L) and/or an FT₄ of 1.6 to 2.2 ng/dL [20–30 pmol/L]). IQs are improved if TSH levels are normalized within the first month of therapy, but no later than 3 months.^{81,82,86,88} Thyroid function tests should be routinely monitored 2 to 4 weeks after starting therapy, then every 1 to 2 months during the first year of life and every 2 to 3 months during the next 2 years of life. Although TSH suppression is the most reliable index of adequate replacement in older children, normalization of the TSH should not be used as the sole monitoring parameter in infants because the TSH may lag behind correction of the T₄ and/or FT₄ levels. Overtreatment should be avoided to prevent brain dysfunction, acceleration of bone age, and premature craniosynostosis. Normal growth and development should also be a treatment goal. Other clinical end points include an improvement in activity level, skin color, temperature, facial appearance, and reversal of other symptoms and signs of hypothyroidism. The child will require lifelong replacement therapy.

Unresponsiveness to Levothyroxine and Drug–Drug Interactions

15. R.T., a 45-year-old woman, complains of weight gain, heavy menses, sluggishness, and cold intolerance. Her present medical problems include Hashimoto's thyroiditis, treated with L-thyroxine 150 mcg daily; hypercholesterolemia treated with

Table 49-9 T₄ Recommended Replacement Dose

| Age | Daily mcg/kg T ₄ |
|---------|-----------------------------|
| 3–6 mo | 10–15 |
| 6–12 mo | 5–7 |
| 1–10 yr | 3–6 |
| >10 yr | 2–4 |

T₄, thyroxine.

cholestyramine (Questran) 4 g QID; anemia, treated with FeSO₄ 325 mg twice a day (BID); menorrhagia treated with conjugated estrogens 1.25 mg QD; and a history of peptic ulcer disease, treated with antacids and sucralfate 1 g BID. She was recently started on calcium carbonate 1 g BID and raloxifene (Evista) 60 mg QD to protect her bones. Her laboratory data include a cholesterol serum concentration of 280 mg/dL (normal, <200), a TSH of 21 μ units/mL (normal, 0.5–4.7), an FT₄ of 0.6 ng/dL (normal, 0.7–1.9), and positive ATgA and TPO antibodies. R.T. admits that she has increased her L-thyroxine dose because she feels better on the higher dose. Why is R.T. apparently unresponsive to thyroid therapy?

[SI units: cholesterol, 7.2 nmol/L (normal, <5.2); FT₄, 8 pmol/L (normal, 9–24); TSH, 21 mIU/L (normal, 0.5–4.7)]

R.T.'s complaints and laboratory values confirm inadequate treatment of hypothyroidism despite thyroid therapy. Possible causes of therapeutic failure include nonadherence, error in diagnosis, poor absorption, subpotent medication, rapid metabolism, and tissue resistance.^{43,89,90} Thyroid resistance is rare, and nonadherence, error in diagnosis, and rapid metabolism do not appear to be reasonable explanations in R.T. An increase in L-thyroxine requirements can result from concomitant anticonvulsants (see Question 3), rifampin,⁹¹ bexarotene,⁹² and imatinib therapy by increasing the metabolism of L-thyroxine. In hypothyroid patients receiving T₄, imatinib increased TSH levels 384%, necessitating a 10% to 47% increase in the L-thyroxine dosage.⁹³

The most likely explanations are poor bioavailability and/or a subpotent preparation. The timing of T₄ administration with her meals should be ascertained because its bioavailability is improved when it is taken on an empty stomach and at night.^{43,45,94} Simultaneous coadministration of T₄ with soy proteins or high-fiber diets (e.g., oat bran, soybean) should also be avoided because T₄'s absorption can be impaired.^{95,96} R.T.'s history does not include surgical bowel resection or GI disorders (e.g., steatorrhea, malabsorption) or cholesterol resin binders that can interfere with the enterohepatic circulation of orally administered thyroid and lead to excessive fecal loss.⁹⁰ Evidence for incomplete absorption of the hormone can be obtained by comparing R.T.'s response to oral and parenteral T₄.⁸⁹

L-thyroxine bioavailability can also be compromised by the numerous medications that R.T. is taking. Estrogen therapy can increase T₄ requirements by increasing TBG to increase T₄ binding.²⁷ Cholestyramine, colestipol, iron sulfate, antacids, sucralfate, calcium preparations, particularly the carbonate salt, and raloxifene can impair thyroid absorption if these medications are administered at the same time.^{43,97–104} Cholesterol-lowering agents (e.g., lovastatin) and phosphate binders are also reported to interfere with thyroid absorption.^{100,105} R.T. should be questioned about the time she takes her thyroid medication. She should be instructed to take it on an empty stomach or at night,⁴⁵ and at least 12 hours apart from the raloxifene and 4 hours apart from the iron, calcium, and cholestyramine.^{97–104} Aluminum-containing products (i.e., antacids, sucralfate) should be discontinued because separating the concurrent administration of T₄ and her aluminum-containing preparations does not consistently correct this interaction.^{101,102} R.T. should be changed to an aluminum- and calcium free antacid (e.g., Riopan)

and, if necessary, an H₂-receptor antagonist. Proton pump inhibitors (e.g., omeprazole) should be avoided because decreased acid secretion may reduce T₄ absorption, although data are conflicting.^{106,107} After R.T. has been instructed on the proper times of administration for her medications, the therapeutic response and thyroid function tests should be re-evaluated in 6 to 8 weeks before any changes are made.

16. Could R.T.'s hypothyroidism be responsible for her hypercholesterolemia?

Type IIa hypercholesterolemia is the most common lipid abnormality observed in patients with primary hypothyroidism.¹⁰⁸ Although the rate of cholesterol synthesis is normal in hypothyroid patients, the rate of cholesterol clearance is decreased. Similarly, slow removal of triglycerides may result in hyperlipidemia. Hypercholesterolemia is frequently observed before the appearance of clinical hypothyroidism. Treatment with T₄ alone should lower the cholesterol levels if no other causes are contributing.

Myxedema Coma

Clinical Presentation

17. R.B., a 65-year-old, agitated woman arrived at the emergency department complaining of chest pain unrelieved by nitroglycerin (NTG). Her medical problems include alcoholic cardiomyopathy, angina, and hypothyroidism. Although she has been advised repeatedly to take her T₄ regularly, she continues to take it sporadically. An FT₄I drawn 4 months ago was 1 (normal, 6.5–12.5). Haloperidol (Haldol) 2 mg IM and morphine sulfate 10 mg IM were given for the agitation. After the injection, the nurse noticed mental depression, lethargy, and shallow breathing. R.B.'s oral temperature was 34.5°C, and she exhibited chills and shakes. What is your assessment of R.B.'s subjective and objective data?

[SI units: FT₄I, 13 (normal, 84–161)]

R.B. has several symptoms consistent with myxedema coma.¹⁰⁹ Myxedema coma is the end stage of long-standing, uncorrected hypothyroidism. The classic features are hypothermia, delayed DTRs, and an altered sensorium that ranges from stupor to coma. Other predominant features include hypoxia, carbon dioxide retention, severe hypoglycemia, hyponatremia, and paranoid psychosis. Typical physical findings (Table 49-3) include a puffy face and eyelids, a yellowish discoloration of the skin, and loss of the lateral eyebrows. Pleural and pericardial effusions and cardiomegaly may be present. Because myxedema coma frequently occurs in older women, it is often difficult to distinguish the signs and symptoms from dementia or other disease states, as illustrated by R.B. Precipitating factors include cold weather or hypothermia, stress (e.g., surgery, infection, trauma), coexisting disease states such as MI, diabetes, hypoglycemia, or fluid and electrolyte abnormalities (especially hyponatremia), and medications such as sedatives, narcotic analgesics, antidepressants, and other respiratory depressants and diuretics.

Haloperidol and morphine might be responsible for what appears to be impending myxedema coma in R.B. In severely myxedematous patients, respiratory depressants (anesthetics, narcotic analgesics, phenothiazines, sedative-hypnotics) alone or in combination with the hypothermic effects of the phenothiazines can aggravate the pre-existing hypothermia and

carbon dioxide retention to precipitate myxedema coma.^{109,110} Tranquilizers such as haloperidol should not be given; small doses of less depressive sedative-hypnotics such as the benzodiazepines should be used only when necessary. Myxedematous patients are also inherently sensitive to the respiratory depressant effects of narcotic analgesics, especially morphine. A dose as small as 10 mg may induce coma in a hypothyroid patient or cause death in a patient who is already comatose. If morphine is required, the dose should be decreased to one-third to one-half the usual analgesic dose, and the respiratory rate should be monitored closely.

Treatment

18. What would be a reasonable therapeutic plan for the management of R.B.'s myxedema coma?

Emergency treatment, usually in the intensive care unit, of myxedema coma is directed toward thyroid replacement, maintenance of vital functions, and elimination of precipitating factors. Despite immediate and aggressive therapy with large replacement doses of thyroid, mortality rates of 60% to 70% are common.¹⁰⁹

Whether T₄ or T₃ is the drug of choice in myxedema coma is controversial because no comparative trials have been conducted. Although T₃ is potentially more cardiotoxic, it has been recommended because its more rapid onset might reverse coma faster, and the peripheral conversion from T₄ to the biologically active T₃ might be inhibited in severe systemic disease.^{110,111–114} T₄ alone, T₃ alone, and a combination of the two have all been used successfully to treat myxedema coma. However, L-thyroxine is generally regarded as the hormone of choice because of greater clinical experience with T₄ than with T₃. Also, mortality has occurred despite the higher T₃ levels achieved after T₃ administration.¹¹⁴ T₃ might be considered after failure of T₄ or if concomitant systemic illness (e.g., heart failure) is likely to impair conversion of T₄ to T₃. Supraphysiological elevations in T₃ levels occur only after oral administration but are not seen after IV T₃ infusion. Factors associated with a higher mortality 1 month after therapy include older age, cardiac complications, and T₄ replacement ≥ 500 mcg/day or T₃ replacement > 75 mcg/day.^{110,114}

L-thyroxine 400 to 500 mcg should be given IV initially in patients < 55 years of age without cardiac disease to saturate the TBG and raise the serum T₄ level to 6 to 7 mcg/dL.^{109,115} This initial dose can be adjusted based on the patient's weight and other restrictive factors (e.g., age, cardiac disease). The initial T₄ dosage for R.B. should be reduced to 300 mcg/day to avoid worsening her angina. If the proper dosage is given, consciousness, restoration of vital signs, and decreased TSH levels should occur within 24 hours. If T₃ is preferred, the usual dose is 10 to 20 mcg IV, followed by 10 mcg every 4 hours for the first 24 hours, and then 10 mcg every 6 hours for a few days until oral therapy can be started.¹⁰⁹

Maintenance doses should be titrated to the patient's clinical response. Because myxedema can impair oral absorption, the IV route is preferred to ensure adequate drug concentrations. Oral administration is permitted once GI function returns to normal. The smallest dosage (without untoward effects) administered should be 50 to 100 mcg/day of T₄ or 10 to 15 mcg of T₃ every 12 hours.^{109,115}

Supportive measures include assisted ventilation, glucose for hypoglycemia, restriction of fluids for hyponatremia, and the use of blood or plasma expanders to prevent circulatory collapse and to maintain blood pressure. The use of blankets to treat R.B.'s hypothermia is not advised because vasodilation will occur and further compromise the cardiovascular components of shock. Although steroids have not been shown to be clearly beneficial in primary myxedema, they may be lifesaving in patients with hypopituitarism masquerading as myxedema coma. Because it is difficult to distinguish between primary and secondary myxedema, hydrocortisone 50 to 100 mg every 6 hours should be given empirically.¹⁰⁹

Appropriate measures should be taken to relieve R.B.'s chest pain while ruling out the possibility of an MI. The use of a narcotic antagonist such as naloxone may be beneficial in this instance because it can reverse the effects of the morphine. Naloxone can also arouse comatose patients intoxicated with alcohol.

Hypothyroidism With Congestive Heart Failure

Clinical Presentation

19. E.B., a 45-year-old woman, is admitted with complaints of substernal pressure and chest pain, SOB, dyspnea on exertion, and orthopnea. Other subjective and objective data suggest CHF complicated by MI. Significant past medical history reveals exertional angina and Graves' disease, which was treated with RAI ablation 10 years ago. Symptoms have not recurred. Physical examination reveals cardiomegaly, diastolic hypertension, obesity, facial edema and puffiness, delayed DTRs, and nonpitting pretibial edema. Pertinent laboratory findings include FT₄, 0.2 ng/dL (normal, 0.7–1.9); TSH, 100 μ units/mL (normal, 0.5–4.7); creatinine kinase, 300 units/L (normal, 32–267); aspartate aminotransferase (AST), 80 units/L (normal, 7–26); lactate dehydrogenase (LDH), 250 units/L (normal, 80–230); and troponin, 0.3 ng/mL (normal, 0.3–1.5). A chest radiograph reveals cardiomegaly and pericardial effusions, and an electrocardiogram (ECG) shows bradycardia and flattened T waves with ST depression. Diuretics, nitrates, angiotensin II inhibitor, and digitalis are instituted. E.B.'s symptoms improve, but her cardiac abnormalities are not reversed. Why do these clinical findings suggest hypothyroidism?

[SI units: FT₄, 5 pmol/L (normal, 9–24); TSH, 100 mIU/L (normal, 0.5–4.7); creatinine kinase, 300 units/L (normal, 32–267); AST, 80 units/L (normal, 7–26); LDH, 250 units/L (normal, 80–230); troponin, 0.3 g/L (normal, 0.3–1.5)]

E.B.'s abnormal thyroid function tests, symptoms, physical findings, and history of RAI therapy are consistent with severe hypothyroidism. "Myxedema heart" can be confused with low-output CHF because the symptoms are similar: cardiomegaly, dyspnea, edema, pericardial effusions, and abnormal ECG.^{55,109} Therefore, hypothyroidism should be excluded in all patients with new or worsening symptoms of cardiovascular disease (e.g., angina, arrhythmia). Although hypothyroidism alone rarely causes CHF, it can worsen an underlying cardiac condition. Rarely, ventricular arrhythmia, including torsades de pointes, can occur from a prolonged QT interval.

Although E.B.'s enzyme elevations (i.e., AST, CK, LDH) are suggestive of an MI, they all may be moderately or significantly increased from chronic skeletal or cardiac muscle damage or from decreased enzyme clearance secondary to

hypothyroidism. The enzymes can be fractionated to determine their origin. The normal troponin level eliminates the possibility of an MI.

Treatment

20. What might be the effect of hypothyroidism on the cardiac treatment and status of E.B.?

If E.B.'s cardiac abnormalities are caused by hypothyroidism rather than organic disease, adequate doses of T_4 will restore the heart size, normalize the diastolic blood pressure, reverse the ECG findings, and normalize the serum enzyme elevations within 2 to 4 weeks. However, improvement in myocardial function begins only at dosages of 50 to 75 mcg/day of T_4 , which may be tolerated poorly by cardiac patients.

The relationship between the altered lipid metabolism of hypothyroidism and increased risk of atherosclerosis is controversial and poorly documented.¹⁰⁸ Interestingly, angina pectoris and MI are rather uncommon among hypothyroid patients. Theoretically, the hypometabolic state associated with hypothyroidism may protect the ischemic myocardium by reducing metabolic demands. However, hypothyroidism actually aggravates subendocardial ischemia during an acute MI by decreasing erythrocyte production of 2,3-diphosphoglycerate, which shifts the oxyhemoglobin dissociation curve to the left. This effect further diminishes oxygen delivery to already ischemic tissues. Angina or premature beats can develop or worsen with the institution of T_4 therapy,^{116–118} so doses should be titrated carefully (see Question 21). Without organic disease, digitalis is ineffective and may even be harmful. Hypothyroid patients show an increased sensitivity to digitalis, and digitalis toxicity is possible unless the maintenance dose is decreased (see Question 26).^{119,120} Nitrates may precipitate hypotension and/or syncope in hypothyroid patients because these patients have a low circulating blood volume and their response to vasodilation can be exaggerated. Furthermore, if β -blockers are required, the cardioselective β -blockers are preferred. The noncardioselective β -blockers have produced coronary spasm by exacerbating the compensatory increase in norepinephrine levels and α -adrenergic tone found in hypothyroidism.

21. How aggressively should thyroid hormone therapy be initiated in a patient like E.B. who has angina? What is the hormone replacement of choice in patients with cardiac disease?

Patients with long-standing hypothyroidism, arteriosclerotic cardiac disease, or advanced age tend to be extremely sensitive to the cardiac effects of thyroid hormone. Initiation of normal or even subtherapeutic doses in these patients might produce severe angina, MI, supra- and ventricular premature beats, cardiac failure, or sudden death. These effects underscore the need to replace thyroid cautiously, and sometimes suboptimally, to avoid cardiac toxicity.^{116–118,121}

The angina and cardiac status should be controlled before initiating T_4 therapy. In the patient with poorly controlled angina, cardiac catheterization is warranted to assess the coronary artery status before starting hormone therapy. Coronary bypass has been performed safely with minimal complications in the hypothyroid patient to control the angina and may

allow institution of full replacement doses without cardiotoxicity.¹²²

For E.B., 12.5 to 25 mcg of T_4 should be initiated cautiously and increased as tolerated by similar increments of T_4 every 4 to 6 weeks until a therapeutic dosage is reached. The rapidity with which the increments can proceed is determined by how well each increased dose is tolerated. If cardiac toxicity occurs, therapy should be stopped immediately. Once symptoms resolve, therapy can be restarted using smaller dosage increments and longer intervals between dosage adjustments. If cardiac symptoms recur, further T_4 therapy should be stopped pending cardiac evaluation. In some patients with severe cardiac sensitivity, complete euthyroidism might never be achieved. In these patients, the correct replacement dosage is a compromise between prevention of myxedema and avoidance of cardiac toxicity.¹¹⁸ E.B.'s clinical status and ECG should be monitored closely during the titration period. T_4 should be discontinued or decreased at the first sign of cardiac deterioration. It is not necessary to monitor thyroid function tests (e.g., TSH or FT₄) during the titration period because the results will remain low until adequate replacement is achieved. Thyroid function tests should be obtained once maximally tolerated or estimated euthyroid dosages are achieved.

Some suggest that T_3 (Cytomel) is the agent of choice in patients with cardiac abnormalities. The onset of action of T_3 is 1 to 3 days compared with 3 to 5 days for T_4 . After therapy is withdrawn, the effects of T_3 dissipate in 3 to 5 days, while a period of 7 to 10 days is needed for T_4 . Thus, if toxicity occurs, the effects of T_3 will disappear rapidly on cessation of therapy, a theoretical advantage in the cardiac patient. Nevertheless, T_3 is not recommended because its greater potency requires finer and more difficult dosage titration to ensure smooth and uniform blood levels. Furthermore, the high serum T_3 levels that occur after oral administration might cause more cardiac toxicity, especially angina.

Subclinical Hypothyroidism

22. M.P., a healthy 53-year-old woman, comes in for her regular checkup. She denies any symptoms of hypothyroidism and feels well. She has no other medical problems, takes no medications, and has no known allergies. Her physical examination is within normal limits. Routine screening laboratory tests are normal except for an FT₄ of 1.2 ng/dL (normal, 0.7–1.9) and a TSH of 8 μ units/mL (normal, 0.5–4.7). Does M.P. require thyroid treatment, based on her clinical presentation and laboratory findings?

[SI units: FT₄, 16 pmol/L (normal, 9–24); TSH, 8 mIU/L (normal, 0.5–4.7)]

M.P.'s free thyroid levels are normal, but her TSH level is elevated, indicating subclinical hypothyroidism (SH). The prevalence of SH ranges from 4% to 10% and increases to 26% in the elderly population, particularly women.^{57,58} It is unclear whether SH represents the early stages of thyroid failure. The estimated risk of developing overt hypothyroidism after 10 years in untreated patients by Kaplan-Meier curves was 0% for a TSH level of 4 to 6 mIU/L, 42.8% for a TSH level of 6 to 12 mIU/L, and 76.9% for a TSH level >12 mIU/L. This risk increased in patients with positive thyroid antibodies.¹²³ Because the most common clinical scenarios involve

asymptomatic patients with TSH levels <10 mIU/L, negative thyroid antibodies, and no history of prior thyroid disease, routine thyroid screening has been recommended, particularly in elderly women.⁵⁸

Mild symptoms of hypothyroidism, including psychiatric and cognitive abnormalities, are found in approximately 30% of patients with SH, but the average TSH level usually exceeds 11 mIU/L. Cardiac dysfunction, including impaired left ventricular diastolic function at rest, systolic dysfunction with exercise, atherosclerosis, CHF, and MI has been reported.^{55,58,124–126} Data showing an increased risk of coronary heart disease (CHD) is conflicting and is influenced by the severity of SH, study design, and length of follow-up. A meta-analysis noted a 1.6 times increased risk of CHD,¹²⁷ a cross-sectional analysis noted an odds ratio of 2.2 only in those with TSH levels of ≥ 10 mIU/L, whereas the 20-year longitudinal analysis found a significant risk (hazard ratio of 1.7) regardless of the degree of TSH elevation.¹²⁸ However, a large prospective cohort study found no significant association with atherosclerotic disease or cardiac mortality but observed an increase in all-cause mortality at 10 years of follow-up.¹⁸⁹ Other atypical and nonspecific signs and symptoms reflecting dysfunction of any part of the body may occur, primarily in the elderly. Failure to thrive, mental confusion, weight loss with poor appetite, incontinence, depression, inability to walk, carpal tunnel syndrome, deafness, ileus, anemia, hypercholesterolemia, and hyponatremia have been reported.^{57,58,124–126}

Treatment of subclinical hypothyroidism with T_4 is controversial because study results are conflicting. Potential benefits of treatment include (a) preventing progression to hypothyroidism, (b) improving the lipid profile and reducing cardiac risks, and (c) reversing symptoms of hypothyroidism. Patients with higher TSH levels (e.g., >10 mIU/L), a history of previously diagnosed thyroid disease, elevated lipid levels, or evidence of positive thyroid antibodies gained the most benefit from L-thyroxine therapy.^{55,123,126,129} L-thyroxine significantly reduced total cholesterol by 0.2 to 0.4 mmol/L (7.9–15.8 mg/dL) and low-density cholesterol concentrations by 0.33 mmol/L (10 mg/dL); serum HDL and triglyceride concentrations remain unchanged.^{58,125,126,129} Improvement of elevated intraocular pressures, memory, mood, somatic complaints, and diastolic dysfunction has also been reported after T_4 replacement.^{123,125,126,129} However, in patients with mild TSH elevations (e.g., <10 mIU/L), well-designed studies showed no improvement in clinical symptoms of hypothyroidism with T_4 supplementation.^{57,58,125,126}

Treatment of older patients requires an assessment of the risks versus benefits of therapy. Thyroid therapy carries the risk of unmasking underlying cardiac disease in older patients. Nevertheless, thyroid replacement appears reasonable in asymptomatic patients with TSH levels >10 mIU/L and especially those with symptoms of mild hypothyroidism, dyslipidemia, laboratory abnormalities, or end-organ alterations.^{57,58,123–126,129} Patients with asymptomatic subclinical hypothyroidism and a TSH level <10 mIU/L do not warrant immediate therapy, but close follow-up is warranted.

Because M.P. is asymptomatic and has a TSH level <10 mIU/L, it is reasonable to delay therapy and recheck the TSH in a few months.

Hypopituitarism and T_4 Replacement With a Normal Thyroid-Stimulating Hormone Level

23. J.P. is a 65-year-old woman who complains of fatigue, cold intolerance, dry skin, and weight gain for the past several months. Her thyroid examination and DTRs are within normal limits. A TSH level was 2.5 μ units/mL (normal, 0.5–4.7). She denies taking any other medications. J.P. is started empirically on a 3-month trial of L-thyroxine. How should the TSH level be interpreted? Is T_4 therapy indicated, based on her presenting findings?

[SI units: TSH, 2.5 mIU/L (normal, 0.5–4.7)]

Despite complaints that could be consistent with hypothyroidism (e.g., fatigue, cold intolerance, dry skin, weight gain), the normal TSH level indicates that J.P. is euthyroid. However, because a diagnosis of hypopituitarism (i.e., TSH level could be normal or low) cannot be ruled out, an FT₄ level should be obtained; a low level would increase the likelihood of hypopituitarism. Some argue that hypopituitarism is underdiagnosed and would advocate adding FT₄ to the primary screening tests.¹³⁰

If the FT₄ level is normal, indicating euthyroidism, then hypopituitarism is unlikely and L-thyroxine therapy is not indicated. A randomized, double-blind, placebo-controlled crossover trial found that T_4 supplementation in patients with hypothyroid symptoms and normal thyroid function tests was not more effective than placebo in improving cognitive function or psychological well-being despite changes in the TSH and FT₄ levels.^{131,132}

In J.P., the T_4 should be discontinued because there is no evidence of its efficacy in euthyroid individuals.

HYPERTHYROIDISM

Clinical Presentation

24. S.K., a 48-year-old woman, is admitted to the hospital for a possible MI. Her complaints include chest pain that is unrelieved by NTG, increasing SOB with exercise, nervousness, palpitations, muscle weakness, weight loss despite an increased appetite, and epistaxis; she also bruises easily. She has a history of deep venous thrombosis treated with warfarin (Coumadin) 5 mg/day; her last prothrombin time (PT) was 18 seconds (normal, 10.5–12.1), and an international normalized ratio (INR) was 1.8 (normal, 1; therapeutic, 2–3). She has angina, treated with NTG 0.4 mg, and CHF, treated with digoxin (Lanoxin) 0.25 mg/day.

Physical examination reveals a thin, flushed, hyperkinetic, nervous woman. Blood pressure (BP) is 180/90 mmHg; pulse is 130 beats/minute, irregularly irregular; respiratory rate is 30 breaths/min; and temperature is 37.5°C. Other pertinent findings include a lid lag with stare, proptosis with tearing, decreased visual acuity, a diffusely enlarged thyroid gland without nodules, a bruit in the left lobe of the thyroid, positive jugular venous distention (JVD), bibasilar rales, warm moist skin with multiple bruises, new-onset atrial fibrillation (AF), slight diarrhea, hepatomegaly, acropachy, 2+ pitting edema, a fine tremor, proximal muscle weakness, and irregular scant menses.

Laboratory data include FT₄, 2.9 ng/dL (normal, 0.7–1.9); TSH, <0.5 μ units/mL (normal, 0.5–4.7); RAIU at 24 hours, 80% (normal, 5%–35%); PT, 40 seconds (normal, 10.5–12.1); INR,

4.8 (normal, 1; therapeutic, 2–3); TPO, 200 IU/mL (normal, <1); alkaline phosphatase, 200 units/L (normal, 41–133); total bilirubin, 1.1 mg/dL (normal, 0.1–1.2); AST, 60 units/L (normal, 7–26); and alanine aminotransferase (ALT), 55 units/L (normal, 3–23). A scan shows a diffusely enlarged gland, three to four times normal size. What subjective and objective data are suggestive of hyperthyroidism in S.K.?

S.K. presents with many of the clinical and laboratory features¹³³ associated with an increased metabolic state resulting from excessive T₄ (Table 49-6). Her ocular symptoms are consistent with Graves' disease and include lid lag (lid falls behind the movement of the eye and a narrow white rim of sclera becomes visible between the upper lid and cornea, producing a "staring" appearance), ophthalmopathy (protrusion of the eyeball), and decreased visual acuity. The thyroid bruit, palpitations, exertional dyspnea, worsening CHF (JVD, bibasilar rales, edema, hepatomegaly), diarrhea, irregular scant menses, nervousness, tremor, muscle weakness, weight loss despite increased appetite, increased perspiration, and flushing of the skin are consistent with a hypermetabolic state. Although sinus tachycardia is the most common arrhythmia in hyperthyroidism, new-onset AF is the presenting symptom in 5% to 20% of patients with hyperthyroidism, particularly in those older than 70 years.¹³⁴ Together with S.K.'s symptoms, a diagnosis of Graves' disease is confirmed by an elevated FT₄ level, an undetectable TSH level, an increased RAIU, positive TPO antibodies, and a diffusely enlarged goiter. Her cardiac status and other medical problems are aggravated by the hyperthyroidism. (Table 49-5 lists the causes of hyperthyroidism.)

Hypoprothrombinemia

25. What factors contribute to S.K.'s hypoprothrombinemia? What effect could this have on her subsequent drug treatment?

The hypoprothrombinemia and bleeding observed in S.K. are most likely related to an exaggerated response to warfarin. This may be related to a decrease in the hepatic metabolism of warfarin (secondary to hepatic congestion), but it is more likely that S.K.'s findings are due to the combined effects of hyperthyroidism and warfarin on vitamin K–dependent clotting factors.

Warfarin Metabolism

Warfarin metabolism and the metabolism of vitamin K–dependent clotting factors can be altered by thyroid status. Net circulating levels of vitamin K–dependent clotting factors are generally not altered in hyperthyroid patients because both the synthesis and catabolism of these clotting factors are increased. However, an enhanced anticoagulant response occurs when the warfarin-induced decrease in clotting factor synthesis is combined with the hyperthyroidism-induced increase in clotting factor catabolism.^{33,135} This may explain S.K.'s elevated prothrombin time, bruising, and history of epistaxis.

The opposite occurs in hypothyroidism, in which a decrease in both the metabolism and synthesis of clotting factors occurs. In hypothyroid patients, the response to oral anticoagulants is delayed because the clotting factors are eliminated more slowly.^{33,135} Therefore, hyperthyroid patients need less warfarin, whereas hypothyroid patients require more warfarin to

achieve the same hypoprothrombinemic response. The anticoagulant response to warfarin should be monitored carefully in patients with thyroid abnormalities, and the dosage adjusted as the thyroid status changes.

Thioamide Effects

Because S.K.'s hyperthyroidism will most likely be treated with a thioamide, caution must be exercised. Treatment of hyperthyroid patients with thioamides, especially PTU, has been associated with hypoprothrombinemia, thrombocytopenia, and bleeding, albeit rarely.¹³⁶ These drugs can depress the bone marrow and the synthesis of clotting factors II, VII, III, IX, X, and XIII; vitamin K and prothrombin times may remain depressed for up to 2 months after discontinuation of therapy. These effects may be caused by a subclinical hepatic alteration in synthesis or hepatotoxicity (see question 38).^{137–139} Symptoms occur 2 weeks to 18 months after starting therapy. The bleeding is responsive to vitamin K or blood transfusions. (Also see questions 31 and 32 for further discussion of treatment with thioamides.)

Response to Digoxin

26. After treatment with RAI, S.K.'s daily dose of digoxin was increased to 0.5 mg because of persistent AF and rapid ventricular response. Six weeks later, she returns with complaints of nausea and vomiting. The gland remains palpable but is decreased considerably in size. The ECG shows ST depression, atrioventricular (AV) block, and occasional bigeminy. Assess these subjective and objective data.

S.K.'s nausea and vomiting, together with the ECG changes of AV block and bigeminy, strongly suggest digitalis toxicity. Although a high dosage of digoxin is appropriate while a patient is thyrotoxic, continuation of this same dose as the hyperthyroidism resolves increases the likelihood of digitalis toxicity.^{119,120}

27. Why was such a large dose of digoxin required initially? What other options can be used to control the ventricular rate?

The AF of hyperthyroidism is often resistant to digitalis. When euthyroid patients with AF were given digitalis before and after exogenous T₃ administration, the daily dose of digoxin required to maintain a ventricular rate of 70 was increased from 0.2 to 0.8 mg after T₃ administration.¹⁴⁰ Higher dosages of digoxin without side effects might be tolerated better by the hyperthyroid patient.^{119,120,140} Nevertheless, the goal of digoxin therapy should be a higher target heart rate (i.e., 100 beats/minute) than that achieved with digoxin in the euthyroid patient with AF to minimize cardiac toxicity. If additional rate control is required, β -blockers or calcium channel blockers (e.g., diltiazem or verapamil) can be added. Unless contraindicated by severe bronchospasm, β -blockers rather than calcium channel blockers are preferred because they are more effective in controlling the ventricular rate and are less likely to cause hypotension.

This apparent resistance to digitalis is attributed to intrinsic changes in myocardial function, to an increased volume of distribution for digoxin, and to an increased glomerular filtration of the glycoside.^{119,120,140} Conversely, hypothyroid patients are inordinately sensitive to the effects of digitalis and require

smaller doses to achieve a therapeutic response. Regardless of the mechanism, one should be aware that higher-than-normal doses might be required in patients with thyrotoxicosis and that the initial dosage should be reduced as the hyperthyroid state resolves.

Cardioversion

28. If the AF persists, when should cardioversion be attempted in S.K.? Is other treatment indicated?

Because S.K. received RAI 6 weeks ago, her thyroid function tests should be rechecked to determine her present thyroid status. Cardioversion, either medical or electrical, should not be attempted if she is still toxic because the success rate is low. AF spontaneously reverted to normal sinus rhythm (NSR) in 56% to 62% of patients within the first 3 to 4 months after control of the hyperthyroidism.¹³⁴ Spontaneous conversion is highly unlikely if the duration of the hyperthyroidism-induced AF exceeds 13 months or if the AF persists after 4 months of euthyroidism.¹³⁴ Older patients with or without underlying heart disorders (except CHF) are also less likely to spontaneously convert to NSR. Patients who meet these criteria are candidates for cardioversion at about the third or fourth month after achieving euthyroidism. Age and the duration of thyrotoxicosis are important determinants of successful cardioversion. Ninety percent of patients achieved NSR after cardioversion; of these, 57% and 48% maintained NSR at 10 and 14 years, respectively, of follow-up.¹³⁴

S.K. should be maintained on warfarin because of a high prevalence of systemic embolization in thyrotoxic patients with AF. Anticoagulation should be started when the AF is first diagnosed and continued until S.K. is euthyroid and in NSR. This is especially true for younger patients at low risk of bleeding with Coumadin. The risks versus benefits of anticoagulation should be weighed before therapy (see Chapter 16). Because an increased sensitivity to warfarin is observed, close monitoring is warranted (see Question 25).

Thyrotoxicosis: Clinical Presentation

29. C.R., a 27-year-old woman, has a 3-month history of intermittent heat intolerance, sweats, tremor, and severe muscle weakness, which has limited her ability to climb stairs. Her weight has increased because of increased appetite. She is also bothered by the pounding of her heart and some minor difficulty in swallowing. There is a family history of thyroid disease, but she denies taking any thyroid medications or any history of radiation to her neck. C.R. previously received iodide drops with symptomatic improvement, but her disease recurred despite its continued administration. Her other medical problems include diabetes, which is controlled with diet, and osteoarthritis, which is treated with aspirin 2.5 g/day. She has a history of noncompliance with her clinic visits.

Pertinent physical findings include a BP of 180/90 mmHg, a pulse of 110 beats/minute, hyperreflexia, lid lag, and a diffusely enlarged thyroid gland that is about four times normal (about 100 g). Laboratory data include TT₄, 6 mcg/dL (normal, 5–12); FT₄, 2 ng/dL (normal, 0.7–1.9); TSH, <0.01 μ units/mL (normal, 0.5–4.7); TPO, 350 IU/mL (normal, <1); and blood glucose,

350 mg/dL (normal, 60–115). Assess these subjective and objective data.

[SI units: TT₄, 77 nmol/L (normal, 64–154); FT₄, 28 pmol/L (normal, 9–24); TSH, <0.01 mIU/L (normal, 0.5–4.7); blood glucose, 19.4 mmol/L (normal, 3.3–6.4)]

C.R.'s clinical findings verify an autoimmune hyperthyroid state. However, the serum FT₄ is elevated only slightly and is disproportionately low relative to the severity of her symptoms, the undetectable TSH level, and her other laboratory findings. The low normal TT₄ could be explained by displacement of T₄ from TBG by aspirin (see Question 3). The possibility of a variant type of hyperthyroidism known as T₃ toxicosis should be considered. The clinical features include signs and symptoms of thyrotoxicosis, normal or borderline high FT₄, an undetectable TSH level, and elevated T₃ levels. The latter occurs through preferential secretion and peripheral conversion of T₄ to T₃. A T₃ level should be obtained to establish the diagnosis.

Asymptomatic elevations of T₃ levels often precede elevation of T₄ levels and the development of overt hyperthyroidism. T₃ toxicosis probably represents an early stage of classic T₄ toxicosis and is useful for early diagnosis or as an early indicator of relapse after discontinuation of thioamide therapy.

Iodides

30. Why were the iodide drops initially effective in improving C.R.'s symptoms and later ineffective? When are iodides indicated? What is their mechanism of action?

Iodides have several effects: They inhibit thyroid hormone release, they block iodotyrosine and iodothyronine synthesis by blocking organification, and they decrease the vascularity of the thyroid gland.¹⁴¹ However, large doses may accentuate hyperthyroidism because they provide a significant increase in available substrate for hormone synthesis (see question 54).^{141,142}

The inhibitory effect of exogenous iodides on the intrathyroidal organification of iodides is known as the Wolff-Chaikoff effect. This is an inherent autoregulatory function of the normal gland to prevent excessive hormone synthesis in the event of a large iodide load. The Wolff-Chaikoff effect occurs when intrathyroidal concentrations of iodides reach a critical level, and this is not overcome by TSH stimulation. However, as illustrated by C.R., the gland can “escape” from this block even with continued iodide use. The gland escapes by decreasing iodide transport or by leaking iodide. Both mechanisms decrease the critical intrathyroidal iodide level, thereby decreasing the block to organification. This effect is illustrated in C.R. Therefore, iodides should not be used as primary therapy for Graves' disease.

Conversely, some patients are responsive to iodide therapy, including (a) patients who already have high intrathyroidal iodine stores (i.e., “hot” nodules, Graves' disease); (b) patients with underlying defects in organic binding mechanisms (i.e., Hashimoto's); (c) patients who develop drug-induced thyroid disorders (see questions 52–55); and (d) patients with Graves' disease made euthyroid with RAI or surgery and who are receiving no thyroid replacement.

These patients are so sensitive that small doses of iodide can elicit the Wolff-Chaikoff effect, resulting in either amelioration of hyperthyroid symptoms or precipitation of

hypothyroidism.^{141–143} For this reason, patients with recurrent hyperthyroidism after surgery or RAI can often be managed with iodides alone.

The most important pharmacologic effect of iodides is their ability to promptly inhibit thyroid hormone release when dosages of 6 mg/day are given.^{141,143} The mechanism is unknown, but it is not related to the Wolff-Chaikoff effect, which may take several weeks to manifest. Unlike the Wolff-Chaikoff effect, this effect can be overcome partially by an increase in TSH secretion. Thus, the normal gland can escape in 7 to 14 days because inhibition of thyroid hormone release stimulates a reflex increase in TSH secretion. Because patients with hyperthyroidism experience an improvement in symptoms within 2 to 7 days of initiation of therapy, inhibition of hormone release must be the predominant mechanism of action for the iodides. This rapid onset is the reason iodides are used in the treatment of thyroid storm and as an ameliorative measure while awaiting the onset of the therapeutic effects of thioamides or RAI.

Large doses of iodides are also used 2 weeks before thyroid surgery to increase the firmness of the thyroid gland by decreasing its size, vascularity, and friability. Iodides facilitate a smoother, less complicated surgery and reduce the risk of postoperative complications by inducing a euthyroid state.¹⁴¹

Stable iodine can be administered orally either as an unpleasant-tasting Lugol's solution (5% iodine and 10% potassium iodide), containing 8 mg/drop of iodide, or as the more palatable saturated solution of potassium iodide (SSKI), containing 50 mg/drop of iodide. The minimum effective daily dose is 6 mg,¹⁴¹ although larger doses (e.g., 5–10 drops QID of SSKI) are often administered.

The advantages of iodide therapy are that it is simple, inexpensive, and relatively nontoxic and involves no glandular destruction. Disadvantages include “escape,” accentuation of thyrotoxicosis, allergic reactions, relapse after discontinuation of treatment, and subsequent interference with RAI if used before therapy.

Treatment Modalities

31. What are the advantages and disadvantages of the different treatment modalities available for C.R.?

The three major treatment modalities for Graves'-related hyperthyroidism are the thioamides, RAI, and surgery (Table 49-10).¹³³ In most cases, any of these three modalities can be used, and there is controversy as to which is the most effective therapy. Often the final decision is empiric, depending on the physician's available resources and the patient's desires. A review of treatment guidelines published by the major endocrine organizations found that RAI is the most common treatment, while surgery is the least common.¹⁴⁴ Patients who are older and those with cardiac disease, concomitant ophthalmopathy, and hyperthyroidism caused by a toxic multinodular goiter are treated best with RAI. Surgery is the preferred therapy for pregnant women who are drug intolerant, when obstructive symptoms are present, or if malignancy is suspected.

Thioamides

The thioamides are the preferred treatment for children, pregnant women, and young adults with uncomplicated Graves' disease.^{133,145,146} This is the only treatment that leaves the thy-

roid gland intact and does not carry the added risk of permanent hypothyroidism often associated with RAI or surgery.

Because the thyrotoxicosis of Graves' disease might be self-limiting, thioamides are used to control the symptoms until spontaneous remission occurs. Thioamides should also be given before treatment with RAI or surgery to deplete the gland of stored thyroid hormone, which prevents subsequent thyroid storm. Although hyperthyroidism from toxic nodules will also respond to thioamides, more definitive therapy (surgery or RAI) is needed because these conditions do not undergo spontaneous remission.

Disadvantages of thioamide therapy include the numerous tablets required, patient adherence, possible drug toxicity, the long duration of treatment, and the low remission rates after discontinuation of therapy (see Question 42).

The use of thioamides in C.R. has several potential drawbacks. Her relatively large gland and severe disease make the prognosis for spontaneous remission somewhat less favorable. A delay in the onset of thioamide's effect may be expected if intraglandular stores of thyroid have been increased by her prior iodide therapy. Furthermore, her nonadherence and difficulty swallowing may necessitate another means of treatment. Thioamides may also be prepared for administration by the rectal routes.^{147–149}

Surgery

Surgery is considered the treatment of choice^{133,150–152} when (a) malignancy is suspected; (b) esophageal obstruction, evidenced by difficulty swallowing, is present; (c) respiratory difficulties are present; (d) contraindications to the use of thioamides (e.g., allergy) or RAI (e.g., pregnancy) exist; (e) a large goiter that regresses poorly on RAI or thioamide therapy is present; or (f) it is the patient's preference. Some argue that surgery is underused in the treatment of Graves' disease.¹⁵⁰ In a prospective, randomized trial comparing the three treatment modalities, surgery produced euthyroidism more quickly and was associated with a lower relapse rate than either RAI or thioamides.¹⁵¹ A meta-analysis of 35 studies encompassing 7,241 patients with Graves' disease found that thyroidectomy was successful in 92% of patients with a low recurrence (7.2%) of hyperthyroidism.¹⁵³ If C.R.'s minor difficulty in swallowing persists because of poor regression of goiter size with drug therapy, then surgery is a reasonable alternative. If surgery is contemplated, C.R. must be brought to surgery in a euthyroid state to prevent rapid postoperative rises in T₄ levels and subsequent thyroid storm (see Question 50). A total or near-total rather than a subtotal thyroidectomy is the procedure of choice when performed by an experienced surgeon.^{150,152,153} Although subtotal thyroidectomy theoretically avoids the predictable risk of hypothyroidism from total thyroidectomy; the likelihood of recurrent hyperthyroidism increases in proportion to the amount of residual thyroid tissue remaining.^{150,151} Recurrent thyrotoxicosis following a subtotal thyroidectomy should be treated with RAI because the incidence of surgical complications increases with a second surgery.

Surgical complication rates are low when the procedure is performed by a competent surgeon and when the patient is adequately prepared for surgery. The disadvantages of surgery are expense, hospitalization, hypothyroidism, the small risk of postoperative complications, and the patient's fear of surgery (see Question 40).^{150,151,153}

Table 49-10 Treatment for Hyperthyroidism

| Modality | Drug/Dosage | Mechanism of Action | Toxicity | Indication |
|---|---|---|--|---|
| Primary Treatment | | | | |
| Thioamides | | | | |
| PTU 50 mg tablet; rectal formulation can be made ^{147,148} | 100–200 mg PO q6–8h (<i>max</i> : 1,200 mg/d) for 6–8 wk or until euthyroid; then maintenance of 50–150 mg QD PO × 12–18 mo | Blocks organification of hormone synthesis, blocks peripheral conversion of T ₄ to T ₃ (PTU only) | Skin rashes, GI symptoms, arthralgias, ↑ transaminases, hepatitis, agranulocytosis | DOC in thyroid storm, pregnancy, and breast-feeding |
| Methimazole (Tapazole) 5-, 10-mg tablet; rectal suppositories can be made ¹⁴⁹ | Methimazole 30–40 mg PO QD or in two divided doses (<i>max</i> : 60 mg/d) for 6–8 wk or until euthyroid, then maintenance of 5–10 mg/d PO × 12–18 mo | Similar to PTU except does not block conversion of T ₄ to T ₃ | Similar to PTU; cholestatic jaundice, reports of aplasia cutis | Thioamide DOC (see PTU) because QD dosing and better compliance |
| Surgery | Preoperative preparation with iodides, thioamides, or β-blockers before surgery; see specific operative agent | Near total thyroidectomy | Hypothyroidism, cosmetic scarring, hypoparathyroidism, risks of surgery, and anesthesia, vocal cord damage | Obstruction, choking, malignancy, pregnancy in second trimester, contraindication to RAI or thioamides |
| RAI | ¹³¹ I radioactive isotope; 80–100 μCi/g thyroid tissue. Average dose, ≈10 mCi; pretreatment with corticosteroids indicated in patients with ophthalmopathy | Destruction of the gland | Hypothyroidism; worsening of ophthalmopathy; fear of radiation-induced leukemia; genetic damage; malignancy; rarely, radiation sickness | Adults, older patients who are poor surgical risks or have cardiac disease; patients with a history of prior thyroid surgery; contraindications to thioamide usage; increasingly used in kids |
| Adjuncts to Primary Usage | | | | |
| Iodides | | | | |
| Lugol's solution 8 mg/drop (5% iodine, 10% potassium iodide; saturated [SSKI] 50 mg/drop) | 5–10 drops TID PO for 10–14 days before surgery; minimum effective dose 6 mg/day | ↓ vascularity of gland and ↑ firmness; blocks release of thyroid hormone | Hypersensitivity reactions, skin rashes, mucous membrane ulcers, anaphylaxis, metallic taste, rhinorrhea, parotid and submaxillary swelling; fetal goiters and death | Preoperative preparation before surgery; thyroid storm, provides symptomatic relief of symptoms. <i>Do not use before RAI or chronically during pregnancy</i> |
| β-Blockers | | | | |
| Propranolol or equivalent β-blocker. <i>Avoid those with ISA</i> | Propranolol 10–40 mg PO q6h or PRN to control HR <100 beats/min; IV 0.5–1 mg slowly | Blocks effects of thyroid hormone peripherally, no effect on underlying disease; blocks T ₄ to T ₃ conversion | Related to β-blockade; bradycardia, CHF, blocks hyperglycemic response to hypoglycemia, bronchospasm, CNS symptoms at high doses; fetal bradycardia | Symptomatic relief while awaiting onset of thioamides, RAI; preoperative preparation for surgery; thyroid storm |
| Calcium channel blockers | | | | |
| | Diltiazem 120 mg TID–QID PO or verapamil 80–120 mg TID–QID PO PRN to control HR <100 beats/min | Blocks effects of thyroid hormone peripherally, no effect on underlying disease | Bradycardia, peripheral edema, CHF, headache, flushing, hypotension, dizziness | Alternative for symptomatic relief of hyperthyroid symptoms in patients who cannot tolerate β-blockers |
| Corticosteroids | | | | |
| | Prednisone or equivalent corticosteroids 50–140 mg/day PO in divided doses; IV hydrocortisone 50–100 mg q6h or equivalent for thyroid storm | ↓ TRAb, suppression of inflammatory process; blocks T ₄ to T ₃ conversion | Complications of steroid therapy | Ophthalmopathy, thyroid storm (use IV steroid), pretibial myxedema, pretreatment before RAI therapy in patients with ophthalmopathy |

CHF, congestive heart failure; CNS, central nervous system; DOC, drug of choice; GI, gastrointestinal; HR, heart rate; ISA, intrinsic sympathomimetic activity; IV, intravenous; mCi, millicurie; PO, orally (by mouth); PRN, as needed; PTU, propylthiouracil; q, every; QD, every day; QID, four times a day; RAI, radioactive iodine; SSKI, saturated solution of potassium iodide; T₃, triiodothyronine; T₄, thyroxine; TID, three times a day; TRAb, thyroid receptor antibody; μCi, microcurie.^{57–59}

Radioactive Iodine

RAI, the most common treatment modality in the United States, is the preferred treatment for (a) debilitated, cardiac, or older patients who are poor surgical candidates; (b) patients who fail to respond to drug therapy or who experience adverse drug reactions; and (c) patients who develop recurrent hyperthyroidism after surgery.^{133,144,151}

Pregnancy is an absolute contraindication to RAI therapy. Previously, the use of RAI was restricted to adults older than an arbitrary age of 20 to 35 years because it was feared that RAI could result in genetic damage or neoplasia. However, its use in adolescents is increasing after more than 50 years of clinical experience with RAI showing that it is safe and effective.¹⁵⁴⁻¹⁵⁶ There is no reported evidence of genetic damage after ¹³¹I ingestion, and the dose of radiation to the gonads is <3 rads, which is comparable to other radiographic diagnostic tests (e.g., barium enemas).¹⁵⁷ The incidence of leukemia or malignancy is no higher in recipients of ¹³¹I than in thyrotoxic patients treated with drugs or surgery.^{154,158} In a retrospective review of 98 adolescents followed for 36 years after receiving ¹³¹I, no cancers of the thyroid or leukemia were reported.¹⁵⁶ One interesting finding is that patients receiving RAI should be warned that they can set off radiation detectors at airport screening terminals for up to 12 weeks after RAI and that they should carry documentation of their treatment.^{159,160}

RAI is painless, effective, economical, and quick, but unsubstantiated fears about radiation and malignancy, as well as the high incidence of hypothyroidism, may deter its use. RAI could be used safely in this nonpregnant young patient. However, C.R.'s prior use of iodides will dilute the ¹³¹I pool. Thus, it will be impossible to achieve therapeutic thyroid concentrations of RAI for as long as 3 to 6 months.

Iodinated Contrast Media

The unavailability in the United States of radiographic iodinated contrast agents (e.g., ipodate, iopanoic acid, sodium tyropanoate) effective in the short-term management of hyperthyroidism may increase the use of less well-studied agents.¹⁶¹ Iodinated contrast media act by inhibiting the 5-monodeiodinase enzyme responsible for the pituitary and peripheral conversion of T₄ to T₃ and also inhibit thyroid hormone secretion. Each gram of the iodinated contrast agents contains 600 to 650 mg iodine. The onset of their therapeutic effect is more rapid than that of the thioamides. After administration of ipodate 0.5 to 1 g/day, a rapid decline in T₃ concentrations by 58% and T₄ levels by 20% occurred within 24 hours; the agent was more effective than 600 mg of PTU, which decreases T₃ levels by only 23%.¹⁶² Significant clinical improvement and maximal reductions of hormone levels were evident within 3 to 7 days. Iodate and other contrast media are useful adjuncts to thioamides in the early treatment of severe hyperthyroidism and with RAI therapy.¹⁶³ However, long-term use is not reasonable because the antithyroid effects are transient. Serum T₃ levels can return to baseline or hyperthyroid levels within 1 month despite continued administration; subsequent response to thioamides might also be impaired.^{161,162} When used as sole therapy, loss of efficacy occurs after 2 to 12 weeks.^{161,162,164,165}

Treatment With Thioamides

Propylthiouracil Versus Methimazole

32. C.R. is started on PTU 200 mg q8h after baseline FT₄I and TSH levels have been obtained. Three weeks later, she angrily complains that her symptoms are worse and that the medication is not working; however, she reluctantly admits missing doses because of difficulty swallowing, nausea, vomiting, diarrhea, fatigue, a cough, and a sore throat. What are the advantages of using either PTU or methimazole in the treatment of hyperthyroidism?

Both thioamides are effective in treating hyperthyroidism. The antithyroid effectiveness of the thioamides primarily depends on their ability to block the organification of iodines, thereby inhibiting thyroid hormone synthesis.^{145,146} Thyroid autoantibody synthesis may also be suppressed. In most hyperthyroid situations, methimazole should be considered the drug of choice rather than PTU because patient adherence and ease of administration are improved.

DOSING AND ADMINISTRATION

Methimazole is effective when administered initially as a single dose compared with the multiple-dose regimen required with PTU to achieve a euthyroid state.^{145,146} Although a single-dose regimen of PTU has been tried acutely, it is most effective when given in divided doses (see Question 41). Compared to PTU, methimazole is also less expensive, requires daily ingestion of fewer numbers of tablets, and is not associated with a bitter tablet taste. However, PTU is preferred over methimazole in thyroid storm because, unlike methimazole, it also blocks the peripheral conversion of T₄ to T₃.¹⁶⁶ Within 24 to 48 hours after PTU administration, a 25% to 40% reduction in peripheral T₃ production is seen, which contributes to PTU's therapeutic effectiveness. A significantly greater fall in T₃ concentration and the T₃:T₄ ratio can be demonstrated in hyperthyroid patients treated acutely with PTU and iodine than with methimazole and iodides. Last, PTU is preferred over methimazole in breast-feeding and pregnant patients (see Question 44).

33. Why was the thioamide therapy ineffective in C.R.? Was the dose of PTU appropriate?

The inadequate response in C.R. suggests poor adherence to the thioamide dosing regimen or a delayed response caused by prior iodide loading of the gland.

The onset of action of the thioamides is slow because they block the synthesis rather than the release of thyroid hormone. Therefore, hormone secretion will continue until the glandular stores of hormone are depleted. If adequate doses were given, some improvement of clinical symptoms should be noted after 2 or 3 weeks.¹⁴⁶

The dosage of PTU is appropriate. Thioamide dosing consists of two phases: initial therapy to achieve euthyroidism, and maintenance therapy to achieve remission. Initially, high blocking dosages of PTU (400–800 mg/day, depending on the severity of the toxicosis) should be given in three or four divided doses, as in C.R.^{133,145,146} Rarely, dosages of 1,200 mg/day of PTU or its equivalent may be required in patients with severe disease or storm.¹⁶⁶ Equipotent doses of methimazole (which is 10 times more potent than PTU on a mg-per-mg basis) can also be used. However, it is usually unnecessary to use >40 mg/day of methimazole to restore a euthyroid state.^{133,145,146}

Toxicity is also less common (see questions 38 and 39). True resistance to thioamides is rare; thus, most cases of unresponsiveness are caused by poor patient adherence, as in C.R.

C.R.'s adherence is also hindered by the frequency of PTU administration. The serum half-life of PTU is short (1.5 hours), but it is the intrathyroidal drug concentrations that should determine the dosing intervals because they are most clearly related to the drug's antithyroid effects¹⁴⁶ (see question 41). PTU must be dosed every 6 to 8 hours initially, or as frequently as every 4 hours in cases of severe hyperthyroidism and thyroid storm. In contrast, methimazole has a serum half-life of 6 to 8 hours, remains in the thyroid for 20 hours, and has a duration of activity of up to 40 hours.^{146,167}

If C.R. is taking her PTU as directed, then an increase in the PTU dosage to 200 mg every 6 hours is reasonable. However, poor adherence is often difficult to ascertain and is more likely when multiple daily doses are required. The best option for C.R. is to change to 30 to 40 mg of methimazole, given once daily to improve adherence, or divided into two doses to decrease GI distress. After methimazole is given for 4 to 6 weeks to achieve euthyroidism, the daily dosage can be reduced gradually by 25% to 30% monthly to a dosage that maintains euthyroidism, usually 5 to 10 mg/day of methimazole or 50 to 150 mg/day of PTU. If C.R. remains hyperthyroid despite adequate doses of thioamides, then the most likely reason is nonadherence.

MONITORING THERAPY

34. What additional objective baseline data should be obtained to monitor both the efficacy and toxicity of thioamides?

Before thioamides are administered, a baseline FT₄ and TSH should be obtained. A baseline white blood cell (WBC) count with differential can also help differentiate the leukopenia associated with hyperthyroidism from drug-induced leukopenia and/or agranulocytosis (see Question 39). Baseline liver function tests can assist in the evaluation of thioamide-induced hepatotoxicity (see Question 38). A repeat FT₄ and TSH should be obtained after 4 to 6 weeks on therapy and 4 to 6 weeks after any change in the dosing regimen. Once the patient is euthyroid on maintenance dosages, thyroid function tests can be obtained every 3 to 6 months.

DURATION OF THERAPY

35. How long should C.R. be continued on thioamide treatment?

Traditionally, thioamide therapy is continued for 1 to 2 years despite the lack of data regarding the optimal treatment period.^{133,145,146} The goal of treatment is to control the symptoms of Graves' disease until spontaneous remission occurs. Graves' disease remits spontaneously in about 25% to 30% of patients.¹⁶⁸ Because it is unknown when or if remission will occur, it is understandable why the optimal duration of therapy is unclear. Short-term therapy (i.e., <6 months) has been advocated to save time and money and improve adherence because earlier studies suggested remission rates comparable to a longer course of therapy. However, short-term therapy is not recommended because longer follow-ups of patients receiving short-term therapy have noted remission rates comparable to those observed with spontaneous remission.^{145,146}

Most data support a 12- to 18-month course of treatment to achieve remission rates of approximately 60%.^{145,146,169,170}

Two prospective randomized trials found that extending treatment from 6 to 18 months was beneficial but that 42 months of therapy was not significantly better than 18 months.^{169,170} However, one retrospective study of patients treated for >12 months observed remission rates of only 17.5%.¹⁷¹ These conflicting results underscore the fact that determining the optimal treatment period is confounded by the large variability that exists with regard to spontaneous remission. Nevertheless, treatment periods of 1 to 2 years are justifiable in adherent patients. Therapy can be reinstated if hyperthyroidism reappears shortly after therapy is discontinued. Thioamides can also be continued indefinitely if there are no side effects and treatment with either RAI or surgery is not desired. In C.R., this goal might not be achievable, given her history of nonadherence.

Precautions

36. Can thioamide therapy affect any of C.R.'s pre-existing medical conditions?

Thyrotoxicosis can activate or intensify diabetes, primarily by increasing the basal hepatic glucose production and the metabolism of insulin.¹⁷² Therefore, effective therapy with thioamides may restore control of C.R.'s diabetes.

C.R.'s arthritis should not be affected by the PTU, although both PTU and methimazole are associated with the development of lupus erythematosus (LE), lupuslike syndromes, and vasculitis.^{146,173} These adverse drug reactions are rare; the incidence is <0.1%. Lupuslike syndromes include skin ulcers, splenomegaly, migratory polyarthritis, pleuritis and pericarditis, periarteritis, and renal abnormalities. Serologic abnormalities may also occur with these connective tissue disorders and include hyperglobulinemia, positive LE preparations, and positive antinuclear antibodies. Recovery occurs with adequate steroid therapy and withdrawal of the thioamides. Because cross-reaction between methimazole and PTU is likely to occur, patients exhibiting these reactions should be treated with surgery or RAI. C.R.'s treatment should be monitored with this lupuslike adverse effect in mind, but the occurrence of this syndrome is so uncommon that a troublefree course of therapy can be anticipated.

Adjunctive Therapy

37. What adjunctive therapy might help alleviate some of C.R.'s symptoms while awaiting the onset of thioamide's effects?

Iodides (see question 30), β -adrenergic blocking agents without intrinsic sympathomimetic activity, or calcium channel blockers can be used acutely to ameliorate some of C.R.'s symptoms.^{174,175} Because iodides were previously ineffective in C.R., a β -blocker should be tried.

β -adrenergic blocking agents rapidly decrease the nervousness, palpitations, fatigue, weight loss, diaphoresis, heat intolerance, and tremor associated with thyrotoxicosis, probably because many of the signs and symptoms mimic sympathetic overactivity.^{133,174} An increase in the number of β -adrenergic receptors rather than an elevation in catecholamine levels is probably responsible for this overactivity. Because the underlying disease process and thyroid hormone levels are not affected significantly by β -blockers, patients generally remain mildly symptomatic and fail to gain weight. For this reason, they should not be used as the sole treatment for thyrotoxicosis.

All β -blockers without intrinsic sympathetic activity (e.g., atenolol, metoprolol, propranolol) are effective in alleviating the hyperthyroid symptoms, but propranolol (Inderal) is the only β -blocker that inhibits peripheral conversion of T_4 to T_3 .¹⁷⁴ Thyroid function tests are generally not affected except for a mild decrease in the T_3 level.

In summary, β -blockers are (a) effective adjuncts in the management of thyroid storm, (b) useful to prepare patients for surgery, and (c) useful in the short-term management of thyrotoxicosis during pregnancy.^{150,166,174} Surprisingly, propranolol also improves many of the neuromuscular manifestations of hyperthyroidism, including thyrotoxic periodic paralysis.

Diltiazem or verapamil are effective alternatives when β -blockers are contraindicated.¹⁷⁵ Diltiazem 120 mg TID or QID can be tried. The dihydropyridine calcium channel blockers are unlikely to be effective.

Because of C.R.'s history of diabetes, the effects of β -adrenergic blocking drugs in patients with diabetes must be considered (see Chapter 50). If β -blockers are instituted, a cardioselective β -blocker would be a better choice. The appropriate dosage should be based on clinical and objective improvement of hyperthyroid symptoms, such as a reduction in heart rate. Metoprolol 25 to 50 mg BID can be started initially and the dosage titrated to maintain the heart rate at <90 beats/minute. Otherwise, diltiazem, verapamil, or a retrial of iodides is warranted.

Adverse Effects

38. A pruritic area over the pretibial aspects of both legs, as well as several maculopapular erythematous patches and abdominal tenderness, were noticed during C.R.'s physical examination. Do these reactions require the discontinuation of her PTU?

THIOAMIDE RASH

Although C.R. may be experiencing a drug rash from PTU, pretibial myxedema or the dermatopathy of Graves' disease may also be possibilities because of the location of the pruritic area. About 4% of patients with Graves' disease who exhibit infiltrative exophthalmos also have dermatologic changes. The skin is thickened, erythematous, and nonpitting because of mucopolysaccharide infiltration and accentuation of hair follicles. Pruritus or pain may be present. Treatment includes topical corticosteroids, control of the Graves' disease, and reassurance.

Both PTU and methimazole can produce a maculopapular pruritic rash in 5% to 6% of treated patients.¹⁴⁶ The rash can occur at any time but is more common early in therapy. If the rash is mild, drug therapy can be continued while the patient's symptoms are treated with an antihistamine and a topical steroid; such rashes generally subside spontaneously. Alternatively, another thioamide can be substituted because cross-sensitivity to this side effect is uncommon. If the rash is urticarial or is associated with other systemic manifestations of a drug reaction (e.g., fever, arthralgias), thioamides should be stopped and nondrug treatment considered.

HEPATITIS

C.R.'s symptoms of nausea, vomiting, diarrhea, fatigue, and abdominal tenderness require further evaluation. Her symptoms could be consistent with mild GI side effects from her

PTU therapy or with impending thyroid storm from nonadherence (see Question 50). Taking the PTU after meals or changing to methimazole could improve medication tolerability and adherence. However, the possibility of drug-induced hepatitis should be considered. Typically, PTU-induced hepatotoxicity is hepatocellular in nature, but cholestasis, hepatic necrosis, and fulminant hepatic failures have been reported.^{137,138,146} Transient elevations in transaminases occur in approximately 30% of asymptomatic patients within the first 2 months of PTU therapy and may not require drug discontinuation.¹³⁷ The liver enzymes usually normalize within 3 months of reducing the PTU to maintenance dosages despite drug continuation. However, PTU should be stopped immediately in patients with clinical symptoms of hepatitis to ensure complete recovery. The mechanism of PTU-induced hepatotoxicity appears to be autoimmune because circulating autoantibodies and in vitro peripheral lymphocyte sensitization to PTU have been detected.¹³⁸ Overt hepatitis typically occurs during the first 2 months of PTU therapy and is not dose related. In contrast, methimazole typically produces a cholestatic jaundice picture and might be more common in older patients and in those receiving higher dosages (i.e., >40 mg/day).¹³⁹ In patients with thioamide-induced hepatitis, changing to the alternative thioamide is not recommended because fatalities have been reported on rechallenge. In such patients, either radioactive therapy or surgery should be used.

The thyroid function tests, transaminases, and bilirubin should be checked in C.R. and the PTU stopped until these results are available. Routine monitoring of liver function tests is not recommended because patients can be asymptomatic. However, routine monitoring might be indicated in patients with a history of liver disease and risk factors for hepatitis (e.g., alcohol use). All patients receiving thioamides should be questioned closely during the first 2 months of therapy for symptoms of hepatitis, and hepatic function tests should be obtained if appropriate.

AGRANULOCYTOSIS

39. Assess C.R.'s complaints of sore throat and cough.

C.R.'s complaints should not be dismissed casually because they might indicate PTU-induced agranulocytosis. Agranulocytosis (<500/mm³ of neutrophils) is the most severe adverse hematologic reaction associated with the thioamides and should be considered strongly in C.R.^{146,176} In contrast, drug-induced leukopenia is usually transient, is not associated with impending agranulocytosis, and is not an indication to discontinue thioamide therapy. An accurate history should be obtained from C.R. The clinician should be particularly alert for a temperature of 101°F for 2 or more days, malaise, or other flulike findings that appeared temporally with her sore throat. If subjective or objective data are consistent with agranulocytosis, the PTU should be discontinued immediately until the results of a repeat WBC count with a differential are obtained. Traditionally, routine serial determinations of WBC counts are not recommended for monitoring the development of agranulocytosis because the onset is so abrupt. Instead, patients should be instructed to immediately report rash, fever, sore throat, or any flulike symptoms. However, one study suggested that weekly monitoring of the WBC count with a differential during the first 3 months of antithyroid therapy might identify

asymptomatic patients with agranulocytosis before infection occurs.¹⁷⁶

The prevalence of agranulocytosis is about 0.5% but ranges from 0.5% to 6%.^{146,176} The risk factors for agranulocytosis are unknown. There is no predilection for either gender, and the reaction may be idiosyncratic or dose related. Some reports suggest that patients older than 40 years or those taking high dosages of methimazole (e.g., >40 mg/day) might be more susceptible than those on any dosage of PTU. Although controversial, patients receiving low dosages of methimazole (e.g., <40 mg/day) might be at less risk than those receiving high or conventional dosages of PTU.^{146,176}

Agranulocytosis typically develops within the first 3 months of treatment, although it can occur at any time and as late as 12 months after starting thioamide therapy.¹⁴⁶ A delayed reaction is more common with methimazole therapy than with PTU. In 55 patients who developed agranulocytosis while taking thioamides, the duration of PTU therapy (17.7 ± 9.7 days) was significantly shorter than for methimazole therapy (36.9 ± 14.5 days).¹⁷⁶ The mechanism of thioamide-induced agranulocytosis is unknown. Both allergic- (idiosyncratic) and toxic-type (dose-related) reactions have been suggested. An autoimmune reaction with circulating antineutrophil antibodies and lymphocyte sensitization to antithyroid drugs has been demonstrated.¹⁷⁷ Death usually results from overwhelming infection.

If agranulocytosis is diagnosed, the drug should be discontinued, the patient monitored for signs of infection, and antibiotics instituted if necessary. Granulocyte colony-stimulating factors may shorten the recovery period.^{146,178} If the patient recovers, granulocytes begin to reappear in the periphery within a few days to 3 weeks; a normal granulocyte count occurs shortly thereafter.^{176,178}

Although some cases of granulocytopenia have resolved with substitution or continuation of thioamides, the risks of drug rechallenge clearly outweigh the benefits, and other treatments should be instituted. Changing to an alternative thioamide should also be avoided because of possible cross-sensitivity between these agents.¹⁴⁶

In summary, all patients receiving thioamide therapy should be well educated regarding the signs and symptoms of agranulocytosis. If these symptoms develop, they should be advised to contact their physician or pharmacist. If they cannot reach their own physician, patients should inform the emergency physician that they are taking thioamides, and a WBC count with differential should be obtained. Routine monitoring of a WBC and differential is not recommended until further studies justify that it is indicated and cost effective.

Preoperative Preparation

40. C.R.'s PTU is discontinued because she developed agranulocytosis and hepatitis, and surgery is scheduled when her granulocyte level returns to normal. What thyroid preparation is needed for C.R. before thyroidectomy? What postoperative complications are associated with thyroidectomy?

C.R. should be in a euthyroid state at the time of surgery to avoid precipitation of thyroid storm and morbidity. Generally, iodides (see Question 30), thioamides, or propranolol can be used.^{141,166,174} The combination of iodides and propranolol is more effective than either used alone. Propranolol used alone

has been associated with thyroid crisis postoperatively and may be less effective than iodides in decreasing gland friability and vascularity.¹⁷⁴

Because C.R. received only 1 week of thioamide therapy, it is likely that her gland still contains large stores of hormone; therefore, pretreatment is necessary.

In addition to the risks of anesthesia and surgery, postoperative complications include hypoparathyroidism, adhesions, laryngeal nerve damage, bleeding, infection, and poor wound healing. However, the surgery can be uneventful if it is performed by experienced surgeons.^{150-153,179} Complications are also higher if a total rather than a subtotal thyroidectomy is performed, but there is a lower risk of recurrent hyperthyroidism. Development of hypothyroidism, especially subclinical hypothyroidism, is greatest during the first year after surgery, with an insidious rise in incidence over the next 10 years. The incidence of permanent hypothyroidism varies from 6% to 75% and is related inversely to the amount of remnant tissue left behind.^{150-153,179} Thyroid function tests should be monitored annually after surgery.

Single Daily Dosing

41. J.R., a 23-year-old man newly diagnosed with Graves' disease, remains hyperthyroid after 6 weeks of PTU 200 mg q8h. He admits he has trouble remembering to take it three times a day and desires a more simplified regimen. Could J.R. be placed on a single daily dose of PTU?

A single daily dose of PTU should not be used as initial therapy because euthyroidism is achieved in only 39% to 68% of hyperthyroid patients using this approach.^{146,180} However, once euthyroidism occurs, single daily doses of PTU are effective. In contrast, several clinical studies have documented that a single daily dose of methimazole is as effective as multiple daily doses in >90% of treated patients.^{145,146} Although a lower dosage of methimazole (e.g., 10-15 mg QD) can produce euthyroidism with fewer side effects, higher initial dosages of 20 to 40 mg/day are recommended to increase the likelihood of euthyroidism in 6 weeks.^{133,145,146}

Methimazole is the preferred agent for once-a-day dosing because of its longer intrathyroidal duration of action (40 hours).^{146,167} However, as previously noted, PTU is preferable in thyroid storm because it acts more rapidly. Despite its short plasma half-life of 4 to 6 hours, a single 30-mg dose of methimazole has a duration of action of 40 hours.¹⁶⁷ The duration of action of PTU is unknown, but it is shorter than methimazole. Apparently, the duration of action of the antithyroid agents correlates best with the size of the dose and the intrathyroidal concentration of the drug.

J.R. should be changed to 20 to 40 mg of methimazole given once daily. Thyroid function tests should be obtained after 4 to 6 weeks and the dosage reduced as necessary to maintain euthyroidism. An effective single daily dose regimen of methimazole should increase patient acceptance and adherence.

Remission Rates With Thioamides

42. B.D., a 30-year-old woman, has been maintained on PTU 100 mg QD for >2 years. Her PTU has been discontinued twice in the past, and each time her hyperthyroidism recurred. She refuses either surgery or RAI therapy. Although she is clinically

euthyroid on the PTU, her gland is larger than normal and has never decreased with therapy. Recent laboratory tests showed an FT₄ of 1 ng/dL (normal, 0.7–1.9) and a TSH level of 6.5 μ units/mL (normal, 0.5–4.7). What is responsible for the enlarging gland? What subjective or objective data in B.D. would influence her remission rate and justify a longer course of thioamide therapy? Would the addition of T₄ be helpful?

[SI units: FT₄, 14 pmol/L (normal, 9–24); TSH, 6.5 mIU/L (normal, 0.5–4.7)]

The high TSH level suggests that TSH stimulation caused by excessive suppression of hormone synthesis by PTU is contributing to the enlarging thyroid gland. The easiest solution to this problem is to decrease the maintenance dose of PTU to 50 mg daily to normalize the TSH value and minimize gland stimulation.

Long-term remission rates achieved with the thioamides are disappointing. Remission rates within 6 years after discontinuing therapy average 50% (range, 14%–75%),^{145,146,169–171} although relapse rates are as high as 80%. The rate of permanent remission is usually <25% if the follow-up period is long enough.^{145,146,181} Why some patients remain in remission while others relapse once thioamides are discontinued is unclear, although patients who remain euthyroid for >10 to 15 years after discontinuing therapy probably do so because of disease progression to Hashimoto's thyroiditis rather than as a direct result of treatment.¹⁶⁸ In other words, the natural course of Graves' hyperthyroidism might be eventual hypothyroidism regardless of the treatment modality used. Several factors have a limited role in predicting relapse and remission and have been used to guide therapy.

A longer duration of thioamide treatment (see Question 35) improved the remission rate by changing the basic underlying abnormality of Graves' disease.^{145,169–171} Numerous studies show that titers of antithyroid receptor (TRAb) and antimicrosomal antibodies fall during therapy with the thioamides but are unchanged during therapy with placebo or β -blockers.^{145,146,170,182} Patients with low or undetectable TRAb titers at the end of 12 to 24 months of thioamide therapy had a 45% chance of remission compared to a <10% chance of remission for those with higher TRAb titers within 1 to 5 years after completing therapy.^{181–184} The best response was obtained in those with smaller goiters, those with less severe disease, and nonsmokers. A higher dosage of thioamides does not appear to improve the remission rate but causes a higher incidence of toxicity, including agranulocytosis, arthralgias, dermatitis, gastritis, and hepatotoxicity.^{145,169,181}

Some clinical features might be predictive of a higher rate of remission and may help clinicians identify patients who deserve a longer trial of drug treatment before changing to RAI or surgery. These clinical features include smaller goiter, mild symptoms of short duration, a reduction in goiter size during treatment, nonsmokers, absence of ophthalmopathy, and undetectable or low TRAb levels.^{146,181,182} Smokers should be advised to discontinue smoking to increase the chance of remission.¹⁸⁵

In a preliminary study, the addition of L-thyroxine to maintenance doses of thioamides given for 1 year, followed by an additional year of L-thyroxine alone, significantly reduced the risk of relapse after thioamides were discontinued.¹⁸⁴

Those receiving the T₄-methimazole combination experienced significant reductions in TSH receptor antibody titers compared to those receiving methimazole alone. At 3 years, the combination-treated patients had a lower rate of recurrence (1.7%) than those receiving methimazole alone (recurrence rate, 34.7%) after all therapy was discontinued. Unfortunately, several prospective studies evaluating the addition of T₄ to thioamides have not validated these initial favorable results.^{181,183,186,187} Support for this therapeutic approach has waned, and the addition of T₄ to existing thioamide therapy is not recommended.

B.D.'s large goiter reduces her chance of remission with longer therapy. Although thioamide therapy can be continued indefinitely if well tolerated, surgery or RAI therapy should seriously be considered for B.D., who already has received PTU for >2 years. Alternative therapy is especially crucial if she plans to become pregnant within the next few years (see Question 44).

Subclinical Hyperthyroidism

43. J.C. is a 68-year-old male who is found to have a TSH level of 0.25 μ units/mL (normal, 0.5–4.7) with normal FT₄ and FT₃ hormone levels on routine blood tests. He is otherwise healthy and denies any symptoms of thyroid dysfunction. On physical exam, his thyroid gland is normal. He denies any family history of thyroid disease and is taking no medications. How should these tests be interpreted? How should J.C. be managed?

[SI units: TSH, 0.25 mIU/L (normal, 0.5–4.7)]

J.C.'s laboratory values of a suppressed TSH value with normal free thyroid hormone levels are consistent with subclinical hyperthyroidism (SHyper). Other causes of a suppressed TSH value that are unlikely in J.C. include medication suppression (e.g., metformin, bexarotene) of the TSH level (Table 49-1), pituitary hypothyroidism, and euthyroid sick syndrome (see Question 2).^{36,188} A suppressed TSH may also be a normal finding in healthy elderly patients.

The dangers of SHyper are similar to those of overt hyperthyroidism, and include cardiac findings (e.g., atrial and ventricular premature beats, atrial fibrillation [AF], left ventricular hypertrophy), loss of bone mineral density in postmenopausal women, and if present, subtle symptoms of hyperthyroidism. In elderly patients, hyperthyroid symptoms, even if overtly hyperthyroid, may not be apparent or "apathetic" due to impaired responsiveness of the sympathetic nervous system. A significant relationship between atrial fibrillation and degree of SHyper is clear, whereas an association with increased atherosclerotic heart disease or mortality is weak.¹⁸⁹ The relative risk of AF in SHyper may be as high as 5.2 and increased by older age, male gender, higher FT₄ levels, and degree of TSH suppression. In two cohorts followed for 10 to 13 years, the relative risk of atrial fibrillation ranged from 1.6 to 3.1, depending on the degree of TSH suppression.^{189,190}

The management of subclinical hyperthyroidism is controversial, especially in asymptomatic patients, because data evaluating treatment outcomes are limited.^{57–59} An expert panel concluded that treatment of subclinical hyperthyroidism should be considered in "elderly" patients and in those with cardiac disease and osteoporosis with TSH levels <0.1 μ units/mL.^{57,58} For patients with TSH levels of 0.1 to

0.45 μ units/mL, the evidence was insufficient to recommend therapy. A recent review recommends RAI or thioamide therapy only if the TSH level is <0.1 μ units/mL in postmenopausal women, those older than 60 years, patients with a history of heart disease, osteoporosis, or hyperthyroid symptoms.⁵⁹ For patients with TSH levels of 0.1 to 0.4 μ units/mL, antithyroid therapy can be considered if they are in the aforementioned groups; otherwise, therapy is not recommended.

In J.C., his thyroid function tests should be repeated. An RAI update and scan should be obtained to detect any hyperactive areas or nodules that might be responsible for the suppressed TSH. Because J.C. is generally healthy, treatment can be considered if there are concerns about cardiac disease or bone loss; otherwise, no therapy is also reasonable based on the available evidence. Close monitoring of thyroid function tests is recommended every 6 months to a year. If hyperthyroid symptoms or changes in cardiac or bone function occur, then RAI therapy is recommended.

In Pregnancy

44. N.N., a 32-year-old woman who is 3 months pregnant, is referred for management of her Graves' disease. What are the therapeutic ramifications of managing thyrotoxicosis during pregnancy?

Hyperthyroidism develops in 0.02% to 1.4% of pregnant women and often precedes conception.¹⁹¹ Symptoms of thyrotoxicosis are typically ameliorated during the second and third trimesters and exacerbated early in the postpartum period. Treatment is crucial to prevent damage to the fetus and to maintain the pregnancy. RAI, chronic iodide therapy, and iodine-containing compounds are contraindicated during pregnancy because they will cross the placenta to produce fetal goiter and athyreosis.¹⁹¹⁻¹⁹³ As little as 12 mg/day of iodide has produced neonatal goiter and death. The long-term use of propranolol should also be avoided because it is associated with fetal respiratory depression, a small placenta, intrauterine growth retardation, impaired response to anoxia, and postnatal bradycardia and hypoglycemia.^{191,192} However, if rapid control of hyperthyroidism is required, short-term use (<1 week) of propranolol or the iodides is safe.¹⁹¹⁻¹⁹³

Either surgery or thioamide is the treatment of choice for hyperthyroidism in the pregnant patient. Surgery is safe during the second trimester with adequate preoperative preparation. During both other trimesters, thioamides are preferred because surgery can precipitate spontaneous abortion. PTU is preferable, although both thioamides are equally efficacious,¹⁹⁴ demonstrate similar placental crossing properties,¹⁹⁵ and produce similar thyroid hormone concentrations in fetal umbilical cord blood samples.¹⁹⁶ Of concern, methimazole has been associated with anecdotal reports of congenital scalp defects (e.g., aplasia cutis) and an embryopathy syndrome (esophageal and choanal atresia).¹⁹⁷⁻²⁰⁰ However, the risks of reversible aplasia cutis were not greater in women receiving methimazole (e.g., 2.7%) compared to PTU (e.g., 3%) or hyperthyroid controls (e.g., 6%).^{194,197,198} Therefore, methimazole can be considered in pregnancy if there is intolerance or nonadherence to PTU.^{191,192,194} (See Chapter 47.) Methimazole may be

preferred by some because its longer half-life allows once-daily dosing.

Fetal hypothyroidism and goiter can develop when large doses of either thioamide are administered to the mother, even if the mother is still hyperthyroid.^{191,192} Therefore, to avoid goiter and suppression of the fetal thyroid gland, which begins to function at about 12 to 14 weeks of gestation, any thioamide should be prescribed in the lowest effective doses that will maintain the mother's T_4 level in the upper ranges of normal. Control of maternal hyperthyroidism increases the risk of fetal hypothyroidism. Initiate therapy with PTU (e.g., maximum of 450 mg/day in three divided doses) or methimazole (e.g., maximum of 20-30 mg given once daily) until control is achieved, and then taper the dosage to 50-150 mg/day of PTU or 5-15 mg/day of methimazole for the remainder of the pregnancy. Some patients can discontinue thioamides in the second half of pregnancy.¹⁹¹ Such modest doses of thioamides provide satisfactory control of maternal hyperthyroidism and should not cause clinically evident thyroid dysfunction in the neonate. Patients requiring more than the maximum recommended thioamide dosages for control may need to consider the possibility of surgery in the second trimester.

Nevertheless, a small but significant reduction in neonatal serum T_4 occurs even when small (100-200 mg) doses of PTU are administered during pregnancy to mothers with Graves' disease.^{191,192,199} It is unclear whether this mild, transient reduction in serum T_4 causes long-term impairment of mental development or is otherwise detrimental to the newborn. To date, no significant differences in intellectual development have been noted between children exposed to PTU or methimazole in utero and their unexposed siblings.²⁰¹⁻²⁰³ However, children exposed in utero to >300 mg/day of PTU had lower IQs.^{201,202}

Although transient fetal or neonatal hypothyroidism does not appear to be a major threat to the baby, it is advisable to maintain the mother in a mildly hyperthyroid state.^{191,192} Mild maternal hyperthyroidism seems to be well tolerated, but maternal hypothyroidism is poorly tolerated by both the mother and the fetus (see Question 13). T_4 levels should be maintained in the upper ranges of normal because normal thyroid function tests are suggestive of hypothyroidism during pregnancy (high TBG and TBPA levels). A normal TSH level should not be the goal of therapy but should remain suppressed because control of maternal hyperthyroidism increases the risk of fetal hypothyroidism.

It is not rational to add thyroid hormone to the mother's regimen to prevent fetal goiter or hypothyroidism because thyroid hormones do not reach the fetal circulation. Thyroid supplementation only complicates the treatment of maternal hyperthyroidism by increasing thioamide requirements, which can further compromise fetal thyroid hormone production.¹⁹¹ If the mother has not been thyrotoxic throughout pregnancy, a normal infant can be expected. All pregnant patients with a history of or active Graves' disease should be screened during pregnancy for TRAb to assess the risk of neonatal hyperthyroidism.¹⁹¹ Last, both thioamides can be safely used in the lactating mother if the maximal dose of PTU does not exceed 200 mg/day (up to 750 mg/day in one report)²⁰⁴ and 10 to 20 mg daily for methimazole.²⁰⁵ Propranolol and iodides are secreted in breast milk and should be avoided. (See Chapter 47.)

Treatment With Radioactive Iodine

Pretreatment

45. B.J., a 35-year-old woman, has newly diagnosed Graves' disease complicated by CHF and angina. After a few days of treatment with PTU 200 mg TID and Lugol's solution, 5 drops/day, B.J. received RAI therapy. Six months later, she is still symptomatic. Evaluate the influence of B.J.'s pretreatment therapy on the efficacy of her RAI therapy.

Patients with severe hyperthyroidism, patients with hyperthyroidism and cardiac disease, and those who are debilitated or older should receive antithyroid treatment before RAI therapy. The goal of pretreatment is to deplete stored thyroid hormone. This minimizes post-RAI hyperthyroidism (which occurs during the first 10 days after ^{131}I administration) and thyroid storm, which is caused by leakage of hormones from the damaged thyroid gland.^{146,166,206} Other patients with hyperthyroidism can be treated safely with RAI without pretherapy.

Lugol's solution or other iodides should not be given before RAI because iodides decrease the effectiveness of this therapy by decreasing the gland's uptake of RAI. This effect of iodides persists for several weeks. Iodides can be used for 1 to 7 days after RAI treatment if they are needed to rapidly control symptoms of hyperthyroidism.

The thioamides can be used before RAI therapy to achieve a euthyroid state, but pretreatment with thioamides may lower the cure rate and increase the need for subsequent doses of RAI.^{146,207-211} A meta-analysis of 14 trials found that use of thioamides (PTU, methimazole, carbimazole) before and after RAI was associated with an increased risk of treatment failure (relative risk of 1.28; 95% CI, 1.07-1.52) and a 32% reduced risk of hypothyroidism regardless of the thioamide used.²¹¹ Purportedly, higher RAI failure rates occur with PTU than with methimazole due to the presence of the radioprotective sulfhydryl group in PTU.²⁰⁷⁻²¹⁰ To facilitate optimal uptake and retention of ^{131}I by the gland, PTU should be stopped at least 7 days before and methimazole at least 4 days before RAI administration.^{207,208,210} If necessary, thioamides can be restarted after RAI administration without impairing its efficacy. β -Adrenergic blocking agents can be used before, during, and after RAI therapy without interfering with its uptake.

B.J. remains symptomatic because pretreatment with the PTU and iodides decreased the effectiveness of RAI therapy. Propranolol should be given to B.J. before RAI therapy to ameliorate symptoms of hyperthyroidism because she has received only a short course of thioamide. Iodides might be preferable to propranolol following RAI therapy if B.J.'s CHF worsens. For subsequent RAI doses, pretreatment with methimazole may be preferable to PTU because it can be stopped a few days prior to RAI therapy, thereby causing a shorter duration of hyperthyroidism.

Onset of Effects

46. B.J. still is symptomatic 2 weeks after a second dose of RAI. When can she expect to experience the therapeutic effects of RAI therapy?

Although some benefits from RAI therapy are evident within 1 month, a period of 8 to 12 weeks is generally required for maximal effects.^{133,206} Euthyroidism or, more commonly, hypothyroidism occurs in approximately 80% to 90%

of patients treated with a single nonablative dose of RAI; the remaining 10% to 20% become euthyroid or hypothyroid after two or more doses. This slow onset is a disadvantage, but symptomatic control can be obtained quickly by administration of a β -adrenergic blocking agent, or iodides starting 1 to 14 days after the ^{131}I dose. Iodides are less preferable if a second dose of RAI is necessary. Thioamides can also be given, although their therapeutic effects are delayed for 3 to 4 weeks.

At least 3 months should elapse before a second radioactive dose of iodide is administered, and most recommend waiting 6 months before repeating ^{131}I administration, unless the patient remains severely thyrotoxic. It is inadvisable to give a second dose before the major effects of the first dose have become apparent. Although the use of iodides before RAI in B.J. may have decreased the amount of ^{131}I retained by her thyroid, it still is advisable to wait at least 3 months before a second dose is given.

Iatrogenic Hypothyroidism

47. S.D., a 54-year-old woman, returns to the thyroid clinic after being lost to follow-up for 6 months. She initially received RAI 3 years ago but required a repeat dose of RAI 1 year ago for recurrence of hyperthyroidism. She currently has no other medical problems and is not taking any medications. She is a mildly obese, puffy-faced woman wearing several layers of clothing. She complains of fatigue and lack of energy. Her reflexes are delayed, and her skin is cool and dry. What is a likely explanation for her symptoms?

S.D.'s clinical presentation and history are compatible with hypothyroidism secondary to RAI therapy. An FT₄ and a TSH level would confirm this diagnosis. Iatrogenic hypothyroidism is the major complication of ^{131}I therapy, although transient hypothyroidism may be seen in the first 3 to 6 weeks after RAI therapy.¹³³ The incidence of iatrogenic myxedema is often reported as 7% to 8%, but it increases at a constant rate of 2.5% per year. The reported prevalence of this complication ranges from 26% to 70% after 1 to 14 years.²⁰⁶

The best predictor of eventual hypothyroidism is the dose of ^{131}I administered. Prevention of iatrogenic hypothyroidism is directed toward calculation of a dose that will produce neither recurrent hyperthyroidism nor hypothyroidism. Unfortunately, when lower doses of ^{131}I were used to avoid hypothyroidism, the cure rate was reduced but the incidence of hypothyroidism was unaffected. Thus, the appearance of iatrogenic hypothyroidism may be inevitable with time. However, hypothyroidism is managed easily and is an acceptable therapeutic end point. Because hypothyroidism after RAI therapy is latent and often insidious, patients should be informed of this and monitored closely at monthly intervals for subsequent hypothyroidism. Awareness of a transient hypothyroidism soon after RAI therapy should minimize the institution of unnecessary hormone replacement.

Ophthalmopathy

Clinical Presentation

48. H.R., a 50-year-old man, first developed "large eyes with stare," weakness, diaphoresis, and thyroid enlargement when he was diagnosed with Graves' disease. RAI therapy caused some worsening of his eye symptoms. Although he is clinically

euthyroid, physical examination reveals severe bilateral conjunctival edema and injection, proptosis of the right eye, incomplete lid closure, and decreased visual acuity. He complains of photophobia, tearing, and extreme irritation, which is worse after smoking cigarettes. His other medical problems include diabetes treated with metformin and pioglitazone. What is the association of H.R.'s ocular changes with Graves' disease?

H.R. presents with symptoms consistent with the infiltrative ophthalmopathy of Graves' disease.^{212,213} The eye signs of Graves' disease are the most striking abnormality of this disorder. Rarely, ophthalmopathy can occur without any evidence of hyperthyroidism. Fortunately, severe ophthalmopathy occurs in only 3% to 5% of patients, while 25% to 50% have some eye findings. Eye disease is more severe in older patients and in men than women. Smokers often have higher levels of TRAb and more severe ophthalmopathy.^{185,213,214}

It is unknown why the eye and its muscles are attacked in Graves' disease. Histologic examination reveals lymphocytic infiltration, increased mucopolysaccharides, fat (due to increased adipogenesis and glycosaminoglycans), and water in all retrobulbar tissue. Ocular symptoms include edema, chemosis, excessive lacrimation, photophobia, corneal protrusion (proptosis), scarring, ulceration, extraocular muscle paralysis with loss of eye movements, and blindness from retinal and optic nerve damage.

The eye involvement can occur at any time and is usually bilateral. The ocular symptoms usually subside or remain stable once the patient is euthyroid; however, some cases will progress during the euthyroid period or following RAI treatment of the hyperthyroidism (see Question 49). Pioglitazone may also increase eye protrusion by 1 to 2 mm by stimulating adipogenesis and increasing retrobulbar fat production.²¹⁵

Management of Eye Symptoms

49. Was previous treatment of H.R.'s hyperthyroidism appropriate? How should his current ocular symptoms be managed?

The optimal treatment of hyperthyroidism and its effect on the course of ophthalmopathy remain controversial.^{212,213,216} Thioamides might improve eye symptoms through an immunosuppressive mechanism of action and control of the hyperthyroidism or exert a neutral effect.²¹² Many clinicians believe that gland ablation with RAI or surgical removal is preferable because it removes the antigen source and prevents progression of the ophthalmopathy.^{150,212} However, several studies have confirmed development or worsening of eye symptoms immediately after RAI therapy.^{214,216} One randomized study demonstrated that the concomitant use of 0.4 to 0.5 mg/kg of prednisone begun 2 to 3 days post-RAI and continued for a total of 3 months after RAI therapy in those with any degree of ocular involvement was well tolerated and prevented further deterioration of eye symptoms.^{214,216} Regardless of the treatment used, control of the hyperthyroidism often improves most eye findings, except for proptosis.

In H.R., prednisone 40 to 60 mg/day should have been started after his RAI treatment and continued for 2 to 3 months until the eye symptoms improved. Because the pathophysiology of the ophthalmopathy is unclear, treatment is limited to symptomatic and empiric measures once the patient is euthyroid.^{212,213} H.R. should also be encouraged to stop smoking to prevent progression of the ophthalmopathy.¹⁸⁵

His pioglitazone should be discontinued as well because thiazolidinediones can increase eye protrusion by 1 to 2 mm via adipogenesis stimulation to increase retrobulbar fat.²¹⁵

Periorbital edema and chemosis are worse in the morning after being in the horizontal position; elevating the head of the bed, treatment with diuretics, and restricting salt intake may be helpful. Protective glasses can relieve photophobia and external irritation. Topical corticosteroid drops are effective in decreasing local irritation, but they should be used cautiously because they increase the risk of infection. Ocular irritants such as smoke and dust should be avoided. Bothersome symptoms (e.g., dry eye, redness, tearing) caused by eyelid retraction can be ameliorated with artificial tears and lubricants.²¹² Incomplete lid closure predisposes the patient to corneal scarring and ulceration, so lubricant eyedrops should be applied several times daily and at night to keep the bulbs moist. Taping the eyelids shut at night helps prevent drying and scarring. Lateral surgical closure of the lids (tarsorrhaphy) may be required to improve lid closure.

When the ophthalmopathy is severe and progressive, an aggressive approach is necessary. Systemic corticosteroids can produce either dramatic or marginal results in the emergency treatment of progressive exophthalmos associated with decreasing visual acuity. Prednisone at dosages of 35 to 80 mg/day is often effective, although dosages as high as 100 to 140 mg/day may be necessary.^{212,213} Pain, irritation, tearing, and other subjective complaints often respond within 24 hours of administration. Therapy for about 3 months is necessary to improve eye muscle and optic nerve function disturbances. Initial large doses should be tapered rapidly once the desired response is obtained to minimize adverse effects. Subconjunctival and retrobulbar injections of steroids are not as effective.

X-ray therapy to the orbit also relieves congestive and inflammatory symptoms.²¹² The combination of orbital irradiation and systemic steroids may be required to achieve maximal benefits. Plasmapheresis and immunosuppressive agents, such as cyclophosphamide, azathioprine, cyclosporine, and methotrexate, have also been used with limited success in combination with steroids.²¹²

When the previous measures and thyroid ablation fail to arrest the progression of visual loss and exophthalmos, then surgical orbital decompression should be considered.

Thyroid Storm

Clinical Presentation

50. H.L., a 48-year-old woman, is admitted to the hospital with a 3-week history of fatigue, weakness, dyspnea on exertion, SOB, palpitations, and inability to keep food and liquids down. One year before admission, she began noticing a preference for cold weather and an increase in nervousness and emotional lability. After her husband died a few days ago, she experienced increased nausea and vomiting, irritability, insomnia, tremor, and a 104°F fever, which she attributed to an upper respiratory tract infection. She denies taking any current medications. Her laboratory data obtained on admission included an FT₄ of 4.65 ng/dL (normal, 0.7–1.9) and an undetectable TSH level. Assess H.L.'s subjective and objective data.

[SI unit: FT₄, 60 pmol/L (normal, 9–24)]

The presentation is consistent with thyroid storm, a life-threatening medical emergency that might have been precipitated by the stress associated with the death of her husband. The clinical manifestations of thyroid storm¹⁶⁶ include the acute onset of high fever (sine qua non), tachycardia, and tachypnea, and involvement of the following organ systems: cardiovascular (tachycardia, pulmonary edema, hypertension, shock), CNS (tremor, emotional lability, confusion, psychosis, apathy, stupor, coma), and GI (diarrhea, abdominal pain, nausea and vomiting, liver enlargement, jaundice, nonspecific elevations of bilirubin and PT). Hyperglycemia was a clinical finding in 12 of 18 episodes.

Thyroid storm develops in about 2% to 8% of hyperthyroid patients. The pathogenesis of thyroid storm is not well understood, but the condition can be described as an “exaggerated” or decompensated form of thyrotoxicosis. The term *decompensated* implies failure of body systems to adequately resist the effects of thyrotoxicosis. It is not attributed solely to the release of massive quantities of hormones, which can occur after surgery or RAI therapy. Catecholamines also play an important role; the increased quantities of thyroid hormone in conjunction with increased sympathetic and adrenal output contribute to many of the manifestations of thyroid storm. Although thyroid hormones exert an independent effect, many of the symptoms of hyperthyroidism are ameliorated by catecholamine-blocking agents such as β -blockers and calcium channel blockers (e.g., diltiazem, verapamil).

Treatment

51. What treatment plan (including route of administration) should be initiated promptly in H.L.?

Accurate, continuous, and immediate treatment can decrease the mortality of thyroid storm significantly. Mortality rates as low as 7% and survival rates as high as 50% are reported. Treatment of thyroid storm should be directed against four major areas discussed in the following sections.¹⁶⁶

DECREASE IN SYNTHESIS AND RELEASE OF HORMONES

High dosages of thioamides, preferably PTU 800 to 1,200 mg/day or methimazole 60 to 100 mg/day, should be given orally in four divided doses. If H.L. cannot take oral doses, a rectal formulation of PTU (better bioavailability with enema than suppository) or methimazole, which is as effective as the oral route, can be administered.^{147–149} No commercial parenteral preparation is available for either drug, limiting their use by the IV route. PTU is the thioamide of choice because it acts more rapidly than methimazole by blocking the peripheral conversion of T_4 to T_3 , a dominant source of the hormone.

Iodides, which rapidly block further release of intraglandular stores of T_4 , should be given at least 1 hour after thioamide administration. Given in this way, the substrate for hormone synthesis is not increased, and the therapeutic effect of thioamide is not blocked. The addition of iodides (e.g., Lugol's solution 15 to 30 drops/day orally in divided doses) to the thioamides often ameliorates symptoms within 1 day.

Cholestyramine 4 g orally (PO) QID may assist in lowering hormone levels rapidly but should be administered apart from other agents to prevent inhibiting their absorption.²¹⁷ Other effective modalities include plasmapheresis, charcoal hemoperfusion, and plasma exchange.

REVERSAL OF THE PERIPHERAL EFFECTS OF HORMONES AND CATECHOLAMINES

β -adrenergic blocking drugs are the preferred agents to decrease the tachycardia, agitation, tremulousness, and other symptoms of excessive adrenergic stimulation seen in thyroid storm. Propranolol is the β -blocker of choice because its clinical efficacy in storm is well documented and because it inhibits the peripheral conversion of T_4 to T_3 .^{166,174} If rapid effects are necessary, propranolol 1 mg by slow IV push can be given every 5 minutes to lower the heart rate to 90 to 110 beats/minute. A 5- to 10-mg/hour IV infusion can be given to maintain the desired heart rate. IV esmolol 50 to 100 mcg/kg/minute can also be given. If perfusion is maintained, oral β -blockers (e.g., propranolol, 40 mg every 6 hours; atenolol, 50–100 mg BID; metoprolol, 50–100 mg daily; nadolol, 40–80 mg daily), titrated to response, can also be given.

SUPPORTIVE TREATMENT OF VITAL FUNCTIONS

This may include sedation, oxygen, IV glucose, vitamins, treatment of infections with antibiotics, digitalization to maintain the cardiac status, rehydration, and treatment of hyperpyrexia with cooling blankets, sponge baths, and the judicious use of antipyretics. Because hypoadrenalism is often suspected, hydrocortisone 100 to 200 mg should empirically be given IV every 6 hours. Because pharmacologic doses of steroids acutely depress serum T_3 levels, a beneficial effect in storm, their routine use is recommended.

ELIMINATION OF PRECIPITATING CAUSES OF STORM

Factors associated with the induction of thyroid storm include infection (most common), trauma, inadequate preparation before thyroidectomy, surgical operations, stress, diabetic acidosis, pregnancy, emboli, discontinuation or withdrawal of antithyroid medications, drug therapy, and RAI therapy.¹⁶⁶

DRUG-INDUCED THYROID DISEASE

Lithium and Antidepressants

52. D.A., a 56-year-old man, complains of sluggishness, cold intolerance, fatigue, and a “rundown” feeling, which doctors attribute to the depressive phase of his bipolar affective illness. He previously had been well controlled with sertraline (Zoloft) 100 mg/day, but lithium carbonate (Eskalith) 900 mg/day was added 4 months ago because of unreasonable mirthfulness and uncontrollable gift-buying tendencies. Physical examination reveals a puffy face and a large goiter. What is a reasonable assessment of these subjective and objective data?

Thyroid function tests (i.e., TSH, FT₄) should be obtained to evaluate the possibility of lithium- and possibly sertraline-induced hypothyroidism and goiter.^{218–221} If appropriate, T₄ should be initiated. Although the incidence of goiter and hypothyroidism in the manic-depressive population is unknown, the incidence of baseline elevated TSH might be higher than in the general population; one study reported an incidence of 15%.²²¹

The antithyroid effects of lithium were noted first in manic-depressive patients. The exact mechanism of lithium's antithyroid effect on the gland is unclear, although it is highly concentrated by the gland. Similar to the iodides, chronic lithium therapy inhibits the release of thyroid hormone from the gland.

The fall in serum T_4 and T_3 hormone levels leads to a compensatory and transient increase in serum TSH levels until a new steady state is achieved.^{219–221}

The incidence of subclinical hypothyroidism (i.e., increased TSH level) occurs in approximately 19% of patients on chronic lithium therapy.²²¹ Typically, the serum thyroid hormone levels decrease and the TSH levels increase during the first few months of treatment, returning to pretreatment levels after 1 year. In one study, TSH levels increased within 10 days after starting therapy. Normalization of the TSH level is less likely to occur in patients with pre-existing positive thyroid antibodies before lithium therapy. Induction of thyroid antibodies and increases in baseline antibody titers also occur after chronic lithium therapy. Because abnormal thyroid function tests can be transient, a longer period of observation is justified before starting thyroid hormone therapy in patients with subclinical hypothyroidism.

Lithium-induced goiter, with or without hypothyroidism, appears in a small percentage of the population after 5 months to 2 years of therapy.^{219–221} Overt hypothyroidism develops most often during the first 2 years of treatment in women with a history of positive antibodies before lithium therapy. A direct goitrogenic effect of lithium might explain the occurrence of euthyroid goiter. The goiters respond to discontinuation of lithium or to suppression with thyroid hormone despite continuation of lithium therapy. Surgical removal of the goiter is required if there are local obstructive symptoms. In D.A.'s case, sertraline could be exerting an additive or synergistic antithyroid effect with lithium because antithyroid effects have also been associated with this drug.²¹⁸

Most patients with lithium-induced thyroid abnormalities are women older than 50 years, have a prior history of compromised thyroid function (e.g., Hashimoto's thyroiditis), positive thyroid antibodies before lithium therapy, or a strong family history of thyroid disease.^{219–221} Therefore, baseline thyroid function tests (i.e., FT_4 , TSH), antibodies, and thyroid ultrasound should be obtained before starting lithium therapy, and levels should be checked annually thereafter or more frequently if clinically indicated. Patients should also be questioned about a positive history or family history for thyroid disease and the concurrent use of other, potentially goitrogenic medications (e.g., tricyclic antidepressants, iodides, iodinated expectorants).

53. A.B., a 66-year-old, otherwise healthy man, is admitted for evaluation of new-onset AF. His only other medical problem is a history of bipolar affective disorder treated with lithium for 1 year. However, A.B. discontinued the lithium 1 month before hospitalization without the knowledge of his physician. His laboratory studies are within normal limits except for a TT_3 of 380 ng/dL (normal, 70–132 ng/dL). What is the potential cause of A.B.'s AF?

[SI unit: TT_3 , 6 nmol/L (normal, 1.1–2)]

AF may be the only manifestation of thyrotoxicosis in older patients.^{190,222} Thyrotoxicosis is reported following lithium withdrawal, and A.B.'s AF most likely is the result of excessive thyroid hormone activity. Lithium's antithyroid action is substantial and is comparable to that of the thioamides; T_4 levels decline by 20% to 35%. Therefore, A.B.'s underlying hyperthyroidism has probably been unmasked by his discon-

tinuation of the lithium. Rarely, lithium-induced thyrotoxicosis occurs.^{219,223,224}

Although lithium is not considered the standard of care for hyperthyroidism, it is recommended as an adjunct to RAI therapy in patients allergic to conventional treatment modalities because it does not interfere with ^{131}I uptake. Furthermore, lithium can increase ^{131}I retention by decreasing its rate of elimination from the gland. The increased thyroidal half-life of ^{131}I by lithium is beneficial in localizing the dose of radiation to the gland and producing faster control of the hyperthyroidism.²²⁴

Because clinical experience with lithium in the treatment of thyrotoxicosis is limited and because it has such a narrow therapeutic index, its use should be restricted to situations when rapid suppression of thyroid hormone secretion is needed, and when thioamides and iodides are contraindicated.

Iodides and Amiodarone

54. C.Y., a 54-year-old man with chronic obstructive pulmonary disease (COPD), presents with a 6-month history of weakness, fatigue, tremor, heat intolerance, palpitations, and cardiac tachyarrhythmias, previously controlled for the last 2 years on amiodarone 400 mg/day. Physical examination reveals a 50-g multinodular gland, which C.Y. says has "been there forever." He denies any family history of thyroid disease or ingestion of any thyroid medication. He recently started to use an iodinated expectorant for his COPD. His current complaints began after an intravenous pyelogram (IVP). What might be responsible for C.Y.'s hyperthyroid symptoms?

The iodine load from the IVP, the iodinated expectorant, or the amiodarone could be responsible for C.Y.'s hyperthyroid symptoms.^{31–33,141,142} Iodide-induced hyperthyroidism, known as the Jod-Basedow phenomenon, was first described in the 1800s when patients residing in iodide-deficient areas became toxic when given adequate iodide supplementation. Other reports have appeared since then. Both T_3 toxicosis and classic T_4 toxicosis have occurred following iodide ingestion or injection of roentgenographic contrast media.

Although it is presumed that both iodide deficiency and a multinodular goiter, as in C.Y., are required to invoke the Jod-Basedow phenomenon, iodide-induced disease has been reported in patients residing in iodide-sufficient areas, as well as in euthyroid patients with normal glands and no apparent risk factors (e.g., family history).^{141,142}

Amiodarone can cause hypo- or hyperthyroidism in susceptible patients because of its high iodine content.^{31–33,141–143} Twelve milligrams (37%) of free iodine is released per 400-mg dose of amiodarone. Patients with multinodular goiters who lose the ability to turn off organification of iodide with increasing iodide loads (Wolff-Chaikoff effect) are most likely to develop iodide-induced thyrotoxicosis. Conversely, patients with positive antibodies or with underlying Hashimoto's thyroiditis who cannot escape from the Wolff-Chaikoff block are most likely to develop hypothyroidism.

Amiodarone-induced hypothyroidism may occur at any time during therapy and does not appear to be related to the cumulative dose. A normal FT_4 and a persistently elevated TSH (see Question 5) are consistent with amiodarone-induced

hypothyroidism, which occurs in 6% to 10% of long-term users. The hypothyroidism responds readily to T₄ therapy, and the amiodarone can often be continued.^{31,32}

In contrast, the development of amiodarone-induced thyrotoxicosis occurs early and suddenly during therapy, so that routine monitoring of thyroid function tests is often not useful. Elevated hormone levels, an undetectable TSH level, and clinical symptoms consistent with hyperthyroidism are the best indicators of amiodarone-induced thyrotoxicosis, which occurs in 1% to 5% of long-term users. Worsening of tachyarrhythmias may be the first clinical clue to amiodarone-induced thyrotoxicosis.

Amiodarone-induced hyperthyroidism can be classified as either type I or type II.^{30,31,33} Type I occurs in patients with underlying risk factors for thyroid disease (e.g., multinodular goiter) and is related to the iodine load. The formation of large amounts of preformed hormone from the massive iodine load produces a protracted course of hyperthyroidism, which is challenging to manage. Type II amiodarone-induced hyperthyroidism results from a direct destructive type of thyroiditis, causing excessive release of thyroid hormone into the systemic circulation. This occurs most often in patients with normal thyroid glands. Unique laboratory findings include a low RAIU and elevated interleukin-6 levels.

The management of amiodarone-induced thyrotoxicosis is complicated because it is not always possible to identify the type of hyperthyroidism. Stopping amiodarone alone does not immediately improve the hyperthyroidism because of the drug's long half-life (22–55 days) and its sequestration in fat. RAI ablation is never appropriate because the high iodine load from amiodarone will suppress therapeutic uptake of the ¹³¹I. The combination of methimazole and potassium perchlorate is the treatment of choice for type I hyperthyroidism.^{31–33,141,142} The addition of corticosteroids to block T₄ to T₃ conversion is less effective because of the already potent inhibitory effects of amiodarone on T₄ to T₃ conversion. However, in patients with type II hyperthyroidism, β -blockers, corticosteroids, and iodinated contrast media if available, rather than the aforementioned agents, are the most appropriate choices.^{31,32,142,225} A total thyroidectomy can be effective by rapidly controlling the thyrotoxicosis, permitting continued therapy with amiodarone if necessary. Despite underlying cardiac disease in these patients, uneventful surgery and a low complication rate were observed if patients were treated before surgery with a short course of an oral cholecystographic agent.²²⁵

Large doses of iodides should be avoided in patients with nontoxic multinodular goiters who are predisposed to thyrotoxicosis (see Questions 5 and 30).

Interferon- α

55. P.R., a 56-year-old woman, complains of hoarseness, fatigue, “slow movement,” and forgetfulness. She is troubled by these new symptoms, which have worsened during the past few weeks. Her medical history includes persistent hepatitis C, which is responding to the combination of pegylated interferon- α injections and ribavirin. She notes that her mother had a history of Graves’ disease treated with RAI ablation. Her medications include pegylated interferon and an over-the-counter dietary sup-

plement, Cellasene, to reduce cellulite. On examination, facial edema, coarse skin, an enlarged thyroid gland without nodules, and delayed DTRs are noted. Thyroid function tests, including thyroid antibodies, are pending. What might be responsible for her new complaints?

The medications that P.R. is taking could be responsible for her complaints and physical findings, which are consistent with hypothyroidism. A detailed history of any other dietary and herbal supplements, especially those containing thyroid or iodine (e.g., kelp tablets), should be obtained. Cellasene, a dietary supplement promoted to reduce cellulite, contains a significant amount of iodine (e.g., 310 mcg of iodine per capsule) and could cause thyroid illness in susceptible patients (see Questions 30 and 54).

Another possible cause for hypothyroidism could be the pegylated interferon- α injections that she has been receiving for the hepatitis C infection.^{226–228} The prevalence of thyroid abnormalities observed with interferon- α ranges from 15% to 46%. Development de novo or aggravation of pre-existing antithyroid antibodies is the most common abnormal finding. The presence of pre-existing antithyroid antibodies (seropositivity) before interferon- α therapy or its persistence at the end of therapy is a significant risk factor for the development of overt thyroid dysfunction. Other predisposing risk factors include female gender, older patients, and Asian ethnicity.²²⁷ The incidence of thyroid dysfunction was 46% in a seropositive group compared to 5.4% in the seronegative group.²²⁷ Likewise, in a group of 114 patients with no pre-existing thyroid disease, those who were seropositive at the end of therapy had the highest risk of developing subclinical hypothyroidism 6.2 years later (odds ratio of 38.7).²²⁸

Hypothyroidism, from Hashimoto’s thyroiditis or a nonautoimmune basis, is more common (40%–50% of patients) than hyperthyroidism (10%–30%). There are two types of hyperthyroidism, an autoimmune Graves’-like disorder with positive antibodies, and a hyperthyroid thyroiditis, similar to the type II amiodarone hyperthyroidism (see question 54). This is due to a direct toxic effect of interferon on the gland. Approximately 20% of patients with a thyroiditis will first have transient symptoms of hyperthyroidism followed by hypothyroidism (biphasic thyroiditis).²²⁹

In patients with positive thyroid antibodies, reversal of thyroid dysfunction is less likely. However, thyroid dysfunction appears to be transient in most patients without positive antibodies, and treatment is not always necessary. L-thyroxine is required only if hypothyroid symptoms are bothersome; otherwise, therapy can be withheld because symptoms often resolve spontaneously within 2 to 3 months after stopping therapy. If T₄ is begun, it should be stopped after 6 months to re-evaluate the need for continued thyroid replacement. Similarly, transient hyperthyroid laboratory indices do not require therapy with β -blockers unless the patient is symptomatic or laboratory values are dangerously elevated. Rarely, thyroid dysfunction is permanent, but it may take up to 17 months after stopping therapy for findings to resolve.

P.R. should be advised to stop taking the Cellasene and to avoid other iodide-containing herbal or dietary supplements. Once the laboratory values confirm hypothyroidism, T₄ should be started concurrently with the interferon- α because of the severity of her symptoms. Once interferon therapy is completed, L-thyroxine should be tapered off to evaluate the need

for continued replacement. The presence of thyroid antibodies may increase the risk of permanent hypothyroidism.

Iodide Prophylaxis for Radiation Emergencies

56. J.M. is a healthy, 43-year-old Russian woman who lives near a nuclear reactor with her two young children. She has relatives living in Chernobyl who were exposed to the 1986 radiation fallout and developed various thyroid abnormalities, including cancer. J.M. would like to protect herself and her children. What prophylaxis and benefits, if any, might be indicated for J.M. in case of a nuclear accident?

The most accurate data for irradiation-induced thyroid abnormalities come from the 1986 Chernobyl incident, where massive amounts of RAI was released into the environment, contaminating air, food, and water supplies. Significant increases in thyroid cancer were found, primarily in children, who received ≥ 5 cGy ^{131}I exposures.²³⁰

The thyroid can be protected against radiation-induced thyroid cancer if potassium iodide (KI) is taken immediately before, coincident with, or possibly 3 to 4 hours after the radiation exposure.²³¹ Administration of KI 130 mg in adults and 65 mg in school-age children lasts approximately 24 hours and should be continued until the risk of exposure is over. Adolescents close to 70 kg should receive the full 130-mg dose; neonates should receive 16 mg. Repeat dosing is not recommended in pregnant women, neonates, or during lactation unless there is ongoing contamination because the risks of repeated KI administration (e.g., neonatal and fetal hypothyroidism) outweigh their protective benefits. In the aforementioned conditions, when repeated doses of KI are not advisable, and in those intolerant to KI, protective measures (e.g., sheltering, evacuation, control of the food supply) should be implemented. Hypothyroidism can be managed with T_4 supplementation. If repeat dosing is necessary during continued contamination, close monitoring for toxicity is recommended. Short-term administration of KI is safer in children than in adults.

Adverse effects include sialadenitis, GI disturbances, rash, and other allergic reactions, which are increased in patients with dermatitis herpetiformis and hypocomplementemic vasculitides. Hyperthyroidism, goiter, and hypothyroidism can occur, especially in adults with underlying thyroid disorders (see Question 54).

NODULES

“Hot” Nodule

57. N.S., a 20-year-old woman, noticed a “lump” in the right side of her neck. There is no history of irradiation and no family history of thyroid disease. She has no local symptoms and no symptoms suggestive of hypo- or hyperthyroidism. The right lobe of the thyroid is occupied by a 3×3 -cm firm, immovable nodule; the left lobe is barely palpable. All thyroid function tests are within normal limits. A scan shows a large “hot” nodule occupying the right lobe and a nonexistent left lobe. How should N.S.’s single “hot” nodule, or Plummer’s disease, be managed?

Hot nodule is a term used to describe a “hyperfunctioning” or iodine-concentrating area of the thyroid as shown on scan; it

appears as an area of greater density than the rest of the gland. The hyperfunctioning autonomous nodule typically suppresses activity in the remainder of the gland, but it need not produce clinical or chemical evidence of hyperthyroidism and may remain unchanged for years. Some nodules may develop into toxic goiters, causing overt symptoms of toxicosis. Most hot nodules are benign; malignancies are rarely reported.²³²

Treatment of the hot nodule depends on the existing clinical situation. If it is suppressing the other lobe of the thyroid, is not causing toxic symptoms, and is the only source of thyroid production, the patient should be left alone and monitored closely for signs of toxicity. A toxic hot nodule is best treated surgically or with RAI ablation. Because hot nodules do not spontaneously resolve, antithyroid drugs are not the treatment of choice. Because the normal thyroid tissue is suppressed, RAI is concentrated only by the hot nodule, sparing the suppressed tissue. After treatment, the suppressed tissue should begin functioning again.

“Cold” Nodule

58. P.L., a 29-year-old woman, is found to have a left thyroid nodule on routine physical examination. She has no history of neck irradiation, no family history of thyroid disease, and no symptoms suggestive of hypo- or hyperthyroidism. A firm, nontender 1-cm nodule occupies the left lobe of the gland. Thyroid function tests are within normal limits. The scan shows a “cold” nodule and the ultrasound reveals a solid mass, ruling out the possibility of a cyst. The results of the fine-needle aspiration (FNA) are pending. Antibodies are negative. What is the significance of a cold nodule, and how should it be managed?

A cold nodule is a “hypofunctioning” area of the thyroid that fails to collect radioiodine. It is depicted on the scan as a lighter or less dense area. The differential diagnosis includes Hashimoto’s thyroiditis, benign adenomas, cysts, and malignant tumors. The absence of thyroid antibodies and identification of a solid mass on ultrasound rules out the possibility of a cyst or Hashimoto’s thyroiditis. Most cold nodules turn out to be benign adenomas rather than cancers. The FNA can help distinguish a benign from a malignant nodule. However, a benign biopsy in a suspicious nodule or in a patient with risk factors for malignancy does not eliminate the possibility of malignancy. In these patients, surgery is recommended. The incidence of malignancy in a cold nodule varies between 10% and 20%.²³² A history of irradiation increases the likelihood of cancer in a nodule, and surgery is recommended in these instances. The nature of the nodule is important. Fixation of the nodule to the strap muscles or the trachea, a hard bulging mass, any pain or tenderness, or voice hoarseness can indicate malignancy.

If the nodule is benign, then close follow-up every 6 to 18 months is recommended to detect any growth. If the nodule increases in size, a repeat FNA is recommended to rule out any malignancy. Although T_4 -suppressive therapy can be considered, only about 10% to 20% of nodules shrink with therapy.^{233,234} Furthermore, L-thyroxine may not actually shrink the nodule itself, but rather the surrounding thyroid tissue, making the nodule appear smaller. Spontaneous resolution of the nodule can also occur. The dangers of excessive L-thyroxine therapy (e.g., osteoporosis, cardiac arrhythmias)

exceed the benefits of benign nodule suppression.^{56,190} Therefore, watchful waiting, with no therapy, is recommended.

Multinodular Goiter

59. G.D., a 35-year-old woman, is referred for a “goiter” discovered on routine physical examination. She denies any symptoms of hyper- or hypothyroidism or any history of irradiation. Her grandmother had hypothyroidism and a goiter. A large “lumpy, bumpy” gland is present, but she has no problems with breathing or swallowing. The FNA shows a benign lesion. The assessment is a nontoxic multinodular goiter. How should this be managed?

Nontoxic multinodular goiter is a common finding, occurring in about 5% of the population.²³² In low-risk patients, long-standing asymptomatic nodules that have not exhibited recent growth are likely to be benign and can be followed or excised surgically for cosmetic reasons. If the patient develops symptoms (swallowing or respiratory difficulty), surgery is the treatment of choice. Observation with close follow-up is the preferred treatment option for most benign multinodular goiters.

T₄ suppression therapy to decrease TSH stimulation and further gland enlargement can be considered if the patient has no cardiac contraindications. Whether T₄ suppression is effective is controversial; studies have noted both reductions in nodular growth and no changes.^{232–234} Some gland shrinkage should be noted 3 to 6 months following the initiation of T₄ 0.1 to 0.2 mg/day to suppress the TSH to subnormal levels. If so, maintenance therapy can be continued. However, the dangers of long-term thyroid suppression therapy (e.g., osteoporosis, cardiac toxicity) outweigh any potential benefits.^{55–59} Patients should be carefully monitored for the development of hyperthyroidism. Most multinodular goiters contain autonomously functioning nodules that are independent of TSH control and could produce excessive thyroid hormone secretion spontaneously.²³² Toxic multinodular goiters are optimally treated with RAI therapy.²⁰⁶ If the nodules grow while the patient is receiving T₄ therapy, rebiopsy or surgery should be considered. Nodular responsiveness to T₄ does not rule out malignancy.

Thyrotropin- α and Thyroid Suppression Therapy for Thyroid Cancer

60. J.R., a 28-year-old man, had a total thyroidectomy last year for papillary cancer followed by RAI therapy. He is clinically euthyroid on 200 mcg L-thyroxine daily with a TSH level of <0.2 μ units/mL (normal, 0.5–4.7). He is hesitant to discontinue his L-thyroxine so that an RAIU scan and thyroglobulin testing can be done to evaluate for tumor recurrence. His doctor is concerned about his suppressed TSH level and is also worried about

taking J.R. off his L-thyroxine because the patient says he “feels incapacitated” while carrying out these tests. What can you tell his physician about the TSH level and the need to stop L-thyroxine during these tests?

[SI units: TSH, 0.2 mIU/L (normal, 0.5–4.7)]

In patients with thyroid cancers, total thyroidectomy, followed by RAI and L-thyroxine therapy to suppress the TSH to subnormal levels, were associated with improved overall survival.²³⁵ The actual degree of thyroid suppression required is unclear but will depend on the severity of the thyroid cancer. An expert task force recommends a TSH level <0.1 μ units/mL to 0.5 μ units/mL for the majority of patients.²³² A low normal TSH of 0.3 to 2 μ units/mL can be considered for disease free patients.

Annually, it is important to assess recurrence of the malignancy by determining whether any residual cancerous or normal thyroid tissue remains. This is done by raising endogenous TSH levels. A rise in thyroglobulin concentrations and/or positive RAIU scan is an indication for additional RAI therapy. If no thyroid tissue is detected, patients are considered free of cancer and an evaluation is repeated in 1 year. Before recombinant human TSH or thyrotropin alfa (Thyrogen) was available, it was necessary to allow recovery of endogenous TSH secretion by discontinuing T₄ for 4 to 6 weeks. The development of hypothyroidism during this withdrawal period is often distressing. Now, thyrotropin- α is indicated as an adjunctive tool for the follow-up assessment of patients with thyroid cancer.²³⁶

Thyrotropin- α is intended to improve the quality of life in these patients by allowing these procedures to be undertaken without stopping the T₄. Clinical trials show that thyrotropin is comparable to the traditional method of T₄ withdrawal to detect distant metastases but that thyroid withdrawal is still superior in identifying recurrent thyroid cancers. Thyrotropin- α failed to detect localized tumor recurrence in 7% of patients compared to 100% detection after hormone withdrawal but detected 100% of patients with metastatic disease.^{232,236}

Thyrotropin- α is generally well tolerated. Nausea, headaches, and asthenia are the most common adverse effects noted. Recombinant human TSH is available as a 0.9-mg vial and is administered once daily for 2 days IM. Thyrotropin costs approximately \$1,118 per two-vial kit and is covered under most health plans. Improved quality of life, avoidance of hypothyroidism, and increased patient productivity may offset the direct costs of thyrotropin. However, concerns exist about the efficacy of thyrotropin- α to detect tumor recurrence compared with the current standard of practice, which is withdrawal of T₄ therapy. Further studies are needed to identify its role in care.

J.R. should be maintained on his current L-thyroxine suppression dosage because his TSH level is appropriately suppressed without hyperthyroidism.

An estimated 20.8 million people, or 7.0% of the United States population, currently has diabetes.¹ Of these, 6.2 million or about one-third were undiagnosed. In 2005 alone, over 1.5 million new cases in adults were diagnosed. Globally, the prevalence of diabetes for all ages is estimated to be 2.8% in 2000

and projected to increase to 4.4% by 2030.² The Centers for Disease Control and Prevention predicts the national incidence of diabetes will rise by 37.5% by the year 2025. The incidence of type 2 diabetes is now epidemic, with alarming increases in prevalence in both adults and children. The dramatic increase

in type 2 diabetes is related to obesity and decreased physical activity levels. Additional factors include genetic predisposition, increased insulin resistance, and progressive β -cell failure. Clinical studies have affirmed that type 2 diabetes can be delayed or prevented in high-risk populations and that good glycemic control and other interventions can slow its devastating complications. Therefore, broad implementation of guidelines and goals established by the American Diabetes Association (ADA) and others, as well as progress in processes of care, which could help to eliminate health disparities, need to be national priorities.³

Definition, Classification, and Epidemiology

Diabetes is a chronic condition caused by a relative or an absolute lack of insulin. Its hallmark clinical characteristics are symptomatic glucose intolerance resulting in hyperglycemia and alterations in lipid and protein metabolism. Over the long term, these metabolic abnormalities contribute to the development of complications such as retinopathy, nephropathy, and neuropathy.

Genetically, etiologically, and clinically, diabetes is a heterogeneous group of disorders. Nevertheless, most cases of diabetes mellitus can be assigned to type 1 or type 2 diabetes (Table 50-1). The term gestational diabetes mellitus (GDM) is used to describe glucose intolerance that has its onset during pregnancy. Glucose intolerance that cannot be ascribed to causes consistent with these three classifications include specific genetic defects in β -cell function or insulin action;

diseases of the exocrine pancreas; endocrinopathies; drug or chemical-induced; infections; and other genetic syndromes.⁴ Subclinical glucose intolerance or “prediabetes” is identified as impaired fasting glucose (IFG) and/or impaired glucose tolerance (IGT).

Approximately 5% to 10% of the diagnosed diabetic population has type 1 diabetes, which usually results from autoimmune destruction of the pancreatic β -cells.⁴ At clinical presentation, these patients have little or no pancreatic reserve, have a tendency to develop ketoacidosis, and require exogenous insulin to sustain life. The incidence of autoimmune-mediated type 1 diabetes peaks during childhood and adolescence, but can occur at any age. A minority of patients diagnosed with type 1 diabetes, mostly of African or Asian ancestry, have no evidence of autoimmunity; the etiology is, therefore, unknown. In these individuals, the rate of pancreatic destruction seems to occur more slowly, leading to a later onset and less acute presentation.

Most people with diabetes have type 2 diabetes, a heterogeneous disorder that is characterized by obesity, β -cell dysfunction, resistance to insulin action, and increased hepatic glucose production. Both the incidence and prevalence of diabetes increase dramatically with age. For example, the prevalence of self-reported diagnosed diabetes is 1.7% among persons 20 to 39 years of age and 15.8% among persons over 65 years of age.⁵ One study estimates that the prevalence of diabetes in persons over 65 years of age increased 62% from 2003 to 2004.⁶ The prevalence of type 2 diabetes also differs among ethnic populations. Relative to Caucasians, the prevalence of diagnosed

Table 50-1 Type 1 and Type 2 Diabetes

| Characteristics | Type 1 | Type 2 |
|-----------------------------------|--|--|
| Other names | Previously, type I; insulin-dependent diabetes mellitus (IDDM); juvenile-onset diabetes mellitus | Previously, type II; non-insulin-dependent diabetes mellitus (NIDDM); adult-onset diabetes mellitus |
| Percentage of diabetic population | 5–10% | 90% |
| Age at onset | Usually <30 yr; peaks at 12–14 yr; rare before 6 mo; some adults develop type 1 during the fifth decade | Usually >40 yr, but increasing prevalence among obese children |
| Pancreatic function | Usually none, although some residual C-peptide can sometimes be detected at diagnosis, especially in adults | Insulin present in low, “normal,” or high amounts |
| Pathogenesis | Associated with certain HLA types; presence of islet cell antibodies suggests autoimmune process | Defect in insulin secretion; tissue resistance to insulin; ↑ hepatic glucose output |
| Family history | Generally not strong | Strong |
| Obesity | Uncommon unless “overinsulinized” with exogenous insulin | Common (60–90%) |
| History of ketoacidosis | Often present | Rare, except in circumstances of unusual stress (e.g., infection) |
| Clinical presentation | Moderate to severe symptoms that generally progress relatively rapidly (days to weeks): polyuria, polydipsia, fatigue, weight loss, ketoacidosis | Mild polyuria, fatigue; often diagnosed on routine physical or dental examination |
| Treatment | Insulin MNT Physical activity Amylin mimetic (pramlintide) | MNT Physical activity Antidiabetic agents (biguanides, nonsulfonylurea insulin secretagogues, sulfonylureas, thiazolidinediones, α -glucosidase inhibitors, incretin mimetics/analogs, DPP-4 inhibitors) Insulin Amylin mimetic (pramlintide) |

MNT, medical nutrition therapy; HLA, human leukocyte antigen; DPP-4, dipeptidyl peptidase-4.

and undiagnosed diabetes is higher in African Americans (1.8 times), Hispanics/Latinos (1.7 times), American Indians and Alaskan Natives (2.2 times), and Asian Americans and Pacific Islanders (>2.0 times).¹ Growth in the aging population as well as greater racial and ethnic diversity in the USA are causing predicted increases in the prevalence of diagnosed diabetes from 5.6% to 12% by 2050.⁷

Diabetes is a serious condition that places people at risk for greater morbidity and mortality relative to the nondiabetic population. Diabetes is the sixth leading cause of death in the United States, although deaths attributed to diabetes and its complications are likely to be underreported.¹ Compared with the general population, the mortality rate for people with diabetes is about twice that for people without diabetes. In addition, disparities in morbidity and mortality attributed to acute and chronic complications associated with diabetes have been documented in certain groups, such as underrepresented minorities and the uninsured.⁸

Medical management of persons with diabetes is costly. In 2007, the total cost of diabetes in the United States was estimated to be \$174 billion, with 1 out of 5 health care dollars being spent on people with diabetes.⁹ The average health care expenditures for people with diabetes were approximately 2.3 times higher than those for individuals without diabetes. The majority (56%) of all health care expenditures attributed to diabetes are used by persons age 65 years and older. Hospital inpatient costs, nursing facility resources, home care, physician visits, and medications (not just insulin and oral agents) made up the majority of these expenditures. Because many expenditures are related to treatment of long-term complications, considerable effort has been directed toward early diagnosis and metabolic control of patients with diabetes.

Carbohydrate Metabolism¹⁰

An understanding of the signs and symptoms associated with diabetes is based on a knowledge of glucose metabolism and the metabolic effects of insulin in nondiabetic and diabetic subjects during the fed (postprandial) and fasting (postabsorptive) states.¹⁰ Homeostatic mechanisms maintain plasma glucose concentrations between 55 and 140 mg/dL (3.1–7.8 mmol/L). A minimum concentration of 40 to 60 mg/dL (2.2–3.3 mmol/L) is required to provide adequate fuel for the central nervous system, which uses glucose as its primary energy source and is independent of insulin for glucose utilization. When blood glucose concentrations exceed the reabsorptive capacity of the kidneys (~180 mg/dL), glucose spills into the urine, resulting in a loss of calories and water. Muscle and fat, which use glucose as a major source of energy, require insulin for glucose uptake. If glucose is unavailable, these tissues are able to use other substrates such as amino acids and fatty acids for fuel.

Postprandial Glucose Metabolism in the Nondiabetic Individual

After food is ingested, blood glucose concentrations rise and stimulate insulin release. Insulin is the key to efficient glucose utilization. It promotes the uptake of glucose, fatty acids, and amino acids and their conversion to storage forms in most tissues. Insulin also inhibits hepatic glucose production by suppressing glucagon and its effects. In muscle, insulin promotes the uptake of glucose and its storage as glycogen. It also stimulates the uptake of amino acids and their conversion to pro-

tein. In adipose tissue, glucose is converted to free fatty acids and stored as triglycerides. Insulin also prevents a breakdown of these triglycerides to free fatty acids, a form that may be transported to other tissues for utilization. The liver does not require insulin for glucose transport, but insulin facilitates the conversion of glucose to glycogen and free fatty acids. The latter are esterified to triglycerides, which are transported by very-low-density lipoproteins (VLDLs) to adipose and muscle tissue.

Fasting Glucose Metabolism in the Nondiabetic Individual

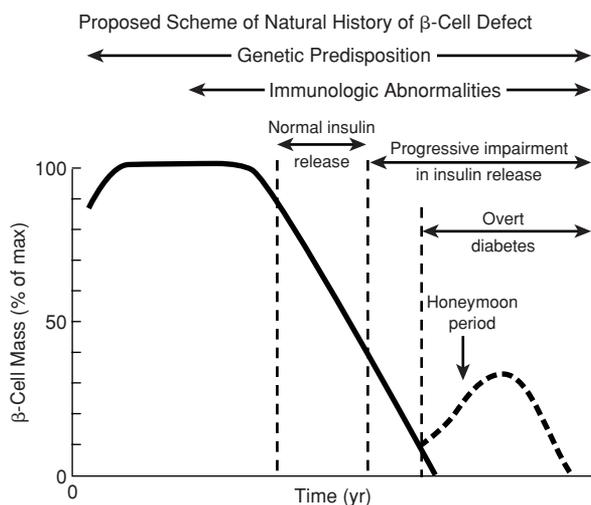

As blood glucose concentrations drop toward normal during the fasting state, insulin release is inhibited. Simultaneously, a number of counter-regulatory hormones that oppose the effect of insulin and promote an increase in blood sugar are released (e.g., glucagon, epinephrine, growth hormone, glucocorticoids). As a result, several processes maintain a minimum blood glucose concentration for the central nervous system. Glycogen in the liver is broken down into glucose (glycogenolysis). Amino acids are transported from muscle to liver, where they are converted to glucose through gluconeogenesis. Uptake of glucose by insulin-dependent tissues is diminished to conserve glucose for the brain. Finally, triglycerides are broken down into free fatty acids, which are used as alternative fuel sources.

Type 1 Diabetes

Pathogenesis¹¹

The loss of insulin secretion in type 1 diabetes mellitus results from autoimmune destruction of the insulin-producing β -cells in the pancreas, which is thought to be triggered by environmental factors, such as viruses or toxins, in genetically susceptible individuals.¹¹ This form of diabetes is associated closely with histocompatibility antigens (human leukocyte antigen [HLA]-DR3 or HLA-DR4) and the presence of circulating insulin antibodies, including insulin antibody, glutamic acid decarboxylase antibody, islet cell antibody (ICA), and islet cell antibody 512 (a tyrosine phosphatase antibody). The capacity of normal pancreatic β -cells to secrete insulin far exceeds the normal amounts needed to control carbohydrate, fat, and protein metabolism. As a result, the clinical onset of type 1 diabetes is preceded by an extensive asymptomatic period during which β -cells are destroyed (Fig. 50-1). β -Cell destruction may occur rapidly, but is more likely to take place over a period of weeks, months, or even years. The earliest detectable abnormality in insulin secretion is a progressive reduction of immediate or *first-phase* plasma insulin response. However, this initial impairment has few detrimental effects on overall glucose homeostasis, and plasma glucose concentrations remain normal. Most affected individuals have circulating antibodies to islet cells or to their own insulin at this stage of the disease. These represent markers of an ongoing autoimmune process that culminates in type 1 diabetes. Fasting hyperglycemia occurs when the β -cell mass is reduced by 80% to 90%. Initially, only postprandial hyperglycemia occurs, but as insulin secretion becomes further compromised, progressive fasting hyperglycemia is seen.

On presentation, approximately 65% to 85% of patients have circulating antibodies directed against islet cells and 20%

Timing of trigger in relation to immunologic abnormalities is unknown. Note that overt diabetes is not apparent until insulin secretory reserves are <10–20% of normal.

FIGURE 50-1 Pathogenesis of type 1 diabetes. In an individual with a genetic predisposition, an event (such as a virus or toxin) triggers autoimmune destruction of the pancreatic β -cells, probably over a period of several years. When the number of β -cells diminishes to approximately 250,000, the pancreas is unable to secrete sufficient insulin and intolerance to glucose ensues. At this point, a stressful event, such as a viral infection, can produce acute symptoms of hyperglycemia and ketoacidosis. Once the acute event has passed, the pancreas temporarily recovers, leading to a remission (honeymoon period). Continued destruction of the β -cell ultimately leads to an insulin-dependent state.

to 60% of patients have measurable antibodies directed against insulin. Within 8 to 10 years of clinical presentation, β -cell loss is complete and insulin deficiency is absolute.

Clinical Presentation

Although the onset of type 1 diabetes seems to be abrupt, evidence now exists for an extended *preclinical period* that can precede obvious symptoms by several years. As insulin secretion becomes compromised, progressive fasting hyperglycemia occurs. When plasma glucose concentrations exceed the normal renal threshold of approximately 180 mg/dL (10 mmol/L), glucosuria results in an osmotic diuresis, producing the classic symptoms of polyuria with compensatory polydipsia. If symptoms are untreated, weight loss occurs as glucose calories are lost in the urine and body fat and protein stores are broken down owing to increased rates of lipolysis and proteolysis. Muscle begins to metabolize its own glycogen stores and fatty acids for fuel, and the liver begins to metabolize free fatty acids that are released in response to epinephrine and low insulin concentrations. An absolute lack of insulin may cause excessive mobilization of free fatty acids to the liver, where they are metabolized to ketones. This can result in ketonemia, ketonuria, and, ultimately, ketoacidosis. Patients present with complaints of fatigue, significant weight loss, polyuria, and polydipsia. A significant elevation in glycosylated hemoglobin confirms weeks or months of preceding hyperglycemia.

Because glucose provides an excellent medium for microorganisms, patients may present also with recurrent respiratory, vaginal, and other infections. Patients also may experience blurred vision secondary to osmotically induced changes

in the lens of the eye. Treatment with insulin is essential to prevent severe dehydration, ketoacidosis, and death.

Honeymoon Period

Within days or weeks after the initial diagnosis, many patients with type 1 diabetes experience an apparent remission, which is reflected by decreased blood glucose concentrations and markedly decreased insulin requirements. This is called the *honeymoon period* because it may last for only a few weeks to months. Once hyperglycemia, metabolic acidosis, and ketosis resolve, endogenous insulin secretion recovers temporarily (Fig. 50-1). Although the honeymoon period may last for up to a year, increasing exogenous insulin requirements are inevitable and should be anticipated. During this time, patients should be maintained on insulin even if the dose is very low, because interrupted treatment is associated with a greater incidence of resistance and allergy to insulin (see Question 26).

Type 2 Diabetes

Pathogenesis

Type 2 diabetes is characterized by impaired insulin secretion and resistance to insulin action. In the presence of insulin resistance, glucose utilization by tissues is impaired, hepatic glucose production is increased, and excess glucose accumulates in the circulation. This hyperglycemia stimulates the pancreas to produce more insulin in an attempt to overcome insulin resistance. The simultaneous elevation of both glucose and insulin levels is strongly suggestive of insulin resistance. Genetic predisposition may play a role in the development of type 2 diabetes. People with type 2 diabetes have a stronger family history of diabetes than those with type 1. There is no association with HLA types, however, and circulating ICAs are absent.^{4,12} People with type 2 diabetes also exhibit varying degrees of tissue resistance to insulin, impaired insulin secretion, and increased basal hepatic glucose production. Finally, environmental factors such as obesity and a sedentary lifestyle also contribute to the development of insulin resistance.

Despite being the most common form of diabetes, the exact pathogenesis of type 2 is the least understood. Basal insulin levels are typically normal or elevated at diagnosis. First- or early-phase insulin release in response to glucose often is reduced and pulsatile insulin secretion is absent, resulting in postprandial hyperglycemia. The effects of other insulinotropic substances such as incretin hormones, which contribute to meal-stimulated insulin release, are also altered.¹³ Over time, β -cells lose their ability to respond to elevated glucose concentrations, leading to increasing loss of glucose control. In patients with severe hyperglycemia, the amount of insulin secreted in response to glucose is diminished and insulin resistance is worsened (glucose toxicity).

Most individuals with type 2 exhibit decreased tissue responsiveness to insulin.¹² Overeating and/or hyperglycemia may contribute to hyperinsulinemia, which over time may lead to a decrease in or downregulation of the number of insulin receptors on the surface of target tissues and organs. Evidence suggests that decreased peripheral glucose uptake and utilization in muscle is the primary site of insulin resistance and results in prolonged postprandial hyperglycemia. Resistance may be secondary to decreased numbers of insulin receptors

on the cell surface, decreased affinity of receptors for insulin, or defects in insulin signaling and action that follows receptor binding. Defects in insulin signaling and action are referred to as *postreceptor* or *postbinding* defects and are likely to be the primary sites of insulin resistance.

Patients with type 2 diabetes also exhibit increased hepatic glucose production (glycogenolysis and gluconeogenesis) reflected by an elevated fasting plasma or blood glucose concentration.¹² As noted, hepatic glucose production is the primary source of glucose in the fasting state. In patients with type 2 diabetes, altered hepatic glucose production may also contribute to or cause postprandial hyperglycemia. Glucagon, produced by the α -cells in the pancreatic islets and secreted in response to low blood glucose, stimulates hepatic glucose production.¹⁴ Its production is inhibited by insulin. Glucagon response to carbohydrate ingestion is altered in patients with type 2 diabetes who have a defective or absent early insulin response secondary to β -cell dysfunction or failure. For patients with type 2 diabetes, untreated fasting and postprandial hyperglycemia caused by decreased glucose uptake and increased hepatic glucose production, hyperinsulinemia and insulin resistance, lead to a vicious cycle that inflicts ongoing damage to tissues and organs.

Patients with type 2 diabetes are often subclassified based on weight. Obese individuals account for over 80% of patients with type 2 diabetes.¹² Patients with type 2 diabetes who are not obese often have increased body fat distributed primarily in the abdominal area. Nonobese individuals account for about 10% of the type 2 population. Typically, they develop a mild form of diabetes during childhood, adolescence, or as young adults (usually before age 25), and their insulin levels are low in response to a glucose challenge. Included in this group are patients who have maturity-onset diabetes of the young (MODY).^{4,12} MODY is associated with a strong family history that suggests an autosomal-dominant transmission. The underlying defect is heterogeneous and to date, abnormalities at 6 different loci on different chromosomes have been discovered. More common defects include those for hepatic transcription factors and glucokinase (the “glucose sensor” in β -cells). Patients with MODY may present with moderate to severe symptoms with or without ketosis. Unlike type 1 diabetes, however, the disease generally is mild and controlled easily with diet, oral agents, or low doses of insulin (<40 units).

Type 2 diabetes is associated with a variety of disorders, including hyperlipidemia, hypertension, and atherosclerosis (Fig. 50-2). Dr Gerald Reaven, who referred to this association as syndrome X, insulin resistance syndrome, or metabolic syndrome, proposed that either the insulin resistance itself, or the compensatory hyperinsulinemia resulting from insulin resistance, may be the fundamental underlying pathophysiological process responsible for the frequent occurrence of these conditions in the same patient.¹⁵ The concept of a single defect explaining this cluster of disorders, however, remains the subject of considerable debate and research activity. Metabolic syndrome is common in the United States, with an estimated prevalence of more than 20% in adults older than 20 years and more than 40% among adults 60 to 69 years of age.¹⁶ Because it is highly correlated with cardiovascular events, the National Cholesterol Education Program has suggested criteria for the diagnosis and treatment of metabolic syndrome to prevent car-

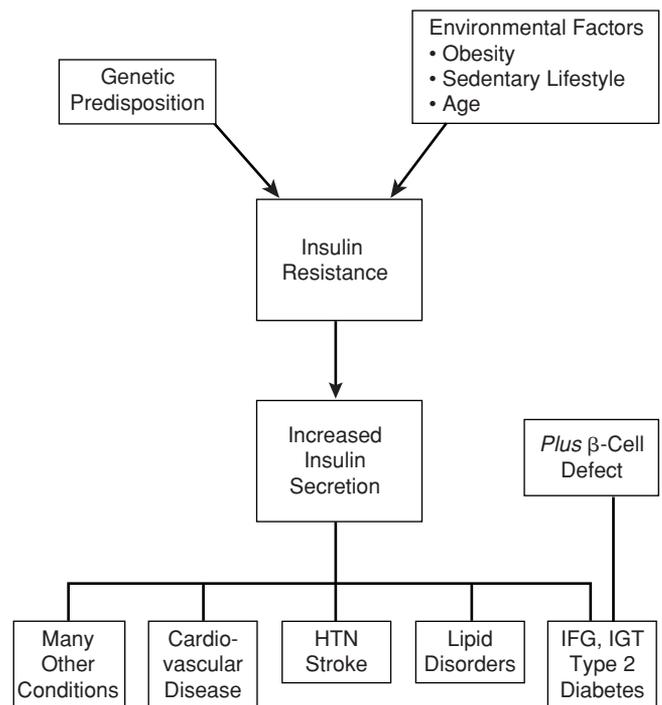

FIGURE 50-2 Metabolic syndrome (insulin resistance syndrome, syndrome X). Genetic and environmental factors (visceral obesity, sedentary lifestyle, aging) predispose some individuals to insulin resistance. To overcome the resistance, the pancreas secretes more insulin, leading to hyperinsulinemia. People with insulin resistance and hyperinsulinemia commonly develop a cluster of medical problems and biochemical abnormalities: cardiovascular disease, hypertension, dyslipidemia, hyperuricemia, and type 2 diabetes mellitus. Only those individuals who are further genetically predisposed to β -cell failure go on to develop IGT and diabetes mellitus. Many people with type 2 diabetes already have evidence of cardiovascular disease at the time of diabetes diagnosis. The cause-and-effect relationships between insulin resistance and/or hyperinsulinemia and these clinical conditions has not been clarified. See text for expanded discussion. DM, diabetes mellitus; HTN, hypertension; IFG, impaired fasting glucose; IGT, impaired glucose tolerance.

diovascular events and diabetes.¹⁷ Not all individuals with the metabolic syndrome progress to IGT or diabetes, but those who do may be genetically predisposed to β -cell dysfunction.

Clinical Presentation

Type 2 diabetes is typically diagnosed incidentally during a routine physical examination or when the patient seeks attention for another complaint. This is because symptoms are so mild and their onset so gradual that they can easily be “explained away.” When giving a history of their illness, people with type 2 diabetes acknowledge fatigue, polyuria, and polydipsia. Because these patients have sufficient insulin concentrations to prevent lipolysis, there is usually no history of ketosis except in situations of unusual stress (e.g., infections, trauma). Weight loss is therefore uncommon because relatively high endogenous insulin levels promote lipogenesis. Macrovascular disease is also often evident at diagnosis. Microvascular complications at diagnosis suggest the presence of undiagnosed or subclinical diabetes for 7 to 10 years. Because type 2 diabetes patients retain some pancreatic reserve at the time of diagnosis, they generally can be treated with medical

Table 50-2 Normal and Diabetic Plasma^a Glucose Levels in mg/dL (mmol/L) and Normal and Diabetic Plasma Glucose Levels for the Oral Glucose Tolerance Test^{4,19}

| | Fasting | ½, 1, 1½ hr | 2 hr |
|------------------------------|-------------------|-------------|--------------------|
| Normal | <100 (5.6) | <200 (11.1) | <140 (7.8) |
| Impaired glucose tolerance | <126 (7.0) | ≥200 (11.1) | 140–200 (7.8–11.1) |
| Impaired fasting glucose | 100–125 (5.6–6.9) | | |
| Diabetes (nonpregnant adult) | ≥126 (7.0) | ≥200 (11.1) | ≥200 (11.1) |

^aEquivalent *venous whole blood* glucose concentrations are approximately 12%–15% lower. *Arterial* samples are higher than venous samples postprandially because glucose has not yet been removed from peripheral tissues. *Capillary whole blood* samples contain a mixture of arterial and venous blood. Fasting levels are equivalent to whole blood venous samples. One hour after a 100-g glucose load, capillary samples may be 30–40 mg/dL higher than venous samples.

nutrition therapy (MNT), physical activity, and oral antidiabetic medications for several years. Nevertheless, many eventually require insulin for control of their symptoms.

Gestational Diabetes Mellitus

GDM affects about 7% of all pregnancies and is defined as “any carbohydrate intolerance with onset or first recognition during pregnancy.”^{4,18} The onset of diabetes during pregnancy and its duration affect the prognosis for a good obstetric and perinatal outcome (see Chapter 46).

Diagnosis

Diagnostic Criteria

The normal fasting plasma glucose (FPG) values and those for diabetes mellitus, along with the glucose values for the oral glucose tolerance test (OGTT) are listed in Table 50-2.^{4,19} The Expert Committee of the ADA has established the diagnostic criteria for diabetes for nonpregnant individuals of any age. For these individuals, a diagnosis of diabetes can be made when one of the following is present⁴:

1. Classic signs and symptoms of diabetes (polyuria, polydipsia, ketonuria, and unexplained weight loss) combined with a random plasma glucose ≥ 200 mg/dL (11.1 mmol/L).
2. A FPG ≥ 126 mg/dL (7.0 mmol/L). *Fasting* means no caloric intake for at least 8 hours.
3. After a standard oral glucose challenge (75 g glucose for an adult or 1.75 g/kg for a child), the venous plasma glucose concentration is ≥ 200 mg/dL (11.0 mmol/L) at 2 hours and >200 mg/dL (11.0 mmol/L) at least one other time during the test (0.5, 1, 1.5 hours); this is the OGTT.

The diagnosis must be confirmed on a subsequent day by any one of these conditions in the absence of unequivocal hyperglycemia with acute metabolic complications.

At times, it may be difficult to classify patients as having type 1 or type 2 diabetes mellitus. Type 1 is more likely when a patient is younger than 30 years of age, lean, has an elevated FPG and signs and symptoms of diabetes. The presence of moderate ketonuria with hyperglycemia in an otherwise unstressed patient also strongly supports a diagnosis of type 1 diabetes. Absence of ketonuria, however, is not of diagnostic value. The presence of antibodies to islet cell components may also indicate the need for eventual insulin therapy.¹¹ Relatively lean older adults believed to have type 2 diabetes because they are initially responsive to oral agents or low doses of insulin

may be subsequently diagnosed with type 1 diabetes. In addition, clinicians are beginning to observe more cases of type 2 diabetes in obese children and adolescents.²⁰

Individuals with FPG values or OGTT values that are intermediate between normal and those considered diagnostic of diabetes are considered to have “prediabetes” or IFG or IGT. These individuals are not given the diagnosis of diabetes because of broad social, psychological, and economic implications. The categories of FPG values are as follows:

1. A normal FPG is <100 mg/dL (5.6 mmol/L).
2. An FPG of 100 to 125 mg/dL (5.6–6.9 mmol/L) is IFG.
3. An FPG ≥ 126 mg/dL (7.0 mmol/L) indicates a *provisional* diagnosis of diabetes that must be confirmed, as described.

The corresponding categories when the OGTT is used for diagnosis are as follows:

1. A 2-hour postload glucose (2-hPG) <140 mg/dL (7.8 mmol/L) indicates normal glucose tolerance.
2. A 2-hPG ≥ 140 mg/dL (7.8 mmol/L) and <200 mg/dL (11.1 mmol/L) indicates IGT.
3. A 2-hPG ≥ 200 mg/dL (11.1 mmol/L) indicates a *provisional* diagnosis of diabetes, which must be confirmed by a second test.

Many factors can impair glucose tolerance or increase plasma glucose. These must be excluded before a definitive diagnosis is made. For example, an individual who has not fasted for a minimum of 8 hours may have an elevated FPG, and one who has fasted too long (>16 hours) or has ingested insufficient carbohydrates before testing may have an IGT. Patients who are tested for glucose tolerance during, or soon after, an acute illness (e.g., a myocardial infarction [MI]) may be misdiagnosed because of the presence of high concentrations of counter-regulatory hormones that increase glucose concentrations. Glucose tolerance often returns to normal in these individuals. Pregnancy, many forms of stress, and lack of physical activity can similarly affect glucose tolerance. Many drugs may alter glucose tolerance due to their effects on insulin release and tissue response to insulin, and their direct cytotoxic effects on the pancreas. Drugs and other chemicals also may falsely elevate the plasma glucose concentrations through interference with specific analytic methods.

Screening for Type 2 Diabetes

The ADA advises against routine screening for type 2 diabetes outside of the health care setting because of the low likelihood

Table 50-3 Risk Factors for Type 2 Diabetes Mellitus²²

| Adults | Children ^a |
|--|---|
| Overweight (≥ 25 kg/m ²) | Overweight (BMI >85th percentile for age and sex; or weight >120% of ideal for height) |
| Family history of diabetes (first-degree relative) | Family history of diabetes (first- or second-degree relative) |
| Physical inactivity | Ethnic predisposition ^b |
| Ethnic predisposition ^b | |
| Previous IFG or IGT | |
| History of PCOS, GDM, or macrosomia | Maternal history of diabetes (including GDM) |
| Clinical conditions associated with insulin resistance (e.g., severe obesity and acanthosis nigricans) | Signs of insulin resistance (e.g., acanthosis nigricans) |
| Hypertension ($\geq 140/90$ mmHg or on antihypertensive therapy) | Conditions associated with insulin resistance (e.g., hypertension, dyslipidemia, or PCOS) |
| Dyslipidemia | |
| HDL-C <35 mg/dL (0.90 mmol/L) | |
| Triglyceride >250 mg/dL (2.82 mmol/L) | |
| Cardiovascular disease | |

^aChildren = <18 years of age.
^bEthnic predisposition = individuals of African American, Hispanic or Latino, Native American, Asian, or Pacific Islander descent.
 IFG, impaired fasting glucose; IGT, impaired glucose tolerance; PCOS, polycystic ovarian syndrome; GDM, gestational diabetes mellitus.

of follow-up care and testing in the case of both negative and positive results.²¹ The FPG is the preferred over the OGTT as a screening test based on cost and convenience. Adults should be screened starting at age 45.²² Repeat testing should take place every 3 years. Adults may be tested at a younger age and more frequently if they are overweight (body mass index [BMI] ≥ 25 kg/m²) and have one or more of the risk factors listed in Table 50-3. Asymptomatic children who are age 10 or who experience the onset of puberty before age 10 should be screened every 2 years for type 2 diabetes if they are overweight (BMI >85th percentile for age and sex; weight for height >85th percentile; or weight >120% of ideal for height) and have two or more of the risk factors listed in Table 50-3.

Long-Term Complications and Their Relation to Glucose Control

The long-term sequelae of diabetes account for most of the morbidity and mortality in the diabetic population. Complications are typically designated as microvascular or macrovascular in nature. Glucose toxicity seems to contribute most to the development and progression of microvascular complications (retinopathy, nephropathy, and neuropathy).²³ Diabetes is the leading cause of new cases of adult blindness and kidney failure in the United States.¹ About 70% of people with diabetes also have some manifestation of peripheral and/or autonomic neuropathy. Severe peripheral neuropathy coupled with abnormalities in immune function likely contribute to the high rate of lower extremity amputations among patients with diabetes.^{1,24}

Finally, poor glucose control promotes development of dental and oral complications and increases the risk of complications during pregnancy for both mother and fetus.^{25,26}

Diabetes mellitus itself is also one of many risk factors for macrovascular disease (peripheral vascular disease, cardiovascular disease [CVD], stroke). These risk factors tend to cluster in people prone to type 2 diabetes. Epidemiologic studies also show, however, a general relationship between degree of glucose control and risk for cardiovascular events.²⁷ In addition, patients with diabetes demonstrate rheological changes, such as platelet hypersensitivity to platelet aggregants and elevated thromboxane production, which may contribute to peripheral and cardiovascular complications.²⁸ Thus, the primary goal for both type 1 and type 2 diabetic individuals is to bring glucose concentrations as close to normal values as is safely possible.

Results of the Diabetes Complications and Control Trial (DCCT) definitively established that intensive treatment of type 1 diabetes can prevent or slow the onset of long-term microvascular complications.²⁹ In this landmark study, intensive treatment reduced the risk of clinically meaningful retinopathy, nephropathy, and neuropathy by approximately 60%. The Epidemiology of Diabetes Interventions and Complications (EDIC) study has followed DCCT cohorts. Patients originally assigned to the intensive treatment group, have enjoyed a persistently lower incidence of microvascular complications even though their glucose control has since been equivalent to the conventional group.^{30,31} The EDIC study has also shown a significant reduction in cardiovascular complications among patients previously assigned to the intensive therapy DCCT arm.³² See Table 50-4 for the glycemic goals of intensive insulin therapy (referred to by these authors as physiological or basal-bolus therapy).

The United Kingdom Prospective Diabetes Study (UKPDS) was the first to report the effect of tight blood glucose control on the microvascular and cardiovascular complications associated with type 2 diabetes.³³ Epidemiologic analysis of the data from this landmark study demonstrated a continuous relationship between glycemia and the risks of microvascular complications. For every percentage point reduction in hemoglobin A_{1c} (HbA_{1c}), there was a 35% reduction in the risk of complications. Whether intensive therapy designed to attain sustained normoglycemia decreased the risk of macrovascular disease was less clear. Although a 21% reduction in the risk of combined fatal and nonfatal MI and sudden death was seen, this combined outcome failed to reach statistical significance ($p = .52$).

Other studies support the use of a more comprehensive approach to preventing microvascular and macrovascular complications in patients with type 2 diabetes. In a UKPDS group substudy, tight blood pressure control (<130/85 mmHg) reduced the risk of stroke by 44% ($p = .013$) and microvascular endpoints by 37% ($p = .0092$).³³ The Steno group found that multifactorial intensive treatment of patients with type 2 diabetes and microalbuminuria for a mean of 7.8 years reduced the risk of microvascular complications and cardiovascular events by 50% compared with conventional treatment. Their interventions included lifestyle education and aggressive use of drugs to lower HbA_{1c}, and blood pressure (BP), and achieve a normal lipid profile.³⁴ See Table 50-5 for the metabolic goals for adults with diabetes.

Table 50-4 Goals of Physiological (Basal-Bolus) Insulin Therapy^a

| Monitoring Parameter | Adults (mg/dL) | School Age (6–12 years) (mg/dL) | Adolescents and Young Adults (13–29 years) (mg/dL) | Pregnancy (mg/dL) |
|----------------------------------|--------------------|---------------------------------|--|-------------------|
| Fasting plasma glucose | 70–130 | 90–180 | 90–130 | 60–90 |
| 2 hr postprandial plasma glucose | <180 | Not routinely recommended | Not routinely recommended | ≤120 |
| 2–4 am plasma glucose | >70 | 100–180 | 90–150 | >60 |
| HbA _{1c} ^b | <7.0% ^c | <8.0% | <7.5% ^d | 5–6% |
| Urine ketones ^e | Absent to rare | Absent to rare | Absent to rare | Rare |

^aModified and extrapolated from references 22, 29, and 344. See Questions 4 and 22 for discussion. Physiological insulin therapy is a complete therapeutic program of diabetes management and requires a team approach.

^bHbA_{1c}, glycosolated hemoglobin. Normal values vary; normalize to laboratory.

^cAcceptable values should be individualized to levels that are attainable without creating undue risk for hypoglycemia. These results are similar to the results achieved in the DCCT trial. ADA recommends HbA_{1c} goal within 1% or upper limit of normal and consideration for <6% as an individual goal. These values may be inappropriate for patients with hypoglycemic unawareness, counter-regulatory insufficiency, angina pectoris, or other complicating features (Table 50-12).

^dA lower goal (<7%) is reasonable if can be achieved without creating excessive risk for hypoglycemia.

^eDoes not apply to type 2 diabetes patients.

Early in 2008, researchers announced that the glucose-lowering arm of the Action to Control Cardiovascular Risk in Diabetes (ACCORD) trial was stopped prematurely because of a higher rate of mortality in the intensive treatment arm. The ACCORD study is a National Heart, Lung and Blood Institute study of approximately 10,000 patients with type 2 diabetes with known heart disease or two cardiovascular risk factors. Patients had an average duration of diabetes of 10 years, average age of 62 years, and baseline HbA_{1c} of 8.2%. In the glycemic control portion of the trial, researchers were testing whether intensive glucose control (goal HbA_{1c} <6%) reduced the rate of cardiovascular events compared with less intensive glucose control (goal HbA_{1c} 7.0%–7.9%). At the time the trial was stopped, the median HbA_{1c} in the intensive and standard treatment groups were 6.4% and 7.5%, respectively. The intensive arm had an excess of three deaths per 1,000 participants per year compared with the standard group over

an average of 4 years on treatment (257 vs. 203 deaths). The higher mortality rate could not be attributed to a specific drug therapy or hypoglycemia.³⁵ Approximately 1 week later, preliminary results from a very similar study, the ADVANCE trial, were released demonstrating no increases in mortality risk in intensively treated patients with type 2 diabetes. ADVANCE, an international study, enrolled over 11,000 patients with type 2 diabetes, (about one-third with known CVD) average age of 66 years, and average duration of diabetes of 10 years. The intensive-therapy group's HbA_{1c} goal was 6.5% or below. The same as the intensive arm in ACCORD. The actual average HbA_{1c} achieved was 6.4%. In the face of these new data, the ADA continues to recommend an HbA_{1c} goal of less than 7% for most people with diabetes. The ADA recommends that patients with type 2 diabetes and CVD or multiple risk factors for CVD discuss their treatment goals with their providers.³⁶

Table 50-5 American Diabetes Association Goals for Adults With Diabetes Mellitus^{22,58}

| | |
|-------------------------------|--|
| Glycemic goals | |
| • HbA _{1c} | <7.0% (normal, 4–6%) ^a |
| • Preprandial plasma glucose | 70–130 mg/dL (3.9–7.2 mmol/L) ^b |
| • Postprandial plasma glucose | <180 mg/dL (<10.0 mmol/L) ^c |
| Blood pressure | <130/80 mmHg |
| Lipids | |
| • Low-density lipoproteins | <100 mg/dL (<2.6 mmol/L) ^d |
| • Triglycerides | <150 mg/dL (<1.7 mmol/L) |
| • High-density lipoproteins | |
| – Men | >40 mg/dL (>1.0 mmol/L) |
| – Women | >50 mg/dL (>1.3 mmol/L) |

Goals must be individualized to the patient. See Questions 4, 45, 73, 76, and 77 for broader discussion.

^aMore stringent goals (i.e., <6%) can be considered for select individuals. American Association of Clinical Endocrinologists/American College of Endocrinology recommends HbA_{1c} goal ≤6.5%.

^bAmerican Association of Clinical Endocrinologists recommends a fasting blood glucose goal of <110 mg/dL (6.1 mmol/L).

^cAmerican Association of Clinical Endocrinologists/American College of Endocrinology recommends goal <140 mg/dL (7.8 mmol/L).

^dMore stringent goals (i.e., <70 mg/dL [1.8 mmol/L]) may be considered for individuals with overt cardiovascular disease.

Prevention of Type 1 and Type 2 Diabetes Mellitus

Because the clinical symptoms of type 1 diabetes mellitus are the overt expression of an insidious pathogenic process that begins years earlier, investigators are focusing attention on strategies that alter the natural history of the disease (Fig. 50-1). First-degree relatives of individuals with type 1 diabetes mellitus have an increased risk for developing the diabetes and can be identified by the presence of immune markers that may herald the disease by many years.¹¹ This has led to attempts at immune intervention at the prediabetes stage with such drugs as nicotinamide and low doses of insulin, but neither was found to delay or prevent diabetes.^{37–39} In contrast, treatment of newly diagnosed diabetes with agents that modify cytotoxic T cells may slow pancreatic destruction and progression of diabetes.⁴⁰

In addition to the 20.8 million people with diabetes in the United States, an estimated additional 41 million Americans have prediabetes (IGT or IFG).¹ The annual risk of progression to type 2 diabetes mellitus in persons with IGT is 1% to 5%.⁴¹ Persons at risk for IGT and who are eligible for further screening include those who are overweight and/or lead a sedentary lifestyle, have a family history of diabetes, are a member of a high-risk ethnic population (e.g., African American, Hispanic/Latino, Native American, Asian American,

Pacific Islander), have a history of gestational diabetes or who have delivered a baby weighing more than 9 lb, and have with a medical history of a high blood glucose test without a diagnosis of diabetes.⁴²

The Diabetes Prevention Program Research Group studied a diverse group of individuals at high risk for developing diabetes to determine if lifestyle interventions or metformin (850 mg PO BID) would prevent or delay the onset of type 2 diabetes.⁴³ Results of the study found that relative to the placebo group, the incidence of diabetes was reduced by 58% and 31% in the intensive lifestyle and metformin groups, respectively. A repeat OGTT was performed in the metformin group who had not developed diabetes 1 to 2 weeks after the drug had been discontinued to determine whether the drug simply masked diabetes through its antihyperglycemic effects. The incidence of diabetes was still reduced by 25% relative to the placebo group.⁴⁴ Other studies have confirmed the value of lifestyle intervention and other drugs (acarbose, troglitazone, orlistat, and rosiglitazone) in the prevention of type 2 diabetes.^{42,45} Lifelong medication therapy, however, is not without its own risks and complications. Current recommendations regarding the treatment for individuals with IFG, IGT, or both include lifestyle modification (5%–10% weight loss and 30 minutes of moderately intense physical activity per day).²² For patients at very high risk of diabetes (age <60, BMI \geq 35 km/m², combined IFG and IGT, and at least one risk factor), the addition of metformin may be considered. Until further evidence becomes available to support their use in the delay or prevention of complications of diabetes and/or cost effectiveness has been established, the use of other pharmacologic agents to prevent the development of type 2 diabetes is not recommended.⁴⁶

1. R.P. is a 43-year-old woman visiting the drop-in clinic to obtain a routine physical examination for her new job. Her past medical history is significant for GDM. She was told during her two pregnancies (last child born 3 years ago) that she had “borderline diabetes,” which resolved each time after giving birth. Her family history is significant for type 2 diabetes (mother, maternal grandmother, older first cousin), hypertension, and CVD. She appears black and when asked identifies herself as African American. She denies tobacco or alcohol use. She states she tries to walk 15 minutes twice a week. Physical examination is significant for moderate central obesity (5 feet 4 inches; 160 lbs; BMI, 30.2 kg/m²) and BP 145/85 mmHg. R.P. denies any symptoms of polyphagia, polyuria, or lethargy. Upon checking her electronic medical record, she has documented hypertension and an FPG value of 119 mg/dL, measured 2 months prior. What features of R.P.’s history and examination are consistent with an increased risk of developing type 2 diabetes?

The features of R.P.’s history that are consistent with an increased risk of developing type 2 diabetes include her age, ethnicity, weight, family history of diabetes, history of GDM, and a documented IFG. In addition, type 2 diabetes is also often associated with other disorders such as hypertension. The fact that R.P. has hypertension that is not well controlled and has a family history of hypertension and CVD may indicate that she is predisposed to insulin resistance, further putting her at risk for developing type 2 diabetes.

2. The physician orders another FPG for R.P., which comes back at 122 mg/dL. How should R.P. be managed at this time?

R.P. should be educated about her risk for developing type 2 diabetes. Working with her physician and/or other health care providers, R.P. should be encouraged and educated on how to institute lifestyle modifications (MNT, physical activity) that will help her to lose weight, improve her cardiovascular health, and decrease her risk for developing type 2 diabetes. A weight loss goal of 5% to 10% should be recommended and she should increase her level of moderate physical activity to at least 150 minutes/week. Her hypertension should be managed. At this time, the use of pharmacologic agents (i.e., metformin) to prevent the development of type 2 diabetes is not recommended.

Treatment

There are three major components to the treatment of diabetes: diet, drugs (insulin and oral hypoglycemic agents, and other antihyperglycemic agents), and exercise. Each of these components interacts with the others to the extent that no assessment and modification of one can be made without knowledge of the other two. Target blood glucose values for pregnant diabetics are very strict.

Medical Nutrition Therapy^{A7}

PRINCIPLES

MNT plays a crucial role in the therapy of all individuals with diabetes. Unfortunately, patient acceptance and adherence to diet and meal planning is often poor, but revised evidence-based recommendations that are more flexible than previous approaches offer new opportunities to increase the effectiveness of nutrition therapy.

Nutrition therapy is designed to help patients achieve appropriate metabolic and physiological goals (e.g., glucose, lipids, BP, proteinuria, weight), select healthy foods, and to take into consideration personal and cultural preferences. Appropriate levels and types of physical activity to achieve a healthier status are incorporated into the nutrition plan.

NUTRITION THERAPY AND TYPE 1 DIABETES MELLITUS

For patients with type 1 diabetes taking fixed doses of insulin, a meal plan is designed to provide adequate carbohydrates timed to match the peak action of exogenously administered mealtime insulin. Regularly scheduled meals and snacks should contain consistent carbohydrate amounts, which are required to prevent hypoglycemic reactions. Fortunately, newer insulins and insulin regimens provide much more flexibility in the amount and timing of food intake. Patients who are taught to “count carbohydrates” can inject rapid- or short-acting insulin doses designed to match their anticipated intake. Integration of food intake, physical activity, and insulin dose is critical and discussed extensively in the cases that follow.

NUTRITION THERAPY AND TYPE 2 DIABETES MELLITUS

For patients with type 2 diabetes, meal plans emphasize normalizing plasma glucose and lipid levels as well as maintaining a normal BP to prevent or mitigate cardiovascular morbidity. Although weight loss reduces insulin resistance and improves glycemic control, traditional dietary strategies incorporating hypocaloric diets have not been effective in achieving long-term weight loss. A sustainable weight loss of 5% to 7% can be achieved within structured programs that emphasize lifestyle changes, physical activity, and food intake that

modestly reduces caloric and fat intake. For weight loss, the ADA recently updated their recommendation on types of diets to include either low-carbohydrate (new recommendation in 2008) or low-fat, calorie-restricted diets for up to 1 year.⁴⁷

SPECIFIC NUTRITION COMPONENTS

MNT is an integral and critical component of diabetes care. For a more extensive discussion of the principles underlying nutrition therapy, the reader is directed to other sources.^{47,48} A few key principles are briefly noted below because they are common sources of misunderstanding.

Carbohydrates and Artificial Sweeteners

Carbohydrates include sugar, starch, and fiber and they are liberally incorporated into the diet of a person with diabetes. In fact, the amount of dietary carbohydrate is the main determinant of insulin demand and is commonly used to determine the premeal insulin dose. Furthermore, patients using fixed doses of insulin or antihyperglycemic medications (e.g., sulfonylureas) must eat meals containing consistent amounts of carbohydrate to avoid hypoglycemia. Avoiding “sugar” or *sucrose* does not prevent “sugar diabetes.” Because isocaloric amounts of sucrose and starch produce the same degree glycemia, sucrose can be substituted for a portion of the total carbohydrate intake and should be incorporated into an otherwise healthful diet.

Whole grains, fruits, and vegetables high in *fiber* are recommended for people with diabetes, as they are for the general population. There is no evidence that larger amounts produce a differential metabolic benefit with regard to plasma glucose and lipid levels. *Non-nutritive sweeteners* (saccharin, aspartame, neotame, acesulfame potassium, sucralose) and sugar alcohols have been rigorously tested by the FDA for safety in people with diabetes and are safe at approved daily intakes. Fructose and the reduced calorie sweeteners called *sugar alcohols* produce lower postprandial glucose responses than sucrose, glucose, and starch. When sugar alcohols (e.g., sorbitol, mannitol, lactitol, xylitol, and maltitol) are consumed, it is recommended to subtract half of their grams from the total carbohydrate amount, because their effect on blood glucose is less. Patients should be advised that when these sweeteners are used in foods labeled “dietetic” or “sugar free,” they still add to the carbohydrate content and provide substantial calories (2 cal/g). Furthermore, excessive intake of sorbitol-sweetened foods (e.g., 30–50 g/day) can induce an osmotic diarrhea, and excessive amounts of fructose can increase total and LDL cholesterol.

Counting Carbohydrates

When patients are taught to estimate the grams of carbohydrate in a meal they are given the following guideline: One carbohydrate serving = 1 starch or 1 fruit or 1 milk = 15 g carbohydrate. Patients vary with regard to their insulin: carbohydrate ratio throughout time and throughout the day; however, a typical starting point is 1 unit/15 g carbohydrate. Examples of one carbohydrate serving include 1 slice bread, 1/4 bagel, 1/2 English muffin or hamburger bun, 3/4 c dry cereal, 1/2 c cooked cereal, 1/2 c legumes, 1/3 c *cooked* pasta or rice, 1/4 large baked potato, 4 c popcorn, 1 small fruit, 1/2 c fruit juice, 1 c milk, 1/2 c ice cream, and 2 small cookies.

Fat

CVD is a major cause of morbidity and mortality in patients with diabetes. Therefore, a reduced fat diet (<30% of the total calories) with <7% of calories from saturated fats is recommended. The intake of *trans* fat should be minimized. The recommended cholesterol intake is <200 mg/day for patients with diabetes. Two servings per week of fish to provide *n-3* polyunsaturated fatty acids and omega-3 fatty acids is advised.

Protein

Data are insufficient to support special dietary protein recommendations for persons with diabetes if kidney function is normal. Generally, 15% to 20% of the daily caloric intake comes from animal and vegetable protein sources in the U.S. diet. This amount may be liberalized in pregnant and lactating women or in elderly people. With the onset of nephropathy, a lower protein intake of 0.8 to 1.0 g/kg/day is considered sufficiently restrictive. For patients in later stages of nephropathy, reduction of protein intake to 0.8 g/kg/day is recommended. High protein diets are not recommended as a long-term method for weight loss, because the effects on kidney function are not known.

Sodium

The ADA recommends a reduced sodium intake of <2,300 mg/day in normotensive and hypertensive individuals. For patients with diabetes and symptomatic heart failure, sodium should be further restricted to <2,000 mg/day to help reduce symptoms. For all other patients, the ADA has no particular restrictions on sodium intake, but recommends individualizing amounts based on the patient’s sensitivity to salt and concurrent conditions such as hypertension or nephropathy.

Alcohol

The ADA’s recommendation for alcohol is consistent with general recommendations of no more than two alcoholic drinks per day for men or one drink per day for women. A drink is equivalent to 12 oz beer, 5 oz wine, or 1.5 oz distilled spirits (each contains about 15 g carbohydrate). Nevertheless, its caloric contribution must be considered (1 alcoholic beverage = 2 fat exchanges), and it should always be taken with food to minimize its hypoglycemic effect. In patients with diabetes, light to moderate alcohol intake (one to two drinks per day) is associated with a decreased risk of CVD. A note of caution: Evening consumption of alcohol in type 1 diabetes may increase the risk of nocturnal and fasting hypoglycemia.

Exercise

Exercise is a key factor in the treatment of diabetes, particularly in type 2 diabetes, because obesity and inactivity contribute to the development of glucose intolerance in genetically predisposed individuals. Regular exercise reduces cholesterol levels, lowers BP, augments weight reduction diets, reduces the dose requirements or need for insulin or antihyperglycemic agents, enhances insulin sensitivity, and improves psychological well-being by reducing stress. Exercise increases glucose utilization, which is provided initially from the breakdown of muscle glycogen and, subsequently, from hepatic glycogenolysis and gluconeogenesis. These effects are mediated through norepinephrine, epinephrine, growth hormone, cortisol, and glucagon, along with the suppression of insulin secretion. In

insulin-dependent diabetic patients, hyperglycemia, normoglycemia, or hypoglycemia can occur secondary to exercise depending on the degree of control, recent administration of insulin, and food intake. Exercise in patients taking insulin must be tempered by increased food intake, potential delay in insulin administration, decreased doses of insulin, or a combination of these actions to minimize hypoglycemia (see Question 29).

In the type 2 diabetic population, plasma glucose concentrations usually decrease in response to exercise; symptomatic hypoglycemia is uncommon. Because diabetic individuals are predisposed to CVD, attention has been focused on the metabolic response of a patient with diabetes to exercise. In general, moderate, regular exercise is highly recommended for individuals with type 2 diabetes treated with diet and/or antidiabetic agents and encouraged in individuals taking insulin if special precautions are taken.

The ADA's recommendation is for people with diabetes to perform at least 150 min/week of moderate-intensity aerobic physical activity (50%–70% of maximal heart rate). Resistance exercise has been shown to improve insulin sensitivity. Therefore, in the absence of any contraindications, patients with type 2 diabetes are encouraged to perform resistance training three times per week. Patients with conditions that may preclude certain types of physical activity (e.g., coronary artery disease, uncontrolled hypertension, severe autonomic neuropathy, severe peripheral neuropathy or history of foot lesions, and advanced retinopathy) that may preclude certain types of physical activity should be carefully evaluated before starting an exercise regimen.

Pharmacologic Treatment

Insulin, along with diet, is crucial to the survival of individuals with type 1 diabetes and plays a major role in the therapy of people with type 2 diabetes when their symptoms cannot be controlled with diet or non-insulin antidiabetic agents. Insulin also is used for patients with type 2 diabetes during periods of intercurrent illness or stress (e.g., surgery, pregnancy). The use of antidiabetic agents is reserved for the treatment of patients with type 2 diabetes whose symptoms cannot be controlled with diet and exercise alone (however, metformin is an exception to this). The clinical use of these agents and the complications associated with their use are discussed later in this chapter.

Pancreas and Islet Cell Transplants

Pancreas transplantation, by either whole pancreas or pancreatic islet cells, is the only available treatment for type 1 diabetes mellitus that induces an insulin-independent, normoglycemic state. Benefits can include improvement in quality of life, retinopathy, and nephropathy.^{49,50} Whole organ pancreas transplantation continues to be widely used in uremic diabetic patients because it can be performed at the same time as kidney transplantation (simultaneous kidney and pancreas transplant [SPK]) or after (pancreas after kidney transplant [PAK]). SPK graft survival rates are 86% and 71% at years 1 and 5, respectively. For PAK, survival rates are slightly lower, at 78% and 57% at years 1 and 5, respectively.⁵¹ Another option is for pancreas transplantation alone; survival rates are similar to PAK. The pancreatic graft is usually placed peritoneally, with duct management by enteric drainage or less commonly by bladder drainage. However, pancreatic transplantation alone in a patient with diabetes mellitus remains controversial because the disad-

vantages of exogenous insulin therapy are replaced with risks of the transplantation procedure itself and the complications of immunosuppressive medications.⁵² The International Pancreas Transplant Registry tracks whole organ pancreas transplantation. As of December 2004, 23,043 pancreas transplants were reported to the International Pancreas Transplant Registry, with 17,127 performed in the United States. SPK accounted for the majority of pancreas transplants.

Islet cell transplants (infusions) have received increased attention with the success of the "Edmonton Protocol," which used a steroid-free immunosuppression regimen as well as other techniques. All patients achieved insulin independence after 1 year in contrast with a previous success rate of 8%.⁵³ At 5 years, approximately 80% of patients had C-peptide present, but only 10% maintained insulin independence with a median duration of insulin independence of 15 months.⁵⁴ Since then, an international trial of the Edmonton Protocol, organized by the Immune Tolerance Network, was published demonstrating proof of concept that the protocol could be replicated.⁵⁵ At 1 year, 44% of patients were insulin independent with adequate glycemic control, and 31% of these remained insulin independent at 2 years. Twenty-eight percent had complete graft loss at 1 year. Although islet cell transplantation does not achieve sustained insulin independence, it can improve quality of life, mainly from reduced hypoglycemia.^{55,56} Currently, islet cell transplantation is considered for patients with type 1 diabetes with severe, recurrent hypoglycemia and hypoglycemic unawareness. Most protocols use sirolimus and tacrolimus for maintenance immunosuppression and a monoclonal anti-CD25 antibody for induction immunosuppression at the first islet infusion.⁵⁷ The Collaborative Islet Transplant Registry reported 319 recipients of islet infusion procedures from 1999 to 2005 in North America. Many issues remain regarding islet cell transplantation, including availability of islet cell transplant material, islet cell preparation, types of immunosuppression, and assessment of long-term outcomes.

Overall Goals of Therapy

The overall goal of diabetes management is to prevent acute and chronic complications. Periodic assessments of HbA_{1c} coupled with regular measurement of fasting, preprandial, and postprandial glucose levels should be utilized to assess therapy. The following overall goals of therapy are agreed upon by most endocrinologists:

1. Strive for glycemic control achieved in DCCT and UKPDS. The landmark randomized, prospective trials of various interventional therapies in patients with both types 1 and 2 diabetes have clearly demonstrated that reductions in hyperglycemia significantly decreases microvascular complications. In general, these trials demonstrated an overall reduction in microvascular complications by 30% to 35% with a 1% absolute reduction in HbA_{1c}. In both the UKPDS and the DCCT, a trend toward a significant reduction in macrovascular complications was observed. Target blood glucose goals may need to be adjusted for patients with frequent, severe hypoglycemia or hypoglycemia unawareness (see questions 35 and 38), or CVD. In addition, established renal insufficiency, proliferative retinopathy, severe neuropathy, and other advanced complications are not likely to be improved by tight glucose control. See Table 50-5 for the ADA glycemic goals. The American Association

of Clinical Endocrinologists and the American College of Endocrinology established glycemic goals as well (Table 50-5).⁵⁸ These authors elected to discuss ADA guidelines throughout this chapter.

2. Try to keep patients free of symptoms associated with hyperglycemia (polyuria, polydipsia, weight loss, fatigue, recurrent infection, ketoacidosis) or hypoglycemia (hunger, anxiety, palpitations, sweatiness).
3. Maintain normal growth and development in children. Intensive therapy is not recommended for children younger than 7 years of age and should be used cautiously in children ages 7 to 13 years old (see Questions 22 and 23).
4. Eliminate or minimize all other cardiovascular risk factors (obesity, hypertension, tobacco use, hyperlipidemia; see Table 50-5 for BP and lipid goals).
5. Try to integrate the patient into the health care team through intensive education. The patient's knowledge and understanding of this disease can favorably influence its outcomes (see Table 50-16).

Methods of Monitoring Glycemic Control

In addition to monitoring signs and symptoms associated with hyperglycemia, hypoglycemia, and the long-term complications of diabetes, an ongoing assessment of metabolic control is an integral component of diabetes management. Ideally, self-monitored blood glucose (SMBG) results combined with laboratory measures of acute and chronic glycemia can be used to evaluate and adjust therapy. Several chemical measurements may be used by the patient and clinician to assess glycemic control directly or indirectly.⁵⁹ SMBG and HbA_{1c} levels continue to be the two primary methods used to access glycemic control. Recently, continuous glucose monitoring (CGM) of interstitial fluid has become available for people with diabetes. CGM is discussed somewhat briefly here, because this method still is currently recommended for consideration, along with SMBG, for patients with type 1 diabetes only, especially those with hypoglycemic unawareness.²²

Urine Ketone Testing

Urine ketone testing is recommended for patients with gestational and type 1 diabetes. Urine ketones should be evaluated when glucose concentrations consistently exceed 300 mg/dL (16.7 mmol/L) or during acute illness.⁵⁹ Persistently high glucose concentrations of this magnitude signal insulin deficiency that can, in turn, lead to lipolysis and ketoacidosis. A positive test may indicate impending or established ketoacidosis and demands a more extensive diagnostic workup. Testing also is recommended during pregnancy and if the patient has symptoms of ketoacidosis. Although there are generally no ketones in the urine, they may be present in people who are on extremely low caloric diets and in the first morning sample of women who are pregnant. Also, see discussions of sick day management and ketoacidosis in other sections of this chapter (Questions 30 and 39 through 43).

Plasma Glucose

FPG concentrations (normal FPG, 3.9–5.6 mmol/dL or 70–100 mg/dL) are commonly used to assess glycemic control in the fasting state because this is when glucose concentrations are most reproducible. FPG concentrations generally reflect glu-

cose derived from hepatic glucose production because this is the primary source of glucose in the postabsorptive state. The FPG is the most frequent test performed by patients when self-monitoring. Postprandial glucose concentrations (1–2 hours after the start of the meal) also are used to assess glycemic control when fasting glucose concentrations are within normal limits or when there is a need to assess the effects of food or drugs (e.g., rapid-acting insulins, α -glucosidase inhibitors) on meal-related glycemia. In nondiabetic individuals, glucose concentrations generally return to below 140 mg/dL (7.8 mmol/L) within 2 hours after a meal. One- to 2-hour postprandial concentrations primarily reflect the efficiency of insulin-mediated glucose uptake by peripheral tissue.

Because any glucose concentration can be affected by various factors (e.g., meals, medications, stress), measurement at a single point in time cannot be used to assess a patient's overall control. Most laboratories measure plasma glucose concentrations rather than whole blood because these values are not subject to changes in the hematocrit. The majority of glucose monitors report plasma-referenced glucose concentrations. Whole blood glucose concentrations are approximately 10% to 15% lower than plasma glucose concentrations because glucose is not distributed into red blood cells. To convert plasma glucose concentrations (mg/dL) to whole blood glucose values (and vice versa), the following equation can be used:

- Whole blood glucose (mg/dL) = plasma glucose (mg/dL) \div 1.12
- To convert a glucose concentration in mg/dL to mmol/L, a factor of 18 is used:

$$\text{Plasma glucose (mmol/L)} = \text{plasma glucose (mg/dL)} \div 18$$

Self-Monitored Blood Glucose

SMBG has made euglycemia, both preprandially and postprandially, an achievable goal (80–140 mg/dL). Patients and their health care providers can use SMBG to assess directly the effects of drug dose changes, meals, exercise, and illness on daily blood glucose concentrations. With improved technology, decreasing costs, and increased coverage by health plans, SMBG is the day-to-day monitoring test of choice for all patients with diabetes. However, SMBG remains expensive for patients without health insurance, is invasive, and is technique dependent. Furthermore, to achieve maximum benefit from SMBG, both the clinician and patient must be motivated and willing to spend the time required to interpret the data and modify therapy to improve glycemic control. Based on the results of the DCCT and UKPDS, most persons with diabetes should attempt to achieve and maintain blood glucose levels as close to normal as is safely possible. This goal can realistically be achieved only by using SMBG. The frequency and timing of performing SMBG should be dictated by the individual's needs and goals. Selection and use of SMBG testing materials are discussed in questions 11 and 12. Patients in whom blood glucose self-monitoring is particularly valuable include the following:

- *Patients with type 1 diabetes:* Frequent blood glucose measurements help the patient to correlate meals, exercise, and insulin dose with blood glucose concentrations. This instant feedback gives the patient an increased sense of control and motivation, leading to improved glucose control.

- **Pregnant patients:** Infant morbidity and mortality are associated with the mother's overall glucose control. Using SMBG, the mother with diabetes who achieves normoglycemia before conception and throughout pregnancy, improves her chances of delivering a live, healthy infant.
- **Patients having difficulty recognizing hypoglycemia:** Over time, many patients with diabetes develop a sluggish counter-regulatory response to hypoglycemia whereby hypoglycemic symptoms are blunted or even absent. This is often referred to as *hypoglycemic unawareness*. Routine SMBG to detect asymptomatic hypoglycemia is essential in these individuals (see question 38). In addition, acute anxiety attacks or signs and symptoms associated with a rapidly falling blood glucose concentration may mimic a true hypoglycemic reaction. This can be evaluated easily by measuring a fingerstick blood glucose concentration.
- **Patients who are using physiological (e.g., basal-bolus) insulin therapy:** Individuals who are on multiple daily doses of insulin or those using an insulin pump should use SMBG to evaluate the effectiveness of their insulin regimens and meal plans and to check for hypoglycemic or hyperglycemic reactions (see Question 12). Knowledge of preprandial, postprandial, bedtime, and nocturnal (e.g., 2 AM) blood glucose concentrations is essential in determining basal and preprandial insulin requirements.

Continuous Glucose Monitoring

CGM has become available in recent years and provides real time information on glucose concentrations. Commercially available CGM monitors currently measure SC interstitial glucose levels. The four main CGM systems in the United States are DexCom STS 3- and 7-day systems, MiniMed Paradigm REAL-Time system (communicates with the Paradigm 522 and 722 insulin pumps), MiniMed Guardian REAL-Time system, and the Abbott FreeStyle Navigator. The CGM systems use electrochemical sensors that are inserted into the skin. Sensor probe length varies from 5 to 16 mm. Depending on the system, the sensors are good for 3 to 7 days. The sensors transmit a signal to a transmitter (wired or wireless), and then to a receiver for display. The system transmits glucose information to the receiver; receivers then display the glucose reading every 1 minute (Navigator) or 5 minutes (DexCom and MiniMed systems). The sensors require a warmup or initialization period and have very specific calibration requirements (e.g., at 2 and 6 hours, then every 12 hours for the life of the sensor with the MiniMed systems). Calibration is performed by using a blood glucose monitor. Interstitial glucose concentrations are displayed on the receiver every 1 or 5 minutes depending on the system. Interstitial glucose levels lag behind plasma or blood glucose levels by 8 to 18 minutes, depending on the glucose rate of change.⁶⁰ Therefore, if a person's glucose is low, or trending downward, SMBG is required. An issue with CGM is severe skin reactions to the adhesive for either the sensor or transmitter. CGM systems have alarms that can go off at certain high and low glucose thresholds. The ability to detect hypoglycemia during the night with these alarms has been a very attractive reason for using CGM. Another key feature is the ability to follow trends and rates of change in blood glucose levels. Small, short-term studies have demonstrated modest improvements in HbA_{1c} (0.3%–0.6% reductions) in adults and children with type 1 diabetes.^{61–64} CGM does not

replace SMBG, but provides a new tool for patients to actively manage their diabetes. A noninvasive, watchlike device called the GlucoWatch G2 Biographer (Animas Corporation, West Chester, PA) used to be available, but the manufacturer ceased selling this in 2007. This device used iontophoresis to obtain glucose samples through intact skin via interstitial fluid.

Glycosylated Hemoglobin

The glycosylated hemoglobin, or HbA_{1c}, has become the gold standard for measuring chronic glycemia and is the clinical marker for predicting long-term complications, particularly microvascular complications. HbA_{1c} is most commonly measured because it comprises the majority of glycosylated hemoglobin and is the least affected by recent fluctuations in blood glucose. HbA_{1c} measures the percentage of hemoglobin A that has been irreversibly glycosylated at the N-terminal amino group of the β -chain; the plasma glucose level and the life span of a red blood cell (RBC; ~120 days) determine its value. Thus, HbA_{1c} is an indicator of glycemic control over the preceding 2 to 3 months. In patients without diabetes, HbA_{1c} comprises approximately 4% to 6% of the total hemoglobin. Values may be three times this level in patients with diabetes.

The current HbA_{1c} assay actually measures several different molecules of hemoglobin A (HbA_{1c}, HbA_{1a}, HbA_{1b}, HbA₀), not just HbA_{1c}. Each laboratory establishes its own normal values for the HbA_{1c} test (most are referenced to the normal range of 4%–6%). The International Federation of Clinical Chemistry has developed a new reference method that only measures glycosylated HbA_{1c} (with a new unit of mmol HbA_{1c} per mol total hemoglobin).⁶⁵ The downside of this method is that the HbA_{1c} values are 1.3% to 2.0% lower than the current values, which would cause great confusion among practitioners. Another movement is to report estimated average glucose (units mg/dL or mmol/L), which is calculated using HbA_{1c} measurements and correlating them to actual glucose measurements (using 7-point blood glucose profiles with SMBG and CGM) over a 3-month period.⁶⁶ The International HbA_{1c}-derived Average Glucose trial will provide new correlations of HbA_{1c} with estimated average glucose and is due to be published in 2008. The current correlation between HbA_{1c} and mean plasma glucose is that is reported is based on DCCT values (see below).^{22,67} In these data, a 1% change in the glycosylated hemoglobin represents a 35-mg/dL change in the mean plasma glucose concentration.

| HbA _{1c} (%) | Mean Plasma Glucose Levels | |
|-----------------------|----------------------------|--------|
| | (mg/dL) | mmol/L |
| 6 | 135 | 7.5 |
| 7 | 170 | 9.5 |
| 8 | 205 | 11.5 |
| 9 | 240 | 13.5 |
| 10 | 275 | 15.5 |
| 11 | 310 | 17.5 |
| 12 | 345 | 19.5 |

Alterations in RBC survival such as hemoglobinopathies, anemias, acute or chronic blood loss, and uremia may affect HbA_{1c} values, resulting in inaccurate indications of glycemic control. Antioxidants such as vitamins C and E also may interfere with the glycosylation process^{68,69} (Table 50-6).

Table 50-6 Factors Affecting HbA_{1c}

| Cause | Effect on HbA _{1c} |
|------------------------------------|---------------------------------------|
| Alterations in RBC Survival | |
| Hemoglobinopathies | Decreased |
| Anemias | |
| Hemolytic | Decreased |
| Iron deficiency | Decreased ^a |
| Blood loss | Decreased |
| Assay Interference | |
| Uremia | Increased or no change ^{b,c} |
| Hemodialysis | No change ^b |
| Antioxidants | Decreased ^d |

^aFor patients receiving iron replacement therapy. Normal levels would be expected in untreated patients.

^bInterference seen in assays using high-pressure liquid chromatography and electroendosmosis. Affinity chromatography seems unaffected.

^cCarbamylated hemoglobin equaling 0.063% of total hemoglobin is formed for every 1 mmol/L of serum urea.

^dReported with vitamins C (1 g/day) and E (1,200 mg/day). Possible mechanism is competitive inhibition of hemoglobin glycosylation.

HbA_{1c}, glycosylated hemoglobin; RBC, red blood cell.

HbA_{1c} can be measured without any special patient preparation (e.g., fasting) and generally is not subject to acute changes in insulin dosing, exercise, or diet. Normalization can indicate whether euglycemia has been achieved. However, HbA_{1c} does not replace the day-to-day monitoring of blood glucose concentrations, which is essential for evaluating acute changes in blood glucose concentrations. These values are needed to adjust the meal plan or medication doses.

CLINICAL USE

Currently, the HbA_{1c} value is used as an adjunct to assessing overall glycemic control in patients with diabetes. Often, it is used to verify clinical impressions related to glucose control and patient adherence. Some also have suggested the use of HbA_{1c} values for diabetes screening and diagnosis; however, until the test is standardized and more studies are completed, it cannot be recommended for these purposes. HbA_{1c} should be measured quarterly in patients who do not meet treatment goals, and at least semiannually in stable patients who are meeting treatment goals.

Glycated Serum Protein, Glycated Serum Albumin, and Fructosamine

Assays for glycated serum proteins reflect the extent of glycosylation of a variety of serum proteins, including glycated serum albumin.⁵⁹ The fructosamine assay is one of the most widely used methods to measure glycated proteins (normal, 2–2.8 mmol/L). Because the half-life of albumin is approximately 14 to 20 days, fructosamine provides an indication of glycemic control over a shorter time frame (1–2 weeks) than does the HbA_{1c}. The ADA does not consider measurement of fructosamine equivalent to that of HbA_{1c}, although it correlates well with this value. Fructosamine levels may be useful as an adjunct to HbA_{1c} in determining whether a patient is improving or worsening in the short term (e.g., a patient on insulin therapy undergoing multiple dosage adjustments; for women with

type 2 diabetes during pregnancy or gestational diabetes) or in patients with conditions such as hemolytic anemia in whom the HbA_{1c} test is inaccurate (Table 50-6). However, the exact role of glycated serum protein in monitoring glycemic control requires further study.

INSULIN

Insulin is a hormone secreted from the pancreatic β -cell in response to glucose and other stimulants (e.g., amino acids, free fatty acids, gastric hormones, parasympathetic stimulation, β -adrenergic stimulation).^{70,71} The hormone is made up of two polypeptide chains (a 21-amino acid α chain and a 30-amino acid β chain), which are connected by two disulfide bonds (Fig. 50-3). Proinsulin, the precursor of insulin, is a single-chain, 86-amino acid polypeptide. In the storage granule of the β -cell, the connecting or C-peptide is cleaved from proinsulin to produce equimolar amounts of insulin and C-peptide. Thus, measurable C-peptide levels indicate the presence of endogenously produced insulin and functioning β -cells. Insulin is crucial to the survival of individuals with type 1 diabetes, whose β -cells have been destroyed. It also plays a major role in the therapy of individuals with type 2 diabetes when their symptoms cannot be controlled with diet and exercise alone or a combination of antidiabetic agents. Insulin also is used in patients with type 2 diabetes during pregnancy or periods of intercurrent illness or stress (e.g., surgery).

Commercially available insulin products differ in their immunogenicity, physical and chemical properties, pharmacokinetics, and pharmacodynamics.

Immunogenicity

Modern manufacturing processes have virtually eliminated contaminants from current products, and most people now use human insulin. Consequently, immunologically mediated sequelae, such as lipodystrophy, hypersensitivity, and insulin resistance caused by “blocking” antibodies, are rare.

Regular insulin is a solution that can be administered by any parenteral route: intravenously, intramuscularly, or subcutaneously. Insulin lispro, insulin aspart, and insulin glulisine are rapid-acting analogs. These insulins are also clear solutions approved by the U.S. Food and Drug Administration (FDA) for SC use. Insulin glargine and insulin detemir, two long-acting insulins are also clear solutions, but neither should be administered IV. Insulin glargine is designed to precipitate at physiological pH and insulin detemir binds to plasma albumin. NPH insulin, an intermediate insulin, is a suspension in which regular insulin has been complexed with protamine to extend its action. Two previously available insulins, Lente and Ultralente, were removed from the market in 2005. NPH insulin must be mixed well before administration and should never be administered IV. All insulin products have a neutral pH, except for insulin glargine, which has a pH of 4.0.

Pharmacokinetics: Absorption, Distribution, and Elimination

After SC injection, insulin is absorbed directly into the bloodstream, bypassing the lymphatic system. The rate-limiting step of insulin activity after SC administration is absorption of

Table 50-7 Insulins Available in the United States

| Type/Duration of Action | Brand Name | Manufacturer |
|---|--------------------------------|-----------------------|
| Rapid Acting | | |
| Insulin lispro | Humalog | Lilly |
| Insulin aspart | NovoLog | Novo Nordisk |
| Insulin glulisine | Apidra | Sanofi-Aventis |
| Short Acting | | |
| Regular | Humulin R Novolin R | Lilly Novo Nordisk |
| Intermediate Acting | | |
| NPH (isophane insulin suspension) | Humulin N Novolin N | Lilly Novo Nordisk |
| Long Acting | | |
| Insulin glargine | Lantus | Sanofi-Aventis |
| Insulin detemir | Levemir | Novo Nordisk |
| Combination Insulins | | |
| NPH/regular mixture (70%/30%) | Humulin 70/30 Novolin 70/30 | Lilly Novo Nordisk |
| NPH/regular mixture (50%/50%) | Humulin 50/50 | Lilly |
| Insulin aspart protamine/insulin aspart mixture (70%/30%) | Novolog Mix 70/30 | Novo Nordisk |
| Insulin NPL/insulin lispro mixture (75%/25%) | Humalog Mix 75/25 | Lilly |
| Insulin NPL/insulin lispro mixture (50%/50%) | Humalog Mix 50/50 | Lilly |

stabilized in a metabolic ward. In actuality, intersubject and intrasubject variations in response to insulin can be substantial because an individual pattern of response to insulin can be affected by numerous factors (e.g., the formation of insulin hexamers, the presence of insulin-binding antibodies, dose, exercise, site of injection, massage of the injection site, ambient temperature, and interactions between insulins that have been

Table 50-8 Insulin Pharmacodynamics^{a,110,254}

| Insulin | Onset (hr) | Peak (hr) | Duration (hr) | Appearance |
|--|------------|--------------------|---------------|--------------------|
| Rapid acting (insulin lispro, aspart and glulisine) | 5–25 min | 30–90 min | <5 | Clear |
| Regular | 0.5–1 | 2–3 | 5–8 | Clear |
| NPH | 2–4 | 4–12 | 12–18 | Cloudy |
| Insulin glargine | 1.5 | No pronounced peak | 20–24 | Clear ^b |
| Insulin detemir | 3–8 | Relatively flat | 5.7–23.2 | Clear ^b |

^aThe onset, peak, and duration of insulin activity may vary considerably from times listed in this table. See text and Table 50-12.

^bShould not be mixed with other insulins or administered IV. Some patients require twice-daily dosing.

Table 50-9 Components of Physiological Insulin Therapy

| | |
|--|--|
| Multicomponent insulin regimen of basal plus preprandial insulin doses | |
| Balance of carbohydrate intake, exercise, and insulin dosage | |
| Daily, multiple self-monitoring of blood glucose levels | |
| Patient self-adjustment of carbohydrate intake and insulin dosage with use of correction/supplemental rapid- or short-acting insulin according to a predetermined plan | |
| Individualized target blood glucose and HbA _{1c} levels | |
| Frequent contact between patient and diabetes team | |
| Intensive patient education | |
| Psychological support | |

| HbA _{1c} , glycosylated hemoglobin. | |
| Modified from reference 100. | |

mixed together; Table 50-10 and Question 16).^{72,74} Nevertheless, knowledge of when one might expect the various insulins to exert their effects is absolutely essential to the rational adjustment of insulin dosages.

Rapid-Acting Insulin

INSULIN LISPRO

Insulin lispro [Lys(B28),Pro(B29)]-human insulin (Humalog, Eli Lilly, Indianapolis, IN) was the first available rapid-acting insulin analog and received FDA approval in 1996. The natural amino acid sequence of the insulin β -chain at positions 28 (proline) and 29 (lysine) is inverted to form lispro. This change results in an insulin molecule that more loosely self-associates into hexamers than does regular insulin. Consequently, the active monomeric form is more readily available, resulting in an onset of activity (15 minutes), peak action (60–90 minutes), and duration (3–4 hours) that more closely simulates physiological insulin secretion relative to meals. Because it can be injected shortly before eating (0–15 minutes), lispro, and all rapid-acting insulins, provide patients greater flexibility in lifestyle. These insulins lower 2-hour postprandial blood glucose levels, and decrease the risk for late postprandial and nocturnal hypoglycemia compared with regular insulin formulations.⁷⁵ Patients who use an insulin pump most often use a rapid-acting insulin instead of regular insulin. One randomized, two-way, cross-over, open-label study compared lispro with regular insulin administered for 3 months by continuous SC insulin infusion.⁷⁶ Lispro resulted in HbA_{1c} values that were significantly lower than those produced by regular insulin (7.41% vs. 7.65%). There were no differences in adverse events. Because lispro has a shorter duration of action than regular insulin, hyperglycemia and ketosis may occur more rapidly if insulin delivery is inadvertently interrupted. Insulin lispro is approved for use in pediatric patients, age 3 and older.⁷⁷ It is pregnancy category B.

INSULIN ASPART

Insulin aspart (NovoLog, Novo Nordisk, West Princeton, NJ) is a rapid-acting insulin analog that differs from human insulin by substitution of aspartic acid at B28. Insulin aspart is approved for use in pediatric patients, age 6 and older.⁷⁸ It is pregnancy category B. Insulin aspart controls postprandial glucose excursions similar to insulin lispro.

Table 50-10 Factors Altering Onset and Duration of Insulin Action

| Factor | Comments | | | | | | | | | | |
|---------------------------------------|---|------|----------------------------|---------|---------|-----|----------|-----|----------|-------|----------|
| Route of administration | Onset of action more rapid and duration of action shorter for IV>IM>SC ¹³⁷ Intrapulmonary insulin has more rapid onset and shorter duration than SC insulin, resembling IV pharmacokinetics ⁷² | | | | | | | | | | |
| <i>Factors altering clearance</i> | | | | | | | | | | | |
| Renal function | Renal failure lowers insulin clearance; may prolong and intensify action of exogenous and endogenous insulin | | | | | | | | | | |
| Insulin antibodies | IgG antibodies bind insulin as it is absorbed and release it slowly, thereby delaying and/or prolonging its effect ³³⁹ | | | | | | | | | | |
| Thyroid function | Hyperthyroidism increases clearance, but also increases insulin action, making control difficult; patients stabilize as they become euthyroid | | | | | | | | | | |
| <i>Factors altering SC absorption</i> | Factors that raise SC blood flow ↑ absorption rates of regular insulin; effect on intermediate- and long-acting insulins minimal | | | | | | | | | | |
| Site of injection | Rate of absorption fastest from the abdomen, intermediate from the arm, and slowest from the thigh; less variation observed in type 2 patients; less variation observed with lispro insulin | | | | | | | | | | |
| | <table border="1"> <thead> <tr> <th>Site</th> <th>Half-life absorption (min)</th> </tr> </thead> <tbody> <tr> <td>Abdomen</td> <td>87 ± 12</td> </tr> <tr> <td>Arm</td> <td>141 ± 23</td> </tr> <tr> <td>Hip</td> <td>153 ± 28</td> </tr> <tr> <td>Thigh</td> <td>164 ± 15</td> </tr> </tbody> </table> | Site | Half-life absorption (min) | Abdomen | 87 ± 12 | Arm | 141 ± 23 | Hip | 153 ± 28 | Thigh | 164 ± 15 |
| Site | Half-life absorption (min) | | | | | | | | | | |
| Abdomen | 87 ± 12 | | | | | | | | | | |
| Arm | 141 ± 23 | | | | | | | | | | |
| Hip | 153 ± 28 | | | | | | | | | | |
| Thigh | 164 ± 15 | | | | | | | | | | |
| Exercise of injected area | Strenuous exercise of an injected area within 1 hr of injection can increase absorption rate; rate of absorption of regular insulin is increased, but little effect on intermediate-acting insulin ^{72,134} | | | | | | | | | | |
| Ambient temperature | Heat (e.g., hot weather, hot bath, sauna) increases absorption rate; cold has opposite effect ^{70,72} | | | | | | | | | | |
| Local massage | Massaging injected area for 30 min substantially increases absorption rate of regular insulin as well as longer acting insulins | | | | | | | | | | |
| Smoking | Controversial; vasoconstriction may down decrease absorption rate ⁷² | | | | | | | | | | |
| Jet injectors | Insulin absorption more rapid, probably secondary to increases surface area for absorption | | | | | | | | | | |
| Lipohypertrophy | Insulin absorption is delayed from lipohypertrophic sites | | | | | | | | | | |
| Insulin preparation | More soluble forms of insulin are absorbed more rapidly and have shorter durations of action (see Table 50-8 and text); human insulin may have shorter action than animal insulin | | | | | | | | | | |
| Insulin mixtures | The short-acting properties of rapid-acting insulins may be blunted if mixed with NPH insulin (see Question 17) | | | | | | | | | | |
| Insulin concentration | More dilute solutions (e.g., U-40, U-10) are absorbed more rapidly than more concentrated forms (U-100, U-500) ⁷⁰ | | | | | | | | | | |
| Insulin dose | Lower doses are absorbed more rapidly and have a shorter duration of action than larger doses | | | | | | | | | | |

IgG, immunoglobulin G; IM, intramuscular; IV, intravenous; SC, subcutaneous.

INSULIN GLULISINE

Insulin glulisine (Apidra, Sanofi-Aventis, Bridgewater, NJ) is a rapid-acting insulin analog that differs from human insulin by substitution of lysine for asparagine at position B3 and glutamic acid for lysine at position B23. Insulin glulisine is currently not FDA approved for use in pediatric patients.⁷⁹ It is pregnancy category C. Insulin glulisine lowers postprandial glucose excursions similar to insulin lispro and insulin aspart.

Short-Acting Insulin

Regular insulin has an onset of action of 30 to 60 minutes, a peak effect at 2 to 4 hours, and a duration of action of 5 to 7 hours. The broad range in peak effect and duration reflects the many variables that affect insulin action (Table 50-8). The 30- to 60-minute onset of action requires proper timing of premeal regular insulin, which is difficult for most patients. Use of regular insulin in patients with type 1 diabetes is much less common with the advent of the rapid-acting insulins.

Previously, an inhaled human insulin powder (Exubera, Pfizer, New York, NY) was available. In October 2007, Pfizer announced that it would no longer make this insulin owing to its infrequent use. In March 2008, Lilly announced that it was cancelling the trials of its inhaled insulin, AIR, which it was developing with Alkermes, Inc. Similarly, Novo Nordisk

in January 2008 announced it would discontinue studies of its insulin inhaler AERx.

Intermediate-Acting Insulin

NPH

NPH (neutral protamine hagedorn or isophane) is an intermediate-acting insulin. Its onset of action is approximately 2 hours (range, 1–3), peak effects occur at approximately 6 to 14 hours, and the duration of action of NPH is approximately 16 to 24 hours. Again, it must be emphasized that this pattern of response is at best a generalization. Patients may have a variable pattern of response to NPH insulin over time, and those on higher doses are likely to have a later peak and a longer duration of action. Up to 80% of these day-to-day fluctuations in blood glucose responses can be accounted for by variation in the absorption of this intermediate-acting insulin.⁷²

Long-Acting Insulin

INSULIN GLARGINE

Insulin glargine (Lantus, Sanofi-Aventis) was approved by the FDA in April 2000 and is pregnancy category C. It is approved for once a day SC administration for the treatment of adult and pediatric patients (age ≥6) with type 1 diabetes or adult patients with type 2 diabetes who require basal (long-acting) insulin for the control of hyperglycemia. It can be

administered anytime during the day, but it is important to take it at the same time each day. It is usually administered at bedtime (this was the original approved administration time) or, second most commonly, in the morning.

Insulin glargine is an insulin analog in which asparagine in position A21 is substituted with glycine and two arginines are added to the C-terminus of the β -chain. This change in the amino acid sequence causes a shift in the isoelectric point from pH 5.4 to 6.7, making it more soluble at an acidic pH.⁸⁰ Once injected, insulin glargine (which is a clear solution with a pH of 4.0) precipitates at physiological pH forming a depot that releases insulin slowly over 24 hours. This results in delayed absorption and a less pronounced peak compared with NPH insulin.⁸¹ Zinc is added to further prolong the duration of insulin glargine. In clinical trials of patients with types 1 and 2 diabetes, once-daily injections of insulin glargine were as effective as NPH in lowering HbA_{1c} values with less nocturnal hypoglycemia.⁸² Insulin glargine is associated with more injection site pain compared with NPH (6.1% vs. 0.3% in one study and 2.7% vs. 0.7% in another), which is likely due to its acidity.^{83,84} Some patients report that they “feel” the insulin glargine injection more than other insulins.

INSULIN DETEMIR

Insulin detemir (Levemir, Novo Nordisk), was approved in June 2005 and joins insulin glargine as the second basal insulin marketed in the United States. It is pregnancy category C. Unlike other insulin analogs, in which the amino acid sequence is modified, for insulin detemir, a fatty acid moiety is added to the last amino acid on the end of the β -chain. Insulin detemir is a neutral, soluble insulin preparation in which the B30 threonine has been removed and the B29 lysine residue has been covalently bound to a 14-carbon fatty acid. The result is an insulin that is more slowly absorbed in the SC tissue because the fatty acid moiety binds to albumin, creating a long-acting insulin.⁸⁵ Insulin detemir's kinetics and dynamics are dose dependent.⁸⁶ When used in type 1 diabetes, two injections daily are usually required to provide adequate basal coverage. Insulin detemir demonstrates less intrasubject variability than NPH or insulin glargine.⁸⁷ The clinical significance and impact of this observation is unclear.

Premixed Insulin

Products that contain premixed NPH and regular insulin in a fixed ratio of 70:30 are available from Lilly as Humulin 70/30 and Novo Nordisk as Novolin 70/30. Lilly also makes a premixed formulation in a 50:50 ratio (Humulin 50/50). Additional premixed formulations are available wherein both insulin lispro and insulin aspart have been co-crystallized with protamine to create an intermediate-acting insulin similar to NPH. Humalog Mix 75/25 and Humalog Mix 50/50 (Lilly) are products with lispro protamine and insulin lispro in a fixed ratio of 75:25 and 50:50, respectively. Novolog Mix 70/30 (Novo Nordisk) is aspart protamine and insulin aspart in a fixed ratio of 70:30. These premixed insulins are available for patients who have difficulty measuring and mixing insulins and are dosed twice daily. These insulins are compatible when mixed together and retain their individual pharmacodynamic profiles (see Question 16).

TREATMENT OF TYPE 1 DIABETES: CLINICAL USE OF INSULIN

Clinical Presentation of Type 1 Diabetes

3. A.H., a slender, 18-year-old woman who was recently discharged from the hospital for severe dehydration and mild ketoacidosis is referred to the Diabetes Clinic from the University Student Health Service (no records available). A fasting and a random plasma glucose ordered subsequently were 190 mg/dL (normal, 70–100) and 250 mg/dL (normal, 140 to <200). Approximately 4 weeks before she was hospitalized, A.H. had moved across the country to attend college—her first time away from home. In retrospect, she remembers that she had symptoms of polydipsia, nocturia (six times a night), fatigue, and a 12-lb weight loss over this period, which she attributed to the anxiety associated with her move away from home and adjustment to her new environment. Her medical history is remarkable for recurrent upper respiratory infections and three cases of vaginal moniliasis over the past 6 months. Her family history is negative for diabetes, and she takes no medications.

Physical examination is within normal limits. She weighs 50 kg and is 5 feet 4 inches tall. Laboratory results are as follows: FPG, 280 mg/dL (normal, <100); HbA_{1c}, 14% (normal, 4%–6%); and trace urine ketones as measured by Keto-Diastix (normal, negative). On the basis of her history and laboratory findings, the presumptive diagnosis is type 1 diabetes. Which findings are consistent with this diagnosis in A.H.?

[SI units: FPG, 15.5 mmol/L (normal, <5.6); HbA_{1c}, 0.14 (normal, 0.04–0.06)]

A.H. meets several of the diagnostic criteria for diabetes. She has classic symptoms of the disease (polyuria, polydipsia, weight loss, glucosuria, fatigue, recurrent infections), a random plasma glucose above 200 mg/dL, and an FPG of 126 mg/dL or higher on at least two occasions⁴ (Tables 50-1 and 50-2). The elevated HbA_{1c} also is consistent with diabetes mellitus. Features of A.H.'s history that are consistent with type 1 diabetes, in particular, include the relatively acute onset of symptoms in association with a major life event (moving away from home), ketones in the urine, negative family history, and a relatively young age at onset.

Treatment Goals

4. A.H. will be started on insulin therapy on this visit. What are the goals of therapy? Will normoglycemia prevent the development or progression of long-term complications?

The goal of diabetes management is the prevention of acute and chronic complications. As discussed in the introduction to this chapter, the results of the DCCT and DCCT-EDIC convincingly demonstrated that lowering blood glucose concentrations through intensive insulin therapy in persons with type 1 diabetes slows or prevents the development of microvascular complications.^{29,30} The ADA recommends an HbA_{1c} goal of less than 7% for patients in general and an individual goal as close to normal as possible (<6%) without significant hypoglycemia.

It is important to understand that physiological or basal-bolus insulin therapy involves a *complete* program of diabetes

management that includes a balanced meal plan, exercise, frequent SMBG, and insulin adjustments based on these factors (Tables 50-4 and 50-9). Because the patient is the key member of the team, A.H. must be highly motivated and able to learn about the complex metabolic interplay between insulin and lifestyle.

In summary, A.H. is a patient newly diagnosed with type 1 diabetes who has not yet developed any signs or symptoms of long-term complications. Therefore, she is an ideal candidate for basal-bolus insulin therapy and, if she is willing and motivated, normoglycemia with rare hypoglycemic reactions is a reasonable long-term goal. This goal should be achieved gradually over several months with insulin therapy, diet, education, and strong clinical support. A desirable goal is an HbA_{1c} value as close to the normal range as possible with rare hypoglycemic reactions.

Basal-Bolus (Physiological) Insulin Therapy

5. What methods of insulin administration are available to achieve optimal glucose control?

A physiological insulin regimen is designed to mimic normal insulin secretion as closely as possible.⁸⁸ Problems with insulin delivery include factors that affect the SC absorption of insulin (Table 50-10). Before the development of the rapid-acting insulin analogs and basal insulins, previous insulins lacked pharmacodynamic profiles that allowed one to closely simulate the basal-bolus model (see text that follows). Clinicians now have more tools to mimic the pancreatic release of the hormone. In the nondiabetic individual, the pancreas secretes boluses of insulin in response to snacks and meals. Between meals and throughout the night, the pancreas secretes small amounts of insulin that are sufficient to suppress lipolysis and hepatic glucose output (basal insulin). Two methods have been used to achieve a similar pattern of insulin release: (a) insulin pump therapy (previously referred to as “continuous subcutaneous infusion of insulin”) and (b) basal-bolus insulin regimens consisting of once to twice daily doses of basal insulin coupled with pre-meal doses of rapid or short-acting insulin (see Question 6).

Insulin Pump Therapy

The use of an insulin pump is currently the most precise way to mimic normal insulin secretion. This consists of a battery-operated pump and a computer that can program the pump to deliver predetermined amounts of regular insulin, insulin lispro, insulin aspart, or insulin glulisine from a reservoir to a subcutaneously inserted catheter or needle (e.g., MiniMed Paradigm 722, Northridge, CA; Animas 2020).^{89,90} These systems are portable and designed to deliver various basal amounts of insulin over 24 hours as well as meal-related boluses. A bolus of regular insulin can be released by the patient 30 minutes before food ingestion. Most patients using an insulin pump, however, prefer to use the rapid-acting insulin analogs in their pump. For meal coverage, the rapid-acting insulin can be given 0 to 15 minutes before eating. The delivery of the bolus can be adjusted depending on the type of food eaten (e.g., piece of cake versus slice of pizza). Caveat: If SC delivery is discontinued, check for rise in glucose and urine ketones after 2 or 3 hours. Because there is no SC pool, effects dissipate quickly.

The preferred meal planning approach for patients using an insulin pump is carbohydrate counting. The “insulin to carbohydrate ratio” or how much carbohydrate is covered by 1 unit of insulin must be determined. One method is to use the “500 Rule.” The number 500 (or 450 for regular insulin) is divided by the total daily dose of insulin the patient is using to determine the insulin to carbohydrate ratio (see Question 13). Insulin pumps are capable of delivering many basal insulin rates. The basal insulin infusion rate may be adjusted depending on the situation. Many patients find it advantageous to decrease the basal rate during the middle of the night when nocturnal hypoglycemia is most likely to occur. The basal rate also may be increased before awakening to avoid hyperglycemia secondary to the “dawn phenomenon”—adjustments that are not possible using subcutaneous basal insulin injections. Features of the current pump models include “bolus wizard,” which calculates accurate boluses based on preset carbohydrate-to-insulin ratios and correction factors, carbohydrate counts for selected foods, and an “insulin-on-board” feature, which avoids stacking of insulin doses by indicating how much insulin from a previously administered dose is still available. Most insurance plans provide coverage for insulin pumps for patients with type 1 and some patients with type 2 diabetes. Factors to consider when choosing a pump include safety features, durability, ability of the manufacturer to provide service, availability of training, clinically desirable features, and cosmetic attractiveness for the user.^{89,91}

MULTIPLE DAILY INJECTIONS

6. How can insulin injections be administered to A.H. in a way that mimics the physiological release of insulin from the pancreas?

Endocrinologists have developed a variety of insulin regimens that are intended to mimic the release of insulin from the pancreas.⁹² Examples of these are displayed in and illustrated in Figure 50-4. A total daily dose of insulin is estimated empirically (e.g., 0.5 unit/kg/day) or according to guidelines listed in Table 50-11. The total daily dose of insulin then is split into several doses. In general, the basal dose comprises approximately 50% of the total daily dose.

A regimen much less commonly used in patients with type 1 diabetes involves injecting a mixture of intermediate-acting and regular or rapid-acting insulin twice daily, before breakfast and before dinner (Fig. 50-4A). The morning dose of regular/rapid-acting insulin is intended to take care of the breakfast meal; the morning dose of NPH takes care of the noon meal and provides basal insulin throughout the day; the evening dose of regular/rapid-acting insulin takes care of the evening meal; and the evening dose of NPH provides basal insulin levels during the night and takes care of any evening snack that is ingested. Because NPH is an intermediate-acting insulin and has a peak effect, it does not provide true basal insulin coverage. Also, when NPH is injected in the morning, the patient must eat lunch on time because of this peak effect, otherwise they will experience hypoglycemia. Also, when NPH is taken with mealtime insulin before dinner, the patient is at risk for nocturnal hypoglycemia from the peak effect of the evening dose of NPH. The advantage of using a rapid-acting insulin (e.g., insulin lispro, insulin aspart, or insulin glulisine) instead of regular insulin in this regimen is to facilitate the patient being able to take their insulin doses immediately before

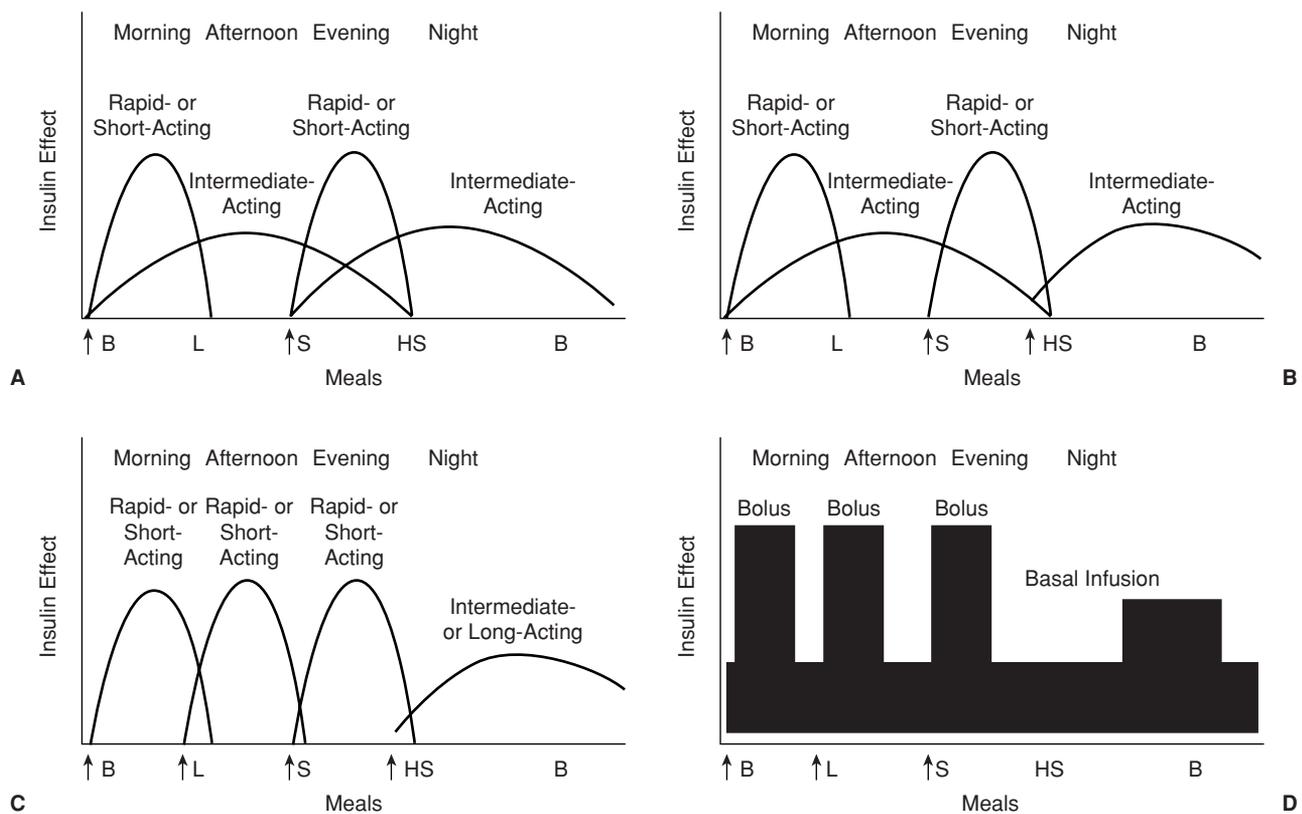

FIGURE 50-4 Theoretical insulin effect provided by various insulin regimens. A: Two daily injections of rapid-acting (insulin aspart, glulisine, or lispro) or short-acting (regular) and intermediate-acting insulin (NPH). **B:** Morning injection of rapid or short-acting insulin and an intermediate-acting insulin, a presupper injection of rapid or short-acting insulin, and a bedtime injection of intermediate-acting insulin. Suggested for patients with early morning hypoglycemia followed by rebound hyperglycemia or for patients with early morning hyperglycemia (rebound phenomenon). **C:** Preprandial injections of rapid or short-acting insulin and long-acting (e.g., insulin glargine or detemir) or intermediate-acting insulin (NPH) at bedtime. **D:** Continuous subcutaneous insulin infusion. B, breakfast; HS, bedtime snack; L, lunch; S, supper. Arrows, time of insulin injection (<15 minutes before meals for rapid-acting insulin and ~30 minutes before meals for short-acting insulin). (Adapted from reference 342.)

a meal. However, the peak effect of the NPH component in this combined dose still presents the same problems. Caveat: When patients are switched to a rapid-acting insulin from regular insulin in this type of regimen, the doses of NPH may have to be increased to minimize preprandial hyperglycemia. This type of insulin regimen does not mimic physiological insulin release.

Figure 50-4B depicts a variation of this method. It is the same except that the evening dose of NPH is given as a third injection at bedtime. This shifts the time of peak effect from approximately 2 to 3 AM to approximately 7 AM. By administering NPH at bedtime, nocturnal hypoglycemia is reduced and peak insulin activity occurs when the patient is more likely to be awake and ingesting food. This method may be useful for patients in whom nocturnal hypoglycemia and fasting hyperglycemia are particularly troublesome; however, this regimen also does not mimic physiological insulin release.

The regimen that most closely mimics physiological insulin release besides the use of an insulin pump, is the use of a once-daily basal insulin such as insulin glargine or insulin detemir to provide basal insulin levels throughout the day, along with doses of regular, insulin lispro, insulin aspart or insulin glulisine before meals (Fig. 50-4C depicts the long-acting in-

sulin given at bedtime, but it can be given alternatively in the morning). When smaller doses are used, twice-daily insulin detemir and possibly insulin glargine will be required for 24-hour coverage.^{93–95} This method theoretically provides insulin similar to the insulin pump works: constant basal levels plus small boluses for meals and snacks. In doing so, it offers some of the same advantages of the pump in that it permits some degree of flexibility in the patient's lifestyle. For example, if a patient with diabetes chooses to skip a meal, he or she omits a premeal bolus; if the patient chooses to eat a larger meal than usual, he or she increases the premeal bolus. Similar dose adjustments can be made to accommodate snacks, exercise patterns, and acute illnesses. Caveat: Insulin glargine and insulin detemir must be injected separately; that is, they may not be mixed in same syringe with other insulins.

7. Should A.H. use an insulin pump or multiple insulin injections?

Indications for basal-bolus insulin therapy are listed in Table 50-12. Patients with type 1 diabetes should be placed on a basal-bolus insulin regimen. A.H. is an ideal candidate to strive for an HbA_{1c} <6%. She is newly diagnosed, has not yet

Table 50-11 Empiric Insulin Doses**Estimating Total Daily Insulin Requirements**

These are initial doses only; they must be refined using SMBG results.

Patients may be particularly resistant to insulin if their blood glucose concentrations are high (glucose toxicity); once glucose concentrations begin to drop, insulin requirements often decrease precipitously. The weight used is actual body weight. Insulin dose requirements can change dramatically over time depending on circumstances (e.g., a growth spurt, modest weight gain or loss, illness).

Type 1 diabetes

| | |
|---|------------------|
| Initial dose | 0.3–0.5 unit/kg |
| Honeymoon phase | 0.2–0.5 unit/kg |
| With ketosis, during illness, during growth | 1.0–1.5 units/kg |

Type 2 diabetes

| | |
|-------------------------|------------------|
| With insulin resistance | 0.7–1.5 units/kg |
|-------------------------|------------------|

Estimating Basal Insulin Requirements

These are empiric doses only and should be adjusted using appropriate SMBG results (fasting or premeal). Basal requirements vary throughout the day, often increasing during the early morning hours. Basal requirements are approximately 50% of total daily insulin needs. The basal requirement also is influenced by the presence of endogenous insulin, the degree of insulin resistance, and body weight. The basal insulin dose is approximately 50% of total daily dose.

Estimating Premeal Insulin Requirements

The “500 rule” estimates the number of grams of carbohydrate that will be covered by 1 unit of rapid-acting insulin. The rule is modified to the “450 rule” if using regular insulin.

$500/\text{total daily dose of insulin (TDD)} = \text{number of grams covered}$

Example: For a patient using 50 U/day, $500/50 = 10$. Therefore, 10 g carbohydrate would be covered by 1 unit of insulin lispro, glulisine, or aspart. This equation works very well for type 1 patients in estimating their premeal insulin requirements. Because patients with type 2 diabetes have insulin resistance, the rule may underestimate their insulin requirements.

Determining the “Correction Factor”

Supplemental doses of rapid-acting insulin are administered to acutely lower glucose concentrations that exceed the target glucose concentration. These doses must be individualized for each patient and again are based on the degree of sensitivity to insulin action. For example, if the premeal or bedtime blood glucose target is 140 mg/dL and the patient’s value is 190 mg/dL, additional units of insulin might be added to the premeal dose or an additional supplemental bedtime dose of rapid-acting insulin might be given. The correction factor determines how far the blood glucose drops per unit of insulin given and is known as the “1700 rule.” For regular insulin, the rule is modified to the “1500 rule.” The equation is as follows:

$1700/\text{TDD} = \text{point drop in blood glucose per unit of insulin}$

Example: If a patient uses 28 U/day of insulin, their correction factor (or insulin sensitivity) would be $1700/28 = 60$ mg/dL. Therefore, the patient can expect a 60 mg/dL drop for every unit of rapid acting insulin administered. Patients with a higher sensitivity factor have lower insulin requirements. Individuals with a lower sensitivity factor (higher insulin requirements) typically achieve a smaller reduction in blood glucose per unit of insulin.

SMBG, self-monitored blood glucose; TDD, total daily dose.
Adapted from references 88, 92, and 102.

Table 50-12 Basal-Bolus (Physiological) Insulin Therapy: Indications and Precautions**Patient Selection Criteria**

Type 1, otherwise healthy patients (>7 years of age) who are highly motivated and compliant individuals. Must be willing to test blood glucose concentrations multiple times daily and inject 4 doses of insulin daily, on average

Women with diabetes who plan to conceive

Pregnant patients with diabetes (pre-existing)

Patients poorly controlled on conventional therapy (includes type 2 patients)

Technical ability to test blood glucose concentrations

Intellectual ability to interpret blood glucose concentrations and adjust insulin doses appropriately

Access to trained and skilled medical staff to direct treatment program and provide close supervision

Avoid or Use Cautiously in Patients Who Are Predisposed to Severe Hypoglycemic Reactions or in Whom Such Reactions Could be Fatal

Patients with counter-regulatory insufficiency

β -Adrenergic blocker therapy

Autonomic insufficiency

Adrenal or pituitary insufficiency

Patients with coronary or cerebral vascular disease

(*Note:* Counter-regulatory hormones released in response to hypoglycemia may have adverse effects in these individuals)

Unreliable, noncompliant individuals, including those who abuse alcohol or drugs and those with psychiatric disorders

developed the long-term complications of diabetes, and should derive the benefits of normoglycemia. Assuming A.H. will be able to comply with basal-bolus insulin therapy, individualized target blood glucose levels that strive for the best level of glucose control possible without placing her at undue risk for hypoglycemia should be prescribed. She must be willing to test her blood glucose concentrations four or more times daily and inject herself four times daily or learn about the use and care of an insulin pump. She also must be willing to keep detailed blood glucose and food records and participate in an extensive education program that enables her to adjust her insulin doses based on blood glucose concentrations, physical activity, and the carbohydrate content of her snacks and meals.

Transition to an insulin pump is facilitated by patients being able to attain these skills using multiple daily SC insulin injections before insulin pump initiation. The ADA recommends that the use of insulin pumps be limited to highly motivated individuals under the guidance of a health care team trained and knowledgeable in their use. Pumps offer the patient the ability to use multiple basal rates over the 24-hour period and assist with the calculation of bolus and correction insulin doses. Most studies have shown that pump therapy provides equivalent and sometimes better glycemic control than does intensive management with multiple injections.^{89,96}

Insulin pumps are particularly useful in patients with frequent, unpredictable hypoglycemia or marked dawn phenomena (see Question 20). Others have described the methods by which insulin doses are established and altered in patients using the insulin pump.^{88,91} Because A.H. has just been diagnosed,

she should be initiated on a basal-bolus SC insulin therapy. Once she has acquired these skills, she may be considered for pump therapy.

Clinical Use of Insulin

Initiating Insulin Therapy

8. How should multiple-dose insulin therapy be initiated in A.H.?

A conservative total daily dose of insulin is estimated empirically or according to guidelines similar to those listed in Table 50-12 in newly diagnosed patients. For a basal-bolus insulin regimen, insulin glargine (Lantus) or insulin detemir (Levemir) is used as the basal insulin with bolus doses of a rapid- or short-acting insulin (insulin lispro, insulin aspart, insulin glulisine or regular) given at meal time. However, the cost of insulin glargine and insulin detemir, their availability on formularies, and their incompatibility with other insulins in the same syringe may force some clinicians and patients to use NPH insulin.

During the initial visit, A.H. needs to learn how to inject her insulin (see question 10), how to test her blood glucose (Table 50-13), how and when to test her urine for ketones, and how to recognize and treat hypoglycemia (Table 50-14). She also needs to understand the importance of meal planning and the relationship between carbohydrate intake and insulin action (Table 50-15). It is very important not to overwhelm A.H. with information on the first visit. One should be particularly

Table 50-13 Self-Monitored Blood Glucose Testing: Areas of Patient Education

When and how often to test

Technique

How and when to calibrate the glucose monitor.

Review all “buttons” and their purposes. Identify battery case. Review cleaning procedures, if applicable.

Preparation

1. Calibrate monitor/set code for batch of test strips, if required.
2. Insert test strip to turn machine on (some meters require user to turn machine on).
3. Prepare all materials: tissue, strip, lancet.
4. Remember to close the lid of the strip container immediately. Strips exposed to air and moisture deteriorate rapidly.
5. Wash hands with warm water. *Dry thoroughly.* A wet finger causes blood to spread rather than form a drop. Milk the finger from the base to ensure an adequate flow of blood.
6. Lance the tip of the finger. Avoid the pads of the finger where nerve endings are concentrated.
7. Hold the finger *below* the heart with the lanced area pointing toward the floor.
8. Once a sufficient amount of blood is available, *quickly* apply blood to designated area of the test strip. Depending on the strip type, the blood sample is placed in an area on the surface of the strip or it is applied to the side of the strip where it is taken up by capillary action.

Record results in a log book and bring to all clinician visits. Include relevant information regarding diet or exercise.

How to use results to achieve normoglycemia

Table 50-14 Hypoglycemia

Definition

Blood glucose concentration <60 mg/dL: Patient may or may not be symptomatic. Blood glucose <40 mg/dL: Patient is generally symptomatic. Blood glucose <20 mg/dL can be associated with seizures and coma.

Signs and Symptoms

Blurred vision, sweaty palms, generalized sweating, tremulousness, hunger, confusion, anxiety, circumoral tingling, and numbness.

Patients vary with regard to their symptoms. Behavior can be confused with inebriation. Patients become combative and use poor judgment.

Nocturnal hypoglycemia: nightmares, restless sleep, profuse sweating, morning headache, morning “hangover.” In one study, 80% of patients with nocturnal hypoglycemia had no symptoms.

Clinical Considerations

Irregular eating patterns

↑ Physical exercise

Gastroparesis (delayed gastric emptying)

Defective counter-regulatory responses

Excessive dose of sulfonylurea

Alcohol ingestion

Drugs

Treatment

Ingest 10–20 g rapidly absorbed carbohydrate. Repeat in 15–20 min if glucose concentration remains <60 mg/dL or if patient is symptomatic. Follow with complex carbohydrate/protein snack if meal time is not imminent.

The following are examples of food sources that provide 15 g of carbohydrate:

| | |
|---|----------------|
| Orange, grapefruit, or apple juice; regular, nondiet soda | 1/2 cup |
| Fat-free milk | 1 cup |
| Grape juice, cranberry juice cocktail | 1/3 cup |
| Sugar | 1 T or 3 cubes |
| Lifesavers | 5–6 pieces |
| Glucose tablets | 3–4 tablets |

If patient is unconscious the following measures should be initiated:

Glucagon 1 mg SC, IM, or IV (mean response time, 6.5 min)

Glucose 25 g IV (dextrose 50%, 50 mL; mean response time, 4 min)

IM, intramuscular; IV, intravenous; SC, subcutaneous.

sensitive to the psychological impact of this diagnosis on A.H., address her major concerns, and provide only the information that is absolutely essential before the next visit. Between visits, she should be assessed and provided information on an as-needed basis by phone. Table 50-16 lists important areas of patient education.

A reasonable first approach for A.H. is to provide a total daily dose of insulin of 24 units (~0.5 unit/kg). Because 50% of the daily dose should be given as basal insulin with the remainder given as rapid-acting insulin divided into three doses, A.H. would take the following: 12 units of insulin glargine (Lantus) once daily (morning or bedtime) with 4 units of insulin aspart (Novolog) given with each meal. An alternative regimen using NPH would be 8 units of NPH in the morning with 8 units of Novolog, 4 units of Novolog with dinner, and

Table 50-15 Interpreting Self-Monitored Blood Glucose Concentrations^a

| Test Time | Target Insulin Dose | Target Meal/Snack |
|------------------------|--|----------------------------|
| Prebreakfast (fasting) | Predinner/bedtime intermediate- or basal insulin | Bedtime snack |
| Prelunch | Prebreakfast regular or rapid-acting insulin | Breakfast/midmorning snack |
| Predinner | Prebreakfast intermediate-acting insulin and/or prelunch regular or rapid-acting insulin | Lunch/midafternoon snack |
| Bedtime | Predinner regular or rapid-acting insulin | Dinner |
| 2-hour postprandial | Premeal regular or rapid-acting insulin | Preceding meal or snack |
| 3 AM or later | Predinner intermediate-acting insulin or basal insulin if given in am | Dinner/bedtime snack |

^aConsiderations: (a) Assumes a normal meal pattern. For patients who travel, have odd working or sleeping hours, or irregular meal patterns, these rules may not apply. (b) Assumes administration of regular insulin 30–60 min before meals or rapid-acting insulin 0–15 min before meals and a normal pattern of insulin response (see for factors that can alter insulin absorption and response). (c) If prebreakfast concentrations are high, rule out reactive hyperglycemia (Somogyi reaction or posthypoglycemic hyperglycemia). Consider contribution of dawn phenomenon as well. Whenever blood glucose concentrations are high, consider reactive hyperglycemia (excessive insulin doses). (d) Consider accuracy of reported test results: (i) Do they correlate with HbA_{1c} and patient's signs and symptoms? (ii) What is the patient's compliance? Could results be fabricated? (iii) Is patient's technique appropriate? Check timing, adequate blood sample, machine, strips, and calibration (Table 50-13). (iv) Are insulin kinetics altered? (v) Meals: Consider content, quality, and regularity.

4 units of NPH at bedtime. Caveat: As A.H.'s glucose concentration returns to normal, glucose toxicity will recede and she may require less insulin.

Selecting an Insulin Syringe

9. What kind of insulin syringe should be prescribed for A.H.?

Delivery of insulin with a syringe is still the most common method of insulin administration in the United States. Insulin syringes are plastic, disposable syringes with needles that are very fine (28–31 gauge), sharp, and well lubricated to ease insertion. Needles and syringes have been improved so that insulin injections are relatively painless if proper technique is used. Less pain is associated with the smaller, 30- or 31-gauge

needles. The “dead space” (air space at the hub of the needle) has been virtually eliminated so that mixing and measuring problems previously associated with its presence are no longer a concern. The lengths of needles are 5/16 inch, 3/8 inch, or 1/2 inch. The shortest needle can be used for children or patients with little SC fat.⁹⁰ A longer needle length (1/2 inch) may be required in patients with excess abdominal fat; use of a short needle (e.g., 3/16 inch) may result in insulin leakage.

Manufacturers produce 1-, 0.5-, and 0.3-mL syringes for U-100 insulin. For patients such as A.H., using fewer than <30 units of insulin per injection, the 0.3-mL syringe is preferred for ease of reading the dose markings on the syringe. This allows the patient to measure insulin more easily. Insulin syringes are available in 1-U increments or 0.5-U increments (BD Ultra-Fine Short Needle Syringe and Precision Sure Dose, 3/10 mL only).⁹⁰ One-half-unit increments are useful for pediatric patients and for patients who are carbohydrate counting, because meal time insulin doses can be rounded to the 0.5 unit.

A 0.3-mL U-100 insulin syringe with a 5/16 inch (8 mm), 30- or 31-gauge needle should be prescribed for A.H. Needle length can be adjusted depending on patient comfort. Cost and patient preference will govern the brand selected. Subjectively, patients can “feel” the difference between different brands, or they may prefer the “ease of bubble removal,” physical characteristics, or packaging of one syringe over another.

Insulin pen and dosing devices (e.g., Innolet) are also available for injecting insulin. Pen devices are gaining in popularity because they make insulin administration much easier, especially for patients who need to take their insulin doses away from home. They also can increase dosing accuracy. These devices are useful in patients with visual or dexterity problems in whom use of a vial and syringe method is difficult. Pens eliminate the need to withdraw insulin, and the insulin dose is dialed up on the device. Pen devices are available to dose insulin in 2-U, 1-U (most), and 0.5-U increments (NovoPen Junior and HumaPen Luxura HD). Pen needles are available in 29, 30, and 31 gauge and 3/16 inch (5 mm), 1/4 inch (6 mm) 5/16 inch (8 mm), or 1/2 inch (12.7 mm) lengths.^{90,97}

Measuring and Injecting Insulin

10. How should A.H. be instructed to administer her insulin injections?

INJECTION

A.H. should prepare an area for injection. Alcohol swabs may be used to clean the rubber stopper of the insulin vial (or pen device). To inject the insulin subcutaneously, A.H. should be instructed to firmly pinch up the area to be injected (this creates a firm surface for the injection) and to quickly insert the needle perpendicularly (90-degree angle) into the center of this area. The syringe should be held toward the middle or back of the barrel, like a pencil. Anxious patients have a tendency to “choke” the hub of the syringe, and this prevents proper needle insertion. A 45-degree angle of injection may be used for infants and very thin individuals who have little SC fat, especially in the thigh area. The skin pinch should be released and the insulin injected.⁹⁷ Gentle pressure should be applied at the site of injection for 5 to 8 seconds to prevent back leakage of the insulin as the needle is removed. The site should not be massaged, because this may accelerate the absorption and onset of action of insulin (Table 50-10). When using an insulin pen or other delivery, the needle should be embedded within the skin for about 5 to 10 seconds after depressing the dosing knob to ensure full delivery of the insulin dose.

Patients who are anxious about self-injection can be helped by applying an ice cube to the site before injection or by using an injection aid. However, injection aids are generally unnecessary once the patient realizes that injections are relatively pain free with proper technique.

ROTATING INJECTION SITES

The primary sites used for injecting insulin are the lateral thigh, abdomen (avoid 2-inch radius around the navel) and upper arm. Previously, patients were advised to rotate injection sites between the arms, thighs, abdomen, and buttocks (Fig. 50-5). The ADA recommends that insulin injections be rotated within the same anatomic region to decrease chances of variability in insulin absorption.⁹⁷ Many practitioners recommend insulin injections into the abdominal area because absorption from this site is least affected by exercise and the most predictable. Alternatively, A.H. can be instructed to rotate her morning injection within one region (e.g., the abdomen) and her evening injection in another anatomic region. This minimizes the variables that can alter her response to insulin.

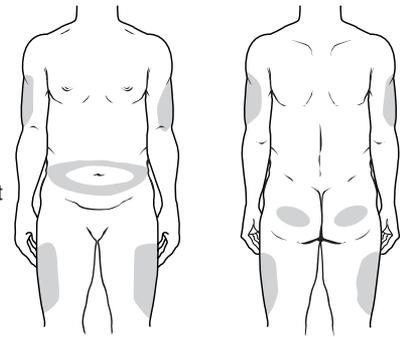

Rotating injection sites also was recommended at one time to avoid the lipodystrophic effect of insulin (lipohypertrophy and lipoatrophy); however, because insulin has been purified, these complications are less common and the importance of rotation is less critical. Nevertheless, repetitive use of the same site of injection may still result in lipohypertrophy and it does toughen the skin, making needle penetration more difficult. Furthermore, insulin absorption from lipohypertrophic sites can be slowed.⁹⁷

AGITATION

A.H. does not need to agitate Lantus or Novolog because these are clear insulins. For NPH insulin, which is a suspension, the vial must be agitated before insulin is withdrawn. A new, unused vial of NPH insulin may require vigorous agitation to loosen the sediment, which may have become packed down with storage. The vial should be rolled between the palms of the hands to minimize foaming. Agitation is only required for insulin suspensions (e.g., insulin 70/30 or other insulin mixtures).

These drawings show areas of the body most suitable for insulin injections:

The actual point of injection should be varied each time within a chosen body area. Give injections at least one inch apart (Patients should consult with their physician or diabetes educator about which area is most appropriate for use.)

Insulin is injected in the subcutaneous tissue (between the skin and the muscle layer). If the skin is pinched up and the needle is pushed all the way in, the needle will reach the proper space under the skin.

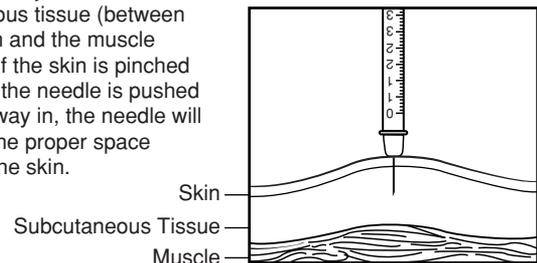

FIGURE 50-5 Selecting insulin injection sites. (Used with permission from reference 343.)

MEASUREMENT

First, A.H. should make sure her hands and the injection site are clean (it is not necessary to use alcohol to clean the site). She should withdraw the plunger to the level of insulin she intends to inject (e.g., 12 units for her Lantus dose); then she should insert the needle into the vial and inject the air to prevent creation of a vacuum within the vial. The vial then should be inverted with the syringe inserted, and 12 units of insulin glargine should be withdrawn. The bevel of the needle should be well below the surface of the insulin to avoid withdrawing air or bubbles into the syringe. Lantus must not be mixed in the same syringe with her insulin aspart, and it should be injected into a different site if it is injected at the same time as her Novolog dose.

The barrel of the syringe should be held at eye level to check for air bubbles and to allow accurate placement of the plunger tip at the 12-U mark. If bubbles are present, they should be removed by tapping the syringe gently to coax the bubbles to the top of the barrel, where they can be injected back into the insulin vial. To remove air bubbles in an insulin pen, prime the needle with 2 units of insulin before each use (repeat until insulin drop appears at tip of pen needle). Also, remove the needle from the pen device in between uses to prevent air bubbles from accumulating.

REUSING INSULIN SYRINGES AND NEEDLES

Those who work with patients with diabetes know that they are extremely resourceful in cutting their health care costs. A frequently encountered practice is the reuse of disposable syringes. In a survey of 254 adult insulin users, 45% reused their syringes for an average of 4 days, 16% refrigerated their

syringes between uses, and 35% wiped their needles with alcohol. Dullness was the major reason for changing to a new syringe. Borders et al.⁹⁸ examined approximately 2,800 injection sites, and no infection was noted.

The ADA does not encourage the reuse of syringes or pen needles. Some of the smaller 30- and 31-gauge needles seem particularly susceptible to bending and can form hooks. The ADA recommends that patients who do reuse syringes inspect injection sites for redness or swelling and to discard syringes into puncture-resistant, disposable containers if they are dull, bent, or have come in contact with surfaces other than the skin. Patients must be able to recap safely. They do not recommend refrigeration or wiping the needle with alcohol between uses, only recapping. Patients who reuse their syringes should inspect their skin for signs of infection.⁹⁷

Self-Monitored Blood Glucose

11. How should A.H. be educated to self-monitor her blood glucose? What types of self blood glucose monitoring tests are available, and what are the major differences between them? How accurate are results obtained from home blood glucose testing? Should she begin continuous glucose monitoring (CGM) at the same time?

The advent of SMBG revolutionized the management of diabetes mellitus by providing a simple and portable method for periodic and repeated measurement of blood glucose in the ambulatory care setting. The ADA recommends that most individuals with diabetes should attempt to attain and achieve normoglycemia as safely as possible. For patients with type 1 diabetes, this can be achieved by using SMBG; therefore, all treatment programs should include the routine use of daily glucose monitoring. SMBG is also important in (a) pregnancy complicated by diabetes, (b) patients with unstable diabetes, (c) patients with a propensity to severe ketosis or hypoglycemia, (d) patients prone to hypoglycemia who may not experience the usual warning symptoms, and (e) patients on insulin pumps. SMBG has been widely accepted by both patients and clinicians. Because blood glucose testing materials constitute a multimillion dollar business, the market has been flooded with a multitude of monitors, and the technology in this area is changing rapidly. New monitors with advanced features are introduced yearly.⁹⁰

All monitors use test strips and are self-timing, requiring no patient action after the blood is placed on the strip. Several factors should be taken into account when evaluating a monitor and its appropriateness for an individual. The primary considerations are ease of use, accuracy relative to a reference standard, reliability, insurance coverage, and cost.^{90,99} Convenience factors include coding requirements (some new monitors do not require coding for test strips), meter size, volume of blood required for testing, site to obtain sample (e.g., finger versus alternate site such as forearm), capacity of the meter to store blood glucose values (memory) and data management, required testing time, size of readout, general availability of strips, ability to turn off audible signals, and availability of technical support. Some devices are less reliable for use in anemic patients (e.g., renal transplant patients), and all function most reliably within certain temperature ranges (usually 60–95°F) and humidity (generally <90%) conditions. Strips

are sensitive to light, moisture, and temperature extremes and must be stored and handled with care.

Periodically, patients should compare the results they get on their monitor with the laboratory blood glucose test for accuracy. The majority of monitors are calibrated to plasma levels (i.e., plasma referenced). Only a few monitors report whole blood glucose; in these monitors, capillary values measured are likely to be 10% to 15% lower than values measured by the laboratory.

Patient education regarding coding procedures, testing procedures, the importance of recording results, and test times are critical. Ultimately, A.H. should be taught how to use blood glucose values to adjust her insulin dose, dietary intake, and exercise pattern (Table 50-17).

Used properly, available monitors provide accurate, precise results that can be used by patients to manage their diabetes. However, several factors can affect the accuracy of monitor results—most commonly, equipment malfunction and human error. Problems with a monitor can be detected by performing a quality-control test once weekly and with each new vial of strips; human error can be minimized with adequate training. If at any time patients think their monitor is not working properly, they can call the 1-800 support service number on the back of the monitor for immediate assistance. Table 50-18 lists factors that can affect results of SMBG test results. Anytime SMBG values are inconsistent with the patient's symptoms or HbA_{1c} values, sources of error should be evaluated. A.H.'s technique should be reviewed periodically, because clinical decisions are based on the patient's blood glucose testing record.

Because A.H. is just starting insulin therapy and SMBG, it would be reasonable to hold off on considering CGM until she becomes comfortable with these skills. Then, she and her practitioner could assess whether CGM would be useful.

Testing Frequency

12. How often should A.H. test her blood glucose concentrations?

Although the exact frequency and timing of blood glucose tests should be dictated by individualized patient goals, most patients with type 1 diabetes using basal-bolus insulin regimens should perform SMBG at least three times daily or more according to the ADA.²² Glucose monitoring should also be performed more frequently whenever therapy is modified. Because A.H. is being initiated on insulin therapy with the goal of normoglycemia, she should self-monitor her blood glucose a minimum of three times per day. Most practitioners recommend at least premeal and bedtime blood glucose testing (at least four times daily).

The objective of ongoing, frequent blood glucose testing is to determine whether normoglycemia is being achieved and to assess the action of specific insulin doses as well as the impact of meals, food, illness, or exercise on blood glucose levels. Ideally, patients should test their blood glucose concentration before meals, 90 to 120 minutes after meals to assess postprandial glycemic control and to determine their “insulin to carbohydrate ratio,” at bedtime, and occasionally, at 2 or 3 AM (i.e., eight times daily). However, most patients are unable to adhere to such a rigorous regimen. At the minimum, to determine her daily insulin requirements, A.H. should test her blood glucose concentrations four times daily: before each

Table 50-17 Guidelines for Dosing Insulin**Basic Insulin Dose**

First, adjust the basic insulin dose (i.e., the dose that the patient will be instructed to take daily). This assumes that diet and physical activity are stable. Set a reasonable goal initially. This may mean the upper limits of the acceptable concentrations may be high initially (e.g., <200 mg/dL). Move toward a more ideal goal slowly.

Only adjust insulin doses if a *pattern* of response is observed under stable diet and exercise circumstances. That is, the same response to insulin is observed for ≥ 3 days. It is important to verify the stability of diet and exercise. Consider adjusting these variables as well.

Unless all levels are >200 mg/dL, try to adjust one component of insulin therapy at a time.

Start with the insulin component affecting the fasting blood glucose concentration. This glucose level often is the most difficult to control and often affects all other glucose concentrations measured throughout the day.

Adjust the basic insulin dose by 1–2 units at a time. The amount prescribed is based on the individual patient's response to insulin. This can be determined by looking at the patient's total daily dose using the "500 rule" (see the following, and Table 50-11).

Supplementary Insulin Doses

Once the basic dose of insulin has been established, supplemental doses of rapid- or short-acting insulin can be prescribed to correct *preprandial* hyperglycemia. For example, if the goal is 140 mg/dL, and the glucose value is 190 mg/dL, administer one additional unit. Supplemental doses also can be used when the patient is ill (Table 50-22).

Algorithms for correction doses are based on the patient's sensitivity to insulin using the "1500 or 1700 rule" (Table 50-11).

If premeal glucose concentrations are <60–70 mg/dL, the dose of lispro, aspart, glulisine, or regular insulin administered before the meal is \downarrow by 1–2 U; insulin administration is delayed until just before the meal; the meal should include an extra 15 g of glucose if the value is <50 mg/dL.

If supplemental doses before a given meal are required for ≥ 3 days, the basic insulin dose should be adjusted appropriately. For example, if a patient taking lispro before meals requires an extra 2 units before lunch for ≥ 3 days, 2 units should be added to the prebreakfast dose.

Anticipatory Insulin Doses

The basic insulin dose is increased or decreased based on the anticipated effects of diet or physical activity.

Increase lispro/aspart/glulisine or regular insulin by 1 unit for each additional 15 g of carbohydrate ingested (e.g., holiday meal) or decrease the usual dose by 1–2 units if the meal is smaller than usual (Table 50-11).

See Table 50-21 for recommended insulin adjustments for exercise.

meal and at bedtime. She also should set her alarm for 3 AM two or three times per week and test her blood glucose. Blood glucose concentrations measured premeals allow patients and clinicians to determine if the rapid-acting insulin dose is appropriate for the amount of carbohydrate consumed; FPG levels are used to determine if the basal insulin dose is adequate; and the 2 to 3 AM blood glucose level is used to identify nocturnal hypoglycemia. For example, the blood glucose measured before dinner reflects the action of A.H.'s prelunch Novolog dose on food she has eaten for lunch, as well as hepatic glucose production between meals. Increasingly, patients who use

carbohydrate counting with rapid-acting insulins are being advised to test 2-hour postprandial levels on initiating therapy to enhance proper dosage adjustment (Table 50-15).

The importance of frequent blood glucose testing cannot be overemphasized. When blood glucose is tested less frequently than four times daily, glucose control deteriorates to baseline levels. This is because complete profiles are no longer available, and it is impossible to adjust insulin doses based on random blood glucose concentrations.¹⁰⁰ If patients refuse to test four times daily, they should be encouraged to test four times daily on representative days of the week or to test at different times of the day each day so that a weekly profile can be developed. A.H. also should be encouraged to test her blood glucose concentration any time she is feeling unusual, if she is experiencing hypoglycemic symptoms, or to evaluate the effect of unusual circumstances on her blood glucose concentration (e.g., increased physical exercise, a large holiday meal, final examinations, a family crisis).

Using Blood Glucose Test Results to Evaluate Insulin Doses

13. A.H. was instructed to inject herself with 12 units of Lantus each morning and give 4 units of Novolog with each meal. She was asked to test her blood glucose four times daily (before meals and at bedtime), to record her results and other unusual events or symptoms during the day, and to bring her records to the clinic. A.H. was also instructed to keep a food diary and record the number of carbohydrates she ingested at each meal. The initial goal of therapy is to achieve preprandial blood glucose concentrations of <180 mg/dL and to eliminate symptoms of hyperglycemia. One week later, trends in her blood glucose concentrations were as follows.

| Time | Glucose Concentration (mg/dL) | mmol/L |
|-------|-------------------------------|----------|
| 7 AM | 160–200 | 8.8–11.1 |
| Noon | 220–260 | 2.2–14.4 |
| 5 PM | 130–180 | 7.2–10.0 |
| 11 PM | 140–180 | 7.8–10.0 |

Occasional 3 AM tests averaged 160 mg/dL and A.H.'s urine is negative for ketones. She eats approximately four carbohydrate servings for breakfast (60 g) and two to four carbohydrate servings for lunch and dinner (30–45 g). Subjectively, A.H. feels a bit better, and her weight has stabilized, but she still urinates two to three

times nightly. How would you interpret these results, and how should A.H.'s insulin doses be altered?

Health care providers should use the data obtained from self-monitoring to (a) set glycemic goals, (b) develop recommendations for pharmacologic therapy, (c) evaluate the effectiveness of pharmacologic therapy, (d) instruct patients to interpret and respond to blood glucose patterns, (f) evaluate the impact of dietary factors on glycemic control, (g) modify therapy during acute/intercurrent illness or whenever patients receive medications known to affect glycemic control, (h) modify the management plan in response to a change in activity levels, and (i) identify hypoglycemic unawareness.⁵⁹

Before using A.H.'s blood glucose results to adjust her insulin dose, it is important to observe and reassess her testing technique. One also should determine whether there were any unusual circumstances in her life, diet changes, or exercise patterns over the past week that might have affected her response to insulin. Once these have been ruled out as confounding factors, one can begin making gross adjustments in A.H.'s insulin dose, realizing that fine-tuning will be impossible until a consistent diet and exercise pattern have been instituted.

Several principles must be kept in mind whenever blood glucose tests are used to adjust a patient's basic insulin dose (Table 50-19). Because many factors can alter a patient's response to insulin, it is important to use blood glucose concentration *trends* measured over a minimum of 3 days to adjust the basic insulin dose (i.e., the dose the patient will use every day). The only exception to this rule is the use of supplemental insulin doses to correct exceptionally high glucose concentrations after A.H. has acquired sophisticated insulin adjustment skills (see Questions 18 and 19). SMBG results should be evaluated in conjunction with other parameters such as HbA_{1c} and periodic laboratory blood glucose measurements.

The daily dose of Lantus is inadequately controlling A.H.'s fasting blood glucose and should be increased to by 2 to 4 U. Although published algorithms would recommend to increase her dose to 16 units each morning, a more conservative approach would be to increase it to 14 units (or bedtime, whichever she will be able to do consistently) and further titrate as needed.¹⁰¹ She is achieving some response from her lunchtime dose of Novolog, but there is room for improvement in her meal insulin coverage overall. The blood glucose concentration of 160 mg/dL at 3 AM indicates that rebound hyperglycemia is an unlikely cause of her high fasting levels (see Questions 15 and 20). As an initial step toward control, A.H.'s daily dose of Lantus could be increased in an attempt to control her fasting hyperglycemia. However, this approach does not address A.H.'s elevated prelunch values. Her intake of carbohydrates also varies from meal to meal. Thus, a more appropriate method would be to calculate the insulin-to-carbohydrate ratio for A.H. and allow her to determine her premeal Novolog dose based on the amounts of carbohydrates she will ingest at each meals. A typical starting point for the insulin-to-carbohydrate ratio is 1 unit to every 15 g carbohydrate. To calculate her insulin-to-carbohydrate, the "500 rule" is used: Divide the number 500 by her total daily dose of insulin (14 units Lantus plus 12 units of Novolog for meal coverage = 26 units):

$$500/26 = 19 \text{ g of carbohydrate covered by 1 unit of insulin}$$

Because most single servings of carbohydrate contain 15 g, A.H. decides to start with a ratio of 1 unit for every 15 g or

Table 50-19 Factors That Can Alter Blood Glucose Control

Diet

Insufficient calories (e.g., alcoholism, eating disorders, anorexia, nausea, and vomiting)
Overeating (e.g., during the holidays)
Irregularly spaced, skipped or delayed meals
Dietary content (e.g., fiber, carbohydrate content)

Physical Activity

See Table 50-21 and Question 29

Stress

Infection
Surgery/trauma
Psychological

Drugs

Certain medications can increase or decrease blood glucose levels. It is important to assess for potential effects on the blood glucose when starting new medications.

Hormonal Changes

Menstruation: Glucose concentrations may increase premenstrually and return to normal postmenses.
Pregnancy
Puberty: hyperglycemia probably related to high growth hormone levels

Gastroparesis

Delays gastric emptying time. Peak insulin action and meal-related glucose excursions may become mismatched.

Altered Insulin Pharmacokinetics

See Table 50-10

Improperly stored insulin (heat or cold)
Crystallized insulin

single serving of carbohydrates she consumes at each meal. If A.H. were using regular insulin for meal coverage, she could use the "450 rule": $450/\text{total daily insulin dose} = \text{grams of carbohydrate covered by 1 unit of insulin}$.

To evaluate the accuracy of her insulin:carbohydrate ratio, A.H. will need to check her blood glucose values 2 hours after each meal (postprandial blood glucose checks) to assess the appropriateness of her meal insulin calculation. She agrees to test her blood glucose level eight times per day and return in 2 weeks.

14. A.H. is getting more comfortable with carbohydrate counting and adjusting her insulin doses accordingly. A review of her

food diary reveals that for the most part, she is able to determine the appropriate serving sizes for 15 g of carbohydrate. She admits to difficulty determining carbohydrate amounts when eating out. As a result, A.H. notices that her preprandial blood glucose concentrations exceed her goal of 80 to 120 mg/dL on occasion. Sometimes they are as high as 200 mg/dL. Evaluate A.H.'s blood glucose trends. How should occasional preprandial glucose concentrations that exceed the desired goal of 80 to 120 mg/dL be managed?

Once the basal insulin dose and insulin-to-carbohydrate insulin dose have been established, one can begin to teach A.H. how to use a correction factor to adjust her dose of insulin when preprandial blood glucose concentrations fall above or below the range of blood glucose concentrations that have been established as her goal of therapy (70–130 mg/dL per the ADA or roughly 80–120 mg/dL; Table 50-17).

A correction insulin dose is used to compensate for unusually high blood glucose concentrations (high sugar correction). To reemphasize, this assumes there are no unusual changes in the patient's overall diet or exercise patterns. Many clinicians favor rapid-acting insulin over regular insulin because its action is brief and patients do not have to worry about residual effects 3 to 4 hours after its injection. This is particularly valuable when correctional doses of insulin are needed at bedtime.

The patient's sensitivity to insulin, as reflected by his or her total daily dose on a unit per kilogram basis is a major determinant of any algorithm developed. Previously, it was advised that 1 to 2 units of supplemental insulin should be given for each 30 to 50 mg/dL elevation above the target level. However, this relationship was observed to apply only to a person of average size on average doses of insulin (i.e., the 70-kg patient on 50 U/day of insulin). A very small person on 10 U/day or a very obese individual with type 2 diabetes on 100 U/day has different responses to a given dose of insulin. An alternative method of estimating the drop in a person's blood glucose per unit of regular insulin is the "1500 rule."⁸⁸ The 1500 rule was developed by Paul Davidson, MD, in Atlanta, Georgia, during the 1990s. The derived value is referred to as the "sensitivity factor": The rule was modified to the "1800 rule" for use with rapid-acting insulin (insulin lispro, aspart, or glulisine). Because these insulins tend to drop the blood glucose level faster and farther, so 1500 turns out to be too aggressive. Others (e.g., Bruce Bode, John Walsh) have recommended other numerators such as 1600, 1700, 2000, and 2200.¹⁰² For this case, the "1700 rule" will be used. The calculation for A.H. would be as follows:

$$1700/24 = 70 \text{ mg/dL}$$

Thus, 1 unit of regular insulin for A.H. will drop her blood glucose level by about 70 mg/dL. The 1500 rule and the 1700 rule have proved to be a valuable way to initiate an algorithm for supplemental insulin. People with a lower sensitivity factor (higher insulin requirements) typically achieve a smaller reduction in blood glucose per unit of insulin compared to those with a higher sensitivity factor (lower insulin requirement). Thus, an algorithm of 1 unit of regular insulin for every 70 mg/dL excursion above her goal of 120 mg/dL is a reasonable place to begin. If this dose of insulin is insufficient, one can increase the dose of insulin or decrease the blood glucose excursion required per unit of insulin dose. Correctional insulin

doses also are used for sick day management (see Question 30). The following is an example of an algorithm for A.H.:

| Glucose Concentrations (mg/dL) | Insulin Aspart |
|--------------------------------|----------------|
| <80 | 1 unit less |
| 80–120 | Usual dose |
| 120–190 | 1 unit extra |
| 191–260 | 2 units extra |
| 261–330 ^a | 3 units extra |
| 331–400 ^a | 4 units extra |

^aCheck urine ketones. If urine ketones are positive and blood glucose concentrations remain >300 mg/dL for ≥12 hours, call the physician for directions.

Evaluating Fasting Hyperglycemia

15. A.H. returns after 1 month. She is currently using 14 units of Lantus each morning, 1 unit of Novolog for each 15 g of carbohydrate ingested at meal time and a correction factor of 1 unit of Novolog for every 70 mg/dL above 120 mg/dL. Her SMBG results are as follows:

| Time | Glucose Concentration mg/dL | mmol/L |
|-------|-----------------------------|----------|
| 7 AM | 140–180 | 7.8–10.0 |
| Noon | 120–150 | 6.7–8.3 |
| 5 PM | 90–130 | 5.0–7.2 |
| 11 PM | 90–120 | 5.0–6.7 |
| 3 AM | 60–90 | 3.3–5.0 |

Overall, A.H. feels her diabetes is in good control. Her energy level has returned to normal and her nocturia has diminished, but she occasionally gets up one or two times nightly to urinate. A.H. has also noticed that nightmares or "sweats" sometimes awaken her. When this occurs, she generally has something to eat because she is "famished." She is able to get back to sleep, but wakes up the next morning with a "splitting headache" and a "hungover" feeling. A.H.'s weight remains the same, and she has begun to develop some consistency in her dietary patterns with the help of a dietitian. She has been consistently correcting her prelunch and predinner insulin doses by adding or subtracting 2 units from her premeal insulin doses based on her carbohydrate counts. The HbA_{1c} from her last visit is 7.3%. Evaluate A.H.'s blood glucose values. What are possible causes of A.H.'s fasting hyperglycemia?

When evaluating morning hyperglycemia, several causes must be considered:

- An insufficient basal dose of insulin. If the basal dose is insufficient, hepatic glucose output during the fasting state will be excessive, thereby producing hyperglycemia.
- Reactive hyperglycemia in response to a nocturnal hypoglycemic episode (Somogyi effect or rebound hyperglycemia).
- An excessive bedtime snack.
- The dawn phenomenon (see Question 20).
- Somogyi effect or rebound hyperglycemia

The presence of normoglycemia at bedtime, low blood glucose concentrations at 3 AM, and symptoms of nocturnal hypoglycemia (nightmares, sweating, hunger, morning headache) in A.H. are consistent with a rebound hyperglycemic reaction in the morning (i.e., posthypoglycemic hyperglycemia; Somogyi effect).¹⁰³ Theoretically, this effect occurs after any episode of severe hypoglycemia and is secondary to an excessive increase in glucose production by the liver that is

activated by insulin counter-regulatory hormones such as cortisol, glucagon, epinephrine, and growth hormone. The waning effects of the basal insulin dose can also be a cause of fasting hyperglycemia because insulin is needed to suppress hepatic glucose output during the fasting state; however, this is not likely in A.H.'s.⁹³ Asymptomatic nocturnal hypoglycemia can occur in 33% of patients taking evening doses of insulin and may account for morning hyperglycemia in more than 10% of patients. Another potential consequence of nocturnal hypoglycemia is prolonged insulin resistance (perhaps a consequence of glucose toxicity), as signified by high postbreakfast glucose concentrations. By correcting the nocturnal hypoglycemia, normalization of A.H.'s fasting hyperglycemia also may be achieved. Thus, a decrease in the daily dose of Lantus by 2 units is warranted. A.H. should continue to monitor her blood glucose concentrations at 3 AM.

Caveat: If A.H. were using NPH BID to supply her basal insulin, one option would be to shift the evening injection of NPH from predinner to bedtime. This preferred method effectively shifts the peak action of NPH to the early morning, when she is awake, and decreases the risk of nocturnal hypoglycemia.^{92,104} This peak action also corresponds to the dawn phenomenon (see Question 20) and the breakfast meal.

Another option if a patient is using NPH and experiencing nocturnal hypoglycemia is to change from NPH to either insulin glargine (Lantus) or insulin detemir (Levemir) because these insulins are associated with less nocturnal hypoglycemia.^{105,106} In this case, the daily dose of NPH should be decreased by 20% to determine the Lantus dose. When switching from NPH to Levemir, a one-to-one dose conversion may be used, although higher doses of Levemir may be required. In one cross-over study of type 1 diabetes patients, the average Levemir basal dose was approximately double that of the NPH basal dose.¹⁰⁷

Mixing Insulins

16. If A.H. were to use NPH as basal insulin, how should she be instructed to measure and withdraw this insulin mixture?

The procedure used to mix and withdraw NPH and mealtime insulin (regular or rapid-acting insulin) is basically the same as that described in Question 8. The major difference is that an adequate volume of air must be injected into the NPH vial before the regular or insulin aspart is measured and withdrawn. Also, the mealtime clear insulin is measured and withdrawn into the insulin syringe *first* to avoid contamination of the vial of regular, aspart, lispro, or glulisine insulin with NPH. For example, contamination with NPH ultimately alters the NPH:regular insulin ratio that is administered. When patients withdraw NPH insulin first, the vial of regular insulin eventually becomes cloudy. In contrast, contamination of the NPH insulin with regular insulin probably is insignificant because the protamine contained in NPH can bind the regular insulin (see Question 17). The procedure A.H. should use to mix her insulins is described in the following section, using her morning dose as an example.

- After dispersing the NPH insulin suspension, inject 14 units of air into the NPH vial and withdraw the needle.
- Inject 7 units of air into the insulin aspart or regular insulin vial, and withdraw the 7 units of insulin as described in Question 10.

Table 50-20 Compatibility of Insulin Mixtures

| Mixture | Proportion | Comments |
|-------------------------------------|--------------------------------|---|
| Regular + NPH | Any proportion | The pharmacodynamic profiles of regular and NPH insulin are unchanged when premixed and stored in vials or syringes for up to 3 months. |
| Regular + normal saline | Any proportion | Use within 2–3 hours of preparation. |
| Regular + insulin diluting solution | Any proportion | Stable indefinitely. |
| Rapid-acting + NPH | Any proportion | The absorption rate and peak action of the rapid-acting insulins are blunted; total bioavailability is unaltered. Rapid-acting insulin and NPH should be mixed just before use (within 15 minutes). |
| Insulin glargine and detemir | Do not mix with other insulins | Pharmacodynamics could be modified. |

- Insert the needle into the NPH vial, and pull the plunger down to the 21-U mark (14 units of NPH plus 7 units of mealtime insulin).

Stability of Mixed Insulins

17. Will mixing NPH with a rapid-acting or regular insulin blunt the rapid action of the mealtime insulins? How stable are other insulin mixtures (Table 50-20)?

Regular insulin and all of the rapid-acting insulin analogs (aspart, lispro, and glulisine) may be mixed with NPH. In general, it is recommended to mix the insulins just before administration.

REGULAR PLUS NPH

The onset and duration of action of regular and NPH insulin administered as a mixture are similar to those observed when the two insulins are administered by separate injections. The pharmacodynamic profiles of these insulins are retained in premixed preparations stored in vials or syringes for 3 months (Table 50-20).^{97,108} This is true even though protamine in NPH binds regular insulin *in vitro*.

RAPID-ACTING INSULIN PLUS NPH

Insulin aspart, glulisine, and lispro are compatible with human NPH insulin manufactured by NovoNordisk (Novolin N), and Eli Lilly and Company (Humulin N). However, relative to aspart, glulisine, and lispro alone, the absorption rate is slowed and the peak concentrations are blunted. The total bioavailability is unaltered. The manufacturers recommend mixing the two insulins just before administration, which should be scheduled 15 minutes before meals. The compatibility of insulin aspart, glulisine, and lispro with other brands of human NPH insulin or animal source NPH is unknown.^{77–79,97}

RAPID-ACTING INSULIN PLUS INSULIN GLARGINE

The long-acting insulin glargine (Lantus) must not be mixed with any other insulins. If Lantus is mixed or diluted with other insulins, its pH will be increased, which will affect its absorption kinetics. The onset of action and duration of effect may be altered unpredictably.⁹³ However, small studies with pediatric patients have demonstrated that insulin glargine when mixed with a rapid-acting analog is effective for glycemic control.¹⁰⁹

INSULIN GLARGINE

Insulin glargine is a long-acting analog that is soluble at pH 4.0; it is designed to precipitate when injected into the neutral pH of subcutaneous tissue. Because all other insulin products have a pH of 7.0, it should not be mixed in the same syringe with other insulins.⁹³

INSULIN DETEMIR

Insulin detemir should not be mixed or diluted with any other insulin.¹¹⁰

Midmorning Hyperglycemia

18. Evaluate A.H.'s noon blood glucose concentration of 120 to 150 mg/dL.

Midmorning hyperglycemia frequently represents the maximum glucose excursion in patients with diabetes and often is the most difficult to manage. The following are possible explanations for midmorning hyperglycemia:

- An insufficient dose of Novolog insulin before breakfast. For A.H., this means that her insulin-to-carbohydrate ratio needs to be adjusted.
- Poor synchrony between meal intake and insulin action. This could be caused by administration of rapid-acting insulin too long before or after the meal (e.g., ≥ 30 minutes). If regular insulin is used, this could be caused by administering regular insulin just before or after meals.
- Delayed onset of Novolog insulin owing to binding with insulin-blocking antibodies.³³⁹ Because A.H. is a newly diagnosed patient with diabetes, it is unlikely that she has developed significant concentrations of insulin-blocking antibodies.
- An insufficient dose of evening Lantus insulin to suppress hepatic glucose production (glycogenolysis and gluconeogenesis) during the fasting state or the dawn phenomenon (see Question 20).
- Excessive carbohydrate ingestion at breakfast.
- Increased peripheral resistance to insulin action caused by high fasting glucose levels (glucose toxicity).

When evaluating midmorning hyperglycemia, it is important to remember that the FPG concentration can contribute up to 50% of this plasma glucose excursion. Therefore, a key to the control of midmorning hyperglycemia may be to normalize the fasting glucose concentration.

Since insulin glargine has been decreased to correct the morning reactive hyperglycemia, this should be the approach used for A.H.

If control of her fasting hyperglycemia does not correct the midmorning hyperglycemia, the following interventions may be considered:

- Increase the dose of Novolog before breakfast. Her insulin-to-carbohydrate ratio should be changed to 1 unit of Novolog for every 12 g of carbohydrate for each meal.
- If regular insulin were used, inject the morning dose of regular insulin 45 to 60 minutes before breakfast in an attempt to match peak insulin concentrations with postmeal glucose excursions. If this maneuver is used, the patient should be warned of possible hypoglycemia before breakfast.
- Alter the carbohydrate content of the meals. This may include decreasing the amount of carbohydrate in the breakfast meal, changing the type of carbohydrate ingested, or adding fiber to that meal to minimize glucose excursions.

Preprandial Hypoglycemia: Use of Rapid-Acting Insulin

19. A.H. is now taking Lantus 12 units each night and using an insulin-to-carbohydrate ratio of 1:15 (1 unit of Novolog for every 15 g of carbohydrate) for each meal. She is continuing with the same high sugar premeal correction of 1 unit of Novolog for every 70 mg/dL over her premeal blood glucose target of 120 mg/dL. Two weeks later, she brings in her blood glucose concentration records.

| Time | Glucose Concentration (mg/dL) | mmol/L |
|-------|-------------------------------|---------|
| 7 AM | 110–120 | 6.1–6.7 |
| Noon | 90–110 | 5.0–6.1 |
| 5 PM | 60–110 | 3.3–6.1 |
| 11 PM | 80–110 | 4.4–6.1 |
| 3 AM | 80–110 | 4.4–6.1 |

A.H. feels that she is now “back to normal.” She has no signs or symptoms of hyperglycemia, and her weight has remained stable. Occasionally, she becomes hypoglycemic before dinner, but this most often occurs when her dinner is delayed because of a hectic work schedule. Evaluate A.H.'s blood glucose trends. What could be the cause of her predinner hypoglycemia and how could she be managed?

A.H.'s blood glucose concentrations indicate that her basic insulin regimen is generally adequate to achieve the overall goal of preprandial blood glucose concentrations of less than 120 mg/dL. Note that correction of A.H.'s FPG concentration ultimately corrected her midmorning hyperglycemia. In fact, if one were to evaluate A.H.'s blood glucose concentrations from the previous visit, it is evident that the prebreakfast dose of Novolog was working well. This domino effect on blood glucose concentrations emphasizes the importance of correcting one blood glucose concentration at a time.

The hypoglycemia A.H. is experiencing before dinner could be caused by insufficient carbohydrate intake at lunch, increased activity during the day, or an excessive dose of Novolog insulin (insulin-to-carbohydrate ratio too high). Thus, the problem could be resolved by augmenting A.H.'s lunch meal, adjusting the lunch insulin-to-carbohydrate ratio to 1 unit of Novolog for every 18 (or 20) g carbohydrate, or adding a midafternoon snack.

Dawn Phenomenon

20. R.D., a 37-year-old man, has had type 1 diabetes since age 14. Over the past 2 years, he has been very well controlled on the following insulin regimen: 20 units Lantus each morning with 3 to 4 units insulin lispro depending on carbohydrate intake before

meals. On this regimen, his blood glucose concentrations for the past 2 weeks have been as follows.

| Time | Glucose Concentration (mg/dL) | mmol/L |
|-------|-------------------------------|---------|
| 7 AM | 140–170 | 7.8–9.4 |
| Noon | 100–120 | 5.5–6.7 |
| 5 PM | 100–130 | 5.5–7.2 |
| 11 PM | 115–140 | 6.4–7.8 |
| 3 AM | 100–120 | 5.5–6.7 |

What are the likely causes of R.D.'s fasting hyperglycemia?

As discussed in question 15, fasting hyperglycemia may be the result of insufficient doses of insulin in the evening, a decline in the effect of insulin over time, and, possibly, reactive hyperglycemia. In R.D.'s case, the dawn phenomenon also must be considered.¹¹¹ The *dawn phenomenon* is a rise in the blood glucose concentration that occurs between 4 and 8 AM after a physiological nadir in the blood glucose concentration that occurs between midnight and 3 AM. This 30 to 40 mg/dL increase in the morning blood glucose concentration cannot be attributed to increases in counter-regulatory hormones secondary to an antecedent hypoglycemic event, but it may be secondary to rising growth hormone levels. This phenomenon is inconsistently observed in individuals with types 1 and 2 diabetes as well as nondiabetic individuals; furthermore, it is inconsistently present from one day to the next.¹¹²

R.D.'s normal 3 AM blood glucose concentration indicates that posthypoglycemic hyperglycemia is an unlikely cause of his fasting hyperglycemia. Thus, the modest increase in his blood glucose concentration between 3 and 8 AM may be attributed to the waning effects of insulin or the dawn phenomenon. In both cases, an increase in R.D.'s daily dose of insulin glargine would be indicated. Another option would be to switch R.D. to an insulin pump. He has demonstrated a desire and ability for intensive management with multiple daily injections, frequent blood glucose monitoring, record-keeping skills, the ability to make appropriate insulin dose adjustments, and accurate carbohydrate counting. The advantage to using a pump is the ability to program an increase in the basal infusion rate at approximately midnight. Because it takes 3 to 4 hours to observe a biologic response following a change in the infusion rate, the response would occur at approximately 3 to 4 AM, when the dawn phenomenon begins.¹¹³

Type 1 Diabetes in Children

Diagnosis and Clinical Presentation

21. J.C., a 7-year-old, 30-kg (95th percentile), 50 inches tall (90th percentile) girl, was brought to the emergency department (ED) by her parents because of nausea, vomiting, and a persistent "stomach ache" secondary to the flu. For the past week, J.C. had flu-like symptoms, resulting in a 6-lb weight loss. Initial laboratory values revealed a blood glucose of 600 mg/dL, serum pH of 6.8 with bicarbonate level of 13 mEq/L, plasma ketone level of 5.2 mmol/L, and positive ketonuria. J.C. was diagnosed with diabetic ketoacidosis (DKA) secondary to new-onset type 1 diabetes. In retrospect and on further questioning, J.C.'s parents realized that she probably had symptoms as early as 4 weeks before her hospitalization. While on a driving vacation, she drank large quantities of juice and had to stop hourly to urinate. She

began experiencing enuresis, which her parents attributed to her increased fluid intake. What signs and symptoms are consistent with the diagnosis of type 1 diabetes in a child?

The diagnosis of type 1 diabetes in children is generally straightforward. Presenting symptoms include a several-week history of polyuria, polydipsia, polyphagia, and weight loss, with hyperglycemia, glucosuria, ketonemia, and ketonuria. J.C.'s presentation is typical for a child newly diagnosed with diabetes who is brought in for medical attention because of severe symptoms related to the flu. An acute viral illness can trigger autoimmune destruction of the pancreas and abdominal pain, which may masquerade as gastroenteritis. Abdominal pain is a common presenting symptom of diabetic ketoacidosis (DKA).¹¹⁴ J.C.'s weight loss probably represents fluid and caloric loss secondary to uncontrolled diabetes as well as decreased caloric intake from the flu. The symptoms of polyuria are less obvious in an infant and are frequently missed until metabolic derangement has occurred. Unlike J.C., infants frequently present with severe dehydration and metabolic acidosis despite a negative history of diarrhea or significant vomiting.

Goals of Therapy

22. What are the goals of therapy for J.C.? Do the results of the DCCT apply to children such as J.C.? Are there age-specific goals?

The goals of therapy for children such as J.C. and adolescents with diabetes mellitus are as follows: (a) achieve normal growth and development, (b) obtain optimal glycemic control, (c) facilitate positive psychosocial adjustment to diabetes, and (d) prevent acute and chronic complications. Attainment of these goals requires a tremendous amount of support and education for the parents and can be best provided by a multidisciplinary team of professionals, including a physician, nurse educator, pharmacist, dietitian, and psychosocial expert.

Growth serves as an important clinical indication of overall general health and well-being in children with diabetes. Height and weight should be measured at each visit and plotted on standard growth grids. If, at the time of diagnosis, a child has fallen behind in height or weight, prompt and appropriate treatment should quickly return the child to the appropriate percentile and pattern of growth. An obese child should be encouraged to achieve a more appropriate percentile of weight gradually, over a period of several months.

Although recommendations for glycemic control are based on data from studies in adult patients with diabetes, achieving the same near normalization of blood glucose levels in children and adolescents is recommended. However, special consideration must be given to the unique risks and consequences of hypoglycemia in young children. A cohort of adolescents included in the DCCT was analyzed separately. The intensive group achieved an HbA_{1c} about 1% higher than the current ADA recommendations for patients in general.¹¹⁵ Similar to the adults in the DCCT, adolescents had sustained benefits from intensive management with little further progression to proliferative retinopathy 4 years after the DCCT was terminated.¹¹⁶ Thus, J.C.'s pediatrician must strive for the best glucose control that she, her family circumstances, and currently available treatment regimens will permit.

The risk of hypoglycemia and potential neuropsychological impairment is of the greatest concern for children younger

than 6 years. This is because the young child may be unable to mount an adequate adrenergic response to hypoglycemia and be unable to effectively communicate symptoms of hypoglycemia. In addition, food intake and physical activity are unpredictable in this age group. To minimize the risk of hypo- and hyperglycemia, an HbA_{1c} value between 7.5% and 8.5% is recommended.¹¹⁷

The management of diabetes in children 6 to 12 years of age, such as J.C., is particularly challenging because many children require insulin with lunch or at other times when they are away from home. Administration of insulin at school demands flexibility and close communications between the parents, the health care team and school personnel. An HbA_{1c} goal of 8% or lower is recommended (Table 50-4).^{22,117}

The greatest amount of evidence-based data exist for adolescents with diabetes (13–19 years). As mentioned, teenagers included in the DCCT achieved a mean HbA_{1c} level of 8.06% in an era before the availability of rapid-acting or basal insulins. An HbA_{1c} goal of <7.5% is recommended in this age group.¹¹⁷

Insulin Therapy

23. How should J.C. be started on insulin? Is the use of an insulin pump appropriate in children such as J.C.?

Generally, rapid-acting insulin analogs, short-acting insulin, intermediate-acting insulin, and basal insulin analogs are used in children. Insulin requirements are generally based on body weight, age, and pubertal status. Newly diagnosed children with type 1 diabetes usually require an initial total daily dose of approximately 0.5 to 1.0 unit/kg. The small insulin requirements of infants and toddlers may be delivered by using diluted insulin to measure doses less than 1 U. Diluents are available for specific types of insulin from the insulin manufacturers. Insulin syringes and pens that deliver insulin in 0.5-U increments are also very useful. Most children are treated with two or three doses of rapid-acting or short-acting insulin combined with intermediate-acting insulin. Multiple daily insulin injection regimens combined with carbohydrate counting are attractive regimens for middle and high school students. Basal/bolus insulin regimens have demonstrated lower fasting blood glucose levels with less nocturnal hypoglycemia versus regimens using NPH in children and adolescents.¹¹⁸ However, many families are reluctant to commit to six to seven insulin injections per day. Children who have lunch at a consistent time and are willing to eat a consistent amount of carbohydrate at lunch do well with a breakfast dose of NPH given to provide meal coverage for lunch and a bedtime dose of a basal insulin such as Lantus or Levemir. Many patients find rapid-acting insulins more convenient because they can be injected 0 to 15 minutes before a meal so that little preplanning is involved. Because children often have erratic eating habits, an advantage of rapid-acting insulins over regular insulin is that they can also be injected immediately after a meal. J.C. should be started on a total daily dose of 14 units given as 4 units of NPH plus 3 units of Novolog at breakfast, 3 units of Novolog with dinner, and 4 units of Lantus at bedtime (three injections per day).^{117,119}

When J.C. gets older and can self-administer her injections, a basal-bolus regimen can be initiated. Also, the use of an insulin pump can be considered. The use of insulin pumps in the pediatric population is increasing rapidly.^{120,121} Young children

(not just adolescents) are now recommended for consideration of insulin pump therapy.¹²² Adult support both at home and school is critical for successful pump use until the child is able to manage his or her diabetes independently.

Injection Sites

24. Are the recommended sites of injection different for children? Does the age of the child play a factor?

Although many studies exist in adults investigating the rate of SC insulin absorption depending on the site and depth of injection, it is not clear whether these results are applicable to children. For infants with abundant SC tissue, injection sites are usually plentiful. For some toddlers who have lost their “baby fat,” locating an appropriate site for injection can be difficult. Injecting insulin into the abdomen of children with minimal SC abdominal fat or in very young children may not be advisable. Rotation of injection sites between arms, thighs, and the upper-outer quadrant of the buttock or hip area, as well as the abdominal area in older children, is recommended. To achieve consistent absorption, insulin injections can be patterned; for example, using the arms for the morning injection and the thighs for the evening injection. Unfortunately, many children and teens consistently inject their insulin into a single area for convenience, accessibility, and comfort. This results in the development of fatty deposits and scar tissue secondary to insulin action at the local tissue level. Insulin absorption from these hypertrophied areas is generally poor and may make glycemic control quite variable. Insulin pen devices are very helpful for use in children because they are less intimidating. Also, spring-loaded injection devices may be helpful in reducing the child’s fear of needles and easing access to difficult-to-reach injection sites such as the back of the arms or buttocks.

Blood Glucose Monitoring

25. How often should J.C. monitor her blood glucose?

The eventual goal for children with diabetes is self-management, with insulin dosing decisions based on interpretation of blood glucose results. Self-management skills and basal-bolus insulin regimens rely on frequent SMBG. For children with type 1 diabetes, four or more blood glucose tests per day are generally necessary. Most of the newer meters allow alternative site testing (arm or thigh), which decreases the discomfort of fingersticks. For infants, the earlobes and heel provide alternative blood sources to fingersticks. Enthusiasm for frequent blood glucose testing tends to wane with duration of diabetes. However, families who are instructed on managing diabetes on the basis of test results are better motivated to persevere with SMBG. CGM may also hold promise for improved assessment of metabolic control in pediatric patients. J.C. should test her blood glucose before each meal and at bedtime, at a minimum. The results will construct a useful profile of her daily fluctuations. Additional tests should be performed whenever J.C. experiences hypoglycemia or ketonuria or when she becomes acutely ill.

Honeymoon Period

26. Over the next 2 months, J.C.’s insulin requirements decreased to a total daily dose of 10 units (~0.3 unit/kg). Has her diabetes gone into remission?

Approximately 20% to 30% of individuals with type 1 diabetes go into a remission phase (honeymoon period) within days to weeks of their diagnosis.¹²³ During this time, which can last for weeks to months, C-peptide can be measured, indicating a return of pancreatic function; insulin requirements may diminish partially or completely. As illustrated by J.C., this presents clinically as markedly decreased insulin requirements to maintain normoglycemia. Although it is tempting to discontinue insulin, diabetes invariably recurs. To minimize the possibility of inducing insulin allergy secondary to intermittent insulin exposure and to avoid engendering a sense of false hope in J.C. that her disease has been cured, many clinicians continue insulin even if the doses are minuscule. J.C. should be followed closely for rising blood glucose concentrations.

Hypoglycemia

27. J.C.'s parents contacted the clinic to report that J.C. is having nightmares and is awakening in the middle of the night complaining of a headache and stomach pain. However, these symptoms resolve by noon the following day. Her current insulin regimen is NPH 3 units with Novolog 2 units before breakfast, 2 units of Novolog with dinner and 3 units of Lantus at bedtime. Could J.C. be experiencing nocturnal hypoglycemia? How do the symptoms of hypoglycemia differ in a child compared with an adult? How can the risk of hypoglycemia be minimized for J.C.?

J.C.'s parents are appropriately worried. Hypoglycemia is a serious and often life-threatening complication of diabetes management in children, and the risk of hypoglycemia increases with attempts to maintain meticulous control of blood glucose levels. Common causes of hypoglycemia include changes in meal amounts, late or skipped meals or snacks, exercise or unusual activity, and administration of excessive insulin. Because very young children may not be able to identify or express symptoms of hypoglycemia, caretakers must observe the child closely and identify symptoms or behaviors associated with a falling blood glucose. Symptoms of hypoglycemia may include crankiness, sudden crying, restless sleep, or nightmares as seen in J.C.

Hypoglycemia is more frequent in children with lower HbA_{1c} values, a prior history of severe hypoglycemia, larger insulin doses, and younger children.¹²⁴ Additional risk factors for hypoglycemia include a longer duration of diabetes and male gender. Nocturnal hypoglycemia is reported in 14% to 47% of children with type 1 diabetes and is thought to be due to impaired counter-regulatory response to hypoglycemia during sleep.¹²⁵ Bedtime blood glucose levels are poor predictors of nocturnal hypoglycemia. J.C.'s parents should be instructed to test her blood glucose at 2 AM closely over the next few nights, and then continue to check at least twice weekly. In children, Lantus can exhibit a small peak effect during the initial 3 to 5 hours after administration, increasing the risk for nocturnal hypoglycemia.¹¹⁷ The Lantus dose should be moved to dinner time. If this does not correct the nocturnal hypoglycemia, then the dose should be reduced. Use of Lantus as basal insulin is associated with less nocturnal hypoglycemia (and asymptomatic nocturnal hypoglycemia) compared with NPH insulin in children and adolescents.^{126,127} A bedtime snack may also be needed. Treatment of hypoglycemia is addressed in Question 37.

Using Insulin in Special Situations

Insulin Stability: Factors Altering Control

28. T.M., a 31-year-old farmer, has had type 1 diabetes for 20 years. He has been relatively well controlled on his current regimen of premeal Humalog and twice daily NPH human insulin for some time. During the winter and spring seasons, his blood glucose concentrations have ranged from 90 to 140 mg/dL, and the HbA_{1c} measured at his last clinic visit 3 months ago was 7.5%. It is now August. For the past 2 months, T.M. has noticed that his diabetes is not under good control. His blood glucose concentrations vary widely from concentrations as low as 60 mg/dL (3.3 mmol/L) to as high as 240 mg/dL (13.3 mmol/L). He has no explanation for this. On inspection, his vial of insulin lispro is cloudy and a white precipitate is clinging to the NPH vial, giving it a frosted appearance. Both vials are approximately one-third full. What factors may be contributing to T.M.'s poor glycemic control?

[SI units: blood glucose concentrations, 5.0–7.8 mmol/L; HbA_{1c}, 0.085 (normal, 0.04–0.06)]

Many factors may be contributing to T.M.'s poor control. These are discussed in the subsequent sections. Physical changes in insulin are addressed here.

PHYSICAL CHANGES

Both of T.M.'s insulin vials have changed in appearance. T.M. should be instructed not to use his insulin lispro if it is discolored; has become cloudy or thickened; or contains small, threadlike or other solid particles. As discussed in Question 17, the cloudiness may be caused by contamination of insulin lispro with NPH. If T.M. reuses his syringes, this also may be caused by the silicone oil that is used to coat needles of disposable syringes.¹²⁸ The silicone oil can denature the insulin, reducing its pharmacologic effect.

FLOCCULATION

NPH can sometimes flocculate or crystallize onto the insulin bottle.¹²⁹ This results in a significant loss of potency, with insulin concentrations in the remaining suspensions varying from 6 to 64 U/mL (labeled 100 U/mL). This phenomenon can occur precipitously, generally after 3 to 6 weeks of use. Incorporation of additional zinc into these preparations during the manufacturing process has minimized this problem. Nevertheless, all patients should be warned to inspect their vials carefully before each injection and to discard or exchange them if they have crystallized (Fig. 50-6).

TEMPERATURE

Insulin is a fragile molecule that can be damaged by temperature extremes. All commercially available insulins are stable for at least 28 days (e.g., ~1 month) at room temperature (68–75°F), and the ADA recommends avoiding temperature extremes (<36°F or >86°F).⁹⁷ In practice, most patients store vials currently in use at room temperature because injection of cold insulin is uncomfortable. All unopened, extra vials or pen devices should be stored in the refrigerator. The *United States Pharmacopeia* recommends that patients discard vials that have not been completely used in 1 month if they have been kept at room temperature.

FIGURE 50-6 Insulin vial with crystallized insulin. (Used with permission from reference 341.)

The stability of insulin at temperatures of 75°F to 100°F is unknown, but all insulins lose significant potency within 1 to 2 months at 100°F. T.M. lives in an area where temperatures frequently exceed 100°F during the summer months. Therefore, it is important that he not store his insulin in an automobile or in the sun, where it may be subject to deterioration. An insulated container or cooling packet (such as the FRIO Wallet) is recommended for T.M. It also is of interest that many wholesale drug distributors and some mail-order pharmacies do not take special packaging precautions when delivering insulins to pharmacies or homes during the summer months. Thus, inadvertent exposure to high temperatures during these months may alter the potency and actions of insulins. Freezing apparently does not affect the potency of insulin, but may cause aggregation of the precipitate. This could alter the absorption kinetics of the preparation.¹³⁰

OTHER FACTORS ALTERING RESPONSE TO INSULIN

Many other factors may be altering T.M.'s response to insulin. The heat in the summer months may increase circulation to the injected site, thus speeding the onset and shortening the duration of action of his insulin. Exercise of the injected limb may affect insulin action similarly. During the summer months, farmers typically are more physically active and, as a consequence, require less insulin than usual. Other factors that can alter insulin action are listed in Tables 50-10 and 50-19.

When patients like T.M. observe that their insulin seems to work less well even when the product is well within the expiration date and there are no obvious physical changes, we recommend that they inject insulin from a fresh vial to assess whether insulin from the original vial has deteriorated. If the response remains the same, they should work with a clinician to identify other reasons for their decreased responsiveness to insulin.

Exercise and Insulin Requirements

29. J.S. is a 17-year-old, nonobese, patient with type 1 diabetes who was diagnosed at age 12. He currently is moderately well controlled on a single daily dose of Lantus 18 units at bedtime with 4 to 6 units of insulin aspart with meals (depending on carbohydrate intake). His HbA_{1c} is 7.8%, and his blood glucose levels before meals range from 150 to 190 mg/dL (8.3–10.5 mmol/L).

Fasting blood glucose concentrations in the clinic range from 130 to 170 mg/dL (7.2–9.4 mmol/L). He has rare hypoglycemic reactions that are associated with skipped meals, and he generally is compliant with his prescribed meal plan. J.S. would like to begin a jogging program. What effect is jogging likely to have on his diabetic control? What precautions, if any, should he take?

[SI unit: HbA_{1c}, 0.10]

Exercise has varying effects on plasma glucose levels in patients, such as J.S., who are taking insulin. In the resting state, muscle derives approximately 10% of its metabolic requirement from glucose. In contrast, almost all of the muscle's metabolic requirements are derived from glucose during moderate to heavy exercise. Muscle glycogen stores are depleted quite rapidly, after which glucose is derived from the peripheral circulation. To meet the increased glucose demands, hepatic glycogenolysis and gluconeogenesis increase. This is mediated primarily through suppression of insulin secretion and increased secretion of counter-regulatory hormones such as glucagon. Low, permissive levels of insulin are required for glucose utilization by the muscle. In nondiabetic individuals, hepatic glucose output and peripheral utilization are balanced such that euglycemia is maintained during exercise.^{131,132}

In a patient like J.S., exercise may cause hyperglycemia or hypoglycemia if he does not take proper precautions. If he is insulin deficient when he commences exercise, hepatic glucose output will be increased, but peripheral utilization will be decreased and hyperglycemia will ensue. Thus, patients like J.S. with type 1 diabetes should not exercise if their blood glucose concentrations exceed 250 mg/dL and they have ketosis or if levels exceed 300 mg/dL (with or without ketosis), because these levels usually indicate insulin deficiency.¹³²

Conversely, excess insulin enhances peripheral utilization of glucose by muscle and suppresses hepatic glucose output. Both can contribute to hypoglycemia. Hypoglycemia is more likely to occur in patients whose blood glucose concentrations are normal or low just before exercise. Thus, if J.S.'s blood glucose concentration is normal or low (<100 mg/dL) before he begins exercise, he should eat a carbohydrate snack (10–20 g) and have additional carbohydrates readily available during and after exercise.¹³² He should delay his dose of insulin lispro until after exercising and adjust the amount according to his postexercise blood glucose level.

It is less well appreciated that peripheral glucose utilization remains high after exercise has been discontinued. This is thought to be related to the replenishment of glycogen stores in the liver and muscle. Thus, if appropriate adjustments are not made in diet and insulin dose after exercise, hypoglycemia can occur 10 to 12 hours thereafter.¹³³

For patients who inject insulin into their thighs, jogging may enhance insulin absorption. The absorption of regular insulin is increased when it is administered just before exercise (within 5 minutes), but it does not appear to be affected if injected 30 to 40 minutes before exercise. Absorption of the intermediate-acting or long-acting insulins is less likely to be augmented by exercise.¹³⁴ Some have suggested that insulin be injected at a site that is not exercised, for example, the abdomen, to minimize this effect. J.S. should inject his insulin in the abdomen.

In summary, J.S. should be encouraged to begin an exercise program. He should test his blood glucose concentrations before, during, and after exercise and adjust his insulin doses

Table 50-21 Exercise in Patients With Diabetes

1. Test blood glucose concentrations before, during, and after exercise.
2. For moderate exercise (e.g., bicycling or jogging for 30–45 min), ↓ the preceding dose of regular rapid-acting insulin by 30%–50%. If glucose concentration is normal or low before exercise, supplement the diet with a snack containing 10–15 g of carbohydrate.
3. To avoid ↑ absorption of regular insulin by exercise, inject into the abdomen or exercise 30–60 min after injection. Avoid exercise when rapid-acting insulin is peaking.
4. Individuals with low glycogen stores may be predisposed to the hypoglycemic effects of exercise. Examples include alcoholics, fasted individuals, or patients on extremely hypocaloric (<800 calories), low-carbohydrate (<10 g/day) diets.
5. Patients taking insulin are more susceptible to hypoglycemia than those taking sulfonylureas. Patients with type 2 diabetes mellitus treated with diet are unlikely to develop hypoglycemia.
6. Watch for postexercise hypoglycemia. Individuals who have been exercising during the day (e.g., skiing) should ↑ their carbohydrate intake and test their blood glucose concentration during the night to detect nocturnal hypoglycemia. Hypoglycemia can occur 8–15 hr after exercise.
7. If the glucose concentration is >240–300 mg/dL, the patient should not exercise. This indicates severe insulin deficiency. These patients are predisposed to hyperglycemia secondary to exercise.
8. Patients with severe proliferative retinopathy or retinal hemorrhage should avoid jarring exercise or exercise that involves moving the head below the waist.

and food intake accordingly. In general, exercise should be avoided at times corresponding to peak insulin action, because high levels can suppress counter-regulatory hormones that stimulate hepatic glucose production (Table 50-21). Regular exercise may increase tissue sensitivity to insulin and eventually lower J.S.'s insulin requirements. Vigorous exercise is contraindicated in patients with retinal or vitreous hemorrhages because retinal detachment may occur.

In overweight or obese individuals with type 2 diabetes mellitus who are treated with diet, exercise is unlikely to cause hypoglycemia. An extremely low-calorie diet (<800 calories) that also is low in carbohydrates may decrease an individual's exercise endurance because muscle glycogen stores are not maintained.¹³¹ Patients with type 2 diabetes who are treated with insulin secretagogues or insulin may become hypoglycemic if insulin levels are high enough to increase peripheral utilization of glucose and suppress hepatic glucose output. Thus, patients with type 2 diabetes who are normoglycemic before exercise also should consider increasing their carbohydrate intake.¹³⁵ Because patients with type 2 diabetes do not have an absolute lack of insulin, they are less likely to become hyperglycemic in response to exercise.

Sick Day Management

30. R.D., a 32-year-old woman with type 1 diabetes, has been well controlled on basal-bolus regimen (four injections daily) for the past 6 months. However, 2 days ago, she began to develop signs and symptoms consistent with the flu. This has made her anorexic and nauseated and now she has begun to vomit; consequently, her food intake has been minimal. Because R.D. is not eating at this time, should she discontinue her insulin?

Insulin requirements always increase in the presence of an infection or acute illness, even if food intake is diminished.

Patients with type 1 diabetes, such as R.D., commonly decrease or eliminate insulin doses under these circumstances, and it is in just this setting that ketoacidosis occurs.

Therefore, R.D. should be instructed to maintain her usual dose of insulin and test her blood glucose and urine ketones every 3 to 4 hours; the latter is particularly important if she has become nonadherent with her blood glucose testing. If blood glucose concentrations are above the usual range, extra doses of her rapid-acting insulin should be administered according to a prescribed algorithm based (e.g., 1 U/50 mg/dL above her blood glucose target). People with type 1 diabetes should be instructed to test the urine for ketones if their blood glucose concentration is 300 mg/dL or higher. R.D. should call her physician if her blood glucose concentration remains above 240 mg/dL after three corrective insulin doses; if she has moderate to large amounts of ketones in her urine, if she has been vomiting or having diarrhea for longer than 6 hours; or if she begins to develop signs and symptoms related to ketoacidosis (polyuria, polydipsia, dehydration, ketonuria, and a fruity breath; (see Question 39). R.D. also should attempt to maintain her fluid, mineral, and carbohydrate intake with easily digested food and fluids (Table 50-22).¹³⁶

Insulin Requirements in Renal Failure

31. M.B., a 32-year-old woman, has had type 1 diabetes for 15 years. Over the past 2 years, a gradual deterioration of her renal function—as reflected by increased proteinuria, serum creatinine (SrCr), and blood urea nitrogen (BUN) values—has been observed. What are the anticipated effects of decreased renal function on M.B.'s insulin requirements?

The effects of renal failure on insulin requirements are complex and, under various circumstances, insulin requirements may increase or decrease. The kidney is the most important site of extrahepatic insulin metabolism and excretion. Renal clearance of insulin is 190 to 270 mL/minute, approximately two-thirds of hepatic clearance (320–400 mL/minute). In nondiabetic individuals, the liver extracts approximately 40% to 50% of insulin secreted endogenously before it reaches the peripheral circulation.^{70,137} Because exogenous insulin is

Table 50-22 Sick Day Management

1. Continue taking your basic dose of insulin *even* if you are not eating well or have nausea or vomiting.
2. Test your blood glucose more frequently; every 3–4 hr.
3. If indicated, give yourself extra doses (high sugar correction) of lispro, aspart, glulisine, or regular insulin: for example, 1–2 units for every 30–50 mg/dL over an agreed-upon target glucose concentration (e.g., 150 mg/dL). Correction doses must be individualized based on the patient's sensitivity to insulin (Table 50-11).
4. Begin testing your urine for ketones if you have type 1 diabetes. If you have type 2 diabetes, begin testing especially when glucose readings exceed 300 mg/dL.
5. Try to drink plenty of fluid (1/2 cup/hr for adults) and maintain your caloric intake (50 g carbohydrate Q 4 hr). Foods such as gelatin, noncarbonated soft drinks, crackers, soup, and soda may be used.
6. Call a physician if your blood glucose concentration remains >300 mg/dL; or your urine ketones remain high after two or three supplemental doses of insulin; or your blood glucose level remains >240 mg/dL for more than 24 hours.

delivered directly to the periphery, the kidneys play a more important role in its elimination. Insulin is filtered by the glomerulus and reabsorbed in the proximal tubules, where it is destroyed enzymatically. The kidney also clears insulin from the peritubular circulation.^{73,138} At that site, insulin can enhance the reabsorption of sodium, which may account for the edema occasionally observed after the initiation of insulin therapy in some individuals.

Diminished renal function can be accompanied by decreased clearance of endogenous and exogenous insulin, resulting in increased plasma concentrations of insulin. Therefore, M.B.'s insulin requirements may diminish as her renal disease progresses. Patients with moderate degrees of renal failure (glomerular filtration rate [GFR] >22.5 mL/minute) remove 39% of insulin from arterial plasma, similar to normal subjects. In contrast, patients with severe renal insufficiency (GFR <6 mL/minute) have a marked reduction in insulin removal from arterial plasma (9%).¹³⁹ Decreased insulin clearance in conjunction with the anorexia, nausea, and decreased food intake associated with uremia can lead to hypoglycemia in such individuals. In some patients with diabetes, particularly those with residual endogenous insulin secretion (type 2), glucose tolerance may normalize as renal function diminishes, eliminating the need for insulin.

In contrast, severe uremia is associated with glucose intolerance. This seems to be related to tissue resistance to insulin secondary to an unknown factor that can be removed by dialysis. Other factors that may alter blood glucose control in patients with renal failure include dialysis against glucose-containing dialysates and high-dose glucocorticoids in patients who have undergone renal transplantation.

As M.B.'s renal function worsens, a reduction in her insulin requirements should be anticipated. During this time, M.B. should monitor her blood glucose concentrations closely and adjust her insulin according to an algorithm.

Traveling With Diabetes

32. J.R. is a 42-year-old woman with type 1 diabetes mellitus who has just taken a position that requires extensive overseas air travel. She is concerned about potential problems she may encounter managing her diabetes under these circumstances. What are some basic travel tips J.R. should consider?

J.R.'s predeparture preparations depend on the duration and destination of her trip. The following sections discuss basic considerations for people with diabetes when traveling. Before a trip, she should obtain a letter from her health care provider indicating her diagnosis (type 1 diabetes), therapy, and the supplies she requires (e.g., syringes). She should also obtain a prescription for her insulins and syringes (or other delivery devices) in case of an emergency.

SUPPLIES

When going through airport security, J.R. should alert the security officer that she has diabetes and is carrying her supplies with her. All diabetes medications, supplies, and equipment are allowed through the checkpoint once they have been screened.

J.R. should carry a plentiful backup supply of insulin, syringes, blood-testing supplies (including an extra battery for her meter), and glucose tablets. She should double her antic-

ipated insulin needs in case of loss, destruction, or unavailability of comparable products in foreign countries. For example, only U-40 and U-80 insulin are available in some parts of the world. J.R.'s insulin supply should be insulated (e.g., using a FRIIO Wallet) and separated in various bags she will carry with her. Most sources advise against placing insulin in checked luggage, because its effectiveness might be altered by x-ray scanning or by freezing that could occur in the unpresurized baggage compartment. J.R. should take with her a brief medical history and a prescription for insulin for emergency situations.

IDENTIFICATION

J.R. should carry some identification that alerts medical personnel or others to her diagnosis in emergency situations. This can take the form of a wallet card or a medical alert bracelet. In certain situations, she could consider informing key individuals that she has diabetes (e.g., airline personnel, hotel managers, tour guides, traveling companions). She should review her insurance policy carefully so that she knows how to obtain care out of the country and bring along her policy and claim forms. Finally, she should provide friends or relatives with a detailed itinerary so that medical care can be summoned promptly if difficulties are encountered.

FOOT CARE

J.R. should wear comfortable shoes and not go barefoot. She should avoid wearing new shoes to prevent formation of blisters. She should check her feet daily, looking for blisters, cuts, and sores and seek medical care if she sees any signs of infection or inflammation.

MEAL PLANNING

J.R. should try to maintain some regularity in her diet (time and amounts). When it is the custom to take the evening meal later than is usual in the United States, a late afternoon or early evening snack should be planned. When flying, she can request a low-carbohydrate/low-fat meal. She should inject her rapid-acting insulin only when her meal has been served to her (or sees the food coming down the aisle) to prevent hypoglycemia. To avoid unforeseen events (e.g., travel delays), J.R. should carry sufficient food and snacks with her on the plane. Anticipating the likely composition of her diet in a foreign country also will help her to design a diet that maintains her pattern of carbohydrate and caloric intake.

INSULIN DOSES

J.R. needs to adjust her basal insulin doses when she flies across several time zones to account for time lost or gained.⁴⁸ When traveling east, the insulin dose should be decreased proportionately for the time lost and a shorter day. Conversely, when traveling west, the basal insulin dose should be increased for the time gained and a longer day. The principle is to provide the same amount of basal insulin per hour. For example, if J.R. is using 10 units of Lantus insulin and is traveling from New York to London (a 5-hour difference), her dose would be reduced to 8 units. This is because she is receiving about 0.4 unit/hour and she will be losing 5 hours as she crosses the time zones ($0.4 \times 5 = 2$ units). When she arrives in London and changes her watch, she may resume her Lantus 10 units at the usual time of administration. When drawing up her insulin

dose while on an airplane, J.R. should inject only half as much air into the vial (if at all); because the cabin pressure is lower than ground pressure, less pressure is needed inside the vial to balance the insulin she withdraws.

JET LAG

Because jet lag may be indistinguishable from symptoms of hypoglycemia or hyperglycemia, J.R. should test her blood glucose concentrations more frequently to better assess her symptoms.

Perioperative Management

33. A.G., a 55-year-old, 60-kg woman with a 35-year history of type 1 diabetes, was admitted to the critical care unit for an abdominal hysterectomy. Before admission, she was well controlled on 24 units insulin glargine at bedtime and premeal doses of insulin aspart. How should A.G.'s diabetes be managed while in the critical care unit?

The hospital management of a patient with diabetes is complex because so many variables can influence insulin requirements. Accordingly, common practice has been to aim for blood glucose concentrations in the range of 150 to 200 mg/dL. Over the past decade, much literature has been published looking at the management of hyperglycemia in critically ill hospitalized patients and the effects of hyperglycemia on mortality and morbidity. The initial Diabetes and Insulin Glucose Infusion in Acute Myocardial Infarction study compared intensive insulin therapy (insulin glucose infusion for ≥ 24 hours followed by SC insulin four times daily for ≥ 3 months) in patients with diabetes after acute MI with standard insulin therapy. Intensive insulin therapy improved long-term survival at 1 year and continued for 3.5 years, with an absolute risk reduction in mortality of 11%.¹⁴⁰ Three more recent studies—Diabetes and Insulin Glucose Infusion in Acute Myocardial Infarction-2, CREATE-ECLA, and HI-5—did not show significant reductions in mortality in post-MI patients using intensive insulin-glucose infusions.^{141–143} In a study of surgical patients in the intensive care unit (ICU) with hyperglycemia (some with diabetes), in which liberal glucose control (blood glucose concentrations of 180–200 mg/dL) was compared with tight control (blood glucose concentrations of 80–110 mg/dL), tight control decreased overall in-hospital mortality and systemic infection.¹⁴⁴ The same researcher performed a subsequent, similarly designed study in medical ICU patients and demonstrated reduced morbidity, but not mortality, in the intensively treated group. Interestingly, patients who were treated for 3 or more days with intensive insulin infusion therapy did have a significant reduction in in-hospital mortality, suggesting that the initial length of intensive insulin therapy (via infusion) in these patients may be an important factor.¹⁴⁵ The incidence of severe hypoglycemia (blood glucose level < 40 mg/dL) was 18.7%, which was much higher than the 5.1% observed in the surgical ICU population.¹⁴⁶ Overall, studies suggest insulin therapy in critically ill patients has a beneficial effect on short-term mortality in different hospital units.¹⁴⁷ Implementation of insulin infusion protocols using tight blood glucose targets (e.g., 80–110 mg/dL) should be carefully implemented, but with careful tracking for hypoglycemia.¹⁴⁸ For patients on general medical-surgical units, blood glucose targets below 180 to 200 mg/dL are reasonable.²²

For perioperative insulin needs, A.G. should receive her usual basal insulin dose (Lantus 24 units) on the night before surgery. If the basal insulin is normally administered in the morning, the usual dose can still be given for patients with type 1 diabetes; for those with type 2 diabetes, 50% to 100% of the basal insulin is administered the morning of surgery. Correction doses of rapid-acting insulin can be administered the morning of surgery if the blood glucose is above 180 mg/dL.¹⁴⁹ If a current HbA_{1c} is not available, it should be measured to assess the patient's glycemic control before admission.

Most insulin infusion protocols include the use of intravenous regular insulin and maintenance IV fluids; D5W, D5W 1/2 NS, or D10W (for fluid restriction or renal failure).¹⁴⁹ The adjustment algorithms are used by nursing to change the rate of infusion depending on the blood glucose level. Most often, the insulin infusion is prepared in a solution of 1 U/1 mL normal saline (e.g., 100 units of regular insulin in 100 mL normal saline). A dedicated IV line is used for the insulin infusion to avoid iatrogenic hypoglycemia. The insulin infusion is connected to the maintenance IV containing dextrose (can be Y-connected). Because insulin binds to plastic, the insulin solution should be flushed (e.g., with 20 mL) through the IV tubing before the line is connected to the patient. An IV dextrose infusion is maintained while a patient is on an insulin infusion. Most patients need 5 to 10 g of glucose per hour (or D5W or D5W-1/2 normal saline at 100–200 mL/hour). Additional maintenance fluids (and electrolytes) can be administered via a different port or line. Some protocols include an initial bolus dose of insulin. The initial insulin infusion rate is primarily based on current blood glucose level and BMI; other factors such as body weight, current daily insulin requirements, and renal function should be taken into consideration. A rate of 1 unit/hour is a typical initial rate (can range from 0.5 unit/hour to ≥ 2 units/hour). Adjustments in the insulin infusion rate are determined by fingerstick blood glucose levels every 30 to 60 minutes hour until the blood glucose is stable and close to target. Then the frequency of blood glucose testing may be reduced to every 2 to 3 hours. Algorithms should consider both the current and previous blood glucose level, the rate of change of the blood glucose level, and the current infusion rate.²²

Insulin infusion should be started at least 2 to 3 hours before the surgery to titrate to the desired level of glucose control. Examples of protocols are available on the Institute for Healthcare Improvement's website (available at <http://www.ihl.org/IHI/Topics/PatientSafety/MedicationSystems/Tools/>) and many are published in the medical literature.^{150,151}

Thus, A.G.'s usual SC insulin regimen should be discontinued, and she should be initiated on an insulin infusion that is adjusted according to an algorithm. Throughout the perioperative period, she should receive a minimum of 100 g glucose daily to prevent starvation ketosis.

Alternative Routes of Administration

34. W.C. is a 22-year-old male college student with type 1 diabetes, who is currently injecting multiple doses of insulin lispro throughout the day and insulin glargine at bedtime; however, he finds the traditional insulin injection process using vials and syringes time consuming and cumbersome. He would like to find an easier, more convenient, and more discreet way to inject his insulin while at school. What insulin delivery devices are

available for W.C.? What alternative routes of insulin delivery may be available for W.C. in the future?

PEN DEVICES AND PREFILLED SYRINGES

Pen devices and prefilled syringes eliminate the need to carry syringes and insulin vials separately. Insulin pens are available as prefilled pens, which are disposable, or reusable pens (referred to as durable pen devices). Prefilled pens contain a built-in, single-use insulin cartridge designed to deliver 300 units of insulin. Novolog and Humalog and their insulin mixtures (Novolog Mix 70/30, Humalog Mix 75/25, and Humalog Mix 50/50) are available in prefilled pens. Lilly has the KwikPen (1-U increments; 60-U maximum dose), which is easier to dial than their original prefilled pens that are still available (1-U increments; 60-U maximum dose). NovoNordisk has the Flexpen (1-U increments; 60-U maximum dose). Lantus insulin is available in a prefilled pen called SoloStar (1-U increments; 80-U maximum dose). Prefilled pens are helpful for patients who have difficulty handling the cartridges in reusable pens or for patients with busy schedules who prefer not to have to change cartridges.

Most durable pens use 3.0-mL cartridges, each holding 300 units. A 1.5-mL cartridge is available for some insulins, but these are used infrequently. A patient inserts an insulin cartridge into the pen's delivery chamber. This may allow greater flexibility for some patients, such as the ability to change the type of insulin injected without needing to purchase another pen if the insulin prescription changes. NovoNordisk makes the NovoPen Junior (0.5-unit increments; 35-units maximum dose) and the NovoPen 3 (1-unit increments; 70-units maximum dose). Lilly makes the HumaPen Luxura HD (0.5-unit increments; 30-units maximum dose) and the HumaPen Memoir (1-unit increments; 60-units maximum dose), which records and displays the last 16 insulin doses given. Sanofi-Aventis insulins (Lantus, Apidra) use the OptiClik pen device (1-unit increments; 80-units maximum dose), which unfortunately is only distributed to physicians (not to pharmacies). Patients are advised to use a new disposable needle for each injection. Pen needles are available in 29- to 31-gauge and needle lengths of 3/16 inch (5 mm), 1/4 inch (6 mm), 5/16 inch (8 mm), and 1/2 inch (12.7 mm).

The pens are particularly useful for patients with (a) regimens consisting of multiple daily doses of rapid- or short-acting insulin before meals and snacks (such as W.C.), (b) a fear of needles, (c) impaired hand dexterity, (d) hectic work/lifestyle, or (e) for training alternate individuals who administer insulin (e.g., school nurses, siblings).

INSULIN PUMPS

Insulin pumps were discussed in Question 5 and have been reviewed elsewhere.¹⁵²

INHALED INSULIN

Developing alternative routes for insulin delivery to avoid injections has been under investigation for several decades. Alternative routes evaluated include gastrointestinal (GI), intranasal, buccal, transdermal, and intrapulmonary. Inhalation of insulin via the lungs is ideal in that the insulin protein passes into the small alveoli, which has enormous surface area, high blood flow, and a thin membrane. Exubera, inhaled human (rDNA origin) and made by Pfizer received FDA approval in

January 2006, but is no longer available. Pfizer decided to cease manufacturing due to its lack of use. Other inhaled insulin products may be approved in the future.

Adverse Effects of Insulin

Hypoglycemia

35. G.O., a 42-year-old, slightly overweight (5 feet 11 inches, 180 lbs) man, has had a history of type 1 diabetes mellitus for 17 years. G.O.'s medical care was sporadic until 1 year ago when he referred himself to a diabetes clinic because he was beginning to develop pain and numbness in his feet. At that time, he was poorly controlled on a single daily dose of 45 units Humulin 70/30. He had not been testing his blood glucose concentrations, and his HbA_{1c} was 13%.

On physical examination, G.O. was found to have an elevated BP (160/94 mmHg), background retinopathy, and decreased pedal pulses bilaterally. He had decreased sensation to vibration and monofilament testing in both feet. G.O. also complained of impotence and "shooting pains" in both legs. A spot collection for microalbuminuria was 450 mg of albumin/g creatinine (normal, 30–299 mg/g creatinine).

G.O. was transitioned to a basal-bolus insulin regimen. His physician gave him a premeal blood glucose target of 70 to 130 mg/dL.²² Over the last several months, he has been treated with the following regimen: 14 to 18 units insulin glulisine before breakfast; 14 to 18 units insulin glulisine before lunch; 16 to 18 units insulin glulisine before dinner; and 40 units insulin glargine at bedtime. If his blood glucose level is high after lunch, he takes additional glulisine (~2 hours after eating). If his blood glucose is high at bedtime (e.g., >150 mg/dL), he takes additional insulin glulisine (7–10 units) because his doctor told him his blood glucose level needed to be lowered significantly. Blood glucose concentrations have been as follows.

| Time | Glucose Concentration (mg/dL) |
|------|-------------------------------|
| 7 AM | 60–320 |
| Noon | 140–280 |
| 5 PM | 40–300 |

Over the past year, G.O.'s HbA_{1c} has decreased to 7.1%. Currently, he has approximately five hypoglycemic episodes per week, primarily in the late afternoon and evenings. These are characterized by intense hunger, sweating, palpitations, and (according to his wife) a short temper. He has found that he can avoid nocturnal hypoglycemia (night sweats, nightmares, and headaches) by eating a large bedtime snack. Over the past 3 months, he has gained 15 lb. Are G.O.'s signs and symptoms consistent with mild, moderate, or severe hypoglycemia? What are the causes?

[SI units: blood glucose 7 AM, 5.5–8.3 mmol/L; 12 PM, 15.5 mmol/L; 5 PM, 2.2–15.5 mmol/L; HbA_{1c}, 0.72]

G.O.'s case illustrates one of the major hazards of aggressive blood glucose targets and intensive insulin therapy: hypoglycemia. Hypoglycemia is a fact of life for patients with type 1 diabetes, virtually all of whom experience a hypoglycemic episode at one time or another. An estimated 4% of deaths related to type 1 diabetes are caused by hypoglycemia.^{29,153,154}

Hypoglycemia is a blood glucose concentration below 60 mg/dL (<2.7 mmol/L), and its occurrence is potentially fatal

if not promptly recognized and treated. However, the exact level at which a patient experiences symptoms is difficult to define. Clinical hypoglycemia is associated with typical autonomic (neurogenic) and neuroglycopenic symptoms relieved by the administration of a quickly absorbed carbohydrate.

PATHOPHYSIOLOGY

Normal brain function depends on glucose, the exclusive fuel for cerebral metabolism. Because the brain is unable to synthesize or store glucose, it must be provided with a constant exogenous quantity via the brain's blood supply. As blood glucose concentrations fall, a series of physiological responses occur to restore glucose levels. These responses create symptoms warning a patient to take corrective action by consuming carbohydrates. If these counter-regulatory responses fail to alert the patient and blood glucose concentrations fall below a critical level, cognitive function becomes impaired and confusion and coma may ensue.

In people without diabetes, the peripheral responses to hypoglycemia are so efficient that clinically important hypoglycemia probably never occurs. As glucose levels fall between 50 and 60 mg/dL (2.7–3.3 mmol/L), a series of neuroendocrine events occur, raising the plasma glucose concentration back toward normal by increasing hepatic glucose output. The major hormone responsible for producing acute recovery from insulin-induced hypoglycemia is glucagon; however, epinephrine alone also can produce near-normal recovery. Rising levels of adrenergic and cholinergic hormones generate warning symptoms of hypoglycemia. When hypoglycemia is prolonged, growth hormone and cortisone play a greater role in producing recovery.

Patients with type 1 diabetes who maintain insulin depots throughout the day are predisposed to severe hypoglycemic reactions because deficiencies in the normal feedback system occur over time. Glucagon secretion becomes deficient within the first 2 to 5 years after diagnosis, and by 10 years or longer, epinephrine secretion may become impaired. The latter defect leads to asymptomatic hypoglycemia or hypoglycemic unawareness (see Question 38).

Certain circumstances predispose patients with type 1 diabetes to severe hypoglycemia. These include (a) a defective counter-regulatory hormonal response to hypoglycemia (see Question 38), which may be further diminished with frequent hypoglycemia, (b) medications such as β -blockers that diminish early warning signs of impending hypoglycemia, (c) intensive insulin therapy that can alter secretion of counter-regulatory hormones, (d) skipped meals or inadequate carbohydrate intake relative to the insulin dose, (e) physical activity, and (e) excessive alcohol intake (Table 50-14).

SYMPTOMS

The signs and symptoms associated with hypoglycemia vary in intensity according to the presence of cognitive deficits and the patient's ability to self-treat the reaction. They vary substantially from one patient to another. Symptoms are conventionally divided into two categories: neurogenic (or autonomic) and neuroglycopenic.¹⁵³

Autonomic symptoms include sweating, intense hunger, palpitations, tremor, tingling, and anxiety. Epinephrine is thought to mediate many of the neurogenic responses to hypoglycemia.

Neuroglycopenic symptoms resulting from neuronal fuel deprivation (glucose) include difficulty concentrating; lethargy; confusion; agitation; weakness; and possibly, slurred speech, dizziness, and fainting. Profound behavioral changes, seizures, and coma are more severe manifestations of neuroglycopenia. Prolonged, severe neuroglycopenia ultimately results in death. Symptoms of mild, moderate, severe, and nocturnal hypoglycemia are as follows:

- *Mild hypoglycemia*: Symptoms include tremor, palpitations, sweating, and intense hunger. Diminished cerebral function is not present and patients are capable of self-treating mild reactions.
- *Moderate hypoglycemia*: Moderate hypoglycemic reactions include neuroglycopenic as well as autonomic symptoms: headache, mood changes, irritability, decreased attention, and drowsiness. Patients may require assistance in treating themselves because of the presence of impaired judgment or weakness. Symptoms are more severe, usually last longer, and often require a second dose of a simple carbohydrate.
- *Severe hypoglycemia*: Symptoms of severe hypoglycemia include unresponsiveness, unconsciousness, or convulsions. These reactions require assistance from another individual for appropriate treatment. Approximately 10% of patients treated with insulin develop at least one severe, disabling episode of hypoglycemia per year that requires emergency treatment with parenteral glucagon or IV glucose.¹⁵³
- *Nocturnal hypoglycemia*: Tingling of the lips and tongue are common complaints of patients who develop nocturnal hypoglycemia. These patients also may complain of headache and difficulty arising in the morning, nightmares, or nocturnal diaphoresis.¹⁵³ Family members should be conscious of any unusual sounds or activity while the patient is sleeping.

G.O. has mild to moderate hypoglycemic reactions, which he is able to self-treat. These are likely due to overinsulinization and insulin “stacking” with his rapid-acting insulin.

Overinsulinization

36. Evaluate G.O.'s overall control. What signs and symptoms in G.O. are consistent with overinsulinization and insulin “stacking”? How should he be managed?

The following is a list of signs and symptoms of overinsulinization in G.O.:

- A total daily insulin dose of more than 1.0 unit/kg. This dose is unusually high for a patient with type 1 diabetes, who should not be resistant to the action of insulin.
- Weight gain over the past several months. This is secondary to the anabolic effects of insulin as well as G.O.'s increased carbohydrate intake to match his high insulin doses or treatment of hypoglycemia.
- Frequent hypoglycemic reactions.
- High glycemic variability (i.e., blood glucose concentrations that fluctuate wildly between hypoglycemia and hyperglycemia). In G.O.'s case, high blood glucose concentrations may represent reactive hyperglycemia or overtreatment of hypoglycemic episodes. His low blood glucose level may represent excessive rapid-acting insulin at bedtime and insulin “stacking” of his rapid-acting insulin after lunch. At lunchtime, he is administering a high sugar correction dose

of insulin glulisine too soon; his mealtime glulisine is still likely at a peak action and working to lower his prandial blood glucose. By administering additional glulisine soon after the meal, the two insulin doses are adding up, or “stacking,” causing hypoglycemia.

- Near-normal HbA_{1c} levels indicate mean blood glucose concentrations that must be within the normal range even though the patient has recorded numerous high blood glucose concentrations. Patients treated with intensive insulin therapy in the DCCT experienced hypoglycemic episodes three times more often than patients treated with standard insulin therapy.²⁹ HbA_{1c} levels were approximately 7.2%.

G.O. should be managed by discontinuing his high sugar corrections at bedtime and after lunch. He should SMBG pre-meal, 1 to 2 hours after meals, and at bedtime to obtain a better picture of his glucose patterns and insulin requirements. He should avoid the large bedtime snack. He should also begin testing his blood glucose at 2 or 3 AM to assess if he is still experiencing nocturnal hypoglycemia after stopping the bedtime insulin glulisine. It will be important that he record the actual dose he administers before each meal and bring the record to clinic so that his insulin doses can be fine tuned. Next, if he is capable, an algorithm for adjusting his preprandial insulin glulisine doses should be provided to minimize hypoglycemic and hyperglycemic reactions (see Question 14), eventually he can transition to counting carbohydrates (see Question 13).

Treatment of Hypoglycemia

37. How should G.O.’s hypoglycemic episodes be managed?

As G.O. illustrates, many patients with diabetes are frightened of hypoglycemia and have a tendency to overtreat their reactions with, for example, large quantities of juice or several candy bars. This should be discouraged because overcorrection together with glucose generated by counter-regulatory hormones ultimately results in hyperglycemia.

The key to successful management of hypoglycemia is recognition and prevention. Because early warning symptoms of hypoglycemia vary from person to person, it is important that G.O. study and learn to recognize his earliest warning symptoms and treat early. Patients generally can recall prodromal symptoms after recovery from a severe hypoglycemic reaction if they have not developed hypoglycemic unawareness (see Question 38). As a caveat, these authors occasionally have seen patients who “feel” hypoglycemic after their blood glucose concentrations have been normalized from very high levels with intensive insulin therapy. We encourage patients to test their blood glucose level any time they “feel unusual” to verify a low blood glucose concentration before treatment. G.O. should treat his symptoms only if he is truly hypoglycemic.

A second component of prevention is determining its cause and taking preventive or corrective action. This entails assessment of his diet (did he skip or delay a meal or change its content?), exercise pattern, time of insulin administration, insulin dose, and accuracy of dose administered. If hypoglycemic reactions consistently occur at a certain time of day, he should determine whether this corresponds with a mealtime dose of his rapid-acting insulin and reduce that insulin dose by 1 to

2 U. If his FBG is running low, his Lantus insulin dose can be reduced.

If a reaction occurs, G.O. should be instructed to treat it as follows (Table 50-14).

MILD HYPOGLYCEMIA

Most hypoglycemic reactions are managed readily with the equivalent of 10 to 20 g of glucose (see Table 50-14 for examples of carbohydrate sources containing 15 g of glucose). If the blood concentration remains low after 15 minutes, the patient should ingest another 10 to 20 g of carbohydrate. This quick-acting source of glucose should be followed by a small complex carbohydrate or protein snack (e.g., milk, peanut butter sandwich) to provide a continual source of glucose if a meal is not scheduled within the next 1 to 2 hours. An easy rule of thumb that can be used by patients is “15-15-15”: 15 g of glucose followed by a second 15 g if the patient is still symptomatic after 15 minutes.

Glucose tablets are available and have the added benefit of being premeasured to prevent overtreatment of hypoglycemia. Glucose gels or small tubes of cake frosting are useful for children or patients who become uncooperative and combative when hypoglycemic.

MODERATE TO SEVERE HYPOGLYCEMIA

Glucagon can be injected by the SC or intramuscular (IM) route into the deltoid or anterior thigh region. Glucagon is used when a patient is unable to self-treat their hypoglycemia. The dose of glucagon recommended to treat moderate or severe hypoglycemia for a child younger than 5 years of age is 0.25 to 0.5 mg; for children 5 to 10 years of age, 0.5 to 1 mg; and for patients older than 10 years, 1 mg. Parents, spouses, or other close contacts should be taught how to mix, draw up, and administer glucagon during emergency situations. Kits with prefilled syringes containing 1 mg glucagon are available. Patients who are given glucagon should be positioned so that their face is turned toward the floor to prevent aspiration in the event of vomiting. As soon as the patient awakens (10–25 minutes), he or she should be fed.

Intravenous Glucose

If glucagon is unavailable, the patient should be taken to the hospital’s emergency department, where he or she can be treated with IV glucose (~10–25 g administered as 20–50 mL of 50% dextrose over 1–3 minutes) in preference to glucagon. Following the bolus injection of glucose, IV glucose (5–10 g/hour) should be continued until the patient has gained consciousness and is able to eat.

Hypoglycemic Unawareness

38. M.M., a 35-year-old, 75-kg, unemployed man, has had type 1 diabetes since the age of 3. As a consequence of the diabetes, he has developed proliferative retinopathy and progressive diabetic nephropathy (current SrCr, 3.0 mg/dL). M.M. has an erratic lifestyle. Because he does not work, he often stays out late at night and sleeps late into the morning. His insulin is injected whenever he awakens, and his meals are irregularly spaced. Each time he comes to the clinic, he brings with him a complete log of glucose concentrations that range from 80 to 140 mg/dL. He has two to three severe hypoglycemic reactions a month that require emergency treatment with IV glucose. On several occasions, his blood

glucose concentration has been 30 mg/dL and he states he may feel a little weak, but otherwise feels “not too bad.” M.M.’s last HbA_{1c} was 10%. He says that he adheres to the following insulin regimen: 18 units NPH/11 units regular insulin before breakfast, 10 units regular insulin before lunch and dinner, and 14 units NPH at bedtime.

At this visit, M.M. comes with his girlfriend. He has a large gash on his nose that occurred 3 days ago when he lost consciousness at approximately 1:30 PM while pushing his stalled car. He was unable to eat lunch at the usual hour because he had problems with his car. Assess M.M.’s hypoglycemic reactions and blood glucose control. Should his current insulin regimen be continued? How should he be managed?

[SI units: SrCr, 265 μmol/L; blood glucose, 4.4–7.8 mmol/L; HbA_{1c}, 0.10]

M.M. illustrates a patient with type 1 diabetes who has defective glucose counter-regulation and, as a result, is unable to counteract a hypoglycemic reaction effectively. He also is an example of a patient who should not have aggressive blood glucose targets because he does not feel the symptoms of a low blood sugar and has already developed end-stage organ damage (proliferative retinopathy and nephropathy). Neither are likely to be reversed with improved glycemic control. In fact, proliferative retinopathy may actually worsen with intensive insulin therapy initially.²⁹ In the DCCT study, severe hypoglycemic reactions were three times more common among patients treated with intensive insulin therapy, and nocturnal hypoglycemia accounted for 41% of the total hypoglycemic episodes.²⁹ In patients with defective counter-regulation, the risk of severe hypoglycemia may be 25 times higher than in patients with adequate counter-regulatory mechanisms treated with intensive insulin therapy.¹⁵³ M.M. is at great risk for death secondary to hypoglycemia.

M.M.’s lifestyle is erratic, he eats irregularly, and his reported blood glucose concentrations (80–140 mg/dL) do not correspond to his elevated HbA_{1c} value. This may indicate that M.M.’s technique is incorrect or that he simply fills in the log with fictitious numbers before he comes to the clinic. Irregular entries in different colored inks and blood stains usually indicate authentic records.

As noted, the primary hormones that are secreted in response to a low blood glucose concentration are glucagon and epinephrine. In patients who have had type 1 diabetes for longer than 2 to 5 years, a deficiency in glucagon secretion is a relatively consistent finding, and these patients must rely on epinephrine to reverse low blood glucose concentrations. Unfortunately, approximately 40% of patients with long-standing type 1 diabetes (8–15 years) have defective epinephrine secretion as well, and this may be related to the development of autonomic neuropathy. Patients whose diabetes is tightly controlled also have reduced counter-regulatory hormone responses to hypoglycemia. As illustrated by M.M., patients with defective epinephrine secretory responses also lose the warning signs and symptoms of hypoglycemia. These patients are said to have “hypoglycemia unawareness” because they have no awareness of blood glucose concentrations below 50 mg/dL. In these individuals, loss of consciousness, seizures, or irrational behavior may be the first objective signs of exceedingly low blood glucose concentrations. The glycemic threshold for symptoms also is lowered in patients on intensive insulin therapy whose glucose concentrations have been lowered to normal or near-normal levels.¹⁵³ Consequently, their hypoglycemic reactions

may go unnoticed and untreated until they lose consciousness. M.M. should be managed as follows.

- Because his waking, sleeping, and eating patterns are highly irregular, M.M. should be treated with an insulin regimen that addresses his lifestyle. For example, he could be instructed to give himself a rapid-acting insulin just before he actually intends to eat. A dose of insulin glargine or detemir could be given before his first meal to supply a basal level of insulin between meals.
- Because M.M. has no warning symptoms for hypoglycemia, the importance of regular blood glucose testing should be emphasized. When blood glucose testing was reviewed with M.M., it was discovered that his eyesight was so poor that he was unable to distinguish between the right and wrong side of the glucose test strip. Furthermore, because he had lost his depth of field, he was unable to apply the drop of blood into the test strip. To address this situation, M.M.’s girlfriend was taught how to perform blood glucose testing. Also, a glucose monitor that requires a very small blood sample and beeps with an adequate blood sample (e.g., Abbott Freestyle Freedom) was provided to him.
- M.M.’s girlfriend also was taught how to recognize and treat symptoms of hypoglycemia. Often, patients ignore early warning symptoms and progress to a point that they lose the judgment needed to treat the condition. If M.M. has not yet become combative, a quick-acting carbohydrate source should be offered. If he has lost consciousness, glucagon should be injected.

All of these maneuvers diminished the frequency of M.M.’s severe hypoglycemic reactions. On the whole, his blood glucose concentrations were maintained below 180 mg/dL, and he remained relatively free of hyperglycemic symptoms. M.M.’s HbA_{1c} using this insulin regimen was 8.0%.

DIABETIC KETOACIDOSIS

39. J.L., a 25-year-old, 60-kg woman with an 8-year history of type 1 diabetes, is moderately well controlled on 24 units insulin glargine plus premeal doses of insulin lispro. Her family brings her to the emergency department, where she complains of abdominal tenderness, nausea, and vomiting. According to her family, J.L. was well until 2 days ago when she awoke with nausea, vomiting, diarrhea, and chills. Because she was unable to eat, she omitted her usual morning dose of insulin. Her GI symptoms progressed, and she was brought to the emergency department when she became lethargic.

Physical examination reveals an ill-appearing woman who is lethargic but responsive. Her temperature is 37°C. Skin turgor is poor, mucous membranes are dry, and her eyeballs are shrunken and soft. J.L.’s lungs are clear, but respirations are deep and her breath has a fruity odor. Cardiac examination is within normal limits.

In the supine position, J.L.’s pulse rate is 115 beats/minute (normal, 60–100) and her BP is 105/60 mmHg. In the upright position, her pulse increased to 140 beats/minute, and her BP dropped to 85/40 mmHg. There is mild, diffuse tenderness over her abdomen.

Laboratory results on admission disclosed the following: blood glucose, 750 mg/dL; sodium (Na), 148 mEq/L (normal, 135–147); potassium (K), 5.4 mEq/L (normal, 3.5–5.0); chloride (Cl),

106 mEq/L (normal, 95–105); HCO₃, 6 mEq/L (normal, 22–28); SrCr, 2.0 mg/dL (normal, 0.6–1.2); hemoglobin, 14.7 g/dL (normal, 11.5–15.5); hematocrit, 49% (normal, 33%–43%); white blood cell (WBC) count, 15,000/mm³ (normal, 3,200–9,800) with 3% bands (normal, 3%–5%), 70% polymorphonuclear neutrophils (normal, 54%–62%), and 27% lymphocytes (normal, 25%–33%); serum ketones were moderate at 1:10 dilution (normal, negative). The urinalysis showed 2% glucose (normal, 0); moderate ketones (normal, 0); pH, 5.5 (normal, 4.6–8); and a specific gravity of 1.029 (normal, 1.020–1.025); there were no WBCs, RBCs, bacteria, or casts. Arterial blood gas results were as follows: pH, 7.05 (normal, 7.36–7.44); PCO₂, 20 mmHg (normal, 35–45); PO₂, 120 mmHg (normal, 90–100). What supports the diagnosis of DKA in J.L.?

[SI units: blood glucose, 41.6 mmol/L; Na, 148 mmol/L; K, 5.4 mmol/L; Cl, 106 mmol/L; HCO₃, 6 mmol/L; SrCr, 176.8 μmol/L; hemoglobin, 147 g/L; hematocrit, 0.49; WBC count, 15 × 10⁸/L with 0.03 bands; polymorphonuclear neutrophils, 0.70; lymphocytes, 0.27; PCO₂, 2.6 kPa; PO₂, 16.0 kPa]

The fact that J.L. has type 1 diabetes puts her at risk for developing ketoacidosis. An absolute or relative insulin deficiency promotes lipolysis and metabolism of free fatty acids to β-hydroxybutyrate, acetoacetic acid, and acetone in the liver. Excess glucagon enhances gluconeogenesis and impairs peripheral ketone utilization. Stress can contribute to the development of DKA by stimulating release of insulin counter-regulatory hormones such as glucagon, catecholamines, glucocorticoids, and growth hormone. Common stress factors include infection, pregnancy, pancreatitis, trauma, hyperthyroidism, and acute MI.

J.L. presented with symptoms of nausea, vomiting, diarrhea, and chills, and these are suggestive of an acute viral gastroenteritis. Patients such as J.L. commonly discontinue their insulin in this setting, which further predisposes them to the development of DKA (see Question 30). Table 50-23 lists patient education points with regard to DKA.

As illustrated by J.L., patients with DKA present with moderate to high serum glucose concentrations secondary to decreased peripheral utilization and increased hepatic production (Table 50-24). This increases serum osmolality, which initially shifts fluid from the intracellular to the extracellular space. When glucose concentrations exceed the renal threshold, osmotic diuresis ensues and water, sodium, potassium, and other electrolytes are depleted. J.L. also has lost fluid and electrolytes from vomiting and diarrhea. Eventually, as losses exceed input, the patient becomes dehydrated (dry mucous membranes; dry skin; soft, shrunken eyeballs; increased hematocrit) and intravascular volume becomes depleted (orthostatic BP and pulse changes).

Evidence of excessive ketone production in J.L. includes ketonuria, ketonemia, and the characteristic fruity odor of acetone on the breath. Elevated levels of these organic acids increase the anion gap and decrease the pH and carbonate levels. The respiratory rate is increased to compensate for the metabolic acidosis leading to hypercapnia.^{114,155}

Treatment

40. How should J.L. be treated?

Treatment of patients with DKA is aimed at expansion of intravascular and extravascular volume, restoration of renal per-

Table 50-23 Diabetic Ketoacidosis: Patient Education

Definition: DKA occurs when the body has insufficient insulin.

Questions to Ask

1. Has insulin use been discontinued or a dose skipped for any reason?
2. If an insulin pump is being used, is the tubing clogged or twisted? Has the catheter become dislodged?
3. Has the insulin being used lost its activity? Is the bottle of rapid-acting/regular or basal insulin cloudy? Does the bottle of NPH look frosty?
4. Have insulin requirements increased owing to illness or other forms of stress (infection, pregnancy, pancreatitis, trauma, hyperthyroidism, or MI)?

What to Look For

1. Signs and symptoms of hyperglycemia: thirst, excessive urination, fatigue, blurred vision, consistently elevated blood glucose concentrations (>300 mg/dL)
2. Signs of acidosis: fruity breath odor, deep and difficult breathing
3. Signs of dehydration: dry mouth; warm, dry skin; fatigue
4. Others: stomach pain, nausea, vomiting, loss of appetite

What to Do

1. Review “Sick Day Management” (Table 50-22)
2. Test blood glucose ≥4 times daily
3. Test urine for ketones when blood glucose concentration is >300 mg/dL
4. Drink plenty of fluids (water, clear soups)
5. Continue taking insulin dose
6. Contact physician immediately

fusions, correction of dehydration, fluid and electrolyte losses, and hyperosmolality (hyperglycemia; Table 50-25).

Fluids

Rapid correction of fluid loss is most crucial. The usual fluid deficit approximates 6 to 10 L or 10% of body weight in most patients with DKA. In the absence of cardiac compromise, hypernatremia or significant renal dysfunction, isotonic saline (0.9% NaCl) should be used.¹¹⁴

Table 50-24 Common Laboratory Abnormalities in Diabetic Ketoacidosis

| | |
|------------------|---|
| Glucose | >250 mg/dL |
| Serum osmolality | Variable, can be >320 mOsm/kg in presence of coma |
| Sodium | Low, normal, or high ^a |
| Potassium | Normal or high |
| Ketones | Present in urine and blood |
| pH | Mild: 7.25–7.30 Moderate: 7.00–7.24 Severe: <7.00 |
| Bicarbonate | Mild: 15–18 Moderate: 10 to <15 Severe: <10 |
| WBC count | 15,000–40,000 cells/mm even without evidence of infection |

^aTotal body sodium is always low.

DKA, diabetic ketoacidosis; WBC, white blood cell.

Table 50-25 Management of Diabetic Ketoacidosis¹¹⁴**Fluid Administration**

Start IV fluids using normal saline (0.9% NaCl) unless patient has cardiac compromise.

Rate is 15–20 mL/kg body weight or 1–1.5 L during first hour
Then, if corrected sodium is normal or elevated, use 0.45% NS at a rate of 4–14 mL/kg/hr (250–500 mL/hr). Use 0.9% NS if corrected sodium is low.

Once serum glucose reaches 200 mg/dL, change to 5% dextrose with 0.45% NaCl at 150–250 mL/hr.

Insulin

Continuous IV infusion of regular insulin is preferred. Use IM route only if infusion is not available.

Bolus dose: 0.1 unit/kg IV

Maintenance dose: 0.1 unit/kg/hr IV

If blood glucose level has not decreased by 50–75 mg/dL after 1 hr, double infusion rate.

Once blood glucose reaches 200 mg/dL, reduce infusion rate to 0.05–0.1 unit/kg/hr and change fluid to 5% dextrose with 0.45% NaCl (do not stop insulin infusion).

When SC insulin can be initiated, administer dose 1–2 hr before discontinuing IV infusion.

For uncomplicated DKA, SC rapid-acting insulin can be considered. A bolus dose of 0.2 unit/kg followed by 0.1 unit/kg every hour *or* an initial dose of 0.3 unit/kg followed by 0.2 unit/kg Q 2 hr until the blood glucose reaches <250 mg/dL; then the SC insulin dose is decreased by half (to either 0.05 or 0.1 unit/kg every 1–2 hr).

Potassium

Establish adequate renal function (urine output ~50 mL/hr). If K is <3.3 mEq/L, hold insulin and give 20–40 mEq/hr until K >3.3 mEq/L. If K is >5.5 mEq/L, do not give K and check serum K Q 2 hr. If K is >3.3 but <5.3 mEq/L, give 20–30 mEq in each liter IV fluid to maintain K between 4–5 mEq/L.

Phosphate

Initiate if level <1 mg/dL, or in patients with cardiac dysfunction, anemia, or respiratory depression. Use potassium phosphate salt, 20–30 mEq added to replacement fluid. Rarely needed.

Bicarbonate

Replacement is controversial and may be dangerous.

For adults with pH <6.9, 100 mmol sodium bicarbonate may be added to 400 mL sterile water with 20 mEq KCl; infuse over 2 hr (200 mL/hr).

For adults with pH of 6.9–7.0, 50 mmol sodium bicarbonate diluted in 200 mL sterile water with 10 mEq KCl; infuse over 1 hr (200 mL/hr).

No bicarbonate is necessary if pH >7.0.

NS, normal saline.

J.L. has evidence of significant dehydration and intravascular volume depletion. A rough calculation indicates that approximately 6 to 7 L will be needed (10% of body weight). It is recommended that fluids be replaced at the rate of 15 to 20 mL/kg/hour during the first hour (~1 to 1.5 L in the average adult). The subsequent choice for fluid replacement depends on the patient's state of hydration, serum electrolyte levels, and urinary output. If the corrected sodium is normal or elevated, 0.45% NaCl infused at a rate of 4 to 14 mL/kg/hour is appropriate. If the corrected serum sodium is low, 0.9% NaCl

is preferred.¹¹⁴ When serum glucose concentrations approach 200, solutions should be changed to 5% glucose in half-normal saline. Glucose is added to prevent hypoglycemia and the cerebral edema that can occur if the osmolality is reduced too rapidly. The use of dextrose also allows for continued insulin administration that is required to resolve the ketoacidosis (see Question 41). These recommendations for fluid replacement must be adjusted in the elderly or those with compromised renal or myocardial function. In these patients, fluid administration must be titrated against the central venous pressure.^{114,155}

Sodium

Total body sodium usually is depleted by 7 to 10 mEq/kg of body weight in patients with DKA. In assessing serum sodium in these patients, it is important to remember that falsely low values (i.e., pseudohyponatremia) may be the result of hyperglycemia and hypertriglyceridemia. A corrected sodium value can be estimated by adding 1.6 mEq/L to the observed sodium value for every 100 mg/dL glucose >100 mg/dL. Sodium is replaced adequately with normal saline.¹¹⁴

Potassium

Potassium balance is altered markedly in patients with DKA because of combined urinary and GI losses. Invariably, total potassium is depleted; however, the serum potassium concentration may be high, normal, or low, depending on the degree of acidosis and volume contraction. Usual potassium deficits in this situation average 3 to 5 mEq/kg of body weight, although they may be as high as 10 mEq/kg.^{114,155}

Thus, J.L. needs approximately 200 to 350 mEq of potassium to replenish her body stores, assuming her normal weight is 70 kg. To prevent hypokalemia, potassium replacement should be started after her serum potassium concentrations decrease to <5.3 mEq/L (assuming an adequate urine output of 50 mL/hour). Generally IV solutions containing 20 to 30 mEq/L are sufficient to maintain the serum potassium between 4 and 5 mEq/L. However, in cases with low serum potassium (<3.3 mEq/L) at presentation, potassium replacement should be initiated with fluid therapy, and insulin therapy delayed until the potassium level is >3.3 mEq/L to avoid cardiac arrest, arrhythmias, and respiratory muscle weakness. In these cases, initial IV solutions should contain KCl 20 to 30 mEq/L.

Phosphate

Routine use of phosphate in the treatment of DKA has resulted in no clinical benefit to patients.¹¹⁴ Phosphate is lost as the result of increased tissue catabolism, impaired cellular uptake, and enhanced renal excretion. Like other electrolytes, serum levels initially may seem normal, even though body stores are depleted. Overzealous replacement can result in severe hypocalcemia. Hypophosphatemia can cause cardiac and skeletal muscle weakness and respiratory depression. To avoid this, phosphate can be carefully replaced in patients with cardiac dysfunction, anemia, respiratory depression, and those with phosphate concentrations below 1.0 mg/dL. Potassium phosphate can be added to the replacement fluids in the amount of 20 to 30 mEq/L.

Insulin

41. What is an appropriate insulin dose and route of administration for J.L.?

Unless the episode of DKA is mild (pH 7.25–7.30) and uncomplicated, regular insulin by continuous infusion is the treatment of choice. Once hypokalemia ($K^+ < 3.3$ mEq/L) is excluded, an IV bolus of regular insulin at 0.1 unit/kg followed by a continuous infusion at a dose of 0.1 unit/kg/hour should be administered. This should decrease the plasma glucose at a rate of 50 to 75 mg/dL/hour. If this does not occur in the first hour, then the rate may be doubled every hour until a steady glucose decline is achieved. Once the plasma glucose reaches 200 mg/dL, the insulin infusion can be decreased to 0.05 to 0.1 unit/kg/hour. At this point, dextrose should be added to the IV fluids (i.e., fluids changed to D₅W with 0.45% NaCl). Thereafter, the rate of insulin administration or the concentration of dextrose is adjusted to maintain the glucose value at around 200 mg/dL until the acidosis is resolved.¹¹⁴ Thus, for J.L., an IV bolus dose of 6 units followed by an infusion rate of 6 units/hour is appropriate.

For uncomplicated DKA, SC rapid-acting insulin has been studied with no differences in patient outcomes. The advantage is that patients can be treated in a non-ICU setting, thus reducing hospital costs. The dosing for rapid-acting insulin is included in Table 50-25.

Sodium Bicarbonate

42. J.L. was treated with fluids, electrolytes, and insulin as discussed in previous questions. Laboratory and clinical data 4 hours after therapy are as follows: pH, 7.1; blood glucose, 400 mg/dL; K, 3.8 mEq/L; SrCr, 3.1 mg/dL; and serum ketones strongly positive at a 1:40 dilution. Her BP was 120/70 mmHg with no orthostatic changes. Urine output over the last 3 hours has been 500 mL. Because serum ketones have increased, should J.L. receive more insulin? Should she receive bicarbonate therapy?

[SI units: blood glucose, 22 mmol/L; K, 3.8 mmol/L; SrCr, 274 μ mol/L]

The assumption that ketosis is worse in J.L. is incorrect. In DKA, low levels of insulin and elevated glucagon levels promote the metabolism of free fatty acids in the liver to acetoacetate and β -hydroxybutyrate. The standard nitroprusside reaction test for ketones measures only acetoacetate, even though β -hydroxybutyrate is the more important ketone. The conversion of acetoacetic acid to β -hydroxybutyrate is coupled closely with the NADH:NAD ratio. If this ratio is high (as in the presence of alcohol) so much β -hydroxybutyrate may be formed that acetoacetate is virtually undetectable; thus, the absence of ketones in the serum does not rule out ketoacidosis.

Conversely, treatment with insulin begins to suppress lipolysis and fatty acid oxidation; NAD is regenerated shifting the reaction back in favor of acetoacetate.^{114,155} Thus, even though there seems to be higher concentrations of ketones in the serum, J.L.'s declining blood glucose concentration, improved bicarbonate concentrations, and improved acid–base and cardiovascular responses indicate that she is responding appropriately. Therefore, no change in the insulin dose is indicated. It is important to emphasize that the glucose concentrations normalize before ketones (4–6 hours vs. 6–12 hours) because the latter are metabolized more slowly. For this reason, it is important to continue insulin to maintain suppression of lipolysis until plasma and urine ketones have cleared.

The use of bicarbonate in patients with DKA has been controversial.¹¹⁴ Most investigators discourage its routine use,

reserving it for patients with severe acidemia (pH <7.0) or those in clinical shock. Coma is correlated most closely with blood glucose concentrations (>700 mg/dL) and hyperosmolality (calculated osmolality >340 mOsm/kg).¹¹⁴ In a randomized, prospective study, bicarbonate did not affect recovery in patients with severe DKA (arterial pH, 6.9–7.14).¹⁵⁶ Thus, even though J.L.'s acidosis seemed severe on admission (pH, 7.05; bicarbonate, 6 mEq/L; Kussmaul respirations), bicarbonate was not administered. It is apparent that with fluid and insulin therapy alone, her acidosis is beginning to improve.

43. What is the expected course of DKA in J.L.?

After 3 L of fluid and a constant insulin infusion of 6 units/hour for 3 hours, J.L.'s glucose concentration had dropped to 400 mg/dL and she had no orthostatic BP changes, reflecting recovery from her volume-depleted status. Potassium (40 mEq/L) was added to her fluids, which were administered at a reduced rate of 300 mL/hour.

Three hours later, the glucose concentration had dropped to 350 mg/dL and her pH had increased to 7.21. The serum potassium remained low-normal at 3.4 mEq/L, and serum sodium increased to 151 mEq/L. In view of these changes, the IV infusion fluid was changed to half-normal saline with 5% dextrose to which 40 mEq/L of potassium was added. The rate was slowed to 250 mL/hour, and the insulin infusion was continued at 6 units/hour.

Four hours later (10 hours after admission), the blood glucose was 205 mg/dL and the serum potassium was 3.5 mEq/dL. The IV fluids were changed to 5% dextrose with 40 mEq/L of KCl, administered at a rate of 250 mL/hour, and the regular insulin infusion was decreased from 6 to 3 units/hour. J.L. continued to improve over the next 12 hours, and she began taking full oral liquids by the second hospital day. At that time, her IV infusion rate was decreased to 200 mL/hour, but her insulin infusion was continued.

Approximately 24 hours after admission, J.L.'s blood glucose concentration was 175 mg/dL, potassium was 4.6 mEq/L, and sodium was 144 mEq/L. There were no ketones in the plasma. The urine contained 1% glucose and moderate amounts of ketones. IV fluids were discontinued and a rapid-acting insulin was administered subcutaneously 1 hour before the insulin infusion was discontinued. J.L. continued to receive rapid-acting insulin subcutaneously every 4 hours according to a sliding scale (see Question 14). Thirty-six hours after admission, J.L. was given her usual dose of insulin glargine and insulin lispro and was sent home for follow-up in the clinic.

TREATMENT OF TYPE 2 DIABETES: ANTIDIABETIC AGENTS

Type 2 diabetes must be managed in the context of the metabolic syndrome. At the time of diagnosis, many people with type 2 diabetes already have evidence of macrovascular and microvascular disease. Every effort to lower glucose concentrations toward normal values, control BP, and lower cholesterol is important to delay the onset or slow the progression of these complications, improve the overall quality of the patient's life, and save the health care system millions of dollars in hospitalization costs to treat these complications. MNT, physical activity, and other lifestyle changes are cornerstones in treating of people with type 2 diabetes. Unfortunately, these measures alone are usually not successful in achieving control for the majority of patients, and drug therapy is eventually

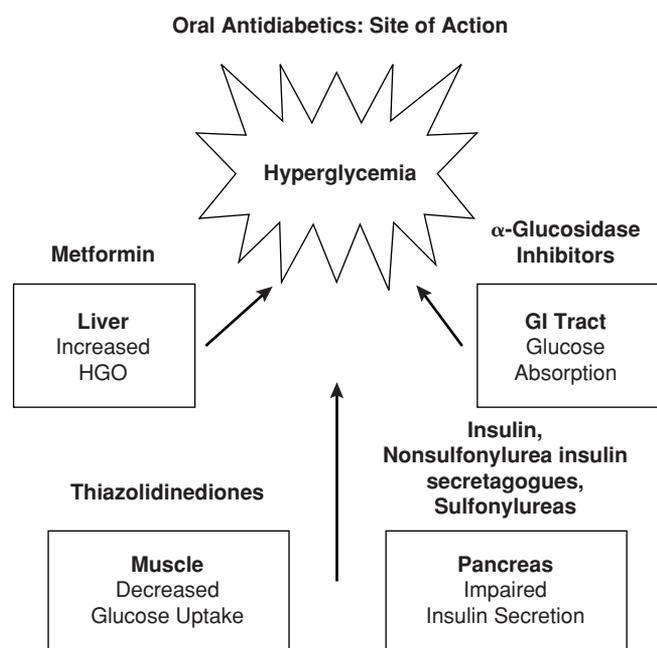

FIGURE 50-7 Sources of hyperglycemia in type 2 diabetes and site of action of oral antidiabetic agents. GI, gastrointestinal; HGO, hepatic glucose output.

required. Because these patients also often require a number of medications to treat related conditions (e.g., hypertension, hypercholesterolemia, and depression) and may also be medicating themselves with over-the-counter drugs, herbal products, and/or nutritional supplements, the aim of therapy for type 2 diabetes should be the simplest and safest regimen that provides the best glycemic control possible.

Figure 50-7 depicts the sources of hyperglycemia in people with type 2 diabetes and the primary site of action for each class of agents. Table 50-26 and Table 50-27 summarize the comparative pharmacology, pharmacokinetics, and dosing of the non-insulin antidiabetic drugs. The clinical use of these agents in specific situations is illustrated in cases presented later in this chapter.

Biguanides

Metformin (Glucophage) belongs to the biguanide class of oral antidiabetic agents. It has been available in the United States since 1995 and became generically available in 2002. The clinical pharmacology of metformin has been extensively reviewed.¹⁵⁷

Mechanism of Action¹⁵⁷

The biguanides are described more accurately as antihyperglycemic agents. Although they lower blood glucose concentrations in people with type 2 diabetes, they do not cause hypoglycemia in nondiabetic individuals. The precise mechanisms by which metformin lowers blood glucose concentrations remain to be elucidated. Evidence suggests metformin lowers FPG concentrations by decreasing hepatic gluconeogenesis

and increasing insulin-stimulated glucose uptake by skeletal muscle and adipose tissue. Metformin also lowers plasma free fatty acid levels and subsequent oxidation. This observation may explain its ability to reduce hepatic glucose production and increase insulin-mediated glucose disposal in the muscle. Metformin also slightly lowers total cholesterol (5%–10%) and triglycerides (10%–20%) and may maintain or improve high-density lipoprotein (HDL) cholesterol levels.¹⁵⁸ The observed effects on lipid metabolism as well as others on clotting factors, platelet function, and vascular function have generated interest in the potential favorable effects of metformin on CVD and outcomes. Unlike the sulfonylureas, thiazolidinediones (TZDs), and insulin, weight loss rather than weight gain is more likely to occur with metformin therapy (mean weight loss of 1.2 kg compared with 1.7 kg increase).¹⁵⁹

Pharmacokinetics

Approximately 50% to 60% of metformin is absorbed from the small intestine. It is eliminated entirely by the kidney unchanged and has a plasma half-life of 6.2 hours and a whole blood half-life of 17.6 hours. It is not bound to plasma proteins.^{158,160}

Adverse Effects

GASTROINTESTINAL EFFECTS

Transient side effects include diarrhea and other GI disturbances such as nausea, abdominal discomfort, metallic taste, and anorexia.¹⁵⁸ Relative to placebo, diarrhea is the most common GI complaint (53.2% metformin vs 11.7% placebo-treated patients). Symptoms can be minimized by taking metformin with food and slowly titrating the dose. To enhance adherence to therapy, patients should be informed of the possibility of GI side effects that will likely subside with time and instructed to discuss any suspected side effects with their provider before discontinuing therapy (see Question 47).

LACTIC ACIDOSIS

Much of the perceived risk of lactic acidosis secondary to metformin use is based on historical data for phenformin, a biguanide that was withdrawn from the market in 1977.¹⁶¹ The risk of lactic acidosis secondary to metformin is 10 to 20 times lower than with phenformin.¹⁵⁷ Unlike phenformin, metformin is not metabolized, does not inhibit peripheral glucose oxidation, and does not enhance peripheral lactate production.¹⁶² However, it may decrease conversion of lactate to glucose (decreased gluconeogenesis) and increase lactate production in the gut and liver.¹⁵⁷ Metformin has rarely been associated with lactic acidosis. The few patients in whom this event has been reported had renal, liver, or cardiorespiratory contraindications to the use of biguanides. Patients should be warned to bring the following symptoms of lactic acidosis to the attention of their physician: weakness, malaise, myalgias, abdominal distress, and heavy, labored breathing (see Question 62).

Contraindications and Precautions

Patients with renal impairment, hepatic disease, congestive heart failure (CHF) requiring pharmacologic treatment or other states predisposing them to hypoxia, acute or chronic metabolic

Table 50-26 Comparative Pharmacology of Antidiabetic Agents

| <i>Agent Generic Name Brand Name Mechanism</i> | <i>FDA Indications</i> | <i>Efficacy</i> | <i>Adverse Effects</i> | <i>Comments</i> |
|---|--|--|---|--|
| Insulin Replaces or augments endogenous insulin | Monotherapy; combined with any oral agent | ↓ HbA _{1c} ∞ ↓ FPG ∞ ↓ PPG ∞ ↓ TG | Hypoglycemia, weight gain, lipodystrophy, local skin reactions. | Offers flexible dosing to match lifestyle and glucose concentrations. Rapid onset. Safe in pregnancy, renal failure, and liver dysfunction. Drug of choice when patients do not respond to other antidiabetic agents. |
| Insulin-Augmenting Agents | | | | |
| Nonsulfonylurea secretagogues (Glinides) Repaglinide (Prandin) Nateglinide (Starlix) Stimulate insulin secretion. | Monotherapy; combined with metformin or TZD | ↓ HbA _{1c} 1.7% ↓ FPG 61 mg/dL ↓ PPG 48 mg/dL | Hypoglycemia, weight gain. | Take only with meals. If a meal is skipped, skip a dose. Flexible dosing with lifestyle. Safe in renal and liver failure. Rapid onset. |
| Sulfonylureas Various; see Table 50-27. Stimulate insulin secretion. May decrease hepatic glucose output and enhance peripheral glucose utilization. | Monotherapy; combined with metformin; combined with insulin (glimepiride) | ↓ HbA _{1c} 1.5–1.7% FPG 50–70 mg/dL ↓ PPG 92 mg/dL | Hypoglycemia, especially long-acting agents; weight gain (5–10 lb). Rash, hepatotoxicity, alcohol intolerance, and hyponatremia are rare. | Very effective agents, Some can be dosed once daily. Rapid onset of effect (1 wk). |
| Incretin-Based Therapies | | | | |
| Glucagon-like peptide -1 receptor agonists/Incretin Mimetic Exenatide (Byetta) Stimulates insulin secretion, delays gastric emptying, reduces postprandial glucagon levels, improved satiety | Combined with metformin, SFU or TZD, combined with metformin + SFU; combined with metformin + TZD | ↓ HbA _{1c} 0.8%–0.9% ↓ FPG 10 mg/dL ↓ PPG 71 mg/dL | GI: nausea, vomiting, diarrhea. Hypoglycemia (with SFUs); weight loss; reports of acute pancreatitis | Take within 60 min before morning and evening meals or before two main meals of the day (≥6 hr apart). Do not use in patients with gastroparesis or severe GI disease. Administered by SC injection; pen device in use does not need to be refrigerated. |
| DPP-4 Inhibitors Sitagliptin (Januvia) Stimulates insulin secretion and reduces postprandial glucagon levels | Monotherapy; combined with metformin, SFU or TZD | ↓ HbA _{1c} 0.7%–0.8% ↓ FPG 12–17 mg/dL ↓ PPG 49–62 mg | Headache, nasopharyngitis, hypoglycemia (with SFU), rash (rare) | Dosed once daily. Taken with or without food. No weight gain or nausea. Need to dose adjust in renal dysfunction. Reduce dose of SFU when combined. |
| Amylin Receptor Agonists | | | | |
| Amylin mimetic Pramlintide (Symlin) Stimulates insulin secretion, delays gastric emptying, reduces postprandial glucagon levels, improved satiety | Type 1: Adjunct to mealtime insulin Type 2: Adjunct to mealtime insulin; ± SFU and/or metformin | T1: ↓ HbA _{1c} 0.33% T2: ↓ HbA _{1c} 0.40% | GI: nausea, decreased appetite. Headache; hypoglycemia; weight loss (mild) | Take only immediately before meals; administered by SC injection. Do not use in patients with gastroparesis. |
| Insulin Sensitizers | | | | |
| Biguanides Metformin (Glucophage) ↓ Hepatic glucose output; ↑ Peripheral glucose uptake | Monotherapy; combined with SFU and/or TZD; or with insulin | ↓ HbA _{1c} 1.5%–1.7% ↓ FPG 50–70 mg/dL ↓ PPG 83 mg/dL | GI: nausea, cramping, diarrhea. Lactic acidosis (rare). | Titrate dose slowly to minimize GI effects. No hypoglycemia or weight gain; weight loss possible. Mild reduction in cholesterol. Do not use in patients with renal or hepatic dysfunction or CHF requiring treatment. |

(continued)

Table 50-26 Comparative Pharmacology of Antidiabetic Agents (continued)

| Agent Generic Name Brand Name Mechanism | FDA Indications | Efficacy | Adverse Effects | Comments |
|---|---|--|--|---|
| Thiazolidinediones Rosiglitazone (Avandia) Pioglitazone (Actos) Enhance insulin action in periphery; increase glucose utilization by muscle and fat tissue; decrease hepatic glucose output | Monotherapy; combined with SFU, TZD or insulin; combined with SFU + TZD | Monotherapy: ↓ HbA _{1c} 0.8%–1.5% Combination: ↓ HbA _{1c} 0.6%–1.2% | Mild anemia; fluid retention and edema, weight gain, macular edema, fractures (in women) | Can cause or exacerbate CHF; do not use in patients with symptomatic heart failure or class III or IV CHF. Rosiglitazone may increase risk of MI. Increased risk of distal fractures in older women. Slight reduction in TG with pioglitazone; slight increase in LDL-C with rosiglitazone. LFTs must be measured at baseline and periodically thereafter. Slow onset (2–4 wk). |
| Delayers of Carbohydrate Absorption | | | | |
| α-Glucosidase inhibitors Acarbose (Precose) Miglitol (Glyset) Slow absorption of complex carbohydrates. | Monotherapy; combined with SFUs | ↓ HbA _{1c} 0.5%–1.0% ↓ FPG 20–30 mg/dL ↓ PPG 25–50 mg/dL | GI: flatulence, diarrhea. Elevations in LFTs seen in doses > 50 mg TID of acarbose. | LFTs should be monitored every 3 months during the first year of therapy and periodically thereafter. Because miglitol is not metabolized, monitoring of LFTs is not required. Titrate dose slowly to minimize GI effects. No hypoglycemia or weight gain. If used in combination with hypoglycemic agents, advise patients to treat hypoglycemia with glucose tablets because absorption is not inhibited as with sucrose. |

CHF, congestive heart failure; FPG, fasting plasma glucose; GI, gastrointestinal; HbA_{1c}, hemoglobin A_{1c}; LDL-C, low-density lipoprotein cholesterol; LFTs, liver function tests; MI, myocardial infarction; PPG, postprandial glucose; SC, subcutaneously; SFU, sulfonylureas; TG, triglycerides; TZD, thiazolidinediones.

acidosis, or a history of lactic acidosis should be excluded from therapy. Metformin can accumulate in patients whose renal function is impaired, thereby increasing their risk for lactic acidosis. Its use is not recommended in patients with decreased GFRs (<60 mL/minute) or elevated creatinine levels (≥ 1.4 mg/dL for females or ≥ 1.5 mg/dL for males). Because even a temporary reduction in renal function could cause lactic acidosis in patients taking metformin, the manufacturer recommends withholding it after some radiologic procedures (see Drug Interactions). Other predisposing factors for lactic acidosis include the following: excessive alcohol ingestion, dehydration, surgery, CHF, hepatic failure, shock, or sepsis. Because aging is associated with reduced renal function, metformin should be titrated to the minimum effective dose and renal function should be monitored regularly. A creatinine clearance (Cl_{Cr}) to ensure adequate renal function should be measured in patients over the age of 80 years, because these patients are more susceptible to developing lactic acidosis.¹⁵⁸

Drug Interactions

- Alcohol potentiates the effect of metformin on lactate metabolism. Patients should be warned against excessive alcohol intake while taking metformin.
- Cimetidine increases peak metformin plasma concentrations by 60%; use of an alternative H₂ blocker or a reduction in metformin dose is recommended.
- Parenteral contrast studies (e.g., pyelography or angiography) that use iodinated materials can result in acute renal failure and metformin-induced lactic acidosis. For patients requiring such a study, metformin should be withheld at the time of, or before, and for 48 hours after the procedure. Metformin should be reinstated only after renal function has been reevaluated and determined to be normal.

Efficacy

As monotherapy, metformin can be expected to reduce the HbA_{1c} by 1.5% to 1.7% and the FPG by 50 to 70 mg/dL. In patients who have developed secondary failure to sulfonylureas, the addition of metformin can be expected to produce a similar or slightly greater improvement in the FPG and HbA_{1c}.¹⁵⁷ Research suggests that certain genetic variations may impact patient response to metformin therapy. Patients exhibiting reduced function polymorphisms of organic cation transporter 1, which is involved in the hepatic uptake of metformin, may be less responsive to metformin therapy.¹⁶³

Table 50-27 Antidiabetic Pharmacokinetic Data

| Drug (Brand Name) Available Tablet Strengths (mg) | Typical Dosing Regimen (mg) | Usual Minimum and Maximum Total Daily Dose/How Divided | Mean Half-Life | Approximate Duration of Activity | Bioavailability Metabolism, and Excretion | Comments |
|--|---|--|--|---|--|--|
| α-Glucosidase inhibitors | | | | | | |
| Acarbose (Precose) 25, 50, 100 mg | 25–100 mg with first bite of each meal. Begin with 25 mg; \uparrow by 25 mg/meal every 4–8 weeks. | Minimum: 25 mg TID; Maximum dose is 50 mg TID if ≤ 60 kg; 100 mg TID if > 60 kg. | 2.8 hr | Affects absorption of complex carbohydrates in a single meal | F = 0.5%–1.7%; extensively metabolized by GI amylases to inactive products; 50% excreted unchanged in the feces | Titrate doses slowly to avoid GI effects |
| Miglitrol (Glyset) 25, 50, 100 mg | 25–100 mg with first bite of each meal. Begin with 25 mg; \uparrow by 25 mg/meal every 4–8 weeks. | Minimum: 25 mg TID Maximum: 100 mg TID | 2 hr | Affects absorption of complex carbohydrates in a single meal | Dose of 25 mg is completely absorbed; dose of 100 mg 50–70% absorbed; elimination by renal excretion as unchanged drug | |
| Biguanides | | | | | | |
| Metformin (Glucophage) 500, 850, 1000 mg; 500 mg/mL liquid | Begin with 500 mg QD or /BID; \uparrow by 500 mg QD every 1–2 weeks. | 0.5–2.5 g BID or TID | Plasma, 6.2 hr Whole blood, 17.6 hr | 6–12 hr | F = 50%–60%; excreted unchanged in urine | Take with food. Avoid in patients with renal dysfunction or those who could be predisposed to lactic acidosis (e.g., alcoholism, CHF, severe respiratory disorders, liver failure) As for metformin |
| Metformin extended-release (Glucophage XR) 500, 750, 1000 mg | 500–1,000 mg/QD with evening meal; \uparrow by 500 mg every 1–2 weeks. | 1,500–2,000 mg QD | As for metformin, but active drug is released slowly | 24 hr | As for metformin | |
| Nonsulfonylurea Insulin Secretagogues (Glinides) | | | | | | |
| Repaglinide (Prandin) 0.5, 1, 2 mg | If HbA _{1c} is $< 8\%$ or if this is first drug, begin with 0.5 mg with each meal. For others, begin with 1–2 mg/meal. | 0.5–4 mg with each meal (16 mg/day)/TID–QID | 1 hr | C _{max} is at 1 hr; duration is approximately 2–3 hr | F = 56%; 92% metabolized to inactive products by the liver; 8% excreted as metabolites unchanged in the urine | Take only with meals. Skip dose if meal is skipped. Maximum dose per meal is 4 mg. |
| Nateglinide (Starlix) 60, 120 mg | 120 mg TID 1–30 min before meals; 60 mg TID for patients with near-normal HbA _{1c} at initiation. | 60 or 120 mg TID | 1.5 hr | Onset, 20 min; peak, 1 hr; duration, 2–4 hr | F = 73%; metabolized to inactive products (predominantly) that are excreted in the urine (83%) and feces (10%) | Skip dose if meal is skipped. |
| First-Generation Sulfonylureas | | | | | | |
| Acetohexamide (Dymelor) 250, 500 mg | 250 or 500 mg/QD; \uparrow by 250 mg daily every 1–2 weeks. | 0.25–1.5 g QD or BID | 5 hr (active metabolite) | 12–18 hr | Activity of metabolite greater than parent drug. Metabolite excreted, in part, by kidney | Caution in elderly and patients with renal disease. Significant uricosuric effects |
| Chlorpropamide (Diabinese) 100, 250 mg | 100 or 250 mg/QD; \uparrow by 100 or 250 mg every 1–2 weeks. | 0.1–0.5 g QD | ≥ 35 hr | 24–72 hr | Inactive and weakly active metabolites; 20% excreted unchanged; varies widely | Caution in elderly and patients with renal impairment. Highest frequency of side effects relative to other sulfonylureas |

(continued)

Table 50-27 Antidiabetic Pharmacokinetic Data (Continued)

| Drug (Brand Name) Available Tablet Strengths (mg) | Typical Dosing Regimen (mg) | Usual Minimum and Maximum Total Daily Dose/How Divided | Mean Half-Life | Approximate Duration of Activity | Bioavailability Metabolism, and Excretion | Comments |
|--|--|--|---|--|---|--|
| First-Generation Sulfonylureas (continued) | | | | | | |
| Tolazamide (Tolinase) 100, 250, 500 mg | 100–250 mg/QD; ↑ by 100 or 250 mg every 1–2 weeks. | 0.2–1 g QD or BID | 7 hr (4–25) | 12–24 hr | Some metabolites with moderate activity excreted via kidney | Active metabolites may accumulate in renal failure |
| Tolbutamide (Orinase) 250, 500 mg | 250 mg/BID before meals; ↑ by 250 mg daily every 1–2 weeks | 0.5–3 g BID or TID | 7 hr | 6–12 hr | Metabolized to compounds with negligible activity | No special precautions. Shortest-acting sulfonylurea |
| Second-Generation Sulfonylureas | | | | | | |
| Glimepiride (Amaryl) 1, 2, 4 mg | 1–2 mg/QD initially; usual maintenance dose is 1–4 mg. | 1–8 mg QD | 9 hr | 24 hr | F = 100% completely metabolized by liver. Principal metabolite is slightly active (30% of parent compound). Excreted by the urine (60%) and feces (40%) | Probably safe in patients with renal failure, but low initial doses recommended for older patients and those with renal insufficiency. Incidence of hypoglycemia may be lower than other long-acting sulfonylureas |
| Glipizide (Glucotrol) 5, 10 mg | 2.5 mg/QD in elderly, 5 mg QD in others; ↑ by 2.5 or 5 mg every 1–2 weeks. | 2.5–40 mg QD or BID ^a | 2–4 hr | 12–24 hr | Metabolized to inactive compounds | No special precautions daily dose > 15 mg should be divided. Dose > 30 min before meals |
| Glipizide extended- release (Glucotrol XL) 5 mg | 5 mg/QD; ↑ by 5 mg every 1–2 weeks. | 5–20 mg QD | 4–13 hr | 24 hr | Same as glipizide | Use with caution in patients with preexisting GI narrowing owing to possible obstruction |
| Glyburide (Diabeta, Micronase) 1.25, 2.5, 5 mg | 1.25 mg/QD in elderly, 2.5 mg QD in others; ↑ by 1.25 or 2.5 mg every 1–2 weeks. | 1.25–20 mg QD or BID | 4–13 hr | 12–24 hr | Metabolized to inactive/weakly inactive compounds; 50% excreted in urine and 50% in feces | Caution in elderly patients with renal failure and others predisposed to hypoglycemia. Daily doses > 10 mg should be divided |
| Micronized Glyburide (Glyname pres'flab) 1.5, 3 mg | 1.5 mg/QD; ↑ by 1.5 mg every 1–2 weeks. | 1.0–12 mg QD | 4 hr | 24 hr | Metabolized to inactive/weakly inactive compounds; 50% excreted in urine and 50% in feces | Daily doses > 6 mg should be divided. ↑ bioavailability relative to original formulation. Resulted in reduced dose |
| Thiazolidinediones | | | | | | |
| Rosiglitazone (Avandia) 2, 4, 8 mg | 4 mg QD; ↑ to 8 mg QD (or 4 mg BID) | 4–8 mg daily in single or divided doses | 3–4 hr | Onset and duration poorly correlated with half-life because of mechanism of action. Onset at 3 weeks; max at ≥4 weeks. Offset likely to be similar | F = 99%; extensively metabolized in liver into inactive metabolites; excreted 2/3 in urine and 1/3 in feces | Food has no effect on absorption. BID dosing may have greater HbA _{1c} lowering effect. No dose adjustments required in renal failure. Avoid in patients with liver disease and heart failure. |
| Pioglitazone (Actos) 15, 30, 45 mg | 15–30 mg QD; ↑ to 45 mg QD. If used with insulin, ↓ insulin dose by 10%–25% once FPG < 120 mg/dL. | 15–45 mg QD | 3–7 hr (16–24 hr for all metabolites) | Same as previous | Extensively metabolized in liver; 15%–30% excreted in urine, remainder eliminated in the feces | Food delays absorption but is not clinically significant. No dose adjustments required in renal disease. Avoid in patients with liver failure. |

GLP-1 receptor agonists/incretin mimetics

Exenatide (Byetta) 5 mcg SC BID; ↑ to 10 mcg SC BID after 1 month 2.4 hr C_{max} is at 2.1 hr; duration 10 hr Glomerular filtration Take within 60 min before morning and evening meal. Nausea usually subsides over time

DPP-4 Inhibitors

Sitagliptin (Januvia) 100 mg QD CrCl ≥ 30 to < 50 mL/min: 50 mg QD CrCl < 30 mL/min: 25 mg QD 12.4 hr 24 hr F = 87%; ~79% excreted unchanged in urine. Requires dose adjustment in renal insufficiency.

Amylin Mimetics

Pramlintide (Symlin) Type 1 DM: 15 mcg SC before major meals; ↑ by 15-mcg increments after minimum of 3 days Type 2 DM: 60 mcg SC before major meals; ↑ to 120 mcg after 3–7 days 48 min C_{max} is 20 minutes Reduce mealtime insulin dose by 50%. Titrated dose if no significant nausea.

Combination Products

| | | | | | |
|--|---|--|-----------------------------------|-----------------------------------|---|
| Glipizide/metformin (Metaglip) 2.5/250 mg, 2.5/500 mg, 5/500 mg | <i>Initial therapy:</i> 2.5/250 mg QD <i>2nd-line therapy:</i> 2.5-5/500 mg BID; ↑ every 2 weeks | 5/1,000-20/2,000 mg in two divided doses | See metformin and glyburide | See metformin and glyburide | See Glucovance |
| Glyburide/Metformin (Glucovance) 1.25/500, 2.5/500 mg 5.0/500 mg | 2.5/500 mg QD or BID; ↑ by 2.5/500 mg every 1-2 weeks. | 7.5/1,500-10/2,000 mg in 2-3 divided doses with meals | See metformin and glyburide | See metformin and glyburide | Effect should be similar to the two agents given in combination. Minimum dose of 1,500 mg metformin is needed for effect. No need to exceed 10 mg glyburide |
| Rosiglitazone/metformin (Avandamet) 1/500 mg, 2/500 mg, 4/500 mg | 2/500 mg BID | 4/1,000-8/2,000 mg in two divided doses with meals | See metformin and rosiglitazone | See metformin and rosiglitazone | Dose titration schedule is dependent on which drug is being adjusted. |
| Pioglitazone/metformin (ActoPlus Met) 15/500 mg, 15/850 mg | 15/500 mg or 15/850 mg QD or BID | 30/1,000-45/2,550 mg in two divided doses with meals | See pioglitazone and metformin | See pioglitazone and metformin | Dose titration schedule is dependent on which drug is being adjusted. |
| Pioglitazone/glimepiride (Duetact) 30/2 mg, 30/4 mg | 30/2 mg or 30/2 mg QD | 30/2-30/4 mg QD | See pioglitazone and glimepiride | See pioglitazone and glimepiride | Dosed once daily with first main meal. |
| Rosiglitazone/Glimepiride (Avanadryl) 4/1 mg, 4/2 mg, 4/4 mg, 8/2 mg, 8/4 mg | 4/1 mg or 4/2 mg QD | 4/1-8/4 mg QD | See rosiglitazone and glimepiride | See rosiglitazone and glimepiride | Dose titration schedule is dependent on which drug is being adjusted. |
| Sitagliptin/Metformin (Janumet) 50/500 mg, 50/1000 mg | 50/500 mg BID | 100/1,000-100/2,000 mg in two divided doses with meals | See sitagliptin and metformin | See sitagliptin and metformin | Starting dose depends on current regimen. Metformin dose is titrated. |

BID, twice a day; CHF, congestive heart failure; CrCl, creatinine clearance; DM, diabetes mellitus; DPP-4, dipeptidyl peptidase-4; FPG, fasting plasma glucose; GI, gastrointestinal; HbA_{1c}, hemoglobin A_{1c}; QD, daily; SC, subcutaneously; T1D, three times a day.

Dosage and Clinical Use

Metformin is the first line of therapy for type 2 diabetes.²² It is usually initiated as monotherapy in combination with lifestyle interventions (e.g., MNT, physical activity) upon diagnosis. To minimize GI side effects, metformin should be initiated at 500 mg once or twice daily, to be taken with food, followed by weekly or biweekly increases in increments of 500 mg daily. Metformin is dosed two to three times daily (500–1,000 mg/dose; maximum dose, 2,550 mg/day or 850 mg PO TID), unless an extended-release preparation is prescribed. Clinicians should obtain a SrCr and hepatic function tests at baseline and then annually. Metformin should not be used in patients older than 80 years unless a CrCl demonstrates normal renal function. Patients are candidates for treatment if the CrCl is above 60 mL/minute. For patients unable to achieve goals of therapy with metformin alone within 3 to 6 months of initiating therapy, addition of insulin or another agent should be considered (also see Questions 54–58).

Nonsulfonylurea Insulin Secretagogues (Glinides)

Repaglinide (Prandin) and nateglinide (Starlix) are nonsulfonylurea insulin secretagogues (i.e., they stimulate insulin secretion).^{70,164,165} They belong to a class of agents referred to as meglitinides and amino acid derivatives, respectively. Repaglinide was approved by the FDA in December 1997 and nateglinide was approved in December 2000 (Table 50-26).

Mechanism of Action

These agents close the adenosine triphosphate (ATP)-sensitive potassium channels in the β -cell, which leads to cell membrane depolarization, an influx of Ca^{2+} , and secretion of insulin.^{164,165} Unlike the sulfonylureas, they have a rapid onset and shorter duration of action, so they are given with meals to enhance postprandial glucose utilization.

Pharmacokinetics

Repaglinide has a bioavailability of 56% and is rapidly absorbed and excreted.¹⁶⁴ Its C_{max} occurs at approximately 1 hour and its half-life is 1 hour. Repaglinide is highly (>98%) protein bound (volume of distribution [Vd], 31 L). It is completely metabolized (CYP 3A4) by the liver to inactive products, with 90% excreted in the feces and 8% excreted in urine. Nateglinide has a bioavailability of 73%.¹⁶⁵ It is rapidly absorbed with a C_{max} occurring within 1 hour after dosing and a half-life of 1.5 hours. Nateglinide is metabolized (CYP2C9, 70%; CYP3A4, 30%) to less potent compounds, which are 75% excreted in the urine and 10% in the feces. Sixteen percent is excreted unchanged in the urine. It is highly (98%) protein bound, primarily to albumin, and, to a lesser extent, to α_1 -acid glycoprotein.

Adverse Effects

Mild hypoglycemia may occur, particularly if patients delay or forget to eat after the dose.^{164,165} A weight gain of 0.9 to 3 kg compared with baseline has been observed. Rare side effects include elevated hepatic enzymes and hypersensitivity reactions. There has been at least one case report of repaglinide-induced hepatic toxicity.¹⁶⁶

Contraindications and Precautions

Because a functioning pancreas is required, these agents should not be used in people with type 1 diabetes. They should be used with caution in patients with liver dysfunction.^{164,165} Repaglinide clearance is reduced in patients with severe renal insufficiency, but may still be used safely at a reduced dose. Nateglinide's clearance is not affected in patients with moderate to severe renal insufficiency.

Drug Interactions

Clinically relevant drug interactions include those that occur when these drugs are taken in combination with other glucose-lowering agents or drugs known to induce or inhibit their metabolism.¹⁶⁷ Therefore, blood glucose levels should be closely monitored when either drug is taken in combination with other agents known to lower blood glucose or affect their metabolism. Repaglinide is metabolized by CYP2C8 and 3A4.¹⁶⁴ Studies have shown that repaglinide has no pharmacokinetic effects on digoxin or warfarin. Cimetidine does not affect its absorption or efficacy. Gemfibrozil should be avoided in combination with repaglinide owing to the risk of hypoglycemia. The combination of gemfibrozil and itraconazole synergistically inhibits repaglinide metabolism and should be avoided. Nateglinide is metabolized largely by CYP2C9 (70%) and to a lesser extent by 3A4 (30%).¹⁶⁵ When evaluated in clinical studies, there were no clinically relevant interactions with nateglinide and glyburide, metformin, digoxin, diclofenac, or warfarin. Concomitant use of either repaglinide or nateglinide with rifampin may lower their efficacy.¹⁶⁷

Efficacy

The efficacy of repaglinide is comparable to metformin and the sulfonylureas.¹⁶⁸ When used as monotherapy, the mean decrease in FPG, postprandial glucose, and the HbA_{1c} values were 61 mg/dL, 104 mg/dL, and 1.7%, respectively, compared with placebo (−31.0 mg/dL, −47.6 mg/dL, and −0.6% compared with baseline). Newly diagnosed patients who have never been treated with oral agents and those whose HbA_{1c} is below 8% respond more profoundly than poorly controlled individuals already on treatment. Nateglinide as monotherapy results in a mean decrease in FPG and HbA_{1c} of 13.6 mg/dL and 0.7%, respectively, compared with placebo (−4.5 mg/dL and −0.5% compared with baseline). In comparison with metformin monotherapy, both drugs produce a similar or slightly smaller reduction in HbA_{1c}. When either drug is used in combination with metformin, a clinically significant additional reduction in HbA_{1c} is observed over metformin alone.

Dosage and Clinical Use

Repaglinide and nateglinide are approved to treat people with type 2 diabetes as monotherapy or in combination with metformin. Repaglinide is also approved for use with TZDs. Because they have the same mechanism of action as the sulfonylureas, combining these agents does not produce any additional benefit. The agents are usually added to therapy for patients with high postprandial glucose values. When repaglinide is used as the initial treatment in patients who are “naive” to oral antidiabetic therapy or in patients with HbA_{1c} values below 8%, the recommended starting dose is 0.5 mg with each

meal. When used in patients who have failed sulfonylureas or in those with HbA_{1c} values above 8%, the initial dose is 1 to 2 mg with each meal. Doses can be titrated weekly at a rate of 1 mg/meal to a maximum of 4 mg/dose or 16 mg/day. The recommended starting dose of nateglinide is 120 mg TID 0 to 30 minutes before meals. For patients close to their HbA_{1c} goal, a dose of 60 mg TID may be used. Doses should be omitted if a meal is skipped and added if an extra meal is ingested (repaglinide only). Repaglinide should be initiated at a 0.5-mg dose in patients with severe renal dysfunction and should be titrated cautiously in patients with liver dysfunction.

Sulfonylureas

Until metformin and other antidiabetics became available in the United States, sulfonylureas were the first-line pharmacologic treatment for people with type 2 diabetes who had failed diet and exercise therapy. Six different sulfonylureas are available in the United States. The three first-generation sulfonylureas (chlorpropamide [Diabinese], tolazamide [Tolinase], and tolbutamide [Orinase]) are considered equally effective despite differences in their pharmacokinetic properties and adverse effect profiles (see the following discussion and Table 50-25).

Glipizide (Glucotrol) and glyburide (DiaBeta, Glynase, Micronase), two second-generation sulfonylureas, were first introduced into the United States in May 1984. Glimpiride (Amaryl) was approved for use in 1995. Despite being approximately 100 times more potent than the first-generation sulfonylureas on a milligram-for-milligram basis, these agents are not more clinically effective. They have a relatively favorable side effect profile and have a duration of activity that allows for once or twice daily dosing.

Mechanism of Action

PANCREATIC EFFECTS

Sulfonylureas stimulate the release of insulin from pancreatic β -cells and enhance β -cell sensitivity to glucose. A specific sulfonylurea receptor closely linked to the ATP-sensitive potassium ion channel exists on the β -cell. Sulfonylureas are believed to inhibit this potassium ion channel, thus blocking the efflux of potassium and lowering the membrane potential to cause depolarization. The voltage-dependent calcium channels then open, increasing intracellular calcium concentration. The increased intracellular concentration of calcium ultimately stimulates insulin secretion.⁷⁰ Insulin levels tend to return to baseline values after a few months of continued sulfonylurea use.

EXTRAPANCREATIC EFFECTS

Sulfonylureas can normalize hepatic glucose production and partially reverse insulin resistance in the peripheral tissues of people with type 2 diabetes. Whether these “extrapancreatic” effects of the sulfonylureas are direct effects or secondary to improved insulin release and lower glucose concentrations remains to be established.¹⁶⁹ In any case, tissues become more responsive to lower concentrations of endogenous insulin in type 2 patients treated with sulfonylureas.¹⁷⁰

Pharmacokinetics

The duration of hypoglycemic activity is related to the half-life of these compounds only in very general terms and may correlate poorly in some cases.¹⁷⁰ All sulfonylureas are highly protein bound (90%–100%), mainly to albumin. Binding characteristics, however, vary among individual sulfonylureas. Food does not impair the extent of drug absorption, but may delay the time to peak levels of some agents. The relationship between sulfonylurea doses and their blood glucose-lowering effect remains unclear. Studies of glyburide and glipizide suggest that these agents may operate within a narrow range of plasma concentrations that may be achieved with low (10 mg/day) doses.^{171–173} The maximum recommended daily doses of 40 mg for glipizide and 20 mg for glyburide may therefore not be more effective. Furthermore, insulin may be indicated for patients no longer responding to 10 mg or higher doses of glyburide or glipizide.

Chlorpropamide has the longest serum half-life and duration of hypoglycemic activity and a variable rate of renal excretion.

Glipizide is an intermediate-acting second-generation agent with a half-life of 2 to 4 hours, but a duration of action of 12 to 24 hours.⁷⁰ Patients receiving <20 mg/day may require only once daily dosing. Food delays its rate of absorption, but not its bioavailability. Patients may therefore take it with or without food. Glipizide is extensively metabolized by the liver to inactive products that are eliminated primarily by the kidney.^{170,174} A sustained-release formulation of glipizide (Glucotrol XL) also is available.

Glyburide (or glibenclamide) is a longer acting second-generation agent similar to glipizide. The half-life is approximately 1.5 to 4 hours after single-dose studies and up to 13.7 hours when chronically administered.¹⁷⁵ Nevertheless, as with glipizide, the duration of action can last for up to 24 hours in many patients, allowing for once daily dosing with small to intermediate doses (<15 mg). Food does not delay the rate or extent of absorption. Glyburide is metabolized completely by the liver to active metabolites, half of which are excreted in the urine and the remainder eliminated via the biliary tract.¹⁷⁶ The micronized tablets (e.g., Glynase Prestabs) are not bioequivalent to the conventionally formulated tablets.⁷⁰ Thus, patients switched between the conventional form and the micronized product must be retitrated.

Glimpiride is a long-acting second-generation sulfonylurea. Its half-life is 9 hours and its duration of action is 24 hours, allowing for once-daily dosing.¹⁷⁷ The absorption of glimepiride is unaffected by food, and its peak effect on plasma glucose concentrations is observed 2 to 3 hours after each dose. Glimpiride is completely metabolized by the liver, and its principal metabolite has 30% of the activity of the parent drug. Metabolites are excreted in feces and urine.

Adverse Effects

The primary side effects of the sulfonylureas are hypoglycemia (particularly for those that are long acting) and weight gain (see questions 63 and 71).¹⁷⁸ Other adverse effects attributed to the sulfonylureas generally are so infrequent and mild that fewer than 2% of patients discontinue these agents because of them. In general, the type, incidence, and severity of reported side effects are similar for all the sulfonylureas. An important

exception is chlorpropamide, which has several unique adverse effects (see following discussion). Adverse reactions to the sulfonylureas include GI symptoms (nausea, fullness, bloating that can be relieved if taken with meals), rare blood dyscrasias, allergic dermatologic reactions, hepatotoxicity, and hypothyroidism (also see Questions 63–65).

A disulfiram (Antabuse-like) reaction occurs when patients take certain oral sulfonylurea drugs and drink ethanol. It is most frequently associated with chlorpropamide, occurring in approximately one-third of all patients receiving it. The flushing reaction is rare with other sulfonylureas.

SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE SECRETION

Chlorpropamide, and to a much lesser extent, tolbutamide, may enhance the release of antidiuretic hormone centrally, enhance the effect of antidiuretic hormone on the kidney, and override the inhibitory effects of waterloading on antidiuretic hormone release, resulting in syndrome of inappropriate antidiuretic hormone secretion.^{170,178} This antidiuretic effect has been used clinically to treat diabetes insipidus. In the UKPDS study, the increase in BP seen in patients on chlorpropamide was likely due to water retention.³³ In contrast to chlorpropamide and tolbutamide, glipizide, glyburide, tolazamide, and acetohexamide have a mild diuretic effect.

Contraindications and Precautions

Contraindications to the use of sulfonylureas include the following¹⁷⁸:

1. Type 1 diabetes
2. Pregnancy or breast-feeding, because these agents (except glyburide) can cross the placental barrier and can be excreted into breast milk
3. Documented hypersensitivity to sulfonylureas
4. Severe hepatic or renal dysfunction
5. Severe, acute intercurrent illness (e.g., infection, MI), surgery, or other stress that can unduly affect blood glucose control

Drug Interactions

Drug interactions with sulfonylureas have a pharmacodynamic or pharmacokinetic basis. Pharmacodynamic interactions are discussed later in this chapter in sections addressing drug-induced hypoglycemia and hyperglycemia. Most of the reported pharmacokinetic drug interactions with the sulfonylureas involve chlorpropamide and tolbutamide. Because most of the clinically significant interactions occur with drugs that alter liver metabolism or urinary excretion, possible interactions with all of the sulfonylureas must be anticipated, even though the outcomes may be quite different. Second-generation sulfonylureas (glipizide, glyburide, and glimepiride) are dosed in milligram rather than gram quantities and are thus less likely to interact with other drugs on a pharmacokinetic basis. Glipizide and glyburide also differ from the first-generation agents in that they are highly bound to albumin at nonionic rather than ionic sites.^{170,174} On this basis, these agents are unlikely to interact with other highly protein-bound drugs, such as phenylbutazone, salicylates, or certain sulfonamide antibiotics that have been reported to enhance the effects of the first-generation sulfonylureas. These

highly protein-bound drugs, however, seem to interact with the sulfonylureas by altering their hepatic metabolism as well. Therefore, glipizide and glyburide should be used cautiously with drugs reported to interact with first-generation sulfonylureas.

Efficacy

Like metformin, the sulfonylureas decrease the HbA_{1c} by 1.5% to 1.7% and the FPG by 50% to 70%. In patients who have developed secondary failure to maximum doses of metformin, the addition of sulfonylureas produces similar improvements in the HbA_{1c} and FPG, unless the disease has progressed and the pancreas is no longer able to respond appropriately. Whether sulfonylureas actually contribute to β -cell dysfunction and decline remains to be clearly determined.¹⁷⁹

Dosage and Clinical Use

The sulfonylureas are very effective, relatively safe, relatively inexpensive, and easy to titrate. Sulfonylureas are usually added on to therapy in patients unable to achieve blood glucose goals on metformin monotherapy. Sulfonylureas may also be considered as monotherapy or first-line agents in patients with contraindications to metformin therapy. The doses of the sulfonylureas are displayed in Table 50-27. As a general rule, one should begin with low doses and titrate upward every 1 to 2 weeks until the desired goal is achieved. Exceeding maximum doses is not likely to produce improvement, but may put the patient at risk for adverse effects (see Questions 53, 70, and 71).

Thiazolidinediones

Rosiglitazone (Avandia, GlaxoSmithKline) and pioglitazone (Actos, Takeda Pharmaceuticals) were approved in 1999 and are the two available TZDs in the United States.

Mechanism of Action

The TZDs are often referred to as insulin sensitizers. The precise molecular actions of these agents remain to be clarified. TZDs bind to and activate a nuclear receptor (peroxisome proliferator-activated receptor- γ [PPAR- γ]), which is expressed in many insulin-sensitive tissues, including adipose, skeletal muscle, and liver tissue.⁷⁰ PPAR- γ regulates transcription of genes that influence glucose and lipid metabolism. For example, PPAR- γ stimulation increases the transcription of GLUT-4, a glucose transporter that stimulates glucose uptake.¹⁸⁰ Reduced expression of GLUT-4 may contribute to the development of insulin resistance.

TZDs either directly or indirectly sensitize adipose tissue to insulin action.^{70,169,180} The effects may include stimulating apoptosis of large adipocytes, increasing the number of small adipose cells, and promoting fatty acid uptake and storage in adipose tissue. The subsequent reduction in free circulating fatty acids may spare other insulin sensitive tissues (e.g., liver, skeletal muscle, β -cells) from the effects of lipotoxicity. TZDs also lower expression of tumor necrosis factor- α , a cytokine produced by adipose tissue that may contribute to insulin resistance and fatty acid release.^{169,180} In fact, TZD interaction with adipocytes may be their primary mechanism of action in sensitizing other tissues to insulin action.

Other observed effects of TZDs that may prove to be beneficial in patients with type 2 diabetes and metabolic syndrome include favorable effects on lipids, reduction of inflammatory mediators, inhibition of vascular smooth muscle cell proliferation, improved endothelial function, and enhanced fibrinolysis.^{169,180}

In summary, the TZDs clinically decrease insulin resistance in muscle and liver, which enhances glucose utilization and decreases hepatic glucose output. Alleviation of insulin resistance also reduces insulin, glucose, and free fatty acid levels and has positive effects on lipid levels.

Pharmacokinetics

Rosiglitazone is completely absorbed, with peak plasma concentrations reached in approximately 1 hour.¹⁸¹ Pioglitazone has a bioavailability of 83%, with peak plasma concentrations reached within 2 hours.^{182,183} Food does not alter absorption of either drug. Both TZDs are extensively (>99%) protein bound, primarily to albumin. The plasma elimination half-life of rosiglitazone is 3 to 7 hours. Pioglitazone has a serum half-life of 3 to 7 hours, and its metabolites have a serum half-life of 16 to 24 hours. Rosiglitazone is extensively metabolized in the liver by CYP 2C8 and to a much lesser extent by 2C9. Its conjugated metabolites are considerably less potent than the parent drug and are excreted two-thirds in urine and one-third in feces. Pioglitazone is hepatically metabolized, mainly by CYP 2C8 and 3A4, into two active metabolites. Approximately 15% to 30% of the dose is recovered in the urine as metabolites, with the remainder excreted into the bile either as unchanged drug or as metabolites.

Because the action of the TZDs relies on gene transcription and protein production, the onset and duration of action are unrelated to the plasma half-life.⁷⁰ The onset of their effect occurs in 1 to 2 weeks, although maximum effects are not usually seen before 8 to 12 weeks. No dose adjustment is necessary in patients with renal impairment or failure.

Adverse Effects

HEPATOTOXICITY

Troglitazone, the first TZD to be approved by the FDA in 1997, was associated with idiosyncratic hepatotoxicity leading to hepatic failure and death in some patients, which became apparent during postmarketing surveillance. During clinical trials, fewer than 2% of troglitazone-treated patients experienced asymptomatic, reversible elevations in liver transaminase (alanine transaminase [ALT]) levels that were greater than three times the normal values.¹⁸⁴ In contrast, the elevations in liver transaminase levels observed during preapproval clinical trials for pioglitazone and rosiglitazone (0.26% and 0.2%, respectively) were similar to placebo (0.25% and 0.2%).^{181,182} Liver failure has been very rarely reported with either rosiglitazone or pioglitazone, although causality in most cases remains uncertain.^{185–187} For both drugs, monitoring of liver function tests (LFTs) is recommended at baseline, and then periodically thereafter (see Contraindications and Precautions).

HEMATOLOGIC EFFECTS

TZD therapy may result in small decreases in hemoglobin and hematocrit and, infrequently, anemia.^{169,180} Transient decreases in neutrophil counts occurred infrequently within the

first 4 to 8 weeks of TZD therapy. These effects may be due to dilutional effects (see below).

WEIGHT GAIN

Dose-related weight gain (2–3 kg for every 1% decrease in HbA_{1c}) has been seen with rosiglitazone and pioglitazone.¹⁸⁰ The cause of weight gain is likely due to fluid retention and/or fat accumulation. The weight gain seems to be associated with an increase in peripheral adipose tissue along with a reduction in visceral adiposity.^{169,180}

VASCULAR AND CARDIOVASCULAR EFFECTS

Increases in plasma volume and peripheral edema (4%–6%), possibly caused by an increased endothelial cell permeability, have been reported with the TZDs.¹⁸⁰ The incidence of peripheral edema is greatly increased when TZDs are used in combination with insulin.

Although no CHF was observed in original clinical trials with either drug, patients with New York Heart Association (NYHA) class III and IV cardiac status were not included. In 2007, the FDA added black box warnings to rosiglitazone and pioglitazone based on association of their use with an increased risk of developing or exacerbating CHF in patients with type 2 diabetes. Recent meta-analyses and retrospective studies have suggested that TZD use may be associated with an increased risk of MI and mortality.^{188,189–193} Whether or not TZDs actually increase rates of MI and morbidity and mortality owing to cardiovascular causes remains to be clearly determined. Some prospective studies are currently underway.

Based on these effects and observations, TZDs are contraindicated for use in patients with NYHA class III or IV CHF. In addition, they should be avoided in patients with symptomatic CHF, such as those requiring nitrate therapy. TZDs should be used with caution in patients with preexisting edema, which may increase the risk of developing new-onset CHF or exacerbating preexisting CHF.

OTHER EFFECTS

Hypersensitivity reactions including rash, pruritus, urticaria, angioedema, anaphylactic reaction, and Stevens-Johnson syndrome have been rarely reported with rosiglitazone.¹⁸¹ Macular edema has been rarely reported with TZDs.^{181,182,194} Patients experiencing changes or worsening in vision should be referred to an ophthalmologist for follow-up. In some cases, macular edema improved or resolved after discontinuation of TZD therapy. An increased risk of distal limb bone fractures (e.g., forearm, hand, wrist, foot, and ankle) and bone loss have been observed in women receiving TZDs.^{181,182,191,195} Potential for fractures in older female patients should be carefully considered before using a TZD.

Contraindications and Precautions

- *Type 1 diabetes:* Because insulin is required for their action, TZDs should not be used in people with type 1 diabetes.
- *Patients with type 2 diabetes using insulin:* TZDs should be used with caution due to the increased risk of developing edema.
- *Preexisting hepatic disease:* Pioglitazone and rosiglitazone should not be used in patients whose ALT is more than 2.5 times normal. TZDs should be discontinued if the ALT is

more than 3 times normal, if serum bilirubin levels begin to rise or if the patient complains of any symptoms that could be attributed to hepatitis (e.g., fatigue, nausea, vomiting, abdominal pain, and dark urine).

- *Symptomatic or severe (NYHA classes III and IV) CHF:* See previous discussion.
- *Premenopausal anovulatory women:* TZDs may cause resumption of ovulation and menstruation in women with polycystic ovarian syndrome, placing these patients at risk for an unwanted pregnancy.
- *History of hypersensitivity to TZDs.*
- *Drugs metabolized by CYP 3A4:* See the Drug Interactions section for further details.

Drug Interactions

Coadministration of a TZD with other antidiabetic medications or insulin does not alter the pharmacokinetics of either drug, but may increase the patient's risk for hypoglycemia. Pioglitazone induces CYP 3A4 and may, therefore, decrease effectiveness of other drugs metabolized by this enzyme, such as estrogens, cyclosporine, tacrolimus, and 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors.¹⁸² Patients taking oral contraceptives or estrogen replacement therapy should be informed of the possible risk of decreased effectiveness of estrogen therapy. Rosiglitazone does not seem to inhibit any of the major CYP enzymes.¹⁸¹ Rifampin decreases the area under the plasma concentration–time curve (AUC) for both rosiglitazone and pioglitazone, although the clinical significance of this interaction is unknown.¹⁹⁶ Gemfibrozil significantly increases the AUC of both drugs. For patients receiving both a TZD and gemfibrozil, a dose reduction of the TZD may be warranted.

Efficacy

The effects of TZDs on HbA_{1c} and FPG are intermediate between that of acarbose and the sulfonylureas or metformin.^{169,180} When combined with other antidiabetic agents in a poorly controlled type 2 patient, one can expect to see an augmented effect on the HbA_{1c} (0.9%–1.3% decrease with a sulfonylurea, 0.8%–1.2% decrease with metformin, and 0.6%–1.0% decrease with insulin).^{181,182} When added to the therapy of a type 2 patient taking insulin, rosiglitazone and pioglitazone can enhance glycemic control while decreasing insulin requirements. Individuals who are minimally responsive or unresponsive to TZD therapy may include those who are not obese and have lower levels of endogenous insulin.

Other potential benefits of the TZDs are their favorable, but variable, effects on lipids.^{180–182} Pioglitazone and to a lesser extent rosiglitazone may decrease triglycerides. Both drugs may increase HDL levels by 10%. Their effects on LDL levels are less clear. Rosiglitazone has been observed to increase LDL cholesterol by 8% to 16%, whereas pioglitazone may not affect LDL. Increases in LDL may be due to a shift from smaller, dense particles to larger, more buoyant ones, which are less susceptible to oxidation.¹⁶⁹ As noted, TZD therapy has been associated with weight gain and this may be substantial when used in combination with sulfonylureas or insulin.

Dosage and Clinical Use

TZDs are usually indicated in patients who are unable to take or have failed metformin or sulfonylurea monotherapy or who

have not responded to combination therapy with other oral antidiabetic agents. A greater glucose-lowering effect has been observed when rosiglitazone is given as two divided doses rather than as a single daily dose. For monotherapy, a typical dose is 4 mg once daily or 2 mg twice daily with or without food. If the response is inadequate, the dosage can be increased to 8 mg once daily or 4 mg twice daily. For combination therapy with a sulfonylurea, metformin, or insulin, rosiglitazone can be initiated at 4 mg once daily and titrated to a maximum daily dose of 8 mg.

For monotherapy or combination therapy with a sulfonylurea, metformin, or insulin, the starting dose for pioglitazone is 15 or 30 mg once daily with or without food. The dose can be titrated up to a maximum of 45 mg/day.

Glucosidase Inhibitors

Acarbose (Precose) and miglitol (Glyset) are the two available oral agents in the α -glucosidase inhibitor class of antidiabetic agents.

Mechanism of Action

The α -glucosidase inhibitors reversibly inhibit glucosidases present in the brush-border of the mucosa of the small intestine.⁷⁰ These enzymes break down complex polysaccharides and disaccharides into glucose and other absorbable monosaccharides. Enzyme inhibition delays carbohydrate digestion and subsequent glucose absorption. Postprandial blood glucose concentrations are therefore lowered when these agents are taken with a meal containing complex carbohydrates.

Pharmacokinetics

Acarbose is minimally absorbed from the GI tract, with an oral bioavailability of parent drug of <2.0%.¹⁹⁷ It is extensively metabolized by GI amylases to inactive metabolites. The elimination half-life for acarbose is 2.8 hours, although there may be a longer terminal half-life. Unlike acarbose, miglitol is absorbed.¹⁹⁸ Absorption is saturable at higher doses (>25 mg). The drug is primarily distributed in extracellular fluids and is not metabolized. After a 25-mg dose, 95% of the drug is excreted unchanged by the kidneys within 24 hours.

Adverse Effects

GASTROINTESTINAL EFFECTS

Flatulence, diarrhea, and abdominal pain are the most frequently reported adverse effects of α -glucosidase inhibitors.¹⁹⁹ In placebo-controlled trials of acarbose, these complaints were experienced by 74%, 31%, and 19% of subjects, respectively. GI side effects are due to fermentation of unabsorbed carbohydrate in the small intestine and can be minimized by slowly titrating the dose of either agent. GI discomfort usually improves with continued therapy as induction of the α -glucosidase enzymes occurs in the distal jejunum and terminal ileum.

ELEVATED LIVER FUNCTION TESTS

In studies using doses of acarbose 300 mg/day or more, a transient increase in serum hepatic transaminases was reported.¹⁹⁷ The manufacturer recommends monitoring hepatic transaminases every 3 months for the first year of therapy

and periodically thereafter. If an elevation of serum transaminases occurs, the dose should be decreased or discontinued if elevations persist. Because miglitol is not metabolized, it does not seem to affect hepatic function.

Contraindications and Precautions^{197,198}

GASTROINTESTINAL CONDITIONS

Because of their profound GI effects (flatulence, diarrhea), acarbose and miglitol are contraindicated in patients with malabsorption, inflammatory bowel disease, or other marked disorders of digestion or absorption, or intestinal obstruction.

RENAL IMPAIRMENT

Acarbose has not been studied in patients with severe renal impairment (SrCr >2.0 mg/dL) and should not be used in these patients.¹⁹⁷

Drug Interactions

Patients who use acarbose or miglitol in combination with other antidiabetic agents may develop hypoglycemia. These reactions should be treated with dextrose because acarbose may limit the availability of the disaccharide, sucrose (table sugar). Because acarbose and miglitol delay carbohydrate passage through the bowel, they could influence the absorption kinetics of concomitantly administered drugs. Conversely, because their own absorption may be diminished by digestive enzyme preparations and charcoal, they should not be taken concomitantly with these agents.^{197,198} Acarbose and miglitol do not affect the absorption of glyburide in individuals with diabetes. The bioavailability of digoxin can be reduced and may require dose adjustment. Miglitol decreases the bioavailability of ranitidine and propranolol by 60% and 40%, respectively.¹⁹⁸

Efficacy

By delaying the absorption of glucose following ingestion of complex carbohydrates and disaccharides, the α -glucosidase inhibitors can lower postprandial plasma glucose concentrations in patients with type 2 diabetes by 25 to 50 mg/dL.¹⁹⁹ FPG concentrations remain unchanged or are slightly lowered (20–30 mg/dL), but this effect may be related to decreased glucose toxicity, which improves insulin secretion and action. Mean HbA_{1c} values decline by 0.5% to 1%. Acarbose and miglitol have no effect on weight or lipid profiles.

Dosage and Clinical Use

Because of their more limited effects on HbA_{1c} and side effect profile, α -glucosidase inhibitors are usually used as add-on therapy in patients who have failed monotherapy or combination therapy with other oral antidiabetic agents. The recommended initial dose of either drug is up to 25 mg three times daily, taken at the start of each meal.^{197,198} The dosage can be gradually increased (e.g., 25 mg/meal) every 4 to 8 weeks to a maximum of 50 mg three times daily for individuals weighing 60 kg or less, or 100 mg three times daily for individuals weighing more than 60 kg. A maximum response is observed at 6 months.

Incretin-Based Therapies

The most recent advances in therapy for type 2 diabetes have revolved around the discovery and exploration of the effects of

incretins. Incretins are insulinotropic hormones secreted from specialized neuroendocrine cells in the small intestinal mucosa in response to carbohydrate ingestion and absorption.¹³ The two hormones accounting for most incretin effects are glucose-dependent insulinotropic polypeptide (GIP) and glucagonlike peptide-1 (GLP-1). GIP and GLP-1 stimulate pancreatic β -cells in a glucose-dependent manner, contributing to the early phase insulin response. GLP-1 also inhibits pancreatic α -cells, thus reducing glucagon secretion and hepatic glucose production. Incretin action is efficient, but short lived. As they enter the blood vessels, incretins undergo rapid metabolism via proteolytic cleavage by dipeptidyl peptidase-4 (DPP-4) to inactive metabolites. Thus, only small amounts are needed to exert their effects on glucose metabolism.

Glucagonlike Peptide-1 Receptor Agonists (GLP-1 Mimetics/Analog)

At the time of writing, exenatide (Byetta) is the only available GLP-1 mimetic in the United States. A long-acting release formulation of exenatide is currently under development.²⁰⁰ Another agent, liraglutide (NN2211, Novo-Nordisk), is currently in phase III clinical trials.²⁰¹

Mechanism of Action

GLP-1 mimetics and analogs that have stability in the presence of DPP-4 have been developed, resulting in a longer duration of action than endogenous GLP-1. Exenatide is a synthetic form of exendin-4, a peptide originally discovered from the saliva of the Gila monster.²⁰⁰ Exendin-4 shares 50% of its amino acid sequence with GLP-1, demonstrating similar affinity for receptor sites but a strong resistance to DPP-4. Liraglutide is a GLP-1 analog with partial resistance to DPP-4. Both agents augment early or first-phase insulin response in response to elevated glucose concentrations, moderate glucagon secretion, and decrease hepatic glucose production without impairing the normal glucagon response to hypoglycemia. In addition, both agents slow gastric emptying, thereby reducing the rate at which glucose is absorbed. They suppress appetite, which may contribute to the prevention of weight gain and the weight loss (1.5–5 kg) observed in patients.

Pharmacokinetics

After subcutaneous (SC) injection, exenatide reaches median peak plasma concentrations in 2.1 hours, with a Vd of 28.3 L and a circulating half-life of 60 to 90 minutes.^{200,202} The injection site (abdomen, thigh, or arm) does not significantly alter its kinetics. Exenatide is eliminated predominantly by glomerular filtration with subsequent proteolytic degradation. The mean terminal half-life is 2.4 hours, substantially longer than endogenous GLP-1, thus allowing for twice daily dosing. Its metabolism and elimination are dose independent; exenatide concentrations are measurable for up to 10 hours after injection. Liraglutide is highly protein bound (>98%), with a half-life of about 10 to 14 hours, allowing for once-daily dosing.²⁰⁰

Adverse Effects

GI side effects are common and dose dependent; 40% of patients report mild to moderate nausea and 15% report vomiting and/or diarrhea.^{200,202} These side effects may be lessened by

starting patients on low doses, ensuring correct timing and administration of the drug, and titrating the dose slowly. Other reported side effects have included decreased appetite and injection site reactions. Hypoglycemic risk can be increased in patients who are also taking a hypoglycemic oral agent (e.g., sulfonylurea) or insulin.

Exenatide use has been rarely related to hypersensitivity reactions, acute pancreatitis, and reversible renal impairment or failure requiring hemodialysis. Patients should be educated about symptoms of acute pancreatitis, including severe abdominal pain accompanied by vomiting, and instructed to report to their practitioner immediately. Patients in whom acute pancreatitis is confirmed with no other probable cause should not be rechallenged with exenatide.

About 40% to 50% of patients taking exenatide develop antibodies with weak binding affinities and low titers. In some patients, high antibody titers may result in treatment failure. Patients who demonstrate adherence to therapy, yet experience no change or worsening in glycemic control, should discontinue therapy and be switched to alternative agents.

Contraindications and Precautions

Exenatide is contraindicated in patients with known hypersensitivity.^{201,202} Exenatide is not recommended for use in patients with severe GI disease, severe renal impairment (CrCl <30 mL/minute), end-stage renal failure, or those requiring hemodialysis.²⁰²

Drug Interactions

Exenatide may increase the risk for hypoglycemia when used with other hypoglycemic agents such as nonsulfonylurea secretagogues, sulfonylureas, and insulin.²⁰² Because of its mechanism of action, exenatide may reduce the rate and extent of absorption of orally administered drugs. Exenatide should therefore be used with caution in patients taking medications that require rapid GI absorption and are dose dependent on threshold concentrations for efficacy, such as antibiotics and oral contraceptives. In these cases, patients may be instructed to take the affected medications at least 1 hour before exenatide injection. There have been case reports of an increased International Normalized Ratio, sometimes associated with bleeding, in patients taking exenatide and warfarin. Patients should be closely monitored, with dose adjustments to warfarin therapy made as needed.

Efficacy

In clinical trials, maximum doses of exenatide combined with a sulfonylurea, metformin, a TZD, or sulfonylurea plus metformin therapy over 30 weeks reduced fasting blood glucose by 8 to 20 mg/dL, 2-hour postprandial blood glucose by 60 to 70 mg/dL, and HbA_{1c} by 0.8% to 1.0%.^{200,202} Exenatide use over 80 weeks has been reported to reduce body weight by 4 to 5 kg. Clinical trials conducted to date with liraglutide monotherapy demonstrate decreases in fasting blood glucose of 30 to 60 mg/dL, HbA_{1c} of 0.6% to 1.75%, and weight of 2 to 3 kg.^{200,201,203}

Dosage and Clinical Use

GLP-1 mimetics and analogs are indicated as add-on agents in patients with type 2 diabetes who have been unable to reach tar-

get goals on monotherapy or combination therapy with other oral agents and/or insulin. In addition, these agents may be helpful in patients with type 2 diabetes who are obese and struggling with weight loss. The starting dose of exenatide is 5 mcg injected SC into the abdomen, thigh, or arm twice daily within 60 minutes before morning and evening meals. Patients who experience severe GI side effects may try injecting just before meals initially and then move to 30 to 60 minutes before meals. If a patient tolerates the 5 mcg dose, then it can be titrated after 1 month of therapy to the maximum dose of 10 mcg SC twice daily. At the time of this writing, the dosing for liraglutide remains to be determined.

Dipeptidyl Peptidase-4 Inhibitors

At the time of writing, sitagliptin (Januvia) is the only available DPP-4 inhibitor in the United States. Vildagliptin (Galvus, Novartis), is expected to be approved sometime in 2009.²⁰⁴ Saxagliptin (BMS-477118, Bristol-Myers Squibb) and denagliptin (GW823093, GlaxoSmithKline) are in phase III clinical trials.

Mechanism of Action

The DPP-4 inhibitors inhibit the degradation of GIP and GLP-1 upon entering the GI vasculature, thus increasing the effects of these endogenous incretins on first-phase insulin secretion and glucagon inhibition.²⁰⁰ Both sitagliptin and vildagliptin reduce DPP-4 activity by 80%, with some inhibition maintained for up to 24 hours after an oral dose.

Pharmacokinetics

Sitagliptin is rapidly absorbed, with an absolute bioavailability of 87%.²⁰⁵ Absorption is unaffected by food. Peak plasma concentrations occur in 1 to 4 hours, with a dose-proportional increase in plasma AUC, a Vd of 198 L, and terminal half-life of 12.4 hours. Only 38% of sitagliptin is plasma protein bound. Seventy-nine percent of the parent drug is excreted unchanged in the urine, primarily by active renal tubular secretion and may involve p-glycoprotein and human organic anion transporter-3. Metabolism by CYP3A4, and to a much lesser extent, CYP2C8, plays a minimal role in the excretion of metabolites in the feces.

Vildagliptin is rapidly absorbed, with an absolute bioavailability of 85%.^{206,207} Food does not affect its absorption.²⁰⁸ Absorption may take place at two sites and median time to peak plasma concentrations occurs 1 hour after oral administration.^{206,207} Body weight may impact the Vd. Plasma AUC increases in a dose-proportional manner and the terminal half-life ranges from 1.32 to 2.43 hours. Renal clearance accounts for 21% of elimination, and may be greater in men than women.

Adverse Effects

Because these agents differ significantly in chemical structure from one another, some adverse events may be unique to the individual agent and may not be indicative of a class-wide effect.²⁰⁰ The most commonly reported side effects with sitagliptin and vildagliptin in clinical trials include increased risk of infection [nasopharyngitis (3.5%–7.9% and 5.8%–9.3%, respectively), upper respiratory tract infection

(4.0%–8.0% and 5.3%–8.6%, respectively), sinusitis (1.4%–3.4% and 0.3%–4.1%, respectively), urinary tract infection (2.1%–4.6% and 1.5%–8.3%, respectively)] and headache (2.9%–4.5% and 5.0%–8.0%, respectively).²⁰⁹ Vildagliptin has also been associated with cough (4.8%–7.4%) and other mild effects including dizziness, dyspepsia, nausea, constipation, and diarrhea.²¹⁰ Case reports of severe hypersensitivity reactions, including anaphylaxis, angioedema, and exfoliative skin reactions—including Stevens-Johnson syndrome—occurring after the first dose to as long as 3 months of therapy have been reported with sitagliptin.²⁰⁵ Some authors have mentioned patients experiencing increased BP as well as musculoskeletal and connective tissue disorders in clinical trials with vildagliptin.^{204,210} Because DPP-4 is expressed on many cell types, including lymphocytes, additional clinical experience and postmarketing studies are needed to clearly establish the long-term safety of these agents.

Contraindications and Precautions

Sitagliptin is contraindicated in patients with a history of serious hypersensitivity reaction to the drug.²⁰⁵ It should be used with caution in combination with antidiabetic agents that cause hypoglycemia such as nonsulfonylurea secretagogues, sulfonylureas, and insulin. In such situations, patients should be instructed to closely monitor their blood glucose and if warranted, have the dose of their nonsulfonylurea secretagogue, sulfonylurea, and/or insulin adjusted. The dose of sitagliptin should be reduced in patients with moderate (CrCL 30–50 mL/minute) to severe (CrCl <30 mL/minute) renal insufficiency and in those with end-stage renal disease (ESRD) requiring hemodialysis or peritoneal dialysis.

Drug Interactions

Sitagliptin is not significantly protein bound.²⁰⁵ It also does not inhibit CYP isoenzymes or induce CYP3A4; therefore, it is not expected to interact with other drugs that are metabolized by these pathways. Despite a lack of documented pharmacokinetic interactions from pharmacokinetic studies and clinical trials, because sitagliptin is a substrate for p-glycoprotein, patients taking digoxin should be monitored for any signs or symptoms of digoxin toxicity.²⁰⁴ Limited information is available regarding drug interactions with vildagliptin. One pharmacokinetic study reports no interactions with digoxin in healthy volunteers.²¹¹

Efficacy

In clinical trials versus placebo, sitagliptin and vildagliptin lower fasting glucose by 15 to 30 mg/dL and HbA_{1c} by 0.62% to 0.85%.^{200,209} In addition, clinical trials with sitagliptin demonstrate reductions in 2-hour postprandial glucose by 63 to 71 mg/dL.²⁰⁵ Clinical trials of vildagliptin have reported statistically significant decreases in 4-hour postprandial glucose (-34.2 ± 9 mg/dL; $p < .0001$).^{209,210} Unlike the GLP-1 mimetics and analogs, sitagliptin and vildagliptin do not seem to significantly affect body weight, appetite, or satiety.^{200,209,210} As is the case for the GLP-1 mimetics/analogues, further studies are needed to more clearly determine the DPP-4 inhibitor effects on long-term preservation of β -cell function.

Dosage and Clinical Use

DDP-4 inhibitors seem to be useful as add-on therapy in combination with sulfonylureas, biguanides, TZDs, and insulin for patients who have been unsuccessful in reaching target goals. Sitagliptin may be initiated at 100 mg taken once daily with or without food.²⁰⁵ Renal function should be assessed before initiation with sitagliptin therapy and periodically thereafter. In patients with moderate renal insufficiency (CrCl 30–50 mg/dL), the dose should be reduced to 50 mg once daily. In patients with severe renal insufficiency (CrCl <30 mg/dL) or those in end-stage renal failure requiring dialysis, the sitagliptin dose should be reduced to 25 mg once daily. Sitagliptin may be administered without regard to the timing of hemodialysis. For patients taking sitagliptin in combination with other antidiabetic agents that may cause hypoglycemia, the dose of the other agent (e.g., sulfonylurea) may need to be reduced.

Amylin Receptor Agonists (Amylinomimetics)

Amylin, or islet amyloid polypeptide, is a hormone found in the β -cells where it is co-manufactured, stored, and released with insulin in response to food intake.²¹² Its actions seem to be centrally mediated and include slowing gastric emptying, suppressing glucagon secretion, and modulating the regulation of appetite. Amylin is absent in patients with type 1 diabetes. In patients with type 2 diabetes, its concentrations are altered to mirror those of insulin at different points in the progression of the disease. Pramlintide (Symlin) is currently the only approved amylin mimetic available in the United States for the adjunctive treatment of both types 1 and 2 diabetes.

Mechanism of Action

Pramlintide is a synthetic amylin analog, differing from the endogenous human substance by three amino acids.²¹³ These modifications render pramlintide equipotent, but with an increased solubility and decreased aggregability compared with endogenous amylin.

Pharmacokinetics

The absolute bioavailability of subcutaneously injected pramlintide is 30% to 40%.²¹³ Injection into the abdomen and thigh allow for more predictable absorption and distribution than injection into the arm. Body mass does not affect absorption or bioavailability. Approximately 40% of the drug is unbound in plasma. The half-life is about 48 minutes. Pramlintide is metabolized by the kidneys to an active metabolite with a half-life similar to the parent drug. It does not seem to accumulate with repeat dosing.

Adverse Effects

GI symptoms—including mild to moderate nausea (up to 95%), vomiting (8%–11%), anorexia (9%–17%), and abdominal pain (8%)—are the most frequently reported adverse reactions associated with therapy.²¹³ GI symptoms are usually transient, subsiding after 4 to 8 weeks of treatment and/or with dose reduction and slow dose escalation. Other reported adverse events from clinical trials include headache, dizziness, fatigue, coughing, pharyngitis, injection site reactions, and allergic reactions. There is a substantial increased risk of severe insulin-induced hypoglycemia within 3 hours of injection (see

Contraindication and Precautions section). There have been no reports of antibody formation to date.

Contraindications and Precautions

Pramlintide is contraindicated in patients with a known hypersensitivity to the drug or any of its components (e.g., metacresol), patients with hypoglycemic unawareness, and those with diagnosed gastroparesis. Severe hypoglycemia can occur when used in combination with insulin or another hypoglycemic agent (e.g., sulfonylurea) due to delayed gastric emptying, which slows carbohydrate absorption. Patients with type 1 diabetes seem to be at greatest risk. The package insert contains a black box warning for individuals while driving, those who operate heavy machinery, and those who engage in other high-risk activities in which serious injuries could result during a hypoglycemic episode. Patients should be closely monitored and have their insulin or oral hypoglycemic agent dose reduced upon initiation of therapy (see Dosage section).

Drug Interactions

As noted, severe hypoglycemia can occur in patients who are concurrently taking an oral hypoglycemic agent (e.g., sulfonylurea) or insulin (see Dosage section).²¹³ There have been no other reported drug interactions to date with pramlintide. Patients concurrently taking anticholinergics or agents that slow gastric absorption should be closely monitored for worsening GI symptoms.²¹² Patients taking any medications that depend on rapid absorption for efficacy (e.g., antibiotics, oral contraceptives, pain medications) should be instructed to take those medications at least 1 hour before or 2 hours after pramlintide injection.

Efficacy

In clinical studies of patients with type 2 diabetes with doses up to 120 mcg/day for 52 weeks, pramlintide combined with oral hypoglycemic agents and/or insulin decreased HbA_{1c} significantly by 0.3% to 0.6% and weight by 0.5 to 4 kg.²¹² Studies suggest that patients with significant obesity (BMI >35 kg/m²) demonstrate the greatest weight reduction when treated with pramlintide versus placebo.

Clinical studies of patients with type 1 diabetes taking insulin in combination with pramlintide or placebo over 29 to 52 weeks demonstrate significant HbA_{1c} reductions of 0.3% to 0.5% and weight loss of 0.3 to 1.8 kg.²¹² In three studies, patients were able to reduce their total daily insulin dose by 3% to 12%.

Dosage and Clinical Use

In clinical practice, pramlintide is considered an add-on agent primarily for patients with type 1 diabetes who have failed to achieve target blood glucose goals on insulin therapy alone. Its practical use is more limited to obese patients with type 2 diabetes who have failed to achieve target blood glucose levels with a regimen that includes a sulfonylurea or insulin. Pramlintide should not be considered for patients who have poor adherence to regular SMBG, medication therapy, and/or maintaining regularly scheduled visits with their health care providers.

Pramlintide is available in a vial and pen device (SymlinPen pen injector).²¹³ It cannot be mixed with any type of insulin. In addition, complex calculations are required to prepare a dose from a multidose vial and insulin syringes. This can impact proper dosage administration and adherence for even highly health literate patients. The pen device is therefore a more practical option when considering pramlintide therapy. Both vials and pens in use may be stored at room temperature (86°F or 30°C) for up to 30 days. Storing pramlintide at room temperature may minimize injection site reactions.

For patients with type 1 diabetes, the initial dose is 15 mcg and for patients with type 2 diabetes the initial dose is 60 mcg. Pramlintide is injected SC into the abdomen or thigh immediately before every major meal. A major meal is one that contains 30 g or more of carbohydrate or 250 kcals or more. If a meal is skipped, the pramlintide dose should be skipped and resumed before the next major meal. Injection sites should be rotated within the same anatomical area at every dose and sites used to inject insulin should be avoided.

When initiating pramlintide therapy, the dose of sulfonylureas, nonsulfonylurea secretagogues and premeal insulins must be reduced. It is recommended to reduce premeal insulin doses by at least 50%. Patients should be closely monitored and instructed to intensively monitor and record blood glucose (fasting, pre-, and postprandial) levels until control has stabilized. Any hypoglycemic episodes should be recorded and reported to the provider. Doses of hypoglycemic oral agents and insulin should then be titrated to optimal blood glucose control.

Pramlintide is titrated based upon achieving optimal glucose control with minimal side effects (e.g., nausea). For patients experiencing moderate to severe nausea, the dose may be reduced. If nausea does not subside, pramlintide therapy should be discontinued and the medication regimen adjusted accordingly. The dose may be increased when no clinically significant nausea has occurred for 3 to 7 days. For patients with type 1 diabetes, doses may be increased in 15-mcg increments up to a maximum meal dose of 60 mcg. For patients with type 2 diabetes, the dose may be increased to 120 mcg before every major meal. Pramlintide should be discontinued in patients who experience recurrent unexplained severe hypoglycemic episodes requiring medical attention.

TREATMENT OF PATIENTS WITH TYPE 2 DIABETES

Clinical Presentation

44. L.H. is a 45-year-old, moderately overweight, Mexican-American woman with central obesity (height, 5 feet 5 inches; weight, 160 lbs; BMI 26.6 kg/m²). She was referred to the diabetes clinic when her gynecologist, who had been treating her for recurrent monilial infections, noted glucosuria on routine urinalysis. Subsequently, on two separate occasions she was found to have an FPG of 150 mg/dL and 167 mg/dL. L.H. denies any symptoms of polyphagia or polyuria, although lately she has been more thirsty than usual. She does complain of lethargy and often takes afternoon naps.

L.H.'s other medical problems include hypertension, which is well controlled on lisinopril 20 mg/day, and recurrent monilial

infections, which are treated with fluconazole. She has given birth to four children (birth weights, 7, 8.5, 10, and 11 lb) and was told during her last pregnancy that she had “borderline diabetes.” She currently works as a loan officer in a local bank and spends her weekends “catching up on her sleep” and reading. L.H. has been smoking one pack of cigarettes per day for 20 years and drinks an occasional glass of wine. She drinks at least two regular sodas daily and has “large” glass of orange juice every morning. Her family history is significant for a sister, aunt, and grandmother with type 2 diabetes; all have “weight problems.” L.H.’s mother is alive and well at age 77; her father died of a heart attack at age 47.

Laboratory assessment reveals an FPG of 147 mg/dL (normal, 70–100); fasting plasma triglycerides of 400 mg/dL (normal, <150 mg/dL); and an HbA_{1c} of 9.2% (normal, 4%–6%). All other values (including the complete blood count, electrolytes, LFTs, and renal function tests) are within normal limits. L.H. is given the diagnosis of type 2 diabetes. What features in L.H.’s history and physical examination are consistent with this diagnosis?

[SI units: plasma glucose, 8.3, 9.3, and 8.1 mmol/L; plasma triglycerides, 6.77 mmol/L; HbA_{1c}, 0.09 (normal, 0.04–0.07)]

The features of L.H.’s history that are consistent with type 2 diabetes include an FPG concentration of 126 mg/dL or higher on more than one occasion, an elevated HbA_{1c}, high BMI with central obesity, age greater than 40, family history of diabetes, and Mexican American descent. L.H. also has delivered large babies, which suggests that she may have had undiagnosed gestational diabetes, a condition that places women at high risk for subsequently developing type 2 diabetes. Diagnosis on routine examination and mild signs and symptoms of hyperglycemia (including increased thirst and lethargy), recurrent monilial infections, hypertriglyceridemia, and indications of CVD (hypertension) also are typical in patients with type 2 diabetes (see Type 2 Diabetes and Table 50-1).

Treatment Goals

45. What should the goals of therapy be for L.H. and other patients with type 2 diabetes? Which biochemical indices should be monitored?

The beginning of this chapter discussed general goals of therapy for all people with diabetes, which include eliminating acute symptoms of hyperglycemia, avoiding hypoglycemia, reducing cardiovascular risk factors, and preventing or slowing the progression of both microvascular and macrovascular diabetic complications. The ADA recommends that otherwise healthy patients with type 2 diabetes strive to achieve the same biochemical goals as those recommended for people with type 1 diabetes^{22,214} (Table 50-4 and Table 50-5).

The UKPDS was the longest and largest study of patients with type 2 diabetes. It conclusively demonstrated that improved blood glucose control reduces the risk of developing retinopathy, nephropathy, and, potentially, neuropathy.³³ A 25% overall reduction in microvascular complication rate was observed among those patients receiving intensive therapy versus conventional therapy. An additional finding of the UKPDS

was that aggressive control of BP also significantly reduced strokes, diabetes-related deaths, heart failure, microvascular complications, and vision loss.^{215,216}

When determining treatment goals for L.H. and others with type 2 diabetes, the same individual characteristics should be considered as for type 1 diabetes, such as the patient’s capacity to understand and carry out the treatment regimen, the patient’s risk for severe hypoglycemia, and other patient-specific factors that may increase the risk or decrease the benefit of intensive treatment (e.g., advanced age, ESRD, advanced cardiovascular or cerebrovascular disease, or other coexisting diseases that may shorten life expectancy). Emphasis should be placed on assessment of all cardiovascular risk factors, including hypertension, tobacco use, dyslipidemia, and family history.

Macrovascular disease is the primary cause of death in this population, and its underlying pathogenesis may or may not be related to hyperglycemia per se. This is a subject of great complexity and controversy. Although the prevalence of cardiovascular morbidity and mortality correlates with HbA_{1c} levels in observational and epidemiologic studies, no prospective, randomized, controlled trials have established a relationship between macrovascular disease and the degree of glycemic control.²⁷ Whether intensive insulin therapy is appropriate for people with type 2 diabetes also has been questioned. Some have worried that hyperinsulinemia associated with intensive insulin therapy or the sulfonylureas actually could accelerate atherosclerosis or increase the risk of cardiovascular events. However, the UKPDS showed no increase in cardiovascular events or mortality in patients assigned to sulfonylurea or insulin therapy, despite their fasting plasma insulin levels being higher than those of the conventionally treated patients.³³ There is also concern that the counter-regulatory hormones released in response to hypoglycemia could endanger those with existing CVD. These views are summarized and analyzed by Colwell^{217,218} and others,²¹⁹ who suggest taking a more aggressive stance toward glycemic control, while attending to the reduction of all risk factors for CVD (e.g., hypertension, dyslipidemia, platelet hyper-reactivity, microalbuminuria).

Glycemic goals for patients with type 2 diabetes must be individualized. Given the conflicting preliminary data from the ACCORD and ADVANCE trials, patients with type 2 diabetes and CVD or multiple CVD risk factors should be carefully assessed before determining their metabolic goals (See Long-term Complications and Their Relation to Glucose Control).^{35,36} For example, less aggressive HbA_{1c} goals should be considered for patients with advanced age or significant cerebrovascular or coronary artery disease because of the serious consequences related to hypoglycemia. However, many treatment options available today are associated with a very low risk of hypoglycemia.

Because L.H. is relatively young and has no symptoms of microvascular disease or neuropathy, every effort should be made to normalize her glucose concentrations to prevent these complications. Furthermore, a lipid panel should be ordered and steps taken to achieve normal LDL cholesterol, HDL cholesterol, and triglyceride levels. Often, triglyceride levels improve as blood glucose concentrations decline and the metabolic response to insulin improves.

(Management of dyslipidemia is addressed more fully later in this chapter.)

Biochemical indices that should be followed to monitor L.H.'s response to therapy include fasting, postprandial, and preprandial blood glucose concentrations, HbA_{1c} values, fasting triglyceride levels, as well as LDL and HDL cholesterol concentrations. Initial metabolic goals for L.H. should be an HbA_{1c} value of <7%, an FPG of <130 mg/dL, postprandial glucose concentrations below 180 mg/dL, LDL-cholesterol below 100 mg/dL, and triglycerides below 150 mg/dL.

Treatment: A Stepped-Care Approach

Lifestyle Interventions and Initial Therapy With Metformin (Step 1)

46. How should L.H. be managed initially?

Initial therapy of type 2 diabetes is aimed at lifestyle changes that will minimize insulin resistance and risk for CVD. In L.H.'s case and in the case of other overweight (BMI 25.0–29.9) or obese (BMI ≥30.0) type 2 individuals, this includes a lower calorie, low-fat, low-cholesterol diet; regular exercise; smoking cessation (see Chapter 85) and aggressive management of dyslipidemia and hypertension. Because obesity is associated with increased tissue resistance to endogenous insulin, L.H. should be strongly encouraged to decrease her caloric intake and lose weight. When signs and symptoms are mild, diet and exercise alone can correct glucose intolerance. SMBG monitoring should be encouraged and education that addresses the serious nature of diabetes mellitus and its long-term consequences also should begin. This is discussed in the previous sections, Medical Nutrition Therapy and Exercise, under Treatment (Table 50-16).

INITIAL PHARMACOLOGIC THERAPY WITH METFORMIN

In 2006, the ADA and the European Association for the Study of Diabetes published a consensus algorithm for the initiation and adjustment of therapy in type 2 diabetes.²²⁰ The major change to the typical approach for glycemic control in type 2 diabetes was the recommendation to begin metformin along with lifestyle intervention as part of the initial therapy. The reasoning behind this recommendation is that patients with type 2 diabetes often fail to achieve the aggressive glycemic goals with lifestyle intervention alone leading to prolonged elevations in HbA_{1c} (Fig. 50-8).

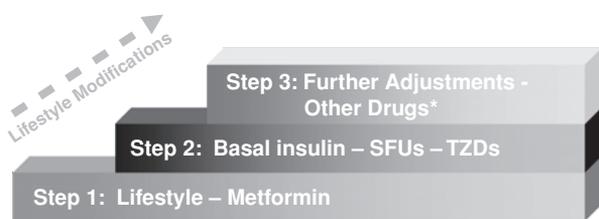

FIGURE 50-8 A stepped-care approach for treating type 2 diabetes. Treatment plans should be individualized. Lifestyle interventions (diet, exercise, weight loss, tobacco cessation, lipid and blood pressure management) are reinforced at every visit. * α -Glucosidase inhibitors, glinides, exenatide, dipeptidyl peptidase-4 inhibitors, glinides, pramlintide. SFUs, sulfonylureas; TZDs, thiazolidinediones.

Although the UKPDS demonstrated that the sulfonylureas, metformin, and insulin reduce glucose with equal effectiveness (TZDs were not studied), metformin is favored as a first-choice agent for overweight, type 2 diabetic patients by many endocrinologists as long as there are no contraindications to its use. This is because metformin lowers blood glucose by decreasing hepatic glucose output and insulin resistance (indirectly) without causing weight gain or hypoglycemia. Metformin also has beneficial effects on plasma lipid concentrations as well.^{33,221} One must always keep in mind that the primary goal is to normalize glucose concentrations, because hyperglycemia has been most closely correlated to the development of long-term complications. Thus, agents that may cause weight gain (e.g., sulfonylureas) are still very effective.

A drawback to metformin is that it requires multiple daily dosing and its dose also must be titrated to minimize GI effects. After the dose is established, it is possible to use a long-acting product that can be dosed once daily. Renal function tests should be evaluated before the drug is initiated. L.H. does not have any contraindications (renal or hepatic dysfunction, cardiorespiratory disease, binge alcohol use) to the use of metformin that could predispose her to its most significant side effect, lactic acidosis (see Question 62). Because L.H. exhibits the typical features of insulin resistance syndrome, has no contraindications for its use, and her HbA_{1c} is about 2% above her goal of <7%, she should be started on metformin. L.H. should take metformin 500 mg twice daily with food. If her HbA_{1c} was much closer to 7%, it would be reasonable to try lifestyle intervention alone before instituting pharmacologic therapy. However, most patients with type 2 diabetes require at least one medication to achieve the glycemic goals set forth by the ADA.

TITRATING METFORMIN DOSES

47. L.H. is started on metformin 500 mg BID with food and instructed to increase her dosage to 500 mg Q AM and 1,000 mg Q PM after 1 week. Three days after starting metformin, she phones the clinic complaining of nausea and diarrhea. She admits to taking her doses on an empty stomach. How should L.H.'s symptoms be addressed?

GI disturbances such as diarrhea, bloating, anorexia, abdominal discomfort, nausea, and metallic taste often dissipate with time and can be minimized by initiating metformin in a single, 500- or 850-mg dose at breakfast or with the patient's largest meal of the day. Consistently taking metformin with food significantly minimizes the GI side effects. The dosage should be slowly increased (e.g., 500 mg/day every 2 weeks) until the appropriate clinical effect is achieved or the patient is taking the maximum dose (1,000 mg twice daily or 850 mg three times a day). Therefore, L.H.'s metformin dose should be reduced to 500 mg daily with her largest meal, and she should be titrated more slowly over a period of several weeks to 500 mg three times a day or higher as tolerated. Metformin is typically dosed two to three times daily (the long-acting formulation is dosed once daily with dinner). If she continues to experience GI symptoms, an alternative approach is to use the extended-release formulation; small studies have demonstrated improved tolerability with the extended-release tablets over the

immediate release dosage form.²²² A drawback to these tablets is their very large size.

MONITORING METFORMIN THERAPY

48. How should metformin therapy be monitored in L.H.?

As is standard with other agents, L.H. should be encouraged to perform SMBG (see Question 49) and have an HbA_{1c} test performed quarterly until she achieves consistent values of <7%. Additional evidence of metformin's therapeutic benefits may include an improved lipid profile and some weight loss. Initially, it is important to follow GI problems and, although lactic acidosis is unlikely, L.H. should be warned to bring to the attention of her physician any sudden symptoms of shortness of breath, weakness, and malaise. A baseline SrCr, LFTs, and complete blood count should be obtained for L.H. and repeated yearly.

Self-Monitoring Blood Glucose in Type 2 Diabetes

49. L.H. is interested in learning how to perform blood glucose testing. What are the advantages and disadvantages of SMBG tests? When and how often should L.H. be instructed to test her blood glucose concentrations?

SMBG is an important self-management tool for patients such as L.H. to assess the efficacy of therapy and guide adjustments in nutrition, exercise, and medications. Performing SMBG also helps patients to monitor for and prevent hypoglycemia. Disadvantages include cost of testing, inadequate understanding by both health care providers and patients regarding the benefits and proper use of SMBG results, patient psychological and physical discomfort associated with obtaining a blood sample, and the inconvenience of testing. However, with the current advances in meter technology and proper patient education, most of these potential barriers can be overcome.

The ADA recommends SMBG for all patients taking insulin, but its stance with regard to patients with type 2 diabetes treated with diet or diet plus antidiabetic agents (other than insulin) is less clear. A meta-analysis of SMBG effects in patients with type 2 diabetes who are not taking insulin concluded the overall effect on HbA_{1c} was a 0.4% reduction; however, these studies often included multiple interventions such as education, diet, and medication adjustments.²²³ The ADA does suggest that the "optimal frequency and timing of SMBG for patients with type 2 diabetes on noninsulin therapy is not known but should be sufficient to facilitate reaching glucose goals."²² We often recommend SMBG for motivated type 2 patients who are learning to adjust their carbohydrate intake and portion sizes and want to measure how well medications and lifestyle changes are working to improve their glucose control. Initially, we may suggest testing four times daily before meals and at bedtime for 1 week so that the patient can observe his or her glucose profiles. Later, once the desired HbA_{1c} has been achieved, we recommend a minimum of testing blood glucose twice daily, but at various times to evaluate fasting glucose concentrations, 2-hour postmeal concentrations, and preprandial concentrations. A study of type 2 patients treated with diet with or without oral agents, but not

insulin, observed that 2-hour postlunch values (<150 mg/dL) and predinner values (<125 mg/dL) most closely correlated with HbA_{1c} values of less than 7%.²²⁴ As emphasized by the ADA, intensive patient education regarding testing technique and interpretation are vital to the cost-effective use of this monitoring tool. The patient must be able to assess his or her glucose profile and institute lifestyle changes that can have a favorable effect.

50. L.H. was quite motivated to improve her glucose control because her grandmother "lost a leg" to diabetes and her aunt is undergoing dialysis because "her kidneys have failed." She is taking metformin 1,000 mg PO BID and tolerating it reasonably well (she occasionally gets some stomach discomfort, but states she is fine with it). She is proud that she remembers to take the metformin everyday as instructed. She met with a dietitian who suggested an 1,800-calorie diet and 45-minute walks three times weekly. After 3 months, L.H. had lost 6 pounds. L.H. stopped drinking regular sodas and juices, but eats either breads or two large tortillas at each meal. She admits to eating only small amounts of "greens" and vegetables. She has not been able to implement her walks three times weekly; more often she only walks once a week. Although her FPG fell to 130 mg/dL (normal, 70–100), more than 50% of her postprandial blood glucose levels were often above 180 mg/dL (normal, <140). Her HbA_{1c} is 7.4% (normal, 4%–6%), and fasting triglyceride levels are now 260 mg/dL (normal, <150). How should her therapy be adjusted? What factors should be considered when deciding on the next steps for pharmacologic therapy?

L.H.'s HbA_{1c} has improved by 1.8%. However, she has not fully instituted lifestyle interventions. Although she has cut out juices and regular sodas, she can improve her diet and lower her postprandial blood glucose (to <180 mg/dL) by eating lower carbohydrate meals and increasing her vegetable intake. She also can increase her physical activity to at least three times weekly. Although the HbA_{1c} is not below 7%, a reasonable approach would be to continue metformin at 1,000 mg PO BID and reinforce lifestyle changes at this point before modifying her pharmacologic therapy.

Type 2 diabetes is a progressive condition, which is highly likely to require drug therapy. In the UKPDS, only 16% and 19% of the subjects achieved a FPG below 108 and HbA_{1c} below 7%, respectively, after 3 years of dietary therapy.²²⁵ By 9 years, only 9% were able to maintain their glycemic goals using diet therapy alone. For patients who elect to start with lifestyle changes, we recommend monotherapy followed by combination therapy with two antidiabetic agents if therapeutic goals are not met. For patients who start with metformin at the time of diagnosis, as in the case of L.H., the next step would be to add a second antidiabetic agent.^{220,226} Selecting an antidiabetic agent to treat type 2 diabetes has become more complex as new agents with unique mechanisms of action have been introduced into the market. As with all therapeutic decisions, clinicians should also blend their knowledge of the drug (e.g., its efficacy, safety, side effects, dosing methods, and cost) with the unique characteristics of the patient (e.g., level of glycemic control, organ function, other concurrent diseases and medications, ability to adhere to complex medication regimens, health care coverage) when making a choice of drug products.²²⁷ The current HbA_{1c} level and

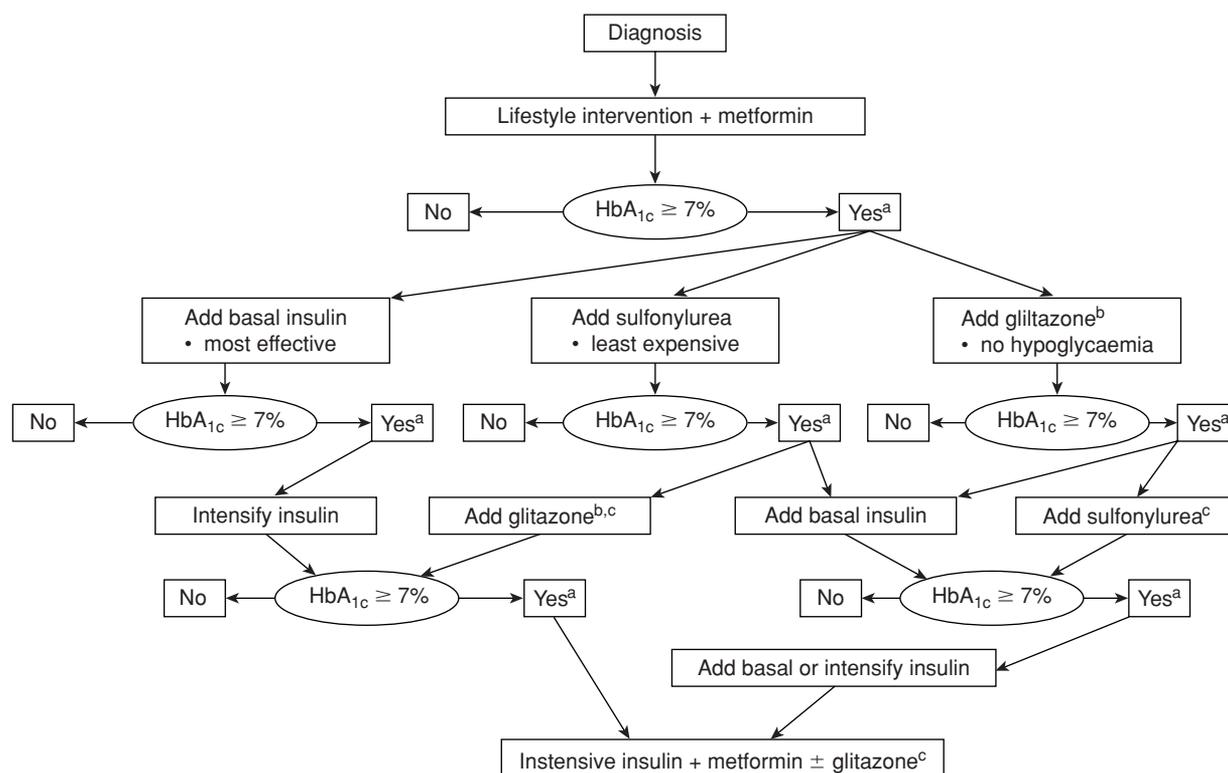

FIGURE 50-9 Suggested treatment algorithm for type 2 diabetes. ^aCheck HbA_{1c} every 3 months until it is below 7%, and then at least every 6 months. ^bAssociated with an increased risk of fluid retention, heart failure, and fractures. Rosiglitazone, but probably not pioglitazone, may be associated with an increased risk of MI. ^cAlthough three oral agents can be used, initiation and intensification of insulin therapy may be preferred based on effectiveness and lower costs. (Used with permission from reference 226.)

reduction required to reach the HbA_{1c} goal is also an important consideration. Practitioners should attempt to avoid unnecessarily complex therapy that may confuse the patient, increase drug costs, and complicate the clinician's ability to assess each medication's contribution to the overall therapeutic outcome (Fig. 50-8). The algorithm proposed by Nathan et al., and endorsed by the ADA, recommends consideration of initiating insulin therapy (most often basal insulin) if the HbA_{1c} is above 8.5%. However, in clinical practice, most would continue to select noninsulin combination therapy until the HbA_{1c} reaches a higher level, closer to 10% (Fig. 50-9). To use the algorithm, practitioners need to take into account the patient's underlying pathogenesis. The pathogenic features are deduced from the patient's body weight. If the patient is obese, it is presumed there is an element of insulin resistance and increased hepatic glucose output. If the patient is lean, he or she is presumed to be insulin deficient. Antidiabetic therapy is chosen to target the pathogenic problem(s).

Table 50-26 compares and contrasts the efficacy, advantages, and disadvantages of antidiabetic agents used to treat type 2 diabetic patients and can be used in conjunction with the basic algorithm to select drugs for a specific patient. Table 50-28 summarizes treatment of type 2 diabetes under special circumstances.

If patients fail therapy with two oral agents, one could move to triple therapy (noninsulin) or add insulin. To avoid injections, many patients and caregivers opt for triple combination therapy (using oral agents with different mechanisms of action),

but this is less well studied.^{228–231,232} One study compared triple oral therapy with insulin 70/30 mix plus metformin in patients with type 2 diabetes poorly controlled on two oral agents.²³³ Both treatments were about equally effective in lowering HbA_{1c} and FPG values (1.77% and 55 mg/dL; and 1.96% and 65 mg/dL, respectively). However, 10.2% of patients in the triple-therapy group were switched to the insulin plus metformin therapy because of an inadequate response, but these patients had higher HbA_{1c} levels (average 10.6%) at baseline. The cost of triple therapy (drug cost plus LFT monitoring for the TZDs) was higher. Other combination options exist now with the availability of exenatide (which is injected), the DPP-4 inhibitors, and pramlintide (although this is very infrequently used).

The combined use of insulin plus oral therapy was once considered a bridge to insulin monotherapy. However, a substudy of the UKPDS demonstrated that the early addition of insulin to patients with inadequate responses to oral sulfonylureas (FPG > 108) improved glycemic control over insulin therapy alone over an average follow-up period of 6 years. Patients on combined therapy with insulin suffered 50% more episodes of major hypoglycemia, but weight gain was comparable.²³⁴ If this fails, the patient is treated with insulin monotherapy. Insulin is being considered earlier in therapy now for patients with type 2 diabetes to achieve glycemic goals. For patients who are gaining weight because they require large insulin doses, metformin can be added to achieve control with lower doses in insulin. Although TZDs have been shown to allow for lower

Table 50-28 Treating Type 2 Diabetes Under Special Circumstances

| Circumstance | Avoid | Consider |
|---|---|--|
| Patients with decreased renal function | Acarbose ^a Long-acting SFUs (e.g., glyburide) Metformin | Glipizide Glimepiride Insulin Glinides (Repaglinide/nateglinide) Sitagliptin Thiazolidinediones |
| Patients with impaired liver function | Acarbose ^a Metformin Thiazolidinediones ? SFUs (severe liver dysfunction) | Insulin Repaglinide ^b Exenatide Sitagliptin Miglitol |
| Patients who are obese or gaining excessive weight | Insulin ^c Sulfonylureas Repaglinide ? Thiazolidinediones ^d | Acarbose Miglitol Metformin |
| Patients with preexisting edema | Thiazolidinediones | SFUs Glinides Exenatide Sitagliptin |
| Patients with heart failure | Thiazolidinediones Metformin | SFUs Glinides Exenatide Sitagliptin Insulin |
| Patients experiencing hypoglycemia due to irregular eating patterns | Insulin Long-acting SFUs | Acarbose Metformin Repaglinide/nateglinide Thiazolidinediones Exenatide Sitagliptin |

^aThis is a labeled recommendation. Although very little acarbose is absorbed into the systemic circulation, the small amount available relies on the kidneys for elimination. This accumulation and doses ≥ 300 mg/day rarely have been associated with elevated liver enzymes. Plasma concentrations of miglitol in renally impaired volunteers were proportionally increased relative to the degree of renal dysfunction.

^bThe manufacturer recommends more cautious dose titration in these cases.

^cThis recommendation presumes that the patient can be controlled on other antidiabetic agents. Often by the time insulin is required in type 2 diabetes, pancreatic function may have deteriorated considerably.

^dRosiglitazone and pioglitazone are associated with mild to moderate weight gain owing to fluid retention and fat accumulation. However, because of their mechanism of action, they are effective in improving glycemic control in insulin-resistant patients who are often overweight or obese. SFUs, sulfonylureas.

L.H. is a typical overweight type 2 patient with early evidence of CVD (hypertension), but with no evidence of microvascular complications. Her liver, renal, and GI functions are normal. Patients like L.H. with moderate to severe type 2 diabetes have varying degrees of β -cell dysfunction and tissue resistance to insulin. In these individuals, pulsatile insulin secretion and first-phase insulin release are absent, and the pancreas is “blind” or unresponsive to high glucose concentrations (glucotoxicity). Because target tissues are less responsive to insulin, hepatic glucose output typically is increased and patients may require higher concentrations of insulin to achieve the same degree of peripheral glucose utilization observed in people without diabetes mellitus. At this stage, technically all classes of oral antidiabetic agents and insulin are likely to work equally well, although metformin is still considered the preferred agent. Insulin causes more weight gain and hypoglycemia than the other antidiabetic agents and is usually reserved for combination therapy unless the initial HbA_{1c} at diagnosis is very elevated ($> 10\%$) or ketonuria is present.²²⁰

Often, *acarbose* is eliminated from consideration because slow titration is required to minimize GI effects; anecdotally, however, people of Mexican American origin, such as L.H., seem less susceptible to flatulence and diarrhea. Also, because acarbose has less dramatic effects on the FPG (20–30 mg/dL decrease) and HbA_{1c} (0.5%–1.0% decrease) than the other agents, biochemical goals are less likely to be achieved in patients whose HbA_{1c} is 8.5% or higher.

Rosiglitazone or *pioglitazone* also can be used as monotherapy and, like metformin, neither is likely to cause hypoglycemia, but weight gain and edema are likely. Their effects on FPG and HbA_{1c} are intermediate between those of acarbose and metformin or the sulfonylureas, so that it is likely that the goals established for L.H. could be achieved with either agent as monotherapy.²²⁰ On the positive side, the TZDs have been shown to have better “glycemic durability” compared with metformin and the SFUs. In a double-blind, randomized, controlled trial of 4,360 patients with type 2 diabetes, time to monotherapy failure, defined as FPG above 180 mg/dL was assessed for rosiglitazone, metformin, and glyburide (A Diabetes Outcome Progression Trial [ADOPT]).²³⁵ Patients were treated for a median of 4 years. The Kaplan-Meier analysis showed that the cumulative incidence of failure at 5 years was 15% for rosiglitazone, 21% for metformin, and 34% for glyburide ($p < .0001$). The suggested explanation for the favorable rosiglitazone results was that it slowed the rate of β -cell function decline. On the negative side, several meta-analyses have called into question the safety of rosiglitazone.^{189,190,236,237}

Given the recent data suggesting a 30% to 40% relative increase in risk of MI, many practitioners are using rosiglitazone more cautiously. Other analyses, however, have not continued an increased risk of MI for either rosiglitazone or pioglitazone, which may even have a protective effect.^{192,238,239} Both rosiglitazone and pioglitazone are associated with an approximate twofold increased risk of heart failure.^{238–240} In the long-term ADOPT trial, rosiglitazone was associated with a mean weight gain of 4.8 kg, whereas weight decreased by 2.9 kg in the metformin group; glyburide-treated patients had a mean weight gain of 1.6 kg during the first year, and then remained stable.²³⁵ Given these adverse effects, most practitioners reserve TZDs for combination therapy.

insulin doses, their use is associated with weight gain and more edema when combined with insulin.

Clinical Use of Antidiabetic Agents

Selecting an Oral Agent

51. Which other antidiabetic agents could be considered for L.H. as monotherapy?

Although the treatment algorithm recommends the use of metformin as step 1 therapy, other antidiabetic agents are approved for use as monotherapy as well.

Sitagliptin, which is approved for monotherapy, is generally reserved for add-on (combination) therapy. However, it can be used as monotherapy for patients in whom the use of other oral agents is precluded (such as renal dysfunction for metformin or severe heart failure for the TZDs).

Finally, one should not forget that until the newer agents became available, sulfonylureas were used quite successfully to treat obese patients with type 2 diabetes. These agents are relatively trouble free with regard to side effects (weight gain and occasional hypoglycemia), and many can be dosed once daily. They are very effective and many are now available in generic form, making them quite affordable when cost is a primary consideration (Table 50-27).

Several new products that combine two oral agents into one medication are available. Although these products are approved as first-line therapy, thus skipping the monotherapy step, we recommend that they be reserved for use in patients whose medication regimens must be simplified to enhance adherence.

Based on this discussion, we favor the use of metformin as initial therapy in L.H.

Thiazolidinediones

52. N.H. is a 46-year-old, obese (BMI 33 kg/m²) man with a history of type 2 diabetes, hypertension, recurrent deep venous thrombosis, and hyperlipidemia. He presents with complaints of fatigue and nocturia. N.H. has smoked 2 packs of cigarettes/day for 15 years and has a strong family history of coronary heart disease (CHD). At diagnosis 3 months ago, he had a random plasma glucose >200 mg/dL on two occasions (248 and 207 mg/dL); a FPG of 150 mg/dL (normal, <126 mg/dL), and an HbA_{1c} of 8.5% (normal, 4%–6%) confirming the diagnosis of type 2 diabetes. Tests of liver and renal function are within normal limits. Current medications include enalapril and lovastatin. N.H. started metformin but stopped taking it because of GI symptoms (loose stools); he refuses to try this medication again. After a 1-month trial of diet and exercise, his glucose concentrations remain above 200 mg/dL. What is a reasonable next monotherapy option for N.H.?

Unfortunately, N.H. did not tolerate metformin. Although this is less common if patients take metformin with food and the dose titrated slowly, some do not overcome the GI adverse effects. N.H. is refusing to even consider a retrial. With a BMI of 33 kg/m², hypertension, and dyslipidemia, N.H. has many components of the metabolic syndrome and insulin resistance (see Pathogenesis). We would not select sulfonylureas or insulin as a next choice of drug of choice for N.H. because they do not exert a favorable effect on plasma lipids and generally are associated with weight gain. We acknowledge that some sulfonylureas remain the least expensive oral antidiabetic agents, and this may be an important factor in the initial selection of therapy for some patients. Although sulfonylureas or insulin decrease blood glucose concentrations in patients like N.H., they do so by increasing insulin concentrations. Patients such as N.H. are likely to have β -cell dysfunction, as evidenced by poor first-phase insulin release; however, in the early stages of type 2 diabetes, they also are likely to exhibit high insulin concentrations, which suggests resistance of peripheral tissues to insulin action. This can be overcome by increasing insulin levels, but hyperinsulinemia promotes fuel storage and

often is accompanied by hunger, occasional hypoglycemia, and weight gain. Interestingly, research suggests that the sulfonylureas may close ATP-sensitive potassium channels in cardiac tissue, similar to their action at the β -cell. In the heart, this effect could limit circulation to an ischemic area.^{198,217}

In light of N.H.'s HbA_{1c} value (8.5%), acarbose as monotherapy is not likely to attain near-normal plasma glucose concentrations. Rosiglitazone or pioglitazone improve peripheral target tissue responses to insulin and lipid profiles. N.H. is taking several other medications, and the convenience of a single-daily-dose therapy may be beneficial to him. In addition to the increased risk of MI demonstrated with rosiglitazone (see Question 52), edema, weight gain, and heart failure are adverse effects associated with TZDs; rosiglitazone and pioglitazone have also been shown to increase the risk of bone fractures. However, this risk has only been seen in older women.^{235,241} It is thought to be due to reduced osteoblast differentiation as a result of increased adipogenesis in the bone marrow.²⁴² TZDs should be used cautiously in older women and patients on chronic steroids.

For N.H., whose liver function is normal, pioglitazone 15 to 30 mg/day is the next reasonable option. He should be started on pioglitazone 15 to 30 mg/day. Liver function tests (ALT) should be performed at baseline (done already), and then periodically thereafter according to the manufacturer.¹⁸² Many practitioners check the LFTs every 3 to 6 months during the first year of therapy and then every 6 to 12 months thereafter.

Clinical Note: N.H. was successful in reducing his HbA_{1c} to 7.1% through a combination of lifestyle modifications and pioglitazone. He was able to lose 10 pounds with walking and reduction in fatty food, despite being on a TZD, which can cause weight gain secondary to fluid retention and fat accumulation. The modest weight loss and improved glucose concentrations likely reduced his insulin resistance, thereby improving tissue responsiveness to his endogenous insulin. N.H. enrolled in a smoking cessation program, but has been unable to quit smoking completely (see Chapter 85).

Sulfonylureas

53. K.M. is a 64-year-old Asian woman with a BMI of 22 kg/m² who was diagnosed with type 2 diabetes. Her HbA_{1c} is 9.0%. Because she is thin, with no evidence of abdominal obesity, the diabetes interdisciplinary team agrees that she is likely insulinopenic and should be treated with a sulfonylurea. Which agents could be used? How should they be dosed?

A minority of patients who are diagnosed with type 2 diabetes are thin, with little to no abdominal obesity. In this type of patient, the major cause of hyperglycemia is likely insulin deficiency, or a β -cell defect. A sulfonylurea would be a reasonable first choice of therapy because it increases insulin secretion. Patients likely to respond most favorably to oral sulfonylureas include those who are older than 40 years of age, have been diagnosed within the last 5 years, are within 110% to 160% of ideal body weight, and have an FPG of more than 200 mg/dL. If patients have been treated with insulin, those whose requirements are <40 units/day (indicating endogenous pancreatic reserve) are most likely to respond.¹⁷⁰ N.H. fulfills these criteria and does not have any contraindications to sulfonylurea use (see Antidiabetic Agents). Approximately two-thirds to three-fourths of the patients who meet all of the

previously specified criteria will achieve satisfactory control initially. The remainder (16%–36%) fail to respond to a 1-month trial of maximum therapeutic doses and are considered primary failures.¹⁷⁰

There is little evidence that any particular oral sulfonylurea is more effective than another in properly selected patients with type 2 diabetes. However, as discussed, there are differences in duration of action and side effects that should be considered in the selection of these agents. (see Table 50-26 and Table 50-27 and the section on Antidiabetic Agents.)

The first-generation agents (chlorpropamide, acetohexamide, tolbutamide, and tolazamide) are less potent than the second-generation agents on a milligram for milligram basis. Because they are now rarely used, they will not be addressed.

Glimepiride, glipizide, and glyburide are second-generation agents. Glipizide is metabolized to inactive products and has an intermediate duration of action. Many patients can be controlled on single daily doses, but twice-daily doses are recommended for patients who require more than 15 mg. Because glyburide has a longer duration of action, it is associated more frequently with severe, prolonged hypoglycemia than is glipizide. For this reason, it should be used cautiously in frail, elderly individuals or in those who, for any reason, are predisposed to hypoglycemia (see Questions 65 and 70). Glimepiride can be dosed once daily and may be associated with a slightly lower incidence of hypoglycemia than glyburide.

For K.M., glimepiride, glipizide, or glyburide would be the agents of choice because they are reasonably safe, can be dosed once daily, and are relatively inexpensive. She should be initiated on low dosages (e.g., 1–2 mg glimepiride, 5 mg glipizide, or 1.25–2.5 mg glyburide) once daily. Every 1 to 2 weeks, the dosage can be increased until the therapeutic goals are achieved or maximum doses of these agents have been reached (Table 50-27). The manufacturers of glipizide and glyburide recommend twice-daily dosing of these agents once a specified dose has been exceeded; whether this actually is necessary has not been documented. Many clinicians recommend taking these agents 30 minutes before meals so that the onset of action more closely matches food absorption¹⁷⁰; this may be less important in patients taking these agents chronically, particularly for the intermediate-acting and longer acting agents.^{243,244} If GI intolerance occurs, these agents should be taken with food.

Because K.M. is starting a medication that can cause hypoglycemia, it is important that she be counseled not to skip meals and taught SMBG. She should be educated about symptoms of hypoglycemia and how to treat them (see Self-Monitored Blood Glucose in Type 2 Diabetes and Table 50-13 and Table 50-14).

Clinical Note: K.M. was successfully treated with diet, exercise, and relatively low doses of glyburide (5 mg/day). Within 4 months, her HbA_{1c} dropped to 6.9% and her SMBG results ranged from 120 to 160 mg/dL.

Failure of Antidiabetic Monotherapy

Pathogenesis

FAILURE OF ORAL MONOTHERAPY

54. Q.R. is a 68-year-old, 5 feet 1 inch, 155-lb (BMI 29.3 kg/m²) woman with an 8-year history of type 2 diabetes who has been treated with diet, exercise, and metformin. According to clinic

records, she was well controlled initially (HbA_{1c} 6.7%–7.2%) for the first 5 years. When her glycemic control worsened (FPG, 130–160 mg/dL; HbA_{1c}, 7.5%–8.5%), her metformin dose was increased over time, from an initial dose of 500 mg PO BID to her current dose of 850 mg PO TID. Recent chart notes indicate that Q.R.'s chief complaints have included loss of appetite and fatigue. She has lost 15 lb over the past year, and her current HbA_{1c} is 8.6%. Other medical problems include hypertension managed with hydrochlorothiazide 25 mg daily and mild peripheral neuropathy managed with naproxen 500 mg twice daily. Her estimated GFR is 70 mL/minute.

At this clinic visit, Q.R., who is well known to you, seems particularly listless and flat in her affect. Her blood glucose records, which are typically meticulous, are incomplete. Blood glucose values consistently exceed 200 mg/dL and range from 202 to 340 mg/dL. While taking her history, you discover that her husband passed away last year and that one of her adult children has recently been diagnosed with a terminal illness. What factors may be contributing to Q.R.'s poor glucose control?

Several factors may be contributing to Q.R.'s deteriorating blood glucose control and apparent lack of responsiveness to maximum dose of metformin over the past year (as evidenced by her elevated blood glucose and HbA_{1c}, listlessness, and weight loss). When SFUs were used exclusively for oral monotherapy (before other oral agents were available), this loss of glycemic control, called *secondary failure*, was fairly common, occurring at a rate of approximately 5% to 10% per year in patients who initially were well controlled on these agents.¹⁷⁰ Monotherapy failure is characterized by progressively poor glucose control that occurs after a 1-month to a several-year period of good response. The cause of failure may be related to progressive pancreatic failure; poor compliance with diet, exercise, or medications; and exogenous diabetogenic factors such as obesity, illness, or drugs that induce hyperglycemia.

The UKPDS confirmed that monotherapy failure represents a natural progression of type 2 diabetes. The investigators found failure occurred at the same rate regardless of the initial treatment selected: glyburide, chlorpropamide, metformin, or ultralente insulin. In all the monotherapy treatment groups, patients required additional therapies over the study duration.²²⁵ At 3 years, fewer than 55% of patients randomized to single pharmacologic therapy could maintain an HbA_{1c} below 7%, and by 9 years this dropped to about 25% of patients. In the ADOPT study, patients were able to maintain HbA_{1c} levels below 7% using monotherapy for 60, 45, and 33 months with rosiglitazone, metformin, and glyburide, respectively.²³⁵ The reason for glycemic deterioration is likely due to the natural progression of type 2 diabetes in which β -cell function declines with increased duration of disease. Also, when the blood glucose becomes very elevated (FPG >250–300 mg/dL; preprandial glucose concentrations \geq 200 mg/dL), the pancreas's ability to secrete insulin is diminished and postreceptor (postbinding) defects in insulin activity become more important. Postreceptor defects are characterized by a reduced responsiveness of tissues to any level of insulin. If glucose concentrations can be normalized, postreceptor defects and pancreatic responsiveness to glucose can be improved. This may be related to the hypothesis that high glucose concentrations in and of themselves may be toxic to the β -cells and peripheral tissues (glucotoxicity).²⁴⁵

Q.R.'s deteriorating control on maximum doses of metformin after 5 years of reasonable response is consistent with the natural progression of type 2 diabetes. However, the stress and depression arising out of her life situation have no doubt contributed to her poor control. The latter may have led to a change in her usual compliance with diet, exercise, and medications and should resolve with time and appropriate management. Although hyperglycemia has been attributed to hydrochlorothiazide, the dose prescribed for Q.R. has few adverse metabolic effects.

Managing Monotherapy Failure

55. How should Q.R. be managed? Should she be switched to another antidiabetic agent?

Q.R. is exhibiting symptoms of depression (e.g., listlessness and flat affect). Her depression likely started after her husband's death. Every effort must be made to address Q.R.'s depression because it is unlikely that she will be able to effectively implement more aggressive treatment of her diabetes until her situation is improved. Resources that may be used include her family, a therapist, and a social worker.

Treatment of monotherapy failure includes identifying and correcting any diabetogenic factors and altering her drug therapy. When failure to any oral agent occurs, one should always add another agent rather than switch to another. This is supported by a study that evaluated the effect of metformin alone in a population of patients who had failed oral sulfonylureas and the effect of metformin plus the sulfonylureas. Substitution of metformin for glyburide did not produce any significant change in glycemic control, but the addition of metformin to glyburide therapy substantially improved glucose concentrations.²⁴⁶ Many combinations of antidiabetic agents can be used. The key is that they should have different mechanisms of action. For example, it is not reasonable to combine a sulfonylurea with a "glinide" (i.e., repaglinide and nateglinide) because they are both insulin secretagogues. It makes more sense to maintain the current agent and add another rather than to change to two new medications. Options for Q.R. include adding one of the following to metformin: insulin secretagogue (sulfonylurea or glinide), acarbose, TZD, sitagliptin, or exenatide.

Table 50-26 summarizes the FDA-approved combination therapy indications. One also could introduce insulin therapy at this time. According to Nathan's algorithm (Fig. 50-9), basal insulin therapy could certainly be initiated. However, because Q.R.'s HbA_{1c} should be effectively lowered with an additional oral agent, we recommend using two noninsulin antidiabetic agents to avoid an unreasonably complicated intervention.

In summary, patients such as Q.R. who are unresponsive to the maximum dose metformin are unlikely to respond to monotherapy with another agent. They should therefore be initiated on combination therapy.

Combination Antidiabetic Therapy (Step 2)

56. As anticipated, Q.R. refuses to consider insulin therapy at this time. Which combination of antidiabetic agents is preferred?

When agents from different antidiabetic classes are combined, their effects are essentially additive. With the availability of many antidiabetic agents, there is no one best combination therapy. As discussed, the choice of therapy should take into account the patient's organ function, amount of HbA_{1c} lowering required to reach an individual's goal, possible adverse effects of a particular drug or drug combination, cost, and patient preference.

Acarbose has been used successfully in combination with both sulfonylureas and metformin, lowering the HbA_{1c} by approximately 1%. However, an agent that can be titrated more quickly than acarbose, does not have significant GI side effects (especially when used with metformin), and one that is more likely to have a profound effect on blood glucose concentrations should be used in Q.R. The TZDs are approved for use in combination with sulfonylureas and metformin. Pioglitazone 30 mg added to metformin monotherapy reduced the FPG by a mean of 38 mg/dL and the HbA_{1c} by 0.8%.¹⁸² Rosiglitazone 4 mg/day added to metformin reduced HbA_{1c} and FPG by 1.0% and 40 mg/dL, respectively, compared with metformin alone.^{181,247}

Metformin also has been used successfully in combination with the sulfonylureas. The combination lowers fasting glucose concentrations by approximately 80 mg/dL and HbA_{1c} values by 2% when metformin is given in full dose (2,500 mg/day in three divided doses).²⁴⁶ In the later stages of the UKPDS, 537 obese and nonobese patients who failed sulfonylurea monotherapy were randomly assigned to continue sulfonylurea monotherapy or to have metformin added. Interestingly, an intention-to-treat analysis of this substudy showed that those patients assigned to the combined metformin-sulfonylurea therapy had a 96% increase in diabetes-related deaths ($p < .039$) and a 60% increase in all-cause deaths ($p < .041$) compared with the sulfonylurea monotherapy group.²²¹ However, these detrimental effects have been questioned because there was no placebo control and the treatments could not be masked. The ADA currently does not recommend any change in the current guidelines, which include the use of metformin and sulfonylureas in combination. They will await a new, appropriately designed, randomized, placebo-controlled trial that can affirm an adverse interaction between these two drugs.

The addition of sitagliptin to metformin results in a 0.7% HbA_{1c} reduction compared with baseline²⁴⁸ and the addition of exenatide to metformin results in a 0.8% HbA_{1c} reduction.²⁴⁹ A disadvantage to exenatide is that it requires an injection; its advantage is that it may result in weight loss.

Although Q.R. has recently lost weight, she remains overweight. Thus, metformin should be maintained and a second agent added. Q.R. would like to remain on oral medications if possible. Sitagliptin may result in slightly less HbA_{1c} lowering compared with adding a sulfonylurea. Therefore, she is started on glimepiride 2 mg PO daily.

Combination Antidiabetic Therapy (Step 3)

57. Q.R. is titrated to glimepiride 4 mg/day and continued on metformin 850 mg PO TID. This improved her FPG and HbA_{1c} modestly for approximately 12 months (FPG, 120–150 mg/dL; currently HbA_{1c}, 7.6%). She remains resistant to starting insulin, despite a 10-minute conversation discussing the rationale for its

use. She has heard about a new diabetes medication called Byetta, and would like to try it because it can cause weight loss.

When a combination of oral agents fails, practitioners often add a third agent before considering insulin. Although this is tempting, depending on a patient's current level of glycemic control, this practice only delays insulin therapy, which is likely to be required to achieve HbA_{1c} goals. However, because Q.R. is close to an HbA_{1c} level of <7%, it is reasonable to try a third, noninsulin antidiabetic agent. Although glimepiride 8 mg/day is the maximum dose, there is little difference in clinical efficacy compared to 4 mg/day. Therefore, increasing glimepiride to 8 mg/day is not likely to achieve her glycemic goals.²⁵⁰

Exenatide (Byetta) is approved for use in patients taking metformin, sulfonylurea, or a TZD alone, or a combination of metformin plus a TZD or metformin plus a sulfonylurea. When added to patients on a sulfonylurea and metformin, exenatide at 10 mcg BID resulted in a 0.8% HbA_{1c} reduction compared with baseline.²⁵¹ Thus for Q.R., the addition of exenatide could result in an HbA_{1c} of <7%. The use of exenatide with a sulfonylurea is associated with an increased risk of mild to moderate hypoglycemia (28% when used with sulfonylurea and metformin and 36% when use with sulfonylurea alone).^{249,251} Most practitioners reduce the dose of the sulfonylurea upon initiation of exenatide and then make adjustments based on the patient's response to exenatide.

Q.R. should be started on exenatide 5 mcg subcutaneously BID, taken within 60 minutes of the two main meals of the day and at least 6 hours apart. She should be counseled about nausea, which is the most frequent side effect; 44% of patients will develop nausea, but there is only 3% dropout rate in the clinical trials. The glimepiride should be reduced to 2 (or 3) mg/day. After 1 month, if she is tolerating exenatide, the dose should be increased to 10 mcg subcutaneously BID. Her HbA_{1c} should be monitored within 3 months of using the 10-mcg dose. An advantage of exenatide (over sitagliptin) is the potential for weight loss. In a 30-week blinded study of exenatide added onto sulfonylurea and metformin, patients on the 10-mcg dose had an average weight loss of 1.6 kg.²⁵¹ In the three open-label, noncontrolled extension trials with exenatide, at 3 years exenatide progressively reduced (−5.3 kg) and sustained weight loss at 3 years.²⁵²

A small proportion of patients will form anti-exenatide antibodies. At high titers, these antibodies could result in failure to achieve adequate improvement in glycemic control. If there is worsening glycemic control or failure to achieve targeted glycemic control while on exenatide, the formation of blocking antibodies should be considered as a reason. A long-acting release formulation of exenatide that is dosed once weekly should be available shortly.²⁵³

Combination Antidiabetic (Step 3) With Insulin Therapy

58. If Q.R. was willing to start insulin, why would it be reasonable to use insulin in combination with oral agents? How should it be combined with oral agents? Is this combination more effective than insulin alone?

Most patients with type 2 diabetes eventually require insulin. The combined use of insulin with a variety of oral agents has been extensively evaluated, but the studies differ in their design. In some studies, single doses of an intermediate- or long-acting insulin or once or twice daily doses of premixed

insulin are added to a single or combination of oral antidiabetic agents in poorly-controlled patients. The primary outcomes that have been evaluated include measures of glycemic control (e.g., HbA_{1c}, FPG) and the extent to which insulin doses have been decreased. Dewitt and Hirsch published a comprehensive review of these studies and readers are referred to this excellent article for this evidence.²⁵⁴ The combined use of insulin and oral agents can be considered at both steps 2 and 3 in the ADA algorithm (Fig. 50-8 and Fig. 50-9).

The traditional approach to adding insulin therapy to an oral agent (i.e., a sulfonylurea) was called BIDS therapy (bedtime insulin, daytime sulfonylurea). Now, with the many available noninsulin antidiabetic options, bedtime basal insulin (using NPH, glargine, or detemir) can be added to single or combination (usually only two) oral agent therapy. Combining a sulfonylurea with insulin can lower the insulin requirements by 25% to 50%, which results in less weight gain. Similarly, use of metformin with insulin has decreased mean insulin requirements by 25%.²⁵⁵ Although metformin is an antihyperglycemic agent, one must be alert for increased susceptibility to hypoglycemia when it is used in combination with insulin. Studies seem to confirm potential advantages of metformin over sulfonylureas when used in combination with insulin. These include its favorable effects on the lipid profile, insulin concentrations, and lack of weight gain. The risk for hypoglycemia may also be lower with metformin than with combined use of sulfonylureas.^{221,256,257} Use of a TZD with insulin is effective in reducing insulin doses and HbA_{1c}.²⁵⁸ However, the disadvantage with this combination is weight gain and significant edema (~15%).

In Q.R.'s case, it makes the most sense to add a single dose of basal insulin to metformin and glimepiride. Advantages attributed to adding insulin to an oral agent as the "next step" after failure, as opposed to using insulin alone, include the following^{254,259,260}.

- Lower insulin dosages can be used, and this minimizes weight gain and hypoglycemia.
- Simpler, single-dose insulin regimens are possible (vs. monotherapy with insulin).
- Lowering the fasting glucose concentrations improves glucose control throughout the day because glucose excursions related to meals are layered over lower values. Furthermore, lower glucose values improve β -cell responsiveness to glucose and enhance tissue responsiveness to insulin action.
- Use of the insulin sensitizers may enhance the effect of exogenous insulin while minimizing weight gain and hyperinsulinemia. They also may have beneficial effects on lipid profiles and other cardiovascular defects.

However, lowering glucose concentrations is the first priority, not attempting to use lower insulin doses. Q.R. should be started on 10 units or 0.2 unit/kg of NPH, insulin glargine, or insulin detemir at bedtime. This dose is based on empiric use of insulin in a variety of studies (0.1–0.35 unit/kg)^{220,261} and a conservative estimate for basal insulin of approximately 0.5 unit/hour (Q.R. weighs 155 pounds, or 70.5 kg). The dose also takes into account the possibility that Q.R. is secreting some basal insulin of her own and will have some residual stimulation of insulin secretion by glipizide. The basal dose should be titrated upward based on the FPG for 3 consecutive days. A common titration method used is the "treat-to-target" schedule.^{262,263}

| FPG (mmol/L) | Adjustment of Basal Insulin Dose (U) |
|---------------------|--------------------------------------|
| ≥180 (≥9.90) | 8 |
| 160–180 (8.80–9.90) | 6 |
| 140–159 (7.70–8.75) | 4 |
| 120–139 (6.60–7.65) | 2 |
| 100–119 (5.50–6.55) | 1 |
| 80–99 (4.40–5.45) | Maintain dose |
| 60–79 (3.30–4.35) | –2 |
| <60 (<3.30) | –4 or more |

Alternatively, the basal insulin dose can be increased by 2 units every 3 days until the FPG is in a target range (70–130 mg/dL).²²⁰ If the FPG is above 180 mg/dL, larger increments can be used (e.g., by 4 units every 3 days). If hypoglycemia occurs or the FPG is less than 70 mg/dL, the dose should be reduced by at least 4 units, or by 10% if the dose is more than 60 units. If there is no improvement in glycemic control after 3 months, Q.R. should be converted to multiple daily insulin injections (see Question 59 and 60).

An alternative for Q.R. is to discontinue all oral agents and begin insulin monotherapy using methods similar to those described for type 1 patients. This option also is rational based on the observation that patients like Q.R. are likely to require insulin therapy because of progressive β -cell failure. Furthermore, insulin monotherapy may be less expensive and easier to assess than combination oral agents plus insulin therapy. Nevertheless, many clinicians use single doses of basal insulin in combination with oral agents as a bridge to eventual insulin monotherapy, especially for those patients unwilling to adhere to multiple daily insulin injections.

Insulin Monotherapy in Patients With Type 2 Diabetes

Insulin Regimens

59. Q.R.'s insulin glargine dose was eventually titrated to 25 units at bedtime. In combination with glimepiride 4 mg/day and metformin 850 mg TID, her fasting glucose levels fell to the 120s and 130s on most occasions; her HbA_{1c} dropped to 7.5%. However, after 1 year, she began to note a gradual rise in glucose concentrations throughout the day. This resulted in a further increase in her bedtime insulin glargine to 40 units (0.57 unit/kg). Currently, her morning glucose concentrations are 120 to 140 mg/dL, and glucose concentrations measured before or after meals range between 170 and 200 mg/dL. A recent HbA_{1c} value was 8.8%. For the past 6 months or so, Q.R. has noted increasing fatigue, bouts of blurred vision, and recurrence of her monilial infections. How should she be managed now?

The next step in managing Q.R.'s diabetes is to institute prandial insulin therapy, which is needed as indicated by her daytime hyperglycemia. Like type 1 patients, those with long-standing type 2 disease may require regular insulin, insulin aspart, glulisine, or lispro before meals to minimize postprandial excursions. Insulin lispro has been shown to decrease postprandial glucose concentrations to a greater extent than regular insulin (30% lower at 1 hour and 53% lower at 2 hours) and was associated with a lower rate of hypoglycemia, particularly between midnight and 6 AM (36%). However, HbA_{1c} levels were not significantly different after 6 months.²⁶⁴ A similar response with insulin aspart and glulisine would be expected.

Because Q.R. is on insulin glargine, the most appropriate next step is to add prandial insulin using a rapid-acting insulin. This requires four injections daily. She needs to be able to handle and be adherent to multiple daily injections. Initiation of basal-bolus insulin regimens are discussed in detail in the type 1 insulin therapy section (see Question 6). Patients with type 2 diabetes may require large insulin total daily doses (>1 units/kg) to reach HbA_{1c} targets below 7%. Because she is taking prandial insulin, glimepiride should be discontinued. Although not technically insulin monotherapy, metformin is often continued to assist in reducing insulin resistance and minimizing weight gain with insulin.

Premixed Insulins

60. Q.R. has difficulty adhering to a basal-bolus insulin regimen. She is currently taking insulin glargine 38 units at nighttime and 7 units of insulin aspart before each meal. What options are available for Q.R.?

Because people with type 2 diabetes retain some pancreatic function, it often is possible to achieve an acceptable level of control with twice-daily doses of intermediate-acting insulin in combination with rapid or short-acting insulins, which are available as premixed insulins. These are referred to as split-mixed insulin regimens. Although convenient, they do limit flexibility in dosing, and thus HbA_{1c} lowering ability without increasing hypoglycemia risk. In the United States, fixed mixtures of NPH and regular insulin in a 70:30 ratio and a 50:50 ratio are available (Table 50-7). Commercial combinations of the rapid-acting insulins plus an intermediate-acting insulin also are available as Humalog Mix 75/25 (a mixture of insulin lispro plus NPL- neutral protamine lispro), Humalog Mix 50/50 (a mixture of insulin lispro plus NPL), and Novolog Mix 70/30 (a mixture of insulin aspart plus aspart protamine suspension). These fixed mixtures are available in prefilled syringes, which can add to their flexibility and convenience for administration.

Q.R. is currently receiving a total daily dose of insulin of 59 U, or 0.84 unit/kg/day. To convert her to a premixed insulin, one could begin with a conservative total daily dose of 0.5 to 0.6 unit/kg/day, split two-thirds in the morning and one-third in the evening. However, many type 2 patients do better splitting the dose 50/50. When starting an insulin-naive type 2 patient on premixed insulin, doses of 5 to 6 units twice daily (administered before breakfast and dinner) are often used, with the doses being titrated prebreakfast (to adjust the dinner dose) and predinner (to adjust the breakfast dose).^{262,265}

If the premixed insulin does not achieve adequate glycemic control, an option is to mix the short- or rapid-acting insulin with NPH in the same syringe. By doing this, each insulin dose can be individually adjusted. A disadvantage to this is the chance for patients to make errors in measuring and mixing insulin, especially the elderly. Alternatively, a prandial dose of insulin (a third injection) can be added at lunch; the breakfast dose of premixed insulin should be decreased as well.²⁵⁴ Q.R. should be instructed to inject the regular/NPH insulin mixture 30 minutes before breakfast and dinner. If she were to use a premixed insulin with either insulin aspart or lispro, she would need to inject the insulin immediately before eating (within 15 minutes of eating).

Q.R. should be started on a rapid-acting premixed insulin twice daily, administered within 15 minutes of eating (for

NPH/R mixture, this would be 30 minutes). A dose of 20 units subcutaneously BID represents a conservative starting dose.

Use of Antidiabetic Agents in Special Situations

Cardiovascular Effects

61. J.A., a 47-year-old man was diagnosed with type 2 diabetes when he developed “very high blood sugars in the 300s” while being treated for a foot infection. He states he has had “borderline diabetes” for longer than 10 years. Other medical problems include hypertension and class III CHF, which is currently well controlled on benazepril (10 mg/day), furosemide (40 mg/day), and digoxin (0.25 mg/day). For the past 3 months, he has adhered to a low-fat diet and exercise program and has managed to lose 10 pounds (J.A. is currently 5 feet 9 inches tall and weighs 190 lbs; BMI, 28.1 kg/m²). FPG concentrations measured over the past 2 months were 160 mg/dL and 145 mg/dL. Liver and renal function tests are within normal limits. How will J.A.’s cardiovascular history affect the choice of oral agents? The package insert for all sulfonylureas includes a special warning on increased risk of cardiovascular mortality. What is the basis of this warning? Are sulfonylureas contraindicated in patients such as J.A. with a history of CVD?

Because J.A. has class III CHF and is under treatment, the use of metformin is not recommended. This is because when metformin-associated cases of lactic acidosis were analyzed, virtually all patients had concurrent conditions that predisposed them to this potentially fatal condition. One of these was clinically significant CHF, a condition that could decrease circulation to the periphery, thereby predisposing the patient to anaerobic metabolism (see Question 62).^{266,267} Although TZDs should not be used in patients with NYHA class III or IV heart failure, practitioners often avoid their use altogether in patients with heart failure because of a concern for CHF exacerbation.

Sulfonylureas are not contraindicated in individuals with a history of CVD. However, the FDA required all manufacturers of sulfonylureas to include in their package inserts a special “black box” warning prescribers of an increased risk for cardiovascular mortality. This was based on an unexpected finding of the University Group Diabetes Program study in 1970. This was a cooperative, prospective study to evaluate the effectiveness of antidiabetic therapy in preventing vascular and other late complications of diabetes in mild type 2 diabetic patients. Unexpectedly, twice as many cardiovascular deaths occurred in the tolbutamide-treated group than in the placebo- and insulin-treated groups.²⁶⁸

After publication of the University Group Diabetes Program results, a great controversy regarding the study’s validity and clinical implications appeared in both the professional and lay press; these are summarized elsewhere.²⁶⁹ Strong evidence that normalization of glucose concentrations may in fact delay long-term complications has diminished any concerns for cardiovascular adverse effects associated with the sulfonylureas. In fact, the UKPDS found no increase in the rates of MI or diabetes-related deaths when participants treated intensively with a sulfonylurea were compared with those treated conventionally.³³

Thus, current evidence indicates that the benefits of sulfonylureas far outweigh their risks in type 2 diabetic patients with CVD. On this basis, their use is not contraindicated.

Lactic Acidosis

62. M.R. is a 76-year-old, 5 feet 11 inch, 150-lb man (BMI, 20.9 kg/m²) with type 2 diabetes who was hospitalized when his son found him in a “near-unconscious state.” According to his son, M.R.’s diabetes had been adequately managed with glipizide 10 mg BID and acarbose 100 mg TID with each meal until approximately 2 months ago, when M.R. was hospitalized for pneumonia. Because M.R. lived alone and adamantly refused to take “shots,” he was discharged on metformin, which was to be added to his other medications. A review of the hospital records revealed a SrCr of 1.4 mg/dL and several random blood glucose concentrations above 190 mg/dL. He also has a history of chronic obstructive pulmonary disease (COPD). His current dose of metformin is 850 mg TID with meals.

On physical examination, the patient was oriented, but appeared acutely ill. Temperature, pulse, and BP were within normal limits. The respiratory rate was 32 breaths/minute. Significant laboratory values included the following: Na, 140 mEq/L (normal, 135–145); K, 6.2 mEq/L (normal, 3.5–5); Cl, 103 mEq/L (normal, 95–105); HCO₃, 5 mEq/L (normal, 22–28); arterial pH, 6.8 (normal, 7.36–7.42); SrCr 3.2 mg/dL (normal, 0.7–1.4); blood glucose, 130 mg/dL (normal, 70–140); serum acetones, negative; serum lactate, 12.3 mmol/L (normal, 0.7–2.0); and serum pyruvate, 0.49 mmol/L (normal, 0.05–0.08).

A diagnosis of lactic acidosis was made. What signs and symptoms are consistent with this diagnosis? What is the relation between metformin and lactic acidosis, and what are the predisposing factors?

The most notorious side effect associated with metformin—although extremely rare—is lactic acidosis. Lactic acidosis is a metabolic acidosis characterized by a significant reduction in the arterial pH and an accumulation of serum lactate, a product of anaerobic metabolism. It is a condition that is highly lethal (50% mortality) and resistant to therapy. Lactic acidosis occurs when there is an increased production of or decreased utilization of lactate. Decreased utilization of lactate occurs when tissues are unable to oxidize lactate to pyruvate (these two substances are normally present in the serum in a ratio of 10:1). Metformin might predispose a patient to lactic acidosis by augmenting anaerobic metabolism or by decreasing the kidney’s ability to handle an acid load. Other factors that might contribute to lactic acidosis include severe cardiac or pulmonary disease (anoxia, increased lactate production), septic shock, renal dysfunction (retention of metformin and lactate), and excessive alcohol intake (increased lactate production and decreased utilization).

Signs and symptoms generally are acute in onset and commonly include nausea, vomiting, diarrhea, and hyperventilation. Hypovolemia, hypotension, confusion, and coma also may occur; death is usually secondary to cardiovascular collapse.

As illustrated by M.R., typical laboratory findings include a low serum bicarbonate and PCO₂, a low arterial pH, an elevated potassium, a normal or low serum chloride, elevated lactate and pyruvate levels, an increased L:P ratio, and an anion gap of 30 mEq/L or higher.

Treatment is empiric and includes correction of any underlying cause of anoxia and elimination of factors predisposing to lactic acidosis, large doses of sodium bicarbonate with frequent arterial pH determinations, hemodialysis, and glucose plus

insulin infusion. The latter are administered in an attempt to improve the metabolic utilization of lactate and pyruvate.^{270,271}

Although metformin rarely is associated with lactic acidosis, the manufacturer and the FDA have taken extreme measures to prevent its improper use because another biguanide, phenformin, which induced this life-threatening condition was removed from the market in 1977.²⁵⁹ The estimated rate of phenformin-induced lactic acidosis was 0.25 to 4 cases per 1,000 users versus 5 to 9 cases per 100,000 users for metformin.^{266,272,273} A group of clinicians from the FDA summarized 47 confirmed cases of metformin-related lactic acidosis (lactate levels ≥ 5 mmol/L) that had been reported to the FDA between May 1995 and June 1996.²⁷³ Unfortunately, the condition continues to be resistant to treatment; the mortality rate was 43%. Importantly, 43 of the 47 cases (91%) had concurrent conditions that predisposed them to lactic acidosis. These included cardiac disease (64%), decreased renal function (28%), and chronic pulmonary disease (6%). Several patients (17%) were over the age of 80 years and may have had decreased renal function despite normal SrCr concentrations. Interestingly, 38% of the patients had CHF, and those who died were more likely to be under treatment with digoxin and furosemide. The mean daily dose of metformin was well within the therapeutic range and was not higher in the group that succumbed ($1,259 \pm 648$ mg in the group that died and $1,349 \pm 598$ mg in the group that survived).

As a consequence of this analysis, the manufacturer has changed its labeling to warn against the use of metformin in individuals who are being treated for CHF. Furthermore, metformin should not be initiated in patients over 80 years old unless a GFR or CrCl evaluation confirms normal renal function. The drug should not be used when patients are septic.¹⁵⁸

Unfortunately, studies assessing the appropriate use of metformin (according to the manufacturer's recommendations) reveal that metformin is frequently used in patients in whom it is contraindicated.²⁷⁴⁻²⁷⁷ A retrospective cohort study of 1,847 patients found that 24.5% of patients who received metformin had conditions for which it was contraindicated (21.0% had CHF and were receiving loop diuretics, and 4.8% had renal impairment).²⁷⁴ Medicare patients hospitalized with the primary diagnosis of heart failure and concomitant diabetes were assessed for metformin and TZD use, both of which are contraindicated in this situation.²⁷⁷ Between 1998 and 1999, 7.1% and 7.2% of patients were treated with metformin and a TZD, respectively, at discharge; these numbers increased between 2000 and 2001 to 11.2% and 16.1%. In patients with renal dysfunction (SrCr ≥ 1.5 mg/dL), metformin was used in 9.3% and 15.2% of patients in 1998 through 1999 and 2000 through 2001, respectively. See question 61 for discussion of TZDs and heart failure. Clinicians need to carefully assess patients for contraindications before initiating antidiabetic agents.

M.R.'s pulmonary disease may have caused an anoxic state, which predisposed him to lactic acidosis. Furthermore, even though his SrCr was below 1.5 mg/dL, this value may not have reflected normal renal function in this elderly gentleman.²⁷⁸ Finally, dehydration caused by extensive vomiting and diarrhea has caused prerenal failure, which is likely contributing to the acidosis.

Clinical Note: M.R. recovered after aggressive treatment with fluids and sodium bicarbonate. Metformin was discontinued and he was managed with insulin.

Hypoglycemia

63. C.A., a 68-year-old woman who has had a 20-year history of type 2 diabetes and a 5-year history of mild renal failure (SrCr, 1.5 mg/dL; BUN, 30 mg/dL), is admitted to the hospital in a coma. According to her daughter, C.A.'s diabetes has been well controlled over the past several months with glyburide 10 mg BID. She took her last dose approximately 5 hours before admission. Three days before admission C.A. developed anorexia, nausea, and vomiting in association with the flu and became progressively lethargic. Laboratory results on admission are as follows: plasma glucose, 20 mg/dL (normal, 70–140); SrCr, 3.0 mg/dL (normal, 0.6–1.2); and BUN, 80 mg/dL (normal, 7–20). What is C.A.'s diagnosis? Were there any predisposing factors?

[SI units: SrCr, 132.6 and 265.2 μ mol/L; BUN, 10.7 and 28.6 mmol/L; plasma glucose, 1.1 mmol/L]

C.A. has developed a case of severe hypoglycemia secondary to glyburide. Hypoglycemia is the most common (incidence, 2.4 per 100 patients per year) and potentially severe (4%–7% mortality) adverse effect of the sulfonylureas. The incidence and severity of this effect increase with the duration of action and potency of the agents. Thus, the incidence of severe, prolonged hypoglycemia secondary to chlorpropamide and glyburide is approximately two times higher than that for glipizide and approximately five times higher than that for tolbutamide.^{170,279} The sulfonylureas account for almost all cases of drug-induced hypoglycemia in individuals older than age 60.

Most sulfonylurea-induced hypoglycemia occurs in patients who are predisposed to hypoglycemia in some way, and C.A. is no exception. She is an elderly woman with renal impairment who was on relatively high doses of an agent, a portion of which is excreted unchanged in the urine. Even in the face of decreased carbohydrate intake (anorexia and vomiting), she continued to take her usual dose of glyburide. Even though the stress of illness most often raises glucose levels, the decreased intake and vomiting probably led to dehydration and further compromised her renal function.

Because glyburide and chlorpropamide have a long duration of action, hypoglycemia induced by these agents may last for several hours, or days in the case of chlorpropamide. Therefore, patients such as C.A. must be hospitalized and treated with continuous glucose infusions until oral intake resumes. Otherwise, severe hypoglycemia may recur.

Renal Dysfunction

64. Glyburide was withheld and C.A.'s kidney function stabilized with fluid replacement (estimated GFR, 37 mL/min/1.73 m²). Because she lives alone, has impaired eyesight secondary to cataracts, and has severe arthritis, insulin treatment is impractical. Oral agents are to be continued. Which agents should be avoided? Which agents could be used?

Once C.A.'s plasma glucose concentrations and renal function have stabilized, reinstatement of antidiabetic therapy must be considered. Sulfonylurea compounds that are metabolized to active products that depend on the kidney for elimination (e.g., acetohexamide, chlorpropamide glyburide, and tolazamide) should be avoided in the elderly and in patients with decreased renal function. Sulfonylureas that are completely

metabolized to inactive or weakly active products may be used (i.e., glipizide, glimeperide, or tolbutamide). Although glyburide is unlikely to accumulate in patients with a CrCl₃₀ above 30 mL/min, it should not be used in C.A. because it caused a severe hypoglycemic reaction. Furthermore, even patients who are not taking sulfonylureas are more likely to experience hypoglycemic reactions if they have renal insufficiency; therefore, any oral hypoglycemic agent should be initiated at a low dose and titrated slowly (Table 50-28). C.A. should be instructed to eat regularly, because skipped meals may result in recurrent hypoglycemia.^{174,280}

Metformin is contraindicated in C.A. because her renal function is abnormal (see Question 62). Decreased renal function can result in accumulation of metformin, which can, in turn, predispose her to lactic acidosis.

The TZDs are primarily metabolized by the liver and are not contraindicated in patients with mild renal failure. The use of rosiglitazone or pioglitazone, beginning with low doses, could be considered as can acarbose, which is poorly absorbed from the GI tract. Sitagliptin can be used, but the dose is reduced in renal dysfunction. Exenatide can be used in patients with CrCl₃₀ above 30 mL/minute and the dose does not need to be adjusted. None of these agents cause hypoglycemia when used as monotherapy.

Hepatic Dysfunction

65. B.R., a 60-year-old man with cirrhosis of the liver, is found to have type 2 diabetes. Glipizide 10 mg/day is initiated. How will B.R.'s liver function affect the disposition of glipizide and his response to this agent?

Because hepatic metabolism is the primary route of elimination for most sulfonylureas, including glipizide, patients with hepatic disease should be expected to have an exaggerated response to those drugs metabolized to less active products.

Tolbutamide, a first-generation sulfonylurea, has been studied most extensively with respect to liver disease. In a double-blind, placebo-controlled trial of 50 cirrhotic patients, hypoglycemia was a complication in 20% of the tolbutamide-treated group.²⁸¹ Tolbutamide's elimination half-life in subjects with cirrhosis has been reported to be increased or unaltered in different studies.²⁸² A complicating factor is that alcohol can induce hepatic enzymes, markedly increasing tolbutamide metabolism in alcoholic patients with cirrhosis.

Liver disease can be a separate predisposing factor for severe, prolonged hypoglycemia because glycogenolysis and gluconeogenesis are impaired; thus, sulfonylureas are relatively contraindicated for cirrhotic patients. If they are used, shorter acting agents are preferred and small initial doses should be used. For B.R., glipizide could be initiated at a dose no greater than 2.5 mg/day and increased if needed by 2.5-mg increments at no less than weekly intervals. Other options are low doses of repaglinide (0.5 mg) or nateglinide (60 mg) with meals.

Diabetes in the Elderly

Clinical Presentation

66. J.M. is a frail, 82-year-old, unresponsive man, who is brought to the emergency department. According to J.M.'s family, he has become increasingly confused, dizzy, and lethargic, with a

recent weight loss of 10 lb. J.M. lives by himself and has been generally healthy with the exception of mild to moderate COPD and arthritis. Fasting serum chemistry reveals the following: Na, 128 mEq/L (normal, 135–145); glucose, 798 mg/dL (normal, 70–140); and serum osmolality, 374 mOsm/L (normal, 280–295 mOsm/kg H₂O). His serum is negative for ketones. On physical examination, J.M. has poor skin turgor, dry mucous membranes, and is responsive only to deep pain. His BP is 90/60 mmHg with a pulse of 96 beats/minute. He has rales at the left lower base of his lung, and a chest radiograph confirms pneumonia. Despite aggressive fluid replacement, J.M.'s blood glucose remains consistently above 250 mg/dL and his HbA_{1c} is 11% (normal, ≤6%). J.M. presents with very high glucose concentrations, but has no history of diabetes mellitus. What special factors contribute to a late and atypical presentation of diabetes in the elderly?

[SI units: Na, 128 mmol/L (normal, 135–145); glucose, 44.3 and >13.9 mmol/L (normal, 3.9–6.1); serum osmolality, 374 mmol/kg; HbA_{1c}, 0.11]

Diabetes in the elderly commonly is underdiagnosed and undertreated because it often presents atypically.^{283–285} Classic symptoms associated with diabetes mellitus may be masked by other illnesses, may be entirely absent, or may be explained away by the normal aging process. For example, polyuria is minimized by higher renal thresholds for glucose or may be confounded by urinary incontinence or “prostate problems.” Thirst is commonly blunted in elderly persons, increasing their risk of dehydration and electrolyte imbalance. Hunger can be altered by medications or depression. Fatigue often is discounted as “part of getting old,” and weight loss, although sometimes profound, may be so gradual that it goes unnoticed for months to years. (See Table 50-29 for a comparison of presenting symptoms for diabetes mellitus in elderly patients compared with younger patients.)

Hyperosmolar Hyperglycemic State

67. J.M. is diagnosed with hyperosmolar hyperglycemic state (HHS). Why are the elderly predisposed to this condition and what signs and symptoms are consistent with this diagnosis?

HHS is a condition characterized by extremely elevated plasma glucose concentrations (>600 mg/mL) and high serum osmolality (>320 mOsm/L) without ketoacidosis. Because patients with type 2 diabetes have some residual insulin production, they are usually protected against excessive lipolysis and ketone production. Measurements of serum ketones and blood pH differentiate this condition from DKA (see Question 39). The condition occurs when urinary fluid and electrolyte losses

Table 50-29 Presentation of Diabetes Mellitus in Elderly Patients Compared With Younger Patients

| Metabolic Abnormality | Symptoms in | |
|-----------------------|-----------------------------|----------------------------------|
| | Young Patients | Symptoms in Elderly Patients |
| Serum osmolality | Polydipsia | Dehydration, confusion, delirium |
| Glycosuria | Polyuria | Incontinence |
| Catabolic state | Polyphagia | Weight loss, anorexia |
| | owing to insulin deficiency | |

secondary to glucosuria are inadequately replaced by oral fluid intake.^{114,286}

HHS primarily occurs in the elderly because several factors predispose this population to hypodipsia. These include an inability to recognize thirst,²⁸⁷ an inability to ask for fluids (e.g., dementia, sedation, intubation), and an inability to get fluids on demand (e.g., physical disabilities or restraints). Infections or other acute illnesses (e.g., MI, GI bleeding, pancreatitis) that exacerbate diabetes can interact with the hyperosmolar diuresis and hypodipsia to produce severe dehydration and hyperglycemia. Drugs that increase plasma glucose concentrations (e.g., glucocorticoids), increase diuresis, or decrease mentation also can contribute to this unfortunate situation.

J.M. presents with several symptoms of HHS dehydration, including osmolality greater than 320 mOsm, plasma glucose greater than 600 mg/dL, decreased skin turgor, hypotension, and the absence of serum ketones. His pneumonia was probably the precipitating factor. The mortality rate for this disorder is 3% in patients younger than 50 years of age; it increases to 30% for those older than 50.²⁸⁸ Treatment involves rapid IV hydration. Fluid replacement is provided in the same manner as with DKA. See Question 40 and Table 50-25 for details.¹¹⁴ Insulin infusion is given simultaneously. The initiation and rate adjustments are the same as with DKA, except that the plasma glucose cutoff to reduce the insulin infusion rate is 300 mg/dL (not 200 mg/dL as with DKA; see Question 41 and Table 50-25 for details). Rehydration and insulin administration corrected J.M.'s metabolic imbalance, allowing his diabetes control to be addressed.

Goals of Therapy

68. What are the goals of therapy for J.M.?

It is widely recognized that strict glycemic control is associated with an increased incidence of hypoglycemia.²⁹ In the elderly patient with age-related autonomic dysfunction, hypoglycemia may present without the usual premonitory symptoms and can result in severe adverse effects such as angina, seizures, stroke, or MI. Therefore, the general tendency when treating elderly diabetic patients is to aim for slightly more liberal outcome objectives.

The basic principles of management are to set less aggressive glycemic goals. Thus, a fasting blood glucose target of 100 and 140 mg/dL with postprandial glucose values below 180 mg/dL and an HbA_{1c} goal of 8%, while avoiding hypoglycemia, is appropriate in this frail patient.²⁸⁹

Diet and Exercise

69. How should diet and exercise recommendations be modified for elderly diabetic patients such as J.M.?

NUTRITION

Because most elderly patients have type 2 diabetes, nutrition and exercise programs are the initial steps in therapy. In 2001, the prevalence of obesity in the United States was 20.9%.²⁹⁰ Elderly persons between the ages of 60 and 69 had a 25.3% prevalence of obesity and people at 70 and older had a prevalence of 17.1%. Older people with diabetes, especially those in a long-term care facility, have a tendency to be underweight rather than overweight.⁴⁷ Therefore, caution should be used when considering a weight loss diet, because this could

cause malnutrition or dehydration. For obese individuals, a modest weight loss of 5% to 10% may be indicated. However, an involuntary weight gain or loss of more than 10 pounds or 10% of body weight in <6 months should be carefully assessed.⁴⁷

Several factors can adversely affect proper nutrition in the elderly. They include an impaired ability to shop for and prepare food, limited finances, an age-related decline in taste perceptions, and coexisting illnesses. Ill-fitting dentures, difficulty in chewing and swallowing, and lack of companionship during meals also can contribute to malnutrition as well.

High-fiber diets may lower blood glucose and improve plasma lipids. However, high-fiber diets in frail, elderly patients, particularly those who are bedridden, should be used cautiously because they can be constipating and result in fecal impaction. Ambulatory patients, on the other hand, generally benefit from increased dietary fiber. Because many elderly patients are malnourished, a daily multivitamin preparation containing the recommended daily allowance of each vitamin should be prescribed.⁴⁷

EXERCISE

Exercise in the elderly provides all the benefits derived by younger individuals. It increases well-being and glucose stability, and may decrease a propensity to fall. Exercise also improves BP, the lipid profile, hypercoagulability, and bone density. Physical activity is necessary to minimize any lean body mass loss that can occur with caloric restriction. For patients with arthritis, aquatic exercise may be substituted. Before such an exercise program is initiated, careful evaluation is mandatory to avoid myocardial ischemia or the acceleration of retinopathy.¹³²

Selecting an Antidiabetic Agent in the Elderly

70. Why is it important to institute drug therapy to treat J.M.'s diabetes? What considerations should be made in selecting an initial treatment regimen?

As in all patients with diabetes mellitus, poor glycemic control increases the risk of long-term complications. Although it is tempting to minimize the importance of glycemic control because these complications take so long to develop, patients such as J.M. may have had unrecognized hyperglycemia for many years before clinical diagnosis. Thus, many have already begun to develop complications. Furthermore, as life expectancy increases one can expect that these individuals will live long enough to experience morbidity related to diabetes if they are not treated. Therefore, pharmacologic treatment should be strongly considered in J.M. and most elderly patients whether or not they are symptomatic.²⁹¹

The general approach to treating an elderly patient with type 2 diabetes is basically the same as described in questions 46, 50, and 51. The initial choice of an antidiabetic agent should be based on the severity of hyperglycemia. Other considerations include body weight, coexisting diseases, and cost of the agent. Patients with IFG (FPG >100, but <126 mg/dL) should be treated with diet and exercise tailored to their individual capabilities. For patients with diabetes (FPG ≥126 mg/dL or 2-hour postprandial blood glucose >200 mg/dL), acarbose, a short-acting insulin secretagogue (e.g., nateglinide or repaglinide), a TZD, and sitagliptin are all appropriate

options. Sulfonylurea-induced hypoglycemia is a concern in these patients. However, if inability to adhere to the multiple-daily regimen is problematic, a short-acting sulfonylurea is an appropriate alternative agent. In J.M.'s case, metformin should probably be avoided because he has COPD. Also, he is older than age 80 and requires an assessment of his GFR. Use of CrCl often overestimates renal function in elderly individuals owing to their reduced muscle mass. There is a strong relationship between the pharmacokinetics of metformin and both kidney function and age. In healthy elderly patients, renal clearance of metformin was 35% to 40% lower than respective values for healthy young individuals.¹⁶⁰ Finally, the favorable effect metformin has on weight is irrelevant in J.M. Thus, although the efficacy of metformin is comparable to that of sulfonylureas, it is not the agent of first choice for elderly patients such as J.M.²⁸⁹

Patients with an FPG above 300 mg/dL and no overt stress should be considered insulin deficient and started on insulin therapy.

Selecting a Sulfonylurea

71. Because his FPG concentrations remain 200 to 250 mg/dL (normal, 70–100), the decision is made to start J.M. on a sulfonylurea. What factors should be considered in selecting a sulfonylurea for J.M.?

There are several age-associated problems with the use of oral hypoglycemic agents. Hepatic blood flow and oxidative metabolism are decreased with aging, resulting in prolonged half-lives of hepatically metabolized drugs. Serum albumin is reduced in the elderly, and this affects the highly protein-bound first-generation sulfonylureas, resulting in increased serum levels of free drug.²⁹² Response to hypoglycemic counter-regulatory hormones is diminished in the elderly, predisposing them to prolonged hypoglycemia. The decreased renal function and mass that occurs with aging decreases the clearance and increases the half-lives of oral agents excreted renally, specifically acetohexamide, chlorpropamide, and glyburide. Chlorpropamide should not be used in the elderly population owing to its long half-life (≥ 35 hours) and high incidence of hypoglycemia and hyponatremia.²⁹² Of the second-generation agents, glipizide is preferred over glyburide in frail, elderly patients like J.M. This is because its duration of action is shorter than that of glyburide and it is metabolized to inactive products. Consequently, it is 50% less likely to cause severe and prolonged hypoglycemia in the elderly population.²⁹³ This is a concern because several factors predispose the elderly to drug-induced hypoglycemia. These include anorexia, irregular or inadequate food intake, and other factors affecting nutrition (see Question 69). Tolbutamide (which is converted to inactive metabolites), glimepiride (which has been studied in renal insufficiency), and repaglinide²⁹⁴ and nateglinide (which are very short-acting) are also appropriate options.

Maturity-Onset Diabetes of the Young

72. B.L. is a 34-year-old, slender (5 feet 6 inches, 120 lbs, BMI 19.4 kg/m²) woman who developed diabetes at the age of 23. Until recently, her diabetes was very well controlled (HbA_{1c}, 6%–7%) on glipizide 5 mg/day. Approximately 3 months ago, her physician

discontinued glipizide and began treating her with very low doses of insulin (7 units of 70/30 insulin twice daily) when she announced her intention to become pregnant. However, she is experiencing frequent hypoglycemic reactions and would like to switch back to glipizide. B.L. has no other medical problems, and her physical examination is within normal limits. B.L.'s mother (onset at age 32) and younger sister (onset at age 25) also have diabetes and are well controlled on oral agents. Assess B.L.'s diabetes. How should she be managed?

It is quite likely that B.L. has a relatively rare form of diabetes often referred to as *maturity-onset diabetes of the young* (MODY).²⁹⁵ Typically, the patient is normal weight, has a strong family history of diabetes, and is diagnosed during his or her young adult years.²⁹⁶ Unlike obese patients with type 2 diabetes, tissue sensitivity to insulin action is normal, but insulin secretion in response to glucose is defective. Consequently, patients such as B.L. respond to oral sulfonylureas and low doses of insulin. The physician's decision to treat B.L. with insulin is rational because she intends to conceive and oral sulfonylureas cross the placental barrier; however, it seems as though her dose and regimen will have to be adjusted.

Complications

Note to the reader: A thorough discussion addressing the clinical presentation of the complications of diabetes is beyond the scope of this chapter. Thus, the following cases and responses are presented to provide an introduction to some of the most common complications and a general approach to their treatment. Also see Chapters 12, 13, and 31.

Hypertension

73. L.S. is a 46-year-old, obese man with an 8-year history of type 2 diabetes. His current problems include a BP of 155/103 mmHg (documented on two occasions), blurry vision, and sexual impotence, which he now admits has troubled him for the last few years. Physical examination reveals decreased pedal pulses bilaterally, loss of sensation to monofilament testing, and evidence of an amputated toe on the right foot. His laboratory values are as follows: FPG, 170 mg/dL (normal, 70–100); HbA_{1c}, 7.8% (normal, 4%–6%); fasting cholesterol, 240 mg/dL (normal, <200); and triglycerides, 160 mg/dL (normal, <150). L.S. has normal electrolyte values and microalbuminuria (180 mg/g creatinine). His only medication is metformin 500 mg PO BID. Describe the pathogenesis of hypertension in patients such as L.S. Why is it so important to treat his hypertension?

[SI units: FPG, 9.4 mmol/L; fasting cholesterol, 13.3 mmol/L; triglycerides, 8.9 mmol/L]

More than 70% of adults with diabetes have a BP greater than 130/80 mmHg or use medication to treat diagnosed hypertension.¹ Patients with type 1 diabetes are usually normotensive in the absence of nephropathy. Hypertension in type 1 diabetes is usually of renal parenchymal origin and occurs 1 to 2 years after the onset of nephropathy as indicated by microalbuminuria (see Question 75).²⁹⁷ The relationship between type 2 diabetes and hypertension is more complex and not as closely correlated to nephropathy. In type 2 diabetes, hypertension is often part of the metabolic syndrome of

insulin resistance and may be present for years before diabetes is actually detectable.

Patients with diabetes and hypertension have an increased risk for developing microvascular complications such as retinopathy and nephropathy. They are also at a twofold increased risk of developing CVD.²⁹⁷ A 5 mmHg reduction in mean diastolic BP can produce a 37% reduction in microvascular complications, and a 10 mmHg reduction in mean systolic BP reduces the risk of MI by 11% and death related to diabetes by 15%.^{215,216,297} Aggressive management is therefore essential for patients with both diabetes and hypertension, such as L.S. Treatment includes weight management, exercise, sodium restriction, smoking cessation, and antihypertensive therapy. Many patients require two or three medications to achieve the target BP goal of <130/80 mmHg.²²

74. What must be considered in selecting an antihypertensive agent for L.S.?

Numerous studies have documented the effectiveness of angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin-receptor blockers (ARBs) in delaying the development and progression of nephropathy. All patients with diabetes and hypertension should be treated with a regimen that includes either an ACEI or ARB.²⁹⁷ If one class is not tolerated, patients should be switched to the other. For patients failing to reach target BP goals on an ACEI or ARB alone, a diuretic should be added. Second-line add-on agents include β -blockers and calcium channel blockers. Other classes of agents are considered for use as add-on therapy after patients have failed combination therapy with the five classes listed. The management of hypertension in people with diabetes is discussed further in Chapter 13.

Nephropathy

75. What is the significance of the presence of albumin in L.S.'s urine? How should it be managed?

Diabetic nephropathy, characterized by nephrotic syndrome and azotemia, accounts for 35% of all patients with ESRD. It is a major cause of death in patients with type 1 diabetes and is an increasing source of morbidity in type 2 diabetic individuals.²⁹⁸ Thickening of the glomerular capillary basement membranes is the hallmark of diabetic nephropathy.²⁹⁹ Diffuse deposition of basement membrane-like material expands the mesangium. This process narrows the capillary lumina, impedes blood flow, and thereby reduces the filtering surface area in the glomerulus. Hyperglycemia causes intraglomerular hypertension and renal hyperfiltration. Hyperfiltration is followed by microalbuminuria with minimal glomerulosclerosis, which still is potentially reversible. If left untreated, overt proteinuria (macroalbuminuria) occurs and the patient usually progresses to nephrotic syndrome. Progression of diabetic renal disease can be accelerated in the presence of hypertension, proteinuria, and diabetic retinopathy. Lipid abnormalities also may contribute to the progression of glomerulosclerosis. Management includes early detection through screening for microalbuminuria; tight glucose control; ACEIs and ARBs for patients with microalbuminuria (to slow progression); aggressive management of hypertension, which can accelerate deterioration of renal function; aggressive management of dyslipidemia; and smoking

cessation. A thorough discussion on the management of diabetic nephropathy and ESRD is discussed in Chapter 31.

SCREENING FOR AND CONFIRMATION OF MICROALBUMINURIA

The preferred method of screening for microalbuminuria is measurement of the albumin-to-creatinine ratio in a random spot collection (preferably the first-void or morning sample). Microalbuminuria is defined as a urinary albumin excretion 30 mcg or more albumin/mg creatinine (or mg albumin/g creatinine) during a spot collection.²⁹⁸ Because of day-to-day variability in albumin excretion, two of three urine samples collected in a 3- to 6-month period need to be abnormal before a designation is made. Annual screening should be performed in patients with type 1 diabetes with duration of at least 5 years and in patients with type 2 diabetes from the time of diagnosis. More frequent screening is indicated if hypertension, any increase in SrCr, and/or retinopathy develop. Urine albumin concentrations can be falsely elevated by exercise within 24 hours, fever, infection, uncontrolled diabetes, uncontrolled hypertension, and CHF. Screening should therefore be delayed if a patient has one of these conditions.

Based on established criteria, L.S. has microalbuminuria (180 mg albumin/g creatinine). Management includes tight blood glucose control, lowering the BP, and correction of his dyslipidemia with medications. An ACEI or ARB to treat the microalbuminuria (L.S. should already be receiving one of these agents to treat his hypertension as noted). After initiation of therapy, continued monitoring of the microalbuminuria is recommended to assess the response to therapy and progression of disease.²² Serum potassium and creatinine levels should be followed as well. A thorough discussion on the management of diabetic nephropathy and ESRD is discussed in Chapter 31.

Cardiovascular Disease

76. L.S. is treated with lisinopril 20 mg/day, which controls his BP and improves his microalbuminuria. His dose of metformin is titrated to 1,000 mg twice daily. Recent laboratory values include an FPG of 130 mg/dL (normal, 70–100), HbA_{1c} of 6.0% (normal, 4%–6%), a triglyceride level of 170 mg/dL (normal, <150 mg/dL), total cholesterol of 204 mg/dL (normal, <200 mg/dL), LDL cholesterol 135 mg/dL (normal depends), and HDL cholesterol of 35 mg/dL (normal, >40 mg/dL). How does the risk of heart disease for patients such as L.S. compare with persons without diabetes? What is the pathogenesis of CHD in persons with diabetes?

[SI units: FPG, 7.2 mmol/L; HbA_{1c}, 0.07; triglycerides, 2.77 mmol/L; total cholesterol, 11.3 mmol/L; HDL, 0.91 mmol/L]

CHD is the leading cause of premature death in the type 2 population and accounts for 50% of the deaths in people with diabetes. Renal complications of type 1 diabetes were previously the principal causes of death; however, with the advent of dialysis and renal transplantation, cardiovascular complications have become the principal cause of morbidity and mortality. Relative to nondiabetic individuals, those with diabetes are two to three times more likely to develop CHD, and their risk of death after an MI also is two to three times higher than their nondiabetic counterparts. Women with diabetes, regardless of their age or menopausal status, have equal risk for CHD to that of nondiabetic men. These sobering figures point to the

importance of minimizing or eliminating all other preventable risk factors for CVD in patients with diabetes (i.e., tobacco use, hypertension, hypercholesterolemia, obesity) through the prescription of exercise, diet, and appropriate medications.³⁰⁰

PATHOGENESIS

The pathogenesis of CVD in people with diabetes is complex. The metabolic syndrome with its attendant cardiovascular risk factors, dyslipidemia, inflammation, and hemostatic abnormalities are only some of the mechanisms under study.^{17,301}

The most common lipid abnormality in type 2 diabetes is hypertriglyceridemia (>150 mg/dL) with low levels of HDL cholesterol (<40 mg/dL in men or <50 mg/dL in women), similar to the lipid profile seen in L.S.³⁰² Poor control of type 1 diabetes also is associated with elevated LDL cholesterol levels as well as hypertriglyceridemia.³⁰³ All of these lipid abnormalities contribute to the risk for CVD.

In patients with diabetes, clinical trials (primarily with statins) have demonstrated primary and secondary CHD prevention. Although the evidence for the reduction in “hard” CVD outcomes (e.g., CHD death and nonfatal MI) is stronger in diabetic patients who have a high baseline CVD risk (i.e., known CVD and/or very high LDL-C levels), the overall benefits of statins in patients with diabetes at moderate or high risk for CVD is convincing.²² Readers are referred to the ADA Standards of Medical Care for more detailed information on the CVD clinical trials in patients with diabetes.

Dyslipidemia

77. Should L.S. be treated with drug therapy for his dyslipidemia?

Adults with diabetes should be screened annually for serum lipoprotein levels, including triglycerides, total cholesterol, LDL cholesterol, and HDL cholesterol. A total cholesterol level of less than 200 mg/dL, triglyceride level <150 mg/dL, and LDL cholesterol levels maintained at 100 mg/dL or lower are acceptable. In almost all instances, a statin should be used in patients with diabetes. The ADA now recommends statin therapy in patients over the age of 40 who have one or more other CVD risk factors regardless of baseline LDL levels.²² For those patients with diabetes and overt CVD, a statin is overwhelmingly indicated.

Diet and exercise are cornerstones in the management of dyslipidemia in patients such as L.S. Weight loss is associated with improvements in insulin sensitivity and glucose control, as well as a reduction in triglycerides, total cholesterol, and LDL cholesterol. Physical activity enhances weight loss and increases HDL cholesterol levels. Thus, L.S.’s diet and exercise habits should be reassessed and instruction in both reinforced as appropriate. Blood glucose concentrations should be optimally controlled with diet, exercise, and oral agents or insulin when indicated. However, the attainment of diabetes control in patients with type 2 diabetes does not necessarily correct lipid abnormalities, as seen in L.S. Because insulin resistance may be the underlying cause of elevated lipids in these patients, efforts should be devoted to reversing insulin resistance as well. Because L.S.’s FPG and HbA_{1c} values indicate that he has achieved diabetes control, a lipid-lowering agent (i.e., a statin) is warranted.

STATIN THERAPY

Simvastatin, pravastatin, lovastatin, fluvastatin, atorvastatin, and rosuvastatin inhibit HMG-CoA reductase, a key regulatory enzyme for cholesterol biosynthesis. As a result, hepatic cholesterol synthesis declines, surface LDL particle receptors increase, and LDL cholesterol clearance increases. The statins’ lipid effects are dose dependent. Rosuvastatin and higher doses of atorvastatin and simvastatin can have a substantial effect on triglycerides, which is helpful in patients with elevations in both LDL cholesterol and triglycerides. They raise HDL cholesterol slightly.

OTHER LIPID-LOWERING MEDICATIONS

Bile acid sequestrants primarily lower total and LDL cholesterol levels with little effect on HDL cholesterol. These agents can elevate triglyceride levels and may be problematic as monotherapy for patients such as L.S. with mild to moderate hypertriglyceridemia. Low doses of bile acid sequestrants may be useful as adjunctive therapy when combined with a fibric acid derivative or an HMG-CoA reductase inhibitor. Of note, colesevelam (Welchol) received FDA approval in January 2008 to be used as adjunctive therapy (added on to metformin, sulfonylurea, or insulin) to improve glycemic control in type 2 diabetes.

Gemfibrozil and fenofibrate are the fibric acid derivatives currently available in the United States. These drugs activate lipoprotein lipase, which reduces triglycerides and increases HDL cholesterol. They exert a variable but generally modest LDL cholesterol-lowering effect. Gemfibrozil or fenofibrate may be useful in patients like L.S. whose dyslipidemia is predominantly characterized by hypertriglyceridemia. Gemfibrozil should not be used in combination with repaglinide or the TZDs because it increases their effects and potential for toxicity.

Niacin effectively lowers LDL cholesterol. However, it has a dose-dependent effect in increasing plasma glucose. Although precise mechanisms by which this occurs are unknown, it may be due to accentuation of insulin resistance. Therefore, niacin’s use as first-line therapy for dyslipidemia in people with diabetes is not recommended.³⁰² Although two studies have demonstrated a minimal glycemic effect (increases in blood glucose by 9 mg/dL and HbA_{1c} 0.3%), practitioners still reserve its use as third-line therapy when combination therapy is indicated.^{304,305}

Because L.S.’s LDL cholesterol is 135 mg/dL and his goal is less than 100 mg/dL (<70 mg/dL if he had overt CVD), he should be started on a statin. The choice of statin is primarily based on formulary coverage; however, potential for drug–drug interactions with each agent should be assessed before starting (see Chapter 12, and reviews on this subject).³⁰²

Retinopathy

78. L.S. is referred to the ophthalmologist for his persistent complaints of vision problems despite improvement in his glycemic control. He is diagnosed with mild background retinopathy. Should L.S. be concerned?

Ocular disorders related to diabetes are the leading cause of new cases of legal blindness in Americans. Patients with diabetes may experience blurred vision associated with poor

glycemic control, but retinopathy, senile-type cataracts, and glaucoma are the complications that threaten sight. Diabetic retinopathy appears as early as 3 years after diagnosis and is evident in 90% of type 1 diabetic individuals after 15 years. Comparable figures for patients with type 2 diabetes treated with insulin and type 2 patients treated with diet and oral agents are 80% and 55%, respectively. Proliferative retinopathy is less prevalent, but nevertheless is present in 30% of people with type 1 diabetes and in 10% to 15% of insulin-treated patients with type 2 diabetes who have had diabetes for 15 years or longer.^{8,41,306,307}

Patients with type 1 diabetes should have a dilated retinal examination within 3 to 5 years of diagnosis; evaluation is not necessary before 10 years of age. Patients with type 2 diabetes should have a comprehensive eye examination soon after diagnosis. The ADA recommends annual comprehensive eye examinations.^{22,307} Less frequent eye examinations (every 2–3 years) can be considered in patients with normal examinations based on the advice of an ophthalmologist.³⁰⁷

Current theories addressing the possible causes of this complication have been thoroughly reviewed.³⁰⁶ Microvascular disease characterized by thickening of the capillary membrane may be the underlying lesion for two forms of retinopathy. The first and most common presentation is a nonproliferative retinopathy, which is characterized by microaneurysms that may progress to hard, yellow exudates, signifying chronic leakage, retinal edema, and punctate hemorrhage. This form of retinopathy may be associated with loss of central vision, but generally is associated with excellent visual prognosis. Focal laser photocoagulation of the retina in patients with nonproliferative diabetic retinopathy and macular edema decreases the likelihood of visual loss by 50%.

A second, less common presentation is proliferative retinopathy. This form is characterized by neovascularization (presumably owing to retinal hypoxia) and occurs in approximately 45% of people with type 1 diabetes and in 15% of people with type 2 diabetes who have had the disease for 15 years. Neovascularization ultimately leads to fibrosis, vitreous hemorrhage, and retinal detachment. Photocoagulation therapy may arrest progression and decrease loss of vision associated with neovascularization.³⁰⁶ Because hypertension, smoking, uremia, and hyperglycemia may lead to more rapid progression of the retinopathy, every effort should be made to eliminate these risk factors for L.S.

Autonomic Neuropathy: Gastroparesis

79. H.D. is a 36-year-old man with a 20-year history of type 1 diabetes. He is in poor glycemic control (HbA_{1c}, 12%) and complains of frequent, severe hypoglycemic reactions that do not make sense. According to H.D., “I have insulin reactions right after I eat, but later on, my glucose concentrations are sky high.” H.D. presents to the diabetes clinic with a 2-month history of nausea, postprandial fullness, and occasional vomiting, all of which are unrelieved by antacids. H.D. also has peripheral neuropathy involving both his hands and feet and manifestations of autonomic neuropathy (impotence and orthostatic hypotension). An upper GI series was ordered to rule out peptic ulcer disease and reflux esophagitis, but the preliminary diagnosis was diabetic gastroparesis. What is the cause of diabetic gastroparesis? How should H.D. be treated?

Autonomic neuropathy may present as gastroparesis with feelings of fullness and nausea, urinary retention, impotence in men (manifested as retrograde ejaculation or an inability to attain an erection), postural hypotension, tachycardia, and diarrhea with incontinence of stool.³⁰⁸ The presence of autonomic insufficiency may have profound effects on the patient’s response to vasodilating drugs and ability to counteract hypoglycemia.³⁰⁹

Impaired diabetic control with “unexplained” hypoglycemia may result from the disrupted delivery of food to the intestine; that is, glucose delivery does not correspond with prandial insulin action. Many patients with diabetic gastroparesis, like H.D., have had diabetes for many years and also have evidence of peripheral and autonomic neuropathies.

Conventional antiemetic therapy is usually not helpful in the treatment of gastroparesis. Prokinetic agents, such as metoclopramide, are considered first-line therapy. Metoclopramide increases gut motility through indirect cholinergic stimulation of the gut muscle. However, symptomatic improvement does not always correlate with improved gastric emptying, which implies that the effectiveness of metoclopramide also is due to its centrally mediated antiemetic activity. A usual starting dose of metoclopramide is 10 mg orally four times daily, 30 minutes before meals and at bedtime. Although treatment may not eliminate all symptoms, it should minimize most of the patient’s complaints. If oral therapy is ineffective for H.D., metoclopramide may be effective in extemporaneously compounded suppository form. Other pharmacotherapeutic interventions include domperidone (not available in the United States), cisapride (withdrawn from the U.S. market), erythromycin, and cholinergic agonists.³¹⁰ They are reviewed by Vinik et al.³⁰⁹ A key component to treating H.D.’s gastroparesis is improving his glycemic control.

Peripheral Neuropathy

80. Six months after institution of metoclopramide 10 mg QID and several insulin adjustments, H.D.’s GI symptoms have been alleviated, and his diabetes is now reasonably well controlled as evidenced by elimination of hypoglycemic episodes and a recent HbA_{1c} of 7.5% (normal, 4%–6%). However, H.D. has been complaining of increasing bilateral foot and leg pain, which he describes as a burning or aching sensation. An examination of his feet reveals cool extremities with absent pulses and loss of monofilament sensation. Outline appropriate steps that can be taken to alleviate H.D.’s peripheral neuropathy.

Diabetic neuropathy may be a consequence of metabolic disturbances in the neurons, microangiopathy affecting the capillary supply to neurons, or an autoimmune process. It affects 60% to 70% of the diabetic population and has a broad spectrum of presentation. Clinically, it most commonly presents as a diffuse symmetric sensorimotor syndrome, as carpal tunnel syndrome, or as autonomic neuropathy. Symptomatic diabetic peripheral neuropathy (DPN) occurs in 25% of patients with diabetes. It is characterized by paresthesia and pain in the lower extremities that may be mild or severe and unremitting; decreased sensation to monofilament testing; decreased ankle and knee jerks; and decreased nerve conduction velocity. The decreased sensation associated with peripheral neuropathy contributes to the progression of foot injuries and infections that may go unnoticed by the patient until they are

severe.^{311,312} The management of diabetic neuropathies has been reviewed.³¹¹

SIMPLE ANALGESICS

Painful neuropathy may respond to simple analgesics (e.g., acetaminophen) or nonsteroidal anti-inflammatory drugs. The analgesic selected should be based on the patient's history of responsiveness to these agents as well as their duration of action and side effect profiles. Side effects include GI upset and bleeding, and renal and hepatic toxicity.

TRICYCLIC ANTIDEPRESSANTS

For painful neuropathy that becomes incapacitating and is unrelieved by simple analgesics, tricyclic antidepressants (TCAs) can be effective and are the most thoroughly studied. TCAs relieve pain by inhibiting reuptake of serotonin and norepinephrine; by a quinidine-like local analgesic effect; or by other, as yet unexplained, mechanisms. Amitriptyline and imipramine are the most commonly prescribed TCAs because of their favorable effects on DPN. Low to moderate (25–150 mg) daily doses have been used, but usually 75 to 100 mg are required for adequate pain relief. The onset of analgesia is evident in 1 to 4 weeks. To minimize side effects, attempts should be made to use antidepressants alone and at bedtime.

81. Amitriptyline (Elavil) 25 mg at bedtime was begun in H.D. with the dose titrated to 100 mg at bedtime over 1 month. H.D. experienced moderate relief of pain, and both his psychological and somatic complaints of depression lessened dramatically. However, H.D. also experienced intolerable constipation, dry mouth, and urinary hesitancy. Attempts to taper the dose of amitriptyline while maintaining pain relief were unsuccessful. What other drugs are effective for treating DPN?

Most of the adverse effects of psychotropic drug therapy (sedation, anticholinergic effects, extrapyramidal reactions, cardiovascular effects) are dose related, except for tardive dyskinesia. Patients with autonomic neuropathy and the elderly are at increased risk for complications. Because desipramine and nortriptyline are less likely to cause sedation, anticholinergic side effects, and orthostatic hypotension, we recommend their preferential use over amitriptyline.

ANTICONVULSANTS

Carbamazepine

For cases of extremely painful DPN resistant to simple analgesics and TCAs, carbamazepine can be tried. Doses have varied from 100 to 400 mg three times daily.²² Dizziness and drowsiness are common, but often transient, and GI disturbances or dermatologic reactions are observed in 5% to 10% of patients. Carbamazepine is now rarely used because of its side effects. Phenytoin (Dilantin) generally is not of value in the treatment of diabetic neuropathy because toxicity (such as nystagmus, ataxia, and sedation) often develops before a therapeutic effect is seen. Furthermore, phenytoin potentially decreases insulin secretion in type 2 patients.

Gabapentin and Pregabalin

Gabapentin and pregabalin's exact mechanism of action in treating neuropathic pain is not known, but it may be through its modulation of calcium channels.³¹³ A randomized, double-blind, placebo-controlled, 8-week trial evaluated the use of

gabapentin in 165 patients with painful diabetic neuropathy.³¹⁴ Gabapentin was titrated from 900 mg daily (divided TID) in the first week up to 3,600 mg/day (divided TID) to assess its efficacy and tolerability. Gabapentin significantly improved pain compared with placebo. Although gabapentin was associated with more dizziness and somnolence, only 2 of the 84 patients treated with gabapentin withdrew because of side effects. Backonja and Glanzman³¹³ reviewed data from five clinical trials of gabapentin and recommends a starting dose of 900 mg/day (300 mg on the first day, 600 mg on the second day, and 900 mg/day on the third day taken in three divided doses); the dose should be titrated to 1,800 to 3,600 mg/day for effective relief of neuropathic pain. An advantage of gabapentin is its lack of significant drug interactions. It needs to be dose adjusted in renal impairment.

Pregabalin is FDA approved for the treatment of painful diabetic neuropathy. It has better bioavailability compared with gabapentin (at higher doses). Doses studied range from 150, 300, and 600 mg per day (divided TID or BID), with 600 mg/day having the greatest effect.³¹⁵ The starting dose is 50 mg PO TID. The most common side effects are dizziness, somnolence, and edema.

Other Anticonvulsants

Lamotrigine and topiramate have been found to be effective in the treatment of painful diabetic neuropathy.^{181,316,317} Lamotrigine can be started at 25 to 50 mg/day and titrated by 50-mg increments to 400 mg/day; patients should be closely monitored for rash. Topiramate can be started at 25 mg/day and increased in 25-mg increments to 400 mg/day (taken in two to three divided doses).

In January 2008, the FDA released information about an increased risk for suicidal thoughts and behaviors (suicidality) in patients taking antiepileptics. They advise that patients be closely monitored and counseled about these risks.

OTHER AGENTS

Another analgesic, tramadol, which binds to μ -opioid receptors and weakly inhibits norepinephrine and serotonin uptake, has been shown to be effective in DPN.^{318,319} Patients can be started on 50 mg/day and titrated in 50-mg increments to 400 mg/day. In one clinical trial, an average dose of 210 mg of tramadol was found to be significantly more effective than placebo in treating painful diabetic neuropathy.³¹⁸

Duloxetine is a selective serotonin norepinephrine reuptake inhibitor that is FDA approved for painful diabetic neuropathy. A recent analysis looked at the number needed to treat at doses of 60 mg/day or BID; the number needed to treat was only 5.2 and 4.9, respectively.³²⁰ Duloxetine should be administered at 60 mg once or twice daily.³²¹

The antiarrhythmics, mexiletine and lidocaine, can be beneficial in the treatment of resistant neuropathy.³²² However, because of inconsistent therapeutic benefits and an increased risk of side effects, these agents are reserved for cases that cannot be treated successfully with other, less toxic agents. The use of clonidine (Catapres) also has been studied for the treatment of DPN because peripheral vasodilation may decrease neuronal ischemia. Transdermal clonidine has also been shown to relieve painful diabetic neuropathy in a subpopulation of patients.

Topical application of 0.075% capsaicin (Zostrix), the active ingredient in hot peppers, is used to treat postherpetic

neuralgia and has been recommended for diabetic neuropathy. This nonprescription preparation enhances the release and prevents the reaccumulation of substance P in nerve terminals of type C nociceptive fibers. In this way, it impedes the conduction and transmission of peripheral pain impulses. Because capsaicin acts to deplete substance P from nerve fiber terminals, initial high levels are released from the fibers, resulting in a burning and stinging sensation. H.D. should be advised that benefit from capsaicin may not occur for several weeks. Patients should use gloves or an applicator to apply capsaicin and avoid contact with the eyes or mucous membranes. Capsaicin may be useful in diabetic patients intolerant of oral medications.³¹¹

The treatment of DPN continues to center on providing symptomatic relief. Gabapentin, pregabalin, duloxetine, or TCAs provide the most effective analgesia. A variety of other medications may provide relief in refractory patients.

82. Can anything be done for H.D.'s peripheral vascular disease?

Peripheral vascular disease or peripheral arterial disease (PAD) presents as diminished or absent foot pulses (35%), intermittent claudication (24%–35%), skin ulcers, gangrene, or amputation. People with diabetes are two to ten times more likely to develop symptoms of PAD than those without diabetes, and half of all nontraumatic amputations in the United States are performed in patients with diabetes. In one study that followed type 2 patients for 7 years, 5.5% had an amputation. The prevalence of this condition increases with age, duration of diabetes, and the presence of risk factors such as hypertension or smoking.^{311,323}

Signs and symptoms of PAD include leg pain, which is relieved by rest; cold feet; nocturnal leg pain, which is relieved by dangling the feet over the bed or walking; absent pulses; loss of hair on the foot and toes; and gangrene. Treatment of this condition includes elimination and treatment of risk factors such as smoking, dyslipidemia, hypertension, and hyperglycemia; antiplatelet therapy; exercise, the mainstay of therapy; and revascularization surgery.³²³ H.D. should be thoroughly educated regarding proper foot care and have frequent foot examinations.^{324,325}

83. Should L.S. be started on aspirin therapy?

L.S. has several cardiovascular risk factors (microalbuminuria, dyslipidemia, hypertension, obesity, and age) and should be started on aspirin therapy as primary prevention. The ADA recommends aspirin therapy as secondary prevention in patients with a history of CVD (e.g., MI, vascular bypass procedure, peripheral vascular disease, stroke or transient ischemic attack, claudication, and/or angina).^{22,28} Primary prevention is indicated in diabetic individuals over 40 years of age or in those who have additional risk factors (a family history of CVD, smoking, hypertension, albuminuria, dyslipidemia). L.S. should take an enteric-coated aspirin, 81 mg/day.

DRUG-INDUCED ALTERATIONS IN GLUCOSE HOMEOSTASIS

Persons with diabetes are likely to take more drugs over their lifetime than any other group of patients. Patients with type 2 diabetes present with a constellation of chronic conditions,

including hypertension, dyslipidemia, and CVD, all of which are amenable to drug therapy. Drugs to manage depression, intermittent infections, obesity, and neurologic and ophthalmologic conditions also are commonly prescribed. Because we know that the actions of drugs are complex, and that for every desired effect there are several other unwanted effects, each time a drug is added to the regimen of someone with diabetes, it is important to assess the patient's situation to determine whether a potential exists for a drug–drug or drug–disease interaction or if the benefit of the newly prescribed drug is likely to outweigh its risks. With the availability of online drug information databases to assist in assessment of drug–drug and drug–disease interactions, a detailed listing of drugs that can exacerbate hyperglycemia and hypoglycemia is not provided. Below, a few case examples are illustrated. The subject has been reviewed by others.³²⁶ Some medications that can have significant hyperglycemic effects include atypical antipsychotics, protease inhibitors, corticosteroids, immunosuppressants (e.g., tacrolimus, cyclosporine), niacin (higher doses), and pentamidine (can also cause hypoglycemia). Patients should be monitored closely for a medication's possible effect on the blood glucose levels.

Drug-Induced Hyperglycemia

Corticosteroids

84. A.L., a 37-year-old obese woman with systemic lupus erythematosus, has been taking 60 mg/day of prednisone for 6 months. During this period, her weight has increased by 30 lb and she has developed glycosuria (no ketones). She was referred to the diabetes clinic, where her FPG was found to be 160 mg/dL. Physical examination shows a 5 feet 2 inch, 150-lb, depressed woman with truncal obesity and an acneiform rash. Her mother and one sister have type 2 diabetes. How do corticosteroids contribute to diabetes mellitus? How should A.L. be treated?

The term *steroid diabetes* was first used to describe the hyperglycemia and glycosuria seen in patients with Cushing syndrome. Now, it is associated more commonly with exogenously administered glucocorticoids and has been a side effect of parenteral, oral, and even topical therapy.³²⁷ Corticosteroids are one of the most common drug groups that unmask latent diabetes or aggravate preexisting disease, and they may produce hyperglycemia and overt diabetes in individuals who are not otherwise predisposed.

Corticosteroids increase hepatic gluconeogenesis and decrease tissue responsiveness to insulin. Although steroid-induced diabetes generally is mild and rarely associated with ketonemia, a wide spectrum of severity may be encountered—from asymptomatic, abnormal glucose tolerance tests to difficult-to-control, insulin-requiring disease. The onset of glucose tolerance can occur within hours to days or after months to years of chronic therapy. The effect generally is considered dose dependent and usually is reversible upon discontinuation of the drug; reversal may take several months.^{328,329}

A.L. exhibits many symptoms that can be attributed to supraphysiological doses of corticosteroids: truncal obesity, depression, acneiform rash, and diabetes. Mildly elevated glucose levels in obese individuals, as in A.L.'s case, sometimes can be controlled by diet, but may require treatment with antidiabetic medications. A person with diabetes before

glucocorticoid use, whose condition is aggravated by use of a glucocorticoid, should modify treatment appropriately to restore glycemic control. It is important to anticipate the need to modify insulin or other antidiabetic therapy as corticosteroid doses are increased or decreased.

Sympathomimetics

85. R.C., a 41-year-old man with type 1 diabetes, is well controlled on a basal-bolus insulin regimen and has been taking pseudoephedrine 30 mg QID for 7 days and Robitussin DM 10 mL QID (which contains 2.92 g/5 mL sugar) for a cold. Recently, glucose concentrations have been higher than usual. Can pseudoephedrine or the cough preparation be the cause of his poor glycemic control? Discuss the use of sympathomimetics and cough preparations in patients with diabetes.

Over-the-counter drug products, such as decongestants and diet aids, which contain sympathomimetics, carry warning labels that caution against their use in patients with diabetes. Standard sugar- and ethanol-containing cough preparations also carry such warning labels. However, clinically significant drug-induced glucose intolerance probably is very infrequent. It is well established that parenterally administered epinephrine increases blood glucose concentrations secondary to increased glycogenolysis and gluconeogenesis. Other sympathomimetics generally do not have as potent an effect on blood glucose as epinephrine, and their use usually does not pose a practical problem in diabetic patients. Nevertheless, therapeutic to high oral doses of phenylephrine caused hyperglycemia and acetonuria in three nondiabetic children.^{330,331} Furthermore, the effects of sympathomimetics on BP must be considered in many patients with diabetes. Therefore, we recommend antihistamines or occasional use of nasal sprays for severe congestion.

In summary, pseudoephedrine or the cough preparation may be aggravating R.C.'s diabetic control, although at these low to normal therapeutic doses, it is quite unlikely. The stress related to R.C.'s underlying cold is more likely to be impairing his glucose tolerance than these low doses of sympathomimetic agents or the small amounts of sugar contained in the cough syrup.

Drug-Induced Hypoglycemia

Ethanol

86. C.F., a 22-year-old woman with newly diagnosed type 1 diabetes, enjoys a glass or two of wine with her evening meal. What effect does alcohol have on a patient with diabetes, particularly one using insulin? Is alcohol contraindicated in C.F. or any person with diabetes?

Clinicians often are reluctant to permit the use of alcoholic beverages in patients with diabetes. However, barring contraindications that are similar in the nondiabetic and diabetic alike (e.g., alcoholism, hypertriglyceridemia, gastritis, pancreatitis, pregnancy), a person with diabetes can safely enjoy a moderate alcohol intake as long as certain precautions are taken. For an in-depth discussion, the reader is referred to two comprehensive reviews of alcohol and diabetes, parts of which are summarized in the following list.^{332,333}

- Drink in moderation. The ADA defines this as a daily intake of one drink for adult women and two drinks for adult men (5 oz wine, 12 oz beer, 1.5 oz distilled liquor). The patient should be aware of his or her own sensitivity to the intoxicating effects of ethanol and adjust consumption downward, if needed. This is particularly important for insulin-dependent patients. When having a drink, be sure to have it with a meal.
- Avoid drinks that contain large amounts of sugar, such as liqueurs, sweet wines, and sugar-containing mixes. Instead, consider dry wines, light beers, and distilled spirits. Not only does the simple sugar content add an additional source of glucose and calories to the diet, but ethanol ingested with simple sugar-containing mixers enhances reactive hyperglycemia.
- Remember to count the calories in alcohol (calories = $[0.8] \times [\text{proof}] \times [\text{oz}]$); substitute 1 oz of alcohol for two fat exchanges.
- Be aware that the symptoms of alcohol intoxication and hypoglycemia are similar. If hypoglycemia is mistaken for intoxication by others, appropriate and potentially life-saving treatment can be delayed.
- Be aware of alcohol-sulfonylurea drug interactions, specifically the alcohol-induced enzyme induction of tolbutamide metabolism and the chlorpropamide-alcohol flush reaction.

- Other Drugs 51-22
 - Age-Related Macular Degeneration 51-22
- Pegaptanib 51-23
- Bevacizumab 51-23
- Ranibizumab 51-23

The eye is a highly complex organ composed of various parts, all of which must function in integration to permit vision. A brief overview of the anatomy and physiology of the eye prefaces the presentation of specific eye disorders. Readers should consult an ophthalmology textbook for an understanding of ocular anatomy, physiology, and general ophthalmology (e.g., Vaughn and Asbury's General Ophthalmology).¹

OCULAR ANATOMY AND PHYSIOLOGY

The eyeball is approximately 1 inch wide and is housed in a cavity (i.e., eye socket) formed by two bony orbits that are

lined with fat, which serves to protect the eyeball. Six ocular muscles facilitate movement of the eyeball (Fig. 51-1).

The outer coat of the eye is made up of the sclera, conjunctiva, and cornea. The *sclera* is the white, dense, fibrous protective coating. The *episclera*, a thin layer of loose connective tissue, contains blood vessels that cover and nourish the sclera. The *conjunctiva* is a mucous membrane that covers the anterior portion of the eye and lines the eyelids. The *cornea* is the transparent, avascular tissue that functions as a refractive and protective window membrane through which light rays pass en route to the retina. The corneal epithelium and endothelium are lipophilic, and the centrally located stroma is hydrophilic.

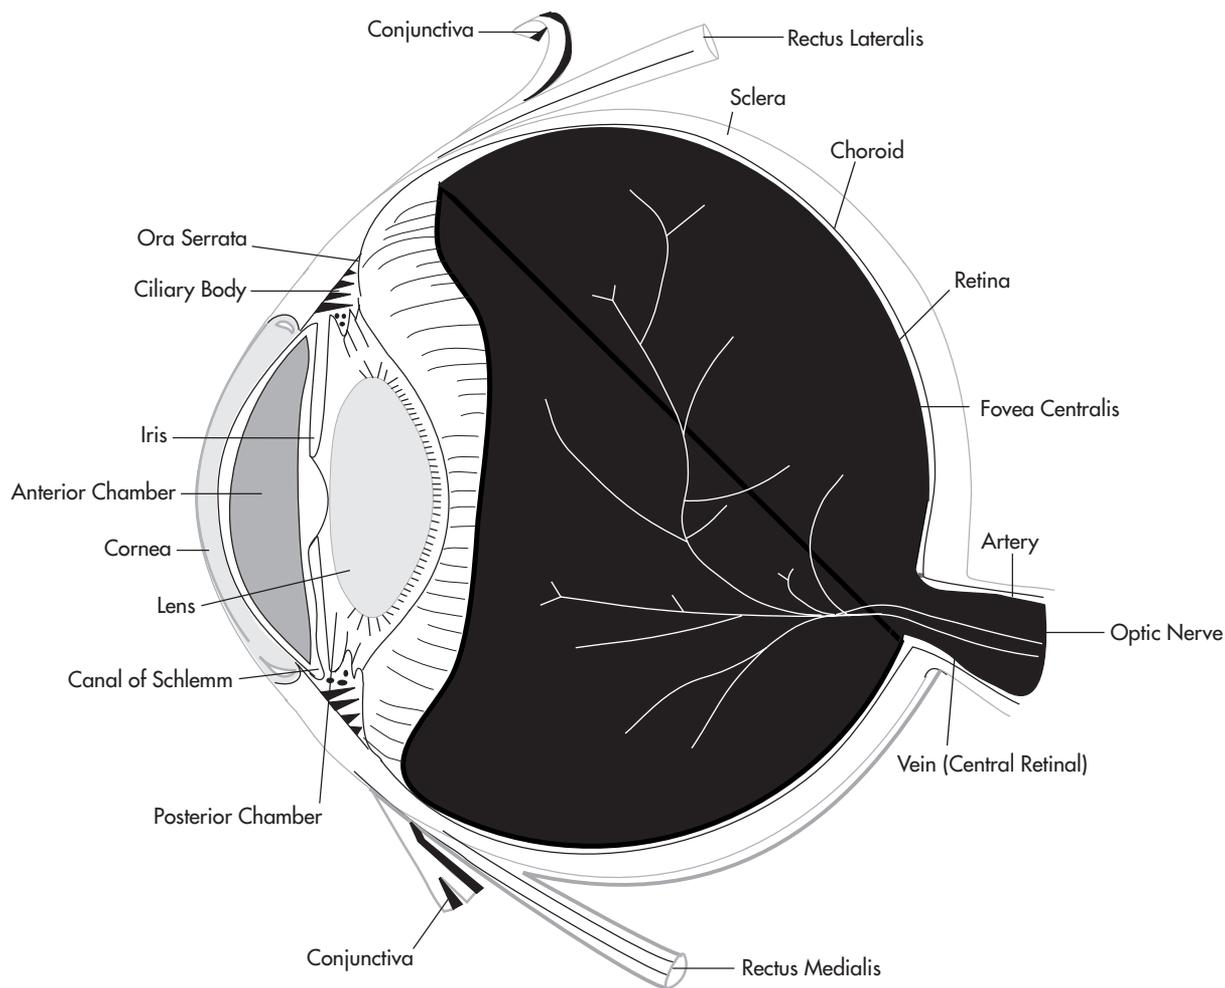

FIGURE 51-1 Anatomy of the human eye. (Adapted from artwork courtesy of Burroughs Wellcome.)

These three corneal layers are particularly important because they affect drug penetration through the cornea. Ophthalmic medications, which are both fat- and water-soluble, are best able to penetrate through the intact cornea.

The iris, choroid, and ciliary body are known collectively as the uveal tract. The *iris* is a colored, circular membrane suspended between the cornea and the crystalline lens. It controls the amount of light that enters the eye. The *choroid*, located between the sclera and retina, is largely made up of blood vessels, which nourish the retina. The *ciliary body* is adherent to the sclera and contains the ciliary muscle and ciliary processes. The ciliary muscle contracts and relaxes the zonular fibers, which hold the crystalline lens in place. The ciliary processes are responsible for the secretion of aqueous humor, a clear liquid that occupies the anterior chamber. The anterior chamber is bounded anteriorly by the cornea and posteriorly by the iris. The posterior chamber lies between the iris and the crystalline lens.

The inner segment of the eye contains the retina with the optic nerve. The *retina*, the light-sensitive tissue at the back of the eye, contains all of the sensory receptors for light transmission. The *optic nerve*, a bundle of more than a million nerve fibers, transmits visual impulses from the retina to the brain.

The crystalline lens, aqueous humor, and vitreous humor assist the cornea with the refraction of light. The *lens*, located behind the iris, functions to focus light onto the retina by changing its shape to accommodate near or distant vision. The innermost part of the lens (i.e., the nucleus) is surrounded by the softer material of the cortex. The *aqueous humor*, the thin watery fluid that fills the anterior chamber (i.e., the space between the cornea and the iris) and posterior chamber of the eye, functions to provide nourishment to the cornea and lens. Disorders involving the aqueous humor are presented in the section on glaucoma. The primary function of the *vitreous humor* (i.e., the jelly-like substance between the lens and the retina) is to maintain the shape of the eye and allow the transmission of light to the retina.

The eyelids and eyelashes are the outermost means of protection for the eye. The eyelids contain various sebaceous and sweat glands, which may become infected or inflamed, contributing to many ocular disorders.

The eye is innervated by both the sympathetic and parasympathetic nervous systems. Parasympathetic fibers, originating from the oculomotor nerve in the brain, innervate the ciliary muscle and sphincter pupillae muscle that constrict the pupil. As a result, parasympathomimetic (cholinergic) medications

generally are associated with *miosis* (pupillary contraction), and parasympatholytic (anticholinergic) agents with *mydriasis* (pupillary dilation) and cycloplegia. The term, *cycloplegia*, refers to a paralysis of the ciliary muscle and zonules (fibrous strands connecting the ciliary body to the lens) that results in decreased accommodation (adjustment of the lens curvature for various distances) and blurred vision. Tear secretion by the lacrimal glands also is a parasympathetic function.

Sympathetic fibers from the superior cervical ganglion in the spinal cord innervate the dilator pupillae muscle, the blood vessels of the ciliary body, the episclera, and the extraocular muscles. Sympathomimetics cause mydriasis without affecting accommodation.

GLAUCOMA

Glaucoma, a leading cause of blindness worldwide, is a non-specific term used for a group of diseases that can irreversibly damage the optic nerve resulting in visual field loss. Increased intraocular pressure (IOP) is the most common risk factor for the development of glaucoma; however, even people with “normal” IOPs can experience vision loss from glaucoma. Generally, the higher the IOP, the greater the risk for developing glaucoma. Increasing age, African American race, family history, thinner central corneas, and larger vertical cup–disk ratios are other risk factors for glaucoma.^{1,2}

Intraocular Pressure

The inner pressure of the eye (i.e., IOP) is influenced by the production of aqueous humor by the ciliary processes and the outflow of aqueous humor through the trabecular meshwork. The tonometry test to measure the IOP is based upon the pressure required to flatten a small area of the central cornea. Generally, an IOP of 10 to 20 mmHg is considered normal. An IOP of 22 mmHg or higher should arouse suspicion of glaucoma, although a more rare form of glaucoma is associated with a low IOP.

Ocular Hypertension

Ocular hypertension has been defined as an IOP >21 mmHg, normal visual fields, normal optic discs, open angles, and the absence of any ocular disease contributing to the elevation of IOP. Only a small percentage of patients with ocular hypertension develop open-angle glaucoma. An ophthalmoscope can examine the inside of the eye, especially the optic nerve, and a diagnosis of glaucoma can be applied when pathologic cupping of the optic nerve is observed.

Open-Angle Glaucoma

Primary open-angle glaucoma occurs in about 1.8% of people older than 40 years of age in the United States; however, glaucoma can affect other age groups, including children.^{1–3} About 2.2 million people in the United States have glaucoma and this number likely will increase to about 3.3 million by the year 2020 as the population ages.³ In patients with primary open-angle glaucoma (POAG), aqueous humor outflow from the anterior chamber is continuously subnormal primarily be-

cause of a degenerative process in the trabecular meshwork. The IOP can vary in the course of a day from normal to significantly high pressures.¹ The decreased outflow appears to be caused by degenerative changes in outflow channels (i.e., the trabecular meshwork and Schlemm’s canal) and tends to worsen with the passage of time.¹ In rare cases, the outflow is normal even during a phase of elevated IOP, and the elevation appears to be to the result of hypersecretion of aqueous humor.¹

The onset of POAG usually is gradual and asymptomatic. A defect in the visual field examination may be present in early glaucoma, but loss of peripheral vision usually is not seen until late in the course of the disease. Visual field defects correlate well with changes in the optic disc and help differentiate glaucoma from ocular hypertension in patients with increased IOP. Patients with normal visual fields and an IOP of 24 mmHg or greater have a 10% likelihood of developing glaucoma in 5 years.³

Angle-Closure Glaucoma

Examination of the anterior chamber angle by gonioscopy, using a corneal contact lens, a magnifying device (e.g., a slit-lamp microscope), and a light source, assists in differentiating between open-angle glaucoma and angle-closure glaucoma. Angle-closure glaucoma accounts for approximately 5% to 10% of all primary glaucoma cases. The sole cause of the elevated IOP in angle-closure glaucoma is closure of the anterior chamber angle.^{1,4}

Angle-closure glaucoma, which is a medical emergency, usually presents as an acute attack with a rapid increase in IOP, blurring or sudden loss of vision, appearance of haloes around lights, and pain that is often severe. When patients are predisposed to angle-closure glaucoma, their pupils should not be dilated (e.g., during an ophthalmic examination) and they should be taught the signs and symptoms of angle closure. Acute attacks can terminate without treatment, but if the IOP remains high, the optic nerve can be irreparably damaged.¹ Patients with chronic angle closure generally experience a gradual closure of aqueous humor outflow channels, and patients can be asymptomatic until the glaucoma is in an advanced stage.¹ Permanent medical management of acute or chronic angle closure glaucoma is difficult: surgical procedures (e.g., peripheral iridectomies) often are needed.

PRIMARY OPEN-ANGLE GLAUCOMA

Therapeutic Agents for Treatment of Primary Open-Angle Glaucoma

Initial Therapy

β -ADRENERGIC BLOCKERS

All of the ocular β -adrenergic blockers (e.g., timolol, levobunolol, metipranolol, carteolol, betaxolol, levobetaxolol) have the same basic mechanism of action. Ophthalmic β -blockers block the β -adrenergic receptors in the ciliary epithelium of the eye and lower IOP primarily by decreasing aqueous humor production. β -adrenergic blockers have been the most commonly prescribed first-line agents for the treatment of POAG.

Timolol (Timoptic)

Timolol, a nonselective β_1 - and β_2 -adrenergic antagonist, is one of the most commonly prescribed glaucoma medications. Because timolol was the first ocular β -adrenergic blocker marketed, subsequently marketed ophthalmic β -blockers usually are compared with timolol for safety and effectiveness. Concentrations or dosages exceeding one drop of timolol 0.5% BID do not produce further significant decreases in IOP.⁵ Therapy usually is initiated with a 0.25% solution administered as one drop BID. Monocular administration of timolol has resulted in equal bilateral IOP reduction and can reduce the cost of therapy and side effects for some patients.⁶ An escape phenomenon, or tachyphylaxis, can occur with timolol.

If a patient has a large initial decrease in IOP, the IOP often stabilizes at a lesser reduction in about 4 to 6 weeks.^{7,8} Timolol, safe and effective in adult and pediatric patients, is at least as effective as pilocarpine and epinephrine and can be more efficacious in daily IOP control.^{9–12}

Timolol has been associated with a modest reduction of resting pulse rate (5–8 beats/minute)^{13,14}, worsening of congestive heart failure, and adverse pulmonary effects (e.g., dyspnea, airway obstruction, pulmonary failure).^{15,16} After chronic administration in susceptible individuals, timolol can cause corneal anesthesia.^{17,18} Although uveitis has been reported in patients receiving ophthalmic timolol, a cause-and-effect relationship has not been established.^{19,20}

In one study, plasma levels after ophthalmic administration of timolol were not detected in all but one human subject, who had a level of 9.6 ng/mL.^{21,22} In another study, the baseline mean plasma timolol level was 0.34 ng/mL in 10 patients, who were more than 60 years of age and receiving chronic timolol. In these patients, the plasma timolol concentration increased to 1.34 ng/mL 1 hour after administration of one drop of 0.5% timolol, and the mean 1-hour plasma timolol level decreased to 0.9 ng/mL with punctal occlusion.²³ The β -blocking plasma concentration of timolol has been estimated to be about 5 to 10 ng/mL.⁸

Although systemic absorption after topical administration does not appear to be significant in most cases, care should be taken when timolol is used in patients with sinus bradycardia, CHF (Chapter 18: Heart Failure), or pulmonary disease. Systemic side effects could be exaggerated in elderly patients secondary to inadvertent overdosing associated with poor administration technique (see Question 3).

A breast milk sample from a nursing mother, obtained 1.5 hours after administration of one drop of 0.5% topical timolol, resulted in a timolol concentration in the breast milk of 5.6 ng/mL and a concomitant plasma concentration of 0.93 ng/mL.²⁴ Timolol should be used cautiously in nursing mothers.

Timoptic XE

Timoptic XE, a timolol ophthalmic gel-forming solution, is administered once daily. The ophthalmic vehicle, gellan gum (Gelrite), is a solution that forms a clear gel in the presence of mono or divalent cations.²⁵ This ion-activated gelation prolongs precorneal residence time and increases ocular bioavailability, allowing timolol to be administered once daily.²⁵ In a 24-week study, Timoptic XE 0.5% once daily and Timoptic solution 0.5% BID were equally effective in lowering IOP.²⁶

Levobunolol (Betagan)

Levobunolol, another nonselective β -adrenergic antagonist, can decrease IOP on average about 9 mmHg with either the 0.5% or 1% solutions and is approved for both once daily or BID administration.^{27,28} When levobunolol 0.5% once daily was compared with BID administration, both regimens reduced IOP similarly.²⁹ When levobunolol 0.5% and 1% BID were compared with timolol 0.5% BID, ocular hypotensive effects, incidence of adverse reactions, and slight to significant decreases in heart rate were noted for both agents.^{30,31} In one 3-month study, levobunolol once daily was more effective than timolol at various concentrations;³² however, in another study, both timolol 0.25% and levobunolol 0.25% once daily were equally effective.³³ Levobunolol can be more expensive than timolol (depending on negotiated contract purchase prices) whether it is administered once or BID.³⁴

Metipranolol (Optipranolol)

Another nonselective β -adrenergic blocking agent, metipranolol 0.1% to 0.6%, is comparable to timolol 0.25% to 0.5% in reducing IOP in patients with open-angle glaucoma.^{35,36} Single-dose metipranolol 0.1% and 0.3% and timolol 0.25% did not significantly change resting heart rate or the resting or exercise mean blood pressure,³⁷ but timolol significantly reduced exercise tachycardia. Metipranolol 0.6% and levobunolol 0.5% BID reduced IOP by about 7 mmHg (29%), and neither significantly reduced heart rate or blood pressure.³⁸ Metipranolol is associated with a greater incidence of stinging or burning upon administration than other ophthalmic β -adrenergic blockers. Topical metipranolol appears to offer no advantage over timolol or levobunolol in the treatment of glaucoma.

Like timolol, metipranolol produces corneal anesthesia, which occurs within 1 minute of instillation and returns to baseline after 10 minutes.¹⁸ Metipranolol has been withdrawn from clinical use in the United Kingdom because it has been associated with granulomatous anterior uveitis. Although this adverse effect was initially attributed to its irradiated plastic containers,³⁹ metipranolol subsequently was deemed to be the responsible agent for these inflammatory reactions.⁴⁰ A significant secondary elevation (57.6%) in IOP occurred in patients with metipranolol-associated adverse reactions.⁴¹ Although metipranolol may be cost-effective, its higher association with ocular burning and stinging and granulomatous anterior uveitis limit its use.

Carteolol (Ocupress)

Carteolol, a nonselective β -adrenergic blocking agent with partial β -adrenergic agonist activity, theoretically, should minimize the bronchospastic, bradycardic, and hypotensive effects associated with other ocular β -adrenergic blockers.³⁷ However, no clinical difference was noted when the cardiovascular and pulmonary function effects of carteolol were compared with timolol. Carteolol 1% and timolol 0.25% administered BID are equally effective in reducing IOP.^{43–45}

Betaxolol (Betoptic) and Levobetaxolol (Betaxon)

In contrast to other β -adrenergic blocking ophthalmic agents, betaxolol and levobetaxolol are selective β_1 -adrenergic blockers. Although levobetaxolol, the S-isomer of betaxolol, is more active than the racemic mixture of betaxolol, its

pharmacological and toxicological effects are similar. Betaxolol 0.125% to 0.5% can reduce IOP up to 35%.⁴⁶ In comparative studies, betaxolol 0.5% and timolol 0.5% BID decreased IOP with similar side-effect profiles including slight, but insignificant, decreases in systolic and diastolic blood pressure (BP).^{46–48} In these studies, timolol was slightly, but not significantly, more effective in decreasing IOP, with fewer patients requiring adjunctive therapy for adequate IOP control. In another study, timolol 0.25% and 0.5% consistently and significantly decreased median IOP more than comparable doses of betaxolol and more of the betaxolol-treated patients required adjunctive therapy.⁴⁹ These two cardioselective β -blockers, betaxolol and levobetaxolol, would be expected to have less adverse effect on pulmonary function than nonselective β -adrenergic blockers in some patients with reactive airway disorders; however, the practical significance of this pharmacological expectation needs validation.

PROSTAGLANDIN ANALOGS

Latanoprost (Xalatan), travoprost (Travatan), and bimatoprost (Lumigan), are all prostaglandin analogs. Latanoprost and travoprost are analogs of prostaglandin F_{α} , and they lower intraocular pressure by serving as selective prostaglandin $F_{2\alpha}$ -receptor agonists. Bimatoprost is a synthetic prostamide analog. The prostaglandin analogs (PGAs) increase uveoscleral outflow of aqueous humor and, thereby, decrease IOP.⁵⁰ These agents often are prescribed as first-line agents for the treatment of POAG, because they are at least as effective as the β -blockers, can be administered once a day, and are associated with minimal adverse effects. Unlike the β -blockers, generic versions of these drugs are not yet available and cost can be a consideration in elderly patients who are on a fixed income.

Latanoprost

Latanoprost (Xalatan) is approved for the initial treatment of POAG or ocular hypertension.⁵¹ When administered once daily in the evening, latanoprost is at least as effective as timolol in decreasing IOP. When the effectiveness of latanoprost 0.005% once daily was compared with timolol 0.5% BID, the IOP-lowering effects of latanoprost were superior to timolol.^{52,53} In addition, the nocturnal control of IOP with latanoprost was superior to that with timolol. Latanoprost 0.005% should be dosed once daily in the evening because the IOP-lowering effects of latanoprost might actually be inferior when administered more frequently.

Systemic side effects are minimal with latanoprost, but local reactions (e.g., iris pigmentation; eyelid skin darkening; eyelash lengthening, thickening, pigmentation, and misdirected growth; conjunctival hyperemia; ocular irritation; superficial punctate keratitis) are relatively common. Latanoprost can gradually increase the amount of brown pigment in the iris by increasing the melanin content in the stromal melanocytes of the iris. This pigment change occurs in 7% to 22% of patients and is most noticeable in those with green-brown, blue/gray-brown, or yellow-brown eyes.^{51,52} The onset of increased iris pigmentation usually is noticeable within the first year of treatment and can be permanent. The nature or severity of adverse events are not affected by the increased pigmentation of the iris.

Latanoprost has additive effects when administered with β -blockers (e.g., timolol), carbonic-anhydrase inhibitors

(e.g., dorzolamide), α_2 -adrenergic agonists (e.g., brimonidine, apraclonidine), and dipivefrin. When added to existing therapy, latanoprost decreases IOP an additional 2.9 to 6.1 mmHg. As a result, latanoprost is a good adjunctive ophthalmic for patients who are unable to adequately lower their IOP with single-agent therapy. Although the complementary IOP-lowering effects of latanoprost are comparable to those of brimonidine (at least a 15% reduction in IOP) in patients inadequately controlled on β -adrenergic blocking agents, brimonidine (an α_2 -adrenergic agonist) has been associated with fewer adverse effects on the quality of life. For example, watery or teary eyes and cold hands and feet were reported more frequently in latanoprost-treated patients.⁵⁴ The effectiveness of latanoprost when used once a day alone or as an adjunct to other IOP-lowering drugs, and its relative tolerability make it an important treatment option for POAG and ocular hypertension.^{53,55–57}

Travoprost

Travoprost (Travatan) is FDA approved for the reduction of elevated IOP and ocular hypertension in patients who are intolerant, or who fail to respond to other agents. Travoprost is used as a first-line agent in clinical practice because it is more effective than timolol and at least as effective as latanoprost. The mean IOP reduction with travoprost in African American patients was 1.8 mmHg greater than in non-African American patients. Travoprost, as adjunctive therapy to timolol in patients not responding adequately to timolol alone, reduced IOP an additional 6 to 7 mmHg. The side-effect profile of travoprost is similar to latanoprost including increased iris pigmentation and eyelash changes.^{58–60} Local irritation from travoprost may be less with the new formulation (i.e., Travatan Z) which replaced the preservative, benzalkonium chloride.

Bimatoprost

Like travoprost, bimatoprost (Lumigan) once daily or BID achieved lower target IOPs than did timolol BID. Bimatoprost BID, however, was less effective than bimatoprost once-a-day. Iris pigmentation changed in 1.1% of bimatoprost-treated patients. In a 6-month randomized multicenter study, bimatoprost once a day lowered IOP more effectively than latanoprost once a day. Side effects were similar between treatment groups; however, conjunctiva hyperemia was more common ($p < 0.001$) in bimatoprost treated patients. Overall, the side effect profile of bimatoprost appears to be similar to latanoprost and travoprost.^{61–63}

α_2 -ADRENERGIC AGONISTS

Apraclonidine (Iopidine) and brimonidine (Alphagan) are selective α_2 -adrenergic agonists similar to clonidine. Apraclonidine is less lipophilic than clonidine and brimonidine; does not cross the blood-brain barrier as readily; and, theoretically, has less systemic side effects (e.g., hypotension, decreased pulse, dry mouth). Brimonidine is more highly selective for α_2 -adrenergic receptors than clonidine or apraclonidine and, theoretically, should be associated with less ocular side effects. α_2 -adrenergic agonists appear to lower IOP by decreasing the production of aqueous humor and by increasing uveoscleral outflow.⁶⁴

Brimonidine is an alternative first-line agent in the treatment of POAG. It may also be used as adjunctive therapy in patients not responding to other agents. Apraclonidine 1% is

indicated to control or prevent postsurgical elevations in IOP after argon laser trabeculoplasty or iridotomy. The 0.5% apraclonidine solution is indicated for short-term adjunctive therapy in patients on maximally tolerated medical therapy. Long-term IOP control should be monitored closely in patients on α_2 -adrenergic agonists because tachyphylaxis can occur. Common ocular side effects include burning, stinging, blurring, conjunctival follicles, and an allergic-like reaction consisting of hyperemia, pruritus, edema of the lid and conjunctiva, and foreign body sensation. Although, ocular side effects are less common with brimonidine than with apraclonidine, systemic side effects (e.g., dry nose and mouth, mild hypotension, decreased pulse, and lethargy) are more common with brimonidine. α_2 -adrenergic agonists should be used with caution in patients with cardiovascular disease, orthostatic hypotension, depression, and renal or hepatic dysfunction.^{64,65} Brimonidine (Alphagan P) is now available with purite as a preservative which facilitates drug delivery into the eye allowing use of a lower drug concentration.⁶⁵

The IOP-reduction effects (peak and trough) of brimonidine 0.2% BID is 14% to 28%. Although the approved dosing schedule of brimonidine is TID, brimonidine 0.2% BID lowers IOP comparably to timolol 0.5% BID, and both are slightly better than betaxolol 0.25% BID.^{65–67} The IOP-lowering effect of brimonidine also may be comparable to that of latanoprost; however, conflicting efficacy and tolerability results in clinical studies may be related to differences in study design.⁶⁸ The combination of brimonidine and timolol is equally tolerable and effective as the combination of dorzolamide and timolol.⁶⁹ The FDA-approved Combigan ophthalmic solution combines a β -adrenergic agonist (brimonidine tartrate 0.2%) with a β -adrenergic blocker (timolol maleate 0.5%).

TOPICAL CARBONIC ANHYDRASE INHIBITORS

Carbonic anhydrase occurs in high concentrations in the ciliary processes and retina of the eye. Carbonic anhydrase inhibitors (CAIs) lower IOP is by decreasing bicarbonate production and, therefore, the flow of bicarbonate, sodium, and water into the posterior chamber of the eye resulting in a 40% to 60% decrease in aqueous humor secretion.

Although CAIs have been used orally for many years in the treatment of elevated IOPs, they have been replaced by the topical ophthalmic CAIs, dorzolamide (Trusopt) and brinzolamide (Azopt), which are safer and better tolerated. Topical CAIs are excellent alternatives to β -blockers in the initial management of elevated IOPs, and are effective as adjunctive agents. Brinzolamide 1% TID reduces IOP comparably to that achieved with dorzolamide 2% TID and to betaxolol 0.5% BID, but slightly less than timolol 0.5% BID. The IOP-reduction effects (peak and trough) of dorzolamide 2% TID is 16% to 25%. Brinzolamide and dorzolamide are approved for TID dosing; however, BID dosing may be adequate. Dorzolamide provides additional IOP-lowering effects when added to existing β -blocker therapy.^{70,71} An ophthalmic solution of dorzolamide hydrochloride and timolol maleate is marketed as Cosopt. The combined use of topical dorzolamide and oral acetazolamide does not result in additive effects and might increase the risk of toxicity. Therefore, the concomitant use of topical and oral CAIs is not advised.^{72–74}

The topical CAIs are well tolerated with few systemic side effects. The most common adverse effects reported with dor-

zolamide are ocular burning, stinging, discomfort and allergic reactions, bitter taste, and superficial punctate keratitis. Brinzolamide causes less burning and stinging of the eyes than dorzolamide, because its pH more closely resembles that of human tears. Dorzolamide and brinzolamide are sulfonamides and may cause the same types of adverse reactions attributable to sulfonamides. These drugs should not be used in patients with renal or hepatic impairment.

PILOCARPINE

Pilocarpine (IsoptoCarpine) historically was an initial treatment of choice, but with the introduction and widespread use of newer agents, pilocarpine has fallen out of favor as an initial treatment. Therapy usually is begun using lower concentrations (0.5%–1%), such as one drop QID. Pilocarpine is a direct-acting cholinergic (parasympathomimetic) that causes contraction of ciliary muscle fibers attached to the trabecular meshwork and scleral spur. This opens the trabecular meshwork to enhance aqueous humor outflow. There also may be a direct effect on the trabecular meshwork. Pilocarpine causes miosis by contraction of the iris sphincter muscle, but the miosis is not related to the decrease in IOP.

EPINEPHRINE

Epinephrine (Glaucon, Eppy/N, Epitrate) is a sympathomimetic that stimulates both

α - and β -receptors. The β -adrenergic stimulation is responsible for increasing aqueous humor outflow and is the probable basis of epinephrine's ability to lower IOP.^{75,76} In contrast, the β -adrenergic blockers decrease aqueous humor production. The α -adrenergic effect of epinephrine predominantly decreases the inflow of aqueous humor, which is not as significant as the increase in aqueous humor outflow.^{75,76} Patients in whom systemic effects of this drug could potentiate pre-existing problems should be monitored closely. Dipivefrin is an epinephrine prodrug that is better tolerated and absorbed than epinephrine. It is usually the preferred product when agents from this class are indicated. Dipivefrin or epinephrine is often used in younger patients or patients with cataracts in which miosis and the resultant decreased vision from cholinergic agents are a problem. Both are second or third-line drugs in the therapy of POAG and are used most often as second agents in combination regimens rather than as monotherapy.

CARBACHOL

Carbachol (Isopto-Carbachol) is reserved as a third-line agent in patients who are unresponsive or intolerant to initial medications. In addition to having direct cholinergic effects, carbachol is more resistant to cholinesterase than pilocarpine. Added benefits include increased release of acetylcholine from parasympathetic nerve terminals and a weak anticholinesterase effect. Carbachol is administered TID.

ANTICHOLINESTERASE AGENTS

If control of IOP is not achieved with optimal use of other topical monotherapy and combination therapy agents, then anticholinesterase agents may be prescribed as a last topical therapy option. Anticholinesterase agents inhibit the enzyme cholinesterase, thereby increasing the amount of acetylcholine and its naturally occurring cholinergic effects.

ECHOTHIOPHATE IODIDE

Echothiophate iodide (Phospholine Iodide), an irreversible cholinesterase inhibitor, primarily inactivates pseudocholinesterase and secondarily inhibits true cholinesterase. Echothiophate iodide is the most widely used cholinesterase inhibitor for open-angle glaucoma and can be used if maximal doses of other agents and combination therapy are ineffective. Echothiophate iodide has a long duration of action that affords good control of IOP; however, miosis and myopia are significant side effects. Concentrations higher than 0.06% are associated with a significant increase in subjective complaints (e.g., brow ache).⁷⁷

Combination Therapy

In general, drugs with different pharmacologic actions have at least partially additive effects in lowering IOP in the treatment of glaucoma. Drugs with similar pharmacologic actions (i.e., from the same pharmacologic class) should not be combined because dose-related adverse effects are more likely and the incremental increase in benefits is likely to be more modest.

Timolol and other β -adrenergic blocking drugs have additive IOP-lowering effects when used in combination with epinephrine,⁷⁸ dipivefrin,^{78,79} miotics, prostaglandin analogs,^{54,80} α_2 -agonists,⁸¹ and CAIs.^{82–84} For example, the IOP-lowering effect is greater when timolol is used in combination with pilocarpine,^{53,85} dorzolamide,⁸⁵ brimonidine,^{54,81,86} and travoprost.^{53,56} Likewise, for example, latanoprost has additive effects when administered with timolol,^{53,58} dorzolamide,^{55,56} α_2 -adrenergic agonists,^{54,55,86} and dipivefrin.^{53,55–57} Other combinations of drugs also provide additive effects when used in combination for the management of increased intraocular pressure.

The trend toward the development of fixed-combination products offers many advantages in the treatment of POAG. These advantages include: improved adherence due to a reduction in the number of dosages and bottles, eliminating the need to instill two separate drugs 5 to 10 minutes apart to prevent a washout effect from the second medication; improving safety and tolerability by limiting the exposure to the benzalkonium chloride preservative; and a cost savings for the patient by potentially eliminating a co-pay for one of the medications. Currently, timolol/dorzolamide (Cosopt) is the only topical β -blocker combination product. The IOP lowering effects of Cosopt are comparable to or greater than latanoprost monotherapy.⁸⁷ Several other combination products are under investigation for POAG that will offer a wide range of options for patients. These investigational agents include timolol/latanoprost (Xalacom), timolol/travoprost (DuoTrav, Extravan), and timolol/bimatoprost.^{88,89}

Predisposing Factors

1. M.H., a 52-year-old African American woman with brown eyes, presented for routine ophthalmic examination. Visual acuity without correction was 20/40 right eye and 20/80 left eye. Tonometry measured an IOP of 36 mmHg in both eyes. Ophthalmoscopy revealed physiologic cupping of the optic discs in both eyes, and visual field examination revealed a nerve fiber bundle defect consistent with glaucoma. Pupils were normal both eyes, and gonioscopy indicated that anterior chamber angles were open in both eyes.

There were no signs of cataract formation. M.H. related a positive family history for glaucoma and presently is being treated for hypertension, CHF, and asthma. Her medications include the following:

| | |
|------------------|------------------|
| Amitriptyline | 75 mg at bedtime |
| Chlorpheniramine | 4 mg Q 6 hr PRN |
| Digoxin | 0.25 mg daily |
| Furosemide | 40 mg BID |
| Nitroglycerin | 1/150 g SL PRN |
| Theophylline SR | 300 mg Q 12 hr |

Findings on examination indicate that M.H. has POAG. What other factors may predispose M.H. to an increased IOP?

POAG is thought to be determined genetically, and M.H. has a positive family history. The disease is more prevalent and aggressive in African Americans.¹ In addition, she is taking several medications that have been associated with increases in IOP.

Anticholinergic Drugs

Most reports dealing with drug-induced increases in IOP center around precipitation of angle-closure glaucoma by topical mydriatic/cycloplegic agents (anticholinergics). In patients with open-angle glaucoma, topical anticholinergics can significantly increase resistance to aqueous humor outflow and elevate IOP while the anterior chamber remains grossly open.² As part of any routine ophthalmic examination, the pupils are dilated with a mydriatic/cycloplegic (unless otherwise contraindicated). The IOP is always measured before this procedure, so the use of these agents would not have influenced the IOP readings in M.H.

If systemic anticholinergic agents are administered in doses sufficient to cause pupillary dilation, the risk of precipitating angle-closure increases. However, it is unlikely that these agents will aggravate open-angle glaucoma unless the amount reaching the eye is sufficient to cause cycloplegia.² Although literature documentation of POAG exacerbation by these agents is scarce, medications with anticholinergic side effects (antihistamines, benzodiazepines, disopyramide, phenothiazines, tricyclic antidepressants) should be considered. M.H. is receiving chlorpheniramine as needed (PRN) and amitriptyline at bedtime, but her pupil examination is normal with no evidence of mydriasis or cycloplegia. Therefore, it is highly unlikely that these medications contributed to her increased IOP.

Adrenergic Drugs

Adrenergic agents, such as central nervous system (CNS) stimulants, vasoconstrictors, appetite suppressants, and bronchodilators, may produce minimal pupillary dilation. These have no proven adverse influences on IOP in patients with either normal eyes or eyes with open-angle glaucoma. Consequently, the use of theophylline in M.H. is also an unlikely source of the increased IOP.

Other Drugs

Conclusive evidence for the production of angle-closure glaucoma by vasodilators is lacking, although slight increases in IOP have been reported. Use of nitroglycerin (NTG) as needed in M.H. is not a cause for concern. There have been isolated reports of other medications causing mydriasis in

glaucoma patients. These include muscle relaxants (carisoprodol), monoamine oxidase inhibitors, fenfluramine, ganglionic blocking agents, salicylates, oral contraceptives, and chlorpropamide. Succinylcholine, ketamine, and caffeine have been associated with increases in IOP. α -chymotrypsin has been reported to increase IOP in patients who have received the medication during operative procedures; these patients' outflow channels probably were obstructed by debris generated from use of the enzyme.⁶⁸ Corticosteroid-induced IOP elevation is presented in Question 14. If M.H. requires administration of any other medications associated with increases in IOP, the risk of potential adverse effects can be minimized by routine follow-up.

Initial Therapy

2. What is the best initial therapeutic treatment in M.H.?

Topical β -blockers or prostaglandin analogs (PGAs) are the initial agents of choice in the treatment of POAG (Fig. 51-2). Their efficacy is well documented in numerous studies, and side effects are well characterized. Brimonidine (Alphagan) and topical carbonic-anhydrase inhibitors (CAIs) are alternative first-line agents. Table 51-1 lists the common topical agents used in the treatment of primary open angle glaucoma.

Timolol or other nonselective β -adrenergic blockers should not be initiated for M.H. because of her history of asthma (the indications and use of β -blockers for patients with heart failure are described in Chapter 18, Heart Failure). Betaxolol, a β_1 -adrenergic blocker, is better tolerated than the nonselective β -adrenergic blocker, timolol, in patients with reactive airway disease and should be considered when topical β -blocker therapy is indicated in patients such as M.H.^{46–48} Betaxolol 0.25% suspension BID would be reasonable for the initial treatment of M.H.'s glaucoma. Nevertheless, adverse pulmonary and cardiac side effects can occur with betaxolol: M.H. should be followed-up closely for these adverse effects. Although ocular burning and stinging have been associated more frequently with betaxolol and metipranolol than with other topical β -blockers, the 0.25% suspension is better tolerated than the 0.5% solution and is as effective.⁴⁹ Brimonidine, a topical CAI, or a prostaglandin analog (e.g., latanoprost) are acceptable alternatives to betaxolol as initial therapy. Although brimonidine, topical CAIs, and latanoprost may not exacerbate her asthma or CHF, they can cause localized side effects and brimonidine can cause systemic hypotension and lethargy.

Patient Education

3. Betaxolol 0.25% suspension, one to two drops both eyes BID, is ordered for M.H. How should M.H. be instructed regarding the proper use of her betaxolol and expected therapeutic side effects?

M.H. should be instructed to hold the inverted betaxolol bottle between her thumb and middle finger and to rest this hand on her forehead to minimize the risk of inadvertent eye injury caused by sudden unexpected movement of the hand. The index finger is left free to depress the bottom of the container, releasing one drop for the dose. With a little practice, this technique is easy to master. The lower eyelid should be drawn downward with the index finger of the opposite hand or

pinched between the thumb and index finger to form a pouch. The patient should look up and administer the drug into the pouch of the eye.

Patients must be encouraged to continue regular use of their medications for effective treatment of glaucoma. Chronic glaucoma is a silent disease and often not associated with symptoms; therefore, the continuation of therapy should be encouraged continuously in patients, especially when side effects to drug therapy can be encountered. Betaxolol is best administered Q 12 hr, because this schedule of administration is consistent with its duration of action (see Table 51-1).

Systemic side effects (e.g., bradycardia, heart block, CHF, pulmonary distress, CNS) are rare with betaxolol, but M.H. should be instructed to report any of these effects to her primary care provider.

Nasolacrimal Occlusion

4. How much would occlusion of the nasolacrimal ducts (punctal occlusion) by M.H. influence systemic absorption or alter the therapeutic effects of betaxolol?

Nasolacrimal, or punctal, occlusion is a technique that can decrease the amount of drug absorbed systemically.⁹⁰ Occlusion of the puncta (through the application of slight pressure with the finger to the inner corner of the eye closest to the nose for 3 to 5 minutes during and after drug instillation) can minimize systemic absorption of ophthalmic medications (e.g., betaxolol) and decrease the incidence of side effects and improve medication effectiveness.^{90–92} When a single drop of ophthalmic timolol 0.5% was instilled into the eyes of patients at various times before cataract surgery and the nasolacrimal duct occluded for 5 minutes, drug levels in the aqueous humor were significantly greater in patients who had their nasolacrimal ducts occluded than those who did not.⁹¹ The average measured maximum aqueous humor timolol concentration of 1.66 mcg/mL in the occlusion group was significantly greater than 0.85 mcg/mL in the nonocclusion group. The area under the curve was 1.7 times greater in patients who used the technique of nasolacrimal occlusion, and the duration of action was prolonged.⁹¹

Nasolacrimal occlusion is effective and can maximize drug benefits because a lower concentration of an ophthalmic formulation can be used and the dose administered less frequently. Pilocarpine 1% and 2% significantly decreased IOP at 6, 8, and 12 hours after instillation when the technique of nasolacrimal occlusion was applied.⁹⁰ Similarly, carbachol 1.5%, 3%, and the combination of carbachol 1.5% with timolol 0.25% Q 12 hr also were maximally beneficial with nasolacrimal occlusion.⁹⁰ Timolol reduced IOP by 15% and maintained this reduction of IOP at 24 hours in 92% of patients when nasolacrimal occlusion was used; in comparison, only 55% achieved comparable IOP reductions when nasolacrimal ducts were not occluded.⁹⁰ When nasolacrimal occlusion is used, pilocarpine 2% and carbachol 1.5% can be administered Q 12 hr rather than the usual TID or QID regimens needed when the technique of nasolacrimal occlusion is not applied.⁹⁰ The Q 12-hr regimen of treatment then can be adjusted according to the patient's response. Timolol can be administered Q 24 hr, if the nasolacrimal occlusion technique is used.⁸⁵ If nasolacrimal occlusion is used consistently and properly, maximal drug effect can be achieved with a reduced frequency of administration

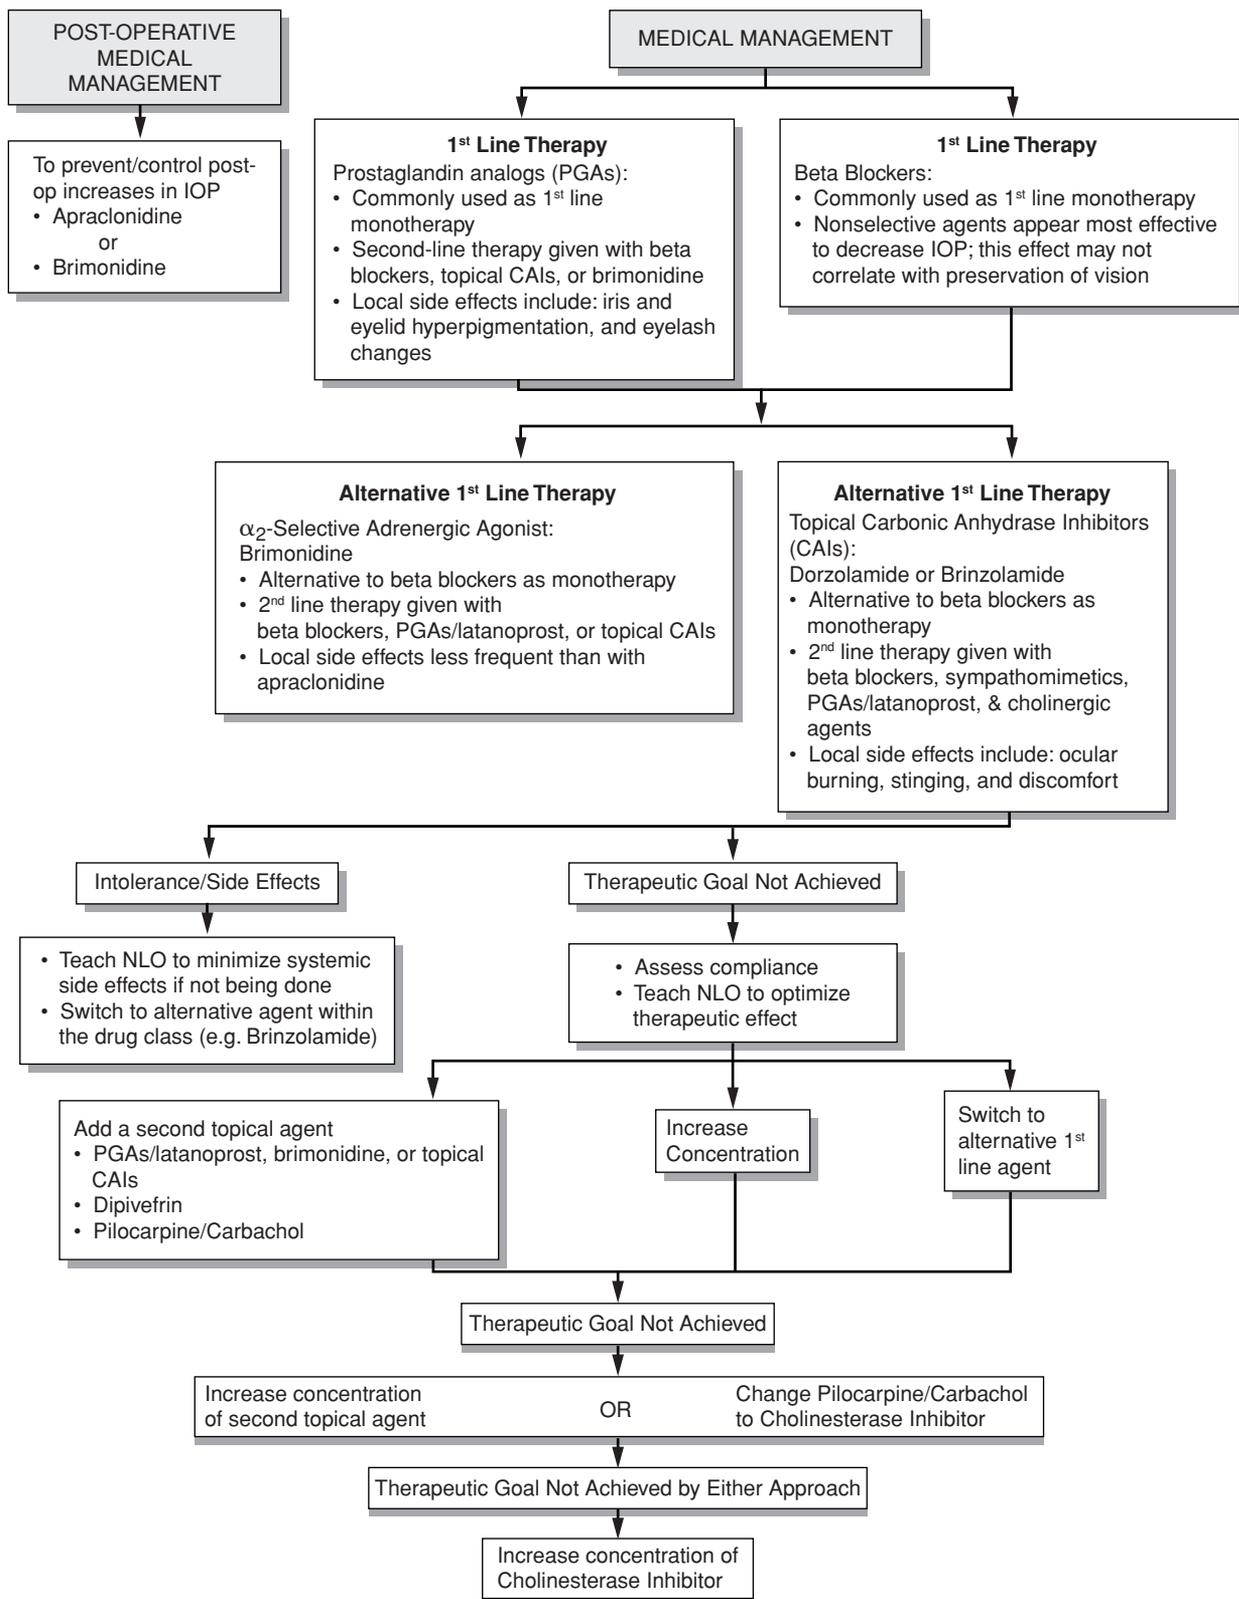

FIGURE 51-2 Medical management of glaucoma. IOP, intraocular pressure; NLO, nasolacrimal occlusion.

Table 51-1 Common Topical Agents Used in the Treatment of Open-angle Glaucoma

| <i>Generic</i> | <i>Mechanism</i> | <i>Strength</i> | <i>Usual Dosage</i> | <i>Comments</i> |
|--|------------------------------------|--------------------|--|--|
| β-Blockers | | | | |
| Betaxolol (Betoptic [solution], Betoptic S [suspension]) | Sympatholytic | 0.25% (suspension) | 1 drop BID | Effective with few associated ocular side effects. BID dosage enhances compliance. May be the ocular β -blocker of choice in patients with pre-existing CHF or pulmonary disease, because of β_1 -adrenergic specificity. Patient response may be less than that seen with timolol. |
| Carteolol (Ocupress) | Sympatholytic | 1% | 1 drop BID | Effective with few associated side effects. BID dosage enhances compliance. Use with caution in patients with pre-existing CHF or pulmonary disease. |
| Levobunolol (Betagan) | Sympatholytic | 0.25%–0.5% | 1 drop Daily or BID | Effective with few associated ocular side effects. Daily BID dosage enhances compliance. Use with caution in patients with pre-existing CHF or pulmonary disease. |
| Metipranolol (OptiPranolol) | Sympatholytic | 0.3% | 1 drop BID | Effective with few associated side effects. BID dosage enhances compliance. Use with caution in patients with pre-existing CHF or pulmonary disease. |
| Timolol (Timoptic) | Sympatholytic | 0.25%–0.5% | 1 drop BID | Effective with few associated ocular side effects. BID dosage enhances compliance. Use with caution in patients with pre-existing CHF or pulmonary disease. Proven long-term effectiveness, with well-defined side effect profile. |
| Timolol Gel Forming Solution (Timoptic XE) | Sympatholytic | 0.25%–0.5% | 1 drop Daily | New once-daily timolol formulation. The ophthalmic vehicle, gellan gum (Gelrite), prolongs precorneal residence time and \uparrow ocular bioavailability, allowing once daily administration. |
| α_2-Selective Adrenergic Agonists | | | | |
| Apraclonidine (Iopidine) | Sympathomimetic | 0.5%–1% | 1 drop preop and postop or 1 drop BID to TID | May be used preop and postop for the prevention of \uparrow IOP after anterior-segment laser procedures. Use of NLO minimizes systemic side effects and allows for BID dosing. Does not penetrate the blood–brain barrier; therefore, negligible systemic hypotension. Local adverse effects fairly common. Tachyphylaxis may be observed. |
| Brimonidine (Alphagan) | Sympathomimetic | 0.2% | 1 BID to TID | Effective long-term monotherapy or adjunctive therapy. Use of NLO minimizes systemic side effects and allows for BID dosing. Penetrates the blood–brain barrier; therefore, may cause mild systemic hypotension, and lethargy. Local adverse effects less common than with apraclonidine. |
| Brimonidine (Alphagan P) | Sympathomimetic | 0.1%–0.15% | 1 BID to TID | Contains PURITE preservative. PURITE preservative and lower concentrations may improve tolerability. |
| Topical Carbonic Anhydrase Inhibitor | | | | |
| Brinzolamide (Azopt) | Decreased aqueous humor production | 1% | 1 drop TID | Effective long-term monotherapy or adjunctive therapy. Well tolerated with few systemic side effects. Less burning and stinging compared to dorzolamide. |
| Dorzolamide (Trusopt) | Decreased aqueous humor production | 2% | 1 drop TID | Effective long-term monotherapy or adjunctive therapy. Well tolerated with few systemic side effects. |

Table 51-1 Common Topical Agents Used in the Treatment of Open-angle Glaucoma (Continued)

| <i>Generic</i> | <i>Mechanism</i> | <i>Strength</i> | <i>Usual Dosage</i> | <i>Comments</i> |
|---|---------------------------------------|--|--|--|
| Prostaglandin Analogs | | | | |
| Latanoprost (Xalatan) | Prostaglandin F _{2α} agonist | 0.005% | 1 drop once a day at bedtime | BID dosing may be less effective than once a day at bedtime dosing. May cause increased pigmentation of the iris. Systemic side effects are rare, but may cause muscle, joint, back pain, headaches, migraines, and skin rash. Effective monotherapy or adjunctive therapy. May cause increased pigmentation of the iris and eyelid. Store unopened bottles in refrigerator. Opened bottles may be stored at room temperature up to 6 weeks. |
| Travoprost (Travatan) | Prostaglandin F _{2α} agonist | 0.004% | 1 drop once a day at bedtime | BID dosing may be less effective than once a day at bedtime dosing. May cause increased pigmentation of the iris and eyelid. Systemic side effects are rare, but may include colds and upper tract infections. Effective monotherapy or adjunctive therapy with timolol. May be more effective than timolol and latanoprost and more effective in African Americans. |
| Travoprost (Travatan Z) | Prostaglandin F _{2α} agonist | 0.004% | 1 drop once a day at bedtime | Benzalkonium chloride preservative replaced with a preservative that may be better tolerated. |
| Bimatoprost (Lumigan) | Prostamide | 0.03% | 1 drop once a day at bedtime | BID dosing may be less effective than QHS dosing. May cause increased pigmentation of the iris and eyelid. Systemic side effects are rare but include colds and upper respiratory tract infections and headache. May be more effective than timolol and latanoprost. |
| Miotics | | | | |
| Pilocarpine (Isopto-Carpine) | Parasympathomimetic | 0.25%–10% 4% (ointment) 20–40 mcg/hr (Ocusert) | 1–2 drops TID or QID 1/2 inch in cul-de-sac daily Weekly | Long-term proven effectiveness. Little rationale for use of concentrations >4% or administration more frequently than Q 4 hr. Side effects of miosis with decreased vision and brow ache are common sources of patient complaints. Once-daily administration of ointment may increase compliance. Effectiveness over 24 hours should be assessed in patients receiving the ointment. Ointment may cause a visual haze and blurred vision. |
| Carbachol (Isopto-Carbachol) | Parasympathomimetic | 0.75–3% | 1–2 drops TID–QID | Used in patients allergic to or intolerant of other miotics. May be used as frequently as Q 4 hr. Corneal penetration is enhanced by benzalkonium chloride in commercial preparations. Side effects are similar to those of pilocarpine. |
| Echothiophate Iodide (Phospholine Iodide) | Anticholinesterase | 0.03%–0.25% | 1 drop BID | Most used anticholinesterase agent. Long duration, although usually dosed BID, which enhances compliance. Available as powder + diluent, following reconstitution stable 30 days room temp, 6 months refrigerated. Side effects similar to those of pilocarpine, especially in concentrations >0.06%. Increased cataract formation has been associated with its use. |

(continued)

Table 51-1 Common Topical Agents Used in the Treatment of Open-angle Glaucoma (Continued)

| Generic | Mechanism | Strength | Usual Dosage | Comments |
|--|-----------------|----------|--------------|---|
| Mydriatics | | | | |
| Epinephrine (Glaucon, Eppy/N, Epirate) | Sympathomimetic | 0.25%–2% | 1 drop BID | Good response often seen with use of lower concentrations (0.5%–1%). Bitartrate salt contains half-labeled strength in epinephrine-free base equivalent. BID dosage enhances compliance. Cosmetic complaints associated with use include hyperemia and pigment deposits on the cornea and conjunctiva. Not recommended for use in aphakic patients because of 20%–30% incidence of cystoid macular edema. |
| Dipivefrin (Propine) | Sympathomimetic | 0.1% | 1 drop BID | Prodrug of epinephrine associated with increase in systemic side effects if absorbed. BID dosage enhances compliance. |

CHF, congestive heart failure; NLO, nasolacrimal occlusion.

and at about half of the drug concentrations typically used. Nasolacrimal occlusion should be incorporated into patient counseling for instillation of all eye drops.⁹⁰

Alternative Therapy

5. Two weeks after initiation of therapy, M.H. returns to clinic for a follow-up evaluation. Her IOP measures 32 mmHg right eye and 30 mmHg left eye. She denies noncompliance and has no complaints of intolerable side effects. How should therapy be altered? Are there alternative dosage forms or drugs that can be used?

Betaxolol may not be as effective as other ocular β -blockers. Therefore, adjunctive therapy may be required. However, M.H. should be evaluated to determine whether she has been using the technique of nasolacrimal occlusion. If not, M.H. should be again instructed on the technique of nasolacrimal occlusion and the importance of this technique in achieving the maximum therapeutic effect of her therapy (see previous question).

After the initiation of therapy, patients should be seen for a follow-up evaluation within about 2 weeks. If M.H. has been adherent to therapy and has been occluding her nasolacrimal ducts, a new course of action is needed because her intraocular pressure still is elevated. When the goal of therapy has not been achieved, the drug concentration of the ophthalmic formulation can be increased; adjunctive therapy (e.g., brimonidine, a topical CAI, a PGA) can be initiated; or an alternative first-line agent can be selected. Patients who are experiencing unstable reductions of IOP should be followed up within 4 months.³ Stable patients usually are evaluated every 6 to 12 months.³

Adverse Effects

6. Several weeks later, dorzolamide 2% solution, one drop both eyes BID is added to M.H.'s betaxolol therapy. Two weeks later, M.H. returns for a follow-up evaluation and complains of bilateral stinging and foreign body sensation. Her IOP measures 30 mmHg in the right eye and 29 mmHg in the left eye. What

are the possible causes of her side effects and poor response to therapy?

The exposure of dorzolamide to the outside environment may result in the aggregation of dry white granules on the tip of the dorzolamide bottle. These granules can drop into a patient's eyes when instilling the medication, leading to local side effects, such as stinging and foreign body sensation. Such foreign bodies may cause enough discomfort to induce noncompliance, resulting in a poor response to therapy. M.H. should be questioned about the presence of dry white granules on the tip of her dorzolamide bottle.⁹³

These complaints may also be a side effect from the medications, regardless of the granule presence. Ocular burning, stinging, and discomfort were reported in one-third of patients in dorzolamide clinical trials. M.H.'s administration technique should also be assessed to determine whether she is administering the two drugs at least 5 to 10 minutes apart so that the first drug is not washed away by the second drug. This should be a consideration when assessing her response to therapy.⁵

7. After further discussions with M.H., it is determined that she has not been adherent to her dorzolamide therapy because of intolerable side effects. The dorzolamide is discontinued and replaced with travoprost 0.004% one drop both eyes once a day at bedtime. Why might this drug selection be especially appropriate for M.H.? What patient education information should be provided to M.H. about travoprost side effects?

Prostaglandin analogs are first-line agents and are appropriate in patients who are not responding or having intolerable side effects from other medications. Travoprost is an ideal choice for M.H., because African Americans respond especially well to travoprost.⁵⁸ M.H. still needs to be informed about the PGA-induced potential for hyperpigmentation of the iris, which may be permanent. She also needs to be educated on the possibility of eyelid skin darkening and increased thickness, length, and pigmentation of her eyelashes, which all may be reversible. These side effects might not be as cosmetically concerning to M.H., because she has brown eyes and will be instilling travoprost eye drops into both eyes.

Table 51-2 CAIs Used in Treatment of Glaucoma

| Agent | Strength | Onset (min) | Peak (hr) | Duration (hr) | Usual Dose |
|-------------------------|------------------|-------------|-----------|---------------|------------|
| Acetazolamide injection | 500 mg | 5–10 | | 2 | 500 mg |
| Acetazolamide tablets | 125 mg 250 mg | 120 | 4 | 6–8 | 250 mg QID |
| Acetazolamide sequels | 500 mg | 120 | 8–18 | 22–30 | 500 mg BID |
| Dichlorphenamide | 50 mg | 30 | 2–4 | 6–12 | 50 mg TID |
| Methazolamide | 50 mg | 120 | 4–8 | 10–12 | 50 mg TID |

CAIs, carbonic anhydrase inhibitors.

ANGLE-CLOSURE GLAUCOMA

Treatment

8. D.H., a 72-year-old man, presents to the emergency department (ED) with an intensely red right eye, a “steamy” appearing cornea, complaints of haloes around lights, and extreme pain. A diagnosis of acute angle-closure glaucoma is made. How should D.H. be managed?

D.H. should be seen by an ophthalmologist, because acute angle-closure glaucoma is a medical emergency. Medical treatment usually consists of pilocarpine 2% to 4%, one drop every 5 minutes for four to six administrations. It is recommended that the puncta be covered during administration to decrease the possibility of systemic absorption. Stronger miotics are contraindicated, because they may potentiate angle closure. Topical timolol also has been used in acute angle-closure glaucoma, commonly in combination with pilocarpine. However, drugs that decrease aqueous humor production may be ineffective in this situation, because they have a decreased ability to reduce aqueous production if the ciliary body is ischemic.⁴

Hyperosmotic Agents

Hyperosmotic agents act by creating an osmotic gradient between the plasma and ocular fluids.⁹⁴ Agents that are confined to the extracellular fluid space (e.g., mannitol) provide a greater effect on blood osmolality at the same dosage than do agents distributed in total body water.⁹⁴ Intravenously administered drugs provide a faster, somewhat greater effect than oral agents. Palatability may be a problem with oral agents and can be improved by serving these agents over crushed ice or with lemon juice or cola flavoring.

Orally, 50% glycerin is the usual drug of choice and is administered in dosages of 1 to 1.5 g/kg.⁹⁵ Isosorbide is an alternative, especially in diabetic patients because it is not metabolized to provide calories.⁹⁶ Ethyl alcohol (2–3 mL/kg) is

effective and can be helpful in emergency situations when other agents are unavailable.⁹⁷ Parenterally, mannitol is the drug of choice. It is administered in doses of 1 to 2 g/kg, is not metabolized to provide calories, and may be used in patients with renal failure.^{98,99}

Primary side effects of hyperosmotic agents include headache, nausea, vomiting, diuresis, and dehydration. It is important that the patient not be allowed to drink because this will counteract the osmotic effects of these agents. Precipitation of pulmonary edema and CHF has been reported with hyperosmotic agents, and an allergic reaction has been reported with mannitol.^{99,100}

Acetazolamide (Diamox) 500 mg intravenously is often administered in addition to hyperosmotic agents (Tables 51-2 and 51-3).

OCULAR SIDE EFFECTS OF DRUGS

9. B.C., a 64-year-old man, has a history of hypertension managed with hydrochlorothiazide 25 mg/day. He takes amiodarone 800 mg/day for cardiac arrhythmia, and chlorpheniramine 12 mg BID PRN for allergies. Four weeks ago, risperidone 1 mg BID was added to his medication regimen. He also takes sildenafil 100 mg an average of twice weekly. He complains of occasional blurred vision. Could these symptoms be related to his medications?

All the drugs that B.C. is taking have been associated with ocular side effects. Thiazide diuretics have been associated with acute myopia that may last from 24 to 48 hours.^{101,102} However, hydrochlorothiazide is an unlikely cause of B.C.’s blurred vision considering its recent onset.

Amiodarone can cause keratopathy, but it is asymptomatic.^{103,104} A high percentage of patients who receive this drug develop microdeposits within the corneal epithelium that resemble the verticillate keratopathy induced by chloroquine.¹⁰³ These corneal deposits are bilateral, dose and

Table 51-3 Hyperosmotic Agents

| Generic | Mode of Administration | Strength | Onset | Peak | Duration | Dose | Ocular Penetration | Distribution |
|---------------|------------------------|-------------------|-----------|--------|----------|------------|--------------------|--------------|
| Mannitol | IV | 5%, 10%, 15%, 20% | 30–60 min | 1 hr | 6–8 hr | 1–2 g/kg | Very poor | E |
| Glycerin | PO | 50% | 10–30 min | 30 min | 4–5 hr | 1–1.5 g/kg | Poor | E |
| Isosorbide | PO | 45% | 10–30 min | 1 hr | 5 hr | 1.5–2 g/kg | Good | TBW |
| Ethyl alcohol | PO | 50% | | | | 2–3 mL/kg | Good | TBW |

E, Extracellular water; TBW, total body water.

duration related, reversible, and unassociated with visual symptoms.

Risperidone has been associated with disturbances of accommodation and blurred vision.^{104, 105}

B.C. may be one of the approximately 1% of the population who experiences blurred vision with chlorpheniramine. This effect has been seen in patients receiving 12 to 14 mg/day.^{100, 101}

Sildenafil has been associated with change in color and light perception as well as blurred vision.¹⁰⁶ These effects generally subside within 4 hours of the dose.

Table 51-4 outlines some of the more common ocular side effects associated with systemic medications. Each case should be evaluated individually and alternative therapy considered in intolerant patients.

OCULAR EMERGENCIES

Chemical Burns

10. S.J., a 24-year-old construction worker, has splashed an unidentified chemical in his eyes and runs into a nearby pharmacy complaining of burning in both eyes. Should the pharmacist attempt to treat S.J. or refer him to the ED?

Chemical burns require immediate attention. The immediate treatment is copious irrigation using the most accessible source of water (e.g., shower, faucet, drinking fountain, hose, bathtub). After at least 5 minutes of initial irrigation, S.J. should be taken immediately to the ED. A water-soaked towel or cloth should be kept on his eyes during transport.

Other Ocular Emergencies

When health care professionals are approached by patients with acute ocular emergencies (e.g., chemical burns, corneal trauma, corneal ulcers, acute angle-closure glaucoma), patients require immediate treatment and should be referred to an ophthalmologist if the practitioner has even the slightest doubt about appropriate therapy. It is difficult to effectively evaluate the severity of ocular disorders without the benefit of a thorough ophthalmologic workup and specialized training. In situations of corneal trauma from abrasion or foreign bodies, the patient often complains of a gritty, scratchy feeling and can be aware of a foreign body's presence. The corneal tissue is an excellent culture medium for bacteria (e.g., *Pseudomonas aeruginosa*), and therapy should be initiated as soon as possible to avoid corneal perforation and possible blindness.¹ Signs and symptoms of acute angle-closure glaucoma are reviewed in Question 8.

Gonococcal conjunctivitis is an ocular emergency and patients should be referred immediately to an ophthalmologist to minimize the potential of corneal perforation.¹ These patients, who can present with symptoms of red, tender, swollen eyelids with exophthalmos and mild pain, may be suffering from orbital cellulitis or endophthalmitis, which require immediate treatment with systemic antibiotics. Conjunctivitis of other origins (see Bacterial and Allergic Conjunctivitis sections later in this chapter) generally are not ocular emergencies.

Any loss of vision (whether sudden, complete, or transient), flashes of light, pain, or photophobia can signify potentially damaging ocular disorders (e.g., retinal artery occlusion, op-

tic neuritis, amaurosis fugax, retinal detachment) and an ophthalmologist should evaluate the patient as soon as possible. Referral also is recommended for patients with blurred vision, pupil disorders, diplopia, nystagmus, or ocular hemorrhage.

COMMON OCULAR DISORDERS

Stye (Hordeolum)

Sties are infections of the hair follicles or sebaceous glands of the eyelids. The most common infecting organism is *Staphylococcus aureus*. Treatment consists of hot, moist compresses and topical antibiotics (e.g., sulfacetamide). Over-the-counter products should not be recommended. Sties that do not respond to warm compresses within a few days should be evaluated by an ophthalmologist.

Conjunctivitis

Conjunctivitis, a common external eye problem that involves inflammation of the conjunctiva, usually is associated with symptoms of a diffusely reddened eye with purulent or serous discharge accompanied by itching, smarting, stinging, or a scratching, and foreign-body sensation. Patients with pain, decreased vision, unequal distribution of redness, irregular pupils, or opacity should be referred immediately to an ophthalmologist, because these are signs of more serious eye disease.

Conjunctivitis can be bacterial, fungal, parasitic, viral, or allergic in origin. Most cases of bacterial conjunctivitis are caused by *S. aureus*, *S. pneumococcus* (in temperate climates), or *Haemophilus aegyptius* (in warm climates), although a number of other organisms may be responsible. The infection usually starts in one eye and is spread to the other by the hands. It also may be spread to other persons. Unlike bacterial conjunctivitis, corneal infections can obliterate vision rapidly; therefore, accurate diagnosis is important.

Acute Bacterial Conjunctivitis (Pink-Eye)

11. L.T. is a 6-year-old boy with diffuse bilateral conjunctival redness that has been present for 2 days. A crusting discharge is deposited on his lashes and the corners of his eyes. His vision is normal, and his pupils are round and equal. The diagnosis of acute bacterial conjunctivitis is made, and sodium sulfacetamide 10% ophthalmic drops, two drops in both eyes Q 2 hr while awake, are prescribed. What other measures should be used? What instructions should his caregivers receive?

Although treatment of typical bacterial conjunctivitis such as this is empirical, a culture should be obtained. Other ophthalmic antibiotic drops or ointments, such as neomycin-polymyxin-B-gramicidin combination (Neosporin), also are used in these situations. Although other antimicrobials, such as the ocular quinolones may be used for bacterial conjunctivitis, these agents should be reserved as second-line therapies, because of cost and the potential development of resistance. Proper management of this infection also includes mechanical cleaning of the eyelids and hygienic measures that prevent spreading the infection to other children. The deposits should be removed as often as possible with moist cotton swabs or cotton-tipped applicators. A mild baby shampoo can be used to moisten the applicator. Firm adherent crusts may be softened with warm, moist compresses. Because this material is

Table 51-4 Ocular Side Effects of Systemic Medications

| <i>Drug Class</i> | <i>Effect(s)</i> | <i>Clinical Remarks</i> |
|--|---|--|
| Analgesics | | |
| Ibuprofen | Reduced vision | Rare; blurred vision reported in patients taking from four 200 mg tablets/wk to six tablets/day; changes in color vision rarely reported. ¹⁵⁷ |
| Narcotics, including pentazocine | Miosis Tearing Irregular pupils Paresis of accommodation Diplopia | Miosis often with morphine in normal doses: slight with other agents; effect secondary to CNS action on the pupilloconstrictor center. ^{101,102} Effects associated with narcotic withdrawal. ^{101,102} |
| Antiarrhythmics | | |
| Amiodarone | Keratopathy Cataracts Optic neuropathy | Dose and duration related; resembles chloroquine keratopathy. Corneal deposits are bilateral, reversible, and unassociated with visual symptoms. Patients taking 100–200 mg/day have only minimal deposits. Deposits occur in almost 100% of patients receiving 400 mg/day. ^{101–104} Previously reported as insignificant, anterior subcapsular lens opacities have been associated with amiodarone therapy. Rarely, such opacities may progress, increasing in density and in the diffuse distribution of the deposits, ultimately covering an area somewhat larger than the undilated pupil's aperture. The mechanism for this effect is unclear, but like chlorpromazine, amiodarone is a photosensitizing agent. Given that the lens changes are limited largely to the pupillary aperture, light exposure may result in the lens changes. ^{101–104} Approximately 2% of patients experience optic neuropathy. ¹⁰⁶ |
| Anticholinergics | | |
| Atropine Dicyclomine Glycopyrrolate Propantheline Scopolamine Trihexyphenidyl | Mydriasis Cycloplegia with ↓ accommodation Photophobia | Systemic and transdermal anticholinergic agents may cause mydriasis and, less frequently, cycloplegia. Mydriasis may precipitate angle-closure glaucoma. Photophobia is related to the mydriasis. Accommodation for near objects. ^{101,102,158} |
| Anticonvulsants | | |
| Carbamazepine | Diplopia Blurred vision | Ocular adverse reactions when dosage >1–2 g/day; disappear when dosage is reduced. ¹⁰¹ |
| Phenytoin | Nystagmus Cataracts | Nystagmus in patients with high blood levels (>20 mcg/mL); rarely occurs with other hydantoin. Cataracts may occur rarely with prolonged therapy. ^{101,102,159} |
| Topiramate | Acute myopia Secondary angle closure glaucoma | Topiramate has been associated with angle-closure glaucoma. Symptoms including ocular pain, headache, nausea, vomiting, hyperemia, visual field defects, and blindness have been reported. This process is usually bilateral, but if symptoms are recognized and the drug is stopped in a timely manner, adverse outcomes may be minimized. ¹⁰⁶ |
| Trimethadione | Visual glares | A prolonged glare or dazzle occurs when eyes are exposed to light. The glare is reversible, occurs at the retinal level, and is more common in adolescents and adults; rarely in young children. ^{101,102} |
| Vigabatrin | Visual field abnormalities | Visual field abnormalities including bilateral, symmetrical, and irreversible peripheral constriction occur in up to 30% of patients. Most patients are asymptomatic and <0.1% of patients are clinically affected. ¹⁰⁶ |
| Anesthetics | | |
| Propofol | Inability to open eyes | 6 of 50 patients undergoing ENT procedures using standardized anesthesia with propofol were unable to open their eyes either spontaneously or in response to verbal commands. This effect lasted from 3–20 min after the end of anesthetic administration. Two patients showed complete loss of ocular motility. This was a transient, myastheniclike weakness. ¹⁶⁰ |

(continued)

Table 51-4 Ocular Side Effects of Systemic Medications (Continued)

| <i>Drug Class</i> | <i>Effect(s)</i> | <i>Clinical Remarks</i> |
|----------------------------------|--|--|
| Antidepressants | | |
| Tricyclic antidepressants (TCAs) | | Mydriasis is most common ocular side effect of TCAs. Cycloplegia is rare. Reports of precipitation of angle-closure glaucoma. ^{101,102} |
| Fluoxetine | Mydriasis Cycloplegia Eye tics | Administration of fluoxetine 20–40 mg/day has been associated with paroxysmal contractions of the muscles around the lateral aspect of the eye. This effect occurred 3–4 wk after initiation of fluoxetine therapy and resolved within 2 wk of discontinuation. ¹⁶¹ |
| Antihistamines | | |
| Chlorpheniramine | Blurred vision Mydriasis, decreased lacrimal secretions | Blurred vision occurs rarely (about 1% of patients taking 12–14 mg/day). ^{101,102} Rare ^{101,102} |
| Antihypertensives | | |
| Clonidine | Miosis Dry itchy eyes | Miosis is seen in overdose. ¹⁰² Rare ¹⁰² |
| Diazoxide | Lacrimation | About 20% experience lacrimation, which may continue after drug is discontinued. ¹⁰¹ |
| Guanethidine | Miosis Ptosis Conjunctivitis Blurred vision | Sporadically documented. One study reported a 17% incidence of blurred vision in patients taking guanethidine 70 mg/day. ^{101,102} |
| Reserpine | Miosis Conjunctivitis | Miosis is slight, but can last up to 1 wk after a single dose ^{101,102} Common, secondary to dilation of conjunctival blood vessels ^{101,102} |
| Anti-Infectives | | |
| Amantadine | Corneal lesions | Diffuse, white punctate subepithelial corneal opacities have been reported, occasionally associated with superficial punctate keratitis. Onset has been 1–2 wk after initiation of therapy with dosages of 200–400 mg/day. Resolves with drug discontinuation. ¹⁶² |
| Chloramphenicol | Optic neuritis | Rare unless a total dose of 100 g and duration >6 wk are exceeded. Vision usually improves after the drug is discontinued. ^{101,102} |
| Chloroquine | Corneal deposits | Some patients using ordinary doses may develop corneal deposits in a few months. The deposits are visible with use of a biomicroscope, appear as white-yellow in color, but are of no consequence. ^{101,102} |
| | Retinopathy (macular degeneration) | Serious retinopathy when total dose >100 g. Usually develops after 1–3 yr; can occur in 6 mon. Visual loss may be peripheral, with progression to central vision loss and disturbance of color vision. Rarely, effects such as blurred vision are seen earlier when larger doses (500–700 mg/day) are used. Macular changes may progress after drug is discontinued. These agents concentrate in pigmented tissue. ^{101,102} |
| Ethambutol | Retrobulbar neuritis | At dosages of 15 mg/kg/day, virtually void of ocular side effects. Such effects are rare at dosages of 25 mg/kg/day for a duration of a few months. Patients treated for prolonged periods should have routine visual examinations including visual fields. Most effects are reversible after the drug is discontinued, but optic neuritis may continue to progress for 1–2 mon after the drug has been discontinued. ^{101,102,106} |
| Gentamicin | Pseudotumor cerebri | Rare, but has been well documented with secondary papilledema and visual loss ^{101,102} |
| Isoniazid | Optic neuritis | Prevalence not well defined, but appears to be significantly less than peripheral neuritis. Evaluation difficult because most patients malnourished, chronic alcoholics, or receiving multiple medications. Pre-existing eye disease does not appear to be a predisposing factor. ^{101,102} |
| Nalidixic acid | Visual sensations | Most common ocular side effect. Main feature a brightly colored appearance of objects; occurs soon after the drug is taken. Although quinolone antibiotics are nalidixic acid derivatives, they have rarely been associated with these ocular side effects. ^{101,102} |
| | Visual loss | Temporary effect (30 min–3 days.) |
| | Papilledema | Primarily in infants and young children and secondary to intracranial pressure; reversible upon withdrawal of the drug. |
| Sulfonamides | Myopia | Acute and reversible; most common ocular side effect. ^{101,102} |
| | Conjunctivitis | Primarily with topical sulfathiazole, 4% incidence between the fifth and ninth days of therapy. ^{101,102} |
| | Optic neuritis | Even in low dosages. Usually reversible with complete recovery of vision. ^{101,102} |

Table 51-4 Ocular Side Effects of Systemic Medications (Continued)

| <i>Drug Class</i> | <i>Effect(s)</i> | <i>Clinical Remarks</i> |
|--|--|---|
| Tetracyclines | Photosensitivity Myopia | Associated with use of sulfisoxazole lid margin therapy. ^{163,164} Appears to be acute, transient, and rare. ^{101,102} |
| Voriconazole | Papilledema Altered visual perception Blurred vision | More common in children and infants than adults; rare. ^{101,102} May be associated with higher doses or plasma concentrations. ¹⁶⁵ |
| Anti-Inflammatory Agents (also see Analgesics; Corticosteroids) | | |
| Cyclo-oxygenase-2 inhibitors | Blurred vision Conjunctivitis | Discontinuation of therapy leads to resolution without long-term effects. ¹⁰⁶ |
| Gold | Corneal Conjunctival deposits | Deposition in the conjunctiva and superficial cornea more common than in the lens or deep cornea. Incidence in cornea of 40%–80% in total doses of 1.5 g; visual acuity is unaffected. One reported case after oral therapy. ¹⁰¹ |
| Indomethacin | Decreased vision | Rare; also changes in color vision have been rarely reported. ^{101,102} |
| Phenylbutazone | Decreased vision Conjunctivitis Retinal hemorrhage | Most common ocular side effect with this drug may be caused by lens hydration. ^{101,102} Occurs less often than vision. The conjunctivitis may be associated with development of Stevens-Johnson syndrome or an allergic reaction. ^{101,102} |
| Antilipemic Agents | | |
| Lovastatin | Cataracts | The crystalline lenses of hypercholesteremic patients were assessed before and after 48 wk of treatment with lovastatin 20–80 mg/day. Statistical analyses of the distribution of cortical, nuclear, and subcapsular opacities at 48 wk showed no significant differences between placebo-treated and lovastatin-treated groups. Visual acuity assessments also were not significantly different among the groups. ¹⁶⁶ |
| Antineoplastic Agents | | |
| Busulfan | Cataracts | Reported with high dosages. ^{101,102} |
| Carmustine | Arterial narrowing Nerve fiber-layer infarcts Intraretinal hemorrhages | These ocular side effects are not well established. Evidence of delayed bilateral ocular toxicity developed in 2 of 50 patients treated with high-dose IV carmustine (800 mg/m ²). Symptoms of ocular toxicity became evident 4 wk after IV treatment. Evidence of delayed ocular toxicity (mean onset 6 wk) ipsilateral to the site of infusion developed in 7 of 10 patients treated with intra-arterial carotid doses of carmustine to a cumulative minimum of 450 mg/m ² in two treatments. ¹⁶² |
| Cytarabine | Keratoconjunctivitis Ocular burning Photophobia Blurred vision | Corneal toxicity and conjunctivitis have been reported with high-dose (3 g/m ²) therapy. ^{168,169} |
| Doxorubicin | Conjunctivitis Excessive tearing | May last for several days after treatment ^{101,102} |
| Fluorouracil | Ocular irritation Lacrimation | Reversible and seldom interfere with continued therapy. ^{101,102} |
| Tamoxifen | Corneal opacities Decreased vision Retinopathy | Generally occurs in patients receiving more than 1 year of treatment with a total dose exceeding 100 g has been taken. ¹⁰¹ |
| Vinca alkaloids (especially vincristine) | Extraocular muscle paresis (EMP) Ptosis | The onset of EMP or paralysis may be seen as early as 2 wk. Dose related. Most recover fully when drug is discontinued. ^{101,102} |
| Barbiturates | | |
| | Miosis Mydriasis Disturbances in ocular movement Ptosis | Most significant ocular side effects occur in chronic users or in toxic states. Pupillary responses are variable; miosis seen most frequently except in toxicity when mydriasis predominates. Nystagmus and weakness in extraocular muscles may be seen. Chronic abusers have a characteristic ptosis. ^{101,102} |
| Bisphosphonates (alendronate, etidronate, pamidronate, risedronate) | | |
| | Blurred vision, pain, photophobia, conjunctivitis, scleritis, uveitis | Adverse events more common with pamidronate. Scleritis and uveitis are of greatest concern. Following persistent reduction in vision of sustained ocular pain, refer patient to an ophthalmologist. Ocular NSAID treatment may be of symptomatic benefit. ¹⁰⁶ |

(continued)

Table 51-4 Ocular Side Effects of Systemic Medications (Continued)

| <i>Drug Class</i> | <i>Effect(s)</i> | <i>Clinical Remarks</i> |
|---|--|---|
| Calcium Channel Blockers | | |
| | Blurred vision Transient blindness | Primarily blurred vision; transient blindness at peak concentrations has been observed in several patients. ²⁰² |
| Corticosteroids | | |
| | Cataracts | Posterior subcapsular cataracts have been associated with systemic corticosteroids in patients who have received > 15 mg/day of prednisone or its equivalent daily for periods > 1 year. ^{101,102} Rare reports of bilateral posterior subcapsular cataracts associated with nasal aerosol or inhalation of beclomethasone dipropionate have been received. Most patients had received therapy for > 5 year, often in higher than the recommended dosage. Approximately 40% of patients also were receiving systemic corticosteroids. ¹⁷⁰ (Also see Question 14.) |
| | ↑ intraocular pressure | More common with topical corticosteroids than with systemic therapy. Of little consequence in patients without pre-existing glaucoma. Glaucoma patients should be monitored routinely if receiving systemic corticosteroids. ^{101,102} (See Question 13.) |
| | Papilledema | Intracranial hypertension or pseudotumor cerebri from systemic corticosteroids has been well documented. The incidence appears to be greater in children than in adults; primarily associated with chronic therapy. |
| Digitalis | | |
| | Altered color vision, visual acuity | Changes in color vision. A glare phenomenon and a snowy appearance in objects have been associated primarily with digitalis intoxication. In a small number of cases, reversible reduction in visual acuity has been noted. Also associated with changes in the visual fields. ^{101,102} |
| | Decreased intraocular pressure | Digitalis derivatives can intraocular pressure, but clinical use for glaucoma is not practical because the therapeutic systemic dose for this effect is very near the toxic dose. ^{101,102} |
| Diuretics | | |
| Carbonic anhydrase inhibitors Thiazides | Myopia | Acute myopia that may last from 24–48 hr. Probably caused by an increase in the anteroposterior diameter of the lens, which may be reversible even if drug use is continued. ^{101,102} |
| Estrogens | | |
| Clomiphene | Blurred vision Mydriasis Visual field changes Visual sensations | 5%–10% experience ocular side effects. Blurred vision is the most common effect, although visual sensations such as flashing lights, distortion of images, and various colored lights (primarily silver) may occur. ^{101,102} |
| Oral contraceptives (OCs) | Optic neuritis Pseudotumor cerebri Retrolbulbar neuritis | Quite rare. In patients with retinal vascular abnormalities, use of OCs is questionable. Numerous other possible ocular side effects are associated with these agents, and further documentation is required. ^{101,102} |
| Hypouricemics | | |
| Allopurinol | Cataracts | Conflicting reports have suggested allopurinol may be associated with anterior and posterior lens capsule changes and with anterior subcapsular vacuoles; 42 cases of cataracts have been reported; these have been observed primarily in age groups in whom normal lens aging changes would not be expected. No cause-and-effect relationship has been proven. ^{101,171} |
| Immune Modulators | | |
| Interleukin-2 | Visual deficits | Interleukin-2 visual complications have occurred during the first or second treatment cycle, usually within 5–6 days of initiation of therapy. Ocular symptoms included diplopia, binocular negative scotomata (isolated areas of varying size and shape in which vision is absent or depressed. These are not perceived ordinarily, but would be apparent upon completion of a visual field examination), and palinopsia (abnormal recurring visual imagery). In most cases, treatment was continued for the entire planned duration of therapy. Symptoms resolved after discontinuation. ¹⁷⁴ |

Table 51-4 Ocular Side Effects of Systemic Medications (Continued)

| <i>Drug Class</i> | <i>Effect(s)</i> | <i>Clinical Remarks</i> |
|---|--|---|
| Phenothiazines | | |
| Chlorpromazine | Deposits on the lens | Rare when total dose <0.5 kg. Visible after a total dose of 1 kg in most cases; incidence may increase to 90% after ≥2.5 kg. Usually, deposits do not affect vision appreciably. The cornea and conjunctiva may be affected after the lens shows pigment changes. ^{101,102} |
| Thioridazine | Retinal pigment deposits Pigmentary retinopathy | The number of reported cases is small; further documentation is necessary. ^{101,102} Primarily associated with maximal daily dosages or average doses more than 1,000 mg. Daily dosages up to 600 mg are relatively safe; 600–800 mg is uncertain, but rarely suspect. If more than 800 mg/day is used, periodic ophthalmoscopic examinations may uncover problems before visual acuity is compromised. ^{101,102} |
| Therapy for Erectile Dysfunction | | |
| Sildenafil Tadalafil Vardenafil | Changes in color and/or light perception, blurred vision, conjunctival hyperemia, ocular pain, photophobia | Color vision alterations are mild to moderate. Blurred vision does not impair visual acuity. Visual alterations usually subside within 4 hr after the dose. ^{172,173,184} Ocular adverse effects are uncommon, dose dependent, and fully reversible to date. Incidence is not related to age, but is related to blood concentration. Peak visual effects usually occur within 60 min following ingestion ¹⁰⁶ |
| α -Blockers Tamsulosin | Floppy iris | Approximately 3% of patients taking tamsulosin for benign prostatic hypertrophy (BPH) experience floppy iris during cataract surgery. Modification of the surgical procedure usually results in successful surgery. ¹⁷⁵ |

CNS, central nervous system; ENT, ear, nose, and throat.

infectious, it should be disposed of in a sanitary fashion. The common use of washcloths by several individuals will spread bacterial conjunctivitis.

Allergic Conjunctivitis

12. N.V., a 10-year-old girl, has experienced redness in both eyes accompanied by “hay fever” for the past 2 months (June and July). There is no crusting on her eyelids, and her vision is normal; she rubs her eyes often because they itch. What treatment is best for N.V.’s allergic conjunctivitis?

Topical vasoconstrictors (e.g., naphazoline, tetrahydrozoline) with or without antihistamines (e.g., antazoline, pheniramine) may be used to treat hyperemia, but they should not be used excessively because rebound congestion can occur secondary to the vasoconstrictors. Antihistamine tablets or syrup can provide considerable, but temporary, relief. Several ophthalmic histamine H₁-receptor antagonists are effective in the treatment of allergic conjunctivitis. Levocabastine 0.05% is administered BID to QID, olopatadine 0.1% BID (separating doses by 6–8 hours) or 0.2% once daily, emedastine 0.05% QID, and ketotifen 0.025% BID to QID.^{107–109} Ketotifen, olopatadine, azelastine, and epinastine exhibit both antihistamine and mast cell stabilizing effects. Olopatadine inhibits the release of other mast cell inflammatory mediators such as tryptase and prostaglandin. Ketotifen and azelastine suppress the release of mediators from cells involved in hypersensitivity reactions and decrease chemotaxis and activation of eosinophils. Azelastine inhibits other mediators involved in allergic reactions such as leukotrienes and platelet activating factor. Epinastine produces antileukotriene, anti-platelet activating factor and antibradykinin effects. Emedastine was more efficacious than levocabastine when used BID for 6 weeks in adult and pediatric patients with seasonal allergic

conjunctivitis.¹¹⁰ Olopatadine provided superior efficacy and a more rapid resolution of the signs and symptoms of allergic conjunctivitis when compared with ketotifen in a small trial involving adult patients.¹¹¹ Azelastine has a slightly quicker onset of therapeutic effect when compared to olopatadine and placebo.¹¹² Information to date is insufficient to definitively recommend one of these products as superior to the others. The ideal treatment would be removal of the allergen, but this usually is impossible when the conjunctivitis is secondary to seasonal allergies. Topical corticosteroids provide dramatic relief, but their use must be limited because of potential adverse effects (see the Ophthalmic Corticosteroids section subsequently).

Sodium cromoglycate, a drug that inhibits the release of histamine in response to antigen, may be effective as an alternative for patients who fail to respond to more conservative measures. Lodoxamide, pemirolast, and nedocromil have a similar mechanism of action to sodium cromoglycate, but these agents also decrease chemotaxis and activation of eosinophils. In comparative studies, lodoxamide tromethamine 0.1% is at least as effective as sodium cromoglycate 2% to 4% in treating allergic ocular disorders, including vernal keratoconjunctivitis.^{113,114} Patients in these studies demonstrated more rapid and greater response when treated with lodoxamide, one drop QID. In a 2-week crossover study of nedocromil and olopatadine involving 28 patients aged 7 years and older, patient acceptance of nedocromil BID was better than for olopatadine BID, but treatment outcomes were essentially equal.^{114,115}

Corneal Ulcers

13. T.S. presents with a diagnosis of bacterial corneal ulcer right eye and prescriptions for “fortified gentamicin” and cefazolin eye

Table 51-5 Ophthalmic Corticosteroids

| Low Potency | Intermediate Potency | High Potency |
|--|---|---------------------------------------|
| Dexamethasone 0.05% (Decadron Phosphate) | Clobetasone 0.1% ^a | Clobetasone 0.5% ^a |
| Dexamethasone 0.1% (Decadron Phosphate) | Dexamethasone Alcohol 0.1% (Maxidex) | Fluorometholone Acetate 0.1% (Flarex) |
| Medrysone 1% (HMS) | Fluorometholone 0.1% (FML) | Prednisolone Acetate 1% (Pred Forte) |
| | Fluorometholone 0.25% (FML Forte) | Rimexolone 1% (Vexol) |
| | Loteprednol 0.2% (Lotemax) | |
| | Loteprednol 0.5% (Alrex) | |

| | Prednisolone Sodium Phosphate 0.125% (Inflamase Mild) | |
| | Prednisolone Sodium Phosphate 1% (Inflamase Forte) | |

^aNot commercially available in the United States.

drops, which are not commercially available. What is the rationale for this therapy?

The initial choice of therapy for bacterial corneal ulcers commonly is based on a Gram's stain and clinical impression of the severity of the ulcer. Single or combination antimicrobial therapy can be prescribed. Although commercial antimicrobial ophthalmic formulations are available, the antimicrobial concentrations in these products might be inadequate to effectively treat bacterial corneal ulcers.^{116,117}

Topical antimicrobials for the treatment of bacterial corneal ulcers can be prepared from parenteral antimicrobials or by the addition of parenteral antimicrobials to “fortify” commercially available products. Commonly prescribed products include bacitracin 5,000 to 10,000 U/mL, cefazolin 33 to 100 mg/mL, gentamicin or tobramycin 9.1 to 13.6 mg/mL, and vancomycin 25 to 50 mg/mL. Fortified gentamicin has been prepared by adding 80 mg of parenteral gentamicin to the commercially available gentamicin ophthalmic solution. The final concentration of this solution is 13.6 mg/mL. Cefazolin ophthalmic solution is prepared by reconstituting 500 mg parenteral cefazolin with 2 mL sterile normal saline. Two milliliters of artificial tears solution are removed from a commercially available 15-mL bottle and replaced with the 2-mL reconstituted cefazolin solution (resulting in a final cefazolin concentration of 33 mg/mL). Therapy initially can be administered as frequently as every 15 to 30 minutes with extension of intervals as the ulcer resolves.^{118,119} The preparation of extemporaneously compounded ophthalmic products must adhere to established federal and state agency guidelines, and must address quality control concerns (e.g., pH, tonicity, sterility, particulate matter). The formulation of sterile products should not be under-

taken without due consideration of well-established practice standards.

OPHTHALMIC CORTICOSTEROIDS

Comparison of Preparations

The topical ophthalmic corticosteroid preparations are described in Table 51-5. The salt form affects the ability of the preparation to penetrate the cornea. For example, biphasic salts penetrate the intact cornea better than water-soluble salts. The ability of a formulation to penetrate the cornea, however, does not indicate increased therapeutic effectiveness. Prednisolone acetate 1% and fluorometholone acetate 0.1% have the best anti-inflammatory effects.^{120–121}

Adverse Effects

Increased Intraocular Pressure

14. L.P. has been treated with topical prednisolone acetate 1%, one drop in each eye QID for 8 weeks. Before therapy, the IOPs in both eyes were 16 mmHg, but on the last follow-up visit, his IOP was 26 mmHg in the right eye and 22 mmHg in the left eye. Assess these observations.

L.P.'s elevated IOP could be related to topical steroid therapy. In one study, the ophthalmic administration of corticosteroid preparations (Table 51-6) increased intraocular pressure in three genetically distinct subgroups.^{122,123} Fluorometholone acetate increased IOP by more than 10 mmHg in known steroid responders in 29.5 days (median), whereas dexamethasone did the same in 22.7 days (median).¹²⁴

Table 51-6 Intraocular Pressure Response to Topical Steroids in Random Populations

| Author | Parameter of Response | No. of Subjects | Low | Medium | High | Mean |
|------------------------------|--|-----------------|--------------|----------------|-------------|-----------|
| Armalay ¹²² | Increase of pressure in eye medicated with 0.1% dexamethasone | 80 | <5 mmHg 66% | 6–15 mmHg 29% | >16 mmHg 5% | 5.5 mmHg |
| Becker et al. ¹²³ | Final pressure in eye medicated for 6 wk with 0.1% betamethasone | 50 | <19 mmHg 70% | 20–30 mmHg 26% | >32 mmHg 4% | 17.0 mmHg |
| | Time to maximum response | | 2 wk | 4 wk | 4 wk | |

In a retrospective follow-up, 13% of high-corticosteroid responders developed POAG and 63.8% developed ocular hypertension. No low responders developed POAG, and only 2.4% developed ocular hypertension.¹²⁴ Although corticosteroid-induced increases in IOP are associated most frequently with topical ophthalmic preparations, systemic corticosteroids may cause a similar response, although the magnitude is somewhat less.¹²⁵ The risk for corticosteroid-induced ocular hypertension is greater in patients with high myopia, diabetes mellitus, or connective tissue disease (particularly rheumatoid arthritis).

Topical corticosteroids exert their effects by decreasing aqueous humor outflow, whereas systemic corticosteroids may increase aqueous humor production.¹²⁵ The effects on IOP apparently are unrelated to the corticosteroid's ability to penetrate the cornea. Dexamethasone has been associated with the greatest IOP increase.¹²⁶ Fluorometholone, medrysone, rimexolone, and loteprednol have been associated with lower, although sometimes significant, increases in IOP.^{127–130} The pressure response often is reversible when the offending agent is discontinued. In subjects with prolonged IOP elevation, glaucomatous field defects are more likely to develop in corticosteroid-responsive patients.¹³¹

Cataracts

15. G.A., who had asthma, has been taking prednisone 10 mg/day for 1 year. A routine ophthalmic examination revealed early cataract formation. Why could this be related to the prednisone?

Systemic and topical ophthalmic corticosteroids have been associated with the development of cataracts. About 23% of patients treated with 10 to 16 mg/day of prednisone orally (or its equivalent dose) for 1 year or more developed posterior subcapsular cataracts (PSC).^{132,133} The estimated occurrence of PSC in patients treated with more than 16 mg/day of prednisone for more than a year increased to more than 70% over the same time period. Patients receiving <10 mg/day prednisone or its equivalent are unlikely to develop PSC, although some contend that the concept of a “safe” dosage should be abandoned because of variable patient sensitivity to this side effect.¹³⁴ As illustrated by G.A., the cataracts cause few subjective complaints and little measurable decrease in visual acuity. Although systemic corticosteroids primarily are implicated, use of topical corticosteroids also has been associated with PSC formation.¹³⁵ Patients treated with alternate-day dosing of oral corticosteroids may be at lower risk for PSC formation.¹³⁶ Any patient receiving long-term corticosteroids should receive routine ophthalmic follow-up.

SYSTEMIC SIDE EFFECTS FROM OPHTHALMIC MEDICATION

16. J.F., a 62-year-old woman, received one drop of phenylephrine 10% in each eye to dilate the pupils. Shortly after administration, her BP increased to 210/130 mmHg for 5 minutes, and she became confused. How common is this type of reaction in patients receiving topical phenylephrine? What other topical ophthalmic medications been associated with systemic effects?

In 33 cases, possible adverse effects had been associated with topical phenylephrine 10%.¹³⁷ In a double-blind study, no statistically significant differences were observed in BP

or pulse rate between experimental and control groups when phenylephrine 10% or tropicamide (Mydracil) 1% was administered to 150 patients.¹³⁸ Nevertheless, care should be taken when phenylephrine 10% is administered in patients with hypertension or cardiac abnormalities in whom systemic absorption could be hazardous. No similar reports have been associated with topical use of phenylephrine 2.5%.

In addition to the systemic effects from topical administration of cholinergic agents, epinephrine, and timolol that were previously described, topical atropine, cyclopentolate (Cyclogyl), and scopolamine have been associated with psychosis.^{139–141} Fatalities have been associated with topical atropine,¹⁴² ataxia with topical homatropine, and one case of unconsciousness with tropicamide.^{142,143}

Topical chloramphenicol-polymyxin-B sulfate ophthalmic ointment has been associated with bone marrow aplasia after intermittent use for 4 months.¹⁴⁴ A cushingoid reaction has been reported in a 30-month-old baby girl treated with dexamethasone alcohol (Maxidex) four times a day in both eyes for 14 months.¹⁴⁵

OCULAR NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

17. W.A. is scheduled to undergo cataract extraction with implantation of an intraocular lens. Preoperative orders include administration of flurbiprofen 0.03% to inhibit intraoperative miosis. The formulary includes only diclofenac 0.1%. Is this a suitable alternative to flurbiprofen?

The administration of ophthalmic prostaglandins and prostaglandin analogs are associated with some systemic effects (Table 51-1), and ocular instillation of nonsteroidal anti-inflammatory drugs (NSAIDs) can inhibit prostaglandin synthesis and reduce prostaglandin-mediated ocular effects.¹⁴⁶ Commercially available ophthalmic NSAIDs (e.g. bromfenac, diclofenac, flurbiprofen, ketorolac and nepafenac) are well tolerated, but can cause transient burning and stinging upon instillation. Although the ocular NSAIDs share a similar mechanism of action, minor clinical differences, which probably are insignificant, exist and approved indications differ. (Table 51-7).

OCULAR HERPES SIMPLEX VIRUS INFECTIONS

18. P.B., a 34-year-old man, presents with a 2-week history of a red, irritated left eye with watery discharge. Recently, vision in his left eye became blurred, and he complained of light sensitivity. A slit-lamp examination with rose Bengal stain revealed a multibranching corneal epithelial defect. This dendritic ulcer is the hallmark of ocular herpes simplex (type I) infection. What is the therapy of choice?

Ocular herpes is common, and can be caused by herpes simplex virus, or less commonly, by the varicella-zoster virus (herpes zoster ophthalmicus). Herpes simplex of the eye typically affects the eyelids, conjunctiva, and cornea and patients often present with symptoms of pain, tearing, eye redness, sensitivity to light, and irritation or a foreign body sensation. When herpes affects the epithelium of the cornea (herpes keratitis), it generally heals without scarring. Occasionally, deeper layers of the cornea are affected (stromal keratitis) and scarring can lead to blindness.

Table 51-7 Ocular Nonsteroidal Anti-Inflammatory Drugs

| Indication | Drug/Approval Status for Indication | Dosage(s) |
|--|---|---|
| Inhibition of intraoperative miosis | Diclofenac 0.1% (Voltaren, U) ¹⁷⁶ | Three reported regimens; 1 drop Q 15–30 min for four doses; 1 drop TID for 2 preoperative days; 1 drop at 2 hr, 1 hr, and 15 min before surgery. |
| Anti-inflammatory postcataract surgery | Flurbiprofen 0.03% (Ocufen, A) ¹⁷⁷ | One drop Q 30 min for 2 hr before surgery. |
| | Ketorolac 0.5% (Acular, U) | One drop Q 15 min beginning 1 hr before surgery. |
| | Bromfenac 0.09% (Xibrom, A) | One drop BID beginning 24 hr after surgery and continuing through the 2 wk of the postoperative period. |
| | Diclofenac 0.1% (A) ^{174,178} | One drop BID to QID, including 24 hr preoperative administration. |
| Prevention/treatment of cystoid macular edema | Nepavanac 0.1% (Nevanac, A) | One drop 3 times daily beginning 1 day prior to cataract surgery, continued on the day of surgery and through the first 2 wk of the postoperative period. <small>(Nevanac prescribing information. Alcon Laboratories, November 2006)</small> |
| | Flurbiprofen 0.03% (U) | One drop 4–5 times daily. |
| | Ketorolac 0.5% (A) ¹⁷⁹ | One drop TID, including 24 hr preoperative administration. |
| Ocular inflammatory conditions (iritis, iridocyclitis, episcleritis) | Diclofenac 0.1% (U) ¹⁸⁰ | Two drops 5 times preoperatively followed by one drop 3–5 times daily |
| | Ketorolac 0.5% (U) ^{179,181} | One drop TID or QID, including 24 hr preoperative administration. |
| Seasonal allergic/vernal conjunctivitis | Diclofenac 0.1% (U) | One drop QID. |
| | Bromfenac 0.1% (U) | One drop BID |
| | Diclofenac 0.1% (U) | One drop Q 2 hr for 48 hr; then QID |
| | Ketorolac 0.5% (A) ^{182,183} | One drop QID |

A, approved use; U, unapproved use.

Trifluridine

In-vitro, trifluridine's mechanism of action is similar to that of idoxuridine (IDU). Trifluridine also inhibits thymidylate synthase, an enzyme required for DNA synthesis. The actual in-vivo antiviral effects of trifluridine have not been determined.

For the treatment of ocular herpes, one drop of trifluridine 1% ophthalmic solution should be instilled into the affected eye every 2 hours while awake with a maximum daily dose of nine drops. Following re-epithelialization, application of trifluridine should be continued for an additional 7 days at a reduced dosage of one drop every 4 hours while awake with a minimum of five drops daily. Continuous administration for periods exceeding 21 days is not recommended because of potential ocular toxicity.

Approximately 96% of treated herpetic corneal ulcers heal within 2 weeks.¹⁴⁷ Therapeutic levels of trifluridine can be found in the aqueous humor after topical administration of a 1% solution, enhancing its possible effectiveness in the treatment of stromal keratitis and uveitis. Trifluridine also is effective in treating HSV infections resistant to IDU and/or vidarabine.

Despite the apparent superiority of trifluridine over its antiviral predecessors (IDU, vidarabine), it is not without disadvantages. Trifluridine is activated by noninfected corneal cells and is incorporated into cellular as well as viral DNA. Punctate lesions in the corneal epithelium are clinical manifestations of trifluridine cytotoxicity.¹⁴⁸ Yet these effects seem to occur less often than with IDU and vidarabine.

Acyclovir

Acyclovir in in vitro plaque inhibition assays have 5 to 10 times the activity of IDU and trifluridine and more than 100 times the activity of vidarabine against strains of type I and type II HSV.¹⁴⁹ Acyclovir's apparent superiority lies in its lack of toxicity to normal host cells.¹⁵⁵ In rabbits (rabbit eyes are sim-

ilar to human eyes), acyclovir 3% ointment healed established herpes simplex epithelial ulcerations at a faster rate and eliminated the virus more effectively than 0.5% IDU, and 3% vidarabine ointments.^{150,152} In humans, ulcerative corneal epithelial lesions appear to respond similarly to acyclovir and IDU.¹⁵³ In comparison to idoxuridine, the topical application of acyclovir or trifluridine resulted in a greater proportion of subjects healing within 1 week and neither was superior for the treatment of dendritic epithelial keratitis.¹⁹⁹ The dose usually is a 1-cm ribbon of ointment instilled five times a day at four-hour intervals for 14 days or at least for 3 days after healing is completed, whichever is shorter. Detailed dosing instructions are available in product literature of specific manufacturers, and brief reviews of acyclovir and acyclovir resistance in Chapter 70: Opportunistic Infections in HIV-Infected Patients; and Chapter 72: Viral Infections.

Other Drugs

Ganciclovir 0.05% and 0.15% gel has been shown to be equivalent to 3% acyclovir ointment in the treatment of superficial herpes simplex keratitis.¹⁵⁵ Cidofovir 1% ointment administered BID was equivalent to trifluridine administered five times daily in the rabbit model.¹⁵⁶ Cidofovir was more efficacious than 3% penciclovir ointment administered two or four times a day.¹⁵⁶

AGE-RELATED MACULAR DEGENERATION

Age-related macular edema is the leading cause of blindness in Americans of European descent who are 55 years of age and older.¹⁹¹ There are two forms of macular degeneration, wet and dry. The dry form, affecting about 85% of patients, develops as a result of the breakdown of light-sensitive cells in the macula.¹⁹² The most common symptom associated with dry macular degeneration is blurred vision. In this situation, details (e.g., faces, words in a book) are seen less clearly. Wet

macular degeneration occurs in 15% of patients and is the more serious form, responsible for the most cases of vision loss. Wet macular degeneration is associated with abnormal growth of blood vessels behind the retina, known as choroidal neovascularization. Vascular endothelial growth factor (VEGF) is associated with the pathogenesis of choroidal neovascularization. VEGF may stimulate neovascularization by influencing endothelial cell proliferation, vascular permeability, and ocular inflammation.¹⁹³ The correlation between VEGF and wet age-related macular degeneration has led to interest in VEGF inhibitors (pegaptanib, bevacizumab, ranibizumab) as treatment agents.

Pegaptanib

Pegaptanib inhibits angiogenesis, decreases permeability of the vascular bed and decreases inflammation. The efficacy of pegaptanib has been evaluated in two concurrent, prospective, randomized, double-blind trials involving 1,208 patients. A total of 1,190 patients received at least one study treatment, with four subjects being excluded from the efficacy analysis due to insufficient assessment of visual acuity at baseline. A combined analysis of 1,186 patients at week 54 showed a statistically significant reduction in vision loss associated with pegaptanib, realized as early as week 6 and continued through week 54.¹⁹⁶ The FDA-approved dose of pegaptanib (0.3 mg IV Q 6 weeks) is no less effective than 1 mg or 3 mg doses and the most serious injection-related adverse events were endophthalmitis (12 patients), traumatic injury to the lens (five patients), and retinal detachment (six patients).¹⁹⁶ Patients should be monitored for elevations in IOP following injection; increases in IOP have been seen within 30 minutes of injection and should be monitored within 2 to 7 days following the injection.

Bevacizumab

Bevacizumab is a recombinant humanized monoclonal immunoglobulin G1 antibody approved for intravenous use for

first- or second-line treatment of metastatic colorectal cancer. This product has been used off-label via the IV and intravitreal route for the treatment of neovascular ocular disorders in more than 3,500 patients.¹⁹³ Intravenous bevacizumab 5 mg/kg was administered every 2 weeks for two or three infusions in 18 patients for whom 12- and 24-week results on subfoveal choroidal neovascularization were published separately. Therapy was associated with improved visual acuity. No serious ocular or systemic adverse effects were noted, although a statistically significant increase in blood pressure was noted at week 3. Nineteen published, uncontrolled case series studies have evaluated the use of intravitreal bevacizumab for the treatment of wet macular degeneration as well as other conditions associated with neovascularization. The most common intravitreal dose was 1.25 mg, usually administered every 4 to 6 weeks. Doses could be repeated if signs of progression occurred. The longest period of study for intravitreal use was 1 year. The majority of patients in these open-label trials were followed for 3 months. Mean visual acuity improved and no serious ocular effects were noted.

Ranibizumab

Ranibizumab is a Fab fragment of bevacizumab approved in June 2006 for the intravitreal treatment of wet macular degeneration. Ranibizumab is approximately one-third the size of bevacizumab. Its size may facilitate retinal penetration following intravitreal injection. Ranibizumab has a shorter-systemic half life and higher VEGF binding affinity than bevacizumab, but bevacizumab has two binding sites per molecule versus one for ranibizumab. The clinical relevance of these pharmacokinetic and pharmacodynamic differences is not known.¹⁹³ The recommended dosage of ranibizumab is 0.5 mg via the intravitreal route administered every 4 weeks. This treatment has been associated with maintenance or improvement of vision for 12 to 24 months.¹⁹⁷ The primary ocular side effects associated with ranibizumab administration include conjunctival hemorrhage, eye pain, and increased IOP.

NEUROLOGIC DISORDERS

Brian K. Alldredge

SECTION EDITOR

CHAPTER 52

Headache

Brian K. Alldredge

Prevalence 52-1
 Classification 52-2
 Primary Headache Disorders 52-2
 Migraine Headaches 52-2
 Cluster Headaches 52-2
 Tension-Type Headaches 52-3
 Secondary Headache Disorders 52-3
 Acute Headaches 52-3
 Subacute Headaches 52-3
 Pathophysiology 52-3
 Drug Therapy 52-4

MIGRAINE HEADACHE 52-4

Pathophysiology 52-4
 Genetics 52-5
 Signs and Symptoms 52-5
 Migraine With and Without
 Aura 52-5
 Diagnostic Tests 52-6
 Therapeutic Considerations 52-6
 Abortive Therapy 52-6
 Aggravating Factors 52-6
 Oral Contraceptives 52-6
 Abortive Therapy Triptans (5-HT_{1B/1D}
 Receptor Agonists) 52-7
 Sumatriptan 52-7
 Adverse Effects 52-8
 Headache Recurrence 52-8
 Drug Interactions 52-9
 Dosing 52-9

Second-Generation Triptans (Zolmitriptan,
 Naratriptan, Rizatriptan, Almotriptan,
 Frovatriptan, Eletriptan) 52-9
 Drug Interactions 52-9
 Ergotamine Tartrate 52-10
 Caffeine 52-10
 Route of Administration 52-10
 Contraindications 52-11
 Adverse Effects 52-11
 Antiemetics 52-11
 Isometheptene Compound 52-12
 Nonsteroidal Anti-Inflammatory Drugs and
 Combination Analgesics 52-12
 Dihydroergotamine Nasal Spray 52-12
 Intractable Migraine 52-12
 Dihydroergotamine 52-12

Clinical features and drug therapy of the common headache syndromes are presented in this chapter. Proposed pathophysiologic features of the major headache types also are presented to provide the reader with an understanding of the rationale for current and future therapies.

Prevalence

In the United States, migraine headache affects approximately 23 million persons, and 11 million experience significant headache-related disability.¹ Headache is the fourth most common symptom reported at outpatient medical visits,² and the

associated economic costs in America are estimated to be between \$1 billion and \$17 billion dollars annually.³ Overall, the prevalence of headache is highest in adolescence and early adulthood and declines with age through the elderly years.^{4,5} Despite numerous potential causes of headaches, more than 90% of patients with a chief complaint of continuous or sporadically recurring headaches are eventually diagnosed as having either tension-type or migraine headache.⁶

Classification

Headache is a symptom that can be caused by many disorders. For example, head pain can result from traction, displacement, or inflammation of pain-sensitive structures within the head, or it can be due to disorders of extracranial structures such as the eyes, ears, or sinuses. For diagnostic and therapeutic purposes, it is useful to categorize headache into one of two major types (*primary* and *secondary*) on the basis of the underlying etiology. *Primary headache disorders* are characterized by the lack of an identifiable and treatable underlying cause. Migraine, tension-type, and cluster headaches are examples of primary headache disorders. *Secondary headache disorders* are those associated with a variety of organic causes such as trauma, cerebrovascular malformations, and brain tumors. Depending on the cause, headache may manifest in a variety of ways or may be accompanied by other associated signs or symptoms. A comprehensive classification scheme of the different types of headaches, modified from the International Headache Society (IHS) is shown in Table 52-1.⁷ Readers are referred to the IHS classification report for the comprehensive headache classification scheme and a detailed description of the specific diagnostic features of each headache type. This classification scheme is useful for grouping headaches with similar clinical features or etiologies. Headache must be accurately evaluated and classified because this symptom may reflect an ominous problem such as the presence of a brain tumor or a much more benign process such as muscle tension. Moreover, effective intervention depends on a correct diagnosis.

Primary Headache Disorders

MIGRAINE HEADACHES

Migraine headaches usually develop over a period of minutes to hours, progressing from a dull ache to a more intense pulsating pain that worsens with each pulse. The headache usually begins in the frontotemporal region and may radiate to the occiput and neck; it may occur unilaterally or bilaterally. Migraine headaches often are accompanied by nausea and vomiting and may last for up to 72 hours. These headaches usually are alleviated by relaxation in a dark room and sleep. Migraine is more common in females than males. Migraine headaches are divided into those with and without an aura. The term, *aura*, refers to the complex of focal neurologic symptoms (e.g., alterations in vision or sensation) that initiate or accompany a migraine attack. Migraine may be precipitated by a variety of dietary, pharmacologic, hormonal, or environmental factors.

CLUSTER HEADACHES

Cluster headaches derive their name from a characteristic pattern of recurrent headaches that are separated by periods of remission that last from months to even years. During those periods when clusters of headaches are experienced, the

Table 52-1 Classification of Headache⁷

Migraine

Migraine without aura
Migraine with aura
Complicated migraine (see Table 52-2)

Tension-Type Headache

Episodic tension-type headache
Chronic tension-type headache

Cluster Headache

Episodic cluster headache
Chronic cluster headache

Miscellaneous Headaches Unassociated with Structural Lesion (e.g., cold stimulus headache, benign exertional headache)

Headache Associated with Head Trauma

Acute post-traumatic headache
Chronic post-traumatic headache

Headache Associated with Vascular Disorders

Acute ischemic cerebrovascular disease (TIA or stroke)
Intracranial hematoma
Subarachnoid hemorrhage
Unruptured vascular malformation
Arteritis
Carotid or vertebral artery pain
Venous thrombosis
Arterial hypertension

Headache Associated with Nonvascular Intracranial Disorder (e.g., high or low CSF pressure, intracranial infection, or neoplasm)

Headache Associated with Substances or their Withdrawal (e.g., withdrawal from alcohol, caffeine, ergotamine, narcotics; also see Table 52-3).

Headache Associated with Noncephalic Infection (e.g., viral or bacterial infection)

Headache Associated with Metabolic Disorder (e.g., hypoxia, hypercapnia, hypoglycemia, dialysis)

Headache or Facial Pain Associated with Disorder of Cranium, Neck, Eyes, Ears, Nose, Sinuses, Teeth, Mouth, or Other Facial or Cranial Structures (e.g., cervical spine, acute glaucoma, refractive errors, acute sinus headache)

Cranial Neuralgias, Nerve Trunk Pain and Deafferentation Pain (e.g., compression, demyelination, infarction, or inflammation of cranial nerves)

Headache Not Classifiable

CSF, cerebrospinal fluid; TIA, transient ischemic attacks.

headaches usually occur at least once daily. The headache generally is unilateral, occurs behind the eye, reaches maximal intensity over several minutes, and lasts for <3 hours. Unilateral lacrimation, rhinorrhea, and facial flushing may accompany the cluster headache. During cluster periods, headache is commonly precipitated by alcohol, naps, and vasodilating drugs. In contrast to migraine headaches, cluster headaches are more common in males than females.

TENSION-TYPE HEADACHES

A dull, persistent headache, occurring bilaterally in a hat-band distribution around the head is characteristic of tension-type headaches. The headache is usually not debilitating and may fluctuate in intensity throughout the day. Tension-type headaches often occur during or after stress, but chronic tension-type headaches may persist for months even in the absence of recognizable stress. Skeletal muscle overcontraction, depression, and occasionally nausea may accompany the headache. Prodrome neurologic symptoms do not occur in association with tension-type headache. More detailed descriptions of migraine, cluster, and tension-type headaches appear in following sections of this chapter.

Secondary Headache Disorders

In addition to migraine, cluster, and tension-type headaches, patients may also experience headache associated with head trauma, vascular disorders, central nervous system (CNS) infection (including HIV), or metabolic disorders. More than 300 disorders capable of producing headache have been identified.⁸ Examples of secondary headache disorders are given in Table 52-1.

The length of time that a patient has experienced headaches provides highly useful information for assessing the nature and etiology of the headaches. A new severe headache in a patient without a previous history is the most useful single piece of information for identifying potentially destructive intracranial or extracranial causes of headache. Such headaches may develop suddenly, over a period of hours to days (acute headache), or more gradually over days to months (subacute headache).

Acute Headaches

Acute headaches can be symptomatic of subarachnoid hemorrhage, stroke, meningitis, or intracranial mass lesion (e.g., brain tumor, hematoma, abscess). The headache that accompanies subarachnoid hemorrhage is typically severe (often described by the patient as the “worst headache of my life”) and may occur in conjunction with alteration of mental status and focal neurologic signs. The headache of meningitis is usually bilateral and develops gradually over hours to days; symptoms such as fever, photophobia, and positive meningeal (Kernig’s and Brudzinski’s) signs often accompany the meningeal headache. Although the acute onset of headache associated with coughing, sneezing, straining, or change in head position is commonly thought to indicate a cranial mass lesion with cerebrospinal fluid (CSF) pathway obstruction, several varieties of exertional headache are benign (see Table 52-1).

Subacute Headaches

Subacute headaches may be a sign of increased intracranial pressure, intracranial mass lesion, temporal arteritis, sinusitis, or trigeminal neuralgia (i.e., tic douloureux). Trigeminal neu-

ralgia usually occurs after the age of 40 and is more common in women than men. The pain usually occurs along the second or third divisions of the trigeminal (facial) nerve and lasts only moments. Trigeminal neuralgia is characterized by sudden, intense pain that recurs paroxysmally, often in response to triggers such as talking, chewing, or shaving.

The clinical manifestations of headache, as described previously, focus on the onset, frequency, duration, site, gender of the patient, distribution, and other unique characteristics of the head pain. A comprehensive medical history and physical examination of the patient often provide sufficient information to make an adequate assessment of a patient’s headache complaint, and may enable the practitioner to rule out headache as a manifestation of more serious illness. Physical examination of the patient suffering from the common, benign forms of headache (e.g., migraine, cluster, and tension-type headaches) is usually normal. When the medical history of the patient is suggestive of a secondary cause of headache, a more extensive evaluation with referral to or consultation by a neurologist is necessary.

Pathophysiology

Intracranially, only a limited number of structures are sensitive to pain. The most important pain-sensitive structures within the cranium are the proximal portions of the cerebral arteries, large veins, and the venous sinuses.⁹ Headache may result from dilation, distention, or traction of the large intracranial vessels. The brain itself is insensitive to pain. Referred pain from inflammation of frontal or maxillary sinuses or refractive errors of the eye are potential, although overdiagnosed, causes of headache.¹⁰ Scalp arteries and muscles are also capable of registering pain and have been implicated in the pathophysiology of migraine and tension-type headache. Extracranially, most of the structures outside the skull (e.g., periosteum, eye, ear, teeth, skin, deeper tissues) have pain afferents. In general, pain can be produced by activation of peripheral pain receptors (nociceptors), injury to CNS or peripheral nervous system, or displacement of the pain-sensitive structures mentioned earlier.

Historically, the primary headache disorders have been thought to be related either to vascular disturbances (migraine and cluster headache) or muscular tension (tension-type headache). However, clinical and experimental evidence now suggests that these headaches have their origin in an underlying disturbance in brain function.¹¹ Evidence in this regard is particularly strong for migraine and cluster headache. Many authors now hold the opinion that these clinically dissimilar primary headache syndromes represent variable manifestations of a common pathogenetic phenomenon that involves neural innervation of the cranial circulation. The specific mechanisms that lead to primary headaches have not been identified. However, a *neurovascular hypothesis* has been proposed in which headache is triggered by disturbances in central pain processing pathways (the trigeminocervical complex) leading to the release of potent neuropeptides (calcitonin gene-related peptide [CGRP], substance P, and neurokinin A) and subsequent vasodilation.¹² Serotonin, a vasoactive neurotransmitter released by brainstem nuclei of the trigeminovascular system, likely plays a role in migraine pathogenesis.¹³ Furthermore, drugs that alter serotonergic function are highly effective for the symptomatic treatment of migraine and cluster headache.

Drug Therapy

Drug therapy for headache is divided into two major categories: (a) abortive therapy to provide relief during an acute headache attack and (b) prophylactic therapy to prevent or reduce the severity of recurrent headaches. Most people with infrequent tension-type headaches self-medicate with over-the-counter (OTC) analgesics to abort the acute event and do not require prophylactic therapy. By contrast, migraine and cluster headache sufferers who experience frequent headaches and who respond poorly to abortive measures are good candidates for preventive therapy.

Although analgesics are often useful for the treatment of episodic tension-type headaches, most patients with migraine and all patients with cluster headaches require other abortive measures. Until recently, ergot alkaloids (e.g., ergotamine and dihydroergotamine) were the most commonly prescribed agents for relief of migraine and cluster headaches. Now, the triptan class of agents (e.g., sumatriptan, zolmitriptan, naratriptan, rizatriptan, almotriptan, frovatriptan and eletriptan) is often preferred because of their favorable efficacy and tolerable adverse effect profiles.¹⁴ However, the greater expense of the triptans limits the availability of these drugs for some patients.

Antidepressant agents (e.g., amitriptyline) are useful for prophylactic treatment of migraine and tension-type headaches. Because many patients suffer from mixed headache types, these agents can be useful for patients who might otherwise require preventive polytherapy. Other agents useful for migraine headache prophylaxis include β -blocking agents (e.g., propranolol), valproate, calcium channel blocking agents (particularly verapamil), and nonsteroidal anti-inflammatory drugs (NSAIDs). Among the agents effective for prophylaxis against episode cluster headaches, verapamil, corticosteroids (e.g., prednisone) and lithium are usually preferred.

MIGRAINE HEADACHE

The word *migraine* comes from the Greek “hemicrania” and historically was used to describe unilateral headaches with associated symptoms. More recently, the IHS described migraine as follows. Migraine is an “idiopathic, recurring headache disorder manifesting in attacks lasting 4 to 72 hours. Typical characteristics of [migraine] headache are unilateral location, pulsating quality, moderate or severe intensity, aggravation by routine physical activity, and association with nausea, photo- and phonophobia.”⁷ Migraine headaches are subclassified according to the presence or absence of aura symptoms. Most persons who suffer from migraine do not experience aura symptoms. In patients with aura, visual symptoms are most common. Complicated migraine is a less common type of migraine in which the neurologic symptoms are more pronounced or disabling; in some cases the aura symptoms may outlast the headache itself. Table 52-2 outlines the predominant types of complicated migraine. Although patients with persistent symptoms should be thoroughly evaluated by a neurologist, permanent neurologic sequelae after migraine are rare even for patients with complicated migraine.

Pathophysiology

Past theories of pathogenesis have focused on alterations in cranial vessel diameter and blood flow as the primary cause

Table 52-2 Types of Complicated Migraine⁷

Migraine with Prolonged Aura

Aura symptoms lasting >60 min but <1 wk

Familial Hemiplegic Migraine

Aura with hemiparesis; identical attacks in a first-degree relative

Basilar Migraine

Aura symptoms arising from brainstem or occipital lobes (e.g., dysarthria, vertigo, ataxia, decreased level of consciousness)

Ophthalmoplegic Migraine

Paresis of one or more ocular cranial nerves

Retinal Migraine

Aura symptoms with monocular scotoma or blindness lasting <1 hr

Status Migrainosus

Migraine headache lasting >72 hr despite treatment

Migrainous Infarction

Aura symptoms lasting longer than 7 days.

of migraine. In this “vascular hypothesis,” it was thought that focal neurologic symptoms preceding or accompanying the headache were caused by vasoconstriction and reduction in cerebral blood flow. The headache was thought to be caused by a compensatory vasodilation with displacement of pain-sensitive intracranial structures. Although blood flow is decreased during the aura of migraine,¹⁵ other observations do not support the vascular hypothesis. The headache phase of migraine with aura has been shown to begin while blood flow is reduced,¹⁵ and migraine without aura is not associated with alterations in regional cerebral blood flow.¹⁶ Furthermore, the therapeutic effect of sumatriptan, a drug highly specific for neurovascular headaches, is not temporally related to its vasoconstrictive effect.¹⁷ More recent evidence suggests that the pain of migraine is generated centrally and involves episodic dysfunction of neural structures that control the cranial circulation (the *trigeminovascular system*). The availability of functional brain imaging has had a dramatic effect on the ability to visualize the pathophysiologic events of a migraine attack.¹² The trigeminovascular system consists of neurons, originating in the trigeminal ganglion, which innervate the cerebral circulation. Several potent vasodilator neuropeptides are contained within these trigeminal neurons, including calcitonin gene-related peptide, substance P, and neurokinin A. In animals, stimulation of the trigeminal ganglion significantly alters regional brain blood flow.¹² Stimulation of the trigeminal ganglion in humans causes facial flushing, an increase in facial temperature,¹⁸ and increases in extracerebral venous concentrations of calcitonin gene-related peptide and substance P.¹⁹ The specific events leading to trigeminovascular dysfunction in migraine are unknown. However, evidence from positron emission tomography (PET) scanning (a technique to measure regional cerebral blood flow as an index of neuronal activity)

suggests that episodic dysfunction of the brainstem, with corresponding effects on the trigeminal system, are involved. Using PET, Weiller and et al.²⁰ found activation of the brainstem (periaqueductal gray, dorsal raphe nucleus, and locus ceruleus) at the onset of migraine headaches in nine patients. This area may represent an endogenous “migraine generator.” Sporadic dysfunction of the nociceptive system (periaqueductal gray and dorsal raphe nucleus) and the neural control of cerebral blood flow (dorsal raphe nucleus and locus ceruleus) is hypothesized to trigger migraine headache via their effects on the trigeminovascular system. Further support for a trigeminovascular mechanism for migraine comes from studies that demonstrate inhibition of trigeminal neurons and associated nociceptive responses by various antimigraine drugs such as dihydroergotamine,²¹ rizatriptan,²² and zolmitriptan.²³ Abnormalities in serotonin (5-HT) activity are also thought to play a role in migraine headache. Plasma 5-HT levels decrease by nearly half during a migraine attack,²⁴ with a corresponding rise in the urinary excretion of 5-hydroxyindoleacetic acid,²⁵ the primary metabolite of 5-HT. Also, reserpine, a drug that depletes 5-HT from body stores, has been found to induce a stereotypical headache in migraineurs and a dull discomfort in patients not prone to migraine.^{24,26} An intravenous (IV) injection of 5-HT effectively relieved both reserpine-induced and spontaneous migraine headache.^{24,26} The therapeutic effects of drugs that stimulate 5-HT₁ receptors (e.g., dihydroergotamine, sumatriptan), antagonize 5-HT₂ receptors (e.g., methysergide, cyproheptadine), prevent 5-HT reuptake (e.g., amitriptyline) or release (e.g., calcium channel blockers), or inhibit brainstem serotonergic raphe neurons (e.g., valproate) all lend support to the hypothesis that 5-HT is an important mediator of migraine. Furthermore, brainstem nuclei activated during migraine have high densities of serotonergic neurons. Specific 5-HT receptor subtypes, 5-HT_{1B} and 5-HT_{1D}, are largely distributed in blood vessels²⁷ and nerves,²⁸ respectively. These same 5-HT receptor subtypes are the targets of antimigraine drugs such as the triptans and ergot alkaloids.

Genetics

A familial predisposition for migraine has been well recognized, although not until recent advances in gene mapping techniques has the genetic basis of a specific migraine disorder been discovered. The first identified migraine gene was found among several unrelated families with familial hemiplegic migraine. The mutations involved a gene encoding the α_1 subunit of a voltage-gated P/Q-type neuronal calcium channel.²⁹ The relevance of this discovery to other migrainous disorders is unknown, but it suggests that some forms of migraine may be fundamentally related to other episodic disorders of neurologic dysfunction known as “channelopathies.”³¹ Recently, genomewide linkage analysis in families with migraine (both with and without aura) have identified susceptibility loci on chromosomes 4 and 14.^{30,31} An improved understanding of the genetics of migraine is likely to improve our understanding of the pathophysiology of the disorder as well as to hold promise for the identification of homogenous subgroups of patients in whom targeted drug (or other) interventions are likely to be highly effective.

In summary, the pathophysiology of migraine probably involves dysfunction of the trigeminal neurons that provide sensory innervation and modulate blood flow for intracranial blood vessels. The endogenous stimulus causing this dysfunction

may arise from a “migraine generator” in the brainstem. Disturbances in 5-HT activity are also probably involved and it is this feature that serves as the target for many migraine-specific therapies.

Signs and Symptoms

Migraine With and Without Aura

1. K.L., a 29-year-old woman, presents to the clinic with a 5-month history of left-sided pulsatile head pain recurring on a weekly basis. Her headaches are usually preceded by unformed flashes of light bilaterally and a sensation of light-headedness. The ensuing pain is always unilateral and is commonly associated with nausea, vomiting, and photophobia. The headache is not relieved by two tablets of either aspirin 325 mg or ibuprofen 200 mg and generally lasts all day unless she is able to lie in a dark room and sleep. The headaches usually interfere with her ability to continue work. K.L. is unable to identify any external factors that precipitate a migraine attack. Both K.L.’s mother and grandmother also were affected by migraine headaches. Medical history is unremarkable, and K.L. denies any other medical problems. Current medications include only the OTC analgesics for headache and the contraceptive, Ortho-Novum 7/7/7. General physical and neurologic examinations are within normal limits. What subjective and objective data from the above description are consistent with a diagnosis of migraine with aura?

Given K.L.’s headache description, normal physical examination, and age of onset, she is most likely suffering from migraine with aura; a benign, though often disabling, disorder.

Approximately 17% of females and 6% of males in the United States suffer from migraine headaches,¹ and the incidence and prevalence of migraine has increased in recent decades.^{32,33} The typical age of onset of migraine headaches is 15 to 35 years; after the age of 50, the onset of new migraine headaches is less common and is suggestive of a secondary cause. Although influenced by physiologic and environmental factors, migraine headaches occur more frequently among first-degree relatives, suggesting a genetic basis for this disorder.³³ K.L.’s gender (female), age (29 years), and positive family history are compatible with these aspects of migraine.

In the assessment of headache, the site or location of the pain, the quality of the pain, the duration and time course of the pain, and the conditions that provoke or palliate the pain should be considered.

The site or location of head pain can provide the clinician with clues as to the potential for secondary causes (e.g., lesions in the frontal sinuses, eyes, ears, teeth, or cerebral arteries). However, pain often is referred from other regions and the location of pain can provide misleading information. Thus, the site of head pain need not be related to the apparent site of the focal neurologic symptoms that accompany migraine with aura. Head pain may be either unilateral or bilateral, and the pain need not recur on the same side if unilateral. In fact, 50% of patients with unilateral headache report that either side of the head may be affected during any individual migraine attack.³⁴

The quality of migraine head pain usually begins as a dull ache that intensifies over a period of minutes or hours to a throbbing headache, which worsens with each arterial pulse. If untreated, the headache lasts from several hours to as long as 3 days or until the patient goes to sleep. The pain usually

is intense enough to interfere with daily activities. Although migraine headaches seldom occur more often than once every few weeks, there is great interpatient variability in the frequency of occurrence. A patient may experience only several migraines in a lifetime, whereas others may suffer several headaches weekly on a chronic basis. K.L., like half of all patients with migraine, describes headaches that recur between one to four times monthly.³⁴ In this patient, the quality of the pain (i.e., interferes with K.L.'s ability to continue work); the duration and the time course of the pain (i.e., usually lasts all day); and the conditions that palliate the pain (i.e., lie in a dark room and sleep) are all compatible with the description of migraine headaches.

Aura symptoms are focal neurologic features that precede or accompany the headache in up to 30% of migraine sufferers.³⁵ When they precede the headache, aura symptoms usually begin 10 minutes to 1 hour before the onset of head pain. Light-headedness and photopsia (unformed flashes of light) are frequently reported and were described by K.L. before the onset of her head pain. Visual disturbances, such as scotoma (an isolated area within the visual field where vision is absent), occur in 30% of migraine patients.³⁵ At times, the scotoma is preceded only by a sensation that something is wrong with vision that cannot be more specifically characterized. At other times, the scotoma may be preceded by other visual distortions (e.g., the "halves of peoples' faces were vertically displaced in such a way that one eye appeared to be 1 or 2 cm lower than the other").³⁶ When scotomata are surrounded by a shiny pattern, they are termed *scintillating scotomata*. These scintillating scotomata can have "the visual quality of images in the kaleidoscopes we looked into as children, with the difference that the scotoma are silvery instead of multicolored as in the toy."³⁶ Other neurologic symptoms of cortical origin (e.g., paresthesias, temporal lobe symptoms) occur less commonly in patients who suffer from migraine with aura. K.L.'s physical and neurologic examinations were within normal limits. The nausea and vomiting that were experienced by K.L. accompany migraine headaches (with or without aura) in 90% of patients. Vomiting is occasionally followed by a gradual resolution of migraine symptoms. Diarrhea may also occur.

In summary, K.L.'s history and relative lack of important physical findings are compatible with a diagnosis of migraine with aura.

Diagnostic Tests

2. What further laboratory or diagnostic tests should be ordered for K.L.?

Headaches are common medical complaints and evaluation of these headaches with sophisticated diagnostic procedures (e.g., computed tomography [CT], magnetic resonance imaging [MRI] scans) are generally unnecessary in the uncomplicated migraine patient. Because K.L.'s headaches are not of recent origin, not progressive, and unassociated with traumatic injury or persistent neurologic deficits, CT or MRI scanning procedures should be unnecessary. Her headaches are unaccompanied by fever or nuchal rigidity, and she does not present with headache described as being "the worst headache of my life." Therefore, a lumbar puncture would not likely be of diagnostic value because meningitis or subarachnoid hemorrhage

is unlikely. The signs and symptoms experienced by K.L., as described in the answer to Question 1, are typical of migraine with aura. The most important diagnostic evaluations of patients presenting with headache should be based on a thorough medical history and physical examination. The role of costly or invasive diagnostic procedures is limited to their usefulness in detecting other more serious disorders that may manifest as migrainous headache.

Therapeutic Considerations

3. What should be the general approach to the treatment of K.L.'s headache attacks?

The concept that moderate to severe headaches can be classified into distinct types with unrelated pathophysiologic features is probably incorrect. Patients commonly complain of more than one type of headache or report symptoms or recurrence patterns that are inconsistent with a single diagnosis. Because the selection of therapy is based primarily on the characteristics of headache gathered from the history, the practitioner needs to be flexible in the choice of treatments when the features do not fit within classic definitions. Even for patients with well-defined headache types, specific therapies may alleviate pain in only 50% to 80% of patients. Still, with careful monitoring of therapeutic response and optimization of effective treatments, patients with a wide variety of headache complaints can be successfully managed with relatively few drugs.

Abortive Therapy

The general approach to treatment of acute migraine headache attacks is one of pharmacotherapy aimed at relieving migraine headache pain and associated symptoms. Such a treatment plan may include (a) 5-HT receptor agonists (e.g., triptans or ergot derivatives), (b) analgesics, (c) sedatives, and (d) antiemetic drug therapy, depending on the exact nature of the patient's complaint. The selection of a specific treatment should be based on the level of disability and associated symptoms such as nausea and vomiting. This "stratified care" approach is preferred over a "step care" approach that may begin with agents that are likely to be ineffective for the patient's headache.³⁷ This latter approach, when applied to all patients regardless of headache severity, only serves to delay effective therapy in many people.³⁸

Aggravating Factors

Clinicians should always search for factors that might precipitate migraine attacks in their patients before initiating drug therapy. Although K.L. could not associate her migraine attacks with any external events, the factors listed in Table 52-3 should be discussed with her in hopes that their elimination or avoidance may improve her headaches. However, complete relief, even in patients who can clearly identify such precipitants, is unlikely.

ORAL CONTRACEPTIVES

4. K.L. recalls being told by her gynecologist that headaches are a possible side effect of oral contraceptive use. She initially started oral contraceptives 2 years ago and did not associate the

Table 52-3 Factors That May Precipitate Migraine Headache

medication with the recent onset of migraine attacks. Why should the discontinuation of Ortho-Novum 7/7/7 be considered in K.L.?

Oral contraceptives may either worsen or precipitate migraine attacks in women without a previous history of this problem.³⁹ Although headaches usually arise within the first few months of oral contraceptive use, headaches developing after several years have been described.⁴⁰ The adverse effect of oral contraceptives on migraine headaches is likely related to the estrogen content. The use of a lower-potency estrogen product decreases the frequency of migraine attacks in some women. Migraine with aura is an independent risk factor for stroke in women, with the highest risk found among those younger than 45 years of age.⁴¹ No consistent increased risk for stroke has been found among men, women older than 45 years old, and women who have migraine without aura.³⁹ Use of oral contraceptives increases the risk of stroke even further. Adjusted odds ratios for stroke risk in women with migraine are 4 for oral contraceptives containing >50 mcg estrogen and 2 for oral contraceptives containing <50 mcg estrogen.³⁹ Several groups recommend against the use of estrogen-containing contraceptives in many women with migraine.^{39a} K.L. should be counseled about her increased risk for stroke and the options for alternative birth control methods. She can then make an informed decision regarding whether or not to continue oral contraceptives. When oral contraceptives are discontinued, 30% to 40% of women⁴² notice an improvement in their headaches, although several months may elapse before a benefit is realized.⁴³ If K.L. elects to discontinue oral contraceptives an alternative form of birth control should be recommended, and the frequency of her headaches should be monitored to detect an improvement in this problem.

Abortive Therapy Triptans (5-HT_{1B/1D} Receptor Agonists)

5. What would be an appropriate drug of first choice for the treatment of K.L.'s acute headaches?

Agents in the triptan class (sumatriptan, zolmitriptan, naratriptan, rizatriptan, almotriptan, frovatriptan and eletriptan) are

effective and well tolerated relative to other agents used for the abortive treatment of acute migraine headaches. Consequently, triptans are appropriate initial therapy for patients with moderate to severe migraine headaches who have no contraindications to their use. Introduction of these agents has had a dramatic effect on the successful relief of disabling headache in many patients. Before this, ergot alkaloids (e.g., ergotamine tartrate) were the preferred agents for migraine headaches when non-narcotic analgesics were ineffective.

Unlike ergotamine, which needs to be taken at the earliest sign of a migraine attack for maximal benefit, the triptans are effective when given 4 hours or longer after the onset of headache.⁴⁴ However, they are more expensive than ergotamine. For this reason, some prescribers and health plans reserve the triptans for patients who are unresponsive or intolerant to less expensive alternatives (e.g., ergotamine, NSAIDs). Pharmacoeconomic studies have suggested an advantage of triptan agents over nontriptan medications when costs are considered from a societal perspective (i.e., take into account lost work productivity in addition to health care costs).⁴⁵

Unlike the ergot alkaloids, which stimulate serotonergic, dopaminergic, and noradrenergic receptors, the triptans have selective agonist activity at 5-HT_{1B/1D} subtype receptors. This feature is likely responsible for the improved tolerability profile for these agents. There are three proposed mechanisms for the effectiveness of the triptans in acute migraine headache: (a) reducing the excitability of neurons in the trigeminovascular system via stimulation of brainstem 5-HT_{1B/1D} receptors, (b) attenuating the release of neuropeptides with inflammatory and vasodilating properties (e.g., CGRP, substance P, and neurokinin A) via a presynaptic 5-HT_{1D} receptor effect, and (c) vasoconstriction of cerebral and extracerebral vessels by stimulation of vascular 5-HT_{1B} receptors.³⁵ The coronary vasculature also contains 5-HT_{1B} receptors; thus, these agents have the potential to cause coronary artery vasoconstriction. For this reason, patients with coronary artery disease and uncontrolled hypertension were excluded from premarketing clinical trials, and the triptans are contraindicated in these patients. Sumatriptan (Imitrex) was the first triptan approved for use, and it is the prototype against which the other “second-generation” triptans are compared. Table 52-4 compares the triptans with regard to selected clinical and pharmacokinetic features.

SUMATRIPTAN

Sumatriptan (Imitrex) is a structural analog of 5-HT that was introduced in 1993 for the abortive treatment of migraine headache (Fig. 52-1). Available formulations include an injection pen device for subcutaneous self-administration, oral tablets, and a nasal spray. All of these formulations (including a rectal formulation not available in the United States) reduce the severity of migraine headache and improve associated symptoms such as nausea, vomiting, photophobia, and phonophobia.⁴⁵ The choice of dosage form depends on the intensity of the headache and the presence of severe nausea. For patients who are nauseated and prone to vomit during an acute attack, the subcutaneous and intranasal dosage forms are preferred. Both formulations have a rapid onset of effect. Reduction in headache intensity is reported within 10 minutes after subcutaneous injection and within 15 minutes after administration of the nasal spray.⁴⁶ Clinical response is delayed after oral administration of sumatriptan tablets,⁴⁶ but this dosage

Table 52-4 Clinical and Pharmacokinetic Features of the Triptans for Acute Migraine Headache⁶⁰

| Drug | Route | Bioavailability (%) | T-max (hr) | Half-Life (hr) | Response Rate at 2 hr (%) | HA Recurrence Within 24–48 hr (%) | Dose/Attack (mg) | Maximum Dose in 24 hr (mg) |
|-----------------------|-------|---------------------|------------|----------------|---------------------------|-----------------------------------|------------------|----------------------------|
| Sumatriptan (Imitrex) | PO | 14 | 1.2–2.3 | 2 | 50–69 | 25–41 | 25–100 | 200 |
| | IN | – | 1–1.5 | 2 | 62–78 | 10–40 | 20–40 | 40 |
| | SC | 96 | 0.2 | 2 | 63–82 | 10–40 | 6–12 | 12 |
| Zolmitriptan (Zomig) | PO | 40–46 | 1.5 | 2.5–3 | 62–67 | 22–37 | 2.5–10 | 10 |
| | IN | 100 | 3 | 2.5–3 | 69 | | 5–10 | 10 |
| Naratriptan (Amerge) | PO | 60–70 | 3–5 | 6 | 43–49 | 17–28 | 1–5 | 5 |
| Rizatriptan (Maxalt) | PO | 40–45 | 1.3 | 1.8 | 60–77 | 35–47 | 5–20 | 30 |
| Almotriptan (Axert) | PO | 70 | 1–3 | 3–4 | 55–65 | 18–30 | 6.25–25 | 25 |
| Frovatriptan (Frova) | PO | 20–30 | 2–4 | 2.6 | 37–46 | 7–25 | 2.5–5 | 7.5 |
| Eletriptan (Relpax) | PO | 50 | 2 | 4 | 47–65 | 6–34 | 20–40 | 80 |

Adapted from reference 60.

form is more convenient and preferred by many patients. During migraine attacks, the gastrointestinal absorption of many drugs is delayed.⁴⁷ This may contribute to the faster onset of action of the nonoral dosage forms of sumatriptan and other drugs.

The efficacy of the triptans has been evaluated using the primary endpoint of headache response (reduction in headache intensity to mild pain or no pain) at 2 hours. Response rates for sumatriptan vary from 50% to 82% (see Table 52-4). Subcutaneous injection is associated with higher response rates than non-parenteral routes of administration. Comparative trials with other antimigraine therapies also support the efficacy of sumatriptan. Subcutaneous sumatriptan is more effective and faster acting than dihydroergotamine (DHE) nasal spray.⁴⁸ When compared with subcutaneous DHE, subcutaneous sumatriptan is more effective at 1 and 2 hours, but the two treatments are equally effective at 3 and 4 hours.⁴⁹ In this trial, headache recurrence rates at 24 hours favored subcutaneous DHE.⁴⁹ Studies of oral sumatriptan show this treatment is more effective than both ergotamine 2 mg with caffeine 200 mg⁵⁰ and aspirin 900 mg plus metoclopramide 10 mg.⁵¹

Adverse Effects

Sumatriptan is usually well tolerated, and this feature offers a significant advantage over ergot alkaloids in many patients.

After oral administration, the most common adverse effects of sumatriptan include nausea and vomiting (which could be related to the migraine itself), malaise, and dizziness. Intranasal sumatriptan is associated with a bitter, unpleasant taste in most patients. Adverse effects following subcutaneous sumatriptan are more common and more uncomfortable than those following oral or intranasal administration. The most common adverse events after subcutaneous administration are mild pain or redness at the site of injection.⁵² These injection site reactions occur in 40% of patients and usually resolve within 60 minutes.⁵² Symptoms of chest pressure or tightness (sometimes extending to the throat) have been reported in 3% to 5% of patients treated with oral or subcutaneous sumatriptan in controlled trials.⁵² However, a questionnaire-based study of 453 users of sumatriptan found a much higher incidence—42% of subcutaneous sumatriptan users and 26% of oral sumatriptan users reported chest symptoms in almost all of their sumatriptan-treated migraine attacks.⁵³ These symptoms are usually mild, resolve within 2 hours, and are unrelated to cardiac ischemia. However, they are uncomfortable enough that 7% to 12% of patients discontinue the drug based on these symptoms.⁵³ Although chest symptoms are rarely serious, sumatriptan has been associated with vascular events, including coronary vasospasm,⁵⁴ angina,⁵⁵ myocardial infarction,⁵⁶ and stroke.⁵⁷ These adverse events usually occur in patients with coronary artery disease or significant risk factors. However, myocardial infarction was reported in one otherwise healthy young woman after sumatriptan.⁵⁸ Because of potential vasoconstrictive effects, sumatriptan should not be used in patients with uncontrolled hypertension, peripheral or cerebral vascular disease, coronary artery disease, previous myocardial infarction, Prinzmetal's angina, or coronary vasospasm. For patients with risk factors of coronary artery disease but who are otherwise deemed appropriate for sumatriptan, the first dose should be administered in a physician's office or an area in which medical support is available.

Headache Recurrence

Another complication of sumatriptan use is recurrent migraine headache. In 25% to 40% of patients, migraine headache recurs within 24 hours after initial successful treatment with sumatriptan.⁵⁹ This phenomenon may be related to the short

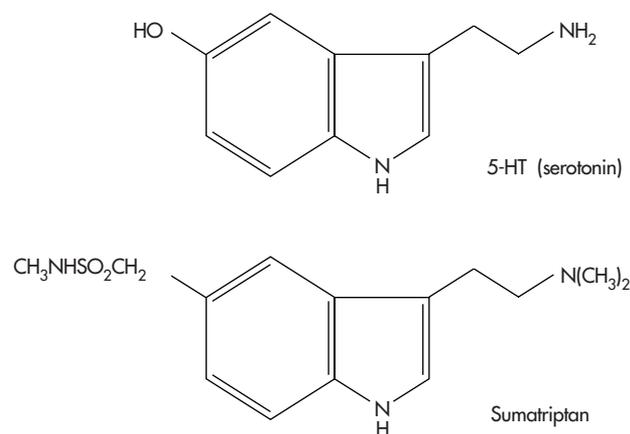

FIGURE 52-1 Structures of 5-HT (serotonin) and sumatriptan.

half-life of the drug, and the recurrent headache often responds to a repeat dose of sumatriptan.⁶⁰

Drug Interactions

Although few drug interactions have been reported with sumatriptan, concomitant use with ergot alkaloids, lithium, serotonin-specific reuptake inhibitors (SSRIs), other triptans, and monoamine oxidase (MAO) inhibitors is not recommended because of the potential for precipitating the serotonin syndrome.⁴⁵ However, several reports describe the safe use of sumatriptan in conjunction with MAO-B inhibitors, SSRIs, and lithium, and clinical evidence of adverse effects is minimal.^{61–63} The potential risks and benefits should be considered when these therapies are used in combination.

Dosing

The recommended dosage of sumatriptan varies according to the route of administration. The initial dose of subcutaneous sumatriptan is 6 mg. If there is no relief within 1 hour, the dose can be repeated. Initial doses of oral and intranasal sumatriptan are 25 to 100 mg and 5 to 20 mg, respectively. These doses may be repeated if there is no relief within 2 hours. When migraine headache recurs after an initial positive response, a repeat dose is often effective. However, the maximum doses in a 24-hour period listed in Table 52-4 should not be exceeded.

SECOND-GENERATION TRIPTANS (ZOLMITRIPTAN, NARATRIPTAN, RIZATRIPTAN, ALMOTRIPTAN, FROVATRIPTAN, ELETRIPTAN)

Since the introduction of sumatriptan, several second-generation triptan agents have been approved for the acute treatment of migraine. In general, these agents have similar pharmacologic features (all are 5-HT_{1B/1D} receptor agonists), and improved oral bioavailability over sumatriptan. Although these agents have similar pharmacologic effects on 5-HT receptors, patients who fail to respond to one triptan may respond to another agent in this class. Like sumatriptan, second-generation triptans also have potential vasoconstrictive effects on coronary arteries. The pharmacokinetic and clinical effects of the second-generation triptans are shown in Table 52-4.

All second-generation triptans have been shown to be superior to placebo for acute migraine relief. Fewer studies compare one agent to another. A recent meta-analysis of 53 controlled clinical trials compared the second-generation triptans with sumatriptan 100 mg orally with regard to efficacy, consistency of relief, and tolerability.^{44,64} Rizatriptan (Maxalt) 10 mg and eletriptan (Relpax) 80 mg were significantly more effective than sumatriptan 100 mg in headache response at 2 hours; naratriptan (Amerge) 2.5 mg, eletriptan 20 mg and frovatriptan (Frova) 2.5 were significantly less effective. Agents were also compared with regard to the percentage of patients with sustained freedom from headache (i.e., no pain at 2 hours, no requirement for rescue medication, and no headache recurrence within 24 hours). Compared with sumatriptan 100 mg, response rates were higher for rizatriptan 10 mg, eletriptan 80 mg and almotriptan (Axert) 12.5 mg, and lower for eletriptan 20 mg. The consistency of therapeutic effect across multiple attacks was also compared. Rizatriptan 10 mg provided more consistent relief than sumatriptan 100 mg. Differences between the triptans in tolerability were generally small. However, the adverse effect rates of naratriptan 2.5 mg and almotriptan 12.5 mg were lower than that for sumatriptan 100 mg.^{44,64}

Although comparison of drugs based on results from different trials may not be reliable, the results of head-to-head comparison studies were consistent with those from single triptan studies when results were pooled for meta-analysis.⁶⁴

Drug Interactions

The metabolism of rizatriptan and zolmitriptan (Zomig) is reduced by MAO inhibitors (particularly MAO-A inhibitors). Thus, like sumatriptan, rizatriptan and zolmitriptan should be avoided in patients taking MAO inhibitors. Propranolol reduces the metabolic clearance of frovatriptan, zolmitriptan, rizatriptan and eletriptan to varying extents. The clinical significance of these interactions is unknown but increased exposure to these triptans should be considered in patients concomitantly receiving propranolol. Inhibitors of CYP3A4 reduce the clearance of almotriptan and eletriptan. For almotriptan, increased exposure to triptans should be anticipated, however no specific dosing adjustments are proposed. The interaction between eletriptan and CYP3A4 inhibitors is more significant, and particular precautions are necessary. Eletriptan should not be used within 72 hours of treatment with potent CYP3A4 inhibitors (e.g., ketoconazole, itraconazole, nefazodone, troleanadomycin, clarithromycin, ritonavir and nelfinavir). As with sumatriptan, there is potential concern regarding the coadministration of second generation triptans and SSRIs. Weakness, hyperreflexia and incoordination have been reported when 5-HT_{1B/1D} agonists are administered to patients taking SSRIs. These potential adverse effects should be considered in patients who require both classes of medication.

Precautions regarding the use of second generation triptans in patients with known or suspected cardiovascular disease are similar to those for sumatriptan and should be strictly followed (see Sumatriptan, Adverse Effects).

All second-generation triptans are available as oral tablets. Rizatriptan and zolmitriptan are also available as oral disintegrating tablets that are placed on the tongue where they dissolve and are swallowed with saliva. Patients who receive these formulations (Maxalt-MLT, Zomig-ZMT) should be told to handle the tablet with dry hands. Zolmitriptan is also available as a nasal spray.

K.L.'s migraine headaches are of moderate to severe intensity (her activities of daily living are negatively affected) and do not respond to moderate doses of aspirin and ibuprofen. Triptans (including sumatriptan and second-generation agents) are appropriate initial antimigraine agents for patients such as K.L. Although her headaches are frequently associated with nausea and vomiting, it is not clear whether these symptoms occur soon after the onset of the attack or whether they evolve gradually as the migraine progresses. If vomiting occurs early, a nonoral route of administration should be considered. Subcutaneous or intranasal sumatriptan are appropriate therapy options. If K.L.'s migraines evolve gradually after the onset of her aura symptoms, then an oral triptan may provide sufficiently rapid relief to be effective. Most patients prefer the convenience of oral dosing. The initial choice of a triptan for oral administration can be made based on cost, pharmacokinetic features and familiarity of the prescriber.

6. Ortho-Novum 7/7/7 was discontinued, and K.L. was fitted for a diaphragm and given instructions on its proper use. She was also given a prescription for sumatriptan 50 mg and told to

take one tablet at the onset of her aura symptoms. At her follow-up clinic visit 2 months later, K.L. reported inconsistent relief from migraine headache with sumatriptan. She experienced six headaches over the past 2 months. The first attack responded to a single dose of sumatriptan 50 mg. The next three migraine attacks failed to respond to the first dose, but responded when she took another 50-mg tablet of sumatriptan 2 hours after the first. However, K.L. is concerned that she is becoming “tolerant” to this medication and has been hesitant to take more than one tablet of sumatriptan for subsequent migraines. Is tolerance a concern with the triptan agents? Should K.L. be changed to another triptan for acute relief of her migraine headaches?

Although there can be some inconsistency in response when triptans are used to treat multiple migraine attacks, the gradual development of tolerance in patients who experience an initial favorable effect is uncommon and not expected. Patients who experience relief after treatment of several migraines with the same dose of a triptan usually continue to experience similar relief over long periods of time.⁵³ Thus, K.L. need not avoid taking sumatriptan (at an effective dosage) because of concerns regarding headache tolerance. In those instances when K.L. experienced adequate relief of her migraine attacks, she usually required two doses of sumatriptan 50 mg. Given this response pattern, she should be encouraged to take 100 mg of sumatriptan at the onset of her migraines in the future. Potential adverse effects should again be discussed with K.L., and she should be informed that these side effects might be more significant with the higher initial dose. However, most patients who tolerate an initial dose of sumatriptan 50 mg are able to tolerate 100 mg as well. At this time, there is no need to consider an alternate triptan for K.L. However, if she is intolerant of sumatriptan 100 mg, then alternate agents such as naratriptan or almotriptan could be considered. However, naratriptan generally has a slower onset of effect than other triptans, and this may be a disadvantage for K.L. If, at a future visit, K.L. is not obtaining adequate relief from sumatriptan 100 mg (followed by an additional dose at 2 hours), then rizatriptan 10 mg should be considered as initial treatment for her migraines. Although eletriptan 80 mg also was superior to sumatriptan 100 mg for migraine response at 2 hours in the meta-analysis discussed above, this dose of eletriptan is higher than that recommended by the manufacturer for initial treatment.⁴⁴

Ergotamine Tartrate

7. What is the role of ergotamine tartrate in the acute treatment of migraine headaches?

Ergotamine tartrate (Bellergal-S, Cafergot) has been used since 1925 for the acute treatment of migraine headaches. Before the availability of agents in the triptan class, ergotamine was widely considered the drug of choice when non-narcotic analgesics were ineffective. The major advantages of this agent are low cost and long history of experience with its use. However, adverse effects of ergotamine are common and potentially serious, particularly when the drug is used in excessive doses or for prolonged periods.⁴² Furthermore, the strength and quality of evidence for ergotamine in acute migraine therapy is less than that for the triptans.³⁸ For these reasons, triptans are often preferred as initial therapy. About 50% to 70% of migraine sufferers benefit from ergotamine given during an acute attack.⁶⁵ Ergotamine is highly specific for migraine and clus-

ter headaches; only occasionally are other types of headaches affected by this drug.

Ergotamine and other ergot derivatives (e.g., dihydroergotamine [DHE]) have numerous pharmacologic effects. However, their precise mechanism of action in migraine is unknown. These drugs are agonists at numerous 5-HT₁ receptor subtypes (5-HT_{1A}, 5-HT_{1B}, 5-HT_{1D}, 5-HT_{1F}), 5-HT₂, adrenergic, and dopaminergic receptors.⁴² Ergotamine has both venous and arterial vasoconstrictive effects. Although it has been presumed that ergot alkaloids relieve migraine by their cerebral vasoconstrictive effects, experimental evidence does not support this as the sole mechanism.⁶⁶ Ergotamine and dihydroergotamine block inflammation of the trigeminal neurovascular system, presumably by inhibiting the release of the neuropeptides discussed above (see Pathophysiology). This action, possibly mediated by 5-HT receptor effects, may be responsible for both the pain-relieving and vasoconstrictive effects of the ergot alkaloids.

Ergotamine should be given at the first sign of a migraine attack in a dosage that is effective and acceptable to the patient. If administration is delayed until the headache is firmly established, ergotamine is rarely effective and other therapies (e.g., DHE, triptans, or narcotic analgesics) are usually required.

CAFFEINE

8. Why is caffeine added to some ergotamine products (e.g., Cafergot)?

Caffeine is combined with ergotamine in several preparations and was originally added to potentiate the vasoconstrictive properties of ergotamine.⁶⁷ Subsequent studies have shown that caffeine improves intestinal ergotamine absorption⁶⁸ and potentiates the pain relief properties of analgesics.⁶⁹ However, it should be kept in mind that caffeine's stimulant effect may prevent sleep, which is beneficial to many migraine sufferers.

9. How do different ergotamine dosage forms compare with each other? What is the usual dosage of ergotamine for acute migraine?

ROUTE OF ADMINISTRATION

Ergotamine tartrate is available for oral, sublingual, rectal, or parenteral use. The rate and extent of drug absorption are erratic following oral, sublingual, and rectal administration. The rectal and sublingual routes of administration bypass the portal circulation, avoid first-pass metabolism, and are more bioavailable than the oral route of administration. However, documentation of improved efficacy is lacking.^{70,71} A metered-dose inhaler containing ergotamine tartrate was previously marketed in the United States, but this product has been withdrawn.

When ergotamine is prescribed, the sublingual preparation is often preferred because it is convenient to use and has a faster onset of action than oral ergotamine.⁷² Acute migraine attacks also are associated with decreased gastric motility.⁷³ This phenomenon is presumably responsible for the impaired oral absorption of aspirin and ergotamine when given during an acute migraine attack.^{47,74} Delayed drug absorption during a migraine attack occurs independent of associated nausea or vomiting and is primarily related to headache severity.⁷⁵ In patients who do not respond to oral or sublingual dosage forms, a trial with ergotamine rectal suppositories may be successful.⁷⁵

Some studies report higher rates of success with rectal administration of ergotamine (i.e., about 70%) than with the oral or sublingual routes of administration (about 50%–60% effective).⁷⁶ This difference may be due to improved bioavailability of ergotamine when administered rectally.⁷⁷ The usual ergotamine dosage (when given by either oral, sublingual, or rectal routes) is 1 to 4 mg given immediately and followed by 1 to 2 mg at 30-minute intervals to a maximum of 6 mg/attack or 10 mg/week. Also, the use of ergotamine should be limited to no more than twice per week to reduce the risk of chronic ergot-related adverse effects (see Question 11).⁴²

CONTRAINDICATIONS

10. What are the contraindications to the use of an ergotamine-containing product?

Contraindications to the use of ergot alkaloids include cardiac, peripheral, and cerebral vascular disease; sepsis; liver and kidney disease; pregnancy; breast-feeding; and concomitant use of triacetyloleandomycin or erythromycin.⁶⁵ The latter drugs can inhibit the metabolism of ergotamine and may potentiate the toxicity of this agent.⁷⁸ The vasoconstrictive effects of ergotamine can be particularly harmful to the patient with these pre-existing conditions. Some sources cite hypertension as a contraindication to ergotamine use, but this is controversial. The usual therapeutic doses of ergotamine used for migraine therapy have minimal effects on blood pressure, and hypertension need not be a strict contraindication to its occasional use.⁷⁹

Concerns about using ergotamine during the aura of migraine when focal neurologic deficits may be due to cerebral ischemia have not been validated. Human studies have found no alteration in regional cerebral blood flow after parenteral administration of either ergotamine or dihydroergotamine and their use during the prodrome is not contraindicated.^{66,80,81} Occasionally, patients experience a prolonged aura or more prominent neurologic symptoms with ergotamine use. In these individuals, ergotamine use should not be continued.⁴²

ADVERSE EFFECTS

11. What adverse effects should be monitored for in patients who receive ergotamine?

Gastrointestinal (GI) disturbances can be a limiting factor to the use of ergotamine for headache therapy. Nausea, vomiting, and anorexia are common, dose-dependent ergotamine adverse effects, which may worsen the GI symptoms that commonly accompany acute migraine headaches. These GI symptoms after ergotamine use are likely the result of central dopamine receptor agonism at the chemoreceptor trigger zone. Because these effects are centrally mediated, they can occur after administration of ergotamine by any bioavailable route. Patients are reluctant to continue therapy if their initial experience with the medication has been unpleasant. Therefore, patients should be educated as to the potential for this adverse effect.

Clinicians can also take measures to minimize migraine-associated and ergotamine-induced GI upset. One useful technique is to determine the smallest dose of ergotamine that will elicit GI distress in a patient during a headache-free interval. For example, if the suppository form of ergotamine is being used, the patient can be instructed to insert one-fourth of a

suppository at hourly intervals until nausea develops. The total dosage is then reduced by one-fourth of a suppository and used as the initial dose for subsequent migraine attacks.⁷⁹ The same technique can be used for patients using oral or sublingual ergotamine by splitting the tablets in half.

The peripheral vasoconstrictive effects of ergotamine most commonly involve the lower extremities and are often characterized by coldness, decreased distal pulses, and a tingling sensation. Continuous paresthesias, limb pain, venous thrombosis, or gangrene necessitating amputation are more severe consequences of ergotamine therapy.⁸² Although some of these symptoms may occur with therapeutic doses in hypersensitive individuals, they are most commonly associated with overdose or excessive therapeutic use of ergotamine. Beta-adrenergic receptor blocking agents, commonly used in migraine prophylaxis, occasionally can potentiate the vasoconstrictive effects of ergotamine.^{83,84} Their concomitant use is not contraindicated, but patients should be closely monitored for the signs and symptoms of peripheral vasoconstriction.

Rebound headache after discontinuation of long-term, daily ergotamine use is another common adverse effect. These rebound headaches respond to larger ergotamine doses, but ultimately the headaches become more frequent and other symptoms of ergotamine overuse become apparent (e.g., symptoms of peripheral vascular insufficiency). This cycle of overmedication and resultant headaches can render patients refractory to other forms of headache treatment.⁸⁵

ANTIEMETICS

12. What is the role of antiemetic therapy for the outpatient treatment of migraine-associated nausea and vomiting?

In most patients, triptan agents provide effective relief of migraine-associated nausea. Therefore, specific antiemetic therapy usually is not required. However, as mentioned above, persistent nausea is more common in patients who use ergotamine for acute migraine therapy. In these patients, and in triptan-treated patients who experience incomplete nausea relief, adjunctive antiemetic therapy should be considered. Phenothiazine antiemetics can provide symptomatic relief from nausea; however, they can also reduce GI motility and further impair absorption of medication taken orally.⁸⁶ Metoclopramide (Reglan) is the antiemetic of choice in migraine.⁸⁷ The recommended dose is 10 mg taken orally as soon as possible. Although the drug has no direct antimigraine effect,⁸⁸ it does provide symptomatic relief from nausea and vomiting while enhancing the oral absorption of medications taken during the migraine attack.⁸⁶ Unfortunately, metoclopramide is not available in a suppository dosage form.

13. In addition to the triptans and ergotamine tartrate, what other abortive agents are available for outpatient treatment of acute migraine headache?

In the stratified care approach, isometheptene compound, NSAIDs, and combination analgesics are reasonable treatment options for patients with mild-to-moderate migraine headaches or those with severe attacks that have responded to these agents in the past.³⁸ Dihydroergotamine nasal spray is indicated for moderate-to-severe migraine headache.³⁸

Isometheptene Compound

Isometheptene, a sympathomimetic amine, is combined with acetaminophen and a sedative (dichloralphenazone) in the product of Midrin. This combination is as effective as oral ergotamine in the treatment of acute migraine headaches^{89,90} and, in many patients, better tolerated. Although the contraindications to Midrin are similar to those of ergotamine, severe adverse effects are less common. Patients unresponsive to ergotamine products occasionally respond to Midrin. In patients with mild to moderate migraine, isometheptene compound provides comparable relief to sumatriptan 25 mg given orally.⁹¹ The usual dosage of Midrin is two capsules taken immediately followed by one additional capsule every hour until the headache is relieved. Subsequent migraine attacks can be managed by administering the same total dose of Midrin that was effective in treating the previous headache, but no more than five Midrin capsules should be taken within a 12-hour period.⁸⁹

Nonsteroidal Anti-Inflammatory Drugs and Combination Analgesics

Many NSAIDs and combination analgesics containing caffeine have been shown to be effective for the acute treatment of migraine headache.⁹² Significant clinical benefit in double-blind, placebo-controlled trials has been shown for aspirin, ibuprofen, naproxen sodium, and combination analgesics containing acetaminophen, aspirin, and caffeine.³⁸ Selected NSAIDs (e.g., naproxen sodium, ketoprofen, diclofenac potassium) are as effective as ergotamine^{93–95} or sumatriptan⁹³ in the relief of migraine headache. However, consistent differences among NSAIDs in migraine therapy have not been demonstrated. If NSAIDs are to be used in the abortive treatment of migraine, the concomitant administration of metoclopramide can enhance their absorption, providing more effective and rapid pain relief.^{47,96}

Dihydroergotamine Nasal Spray

A nasal spray formulation of dihydroergotamine (DHE) (Migranal) is available for abortive therapy of migraine. Previously, this agent was available for parenteral use only and was usually restricted to use in clinic and emergency department (ED) settings (see Intractable Migraine). DHE is less likely than ergotamine to cause severe nausea and vomiting, and it is a less potent arterial vasoconstrictor.⁹⁷ In clinical trials, DHE nasal spray is more effective than placebo in relieving pain (beginning as early as 30 minutes after treatment) and reducing post-treatment nausea.^{98–100} In an unpublished, active control trial, DHE nasal spray was equally effective and better tolerated than an ergotamine/caffeine combination product (Cafergot).¹⁰¹ Patients given this treatment should self-administer one spray (1 mg) into each nostril followed in 15 minutes by an additional spray in each nostril for a total of four sprays (4 mg). DHE nasal spray is reasonable to consider as an initial agent for moderate to severe migraine headache.³⁸

Intractable Migraine

14. K.L. used sumatriptan 100 mg PO for her next two migraine headache attacks and obtained good relief. K.L. experienced another headache with severe nausea. She took sumatriptan 100 mg PO but vomited immediately thereafter, and the headache continued to worsen throughout the day until she could no longer work.

K.L. was taken to the ED by a friend. The diagnosis of intractable migraine was made. How should K.L. be treated?

Dihydroergotamine

Intractable migraine with associated vomiting usually requires parenteral therapy with ergot derivatives, sumatriptan, or potent narcotic analgesics. DHE-45, 1 mg subcutaneously¹⁰² or intramuscularly¹⁰³ or 0.75 mg intravenously,¹⁰⁴ is particularly effective in the treatment of acute and intractable migraine headaches and thereby reduces the necessity for narcotic analgesics. If ineffective, a second dose of DHE should be administered 30 to 45 minutes later. An IV antiemetic (prochlorperazine 5 to 10 mg or metoclopramide 10 mg) should be administered 15 to 30 minutes before DHE to minimize the GI side effects of this agent. Intramuscular administration of ergotamine tartrate 0.5 mg is also effective, but ergot-related side effects are more severe with ergotamine tartrate than with DHE. Ergotamine tartrate administered by the oral, sublingual, or rectal routes is unlikely to be effective in this setting.

Sumatriptan

Sumatriptan 6 mg subcutaneously is also effective for the treatment of established migraine.⁵³ If the first injection does not provide relief at 1 hour, a second injection may be administered. However, the daily dosage should not exceed 12 mg. Sumatriptan should not be administered within 24 hours of ergot alkaloids because of the potential for prolonged vasospastic reactions.

Prochlorperazine

Prochlorperazine (Compazine) is an antiemetic agent often used as an adjunct for patients with migraine-associated nausea and vomiting. However, when given by IV route prochlorperazine is also a nonspecific yet highly effective agent for aborting intractable migraine.³⁸ In randomized, controlled trials, prochlorperazine 10 mg IV was more effective than placebo, IV metoclopramide, IV ketorolac, and IV valproate for the treatment of acute migraine in the emergency department.^{105–107}

Chlorpromazine

Like prochlorperazine, chlorpromazine (Thorazine) given parenterally has both antimigraine and antiemetic properties and has gained increased acceptance in EDs as a pharmacologic alternative to potent narcotic analgesics such as meperidine. In a double-blind, controlled trial, IV chlorpromazine (0.1 mg/kg) provided more effective pain relief from intractable migraine than meperidine (0.4 mg/kg) plus dimenhydrinate.¹⁰⁸ Chlorpromazine 1 mg/kg intramuscularly has also been shown to relieve migraine headache more effectively than placebo.¹⁰⁹

Narcotic Analgesics

Parenteral narcotic analgesics also effectively relieve intractable migraine headache pain, but they should generally be reserved for second- or third-line therapy after patients have failed to respond to parenteral sumatriptan, DHE, prochlorperazine or chlorpromazine. ED treatment of headache with narcotics is a common antecedent to iatrogenic drug addiction.¹¹⁰ In some EDs that deal with a large number of drug-seeking patients, the use of synthetic narcotic agonist/antagonists (e.g., butorphanol, nalbuphine) has been advocated for treatment of intractable migraine.^{111,112} Butorphanol is also available as a

Table 52-5 Drug Treatment of Acute Migraine Headache^a

| Drug | Route | Dose | Contraindications | Adverse Effects | Comments |
|---|----------------|---|---|--|---|
| Sumatriptan (Imitrex) | PO IN SC | 6 mg SC stat; may repeat in 1 hr | Ischemic heart disease, within 24 hr of ergot alkaloids | Heavy sensation in head or chest, tingling, pain at injection site | First-line therapy for moderate-to-severe headaches; SC for intractable migraine |
| Ibuprofen (Motrin) or other NSAIDs | PO | 400–800 mg | Aspirin or NSAID-related bronchospasm | N, V, bleeding, renal dysfunction | First-line therapy for mild-to-moderate headaches |
| Dihydroergotamine (Migranal) | IN IM IV | 2 mg IN stat; repeat in 15 min | See Ergotamine | Rhinitis, dizziness, N, V | For moderate-to-severe headaches; parenteral use for intractable migraine |
| Ergotamine tartrate (Cafergot, Ergostat) | PO SL PR | 1–4 mg stat, then 1–2 mg Q 30 min to max of 6 mg/attack or 10 mg/wk | CV disease, sepsis, liver or kidney disease, arterial insufficiency, pregnancy, breast feeding, concomitant macrolide use | N, V, anorexia, limb paresthesias or pain | Use at HA onset for max effect; ↓ N and V by using smallest effective dose |
| Isometheptene/dichloralphenazone/acetaminophen (Midrin) | PO | 2 cap stat, then 1 cap Q hr to max 5 cap/12 hr | See Ergotamine tartrate; avoid in patients taking MAOIs | N, V, dizziness, drowsiness | As effective as ergotamine tartrate |
| Prochlorperazine (Compazine) | IM IV | 10 mg stat | CV disease | Extrapyramidal reactions, sedation, dizziness | IV/IM for adjunctive antiemetic therapy; IV for antimigraine effect in intractable migraine |
| Chlorpromazine (Thorazine) | IM | 1 mg/kg | CV disease, history of seizures | Extrapyramidal reactions, sedation, hypotension | For intractable migraine; also has antiemetic properties |
| Morphine (or meperidine) | IM | 5–10 mg | ↑ ICP or head trauma with fundoscopic changes | Sedation, hypoventilation | For intractable migraine |
| Metoclopramide (Reglan) | PO IM | 10 mg stat | GI hemorrhage or obstruction; pheochromocytoma | Extrapyramidal reactions, sedation, restlessness | For adjunctive antiemetic therapy; prochlorperazine also effective |

^aSee text for references and additional details. See Table 52-4 for additional information on sumatriptan and other triptan agents.

CV, cardiovascular; GI, gastrointestinal; HA, headache; ICP, intracranial pressure; IM, intramuscular; IN, intranasal; MAOIs, monoamine oxidase inhibitors; N, nausea; NSAID, nonsteroidal anti-inflammatory drug; PO, oral; PR, rectal; SC, subcutaneous; SL, sublingual; V, vomiting.

nasal spray for self-administration during migraine headache. Although this product was initially thought to have a low addiction liability, subsequent experience suggests that the product is often misused or diverted for misuse purposes.¹¹³ Patients receiving this medication should be monitored for excessive use. In a comparison with intramuscular butorphanol and intramuscular meperidine plus hydroxyzine, the superiority of IV DHE plus metoclopramide was clearly demonstrated.¹¹¹

In general, narcotic analgesics can be highly effective therapies for acute and intractable migraine. However, these agents often cause or exacerbate nausea and vomiting. Also, excessive use should be monitored closely because of the risk of addiction and dependence. Alternative symptomatic therapies should be pursued for those patients who require frequent use of narcotic analgesics (usually defined as two or more treatments per week).⁴⁴

Corticosteroids

Prednisone 40 to 60 mg orally for 3 to 5 days or dexamethasone 4 to 16 mg intramuscularly may be used as alternative

treatments for intractable migraine and presumably work by suppressing the sterile perivascular inflammation of resistant headache.¹¹⁴ Table 52-5 summarizes the agents commonly used for the treatment of acute migraine headaches.

Appropriate treatments for K.L.'s current headache include DHE (by subcutaneous, intramuscular, or IV route), subcutaneous sumatriptan, or intravenous prochlorperazine. Each of these treatments has proved effective in at least two double-blind trials.⁴⁴ Although ergot alkaloids should not be administered within 24 hours of sumatriptan, K.L. vomited immediately after taking sumatriptan and it is unlikely that she absorbed the drug. Thus, DHE is not contraindicated. Since K.L. has responded to oral sumatriptan in the past, subcutaneous administration of this drug would be appropriate initial therapy at this time. Adjunctive therapy with prochlorperazine (5 mg intramuscularly or intravenously) would provide relief from nausea and vomiting, and may also contribute to a reduction in headache severity. If K.L.'s headache persists after 6 mg subcutaneous sumatriptan, a second injection can be given 1 hour after the first.

Prophylactic Therapy

15. K.L. returns to the clinic 6 weeks later for follow-up. Her current medications include oral sumatriptan and acetaminophen with codeine. Acetaminophen with codeine 30 mg (#20) was prescribed by the ED physician who treated her single episode of intractable migraine. Since that episode, about 75% of her headaches have responded to sumatriptan 100 mg orally. The remainder of her attacks have been aborted with two acetaminophen with codeine tablets and rest. Her concern is that these resistant headaches occur as often as once or twice monthly and necessitate her taking the rest of the day off from work. K.L. reports no adverse effects from sumatriptan.

K.L.'s primary care physician wants to initiate treatment to reduce the frequency and severity of K.L.'s migraine attacks and chooses propranolol as the initial agent. When should prophylactic therapy of migraine be considered? Is propranolol a reasonable choice for K.L.?

Criteria for Use

K.L.'s present drug regimen is effectively aborting about 75% of her migraine attacks. The frequency of her disabling, drug-resistant headaches, however, is sufficient to warrant additional therapy that is directed toward preventing migraine attacks. Prophylactic migraine treatment not only reduces the frequency of migraine attacks, but also may reduce the severity of ensuing headaches, render them more responsive to abortive measures, or reduce the duration of headaches. The usual criteria for migraine prophylaxis are (a) headaches that impact a patient's life despite the use of abortive treatments (e.g., twice monthly or more), (b) headaches occurring so frequently that acute medications are overused, (c) disabling headaches that are unresponsive to abortive treatments, (d) patients in whom abortive agents are contraindicated, and (e) headaches that present a significant risk for future morbidity or mortality (e.g., hemiplegic migraine, migraine with prolonged aura, basilar migraine, or migraines associated with stroke).¹¹⁵ Given the frequency with which K.L. continues to experience migraine headaches and the detrimental effect they have on her job performance, prophylactic migraine therapy is warranted.

Various prophylactic agents have been advocated to reduce the frequency and severity of migraine headaches. For many of these drugs, it is difficult to make an adequate assessment of relative efficacy based on the available literature. Therapeutic trials often are not optimally designed to establish the relative usefulness of a given drug relative to other prophylactic agents. For example, the efficacy of newer therapies may be repeatedly compared with placebo rather than with other agents whose effectiveness is well documented, whose dosages are often suboptimal, or whose duration of therapy may be insufficient to document maximal efficacy. Ideally, the evaluation of migraine drug therapy should be based on double-blind, controlled, crossover trials with optimal dosage titration (to effect, toxicity, or established maximum dosing recommendations) and with sufficient wash-out periods to minimize ambiguous results. Many prophylactic therapy recommendations are not so well grounded. Recently, a structured, evidence-based guideline for prophylactic treatment of migraine headache was published.^{115,116} Recommendations given below are based on these guidelines, which represent a synthesis of the results

from published trials and expert opinion. Generally, the preferred agents for prophylaxis of migraine headache are propranolol, timolol, amitriptyline, and valproate (including divalproex sodium). The use of these agents is supported by multiple randomized controlled trials and mild-to-moderate adverse effects. Other agents discussed below either have less evidence basis for a strong recommendation (i.e., few or no randomized controlled trials), or have been associated with significant adverse effects that limit their usefulness. In the United States, the only agents approved by the FDA for migraine prophylaxis are propranolol, timolol, valproate, topiramate and methysergide. Table 52-6 contains a list of the more well-established drugs used for migraine headache prophylaxis.

Propranolol

K.L.'s primary care physician has chosen propranolol for prophylactic therapy of migraine. This is an appropriate choice. Propranolol (Inderal) is a first-line agent for migraine prophylaxis because of its safety, efficacy, favorable adverse effect profile, and the large number of studies that support its effectiveness.^{117,118} Although the effectiveness of propranolol in the prophylaxis of migraine is well established, not all individuals respond to this treatment.¹¹⁸⁻¹²⁴ When propranolol is used, approximately 50% to 80% of patients obtain complete or partial relief from migraine attacks^{118,124,125}; most patients who initially respond to propranolol continue to benefit without any evidence of drug tolerance.¹²⁴

The mechanism by which propranolol exerts its antimigraine effects is unknown. It was generally assumed, without evidence to support the hypothesis, that β -receptor blockade prevented the vasodilatory phase of migraine; however, propranolol has no significant effect on cerebral blood flow.¹²⁶ The mechanism of action may be related to the drug's effects on the serotonergic system.^{127,128} Propranolol has a high affinity for serotonin receptors¹²⁸ and has been shown to inhibit platelet uptake of serotonin in vivo and in vitro.¹²⁹

Other β -adrenergic blocking drugs such as timolol¹³⁴ and the cardioselective agents, metoprolol¹³⁰ and atenolol,^{131,132} appear to be as efficacious as propranolol in double-blind, crossover trials. However, besides propranolol, timolol is the only β -blocker with FDA approval for this indication. Atenolol is an appropriate therapeutic alternative for patients who cannot tolerate propranolol's CNS adverse effects. The lack of efficacy demonstrated for pindolol,¹³³ acebutolol,¹³⁴ alprenolol,¹³⁵ and oxprenolol¹³⁶ may be related to their intrinsic sympathomimetic activity, and these agents should not be used.

DOSING

16. What dose of propranolol should be prescribed for K.L.? When can she expect a response?

Propranolol 80 to 240 mg/day in two to four divided doses is effective in the prophylaxis of migraine headaches.^{115,118} Because the dosage range is wide, propranolol therapy should be initiated with 20 mg two or three times a day; this dose can be increased gradually at weekly intervals according to patient tolerability or to a maximum of 320 mg/day.¹¹⁷ Once the daily dosage of propranolol required to control headaches is established, patient adherence may be improved by changing to a long-acting oral dosage form (e.g., Inderal LA). Although the

Table 52-6 Drugs Useful for Migraine Headache Prophylaxis^a

| Drug | Dose | Dosage Forms/Strengths | Effectiveness | Comments |
|----------------------------|---|---|--|---|
| Propranolol (Inderal) | 20 mg BID–TID; gradually ↑ dose at weekly intervals to effect or max of 320 mg/day | Tab: 10, 20, 40, 60, 80, 90 mg ER Cap: 60, 80, 120, 160 mg | 50–80% obtain complete or partial relief; comparable to methysergide | First line therapy; atenolol, metoprolol, and timolol also effective |
| Amitriptyline (Elavil) | 10–25 mg HS; ↑ by 10–25 mg/day at weekly intervals to max 150 mg/day; most should benefit from 50–75 mg/day | Tab: 10, 25, 50, 75, 100, 150 mg | Effectiveness comparable to propranolol and methysergide | First line therapy effective for prophylaxis of migraine and tension-type headache |
| Valproate (Depakote) | 250 mg BID; ↑ by 250 mg/day at weekly intervals to effect or adverse effects; most should benefit from 1,000–2,000 mg/day | Cap ^b : 250 mg DR Tab ^c : 125, 250, 500 mg ER Tab: 250, 500 mg SCaps: 125 mg | 50% obtain complete or partial relief | First line therapy |
| Verapamil (Isoptin, Calan) | 80 mg TID. If needed, ↑ dose gradually to max of 480 mg/day | Tab: 40, 80, 120 mg ER Cap: 120, 240 mg ER Tab: 180, 240 mg | 50% obtain complete or partial relief | Second line therapy Delay of 1–2 months for maximal effect; efficacy of nifedipine and diltiazem questionable |
| Methysergide (Sansert) | 2–8 mg/day in 3–4 divided daily doses to be taken with food | Tab: 2 mg | 60–70% obtain complete or partial relief | Use limited by propensity for frequent and sometimes severe adverse effects; drug holidays should be planned every 6 mo. Rarely used |
| Naproxen sodium | 550 mg BID | Tab: 220, 275, 550 mg | 30% obtain complete or partial relief | Second line therapy Modest efficacy; effective for menstrual migraine; naproxen, flurbiprofen, ketoprofen, mefenamic acid also effective |

^a See text for references and additional details.

^b Valproic acid capsules.

Cap, capsules; DR, delayed release; ER, extended release; SCap, sprinkle capsules containing coated particles; Tab, tablets.

usual dosage for migraine prophylaxis is 80 to 240 mg/day, up to 30% of patients prophylactically treated with propranolol would not have benefited in one clinical study of 865 patients if the propranolol dosage had not been titrated to a maximum of 320 mg/day.¹²⁵ Most propranolol responders will experience relief within 4 to 6 weeks of beginning therapy.⁷⁹ However, in unusual circumstances, 3 to 6 months may be required before maximal benefit is realized.¹²⁵ Tolerance to the antimigraine effects of propranolol over long-term therapy does not occur.¹²⁴

Because propranolol is highly effective and well tolerated in most patients, it is an appropriate prophylactic agent for K.L. She has no pre-existing disease states that would prohibit its use. K.L. should be started at a low dosage with gradual titration to either therapeutic response, side effects, or a maximum dose of 320 mg/day. Six weeks or longer may be required before optimal results are achieved.

Methysergide

17. G.W., a 46-year-old man with an 11-year history of migraine without aura, comes to a clinic with a complaint of epigastric distress for the past 2 days. Current medications include Fiorinal (aspirin 325 mg, butalbital 50 mg, caffeine 40 mg) two capsules PO at headache onset, methysergide (Sansert) 2 mg PO TID, salmeterol inhaler 1 puff every 12 hours, fluticasone (44 mcg/puff)

2 puffs every 12 hours, albuterol metered-dose inhaler 2 puffs as needed for shortness of breath, and Theo-Dur 300 mg PO BID. G.W.'s headaches are notable for bilateral, throbbing, temporal head pain and the absence of associated GI or focal neurologic symptoms. Migraine prophylaxis with methysergide has reduced his headache frequency from three headaches monthly to about one headache every 2 to 3 months. A review of G.W.'s medical record reveals that methysergide therapy was initiated 2 years ago and that a drug holiday was not taken. Past medical history includes asthma since adolescence, with frequent ED visits for exacerbation of symptoms and a 3-year history of painful lower extremity peripheral vascular disease (PVD). Why is methysergide an inappropriate alternative to propranolol prophylaxis of migraine in this asthmatic patient with PVD?

Methysergide, a semisynthetic ergot alkaloid with 5-HT₂-receptor antagonist properties, is one of the most effective agents for migraine prophylaxis;¹³⁷ in past decades, it was the standard by which newer therapies were often judged. However, its use is limited by a propensity for frequent, and sometimes severe, side effects. For this reason, methysergide is considered a fourth-line agent for migraine prophylaxis.¹¹⁵

Within the usual dosage range of 2 to 8 mg in three to four daily divided doses, as many as 40% of patients treated with methysergide will experience side effects. Adverse effects are severe enough to require discontinuation in 10% of patients.

CONTRAINDICATIONS

Like other ergot alkaloids, methysergide has peripheral vasoconstrictive properties that may preclude its use in some patients. Contraindications to methysergide use include PVD, coronary artery disease, thrombophlebitis, and pregnancy. Even when such precautions are kept in mind, some patients experience side effects attributable to the drug's vasoconstrictive properties (e.g., coldness, numbness, and tingling of the extremities or even anginal pain).

Given G.W.'s history of PVD, methysergide is not an appropriate agent for migraine prophylaxis. Although he had a history of PVD before methysergide was initiated, the continued use of this drug may have aggravated his condition. G.W.'s methysergide should be tapered immediately and an alternative treatment regimen initiated.

ADVERSE EFFECTS

18. In addition to G.W.'s history of PVD, what is another reason for discontinuing his methysergide therapy, and how should it be tapered?

Retroperitoneal, endocardial, and pleuropulmonary fibrosis are severe complications of methysergide. Fibrosis has developed after 7 to 79 months of methysergide therapy and has been associated with dosages in excess of 8 mg/day.⁷⁹ Because most fibrotic complications have been reported following long-term, uninterrupted use of methysergide,¹³⁸ drug-free holidays of 3 to 4 weeks are recommended after each 6-month treatment period to minimize this risk. However, the discontinuation of methysergide should be gradual to avoid the rebound vascular headache that can occur after abrupt discontinuation. Patients receiving long-term therapy should be counseled to report any flank pain, dysuria, or chest pain to their physician. During each patient visit, cardiac auscultation should be performed. An IV pyelogram and chest radiograph also should be obtained after 6 months of therapy to monitor for the development of fibrosis. When the therapeutic benefits of methysergide become evident (~3 to 4 weeks after initiation of therapy), the dose of this drug should be reduced to the minimum effective amount.⁷⁹

Because G.W. has received methysergide continuously for 2 years without a drug holiday, he is at risk for developing methysergide fibrosis. The methysergide should be discontinued in G.W. because of the risk of drug-induced fibrosis and because of his history of PVD. His methysergide therapy should be gradually tapered to discontinuation over a 3-week period to avoid migraine headache rebound. Subsequently, another form of prophylactic therapy should be initiated for G.W.

19. G.W. has been experiencing nausea for the past 2 days. What is one approach to resolving these GI complaints?

GI distress is the most common side effect to methysergide therapy. However, the discomfort is usually mild and disappears within the first several days to weeks of therapy. GI distress can be minimized by administering methysergide doses with food and by avoiding rapid increases in dose. Because G.W. has received methysergide therapy for 2 years and his GI complaints appear to be of recent origin, other potential causes for GI distress should be investigated. Methysergide can also activate latent peptic ulcer disease,¹³⁹ presumably by increasing gastric acid secretion.¹⁴⁰ However, G.W. has no known his-

tory of ulcer disease and his GI complaint does not specifically suggest this complication.

G.W.'s GI distress may be the result of gastritis or peptic ulcer disease caused by the aspirin component in Fiorinal (G.W. receives 650 mg aspirin with each two capsule Fiorinal dose). The nausea also could be due to theophylline toxicity. These potential causes of G.W.'s nausea should be evaluated. A laboratory determination of G.W.'s hemoglobin (Hgb) concentration and evaluation of his stools for occult blood would be helpful in assessing aspirin-induced gastritis with blood loss. A serum theophylline concentration also should be obtained. A more detailed history that focuses on the relation between nausea and medication use or other concurrent illness may also provide useful information for assessing G.W.'s GI distress.

20. What drug should be prescribed in place of methysergide to prevent G.W.'s migraine attacks?

Along with propranolol, amitriptyline and valproate are effective first-line therapies for prevention of migraine headache. The effectiveness of these agents is supported by randomized controlled trials, and adverse effects are generally mild-to-moderate in severity.

Amitriptyline

Amitriptyline (Elavil) is effective for prevention of both migraine and tension-type headaches. It may be the drug of choice for patients whose symptoms suggest features of both headache types (i.e., mixed tension-type/migraine headaches), and for those with coexisting depression. Along with propranolol and valproate, amitriptyline is considered a first-line therapy for migraine prophylaxis.¹¹⁵

In a double-blind, placebo-controlled, cross-over study, amitriptyline was as effective as propranolol.¹⁴¹ It also was as effective as methysergide based on comparative results from previous studies.¹⁴² The mechanism of amitriptyline's antimigraine effect is independent of its antidepressant activity^{141,143} and may be related to its ability to block the reuptake of serotonin at central sites.¹⁴⁴ However, other antidepressant agents that block 5-HT reuptake (e.g., clomipramine) have been ineffective for migraine prophylaxis.¹⁴⁵ Amitriptyline and other antidepressants have been reported to down-regulate 5-HT receptors, although this effect has been inconsistent in published reports.¹⁴⁶

DOSING

The initial dose of amitriptyline is 10 to 25 mg at bedtime. This nightly dose can be increased at weekly intervals by 10 to 25 mg until the maximum dose of 150 mg/day is reached. Most patients achieve optimal benefit from 50 to 75 mg/day of amitriptyline; doses greater than 150 mg/day are unlikely to produce better results.⁷⁹ Two-thirds of patients note a decrease in the number of headaches within 7 days of starting amitriptyline therapy, but a 6-week trial is warranted before the drug should be considered ineffective.^{142,143}

No other antidepressant agents have been studied as extensively as amitriptyline for migraine prophylaxis and their efficacy remains unproven. Fluoxetine (Prozac) was effective in one small trial.¹⁴⁷ However, the favorable results were not reproduced in a larger, subsequent study.¹⁴⁸ A study of amitriptyline 25 mg/day and fluvoxamine 50 mg/day demonstrated

reductions in headache frequency for both drugs when pre-treatment and post-treatment periods were compared.¹⁴⁹

Valproate

The antiepileptic drug valproate (and divalproex sodium, Depakote) is also approved for the prevention of migraine headaches and is useful as a first-line agent in this regard.^{115,150} In a randomized, double-blind, parallel treatment comparison of valproate (titrated to trough serum concentrations of 70 to 120 mcg/mL) and placebo, 48% of valproate-treated patients had a 50% or greater reduction in the frequency of migraine.¹⁵¹ In a single-blind comparison of valproate and propranolol, both agents were equally effective as prophylaxis for migraine without aura.¹⁵²

DOSING

The initial dose of valproate is 250 mg PO BID. The dose can be increased in 250- to 500-mg/day increments at weekly intervals. The usual range of effective doses is 500 to 1,500 mg/day. Serum levels of valproate may be useful to monitor therapy; however, a clear relation between concentration and antimigraine effect has not been established. Enteric-coated products (e.g., Depakote) are preferred over immediate release products (e.g., Depakene) to minimize gastrointestinal upset. An extended-release dosage form (Depakote ER) is approved for once-daily dosing and may be useful to improve medication adherence.

Either amitriptyline or valproate would be reasonable choices for prevention of migraine headaches in G.W. Although direct comparative trials have not been performed, these agents appear to be equally effective. Thus, the choice can be made on the basis of the adverse effect profile of these agents. The most common adverse effects of amitriptyline include dry mouth, reflex tachycardia, blurred vision, weight gain, and difficulty with cognition. The most common adverse effects of valproate include nausea, alopecia, tremor, and weight gain. The adverse effect profiles of each agent should be discussed with G.W., and, on the basis of his preference, a choice between these agents should be made.

21. S.A. is a 31-year old woman with a 4-year history of disabling migraine headaches (with aura) occurring two to three times weekly. She is currently using zolmitriptan (Zomig) 5 mg for abortive therapy, and the clinic physician is concerned about overuse of this agent. Medical history includes bipolar affective disorder and a history of polydrug abuse. S.A. has failed prophylactic therapy with propranolol (ineffective) and valproate (modestly effective, but caused unacceptable weight gain). She is currently taking lithium for her bipolar disorder, and her serum levels have been stable at 0.8 mEq/L. Her physician wishes to avoid antidepressants because of her psychiatric history. What other prophylactic therapies are available?

Nonsteroidal Anti-Inflammatory Drugs

In addition to being effective as symptomatic therapy for migraine, selected NSAIDs are also effective as prophylactic agents. However, their effectiveness as preventive therapy is considered to be modest compared with the first-line agents, propranolol, amitriptyline, and valproate.¹¹⁵ The rationale for their use is that inhibition of prostaglandin and leukotriene synthesis might inhibit the neurogenic inflamma-

tion of migraine. However, their actual mechanism of action is unknown. Placebo-controlled trials have documented the effectiveness of naproxen,¹⁵³ naproxen sodium,^{154,155} ketoprofen,¹⁵⁶ flurbiprofen,¹⁵⁷ and mefenamic acid.¹⁵⁸ A comparative study of naproxen sodium 1,100 mg/day and propranolol 120 mg/day found a trend favoring propranolol, although the difference in response between the two treatments was not significant.¹⁵⁹ Given the favorable trend toward propranolol and the use of a suboptimal dose of the drug in this trial, it is unlikely that naproxen sodium is a superior agent for migraine prophylaxis. The NSAIDs mentioned above may be effective as short-term therapy for menstruation-associated migraine.¹¹⁵

Calcium Channel Blockers

VERAPAMIL

Calcium channel blockers influence the final common pathway of vascular reactivity by altering calcium flux across smooth muscle. Hormone and neurotransmitter secretion are also calcium-dependent processes that can be altered by calcium channel blockers.¹⁶⁰ Whether the efficacy of calcium antagonists in migraine therapy is due to their vasoactive properties, modulation of neurotransmitter release, or a serotonergic effect is unknown.

Verapamil (Isoptin, Calan, Verelan) is the calcium channel blocker of choice for preventive migraine therapy because it is effective and has been most extensively studied in randomized controlled trials. Most patients respond to verapamil at doses of 240 to 320 mg/day. Therefore, treatment can be initiated with an 80-mg dose three times a day and increased to 80 mg four times a day after 1 week. Observable benefits from this treatment may not be apparent for 3 to 8 weeks; as a result, verapamil should be continued for at least 2 months to properly evaluate response to therapy. This is one of the limiting properties of calcium channel antagonists. If an adequate response is not achieved in this interval, the verapamil dose can be increased weekly by increments of 80 mg to a maximum of 480 mg/day. Sustained-release (SR) formulations (Calan SR, Isoptin SR) and extended-release formulations (Covera-HS, Verelan) of verapamil, are available and are often useful in improving patient adherence with long-term therapy. Headache frequency, intensity, and duration are reduced in 50% of patients treated with verapamil.¹⁶¹⁻¹⁶³ Patients who suffer from migraine with or without aura respond equally well.^{161,162} Verapamil may be particularly effective for patients with a prolonged or atypical migraine aura.¹¹⁶ Although there are few comparative studies, most practitioners consider the benefits of calcium channel blockers to be modest relative to β -blockers, valproate, and amitriptyline. For this reason, verapamil is usually considered when these agents fail or are contraindicated.^{8,117}

NIFEDIPINE, DILTIAZEM AND NIMODIPINE

Nifedipine (Procardia) and diltiazem (Cardizem) are other calcium antagonists that have been used to treat migraine.¹⁶⁴⁻¹⁶⁶ Although preliminary experience suggested that nifedipine was effective, a double-blind, crossover study found nifedipine to be no more effective than placebo for preventing migraine headaches with aura. This study was designed to detect a 50% reduction in migraine frequency during treatment.¹⁶⁷ The effectiveness of diltiazem is based on two open-label studies with no control treatment.^{166,168} As yet, no placebo-controlled, crossover studies have been reported. On

the basis of current evidence, neither nifedipine nor diltiazem can be recommended for prophylaxis of migraine headache until other, better-established therapies (see Table 52-6) have been adequately tried and yielded unsatisfactory results.

Nimodipine (Nimotop) is a calcium antagonist with marked selectivity for the cerebral vasculature.¹⁶⁹ The drug is approved only to improve neurologic deficits after aneurysmal subarachnoid hemorrhage. Results from double-blind, placebo-controlled trials have been inconsistent in showing a benefit of nimodipine for preventing migraine headaches.^{170–173}

In most studies, the dose of oral nimodipine was 40 mg given three times daily.^{171–173} Unfortunately, no adequate studies are available that compare nimodipine to other first-line preventative therapies. In light of the inconsistent results from placebo-controlled trials and the high cost of this drug, nimodipine appears to have little utility as a prophylactic agent.

Other Prophylactic Therapies

Some of the less established therapies occasionally recommended for migraine prophylaxis are listed in Table 52-7.^{79,115,174–177} Evaluative reports for some of these agents do not meet the criteria for establishing a clear benefit in migraine. In general, a significant reduction of headache frequency in 50% of patients should be demonstrated before a drug can be said to be more effective than placebo. Placebo response rates for migraine and other painful conditions range from 30% to 50%^{10,178,179} and may be maintained over several months.¹⁷⁹ This significant effect should also be considered when evaluating studies of migraine therapy.

On the basis of efficacy, either NSAIDs (i.e., naproxen, naproxen sodium, flurbiprofen, ketoprofen or mefenamic acid) or verapamil could be considered for prophylactic therapy to reduce the frequency of S.A.'s migraine headaches. However, NSAIDs are likely to interact with her lithium therapy, resulting in an increase in serum concentration and risk for adverse effects. For this reason, NSAIDs are best avoided at this time. S.A. should be started on verapamil 80 mg three times a day with gradual dosage titration to side effects, cessation of migraine attacks, or a maximum dose of 480 mg/day. She should be counseled regarding the possible occurrence of constipation and the appropriate management of this common side effect of verapamil. A 2-month trial may be necessary to demonstrate optimal therapeutic effect. Prophylactic therapy for migraine should be continued for 3 to 6 months. If a satisfactory response is achieved, the prophylactic agent should be gradually

discontinued over several weeks to assess the continued need for this mode of therapy.

Analgesic Overuse

22. L.D. is a 39-year-old woman with a 7-year history of migraine (without aura) and tension-type headache who comes to clinic requesting a refill of her Fiorinal (aspirin, butalbital, and caffeine) and acetaminophen with codeine (30 mg). She reports an increase in the frequency of both her “throbbing” and “dull, pressure-sensation” headaches over the past year, and lately she has had difficulty distinguishing the two types. Over the past 2 months, she has had only 5 days with no headache, and she has been much less productive in her work as a magazine editor. A review of her medication refill records indicates that she has had four refills of Fiorinal (#30) and three refills of acetaminophen with codeine (#20) in the past 2 months and that her use of these drugs has increased over the past year. During the visit, she also indicates that she uses OTC acetaminophen and naproxen sodium on an “as-needed” basis. Although L.D. had experienced relief of mild headaches in the past with the use of OTC analgesics, these medications no longer reduce the intensity of her pain. What is the potential role of analgesic overuse in the worsening of L.D.'s headaches? How should her condition be managed?

Narcotics, NSAIDs, and other analgesics can be very effective for the treatment of infrequent, episodic migraine and other headache types. However, the use of these agents in patients with frequent headaches should be undertaken with caution. Analgesic overuse is common in these patients and associated with a gradual worsening of the headache symptoms. Any type of headache syndrome (e.g., migraine, tension-type, and other headaches) can be worsened by analgesic overuse.¹⁸⁰ This exacerbation is termed *analgesic-induced headache* (also, *analgesic rebound headache*) and is characterized by an increase in the use of analgesics, development of tolerance to the pain-relieving effect of these drugs, an increase in headache intensity, and an increase in headache frequency. In severe circumstances, a pattern of chronic daily headache can emerge. These chronic daily headaches often have features of both migraine and tension-type headaches.¹⁸¹ The mechanism of analgesic rebound headache is unknown. However, alterations in serotonergic transmission are suspected.^{182,183} L.D. displays many of the features of analgesic-induced headache. She reports an increase in the frequency of headaches to a near-daily pattern and she is no longer able to distinguish between migrainous

Table 52-7 Other Drugs for Migraine Headache Prophylaxis^a

| Drug | Dose/Day (Oral) | Comments |
|--------------------|--|---|
| Clonidine | 0.1–0.2 mg BID–TID | No benefit found in some studies |
| Cyproheptadine | 4–8 mg TID–QID (adults) | Particularly useful for migraine in children |
| Ergonovine maleate | 0.2 mg TID–QID during menses or continuously | Effective for menstrual migraine and when other prophylactic agents contraindicated; recommended by some authors as a first-line prophylactic agent |
| Feverfew | Variable | Demonstrated effective in randomized, controlled trial though additional study needed |
| Phenelzine | 15 mg TID–QID | Caution when used simultaneously with antidepressants and β -blockers |
| Phenytoin | 200–400 mg QD | Benefits in children and adults established by uncontrolled studies |
| Riboflavin | 400 mg QD | Demonstrated effective in a randomized, controlled trial though additional study needed |
| Topiramate | 100 mg/day (given BID) | Effective in three randomized controlled trials |
| Gabapentin | 900–2400 mg/day (given TID) | Effective in one randomized controlled trial |

and tension-type headaches. Furthermore, the exacerbation of her headaches appears to coincide with the escalating use of analgesics. L.D. should be questioned carefully to determine the total amount of acetaminophen, naproxen sodium, and aspirin that she consumes daily and weekly. Daily users of analgesics are at increased risk for chronic renal disease, chronic liver disease, and acute GI bleeding.^{183–185} Laboratory tests should be ordered to assess L.D.'s renal and hepatic function, and she should be questioned regarding the occurrence of GI discomfort, acute bleeding, or a change in her stool color.

In general, patients who receive analgesics for headache treatment should be counseled to restrict their use of these agents to no more than twice per week.⁴⁴ However, in patients with analgesic-induced headache, a reduction in the use of these drugs will likely worsen their headache condition. The management of analgesic-induced headache is a challenge to clinicians and the patients who suffer from them. These headaches are often unresponsive to the usual abortive and prophylactic therapy measures discussed in earlier sections of this chapter. Successful management requires gradual withdrawal from the overused drugs. This process can be protracted and made even more difficult when barbiturate, codeine, or ergotamine-containing drugs are involved.¹⁸¹ Withdrawal can usually be accomplished on an outpatient basis although in some patients, inpatient detoxification is required. Once the frequency and quantity of analgesic use by L.D. have been adequately quantified, a process of gradual drug removal should be initiated. Medications taken on an infrequent basis (e.g., fewer than two times per week) can be abruptly stopped. For medications currently taken on a daily basis, L.D. should be counseled to reduce the medication by one tablet per day at 3-day intervals.¹⁸¹ She should be informed that her headaches may worsen during this period but that symptoms will gradually improve as she proceeds through the detoxification process.

L.D.'s use of acetaminophen with codeine does not appear to be frequent enough to place her at risk for the development of opiate withdrawal symptoms. However, she should be counseled to report symptoms such as anxiety, tremulousness, insomnia, or diarrhea. If these symptoms occur, the rate of drug withdrawal should be reduced. Some clinicians prescribe a tricyclic antidepressant such as amitriptyline during the withdrawal period.¹⁸¹ These agents can be useful for their central pain-relieving properties, antidepressant effects, and for their effect as preventative therapy for both migraine and tension-type headaches. Even if a tricyclic antidepressant is not prescribed during the withdrawal period, L.D. should be considered as a candidate for prophylactic headache therapy once analgesic withdrawal has been accomplished. If prophylaxis of both migraine and tension-type headache is necessary, amitriptyline would be an appropriate choice for L.D. After withdrawal is complete, L.D. should be educated regarding the future risk of analgesic-induced headache. A medication other than the withdrawn drugs should be prescribed for treatment of her acute attacks. For example, a triptan agent may be useful for abortive treatment of her migraine headaches. An NSAID may be considered for acute treatment of her tension-type headaches. L.D. must clearly understand that these agents should not be used more than twice per week, and her use of all abortive or symptomatic therapies should be monitored closely.

In extreme circumstances, analgesic abuse can precipitate chronic daily headache. In addition, analgesic abuse is a common cause of failure of the usual abortive treatment measures (e.g., sumatriptan and ergotamine). Successful abortive and prophylactic treatment of migraine headache in patients with a history of analgesic overuse necessitates detoxification from the abused agents.¹⁸⁶ Headaches often worsen during the withdrawal period, but within several weeks the headache characteristics return to baseline and responsiveness to traditional pharmacotherapy is restored. To minimize the risk of analgesic abuse and rebound headaches, patients should restrict their use of these agents to no more than twice per week.⁴⁴

CLUSTER HEADACHE

Cluster headache is a relatively infrequent headache disorder (estimated prevalence 0.07–0.4%) that derives its name from the characteristic pattern of headache recurrence—headaches tend to occur nightly over a relatively short period of time (i.e., several weeks or months), followed by a long period of complete remission.¹⁸⁷ Cluster headaches occur more commonly in males than females. There may be a seasonal predilection to cluster attacks with the spring and fall being common times for headache recurrence. Headaches are usually of short duration and present as severe, unrelenting, unilateral pain occurring behind the eye with radiation to the territory of the ipsilateral trigeminal nerve (temple, cheek, or gum).

The different clinical characteristics between cluster and migraine headaches (e.g., sex ratio, periodicity of attacks, duration of headaches, aura symptoms) suggest that these two types of vascular headaches are different clinical entities.¹⁸⁸

Pathophysiology

The pathophysiology of cluster headache is undetermined. As in migraine, vascular, neurogenic, metabolic, and humoral factors have been proposed to play a role in cluster headache pathogenesis. Precipitation of headaches during a cluster period by vasodilators and response to vasoconstrictors suggests an underlying vascular component. During a cluster headache, thermography shows increased periorbital heat emission ipsilateral to the head pain.¹⁸⁹ Also, patients commonly report flushing in the same area, and these observations suggest that extracranial vasodilation occurs in cluster headache. However, intracranial blood flow studies fail to show consistent changes during a cluster attack,^{190–192} and the alterations in extracranial blood flow follow the onset of head pain,¹⁹³ suggesting that vasodilation occurs in response to some other initiating stimulus. Abnormal plasma levels of melatonin, growth hormone, testosterone, and prolactin have been reported in patients with cluster headache. These findings, along with the cyclic recurrence pattern of the disorder suggest a disturbance in hypothalamic function.¹⁹⁴

Observations that suggest a neural component to cluster headache include the occurrence of headache in the distribution of the trigeminal nerve, accompanying autonomic symptoms, and the fact that headache precedes extracranial vasodilation. Stimulation of the trigeminal nerve results in the release of substance P and vasoactive polypeptides, vasodilation, and pain.¹⁹⁵ These features implicate the trigeminovascular system in cluster headache pathogenesis. However, a coherent theory

to explain the symptoms, periodicity, and circadian regularity of cluster headaches remains elusive.

In recent years, the role of heredity in cluster headache has been appreciated.¹⁸⁷ Cluster headache has been reported in monozygotic twins,¹⁹⁶ and first-degree relatives of individuals with cluster headache have a 14-fold higher risk of also having cluster headaches.¹⁹⁷ However, a specific genetic basis for the disorder remains elusive.¹⁹⁸

Signs and Symptoms

23. R.H. is a 31-year-old man with a 3-year history of episodic cluster headache. He has been headache free for the past year but today states that the headaches are returning in their characteristic fashion. He reports abrupt onset of right-sided retro-orbital pain with occasional superimposed knifelike “jabs” that increase in intensity over several minutes to a severe, unrelenting pain lasting about 90 minutes. The headache then gradually subsides. Associated symptoms include right-sided lacrimation, conjunctival injection, and rhinorrhea. He denies any premonition of ensuing headache or GI upset during the attacks. Physical examination during a cluster headache shows right eyelid droop and pupillary miosis. R.H.’s cluster periods characteristically last about 2 months and usually recur once or twice yearly. The first headache of the current bout awoke him from a short nap. R.H. expects to suffer one or two such headaches daily because this has been the usual pattern during each cluster period. Previous cluster headaches have been symptomatically treated with aspirin and codeine 30 mg. However, R.H. reports only modest relief with this treatment approach.

R.H.’s medical history is unremarkable. He does not use tobacco but admits to occasional social drinking. What subjective and objective evidence in this case is consistent with a diagnosis of cluster headaches?

R.H.’s gender, age of onset, quality and intensity of headache pain, periodicity of headache attacks, and associated symptoms all support the diagnosis of cluster headaches.

Cluster headaches affect men more commonly than women by a ratio of 5:1,^{189,199} and have their usual onset between the second and fourth decades of life.¹⁹⁹ R.H.’s gender (male) and age of onset (28 years) are compatible with these aspects of cluster headaches.

Recurrent cluster headaches are usually severe and throbbing and affect the same side of the head. Occasionally, cluster headaches may involve the entire hemicranium. The pain starts abruptly, often waking the patient from sleep, reaches maximum intensity over 5 to 15 minutes, and usually lasts 45 to 60 minutes.¹⁸⁹ Unlike migraine, cluster headache is not preceded by an aura. Thus, patients have no warning before onset of head pain. Cluster periods often last from 2 to 3 months and recur once or twice yearly.¹⁸⁹ Patients suffering from chronic cluster headaches have bouts that last 12 months or longer. R.H.’s headache quality (severe, unrelenting pain), site (unilateral), evolution and resolution pattern (worsens over several minutes and resolves within 90 minutes), and periodicity of attacks (one or two headaches occurring daily for about 2 months followed by a period of remission that lasts about 1 year) are all compatible with the usual character of cluster headaches.

Associated features may include ipsilateral lacrimation, injected conjunctiva, and rhinorrhea or blocked nasal passage.

A partial Horner’s syndrome (ptosis with miosis) occurs in one-third of patients and is often the only abnormal physical finding during a cluster headache. Nausea, vomiting, and focal neurologic symptoms are often absent. Associated symptoms reported by R.H. during headache attacks (e.g., lacrimation, rhinorrhea, conjunctival injection) and the absence of GI or neurologic disturbances are also compatible with the diagnosis of cluster headaches.

During a cluster period, headaches may be precipitated by alcohol (even in small amounts), vasodilators, stress, warm weather, missed meals, and excessive sleep. Therefore, during the current cluster period, R.H. should be counseled to avoid all alcohol and daytime naps.

Abortive Therapy

24. What abortive measures are available for symptomatic treatment of individual headaches during R.H.’s current cluster period?

The treatments of choice for abortive treatment of cluster headaches are sumatriptan by subcutaneous injection and oxygen inhalation.^{187,198} The expense and inconvenience of having oxygen inhalation apparatus close at hand limit the usefulness of this treatment for many patients. A recent community-based study found that most patients suffering from cluster headaches do not receive optimal treatment for their condition.²⁰⁰ Table 52-8 is a summary of drugs commonly used for the acute treatment of cluster headache.

Sumatriptan

Sumatriptan 6 mg subcutaneously has been shown to effectively relieve cluster headache in randomized, double-blind, placebo-controlled trials. Cluster headaches are reduced in severity in 74% of attacks within 15 minutes, compared with 26% of attacks treated with placebo.¹⁸⁷ An additional injection of 6 mg does not appear to give additional headache relief.²⁰¹ However, in patients who experience a recurrent headache after initial relief with sumatriptan, a second injection is often useful.¹⁹⁴ Sumatriptan should not be used more often than twice daily during cluster bouts. For patients who experience more than two attacks per day, adjunctive therapy with oxygen inhalation should be considered.¹⁸⁷

Intranasal and oral sumatriptan have also been evaluated in patients with cluster headache. A randomized, open-label comparison of sumatriptan by intranasal (20 mg) and subcutaneous (6 mg) routes found a much higher response with the injectable form of the drug at 15 minutes post-treatment (94% versus 13%, respectively). Patients included in this study indicated a clear preference for the subcutaneous dosage form.²⁰² Oral sumatriptan (100 mg three times a day) was studied as a prophylactic agent during cluster headache bouts and found to be ineffective.²⁰³

Oxygen

Oxygen inhalation is preferred not only for in-hospital treatment of cluster headache but also for use by some patients at home or at work. Oxygen is also useful for patients with frequent cluster headaches who would otherwise exceed maximum dosing restrictions of sumatriptan.¹⁸⁷ The benefits of oxygen inhalation at 7 L/minute for 15 minutes, are superior

Table 52-8 Drugs Commonly Used for Acute Treatment of Cluster Headache^a

| Drug | Route | Dose | Contraindications | Adverse Effects | Comments |
|--|------------|--|---|--|--|
| Sumatriptan (Imitrex) | SC | 6 mg at HA onset | Ischemic heart disease, within 24 hr of ergot alkaloids | Heavy sensation in head or chest, tingling, pain at injection site | Not an FDA-approved indication; costly but well tolerated |
| Oxygen | Inhalation | 7 L/min for 15 min | | | Fast onset of effect; equally effective as ergotamine tartrate |
| Ergotamine tartrate (Ergostat, Cafergot) | SL, PR | 1–2 mg at HA onset; may repeat in 5 min (SL only); do not exceed 6 mg/attack or 10 mg/wk | CV disease, sepsis, liver or kidney disease, arterial insufficiency, pregnancy, breast feeding, concomitant macrolide use | N, V, anorexia, limb paresthesias or pain | SL ergotamine may have faster onset of effect; ↓ N and V by using smallest effective dose |
| DHE-45 | SC, IM, IV | 1 mg (SC, IM) or 0.75 mg (IV) stat; may repeat in 45 min | CV disease, sepsis, liver or kidney disease, arterial insufficiency, pregnancy, breast feeding | N, V, limb paresthesias or pain | More effective and faster onset than SL or PR ergotamine. Premedicate with antiemetic (e.g., metoclopramide or prochlorperazine) |

^aSee text for references and additional details.

to placebo²⁰⁴ and equal to those of ergotamine²⁰⁵ in relieving cluster headaches. In addition, oxygen is very fast-acting, with most patients experiencing headache relief within 7 minutes of beginning inhalation.²⁰⁵ The mechanism of oxygen's effect is unknown but may be related to a direct vasoconstrictive action.¹⁸⁷

Ergotamine Tartrate

Inhalational, sublingual, and parenteral routes of ergotamine administration have a rapid onset of action and are effective for aborting acute cluster headaches.²⁰⁶ Ergotamine by inhalation or sublingual administration is effective in 70% to 80% of patients,^{207,208} and traditionally these routes of administration have been preferred. Unfortunately, no inhaled ergotamine product is currently marketed in the United States, and the product is likely to remain unavailable. Ergotamine tartrate 2 mg given rectally also can be effective if given early in the attack.²⁰⁷ Ergotamine tartrate 0.5 mg and DHE 1 mg given intramuscularly are equally effective; DHE is better tolerated and less likely to cause vasoconstrictive adverse effects.²⁰⁷

Other Therapeutic Interventions

Cluster headaches also can be relieved by less commonly used therapeutic interventions such as intranasal capsaicin,²⁰⁹ dexamethasone 8 mg orally,¹⁹⁴ methoxyflurane inhalation (10–15 drops applied to a handkerchief and inhaled for several seconds),⁷⁹ somatostatin IV infusion (25 mcg/minute for 20 minutes),²¹⁰ and local anesthesia with either intranasal application of 1 mL of 4% lidocaine hydrochloride²¹¹ or 0.3 mL of a 5% to 10% solution of cocaine hydrochloride²¹² to the ipsilateral sphenopalatine fossa.

Orally administered narcotic analgesics are usually ineffective in cluster headache,¹⁸⁹ and R.H. has suffered several cluster periods with inadequate therapy. Improved response can be expected with the use of a more effective agent that has a faster onset of action. Reasonable options for the acute treatment of R.H.'s acute cluster headaches include subcutaneous sumatriptan or oxygen inhalation. The success rate with each of these therapies is high. For many patients, oxygen is a less

convenient therapy since the equipment is not easily portable and the patient must sit still during the treatment. The choice can be made on the basis of patient preference or cost.

Prophylactic Therapy

25. What therapeutic agents are available for headache prophylaxis during an active cluster period?

Pharmacotherapy aimed at preventing cluster headaches during an active period should be considered if symptomatic therapy is ineffective, intolerable, or if headaches occur more frequently than twice daily. Table 52-9 contains a list of available drugs for cluster headache prophylaxis.

Verapamil

Verapamil is effective for the prevention of cluster headaches,^{165,213,214} and many authors now considered this agent to be the prophylactic agent of choice.^{187,189} The usual effective daily dose is 240 to 480 mg/day and approximately two-thirds of patients have a 50% or greater reduction in headache frequency. Verapamil can be combined with lithium for prophylaxis in patients with chronic cluster headaches.¹⁸⁷

Prednisone

Prednisone 40 to 80 mg daily provides relief from episodic cluster headache in 50% to 75% of patients^{215,216} and is superior to methysergide in both episodic and chronic cluster types.²¹⁶ Prednisone also has a faster onset of action than many other agents used for cluster headache prophylaxis. The beneficial effect is usually evident within 48 hours of initiating treatment.⁷⁹ Corticosteroids are best used for short bouts of cluster headaches (1–2 months or less) because of the side effects associated with prolonged use.

Ergotamine

Ergotamine's use as a prophylactic agent is particularly attractive when headache recurrence follows a predictable pattern (e.g., nocturnal attacks). Prophylactic administration at

Table 52-9 Drugs for Prophylaxis of Cluster Headache^a

| Drug | Dose/Day | Route | Comments |
|---|--|----------------|---|
| Ergotamine tartrate (Cafergot, Ergostat) | 0.25–0.5 mg BID–TID 5 days/wk 1–2 mg BID or HS for nocturnal HA; max 12 mg/wk | SC, PO, SL, PR | Effective when given 30 min before anticipated cluster HA |
| Indomethacin (Indocin) | 50 mg TID | PO | Effective for chronic cluster HA |
| Lithium carbonate | 600–1,500 mg | PO | Effective for chronic cluster HA; effective in 80% of patients |
| Melatonin | 10 mg QD | PO | Efficacy demonstrated in 1 randomized controlled trial; patients with chronic cluster headache did not respond |
| Methylergonovine maleate | 0.2 mg TID–QID | PO | Effective in 75% of patients in one retrospective study |
| Methysergide (Sansert) | 2 mg TID–QID | PO | Effective in 65–70% of patients with episodic cluster HA; less effective for chronic cluster HA |
| Prednisone | 40 mg QID × 2 days, then taper by 5 mg/day to maintenance dose of 15–30 mg QID | PO | A first-line agent for episodic cluster HA; more effective and faster-acting than methysergide; benefits usually within 48 hr; best for short bouts of cluster HA because of long-term adverse effects |
| Triamcinolone (Aristocort) | 4–8 mg QID | PO | May be useful in patients unresponsive to prednisone |
| Valproate (Depakote) | 600–2,000 mg/day divided TID–QID | PO | Effective in 73% of patients in 1 open trial |
| Verapamil (Isoptin, Calan) | 240–480 mg/day divided TID–QID | PO | Drug of choice for prophylaxis |

^aSee text for references and additional details.

HA, headache; PO, oral; PR, rectal; SC, subcutaneous; SL, sublingual.

bedtime or at least 30 minutes before the anticipated headache often will prevent the attack.¹⁸⁹

Methysergide

Methysergide is effective in 65% to 70% of patients with episodic cluster headache and can be used for cluster periods of less than 3 months' duration without the same degree of concern for fibrotic complications because of the anticipated shorter period of drug exposure.^{207,216} A limitation to the use of methysergide as the sole prophylactic agent for cluster headache is the delay in symptomatic response, which may be up to 2 weeks in some patients. Chronic cluster headache responds less dramatically to methysergide and other agents (e.g., lithium) are preferred.²⁰⁷

Lithium Carbonate

Lithium carbonate is effective in preventing episodic and chronic cluster headache.^{207,217,218} Benefits from lithium prophylaxis are observable 1 to 2 weeks after initiation of therapy^{79,217,218} and are maintained with long-term use.²¹⁹ Lithium serum levels associated with efficacy in cluster headache prophylaxis are usually between 0.6 and 1.2 mEq/L.¹⁸⁹ However, lower levels (0.3–0.8 mEq/L) may also be effective.¹⁸⁷ Adverse effects from long-term lithium use (e.g., renal toxicity) are discussed in Chapter 80, Mood Disorders II: Bipolar Disorders.

Other Therapies

Valproate has not been adequately studied, but one open trial reported that 73% of patients with cluster headache responded to this treatment.²²⁰ In a recent pilot study, melatonin was superior to placebo for prophylaxis of cluster headache.²²¹ β -Blockers, antidepressants, and carbamazepine have no proven usefulness in the treatment of cluster headaches.⁷⁹

R.H. should be evaluated at his next clinic visit for response to abortive sumatriptan or oxygen therapy. Prompt consideration should be given to the aforementioned additional treat-

ments if suppression of headaches during the cluster period is warranted. In general, after response to a prophylactic agent has been established and maintained for at least 2 weeks, attempts can be made to discontinue the drug. Treatment should be reinstated if headaches recur.

TENSION-TYPE HEADACHE

Tension-type headache is the most common headache type with a lifetime prevalence of 88% in women and 69% in men.²²² In a population-based study, the 1-year prevalence of tension-type headache was 38%. Highest prevalence rates were found in women between 30 and 39 years of age and, in both sexes, those with higher education levels.²²³ Tension-type headaches (previously known as *tension* or *muscle contraction* headaches) are usually characterized by a dull aching sensation bilaterally that occurs in a hatband distribution around the head. The pain is usually mild to moderate in severity and has a nonpulsating quality.²²⁴ Tension-type headaches are not associated with aura symptoms, nor are they accompanied by nausea, vomiting, or photophobia. The headache is usually not of sufficient intensity to interfere with daily activities but may be a nuisance by virtue of its persistent nature. Headache frequency varies widely between patients. Chronic tension-type headache occurs in approximately 2% of the population (1-year prevalence rate) and sufferers may have headache continuously for months or even years.²²³

Pathophysiology

The throbbing pain associated with migraine headaches is not characteristic of tension-type headaches, although it may occur in 25% of tension-type headache sufferers when the pain becomes severe.⁷⁹ Such patients may be diagnosed more appropriately as having a mixed tension-type/migraine headache disorder.²²⁵ Indeed, in recent years the traditional boundaries distinguishing migraine from tension-type headaches have

become less clear. Headache features such as neck muscle contraction and precipitation by stress were previously thought to be specific for tension-type headaches but are now recognized to occur in migraine as well.

For many years, excessive muscle contraction with constriction of pain-sensitive extracranial structures was thought to be the cause of tension-type headache.²²⁶ More recent evidence shows no correlation between muscle contraction and the presence of tension-type headache.²²⁷ Abnormal vascular reactivity was also thought to play a role in tension-type headache, but temporal muscle blood flow is unaltered compared with controls.²²⁷ Platelet 5-HT content is lower in patients with chronic tension-type headache suggesting that migraine and tension-type headaches share some pathophysiologic features.²²⁴

Tension-type headaches also may be associated with depression,²²⁵ repressed hostility, or resentment.²²⁸ However, these psychological associations may be the result of the chronic pain syndrome rather than a cause or feature of the headache disorder. Patients with recurrent tension-type headaches probably do not experience more frequent stressful events, but may use less effective coping strategies in stressful situations.²²⁹

General Management and Abortive Therapy

26. K.B., a 27-year-old female financial analyst, presents to her general practitioner with a complaint of recurring headaches that worsened when she started her current job. Before this time, she had experienced infrequent headaches, which she associated with periods of stress. The headaches would occur three to four times yearly, were of a constant, dull, or “pressing” character and were present around the entire head. Recently, headaches of similar character have been occurring about one to two times weekly, usually toward the end of her work day. The pain usually lasts the rest of the day but varies in intensity. Occasionally, a headache is present when she wakes up in the morning as well. K.B. denies GI and aura symptoms associated with her headaches. She has noticed that relaxation and alcohol ingestion seem to relieve these headaches, but aspirin and acetaminophen have been ineffective. Her blood pressure is 120/74 mmHg; her physical and neurologic examinations are completely normal. What measures should be taken to relieve K.B.’s headaches? What is an appropriate goal for treatment?

As in the treatment of other chronic headache disorders, a cure for recurrent tension-type headache is unlikely. K.B. should clearly understand that the goal of treatment is a reduction in the frequency and severity of headache. Drug therapy and relaxation techniques are the primary means by which tension-type headaches are treated.

Analgesics

Analgesics are the drugs of choice for treatment of acute tension headache attacks.²²⁴ The initial choice of an analgesic should be based on the severity of the pain. Acetaminophen, aspirin, and NSAIDs are often effective, although their benefits may be short lived. Acetaminophen 1,000 mg provides equal relief from moderately severe tension-type headache when compared with 650 mg aspirin; both are superior to placebo.²³⁰ Ibuprofen is as effective as aspirin for relief from

tension headache discomfort, and side effects with both 400 and 800 mg ibuprofen are less common than with aspirin.²³¹ Ibuprofen 400 mg is superior to acetaminophen 1,000 mg for relief of tension-type headache pain.²³² Naproxen sodium 550 mg is more effective than placebo and acetaminophen 650 mg for relieving the pain of tension-type headache.²²⁴ The potency of some analgesics may be enhanced by combination with an antihistamine (e.g., doxylamine).²³³ Because the relative potencies of non-narcotic analgesics are equivalent, the choice between agents should be guided by cost and patient preference.

Sedatives (e.g., butalbital),⁷⁹ anxiolytics (e.g., meprobamate,²³⁴ diazepam²³⁵), and skeletal muscle relaxants (e.g., orphenadrine) have also been used to treat tension-type headache and occasionally, patients respond to their concomitant use when an analgesic alone affords insufficient relief.

Nondrug Techniques

Nondrug techniques such as massage, hot baths, acupuncture, and various relaxation methods can provide relief from tension headache and are often effective adjuncts to drug therapy.²³⁶ The literature both supports and refutes the effectiveness of acupuncture,^{10,237} EMG (electromyography) biofeedback,^{238–240} and other relaxation techniques in the therapy of tension-type headache. The utility of biofeedback and other relaxation techniques is based on the premise that voluntary control of muscle contraction could benefit the headache sufferer. These techniques are most successful in young, episodic headache sufferers who are motivated to apply the techniques as instructed.²⁴¹ A randomized, controlled trial of spinal manipulation for the treatment of tension-type headache failed to demonstrate a benefit of this approach.²⁴²

An NSAID (e.g., ibuprofen or naproxen) would be an appropriate recommendation for therapy of K.B.’s tension-type headaches because of her previous inadequate responses to aspirin and acetaminophen. Drug use should be carefully monitored because analgesic abuse in patients with frequently recurring tension headache is a primary factor in the perpetuation of chronic pain syndromes.²⁴³

Prophylactic Therapy

27. Ibuprofen 400 mg Q 4 to 6 hr as needed for headache was prescribed for acute relief of K.B.’s recurrent tension-type headaches. At her next scheduled follow-up visit, K.B. reported moderate relief with ibuprofen but complained of GI upset with each dose, even when taken with food. Because headaches have been occurring more frequently, her use of ibuprofen has also increased. What prophylactic agents are available for continuous suppression of K.B.’s tension-type headaches?

Antidepressants are the most useful group of agents in the prophylaxis of tension-type and mixed-type headaches. Amitriptyline (Elavil) is considered the drug of choice because it is most effective^{244,245}; 65% of patients improved by more than 50% and 25% became headache-free in an early report.²²⁵ The effective daily dose of amitriptyline for most patients is 10 to 75 mg,²⁴⁴ although up to 300 mg/day may be required.⁷⁹ Response to amitriptyline does not require a history of depressive symptoms, and benefit to the tension-type headache sufferer is usually evident within 2 to 10 days.⁷⁹ Amitriptyline should be

initiated at a dose of 10 to 25 mg/day at bedtime and increased gradually as needed to allow for the development of tolerance to the sedative and anticholinergic side effects of this drug. About 7% of patients discontinue amitriptyline because of side effects.¹⁰ Although there is less experience with their use, doxepin (Sinequan),²⁴⁶ imipramine (Tofranil),^{6,225} maprotiline (Ludiomil),²⁴⁷ and protriptyline (Vivactil)²⁴⁸ are also effective in tension-type headache prophylaxis. Like amitriptyline, these agents have significant anticholinergic activity. If an agent with less anticholinergic activity is desired, desipramine (Norpramin) may be used. Although fluoxetine has been suggested as an alternative for the treatment of tension-type headache,²⁴⁹ its effectiveness has not been established in a randomized, controlled trial. A randomized placebo-controlled trial comparing citalopram (an SSRI) with amitriptyline found that citalopram was not effective for prophylaxis of chronic tension-type headache.²⁵⁰ At this time, SSRI antidepressants are not rec-

ommended for tension-type headache prophylaxis.²⁴⁴ Given K.B.'s increasing frequency of tension-type headache and her intolerance to moderate doses of ibuprofen, prophylactic treatment with amitriptyline would be appropriate. A starting dose of amitriptyline 10 mg nightly, increasing by 10 to 25 mg at 1-week intervals to a maintenance dose of 50 mg/day should be prescribed, at which time headache response can be assessed and the dose increased or decreased as necessary. If effective, amitriptyline should be continued for 3 to 4 months before gradually decreasing the dose until the drug is completely discontinued. Therapy should be reinstated if headaches return.

Because the dividing line between migraine and tension-type headache is often vague, the entire range of migraine drugs may be tried in refractory cases of tension-type headache or when symptoms suggest a mixed tension-type/migraine headache disorder.

PARKINSON'S DISEASE

Incidence, Prevalence, and Epidemiology

Parkinson's disease (PD) is a chronic, progressive movement disorder in which drug therapy plays a central role. Nearly 200 years have elapsed since Dr. James Parkinson published his case series "An Essay on the Shaking Palsy" in 1817, becoming the first to describe features of the disease that bears his name. Since then, the term *parkinsonism* has come to refer to any disorder associated with two or more features of tremor, rigidity, bradykinesia, or postural instability.¹ Most cases of PD are of unknown cause, and referred to as *idiopathic parkinsonism*; however, viral encephalitis, cerebrovascular disease, and hydrocephalus have symptoms similar to PD as part of their clinical presentation.¹ Unless otherwise stated, all references to PD in this chapter refer to the idiopathic type.

The age at onset of PD is variable, usually between 50 and 80 years, with a mean onset of 55 years.² The prevalence of PD is about 100 cases per 100,000 population, and the incidence is estimated at 20 cases per 100,000 people annually.³

An estimated 1 million Americans, or 1% of the population age > 65 years, have PD.⁴ Men are affected slightly more frequently than women.⁵ Despite the availability of effective symptomatic treatments to improve both quality of life and life expectancy, no cure exists and the disease is associated with increased morbidity and mortality.⁶ The symptoms of PD are progressive and, within 10 to 20 years, total immobility results for most PD patients.⁷ The patient's age at the time of onset of clinically recognizable disease may significantly influence the rate of disease progression. A more rapid rate of progression has been observed in elderly patients and may be associated with a greater degree of motor disability.⁸ Death is not usually caused by the disease itself, but rather by complications related to immobility (e.g., aspiration pneumonia, cardiovascular, and cerebrovascular disease).⁷

Several organizations provide services for persons with PD (as well as other movement disorders) and their families. Valuable information in the form of internet monographs, books, newsletters, videos, and audiotapes in addition to information

about local support groups is available from the organizations listed in Table 53-1.

Etiology

Many theories have been advanced regarding the origin of PD. Environmental factors have been implicated since it was discovered that many patients developed a parkinsonian syndrome following the epidemic of encephalitis lethargic in the United States between 1919 and the early 1930s.⁹ Attempts to isolate a virus as a causative agent of the disease have been unsuccessful, however. Renewed interest in environmental factors resurfaced with the discovery that ingestion of a meperidine analog, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), causes irreversible parkinsonism.¹⁰ The discovery of an autosomal dominant familial form of PD caused by a mutation in the

α -synuclein gene has sparked interest in genetic constitution as a factor explaining the development of PD.¹¹ In addition to environment and genetics, it has also been reported that byproducts of normal dopamine metabolism (e.g., hydrogen peroxide) can lead to the production of free radicals that cause peroxidation of cell membranes and cell death. Thus, the most attractive hypothesis for the etiology of PD is that the disease results from a complex interplay of age-related changes to the nigrostriatal tract, genetic predisposition, and toxin exposure.

Pathophysiology

Parkinson's disease is a disorder of the extrapyramidal system of the brain involving the basal ganglia. The extrapyramidal system is involved with maintaining posture and muscle tone and with regulating voluntary smooth motor activity. For reasons not understood, melanin-containing cells within the substantia nigra are lost in PD. The pigmented neurons within the substantia nigra have dopaminergic fibers that project into the neostriatum and globus pallidus. Together, the substantia nigra, neostriatum, and globus pallidus make up the basal ganglia. In PD, dopamine (the inhibitory neurotransmitter) is progressively lost in the nigrostriatal tracts, and acetylcholine (the excitatory neurotransmitter) is relatively increased. It is generally believed that a 70% to 80% loss of nigral neurons must occur before PD becomes clinically recognizable.¹ On pathologic examination of postmortem basal ganglia, the presence of Lewy bodies (spherical, abnormal intraneuronal protein aggregates) are noted within the remaining dopaminergic cells of the substantia nigra.¹² The presence of Lewy bodies is considered pathognomic for the disease.

Overview of Drug Therapy

Because the salient pathophysiologic feature of PD is the progressive loss of dopamine from the nigrostriatal tracts in the brain, drug therapy for the disease is aimed primarily at replenishing the supply of dopamine (Table 53-2). This is accomplished through one, or a combination, of the following methods: (a) administering exogenous dopamine in the form of a precursor, levodopa; (b) stimulating dopamine receptors within the corpus striatum through the use of dopamine agonists (e.g., pramipexole, ropinirole); or (c) inhibiting the major metabolic pathways within the brain that are responsible for the degradation of levodopa and its metabolites. This latter effect is achieved through the use of aromatic L-amino acid decarboxylase (AADC) inhibitors (e.g., carbidopa), catechol-O-methyltransferase (COMT)-inhibitors (e.g., entacapone), or monoamine oxidase type B (MAO-B) inhibitors (e.g., selegiline, rasagiline). Additional therapies, such as anticholinergics, may occasionally be used to counterbalance the negative effects of the relative increase in acetylcholine activity and improve tremor symptoms.

Parkinson's disease is a debilitating disorder that affects both physical and mental functions of the body. Despite our best treatment efforts to restore dopaminergic function and preserve dopamine production, the disease will invariably progress. In many instances, adverse effects of the medications themselves can lead to additional problems. Supportive drug treatment of the complications of PD is also necessary. These complications include neuropsychiatric problems (cognitive impairment

Table 53-2 Medications Used for the Treatment of Parkinson's Disease

| <i>Generic (Trade) Name</i> | <i>Dosage Unit</i> | <i>Titration Schedule</i> | <i>Usual Daily Dose</i> | <i>Adverse Effects</i> |
|--|---|---|---|---|
| Amantadine (Symmetrel) | 100-mg capsule Liquid: 50 mg/5 mL | 100 mg QD; increased by 100 mg 1–2 wk | 100–300 mg | Orthostatic hypotension, insomnia, depression, hallucinations, livedo reticularis, xerostomia |
| Anticholinergic Agents | | | | |
| Benztropine (Cogentin) | 0.5-, 1-, and 2-mg tablets Injection: 2 mL (1 mg/mL) | 0.5 mg/day increased by 0.5 mg Q 3–5 days | 1–3 mg given QD to BID | Constipation, xerostomia, dry skin, dysphagia, confusion, memory impairment |
| Trihexyphenidyl (Artane) | 2- and 5-mg tablets Liquid: 2 mg/5 mL | 1–2 mg/day increased by 1–2 mg Q 3–5 days | 6–15 mg divided TID to BID | Constipation, xerostomia, dry skin, dysphagia, confusion, memory impairment |
| Combination Agents | | | | |
| Carbidopa-Levodopa (immediate release)/ entacapone (Stalevo) | 12.5/50/200, 25/100/200, and 37.5/150/200 mg tablets | Titrate with individual dosage forms (carbidopa/levodopa and entacapone) first, then switch to combination tablet | Varies (see listings for individual drugs) | See listing for individual drugs |
| Dopamine Replacement | | | | |
| Carbidopa-Levodopa (Regular) (Sinemet) | 10/100, 25/100, and 25/250 tablets | 25/100 mg BID, increased by 25/100 weekly to effect and as tolerated | 30/300 to 150/1,500 divided TID to QID | Nausea, orthostatic hypotension, confusion, dizziness, hallucinations, dyskinesias, blepharospasm |
| Carbidopa-Levodopa (CR) (Sinemet CR) | 25/100 and 50/200 tablets | 25/100 mg BID (spaced at least 6 hr apart), increased Q 3–7 days | 50/200 to 500/2,000 divided QID | Same as regular Sinemet |
| Carbidopa-Levodopa ODT (Parcopa) | 10/100, 25/100, and 25/250 mg tablets | 25/100 BID, increased Q 1–2 days; if transferring from regular levodopa <1,500 mg/day) start 25/100 mg TID to QID (start 25/250 mg TID to QID if already on >1,500 mg/day of regular levodopa) | 25/100 to 200/2,000 divided TID to QID | Same as regular Sinemet; may occur more rapidly than with regular Sinemet |
| Dopamine Agonists | | | | |
| Bromocriptine (Parlodel) | 2.5-mg tablet, 5-mg capsule | 1.25 HS, titrate slowly as tolerated over 4–6 weeks | 10–40 mg divided TID | Orthostatic hypotension, confusion, dizziness, hallucinations, nausea, leg cramps; retroperitoneal, pleural, pericardial fibrosis; cardiac valve thickening |
| Pramipexole (Mirapex) | 0.125-, 0.25-, 0.50-, 1-, 1.5-mg tablets | 0.375 divided TID; titrate weekly by 0.125–0.25 mg/dose | 1.5–4.5 mg divided TID | Orthostatic hypotension, confusion, dizziness, hallucinations, nausea, somnolence |
| Ropinirole (Requip) | 0.25-, 0.5-, 1-, 2-, 4-, 5-mg tablet | Titrate weekly by 0.25 mg/dose | 3–12 mg divided TID | Orthostatic hypotension, confusion, dizziness, hallucinations, nausea, somnolence |
| Apomorphine (Apokyn) | 10 mg/mL injection | Initial 2-mg test dose, then begin 1 mg less than tolerated test dose; increase by 1 mg every few days; approved for “rescue” during periods of hypomobility | 2–6 mg TID | Nausea, vomiting; administer with trimethobenzamide (not 5- hydroxytryptamine-3 [5HT3] antagonists) |
| Rotigotine (Neupro) | 2-, 4-, 6-mg/24 hr transdermal delivery system | 2 mg/24 hr; titrate weekly by 2 mg/24 hr until response noted or maximal dose of 6 mg/24 hrs reached. Application site should be rotated daily between abdomen, thigh, hip, flank, shoulder, or upper arm | 4–6 mg/24 hr | Hallucinations, abnormal dreaming, insomnia, somnolence, nausea, vomiting, application site reactions; avoid in patients with known sulfite sensitivity |

(continued)

Table 53-2 Medications Used for the Treatment of Parkinson's Disease (Continued)

| Generic (Trade) Name | Dosage Unit | Titration Schedule | Usual Daily Dose | Adverse Effects |
|--------------------------|----------------------|--|--|---|
| COMT Inhibitors | | | | |
| Entacapone (Comtan) | 200-mg tablet | One tablet with each administration of levodopa/carbidopa, up to 8 tablets daily | 3–8 tablets daily | Diarrhea, dyskinesias, abdominal pain, urine discoloration |
| Tolcapone (Tasmar) | 100-, 200-mg tablet | 100–200 mg TID | 300–600 mg divided TID | Diarrhea, dyskinesias, abdominal pain, urine discoloration, hepatotoxicity |
| MAO-B Inhibitors | | | | |
| Selegiline (Eldepryl) | 5-mg tablet, capsule | 5 mg AM; may increase to 5 mg BID | 5–10 mg (take 5 mg with breakfast and 5 mg with lunch) | Insomnia, dizziness, nausea, vomiting, xerostomia, dyskinesias, mood changes; use caution when coadministered with sympathomimetics or serotonergic agents (increased risk of serotonin syndrome); avoid tyramine-containing foods |
| Selegiline ODT (Zelapar) | 1.25-mg tablet | 1.25 mg QD; may increase to 2.5 mg QD after 6 wk | 1.25–2.5 mg QD | Insomnia, dizziness, nausea, vomiting, xerostomia, dyskinesias, mood changes; use caution when coadministered with sympathomimetics or serotonergic agents (increased risk of serotonin syndrome); avoid ingestion large amounts of tyramine-containing foods |
| Rasagiline (Azilect) | 0.5 mg tablet | 0.5 mg QD; may increase to 1 mg QD | 0.5–1 mg/day | Similar to selegiline |

and dementia, hallucinations and delirium, depression, agitation, anxiety), autonomic dysfunction (constipation, urinary problems, sexual problems, orthostasis, thermoregulatory imbalances), falls, and sleep disorders (insomnia or sleep fragmentation, nightmares, restless leg syndrome).

CLINICAL PRESENTATION OF PARKINSON'S DISEASE

1. L.M., a 55-year-old, right-handed male artist, presents to the neurology clinic complaining of difficulty painting because of unsteadiness in his right hand. He also complains of increasing difficulty getting out of chairs and tightness in his arms and legs. His wife claims that he has become more “forgetful” lately, and L.M. admits that his memory does not seem to be as sharp. His medical history is significant for depression for the past year, gout (currently requiring no treatment), constipation, benign prostatic hypertrophy, and aortic stenosis. On physical examination, L.M. is noted to be a well-developed, well-nourished man who displays a notable lack of normal changes in facial expression and speaks in a soft, monotone voice. A strong body odor is noted. Examination of his extremities reveals a slight “ratchetlike” rigidity in both arms and legs, and a mild resting tremor is present in his right hand. His gait is slow, but otherwise normal, with a slightly bent posture. His balance is determined to be normal, with no retropulsion or loss of righting reflexes after physical threat. His genitourinary examination is remarkable only for prostatic enlargement. The

remainder of L.M.’s physical examination and laboratory studies are within normal limits. What signs and symptoms suggestive of PD are present in L.M.? Which of these symptoms are among the classic symptoms for diagnosing PD and which are considered “associated” symptoms? How should L.M.’s PD and associated symptoms be treated?

Establishing the diagnosis of PD is based on careful history taking and physical examination.¹² No laboratory or radiological tests have demonstrated consistent benefit in diagnosing the disease.⁸ The four classic features of PD—tremor, rigidity, bradykinesia, and postural disturbances—are easily recognized. Tremor, which is most often the first symptom observed, is usually unilateral on initial presentation. Frequently, the tremor is of a “pill-rolling” type involving the thumb and index finger; it is present at rest, worsens under fatigue or stress, and is absent with purposeful movement or when asleep.¹ These features help distinguish it from essential tremor, which usually causes a symmetric tremor in the hands and is often accompanied by head and voice tremor.¹² Muscular rigidity resulting from increased muscle tone often manifests as a “cogwheel” or “ratchet” (catch-release) type of motion when an extremity is moved passively.¹ Rigidity may also be experienced as stiffness or vague aching or limb discomfort.¹² Bradykinesia refers to an overall slowness in initiating movement. Early in the disease, patients may describe this as weakness or clumsiness of a hand or leg.¹² As the disease progresses, difficulty initiating and terminating steps results in a hurried or festinating gait;

the posture becomes stooped (simian posture), and postural reflexes are impaired.¹ Symptoms that were unilateral on initial presentation progress asymmetrically and often become bilateral and more severe with disease progression.¹ Patients with PD develop “masked facies,” or a blank stare with reduced eye blinking.

Patients with PD are often misdiagnosed, leading to inappropriate, ineffective, or delayed treatment.¹ It is important to note that all four symptoms do not need to be present to make the diagnosis of PD. For example, unilateral tremor (frequently on the right side) is one of the most common initial presenting symptoms, but approximately 30% of patients with idiopathic PD do not present with tremor.¹³ Patients with PD may have an insidious onset of nonspecific symptoms such as generalized malaise and fatigue.¹ Several conditions can be mistaken for PD, and include multiple system atrophy (formerly known as Shy-Drager syndrome), progressive supranuclear palsy, and normal pressure hydrocephalus. These conditions are referred to as “parkinson-plus” syndromes and are important to distinguish from PD because they respond poorly to antiparkinsonian medications and are associated with worse prognosis.¹² Magnetic resonance imaging can be useful in some situations to exclude these conditions, particularly when clinical signs suggest an alternate diagnosis. Falls or dementia early in the disease, symmetric parkinsonism, wide-based gait, abnormal eye movements, marked orthostatic hypotension, urinary retention, and marked disability within 5 years after the onset of symptoms suggest alternate diagnoses other than PD.¹² Drugs with strong antidopaminergic activity (e.g., neuroleptics, prochlorperazine, and metoclopramide), and other drugs, such as valproate, amiodarone, phenytoin, and lithium, may also cause a state of drug-induced parkinsonism that mimics idiopathic PD. It is important to rule out drugs as a cause of symptoms before the diagnosis of PD is established. Although reversible, symptoms may persist for weeks or months after discontinuation of the offending agent.¹²

L.M. presents with many of the classic symptoms of PD. A noticeable unilateral resting tremor is present along with decreased manual dexterity, as evidenced by his difficulty handling a paintbrush. Rigidity (“ratcheting” of the arms), bradykinesia (slowness of movement), and a masklike facial expression also are present. Although he has a partially stooped posture, it is difficult to attribute this entirely to the disease because postural changes commonly occur with advancing age and, on physical examination, his balance was normal. To confirm the diagnosis of PD, a therapeutic trial of levodopa may be considered. A resulting improvement in motor or cognitive function in response to levodopa therapy suggests the diagnosis of PD. Patients with the tremor-predominant form of the disease may, however, not respond to levodopa, especially in the early stages of the disease.¹³ In addition, lack of a positive response to an acute dopaminergic challenge may not exclude a positive response to chronic therapy. At least 30% of patients with PD will not respond to an acute dopaminergic challenge (false-negative response).⁸ Therefore, this approach would not be routinely recommended in a patient such as L.M.

In choosing when to treat the symptoms of PD and which therapy to use, care must be exercised to approach each patient individually. Although no consensus has been reached about when to initiate symptomatic treatment, most health care professionals agree that treatment should begin when the patient

begins to experience functional impairment as defined by (a) threat to employment status; (b) symptoms affecting the dominant side of the body; or (c) bradykinesia or rigidity. Individual patient preferences also should be considered. Judging by the symptoms L.M. is displaying, he would likely benefit from immediate treatment. His symptoms are unilateral but are occurring on his dominant side and are interfering with his ability to paint, thus affecting his livelihood. He is also showing signs of rigidity and bradykinesia but can otherwise live independently.

Numerous features are associated with PD. Handwriting abnormalities occur frequently, particularly micrographia, a symptom of bradykinesia. Because L.M. is an artist, this abnormality would be particularly troublesome. He also is showing signs of autonomic nervous system dysfunction, such as drooling (sialorrhea), seborrhea, and constipation, all of which can be particularly embarrassing to the patient. Drooling also may be a consequence of impaired swallowing.¹³ The foul body odor exhibited by L.M. could be ascribed to excess sebum production. L.M.’s seborrhea can be treated with coal tar or selenium-based shampoos twice weekly, topical hydrocortisone, or topical ketoconazole.¹³ His constipation should be managed first by evaluating his diet and exercise level, by stopping all medications such as anticholinergics (including over-the-counter cold and sleep medications) that may exacerbate constipation, and by trying a stool softener such as sodium or calcium docusate. In more severe cases, lactulose, mild laxatives, or enemas may be required.

L.M. should also be evaluated for other manifestations of dysautonomia, including urinary problems, increased sweating, orthostatic hypotension, erectile dysfunction, pain or dysesthesias, and problems swallowing. L.M. has benign prostatic hypertrophy; therefore, a urologic workup may be necessary. He also should be counseled to avoid anticholinergic agents that may exacerbate this problem. Anticholinergic agents also should not be used to treat his hypersalivation, but he should be referred to a speech and swallowing expert because dysphagia can result in impaired absorption and lead to aspiration.¹³ A soft diet may be indicated. L.M.’s soft, mumbled, or monotone voice is also consistent with the disease and is often one of the first symptoms noted. Speech therapy is often beneficial for managing this problem.¹⁴

Psychiatric disturbances, such as nervousness, anxiety, and depression, occur commonly in patients with PD and they should be screened regularly for these conditions.^{13,15} L.M. has a history of depression that could be attributable to PD. Finally, the prevalence of cognitive decline and dementia among parkinsonian patients ranges from 10% to 30% and may be associated with a more rapid progression of disease-related disability.⁸ The development of hallucinations in patients with PD with dementia is a poor prognostic sign.¹⁶ The “forgetfulness” and decreased memory described by L.M. could be early signs of dementia and warrant close observation.

Staging of Parkinson’s Disease

2. What are the stages of PD? In what stage of the disease is L.M.?

The symptomatology and progression of symptoms among parkinsonian patients is tremendously variable. To assess the

Table 53-3 Staging of Disability in Parkinson's Disease

| | |
|-----------|--|
| Stage I | Unilateral involvement only; minimal or no functional impairment |
| Stage II | Bilateral involvement, without impairment of balance |
| Stage III | Evidence of postural imbalance; some restriction in activities; capable of leading independent life; mild to moderate disability |
| Stage IV | Severely disabled, cannot walk and stand unassisted; significantly incapacitated |
| Stage V | Restricted to bed or wheelchair unless aided |

From reference 2, with permission.

degree of disability and determine the rate of disease progression relative to treatment, various scales have been developed. The most common of these is the Hoehn and Yahr scale (Table 53-3).² In general, patients in Hoehn and Yahr stage I or II of PD have mild disease that does not interfere with activities of daily living or work and usually requires minimal or no treatment. In stage III disease, daily activities are restricted and employment may be significantly affected unless effective treatment is initiated.

With advanced-stage disease (III to IV), most patients require levodopa therapy (with a peripheral decarboxylase inhibitor such as carbidopa [Sinemet]) and often in combination with a COMT inhibitor such as entacapone or a dopamine agonist such as pramipexole (Mirapex), or ropinirole (Requip). In some cases, selegiline (Eldepryl), rasagiline (Azilect), or amantadine may provide further symptomatic relief. Patients with end-stage disease (stage V) are severely incapacitated and, because of extended disease progression, often do not respond well to drug therapy.

TREATMENT OF PARKINSON'S DISEASE

An algorithm for the management of cases of PD is presented in Figure 53-1. No cure is known for PD; therefore, treatment is symptomatic only. The long-term, individualized treatment plan is usually characterized by frequent dosage adjustments over time because of the chronic and progressive nature of this disease. Although most of this chapter is devoted to the drug therapy of PD, the importance of supportive care cannot be overemphasized. Exercise, physiotherapy, and good nutritional support can be beneficial at the earlier stages to improve mobility, increase strength, and enhance well-being and mood.¹³ Speech therapy may be helpful, and psychological support is often necessary in dealing with depression and other related problems. Newly diagnosed patients need to be educated about what to expect from the disease and the various forms of treatment available. In addition, enlisting the support of family members is vital in establishing an overall effective therapeutic plan.

Dopamine Agonists

Initial Therapy

3. The decision is made to begin drug therapy for L.M. Should therapy be initiated with a dopamine agonist or levodopa?

Levodopa, without question, has revolutionized the treatment of PD. It is considered to be the most effective antiparkinsonian agent.¹² Declining efficacy and response fluctuations encountered with long-term levodopa therapy, as well as a high frequency of undesirable side effects, prompted investigators to search for agents that could directly stimulate dopamine receptors. This led to the development of the dopamine agonists.

In clinical trials comparing dopamine agonists and levodopa, activities of daily living and motor features are improved 40% to 50% with levodopa compared with 30% with dopamine agonists.¹⁷⁻¹⁹ Although they are not as effective as levodopa, the dopamine agonists have a number of potential advantages over levodopa. Because they act directly on dopamine receptors, they do not require metabolic conversion to an active product and therefore act independently of degenerating dopaminergic neurons.¹³ Unlike levodopa, circulating plasma amino acids do not compete with dopamine agonists for absorption and transport into the brain. Dopamine agonists have a longer half-life than levodopa formulations, reducing the need for multiple daily dosing. Initial therapy with dopamine agonists is associated with fewer motor complications and can delay the need for levodopa.^{17,18,20} As a class, dopamine agonists provide adequate control of symptoms when given as monotherapy in up to 80% of patients with early-stage disease. These benefits are sustained for 3 years or more in most patients. With disease progression, levodopa therapy will eventually be necessary, however.

Guidelines from the American Academy of Neurology support either dopamine agonists or levodopa as initial therapy for PD.²¹ In younger patients (e.g., age <65 years) with milder disease, such as L.M., the initiation of a dopamine agonist as a first-line agent is a strategy used to delay the introduction of levodopa. This levodopa-sparing effect, as well as the reduction in motor complications observed with early dopamine agonist therapy, is the reason why many clinicians opt for using this class of drugs as initial treatment for PD in younger patients who would be expected to live many years with the disease.¹³ In older patients (e.g., age >65 years) with PD, it may be more appropriate to initiate treatment with levodopa instead of a dopamine agonist, because these patients are less likely to live sufficiently long with the disease to experience the levodopa-related motor complications that occur after prolonged therapy with the drug.¹³ An additional consideration is that dopamine agonist therapy is more costly than levodopa.²¹

In the case of L.M., his relatively young age (<65 years) and mild disease make him a good candidate for initial therapy with a dopamine agonist. L.M. will certainly require levodopa therapy later, when he reaches more advanced stages of the disease. By initiating therapy first with a dopamine agonist, rescue levodopa therapy can likely be started at smaller doses, and the onset of motor complications that often occur with escalating doses and extended therapy with levodopa may be delayed.

Selection of Agents

4. L.M. is to be started on a dopamine agonist. Which agent should be selected?

Two generations of dopamine agonists have been used for the treatment of idiopathic, early-stage PD as monotherapy, or as an adjunct to levodopa in patients with advanced disease.

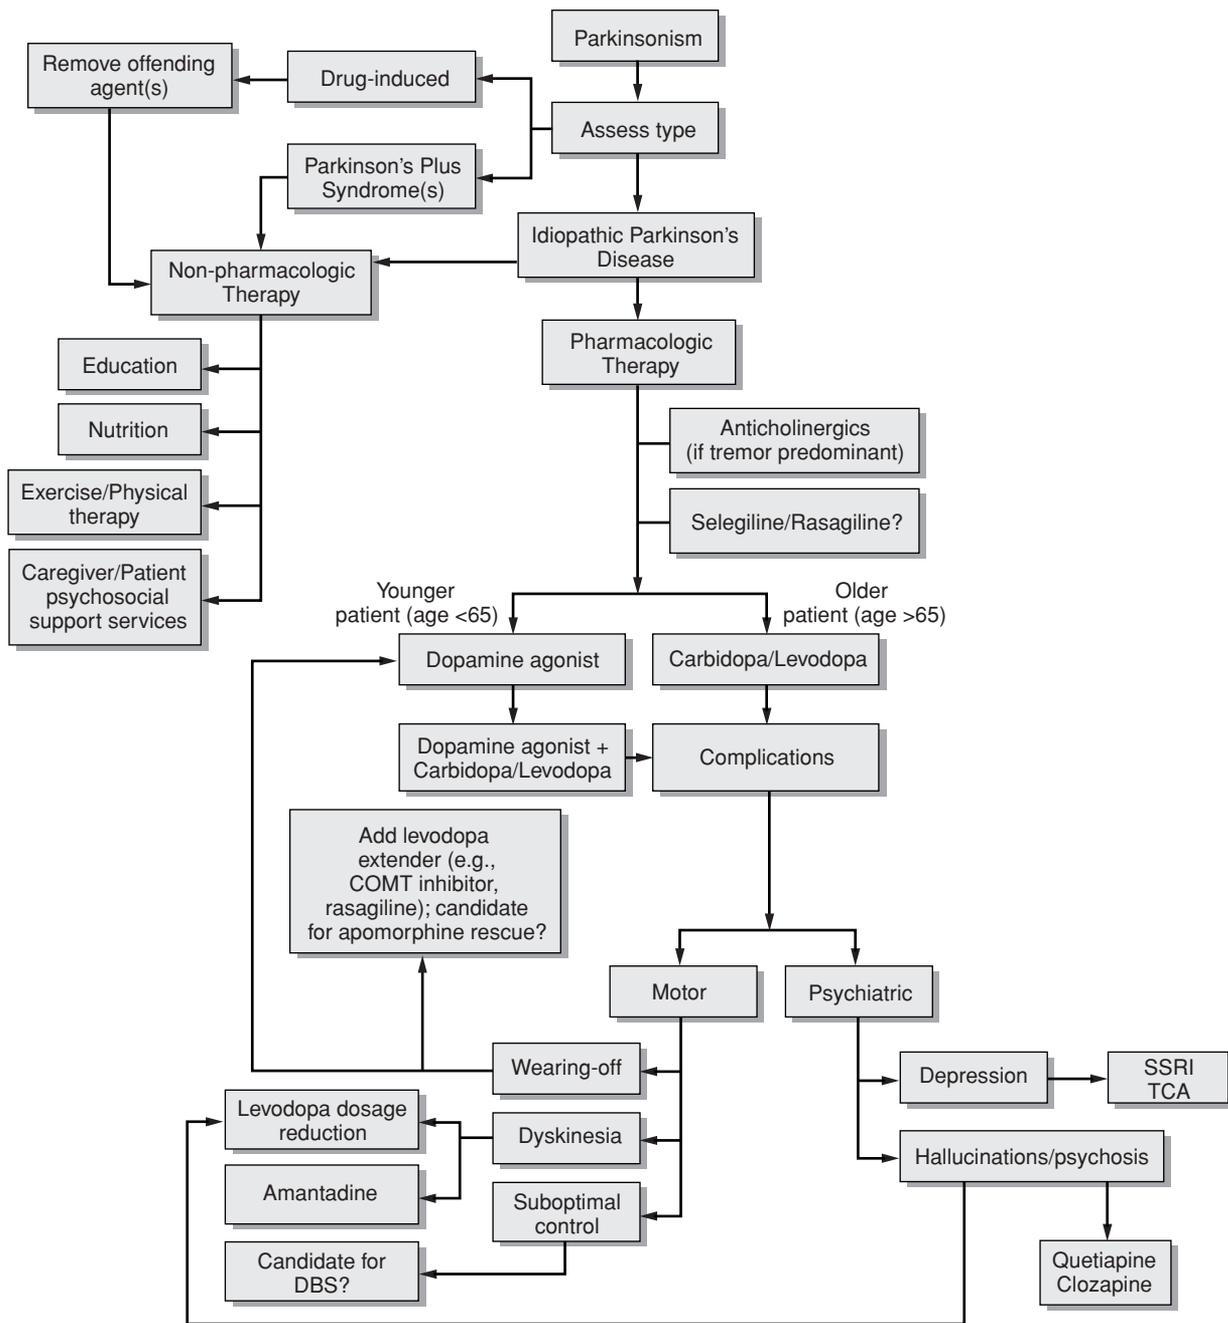

FIGURE 53-1 Suggested treatment algorithm for the management of Parkinson's disease. DBS, deep brain stimulation. (Modified with permission from the American College of Clinical Pharmacy. Michael E. Ernst. Parkinson's Disease. In: Dunsworth T et al, eds. Pharmacotherapy Self-Assessment Program, 6th ed., Neurology and Psychiatry module. Lenexa, KS: American College of Clinical Pharmacy; 2007:22.)

The comparative pharmacologic and pharmacokinetic properties of these agents are shown in Table 53-4. The first generation, ergoline-class dopamine agonists, which are derived from ergot alkaloids, include bromocriptine, pergolide, and cabergoline. Although cabergoline is widely used in Europe, it is only indicated in the United States for treating hyperprolactinemia. Pramipexole, ropinirole, apomorphine, and rotigotine are newer, nonergoline dopamine agonists. Apomorphine is only available in injectable form, and is used as a rescue agent approved for the treatment of hypomobility or “off” episodes in patients with PD. Rotigotine is the newest dopamine agonist

approved for use in PD, and is formulated in a once-daily transdermal delivery system.

The dopamine agonists work by directly stimulating post-synaptic dopamine receptors within the corpus striatum.²² The two families of dopamine receptors are D₁ and D₂. The D₁ family includes the D₁ and D₅ dopamine subtype receptors and the D₂ family includes D₂, D₃, and D₄ dopamine subtype receptors. Stimulation of D₂ receptors is largely responsible for reducing rigidity and bradykinesia, whereas the precise role of the D₁ receptors remains uncertain.²² Although the dopamine agonists differ slightly from each other in terms of their affinities for

^aAntagonist.

dopamine receptors, these agents produce similar clinical effects when used to treat PD and no compelling evidence favors one agent over another strictly on efficacy measures.^{13,22,23} Older ergoline derivative agents have been associated, however, with an increased risk for retroperitoneal, pleural, and pericardial fibrosis, as well as a two- to fourfold increased risk for cardiac valve fibrosis compared with nonergoline dopamine agonists and controls.^{12,24,25} On March 29, 2007 the U.S. Food and Drug Administration (FDA) notified health care professionals and patients that companies that manufacture and distribute pergolide have voluntarily agreed to withdraw the drug from the market owing to this increased risk. Because L.M. has aortic stenosis, the potential risk for further damage to his valve would have precluded using a first-generation dopamine agonist, such as bromocriptine or pergolide, anyway. Instead, experience with the nonergoline dopamine agonists, pramipexole or ropinirole, makes them currently preferred as initial dopamine agonists.¹² No studies have directly compared these two agents, and individual studies of efficacy appear to demonstrate similar benefits.

5. The decision is made to begin pramipexole in L.M. How effective is pramipexole in the initial treatment of PD? How does ropinirole compare?

PRAMIPEXOLE

Efficacy

The efficacy of pramipexole has been proved in two populations of patients: (a) patients with early-stage PD receiving pramipexole as monotherapy^{26–29} and (b) patients with advanced-stage disease receiving pramipexole as an adjunct to levodopa therapy.^{30,31} These trials were multicenter, placebo-controlled, parallel-group studies, and the primary outcome measures included improvement in activities of daily living (ADL, part II) and motor function scores (part III) as measured by the Unified Parkinson Disease Rating Scale (UPDRS).³² Each evaluation on the UPDRS is rated on a scale of 0 (normal) to 4 (can barely perform). Lower scores on the UPDRS after treatment indicate an improvement in overall performance.

Two large-scale, double-blind, placebo-controlled studies were performed that included a total of 599 patients with early-stage PD (mean disease duration of 2 years). In the first study, 264 patients were randomized to receive one of four fixed doses (1.5, 3.0, 4.5, or 6.0 mg/day) or placebo.²⁸ At the end of the 4-week maintenance period, no significant dose-response ef-

fect was detected after comparison of UPDRS scores for the four pramipexole-treated groups. The pramipexole-treated patients, however, had a 20% reduction in their total UPDRS scores compared with baseline values, whereas no significant improvement was observed in the placebo-treated patients. A trend toward decreased tolerability was noted as the pramipexole dosage was escalated, especially in the 6.0-mg/day group.

In the second study that included 335 patients, the dose was titrated up to the maximal tolerated dose (not to exceed 4.5 mg/day) and then were followed for 6 months during a maintenance phase.²⁹ The mean pramipexole maintenance dosage was 3.8 mg/day. At the end of the 6-month maintenance phase, subjects treated with pramipexole experienced significant improvements in both the ADL scores (22%–29%) and motor scores (25%–31%), whereas no significant change was noted in the placebo group ($p < 0.0001$).

Pramipexole and levodopa were compared in a randomized, controlled trial as initial treatment of early PD.²⁰ This study evaluated the risk for development of motor complications with the two therapies. A total of 301 untreated patients with early PD were randomized to receive either pramipexole 0.5 mg three times daily or carbidopa/levodopa 25/100 mg three times daily. Doses could be escalated during the first 10 weeks of the study, following which open-label levodopa was permitted if necessary. The primary endpoint was the time to the first occurrence of wearing off, dyskinesias, or on-off motor fluctuations. After a mean follow-up of 24 months, patients in the pramipexole group were receiving a mean daily dose of 2.78 mg pramipexole and 264 mg of supplemental levodopa, whereas patients in the levodopa group were receiving a mean total of 509 mg/day levodopa. Fewer pramipexole-treated patients reached the primary endpoint (28% vs. 51%; $p < 0.001$) than the patients initially randomized to levodopa therapy. Dyskinesias were noted in only 10% of pramipexole-treated patients compared with 31% of levodopa-treated patients ($p < 0.001$), and fewer wearing-off effects were reported with pramipexole (24% vs. 38%; $p = 0.01$).

ROPINIROLE

Efficacy

Ropinirole is a synthetic nonergoline aminoindolone and a full dopamine agonist with selectivity for D₂ receptors; as with pramipexole, however, it has no significant affinity for D₁ receptors.³³ Although the drug is pharmacologically similar to pramipexole, it has some distinct pharmacokinetic properties,

as shown in Table 53-4. Unlike pramipexole, which is primarily eliminated by renal excretion, ropinirole is metabolized by the cytochrome P450 (primarily CYP1A2) oxidative pathway and undergoes significant first-pass hepatic metabolism.³⁴ Ropinirole is approved for use as monotherapy in early-stage idiopathic PD and as an adjunct to levodopa therapy in patients with advanced-stage disease.

The efficacy of ropinirole as monotherapy in patients with early PD has been evaluated in several randomized, double-blind, multicenter, parallel group studies.³⁵⁻³⁷ One study was placebo-controlled, another study compared ropinirole with bromocriptine, and the third study compared initial therapy with ropinirole versus levodopa in early PD. After 6 months of maintenance therapy with ropinirole, all three studies showed a significant improvement in UPDRS motor scores compared with baseline values (20%–30%). In the placebo-controlled study, ropinirole-treated patients had a 24% reduction in their UPDRS motor scores compared with their baseline values, whereas the placebo-treated patients decreased their scores by only 3%.³⁶ In the study comparing the effectiveness of ropinirole with bromocriptine, a significantly greater number of ropinirole-treated patients (58%) experienced a 30% reduction in their UPDRS scores compared with bromocriptine-treated patients (43%).³⁷ A 6-month interim analysis of the third study, which compared the efficacy of ropinirole (mean dosage, 9 mg/day) with levodopa (mean dosage, 464 mg/day), reported that the levodopa-treated patients had a 44% improvement in their UPDRS motor scores compared with a 32% improvement in the ropinirole-treated patients.³⁵ When the two treatments were stratified for disease stage, however, the two treatments were equally effective in patients with mild PD.

After 5 years of follow-up, ropinirole-treated patients had a reduced risk for developing dyskinesias compared with initial therapy with levodopa.¹⁸ At the end of the study, the mean daily dose of ropinirole was 16.5 mg plus 427 mg of open-label levodopa, compared with a mean daily dose of 753 mg of levodopa for the levodopa group. Of patients in the ropinirole group, 66% required open-label levodopa supplementation compared with 36% in the levodopa group. Dyskinesias developed in 20% of the ropinirole-treated patients compared with 45% of the levodopa-treated patients (hazard ratio for remaining free of dyskinesia in the ropinirole group, compared with the levodopa group, 2.82; $p < 0.001$). This difference between the two groups was not dependent on whether the patient received open-label levodopa supplementation. For ropinirole-treated patients who were able to remain on monotherapy without open-label levodopa supplementation, only 5% developed dyskinesia, compared with 36% of those receiving levodopa monotherapy.

DOSING

6. What is the most effective way to dose pramipexole or ropinirole?

Pramipexole should always be initiated at a low dosage and gradually titrated to the maximal effective dose, as tolerated. This approach minimizes adverse effects that may result in noncompliance or discontinuation of the drug. In clinical trials, the maximal effective dose was variable and correlated with disease severity and tolerability. One fixed-dose study in early PD showed, however, that most patients responded maximally at a dosage of 0.5 mg three times daily.²⁸ In patients with advanced-stage disease, an average of 3.4 mg/day is usu-

ally required to reach the maximal effect of pramipexole.³¹ Studies have shown that pramipexole is nearly equipotent with pergolide, about tenfold more potent than bromocriptine, and about threefold more potent than ropinirole.³⁸

L.M. has normal renal function and therefore should be started at an initial dosage of 0.125 mg three times daily for 5 to 7 days. At week 2, the dosage should be increased to 0.25 mg three times daily. Thereafter, his dosage may be increased weekly by 0.25 mg/dose (0.75 mg/day) as tolerated and up to the maximal effective dose, not to exceed 1.5 mg three times daily.³⁹ The titration period usually takes about 4 to 7 weeks, depending on the optimal maintenance dose.

Patients with a creatinine clearance of <60 mL/minute should be dosed less frequently than those with normal renal function.³⁹ Patients with a creatinine clearance of 35 to 59 mL/minute should receive a starting dose of 0.125 mg twice daily up to a maximal dose of 1.5 mg twice daily; patients with a creatinine clearance of 15 to 34 mL/minute should receive a starting dose of 0.125 mg daily up to a maximal dose of 1.5 mg daily. Pramipexole has not been studied in patients with a creatinine clearance of <15 mL/minute or those receiving hemodialysis.

Ropinirole should be initiated at a dosage of 0.25 mg three times daily with gradual titration in weekly increments of 0.25 mg/dose over 4 to 6 weeks.¹³ Clinical response to ropinirole is usually observed at a daily dose of 9 to 12 mg given in three divided doses. No dosage adjustments are necessary with renal dysfunction.

ADVERSE EFFECTS

7. What are the adverse effects of pramipexole and ropinirole? How can these be managed?

Because pramipexole and ropinirole are approved for use as both monotherapy in early-stage disease and as adjunctive therapy in advanced-stage disease, the adverse events of these agents have been evaluated as a function of disease stage. In studies of pramipexole-treated patients with early-stage disease, the most common adverse effects were nausea (28%–44%), dizziness (25%), somnolence (22%), insomnia (17%), constipation (14%), asthenia (14%), and hallucinations (9%).^{26-29,39,35-37,40} Nausea, with or without vomiting, can be a significant problem, particularly with higher doses.³⁹ Administering the drug with food may partially alleviate this problem. With continued use, many patients develop tolerance to the gastrointestinal side effects of pramipexole. Mental changes were the most common reason for discontinuation of pramipexole in both patient populations. Patients >65 years of age are threefold more likely to experience hallucinations with dopamine agonists.⁴¹ The incidence of orthostatic hypotension was relatively low (1%–9%) and may in part reflect the exclusion of patients with underlying cardiovascular disease in several of the studies.³⁹

In advanced-stage disease, the most common adverse events of dopamine agonists were nausea (25%), orthostatic hypotension (10–54%), dyskinesias (26%–47%), insomnia (27%), somnolence (11%), confusion (10%), and hallucinations (11% to 17%).^{31,39,40,42} As expected, in patients with advanced-stage disease, the most common reasons for discontinuing these agents are mental disturbances (nightmares, confusion, hallucinations, insomnia) and orthostatic hypotension. Dyskinesias experienced when pramipexole is used in combination

with levodopa in advanced-stage disease may be managed by first lowering the daily dose of levodopa. If unsuccessful, the dopamine agonist dose can be lowered; however, parkinsonian symptoms may worsen.

Excessive daytime somnolence during ADL, including driving, has been reported with dopamine agonists and has resulted in accidents.^{43,44} Affected patients have not always reported warning signs before falling asleep and believed they were alert immediately before the event. Labeling for these drugs has since been changed to warn that patients should be alerted to the possibility of falling asleep while engaged in ADL. Patients should be advised to refrain from driving or engaging in other potentially dangerous activities until they have gained sufficient experience with pramipexole to determine whether it will hinder their mental and motor performance. Caution should be advised when patients are taking other sedating medications or alcohol in combination with pramipexole and ropinirole. If excessive daytime somnolence does occur, patients should be advised to contact their physician.

Recently, several reports of compulsive gambling and other impulse control disorders (hypersexuality, alcoholism, kleptomania) have been reported with dopamine agonist use.⁴⁵⁻⁴⁸ In one study, a prevalence of 6.1% was noted for pathologic gambling in patients with PD compared with 0.25% for age and sex-matched controls.⁴⁸ These cases may represent variations of a behavioral syndrome termed “hedonistic homeostatic dysregulation” or “dopamine dysregulation syndrome.”⁴⁹ Other features of the syndrome have been reported, including punting (carrying out repetitive, purposeless motor acts), hypersexuality, walkabout (having the urge to walk great distances during “on” times, often with no purpose or destination, and abnormalities in time perception), pathologic gambling and shopping, alterations in appetite, drug hoarding, and social independence or isolation.⁴⁹ The syndrome appears to be more common among younger, male patients with early onset PD, as well as those having “novelty seeking” personality traits, depressive symptoms, and increased alcohol intake.⁵⁰

Although L.M. is <65 years of age, he is experiencing memory difficulty and may be at increased risk for visual hallucinations and cognitive problems from dopamine agonist therapy. He should be monitored closely for occurrence or exacerbation of these problems. He should also be evaluated for lightheadedness before initiation of pramipexole and counseled to report dizziness or unsteadiness, because this may lead to falls. He should also be reassured that if these effects are caused by pramipexole, they should subside with time and that he should not drive or operate complex machinery until he can assess the drug’s effect on his mental status. L.M. should be counseled about the possibility of excessive, and potentially unpredictable, daytime somnolence as pramipexole is introduced. L.M. and his family should be educated about the reports of pathologic gambling and advised to report any unusual or uncharacteristic behaviors.

ROTIGOTINE

8. What type of dopamine agonist is rotigotine? How is it used?

Rotigotine is a new nonergolinic dopamine receptor agonist approved in May 2007 for the treatment of early stage idiopathic PD. It has previously been available only in Europe. Rotigotine is unique among PD medications because it is for-

mulated in a transdermal patch delivery system designed for once a day application.⁵¹ Other dopamine agonists currently available offer longer half-lives than levodopa; however, they do not provide a truly continuous stimulation of dopamine receptors and must be dosed multiple times daily. In theory, the transdermal application system may provide a more continuous stimulation of dopamine receptors than traditional oral formulations, which may translate into improved efficacy. Three strengths are available, based on drug delivery rate (total rotigotine content per system): 2 mg/24 hours (4.5 mg), 4 mg/24 hours (9 mg), and 6 mg/24 hours (13.5 mg).

Rotigotine has been studied in both early and advanced stages of disease, although it is currently indicated for use in the United States only as monotherapy in early stage PD. As monotherapy in clinical trials of patients with early-stage PD, rotigotine has been dosed in a range of 2 mg/24 hours up to 18 mg/24 hours.⁵²⁻⁵⁴ In the 2 to 8 mg/24 hour dosing range, mean differences from placebo in the UPDRS ranged from -2.1 to -5.0. Rotigotine is initiated at 2 mg/24 hours and titrated each week by 2 mg/24 hours until response is noted. The maximal recommended dose is 6 mg/24 hours.⁵⁵ Doses beyond 6 mg/24 hours did not result in additional improvement in the UPDRS and resulted in an increased incidence of adverse effects.

Rotigotine has also been studied in slightly higher doses as adjunctive therapy to levodopa in patients with advanced stages of PD. In one 6-month trial that included 351 patients, 8 mg/24 hours and 12 mg/24 hours reduced “off” time an average of 2.1 and 2.7 hours, respectively, from baseline compared with a 0.9-hour decrease in the placebo group.⁵⁶ Adverse events with rotigotine appear similar to those observed with other dopamine agonists (nausea, vomiting, somnolence, dizziness). As with other dopamine agonists, patients should be warned about the possibility of sudden sleep attacks. Transient application site reactions, including mild skin irritation, erythema, and rash at the patch site are also reported.^{52,53,55} Rotigotine contains sodium metabisulfite and should not be used by patients with known sulfite sensitivity owing to the risk for anaphylaxis. If rotigotine is discontinued, it should be done so gradually by 2 mg/24 hours every other day to reduce the possibility of a neuroleptic malignant syndrome that has been reported with rapid dose reduction or withdrawal of other anti-parkinsonian therapies. The pharmacokinetic profile of rotigotine reveals an initial half-life of 3 hours, and after removal of the patch, plasma levels decreased with a terminal half-life of 5 to 7 hours.⁵⁵

Although clinical experience with rotigotine in the United States is limited, the encouraging study results and unique drug delivery system appear poised to place rotigotine as an important addition to the dopamine agonist class of medications. Only the results of future studies will determine how well the agent compares with existing first-line dopamine agonists, ropinirole and pramipexole, in delaying the eventual need for levodopa and in reducing the risk for dyskinesias.

Levodopa

Timing of Initiation of Therapy

9. L.M. has responded well to pramipexole 1.0 mg three times daily (TID) for the past 18 months, with an increased ability to paint and carry out ADLs. Over the past few weeks, however, he

has noticed a gradual worsening in his symptoms and once again is having difficulty holding a paintbrush. He currently complains of feeling more “tied up,” he has more difficulty getting out of a chair, and his posture is slightly more stooped. Otherwise, he can carry out most of his ADLs without great difficulty. Should levodopa be considered for the treatment of L.M.’s PD at this time?

For patients with advancing PD, levodopa remains the mainstay of treatment. Nearly all patients will eventually require treatment with the drug, regardless of initial therapy. Because PD is characterized by the absence of dopamine in the brain, the most rational approach to treatment is to replenish the depleted dopamine. Dopamine itself does not cross the blood–brain barrier, however. In high doses, levodopa, a dopamine precursor with no known pharmacologic action of its own, penetrates into the brain, where it is converted by aromatic amino acid (dopa) decarboxylase to dopamine.⁵⁷ Early trials by Cotzias et al.^{57,58} and Barbeau⁵⁹ demonstrating significant and dramatic improvement in the classic features of the disease soon led to further studies, which clearly established levodopa as the drug of choice for long-term treatment of PD. Although levodopa is the most effective therapy for treating the rigidity and bradykinesia of PD, as with other dopaminergic agents, it does not effectively improve postural instability, or reduce dementia, autonomic dysfunction, or “freezing,” an extreme type of akinesia that often occurs in advanced-stage disease.⁶⁰

The question of when to begin levodopa in the treatment of PD has been historically debated. With long-term use, the efficacy of levodopa decreases, and the development of motor fluctuations and dyskinesias occurs. These observations led to the belief that chronic levodopa therapy may actually accelerate the neurodegenerative process through formation of free radicals via dopamine metabolism.^{61,62} The Earlier versus Later Levodopa Therapy in Parkinson’s Disease (ELLDOPA) study was designed to answer the question of whether long-term use of levodopa accelerates neurodegeneration and paradoxically worsens PD.⁶³ The investigators of this study randomized 361 patients with early PD to either carbidopa/levodopa 37.5/150 mg, 75/300 mg or 150/600 mg/day or placebo for 40 weeks followed by a 2 week withdrawal of treatment. After 42 weeks, the severity of symptoms as measured by changes in the total UPDRS score increased more in the placebo group than in all of the groups receiving levodopa. The findings of this study provide assurance that early levodopa use does not result in accelerated progression of the disease based on clinical evaluations.

The optimal time to initiate levodopa therapy must be individualized. Most clinicians agree that there is little reason to start levodopa until the patient reports worsening of functionality (socially, vocationally, or otherwise). Before levodopa is started, patients must fully understand the nature of the disease and what to expect with long-term therapy. L.M. should be considered for levodopa therapy because his disease has progressed sufficiently to threaten his job performance, and his symptoms have progressed despite therapy with a dopamine agonist.

Sinemet: Advantages and Disadvantages

10. What are the advantages and disadvantages of Sinemet over levodopa alone?

Although levodopa is highly effective, its use is not without problems including many undesirable side effects, such as nausea, vomiting, and anorexia (50% of patients); postural hypotension (30% of patients); and cardiac arrhythmias (10% of patients).^{59,60,64} In addition, mental disturbances (see Question 12) are encountered in 15% of patients, and abnormal involuntary movements (dyskinesias) can be seen in up to 55% of patients during the first 6 months of levodopa treatment.^{59,60,64,65} Because significant amounts of levodopa are peripherally (extracerebrally) metabolized to dopamine by the enzyme aromatic amino acid (dopa) decarboxylase, extremely high doses would be necessary if administered alone. For this reason, levodopa is always administered with a dopa decarboxylase inhibitor.

By combining levodopa with a dopa decarboxylase inhibitor that does not penetrate the blood–brain barrier, a decrease in the peripheral conversion of levodopa to dopamine can be achieved, while the desired conversion within the basal ganglia remains unaffected (Fig. 53-2).⁶⁶ The two peripheral decarboxylase inhibitors in clinical use are benserazide (unavailable in the United States) and carbidopa (Lodosyn).¹³ Sinemet is the fixed combination of carbidopa and levodopa and is available in ratios of 1:4 (Sinemet 25/100) and 1:10 (Sinemet 10/100 and 25/250).¹³ A controlled-release product (Sinemet CR) is available in a ratio of 25/100 and 50/200. In addition, carbidopa/levodopa is also available as an orally disintegrating tablet.

Combining levodopa with carbidopa enhances the amount of dopamine available to the brain and thereby allows the dose of levodopa to be decreased by 80%.⁶⁷ This combination also shortens by several weeks the time needed to increase the levodopa dose to achieve maximal effects because carbidopa substantially decreases levodopa-induced nausea and vomiting.^{13,60}

CARBIDOPA/LEVODOPA (SINEMET) DOSING

11. The decision is made to begin L.M. on carbidopa/levodopa (Sinemet). How is Sinemet dosed?

About 75 to 100 mg/day of carbidopa is necessary to saturate peripheral dopa decarboxylase.¹³ It is usually unnecessary and more costly to give higher amounts of carbidopa than this. Therapy should be initiated with Sinemet 25/100 (carbidopa/levodopa) at a dosage of one tablet three times a day. The dosage can then be increased by 100 mg levodopa every day or every other day up to eight tablets (800 mg) or to the maximal effective dose, to individual requirements, or as tolerated. If troublesome dyskinesias occur at dosages needed for maximal response (as is frequently the case), the levodopa dose can be decreased in approximately 25-mg increments while monitoring for recurrence of symptoms. If the dyskinesias occur only at the peak plasma concentration of levodopa, the dose can be lowered and given more frequently. Alternatively, a levodopa-extender such as a COMT inhibitor, dopamine agonist, or rasagiline can be added and the levodopa dose decreased. The goal of optimizing therapy lies in balancing the most therapeutic dose with that which does not produce unacceptable side effects.

Because L.M. is currently treated with a dopamine agonist, he may respond to lower doses of levodopa than patients who are naïve to dopaminergic therapy. He must also be monitored

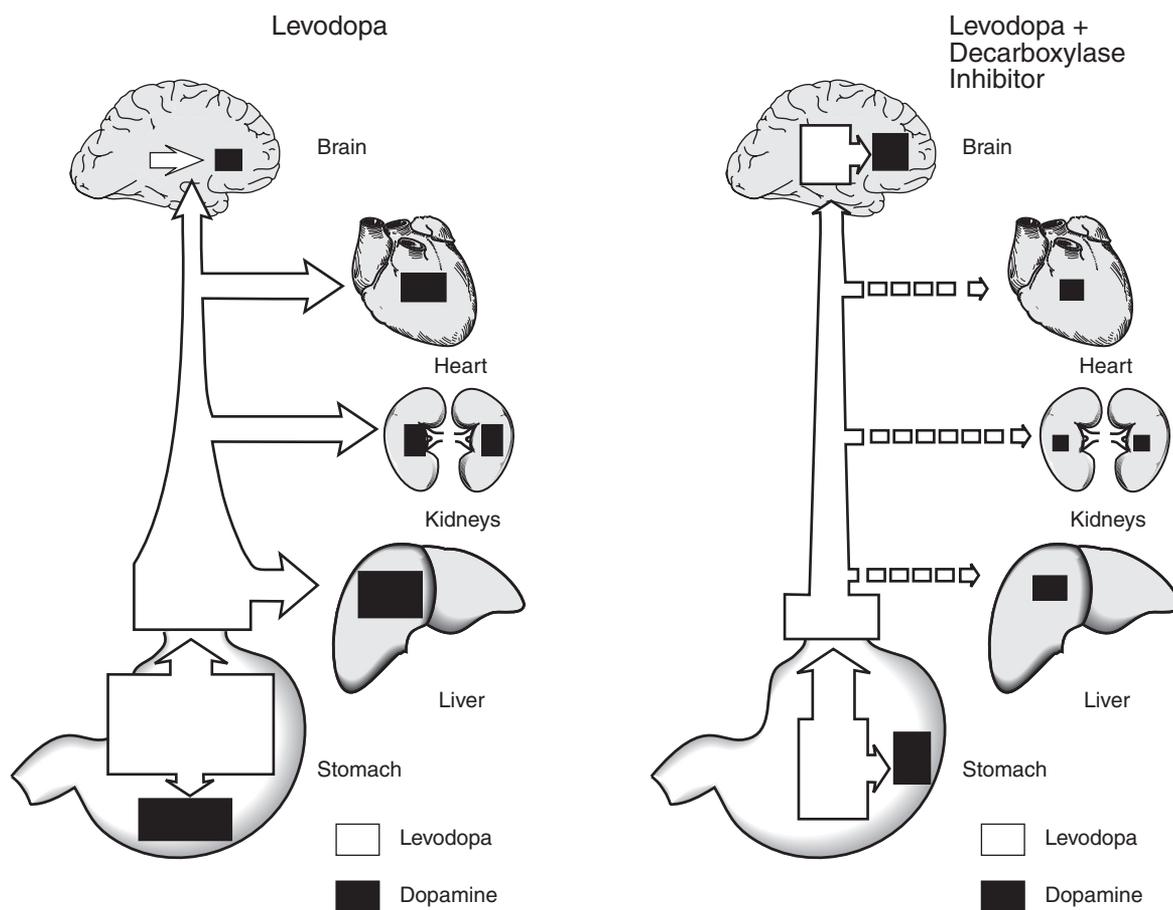

FIGURE 53-2 Peripheral decarboxylation of levodopa when given alone (*left*) and with a peripheral decarboxylase inhibitor (*right*). When combined with a decarboxylase inhibitor, less drug is required and more levodopa reaches the brain. (Reproduced with permission from Pinder RM et al. Levodopa and decarboxylase inhibitors: a review of their clinical pharmacology and use in the treatment of parkinsonism. *Drugs* 1976;11:329.)

closely for the development of motor complications with the addition of levodopa. Therefore, for best results, long-term follow-up with frequent subtle dosage adjustments is the preferred approach.

Most patients respond to levodopa dosages of 750 to 1,000 mg/day when given with carbidopa.¹³ When levodopa dosages exceed 750 mg/day, patients such as L.M. can be switched from the 1:4 ratio of carbidopa/levodopa to the 1:10 ratio to prevent providing excessive amounts of decarboxylase inhibitor. For example, if L.M. needed 800 mg/day of levodopa, two Sinemet 10/100 tablets four times daily could be given. If L.M. had not been initially treated with a dopamine agonist, some clinicians would consider adding a dopamine agonist after the daily levodopa dose has been increased to >600 mg because dopamine agonists directly stimulate dopamine receptors, have longer half-lives, and result in a lower incidence of dyskinesias, thus providing a smoother dopaminergic response.^{13,41}

Clinical response to L.M.'s levodopa therapy may be improved by modifying dietary protein ingestion.^{13,68} Levodopa is actively transported across the blood–brain barrier by a large neutral amino acid transport system. This transport system also facilitates the blood-to-brain transport of amino acids such as L-leucine, L-isoleucine, L-valine, and L-phenylalanine. Le-

vodopa and these neutral amino acids compete for transport mechanisms, and high plasma concentrations of these amino acids can decrease brain concentrations of levodopa.⁶⁸ Patients are generally instructed to take immediate-release Sinemet 30 minutes before or 60 minutes after meals for maximal effect.

ADVERSE EFFECTS: MENTAL CHANGES

12. Since initiating carbidopa/levodopa, L.M. reports he feels confused at times and has trouble remembering things that happened recently. To what extent is levodopa contributing to these mental problems? How should they be managed?

Several psychiatric side effects have been associated with levodopa therapy. These include confusion, depression, restlessness and overactivity, psychosis, hypomania, and vivid dreams.⁶⁹ Mental side effects occur in approximately 20% of patients receiving levodopa, but the incidences vary. The combination of levodopa and a decarboxylase inhibitor has little effect on the incidence of mental disturbances.⁷⁰ Patients predisposed to levodopa-induced mental disturbances include those with underlying or pre-existing psychiatric disorders and those receiving high doses for prolonged periods.⁶⁹

An organic confusional state with disorientation, which may progress to delirium, is the most commonly observed mental side effect.⁶⁹ This side effect can be exacerbated by concurrent anticholinergic or amantadine therapy. Because of its ability to improve disease symptoms and profoundly affect neurologic function, levodopa often produces an elevation in mood, but this is not always the case. Depression, often out of proportion to the degree of neurologic impairment, is another commonly observed finding and may precede motor dysfunction.⁶⁹

Some patients receiving levodopa experience psychomotor excitation. Symptoms associated with psychomotor activation include overactivity, restlessness, and agitation. Similarly, hypomania has been reported in up to 8% of patients and is characterized by grandiose thinking, flight of ideas, tangential thinking, and poor social judgment. Normal sexual activity often is restored with improved motor function; however, hypersexuality and libido are increased in about 1% of levodopa-treated patients.⁶⁹ Hypersexuality is most likely an associated feature of levodopa-induced hypomania.

In general, most of the mental disturbances are dose related and can be lessened by reducing the dosage of levodopa. In patients such as L.M. who are concurrently receiving levodopa and a dopamine agonist, the dosage reduction should be attempted first with levodopa. If symptoms do not improve, a reduction in the dosage of the dopamine agonist may also be warranted. These dosage reductions may, however, be impractical for L.M. because a return of parkinsonian symptoms is likely, and the benefits of levodopa therapy may outweigh the risk for mental disturbances.

Motor Complications

13. L.M. had a dramatic improvement in all of his parkinsonian symptoms with the initiation of levodopa therapy after being maintained on 25/250 regular Sinemet four times a day. After 6 months of treatment, he began to experience dyskinesias. These usually occurred 1 to 2 hours after a dose and were manifested by facial grimacing, lip smacking, tongue protrusion, and rocking of the trunk. These dyskinetic effects were lessened by decreasing his pramipexole dose to 0.5 mg TID and gradually decreasing his dosage of Sinemet to 25/250 TID, but the effects have not totally cleared.

After 3 years of levodopa therapy, more serious problems have begun to emerge. In the mornings, L.M. often experiences immobility. Nearly every day, he has periods (lasting for a few minutes) in which he cannot move, followed by a sudden switch to a fluid-like state, often associated with dyskinetic activity. He continues to take Sinemet (25/250 TID), but gains symptomatic relief only for about 3 to 4 hours after a dose. Also, the response to a given dose varies and is often less in the afternoon. At times, he becomes “frozen,” particularly when he needs to board an elevator or is required to move quickly. What are possible explanations for these alterations in clinical response?

For most patients, the initial response to levodopa is favorable, and this early phase is called the “honeymoon period.” Although variable, the honeymoon period can last for up to 5 years. After an initial period of stability, however, 50% to 90% of patients with PD will experience motor complications after receiving levodopa for 5 or more years.¹³ In attempting to describe response fluctuations, it is important to separate

those effects attributable to the disease and those attributable to the drug. Levodopa-induced dyskinesias often appear concurrently with the development of motor fluctuations.^{13,71} Reducing the levodopa dosage will often reverse these symptoms. The reduction in levodopa dosage usually results, however, in deterioration in the control of the disease.

Because levodopa is a short-acting agent with an elimination half-life of about 1.5 hours, much of the effect from the evening dose has dissipated by morning.⁶⁷ For this reason, it is not surprising that L.M. is experiencing a period of immobility on arising. This is alleviated in most patients shortly after taking the morning dose.^{72,73}

Two of the more common motor complications are the true “on-off” effect and the “wearing off,” or “end-of-dose deterioration” effect.^{71,72} The true “on-off” effect is described as random fluctuations from mobility to the parkinsonian state, which appears suddenly as if a switch has been turned. These fluctuations can last from minutes to hours and increase in frequency and intensity with time. Although most patients prefer to be *on* with dyskinesias rather than *off* with akinesia, dyskinesias in some patients can be more disabling than the parkinsonism.¹³ Early in the course of disease, it is usually possible to adjust the amount and timing of the doses of levodopa to control parkinsonian symptoms without inducing dyskinesias; however, as the disease advances and the therapeutic window narrows, cycling between *on* periods complicated by dyskinesia and *off* periods with resulting immobility is common.¹³

Eventually, despite adjustments in levodopa dosage, many patients with end-stage PD experience either mobility with severe dyskinesias or complete immobility.^{74,75} In most patients, this effect bears no clear-cut relation to the timing of the dose or levodopa serum levels.⁷⁶⁻⁷⁸ The *wearing off* or *end-of-dose* effect is a more predictable effect that occurs at the latter part of the dosing interval following a period of relief; it can be improved by various means such as shortening the dosing interval or by adjunctive dopamine agonist or adding a levodopa extender such as a COMT inhibitor.

The reasons for these motor complications are not entirely clear, but incomplete delivery of dopamine to central receptors is at least partially responsible. As the disease progresses, dopamine terminals are lost and the capacity to store dopamine presynaptically is diminished.⁷⁹ This can impair buffering of the rising and falling concentrations of levodopa. Consequently, dopamine receptors are subject to intermittent or phasic stimulation rather than by physiologic tonic stimulation. Variations in the rate and extent of levodopa absorption, dietary substrates (e.g., large neutral amino acids) that compete with cerebral transport mechanisms, levodopa drug-drug interactions (Table 53-5), and competition for receptor binding by levodopa metabolites can explain these variable responses to levodopa.^{71,76} Furthermore, early in the course of the disease, sufficient dopaminergic neurons remain that can store dopamine derived from levodopa administration and release it in a more physiologic manner. These neurons act as a buffer against fluctuating levodopa concentrations. With disease progression, the buffering capacity of these neurons is diminished and motor response becomes more dependent on fluctuations in synaptic dopamine concentrations.^{72,76,77,79}

14. What options are available to reduce L.M.’s motor fluctuations?

Table 53-5 Levodopa Drug Interactions

| Drug | Interaction | Mechanism | Comments |
|---|-----------------------------------|--|--|
| Anticholinergics | ↓ Levodopa effect | ↓ Gastric emptying, thus ↑ degradation of levodopa in gut, and ↓ amount absorbed | Watch for ↓ levodopa effect when anticholinergics used in doses sufficient to ↓ GI motility. When anticholinergic therapy discontinued in a patient on levodopa, watch for signs of levodopa toxicity. Anticholinergics can relieve symptoms of parkinsonism and might offset the reduction of levodopa bioavailability. Overall, interaction of minor significance. |
| Benzodiazepines | ↓ Levodopa effect | Mechanism unknown | Use together with caution; discontinue if interaction observed. |
| Ferrous sulfate | ↓ Levodopa oral absorption by 50% | Formation of chelation complex | Avoid concomitant administration. |
| Food | ↓ Levodopa effect | Large, neutral amino acids compete with levodopa for intestinal absorption | Although levodopa usually taken with meals to slow absorption and ↓ central emetic effect, high-protein diets should be avoided. |
| MAOI (e.g., phenelzine, tranylcypromine) | Hypertensive crisis | Peripheral dopamine and norepinephrine | Avoid using together; selegiline and levodopa used successfully together. Carbidopa might minimize hypertensive reaction to levodopa in patients receiving an MAOI. |
| Methyldopa | ↑ or ↓ levodopa effect | Acts as central and peripheral decarboxylase inhibitor | Observe for response; may need to switch to another antihypertensive. |
| Metoclopramide | ↓ Levodopa effect | Central dopamine blockade | Avoid using together |
| Neuroleptics (e.g., butyrophenones, phenothiazines) | ↓ Levodopa effect | Central blockade of dopamine neurotransmission | Important interaction; avoid using these drugs together. |
| Phenytoin | ↓ Levodopa effect | Mechanism unknown | Avoid using together if possible. |
| Pyridoxine | ↓ Levodopa effect | Peripheral decarboxylation of levodopa | Not observed when levodopa given with carbidopa |
| TCA | ↓ Levodopa effect | Levodopa degradation in gut because of delayed emptying | TCA and levodopa have been used successfully together; use with caution |

MAO-A, monoamine oxidase A; MAO-B, monoamine oxidase B; MAOI, monoamine oxidase inhibitor; TCA, tricyclic antidepressants.

Controlled-Release Sinemet

The ability to partially alleviate response fluctuations by using continuous infusions of levodopa prompted the development of slow-release carbidopa/levodopa formulations in an attempt to ensure a smoother, more sustained delivery of drug.⁸⁰ Sinemet CR contains 25 mg carbidopa and 100 mg levodopa or 50 mg carbidopa and 200 mg levodopa in an erodible polymer matrix that retards dissolution in gastric fluids. By gradually dissolving, Sinemet CR may provide a more gradual absorption of levodopa and more sustained plasma concentrations of levodopa compared with standard Sinemet.⁸⁰ While *off* time should theoretically be reduced by the slower rate of plasma levodopa decline, clinical studies have generally not found a difference in *off* time with the controlled-release preparation compared with the immediate-release preparation. As a result, the American Academy of Neurology Practice Parameter for treatment of motor fluctuations and dyskinesias does not recommend switching to controlled-release carbidopa/levodopa as a primary strategy to reduce *off* time.⁸¹

Controlled-release Sinemet is about 30% less bioavailable than immediate-release Sinemet. Patients converted from standard Sinemet should receive a dose of Sinemet CR that will provide 10% more levodopa, and then the dose should be titrated upward to clinical response.¹³ If L.M. were converted to Sinemet CR, the dosage of Sinemet CR would need to be increased about 10% (100 mg) to offset the relative decrease in bioavailability.

Assuming L.M. prefers not to convert to Sinemet CR, his condition may be improved by taking his daily doses of immediate-release Sinemet at shorter dosing intervals while

avoiding substantial increases in the daily dosage, which could worsen his dyskinesias. Taking his morning dose before arising from bed may help with his early morning problems and prevent other response fluctuations.

Other means for reducing motor fluctuations include the use of adjunctive agents such as the dopamine agonists, apomorphine rescue, COMT inhibitors, and MAO-B inhibitors, such as selegiline or rasagiline. In severe cases, continuous duodenal infusion of levodopa or administration of liquid levodopa has been useful in managing motor fluctuations (wearing off, unpredictable on and off times, and dyskinesias).^{82,83} Liquid levodopa is administered by crushing 10 immediate-release 25/100 tablets and dissolving them in 1 L of tap water, ginger ale, juice, or lemon-lime soda (final concentration is 1 mg/L levodopa). Vitamin C (four 500-mg tablets or 2 g of powder) should be added as a preservative and the mixture shaken well. This provides a solution that is stable for 24 hours at room temperature or 3 days refrigerated. Although this is an effective means for achieving fine titration increments and managing dyskinesias, the duration of effect is extremely short (60–90 minutes), and frequent administration is needed.^{13,83}

Dopamine Agonists

The effectiveness of pramipexole as an adjunct to levodopa therapy was evaluated in one large multicenter, placebo-controlled study of 360 patients with a mean disease duration of 9 years and an average duration of levodopa therapy of 8 years.³¹ Doses were titrated gradually to their maximal effective dosage as tolerated and not >4.5 mg/day in three divided doses. At the end of a 6-month maintenance period,

the patients treated with pramipexole had a 22% improvement in their ADL ($p < 0.0001$) and a 25% improvement in their motor scores ($p < 0.01$) compared with baseline values. Patients treated with pramipexole also had a 31% improvement in the mean off time, compared with a 7% improvement in the placebo-treated group ($p < 0.0006$). Levodopa dose reduction was permitted for increased dyskinesias or hallucinations and occurred in 76% of the pramipexole group compared with 54% in the placebo group. The total daily levodopa dose was decreased by 27% in those treated with pramipexole compared with 5% in the placebo group.

Ropinirole has also shown efficacy in improving motor scores when added to levodopa therapy in patients with advanced-stage disease.⁴² In a multicenter, double-blind, randomized parallel-group study, patients treated with ropinirole experienced an average *off* time that was decreased by 1.9 hours daily. In those treated with ropinirole, the total daily levodopa dose was decreased by an average of 19%. Of patients, 28% experienced at least a 35% reduction in both *off* time and in their levodopa dose, compared with 13% of the those in the placebo group. After 1 year of treatment, 47.5% of patients ($n = 865$) continued treatment with ropinirole as an adjunct to levodopa therapy in advanced-stage disease.

APOMORPHINE

Apomorphine is a dopamine agonist that is approved as rescue therapy for treatment of hypomobility or *off* episodes in patients with PD. It is available only in injectable form. In a randomized, double-blind, parallel-group study of 29 patients, rescue treatment with apomorphine resulted in a 34% reduction (~2 hours) in *off* time compared with 0% in the placebo group ($p = 0.02$).⁸⁴ Mean UPDRS motor scores were reduced by 23.9 points (62%) in the those treated with apomorphine, compared with 0.1 (1%) in those receiving placebo ($p < 0.001$). Adverse events in the apomorphine group included yawning (40%), dyskinesias (35%), drowsiness or somnolence (35%), nausea or vomiting, (30%), and dizziness (20%), although only yawning was statistically different than placebo (40% vs. 0%; $p = 0.03$).

Because nausea and vomiting frequently occur with apomorphine treatment, it should be administered with an antiemetic such as trimethobenzamide. The antiemetic should be started 3 days before initiating apomorphine and continued for the first 2 months of treatment. Apomorphine should not be used with ondansetron and other serotonin antagonists used to treat nausea because the combination may cause severe hypotension. In addition, other antiemetics, such as prochlorperazine and metoclopramide, should not be given concurrently with apomorphine because they are dopamine antagonists and can decrease the effectiveness of apomorphine.

Doses of apomorphine range from 2 to 6 mg per subcutaneous injection. A 2-mg test dose is recommended while monitoring blood pressure. If tolerated, the recommendation is to start with a dose of 1 mg less than the tolerated test dose, and increase the dose by 1-mg every few days if needed. Peak plasma levels are observed within 10 to 60 minutes after dosing, so the onset of therapeutic effect is rapid. Two main disadvantages of apomorphine are that the test dose and titration are time-consuming and must be done under physician supervision; and, secondly, patients may require someone else to inject the drug once hypomobility has occurred.

Catechol-O-Methyltransferase (COMT) Inhibitors

Although levodopa has been the mainstay of symptomatic treatment of PD, the increased incidence of motor complications and mental disturbances that occur after prolonged therapy prompted the development of therapies other than replenishment of dopamine. One of these strategies is to prevent the peripheral degradation of levodopa by metabolizing enzymes. COMT is an enzyme found in many body tissues, especially the liver, kidney, and intestines.⁸⁵ COMT, which catalyzes the transfer of a methyl group of S-adenosyl-L-methionine to a phenolic group of the catechol, is responsible for the biotransformation of many catechols and hydroxylated metabolites.⁸⁶ Carbidopa, an inhibitor of aromatic AAD, prevents the peripheral conversion of levodopa to dopamine. With AAD inhibitors, such as carbidopa or benserazide, the conversion of levodopa to 3-O-methyldopa (3-OMD) by COMT becomes a major metabolic pathway and is increased.⁸⁵ The metabolite 3-OMD lacks antiparkinsonian activity and may compete with levodopa for transport into the circulation and brain.

Entacapone and tolcapone are selective, reversible, and potent COMT inhibitors that increase the amount of levodopa available for transport across the blood-brain barrier (Fig. 53-3).⁸⁷⁻⁸⁹ This effect improves and prolongs the response to levodopa as measured by an increase in the amount of time spent *on* and a decrease in the daily levodopa dosage.⁸⁵ The pharmacologic and pharmacokinetic effects of entacapone and tolcapone are compared in Table 53-6. Tolcapone is slightly more potent and has a longer duration of action than entacapone.^{90,91} Unlike entacapone, which is usually given with every administration of carbidopa/levodopa (up to eight tablets per day), tolcapone is dosed three times daily. Tolcapone, however, is associated with cases of fatal, acute fulminant liver failure which have led to stringent liver function monitoring requirements.⁹² It is recommended for use only in patients taking levodopa who are experiencing motor fluctuations and are not responding adequately to, or are not appropriate candidates for, other adjunctive therapy.⁸¹ When initiated, liver function monitoring should be performed at baseline and every 2 to 4 weeks for the first 6 months, followed periodically thereafter as clinically necessary.⁹³ Because of the risks for hepatotoxicity associated with tolcapone, entacapone is the preferred COMT inhibitor.⁸¹

ENTACAPONE

15. Six months after adjusting the frequency of his carbidopa/levodopa, L.M. reports that his dyskinesic activity is not too bothersome, but he is having increased periods (lasting a few minutes) in which he cannot move. He is currently taking pramipexole 0.5 mg TID, immediate-release carbidopa/levodopa 25/250 five times a day, but “even on a good day” gains symptomatic relief for only about 2 to 3 hours following a dose. The decision is made to initiate entacapone therapy and gradually discontinue pramipexole as symptoms or side effects demand. How effective is entacapone for reducing the symptoms of PD?

Efficacy

Several trials have investigated the efficacy and safety of entacapone as an adjunct to levodopa therapy. The Nordic Multicenter Study on Entacapone, The COMT Inhibitor Trial (NOMECOMT) study was conducted in the Nordic

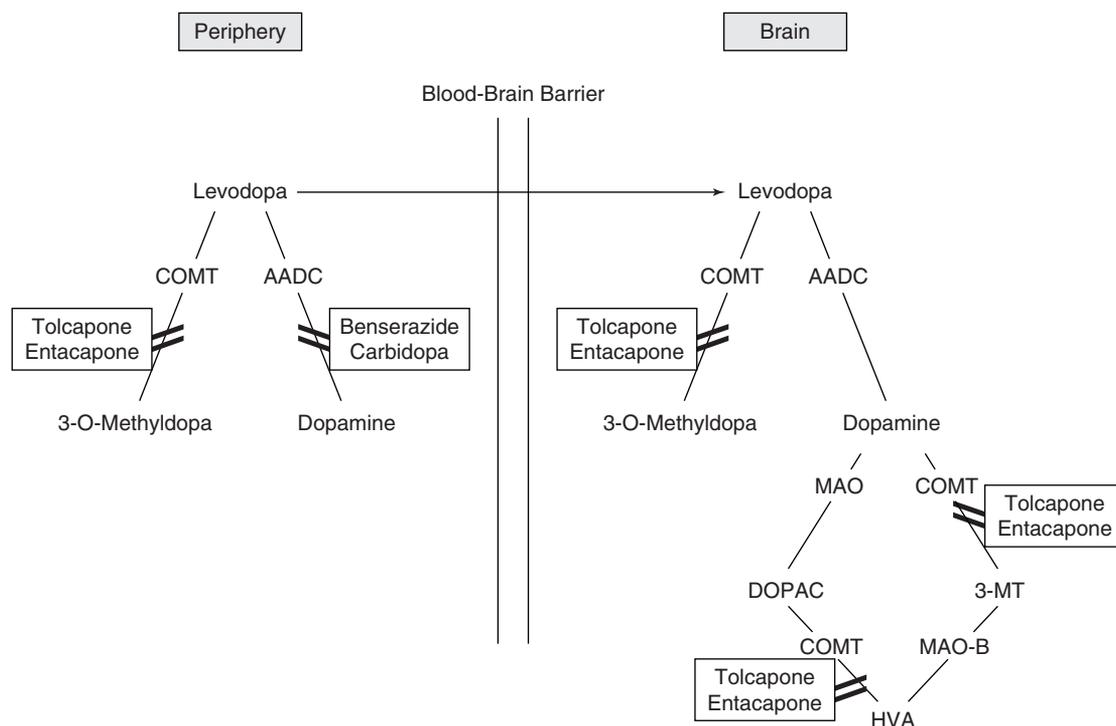

FIGURE 53-3 Levodopa metabolism in the human body. COMT, catechol-O-methyltransferase; AADC, aromatic amino acid decarboxylase; DOPAC, dihydroxyphenylacetic acid; 3-MT, 3-methoxytyramine; MAO, monoamine oxidase.

countries⁹⁴; the Safety and Efficacy Study of Entacapone Assessing Wearing Off (SEESAW) study⁹⁵ was conducted in North America. Both trials were multicenter, randomized, double-blind, placebo-controlled, parallel-group studies. Subjects for both studies had idiopathic PD with motor fluctuations, including *wearing off* phenomena, despite maximal tolerated doses of levodopa.

In the NOMECOMT study, 171 patients were randomized to receive either entacapone 200 mg or placebo (4–10 doses per day) with each dose of carbidopa/levodopa. After 6 months, the mean *on* time per 18-hour period increased by 1.5 hours in the entacapone-treated group compared with the placebo-treated group ($p < 0.001$). Withdrawal of entacapone resulted in a return to baseline *on time* levels. Mean *off time* over an

18-hour day decreased by 1.2 hours in the entacapone-treated group compared with the placebo-treated group ($p < 0.001$). Motor scores on the UPDRS decreased by about 10% from baseline in the entacapone-treated group compared with the placebo group ($p < 0.01$). Improvements of approximately 10% to 20% in these motor scores usually produce clinically significant improvements as indicated by increased functional capacity and decreased parkinsonian symptoms (bradykinesia and rigidity).¹³ Patients who received entacapone could also lower their levodopa daily dose by an average of 79 mg, whereas placebo-treated subjects required an increase of 12 mg in their average daily levodopa dose ($p < 0.001$). A 3-year open-label extension of this trial demonstrated continued efficacy and tolerability of entacapone.⁹⁶

Table 53-6 Pharmacologic and Pharmacokinetic Properties of Catechol-O-Methyltransferase Inhibitors

| | <i>Tolcapone</i> | <i>Entacapone</i> |
|--|--|---------------------------------------|
| Bioavailability | 65% | 30–46% |
| T _{max} (hr) | 2.0 | 0.7–1.2 |
| Protein binding | 99.9% | 98% |
| Metabolism | Glucuronidation; CYP 3A4, 2A6 Acetylation; methylated by COMT | Glucuronidation |
| Half-life (hr) | 2–3 | 1.6–3.4 |
| Time to reverse COMT inhibition (hr) | 16–24 | 4–8 |
| Maximum COMT inhibition at 200-mg dose | 80%–90% | 60% |
| Increase in levodopa AUC | 100% | 30%–45% |
| Increase in levodopa half-life | 75% | 60%–75% |
| Dosing method | TID, spaced 6 hrs apart | With every administration of levodopa |

COMT, catechol-O-methyltransferase; TID, three times daily.

In the SEESAW study, 205 patients were randomized to receive either entacapone 200 mg or placebo (up to 10 doses per day) with each dose of carbidopa/levodopa. At baseline, patients had experienced about 4 years of motor fluctuations and had been taking levodopa for about 9 years. Approximately 80% of the study subjects continued to take other antiparkinsonian therapies, including anticholinergic agents, selegiline, dopamine agonists, and amantadine. Compared with placebo over 8 to 24 weeks, daily, *on time* increased by about 1 hour ($p < 0.05$) in patients treated with entacapone, with the greatest improvements observed in those who had a smaller percentage of *on time* at baseline. Those treated with entacapone also had about a 10% reduction in their total UPDRS scores, and they decreased their daily levodopa dose by about 100 mg (13%).

Dosing

16. When should entacapone be initiated, and what is the most effective method for dosing the drug?

Both COMT inhibitors available in the United States are approved for use as adjunctive therapy to levodopa for the treatment of PD in patients experiencing “wearing-off” or “end-of-dose deterioration.” No studies have yet examined the effect of early initiation of a COMT inhibitor from the time levodopa is first introduced. This strategy has been proposed as a way of reducing the risk for levodopa-induced motor complications, because the administration of a COMT inhibitor results in a functional extension in the half-life of levodopa.⁹⁷ The more stable plasma levels of levodopa resulting from the coadministration of the three-drug combination (levodopa, carbidopa, COMT inhibitor) may lessen levodopa-induced pulsatile stimulation of striatal dopamine receptors and consequently delay motor complications.¹³

Entacapone should not be titrated. It should be given as one 200-mg tablet with each carbidopa/levodopa administration, up to eight tablets per day. It is available in a combination tablet (Stalevo) with a 1:4 ratio of immediate-release carbidopa/levodopa that patients can be switched to once they are stabilized individually on carbidopa/levodopa and entacapone. If dyskinesias occur, it may be necessary to lower the levodopa dose by approximately 10% to 25%, particularly if the patient is receiving > 800 mg/day of levodopa. L.M. should be monitored for dyskinesias, especially during the first few weeks of therapy, to determine the need for lowering his carbidopa/levodopa dose.

Adverse Effects

17. What are the adverse effects of entacapone, and how should they be managed?

Most entacapone-induced adverse effects are consistent with increased levodopa exposure. They include dyskinesias (50%–60%), nausea (15%–20%), dizziness (10%–25%), and hallucinations (1%–14%).^{94,95} Reducing the levodopa dosage by 10% to 15% as a strategy for circumventing these effects was successful in about one-third of patients experiencing dyskinesias. One study evaluated the incidence of dyskinesias compared with baseline frequency and found an increase of 8% in the entacapone-treated group.⁹⁴ Adverse effects related to entacapone include urine discoloration (11%–40%), abdominal pain (6%), and diarrhea (10%).^{94,95} Urine discoloration

(brownish-orange) is attributed to entacapone and its metabolites and is considered benign, but patients should be counseled regarding this effect to avoid undue concern. The most common reason for withdrawal from clinical studies and discontinuation of therapy was severe diarrhea (2.5%). No monitoring of liver function tests is required during entacapone therapy.

Monoamine Oxidase-B (MAO-B) Inhibitors

Selegiline and Rasagiline

18. What type of antiparkinsonian drugs are selegiline and rasagiline, and what place do they have in the treatment of PD?

SELEGILINE

Selegiline (also referred to as deprenyl) is an MAO inhibitor that irreversibly inhibits MAO type B. Two types of MAO enzymes are present: type A (MAO-A) oxidatively deaminates catecholamines, such as serotonin, norepinephrine, and tyramine, and MAO-B, among other actions, is responsible for the metabolism of dopamine.^{13,98} Within the brain, approximately 80% of MAO activity is attributable to MAO-B.⁹⁸ The antiparkinsonian activity of selegiline presumably lies in its ability to act centrally to prevent the destruction of endogenous and exogenously administered dopamine.⁹⁸ Because selegiline selectively binds to MAO-B, in usual doses (≤ 10 mg/day), it does not produce a hypertensive reaction (“cheese effect”) with dietary tyramine or other catecholamines.⁹⁸ It is still recommended, however, that patients be counseled regarding this potential risk.

Selegiline is available in a 5-mg capsule or tablet, and as a 1.25-mg orally disintegrating tablet. The bioavailability of conventional selegiline is low, however, and it undergoes extensive hepatic first-pass metabolism into amphetamine-based metabolites.⁹⁹ The usual dosage of conventional selegiline is 10 mg/day given in 5-mg doses in the morning and early afternoon. It is not given in the evening, because excess stimulation from metabolites (L-methamphetamine and L-amphetamine) can cause insomnia and other psychiatric side effects.⁹⁸ The orally disintegrating tablet formulation dissolves in the mouth on contact with saliva and undergoes pregastric absorption. This minimizes the effect of first-pass metabolism and results in higher plasma concentrations of selegiline and reductions in the amphetamine-based metabolites.¹⁰⁰

Efficacy

Selegiline has been studied in PD since the 1970s. Attention initially focused on the potential of selegiline as a “neuroprotective” agent that could conceivably slow the progression of PD.^{98,101} With the discovery of parkinsonism developing in addicts who injected MPTP, a synthetic meperidine analog, new information regarding the pathophysiology of PD and the potential for new forms of treatment began to emerge.^{102,103} The isolation and identification of this compound fostered the development of superior animal models in which it was found that the neurotoxicity associated with MPTP is not caused by MPTP itself, but rather the oxidized product, L-methyl-4-phenylpyridinium (MPP) ion, a compound that can persist for long periods in the brain.¹⁰³ The conversion of MPTP to its neurotoxic metabolite MPP is a two-step process mediated in part by MAO-B.^{103,104} Inhibition of MAO-B can

inhibit the oxidative conversion of dopamine to potentially reactive peroxides. In animals, pretreatment with selegiline protects against neuronal damage following the administration of MPTP.¹⁰¹

The Deprenyl and Tocopherol Antioxidative Therapy of Parkinsonism (DATATOP) study was designed to test the hypothesis that the combined use of both an MAO-B inhibitor (selegiline) and an antioxidant (α -tocopherol) early in the course of the disease may slow disease progression.¹⁰⁵ The primary outcome was the length of time that patients could be sustained without levodopa therapy (an indication of disease progression). Results of this study demonstrated that early treatment with selegiline 10 mg/day delayed the need to start levodopa therapy by approximately 9 months compared with patients given placebo.¹⁰⁵ Long-term observation demonstrated, however, that the benefits of selegiline diminished over time. During an additional year of observation, patients originally randomized to selegiline tended to reach the endpoint of disability more quickly than did those not assigned to receive selegiline. Initial selegiline treatment also did not alter the development of levodopa's adverse effects such as dyskinesias and "wearing-off" and "on-off" phenomena. In other words, early treatment with this agent did not produce a sustained benefit.¹⁰⁶ The finding that selegiline as initial therapy does not alter the development of motor fluctuations was corroborated in a study by Caraceni et al.¹⁰⁷

Selegiline has also been studied as a symptomatic adjunct to levodopa in more advanced disease. Early studies found improvement in the "wearing off" effect of levodopa in 50% to 70% of patients treated with selegiline and a reduction in as much as 30% in the total daily dose of levodopa.^{108,109} The *on-off* effect was less responsive to the addition of selegiline. A second follow-up study involving the original DATATOP cohort randomized patients who had been treated with selegiline initially whose disease had advanced to their requiring levodopa to continue selegiline or switch to placebo. After 2 years, no significant difference was found in the primary outcome events of *wearing off*, dyskinesias, or *on-off* motor fluctuations between the groups.¹¹⁰ In contrast, the orally disintegrating tablet has been shown to reduce *off* time by 32% (2.2 hours) compared with 9% (0.6 hours) for placebo in a 12-week, randomized, multicenter, parallel group, double-blind study.¹¹¹ This, in part, may be owing to the improved bioavailability and increased plasma concentrations of selegiline that are observed with the orally disintegrating tablet formulation.

In summary, no convincing evidence indicates that selegiline offers neuroprotection in patients with PD.¹¹² The benefits of selegiline are modest in early disease, and tolerance to the beneficial effects is seen with long-term use. In more advanced disease, selegiline (particularly the orally disintegrating tablet formulation) could be considered for adjunctive therapy.⁸¹ Its efficacy in reducing the *wearing off* effect is modest at best, and insufficient evidence exists to determine whether it would be effective in controlling the *on-off* effect that L.M. has been experiencing. Thus, for L.M., selegiline does not appear to offer any advantages at this time.

RASAGILINE

Rasagiline is a new, second-generation, propargylamine-type irreversible selective inhibitor of MAO-B. It is indicated

as monotherapy in early disease or as adjunct therapy to levodopa in advanced disease. Rasagiline is differentiated from selegiline primarily in that it is a more potent inhibitor of MAO-B, and it is not metabolized into amphetamine-based metabolites.¹¹³ Rasagiline has been found to protect from MPTP-induced parkinsonism in animal models, possibly through a multifactorial process that includes suppression of oxidant stress and stabilization of mitochondrial apoptosis.¹¹⁴ Rasagiline is approximately 60 to 100 times more selective in inhibiting MAO-B than MAO-A.¹¹³

Rasagiline is available in 0.5- and 1-mg tablets. When used as monotherapy, it is initiated at 1 mg daily. When combined with levodopa, the initial dose is lowered to 0.5 mg daily, and can be increased to 1 mg daily based on response. Although tyramine-challenge studies have not demonstrated any clinically significant reactions, the product labeling still contains a warning that patients should be advised to restrict tyramine intake.^{115,116}

Efficacy

Rasagiline was studied as monotherapy in early PD in a randomized, double-blind, placebo-controlled trial comparing rasagiline 1 mg ($n = 134$) or 2 mg ($n = 132$) daily with placebo ($n = 138$). After 6 months of therapy, the mean adjusted change in UPDRS score was -4.2 and -3.56 in the 1- and 2-mg groups, respectively, compared with placebo ($p < 0.001$ for both).¹¹⁷ These changes are quantitatively similar to those observed with levodopa therapy. Quality-of-life measurements were significantly improved in both rasagiline groups compared with placebo; however, the time to requiring levodopa did not differ between groups. At the end of the initial 6 months of treatment, patients who received placebo were then switched over to receive active treatment with rasagiline, while the rasagiline-treated patients continued on therapy. After an additional 6 months of study, it was found that patients receiving rasagiline for all 12 months had less functional decline than patients in whom rasagiline was delayed.¹¹⁸ The mean adjusted difference at 12 months for patients receiving rasagiline 2 mg/day for all 12 months was -2.29 compared with the delayed-start rasagiline 2 mg group ($p = 0.01$). In an ongoing, open-label extension, the advantage of earlier treatment appears to persist even after 5 years of treatment.¹¹⁹ Further human studies are ongoing to investigate the potential disease-modifying effects of rasagiline.

In advanced disease, rasagiline added to levodopa therapy appears to improve motor fluctuations, reducing *off* time by 1.4 hours and 1.8 hours compared with 0.9 hours for placebo ($p = 0.02$ and $p < 0.0001$ for 0.5- and 1-mg/day groups, respectively).¹²⁰ Significant improvements were reported in the UPDRS subscores for ADL in the *off* state and motor performance in the on state, as well as clinician global assessments. Dyskinesias were slightly worsened in the 1-mg/day group. As adjunctive therapy to levodopa, rasagiline appears to provide similar benefit to entacapone. When compared with entacapone 200 mg administered with each levodopa dose, rasagiline 1 mg/day reduced total daily *off* time in a similar manner (decrease of 21% or 1.18 hours for rasagiline and 21% or 1.2 hours for entacapone).¹²¹

Rasagiline is well-tolerated. Headache, dizziness, and nausea appear to be the most common adverse effects when rasagiline is given as monotherapy.¹¹⁶ When administered in

combination with levodopa, treatment-emergent dyskinesias and orthostasis also occur. Reduction of levodopa dose may be necessary if dyskinesias occur when rasagiline is added. Similar precautions regarding drug interactions exist with rasagiline as selegiline; that is, sympathomimetics, meperidine, dextromethorphan, other MAO inhibitors, and serotonin reuptake inhibitors (SSRI) should be avoided or used with caution. Because rasagiline is metabolized by CYP1A2, inhibitors such as ciprofloxacin may increase plasma concentrations of rasagiline.

Because L.M. is currently receiving entacapone, administration of rasagiline is not indicated. In patients with early disease, rasagiline is as effective as monotherapy in reducing symptoms; and in patients with advanced disease, consensus recommendations support the use of either entacapone or rasagiline as treatments of choice to reduce *off time*.^{81,112}

Anticholinergics

19. What role do anticholinergic drugs play in the treatment of PD?

Anticholinergic drugs have been used to treat PD since the mid-1800s, when it was discovered that symptoms were reduced by the belladonna derivative hyoscyamine sulfate (scopolamine).¹³ These drugs remained the mainstay of treatment until the late 1960s, when amantadine and levodopa were introduced. Because of their undesirable side effect profile and poor efficacy, anticholinergic agents have been abandoned as first-line agents.

In PD, the loss of dopamine-producing neurons results in a loss of the balance that normally exists between acetylcholine and dopamine-mediated neurotransmission. The anticholinergic agents work by blocking the excitatory neurotransmitter acetylcholine in the striatum, thereby minimizing the effect of the relative increase in cholinergic sensitivity. This form of therapy is usually reserved for the treatment of resting tremor early in the disease, particularly in younger patients with preserved cognitive function. Anticholinergic agents are considered less effective than carbidopa/levodopa and dopamine agonists for the treatment of bradykinesia and rigidity.¹³ Overall, only a mild reduction in symptoms can be expected with anticholinergic therapy, and the risk for side effects would probably outweigh any benefit in L.M.^{13,41}

Anticholinergic drugs produce both peripherally and centrally mediated adverse effects. Peripheral effects, such as dry mouth, blurred vision, constipation, and urinary retention, are common and bothersome.¹³ Anticholinergic agents can increase intraocular pressure and should be avoided in patients with angle-closure glaucoma. Central nervous system effects can include confusion, impairment of recent memory, hallucinations, and delusions.¹³ Patients with PD are more susceptible to these central effects because of advanced age, intercurrent illnesses, and impaired cognition.¹³

Given his history and clinical presentation, L.M. probably should not be given an anticholinergic drug. He originally presented with signs of intellectual impairment and subsequently developed hallucinations. These symptoms may worsen on anticholinergic therapy. L.M. also has prostatic hyperplasia and his symptoms of urinary retention may be exacerbated by anticholinergic drugs. The mydriasis and cycloplegia associated

with these drugs could interfere with his ability to paint. Finally, anticholinergic drugs also could aggravate his constipation.

Amantadine

20. How does amantadine work in PD, and what place does it have in treatment of the disease?

Efficacy and Dosing

Amantadine, an antiviral agent, was discovered serendipitously to have antiparkinsonian activity when a patient given the drug for influenza experienced a remission in her tremor, rigidity, and bradykinesia.¹²² Shortly thereafter, clinical trials documented its effectiveness when used alone and in combination with levodopa to treat mild forms of PD.^{123–125} The mechanism of action of amantadine for PD treatment is not entirely understood, but it probably augments dopamine release from presynaptic nerve terminals and possibly inhibits dopamine reuptake into storage granules.¹²⁶ Others have suggested an anticholinergic mechanism of action because certain anticholinergic-type side effects are caused by the drug.¹²³

Amantadine reduces all the symptoms of parkinsonian disability in about 50% of patients, usually within days after starting therapy; however, a substantial number of patients develop tachyphylaxis within 1 to 3 months. Temporary withdrawal, discontinuation, and subsequent reinstitution of amantadine at a later date can be beneficial in some patients.¹²⁵ In addition, amantadine is associated with neuropsychiatric side effects, which limits its use.

More recently, amantadine has been found to be an antagonist at *N*-methyl-D-aspartate (NMDA) receptors; therefore, it may block glutamate transmission and attention dyskinesias.¹²⁷ This finding has been corroborated in studies of patients with PD with levodopa-induced dyskinesias, which have found a reduction in dyskinesia scores with amantadine.^{124,128–130} With more effective agents available for use in early disease, the main role of amantadine in the treatment of PD appears limited to add-on therapy for treating levodopa-induced dyskinesias.

When used, amantadine should be started with one 100-mg capsule taken with breakfast; an additional 100-mg capsule can be taken with lunch 5 to 7 days after the initiation of the drug.¹²³ The dosage can be increased to a maximum of 300 mg/day; however, doses >200 mg/day are rarely necessary and pose a greater risk of adverse effects. The second dose is best taken in the early afternoon to minimize the likelihood of insomnia. Amantadine also is available in a liquid preparation, which is advantageous for patients with dysphagia. Amantadine is renally excreted and the dosage needs to be reduced in patients with renal impairment.¹³¹

Adverse Effects

Side effects of amantadine mainly involve the gastrointestinal, cardiovascular, and central nervous systems. In one large-scale study, at least one side effect was experienced by 15% of patients, whereas 9% had two or more adverse effects.¹²³ Seen most frequently are neuropsychiatric complaints, which include dizziness, confusion, disorientation, depression, nervousness, irritability, insomnia, nightmares, and hallucinations.^{60,123,124} Convulsions have been observed on

rare occasions with high dosages (>800 mg/day), particularly in patients with renal impairment.⁶⁰ Amantadine does have some anticholinergic properties, and patients concomitantly receiving anticholinergic agents appear to experience more prominent central nervous system side effects.^{60,123,124} Dry mouth, nausea, vomiting, cramps, diarrhea, and constipation are less frequently encountered. Ankle edema occurs in up to 10% of patients and is usually seen in association with livedo reticularis.⁶⁰ Elevation of the legs, diuretic therapy, and dosage reduction often alleviate the edema.

Livedo reticularis is a rose-colored mottling of the skin, usually involving the lower extremities (but can involve the upper extremities as well), that occurs in up to 80% of patients receiving amantadine.^{60,124,125,132} It can be observed as early as 2 weeks after initiating amantadine therapy and persists until therapy is discontinued, often intensifying to a blackish-purple color.¹²⁴ It is more commonly observed in women taking higher dosages (>200 mg/day) and is worse on standing and in colder climates.^{60,124} Livedo reticularis is believed to be caused by local release of catecholamines, which cause vasoconstriction and alter the permeability of cutaneous blood vessels.¹³² The consequences of livedo reticularis are entirely cosmetic; therefore, discontinuation of therapy is unnecessary.

Investigational Pharmacotherapy

21. What antioxidants, dietary supplements, or other investigational therapies have been evaluated in the treatment of PD?

Antioxidants

If free radical generation is important in the pathophysiology of PD, then adjunctive therapy with antioxidant drugs early in the course of disease should theoretically provide benefit.¹³³ The most comprehensive evaluation of antioxidant therapy for PD has come from the DATATOP study.^{105,134,135} In this study, patients were assigned to one of four treatment regimens: α -tocopherol (2,000 IU/day) and selegiline placebo; selegiline 10 mg/day and α -tocopherol placebo; selegiline and α -tocopherol active treatments; or placebos. The primary endpoint was time to requirement of levodopa therapy. After approximately 14 months of follow-up, no difference was seen between the α -tocopherol group and placebo group in time to require levodopa.¹³⁵ Thus, despite the theoretic benefit, clinical data are lacking to support the routine use of α -tocopherol and it is not recommended.¹⁴

Coenzyme Q10

Coenzyme Q10 (CoQ₁₀), also known as ubiquinone, is an antioxidant involved in the mitochondrial electron transport chain that has been shown to have reduced activity in patients with PD.¹³⁶ The finding that MPTP can induce parkinsonism through inhibition of complex I in the mitochondrial electron transport chain and result in injury of nigral dopaminergic neurons, led investigators to evaluate whether supplementation with CoQ₁₀ could restore dysfunctional mitochondria.¹³⁷ In a randomized, placebo-controlled trial, 80 patients with early untreated PD were randomly assigned to placebo or CoQ₁₀ at dosages of 300, 600, or 1,200 mg/day in four divided doses.¹³⁸ Subjects were followed for up to 16 months or until therapy with levodopa was required. The primary outcome was

a change in total score on the UPDRS from baseline to the last visit. Total UPDRS scores increased (indicating worsening of symptoms) to a greater extent in placebo-treated patients than in those treated with CoQ₁₀ (+11.99 for placebo, +8.81 for 300 mg/day, +10.82 for 600 mg/day, and +6.69 for 1,200 mg/day). These results indicated a linear trend between CoQ₁₀ dosage and changes in UPDRS scores. Time to requirement of levodopa, however, did not differ among the groups. Side effects of CoQ₁₀ were minimal and not different than placebo.

In a larger, National Institute of Health-sponsored futility-design study, CoQ₁₀ 600 mg four times daily was compared with placebo in 213 patients with early PD not requiring medications.¹³⁹ This was a randomized, double-blind, placebo-controlled trial. The primary outcome measure was the mean change in total UPDRS score from baseline to either the time required for symptomatic therapy or 12 months, whichever came first. The threshold value for futility of CoQ₁₀ was defined as 30% less progression on the total UPDRS than the 10.65 unit change observed historically in the placebo arm of the DATATOP trial, or 7.46. After 12 months of therapy, the mean change in the CoQ₁₀ group was 7.52 compared with 6.31 in the placebo group. Based on the prespecified criteria, although CoQ₁₀ did not meet the prespecified endpoint of a change of 7.46 or less, it could not be rejected as futile and met criteria for further clinical testing. At this time, it is premature to recommend routine use of CoQ₁₀ in PD. Future studies should focus on clinically meaningful outcomes to prove or disprove the clinical efficacy of CoQ₁₀.

Creatine and Minocycline

Creatine is a dietary supplement marketed for performance enhancement. Similar to the theory for efficacy of CoQ₁₀, creatine plays a role in mitochondrial energy production and has been shown to protect from MPTP-induced dopamine depletion in animal models.¹⁴⁰ Minocycline is a second-generation tetracycline used to treat various infections, but has also been shown to display anti-inflammatory effects, which have resulted in improvements in chronic inflammatory conditions such as rheumatoid arthritis.¹⁴¹ An inflammatory response occurs with loss of dopaminergic neurons in PD, and minocycline has been shown to be protective in MPTP animal models of PD.¹⁴²

Both creatine and minocycline were examined for use in PD in a futility study that was similar in design to that conducted with CoQ₁₀. In this randomized, double-blind, placebo-controlled trial, 200 patients with early PD not requiring therapy were randomized to receive creatine (n = 67) 10 g/day, minocycline 200 mg/day (n = 66), or placebo (n = 67).¹⁴³ The primary outcome measure was the mean change in total UPDRS score from baseline to either the time required for symptomatic therapy or 12 months, whichever came first. The threshold value for futility of creatine or minocycline use was defined as 30% less progression on the total UPDRS (≤ 7.46 units) than the historical DATATOP trial cohort (10.46 units). After 12 months, the mean change in the total UPDRS was 5.6 units in the creatine group, 7.09 in the minocycline group, and 8.39 in the placebo group. Based on the prespecified criteria, neither creatine nor minocycline could be rejected as futile and met criteria for further clinical testing. Although it is too early to recommend either agent for use, future studies will likely proceed based on the encouraging results of this study.

Surgery

22. L.M. has gained additional improvement in rigidity, bradykinesia, and posture, as well as improvement in the “on-off” and “wearing off” effects, with the combination of Sinemet (carbidopa/levodopa) and entacapone. He has experienced little if any reduction in his tremor, which is one of the most debilitating symptoms of his disease. What are other therapies for severe parkinsonian tremor?

Parkinsonian tremor is often less responsive to dopaminergic therapy than other symptoms. There can be considerable interpatient variability in the frequency and amplitude of parkinsonian tremor. Tremor can be worsened by peripheral factors, such as catecholamine release, often in association with stress or anxiety, as well as central factors inherent to the disease.¹⁴⁴

Surgery has played a role in the treatment of PD, particularly in patients who cannot achieve a satisfactory response to available medications. Before the introduction of levodopa, PD was primarily viewed as a surgically treated condition. With the availability of effective drug therapies, the importance of surgical intervention lessened. Posteroventral pallidotomy is an effective method for reducing dyskinesias on the contralateral side and may permit the use of higher dosages of levodopa for managing rigidity and bradykinesia.^{145,146} One of its disadvantages is the need to make a lesion near the optic tract; however, studies have shown significant improvements in rigidity and bradykinesia and also relief from tremor following posteroventral pallidotomy. The risks of pallidotomy include visual loss; weakness, including paralysis; and hemorrhage that can cause stroke and speech difficulty.

In patients with mild forms of parkinsonism in which bradykinesia and gait disturbances are absent, symptoms of debilitating tremor and rigidity can benefit from stereotaxic thalamotomy. This intervention has eliminated contralateral tremor in 80% of patients, and improvement has been sustained for up to 10 years.^{146,147} A disadvantage of both pallidotomy and thalamotomy is the need to make an irreversible lesion in the basal ganglia that may limit the effectiveness of newer procedures as they become available.

Deep brain stimulation (DBS) is a method that uses an implanted electrode in the brain (either the subthalamic nucleus [STN] or the globus pallidus interna [GPi]) with a lead connected to a subcutaneously implanted pacemaker.^{148,149} This permits delivery of a high-frequency stimulation to the desired target. Advantages of DBS include no need for an irreversible brain lesion, and it provides flexibility for altering the target site and program stimulation parameters. Candidates for DBS should have idiopathic PD and be levodopa-responsive, but continue to experience motor complications or tremor despite optimal pharmacotherapeutic regimens.⁸¹ It should be avoided in patients with pre-existing cognitive or psychiatric problems owing to a slight risk of decline in cognition. No strict age limitation for DBS exists, but patients <70 years of age appear to recover from surgery more quickly and show greater motor improvements. Although studies have shown that both DBS of the GPi and STN improve tremor, bradykinesia, and rigidity in patients with PD, DBS of the STN is currently the preferred approach as the available data consistently demonstrate marked reduction in the need for escalating levodopa dosages compared with DBS of the GPi.^{81,150,151}

Attention also has been directed toward surgical treatment of PD by transplanting fetal dopaminergic neurons directly into dopamine-depleted regions of the basal ganglia in the hopes of providing a localized infusion of dopamine from these cells.^{149,152} The observed benefits from this procedure have included improved motor response while lowering the incidence and severity of dyskinesias.¹⁴⁹ Research efforts also include transplanting genetically engineered cell lines such as those capable of overexpressing tyrosine hydroxylase or neurotrophic factors. All of these methods are considered experimental, however, and are not routinely available.¹⁴⁹

Other Treatment Considerations in Parkinson's Disease

Dementia

23. As L.M.'s disease has progressed, he has become increasingly demented and reliant on family members for help in performing ADL. He scored 16 (below normal) on his most recent Mini-Mental Status Examination, and his family describes periodic episodes of confusion and agitation. Neuropsychiatric testing is performed to help distinguish whether his confusion and agitation are caused by his progressing dementia or whether depression is contributory. Subsequent recommendations from the neuropsychiatrist are that he avoid driving and receive 24-hour supervision, along with participation in structured leisure activities such as adult daycare several hours per week to help relieve his wife's caregiver burden. In addition, he has a significant depressive component to his dementia that should be treated. How should L.M.'s progressive cognitive decline and depression be treated?

Cognitive impairment, manifested by bradyphrenia (slowed mental processes), altered executive functions, memory loss, decreased attention span, or inappropriate behavior, is common in patients with PD. The prevalence of dementia in patients with PD increases with age and duration of disease and is approximately 6- to 12-fold greater than in age-matched controls.¹³ Successful management of cognitive impairment in patients with PD requires first that all potentially reversible causes or contributing factors be addressed. These include treating infections, dehydration, and metabolic abnormalities, as well as eliminating unnecessary medications (particularly anticholinergics, sedatives, anxiolytics) that can exacerbate dementia or delirium.

Experience with cholinesterase inhibitors such as donepezil (Aricept) and rivastigmine (Exelon) for treating cognitive impairment in PD is limited, but preliminary studies suggest that some improvement may occur with their use.¹⁵³⁻¹⁵⁶ Outcomes of these studies are usually measured using different scales, such as the Mini Mental Status Examination, the Alzheimer's Disease Assessment Scale-Cognitive Subscale, the Alzheimer's Disease Assessment Scale-Clinicians Global Impression of Change, and the Clinicians Interview Based Impression of Change Plus Caregiver Input. Compared with placebo, the cholinesterase inhibitors often result in a marginal change of a couple of points in these scales that is statistically significant. It is unclear, however, to what extent the changes in the scores of these outcome measures are clinically relevant in such areas as ability to perform ADL without assistance, and delay in nursing home placement.

Although donepezil or rivastigmine can be considered for demented patients with PD such as L.M., they are expensive,

and he must be monitored closely for signs of deterioration of motor function such as worsening of tremor.¹⁵ Cholinesterase inhibitors are also associated with adverse events that may be overlooked and attributed to the disease itself in patients with PD, including sialorrhea, excessive lacrimation, incontinence, nausea, vomiting, and orthostasis. More importantly, adequate supportive home care for L.M. should be ensured. As he becomes further dependent on family members for assistance with ADL, the increased needs of the caregiver(s) should also be considered. In L.M.'s case, attending adult daycare several times weekly if available, would provide a structured, supervised environment for interaction with others, as well as providing a rest period for his caregiver. When severe, dementia is a leading cause of nursing home placement for patients with PD.¹³

Depression

Depression occurs frequently in patients with PD. The physical appearance of the patient may, however, make it difficult to determine whether the symptoms are attributed to depression or to the PD.¹³ Patients manifesting symptoms of hypomimia (facial masking), hypophonia (weak voice), psychomotor retardation, and a stooped posture may be incorrectly diagnosed with depression if these features are solely the result of the PD. In contrast, depression in patients with loss of energy, decreased appetite, reduced libido, and insomnia may go unrecognized, because the symptoms are often attributed to the PD.¹³

Treatment of the depressed patient with PD should first focus on providing adequate treatment of the symptoms of PD through restoring mobility and independence, particularly in patients whose depression can be attributed to lengthy *off* periods. Antiparkinson drugs, such as pramipexole, can be associated with mood-enhancing effects independent of their ability to reduce time in the *off* state.¹⁵⁷ Depression in patients with PD can be successfully treated with antidepressant drugs, although controlled research trials in this area are lacking.¹⁵⁸ SSRI are often considered for prolonged bouts of depression, but other classes of antidepressants, such as tricyclic antidepressants, may also be effective.¹⁵ Bupropion, a dopamine reuptake inhibitor, should theoretically reduce PD symptoms as well; however, limited evidence supports this hypothesis.¹⁵⁹ It is important to note that some SSRI, such as fluoxetine, can be activating. Although this may be beneficial in patients who are apathetic or withdrawn, it may worsen symptoms in agitated patients.¹³ Fluoxetine also has a prolonged elimination half-life and is metabolized to an active metabolite, which can increase the risk for side effects even after the drug is withdrawn. With tricyclic antidepressants, care must be taken to observe for anticholinergic side effects that may worsen PD symptoms, such as delayed gastric emptying (which may reduce levodopa effectiveness by increasing levodopa degradation in the gut), orthostatic hypotension, and a subsequent increased risk for falls. Psychotherapy can also be considered in patients with PD who are depressed. Lastly, electroconvulsive therapy may be beneficial if medications fail.

Based on L.M.'s symptoms, it is reasonable to start him on an antidepressant. Regardless of which agent or class of antidepressant is selected, therapy should be started at the lowest dose and gradually titrated to effect. He should be monitored closely for side effects, particularly anticholinergic symptoms with tri-

cyclic antidepressants, and for any adverse effects on mobility. He should be observed carefully for changes in parkinsonian symptoms, including development of extrapyramidal symptoms, as well as any signs of psychomotor agitation.¹⁶⁰

Psychomotor Agitation

The incidence of hallucinations and delirium increases with age and cognitive impairment in patients with PD. These symptoms are often caused or exacerbated by medications.¹³ Symptoms are often more pronounced at night (the "sundowning" effect), and hallucinations are typically visual. As with the management of cognitive impairment, it is important to eliminate or minimize any potential causative factors, particularly anticholinergic medications that could be contributing to the hallucinations or delirium. In some patients, reducing the dose of levodopa improves mental function and also provides satisfactory control of motor features (see Question 12). If it is not possible to achieve a balance between preserving motor control and decreasing neuropsychiatric symptoms through reduction in levodopa dosage, antipsychotics may be considered.

Older antipsychotic medications, such as haloperidol, perphenazine, and chlorpromazine, block striatal dopamine D₂ receptors and may exacerbate parkinsonian symptoms. Therefore, these agents are not recommended.¹³ Newer "atypical" antipsychotics are more selective for limbic and cortical D₃, D₄, D₅ receptors; they have minimal activity at D₂ receptors and can control symptoms without worsening parkinsonism. Of these agents, clozapine has the best evidence of efficacy in patients with PD.^{15,161} Its use is limited, however, by the need for frequent monitoring of white blood cell counts owing to the risk of agranulocytosis. Other newer agents, particularly quetiapine (Seroquel), appear promising and have controlled psychosis without worsening parkinsonism.^{162,163} Risperdal (Risperdal) and olanzapine (Zyprexa) have also been studied, but both worsened parkinsonism and were inferior to clozapine in patients with PD.¹⁶⁴⁻¹⁶⁷

Agitation, characterized by restlessness, irritability, apprehension, and dysphoria, occurs commonly in patients with PD.¹³ These symptoms often occur during off periods and may be a manifestation of underlying anxiety. Treatment should begin by ensuring optimal control of motor fluctuations, followed by discontinuation or reduction in dosage of any antiparkinsonian drugs, particularly anticholinergic agents that might exacerbate the symptoms. Short-term use of short-acting benzodiazepines, such as lorazepam or alprazolam, may also provide relief.¹³

Autonomic Dysfunction

Patients with PD also experience symptoms of dysautonomia, including orthostasis, erectile dysfunction, constipation, nocturia, sensory disturbances, dysphagia, seborrhea, and thermoregulatory imbalances.¹³ Management of these symptoms is generally supportive, and appropriate medical interventions similar to those used in other geriatric patients can be used to treat these symptoms whenever encountered. In some cases, fludrocortisone or midodrine can be considered if orthostatic hypotension is severe.

Falls

Patients with PD and their caregivers should be counseled on the prevention of falls, because they can result in serious

morbidity and mortality. Falls generally result from one of several factors, including postural instability, freezing and festination, levodopa-induced dyskinesia, symptomatic orthostatic hypotension, coexisting neurologic or other medical disorders, and environmental factors.¹³ Prevention remains the best strategy and includes environmental precautions, such as proper lighting, use of handrails, removing tripping hazards, and incorporating physical and occupational therapy. Reversible causes of postural or gait instability should be addressed whenever suspected.

Sleep Disorders

The sleep disorders often experienced by elderly persons are accentuated in PD patients.¹³ Insomnia, sleep fragmentation owing to PD symptoms, restless legs syndrome, and nightmares are common and a source of decreased quality of life. When sleep dysfunction can be directly attributed to PD symptoms, such as akinesia, tremor, dyskinesia, or nightmares, dosage adjustment of dopaminergic medications is indicated. Proper sleep hygiene should be encouraged. Short-acting benzodiazepines can be used if insomnia occurs; however, a longer-acting agent or controlled-release formulation may be preferred if the patient wakes early and is unable to return to sleep. If excessive daytime drowsiness occurs, modafinil may be considered. Similar to dysautonomia, management of sleep disorders that are not directly attributable to PD symptoms can be managed supportively, as in other geriatric patients.

RESTLESS LEGS SYNDROME

Clinical Presentation

24. J.J., a 42-year-old woman, presents to her family physician complaining of intermittent difficulty sleeping at night because of “jumpy legs.” Her symptoms bother her most in the evening, and she reports being able to sleep only 4 to 5 hours per night because of the accompanying restlessness. On further questioning, she describes the sensation in her legs as being like “bugs crawling under the skin.” The sensation is not painful. She explains that the symptoms worsen in the evening and at night and are partially relieved with walking. She recalls that her mother had similar symptoms. J.J.’s spouse notes that she often “kicks” him in her sleep. Review of her medical history shows an otherwise healthy postmenopausal female. What signs and symptoms are suggestive of restless legs syndrome (RLS) in J.J.? What laboratory tests or diagnostic procedures should be performed in J.J. to evaluate her condition?

Restless legs syndrome is an increasingly recognized and disabling sensorimotor disorder estimated to affect approximately 10% of the adult population.¹⁶⁸ Although most patients with mild symptoms will not require treatment, RLS can be associated with adverse health outcomes, including sleep onset insomnia, missed or late work, anxiety, depression, marital discord, and even suicide in severe cases.

Four essential criteria have been established by the International Restless Legs Syndrome Study Group to diagnose RLS (Table 53-7).¹⁶⁹ The pathognomonic trait of RLS is an almost irresistible urge to move the legs (akathisia), often associated with uncomfortable paresthesias or dysesthesias felt deep inside the limbs. Patients describe the sensation as “creepy-

Table 53-7 Clinical Features of Restless Legs Syndrome

Essential Criteria

- Urge to move legs, associated with paresthesias or dysesthesias
- Relief of symptoms with movement
- Onset or exacerbation of symptoms at rest
- Onset or worsening of symptoms during nighttime

Supportive Clinical Features

- Accompanying sleep disturbance (sleep onset insomnia)
- Periodic leg movements
- Positive response to dopaminergic therapy
- Positive family history of RLS
- Otherwise normal physical exam

crawly” or “like soda water in the veins.”¹⁷⁰ The symptoms may occur unilaterally or bilaterally, affecting the ankle, knee, or entire lower limb. With progressive disease, symptoms can begin earlier in the day, and progressive involvement of the arms or trunk may occur.¹⁷¹ Temporary or partial relief of symptoms can be achieved with movement. If patients attempt to ignore the urge to move the legs, akathisia will progressively intensify until they either move their legs or the legs jerk involuntarily.¹⁷⁰ Symptoms usually manifest in a circadian pattern with onset or worsening during nighttime hours (usually between 6 PM and 4 AM, with peak symptoms between midnight and 4 AM). The circadian pattern persists even in patients with inverted sleep-wake cycles. As a result of their symptoms, patients with RLS become “nightwalkers,” spending significant time walking, stretching, or bending the legs in an effort to relieve symptoms.

J.J.’s case is an example of a classic presentation of RLS. The prevalence of RLS increases with age and appears to be slightly more common in females.¹⁷² She describes “creepy-crawly” sensations that are relieved partially with walking, a core feature of RLS. Her symptoms are worse during the evening hours. J.J. reports her mother suffered from similar symptoms. The observation of a familial tendency suggests a genetic component and several chromosomal loci have been linked to the disease.¹⁷³ A strong family history of RLS appears to correlate with an early age of onset (<45 years), whereas presentation at a later age is associated with more neuropathy and accelerated disease progression.¹⁷⁰ J.J.’s spouse has noticed what are likely periodic limb movements of sleep (PLMS). Approximately 80% of patients with RLS will also have PLMS, but their clinical significance is uncertain because they are not definitively linked to poor sleep quality.¹⁷⁴ Furthermore, not all patients with PLMS have associated RLS, further questioning their value in the diagnosis.

Most cases of RLS are considered primary or idiopathic; therefore, the diagnosis does not require elaborate laboratory tests or diagnostic procedures. Several conditions are known to be associated with RLS, and include iron deficiency, pregnancy, and end-stage renal disease. A thorough medical history should be taken in J.J. to rule reversible causes of RLS or other conditions with similar characteristics. It should be relatively straightforward to rule out other disorders of the RLS differential if the diagnostic criteria and characteristics of the patient’s complaint are kept in mind.¹⁷³ Several medications and substances are known aggravators of RLS, including

medications with antidopaminergic properties, such as metoclopramide and prochlorperazine. Nicotine, caffeine, and alcohol can aggravate RLS, through their own ability to interfere with quality of sleep. Additionally, SSRI, tricyclic antidepressants, and commonly used over-the-counter antihistamines, such as diphenhydramine, can trigger or worsen RLS symptoms.¹⁷³ Hypotensive akathisia, leg cramps, and other conditions such as arthritis which can cause positional discomfort with extended periods of sitting in one position can mimic RLS. These conditions are easily distinguished from RLS, because they are usually localized to certain joints or muscles, do not have a circadian pattern, and are not associated with an uncontrollable urge to move.

With an otherwise unremarkable physical examination and medical history, specific laboratory tests that should be performed in J.J. are limited to serum ferritin and percent transferrin saturation (total iron-binding capacity) to rule out iron deficiency anemia. It is important to note that ferritin is an acute phase reactant and may be artificially elevated owing to inflammatory or infectious comorbid conditions. Therefore, the ferritin level should always be accompanied by the percent transferrin saturation. Several studies have documented a relationship between low ferritin concentrations and increased symptom severity.^{175,176} J.J. is postmenopausal, so a pregnancy test is not necessary. Polysomnography is not usually indicated unless there is clinical suspicion for sleep apnea or if sleep remains disrupted despite treatment of RLS. When clinical

suspicion from the physical examination or medical history suggests a possible peripheral nerve or radiculopathy cause, a routine neurologic panel, including thyroid function tests, fasting glucose, vitamins B₆ and B₁₂, and folate, should be obtained.¹⁷³ Renal function tests (serum creatinine and blood urea nitrogen) can be obtained to screen for uremia, although RLS does not usually occur in this situation until the patient has reached end-stage renal failure.

Treatment

25. The decision is made to treat J.J.'s symptoms with medication. What pharmacologic therapy should be selected? What nonpharmacologic therapies should be recommended?

Figure 53-4 presents an approach to the treatment of RLS. Iron supplements can potentially cure RLS symptoms in patients found to be iron deficient.¹⁷³ If J.J. is iron-deficient, she should be prescribed supplemental iron 50 to 65 mg of elemental iron one to three times daily on an empty stomach with 200 mg of vitamin C to enhance absorption. After ruling out possible reversible causes of RLS, it is important to establish the frequency of J.J.'s symptoms and whether or not they are associated with pain. This information will help determine appropriate therapy.

Several classes of medications are effective for treating RLS, including dopaminergics, benzodiazepines, anticonvulsants,

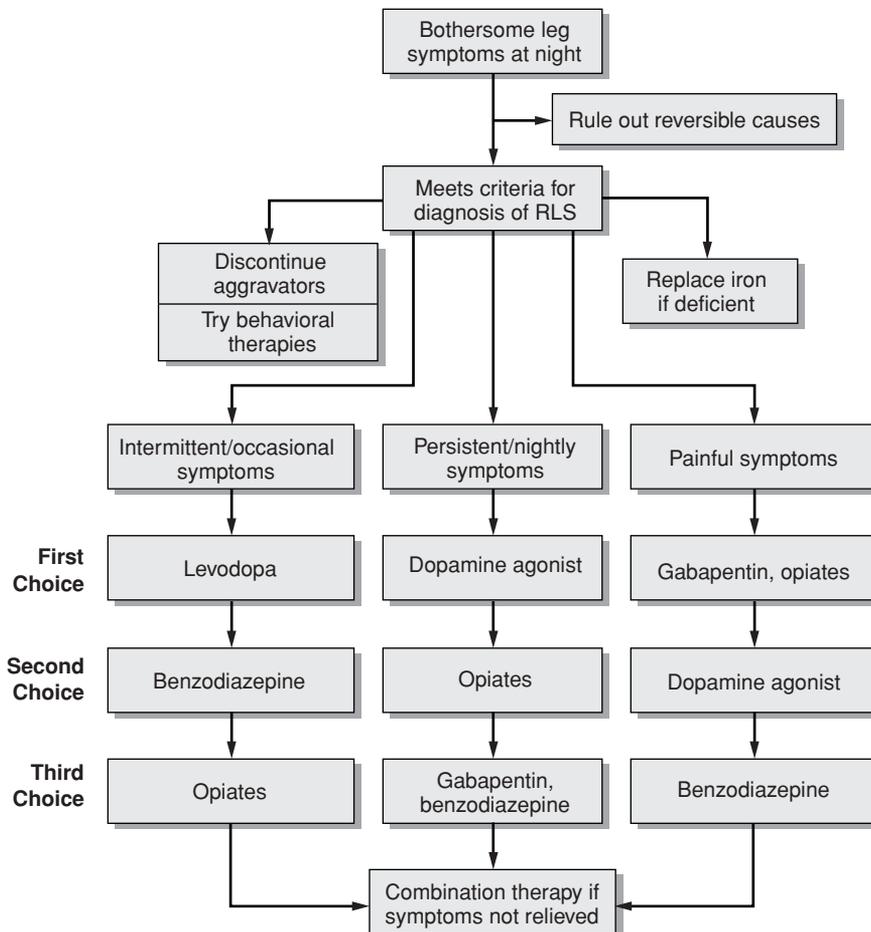

FIGURE 53-4 Approach to the treatment of restless legs syndrome.

and opiates. Dopaminergic therapies have demonstrated the most consistent efficacy in most patients for relieving RLS symptoms, improving sleep, and reducing leg movements.¹⁷⁷ The available dopaminergic therapies that have been evaluated in RLS are carbidopa/levodopa, pramipexole, ropinirole, and pergolide.¹⁷⁷ In addition, amantadine and selegiline have also been studied. The earliest clinical trials of dopaminergic therapies for RLS were of carbidopa/levodopa, which demonstrated improvement in both subjective and objective quality of sleep measures in patients with idiopathic or uremic disease.^{178,179} Carbidopa/levodopa is usually recommended as initial therapy in patients with mild, intermittent, nonpainful symptoms.^{173,170} Because J.J.'s symptoms are mostly intermittent at the present time and do not cause her pain, carbidopa/levodopa would be an appropriate initial therapy. It should be initiated at one-half of a 25/100 mg tablet, administered 1 or 2 hours before bedtime. The dose can be titrated according to symptoms up to a usual daily dose range of 100 to 250 mg of levodopa. With the immediate-release formulation, relief of symptoms occurs in as little as 20 minutes. Because levodopa has a short half-life, patients may wake from their sleep with rebound symptoms and require an additional dose of carbidopa/levodopa.¹⁸⁰ Two studies have demonstrated that a combination of slow-release and immediate-release carbidopa/levodopa may be superior to the immediate-release product used alone.^{181,182}

Benzodiazepines have been shown to relieve RLS symptoms in small, open-label studies; however, controlled clinical trials have yielded less promising results.¹⁸⁰ They are recommended as an alternate to carbidopa/levodopa if the RLS symptoms are intermittent, or as add-on therapy in patients refractory to other treatments.¹⁷³ The dosing and adverse effects of the benzodiazepines used in RLS are similar to their use in the general population. No evidence suggests that one benzodiazepine is more effective than another for RLS, and selection should be based on the patient's primary sleep disorder complaint. For example, a newer short-acting benzodiazepine with quick onset of action may be preferred in a patient whose primary problem is getting to sleep. Because benzodiazepines appear to be less effective overall than dopaminergics, they would probably not be a first-line choice in J.J.

If J.J. experienced her symptoms on a nightly basis or during the day, a dopamine agonist should be recommended.^{177,180} They are longer acting than levodopa, which allows for more sustained efficacy.¹⁷³ Ropinirole (0.25 mg initially, up to 0.5–8.0 mg/day) and pramipexole (0.125 mg initially, up to 0.5–1.5 mg/day) are both FDA-approved for treating RLS. Several randomized, controlled clinical trials have documented efficacy of these agents in both objective and subjective ratings of improvement by patients and clinicians with either short- or long-term use.^{177,183–187} Between ropinirole and pramipexole, there does not appear to be greater efficacy or fewer adverse effects with one agent over the other. An older dopamine agonist, pergolide, has also demonstrated efficacy in RLS; however, the increased risk for pulmonary fibrosis and cardiac valvulopathy with this ergot derivative precludes its routine use when dopamine agonists are indicated.^{24,25} When used for RLS, ropinirole and pramipexole should be administered 2 hours before bedtime. Adverse effects are similar to those seen with their use in PD and patients should be counseled accordingly (see Question 7).

In addition to her carbidopa/levodopa, nonpharmacologic therapies and behavioral techniques should also be recom-

mended for J.J. Most important among these include discontinuing all RLS aggravators, and practicing good sleep hygiene. Physical and mental activity (e.g., reading, playing card games, or working on the computer) if patients are unable to sleep can reduce symptoms.¹⁷³ Counter stimuli such as massage or hot baths have also been helpful.¹⁷³

26. After careful consideration, J.J. and her doctor choose levodopa to treat her RLS. She initially responds well to the therapy. One year later, J.J. returns for follow-up. Her dose of carbidopa/levodopa has progressively increased to three 25/100 mg tablets at bedtime. She describes continued worsening of her symptoms and they do not seem to be relieved with increasing doses of carbidopa/levodopa. Her symptoms are now starting earlier in the evening, occur almost every night, and are now painful. How should J.J.'s therapy be further adjusted?

J.J. is likely experiencing augmentation, a common problem with long-term use of dopaminergic drugs. Augmentation is described as a progressive symptomatic worsening of RLS symptoms after an initial improvement.¹⁷³ It is the most common side effect occurring with long-term use (>3 months) of dopaminergic agents. It usually occurs 6 to 18 months after therapy is initiated.¹⁷³ The most common presentation of augmentation is that RLS symptoms become more intense, occurring earlier in the evening, with movements spreading to other parts of the body. Increasing doses of dopaminergic agents will initially relieve symptoms; however, with each incremental dose increase symptoms progress more rapidly until they may occur continuously throughout the day.¹⁷³ The highest risk for augmentation is with levodopa. An estimated 50% to 85% of patients on levodopa will develop augmentation, compared with only 20% to 30% with dopamine agonists.¹⁸⁰ The primary treatment strategy in dealing with augmentation is to withdraw the dopaminergic agent and substitute other agents. Given her presentation, J.J. should have her carbidopa/levodopa discontinued. She should be counseled that her symptoms will likely rebound severely for 48 to 72 hours, but approximately 4 to 7 days later her symptoms should gradually return to baseline or pretreatment state.¹⁷³

With the discontinuation of carbidopa/levodopa in J.J., an alternate therapy should be selected. Anticonvulsants (particularly gabapentin, lamotrigine, and carbamazepine), and opiates have also been studied for treatment of RLS and are particularly useful if patients have pain with their symptoms. Gabapentin in a dose of 600 to 2,400 mg/day has demonstrated relief in subjective symptoms as well as PLMS and sleep architecture in 50% to 90% of patients in open-label and controlled trials.^{180,188,189} Lamotrigine (25 mg/day up to 200 mg/day) and carbamazepine (100–400 mg/day) have also demonstrated efficacy, mostly in open-label studies.¹⁸⁰ Because of its high efficacy and more favorable risk profile, gabapentin is preferred as first-line therapy in patients with RLS who have coexisting neuropathy or associated pain.¹⁷⁰ Because J.J. describes increasing pain from her RLS, after discontinuation of her carbidopa/levodopa it would be appropriate to initiate gabapentin. If necessary, a dopamine agonist could be added at a later time if her symptoms are not completely controlled on gabapentin. If gabapentin is ineffective or not tolerated, J.J. could be prescribed an opiate, which is also an acceptable choice in patients with RLS who have neuropathy or painful dysethesias.¹⁷³ Hydrocodone, oxycodone,

methadone, codeine, and tramadol have all demonstrated efficacy in RLS.¹⁷³ For intermittent symptoms, it is recommended to use short-acting agents. If symptoms extend beyond 8 hours, patients may require twice daily dosing or a switch to a longer acting agent.¹⁷³

ESSENTIAL TREMOR

Clinical Presentation

27. K.H. is a 52-year-old white female office manager who was referred to a neurologist for evaluation of tremor. She is otherwise healthy and reports not taking any regularly prescribed medications. She describes her tremor as being present mainly when she performs voluntary movements. The tremor is not noticeable during rest. She also notices the tremor seems to disappear in the evening after drinking a couple of glasses of wine. The tremor interferes with several of her ADL, including writing, eating, drinking from a cup, and inserting her keys into the ignition. She reports mild interference with her job function and some social embarrassment. No bradykinesia or rigidity is elicited on physical examination. A handwriting sample reveals large characters that are difficult to decipher. Family history reveals that her maternal grandmother and mother both had similar symptoms. What signs and symptoms are consistent with essential tremor in K.H.?

Essential tremor (ET) is a common neurologic disorder that has been written about since ancient times.¹⁹⁰ Beginning in the mid-20th century, the term essential tremor has been consistently used to describe this form of kinetic tremor for which no definite cause has been established.¹⁹⁰ ET has traditionally been viewed as a monosymptomatic disorder of little consequence, but more recently it is recognized to be complex and progressive and to result in significant disability in ADL and job performance, and is a cause of social embarrassment.¹⁹⁰ The incidence of ET is estimated to be approximately 616 cases per 100,000 person-years, and the prevalence rate ranges from 6% to 9%.^{191,192} Both incidence and prevalence of ET increase with age. In addition, ethnicity and family history of ET are consistently identified risk factors; it is approximately five times more common in whites than blacks, and approximately 50% of patients report a positive family history. The latter finding suggests that genetic predisposition may play a role in ET; however, differences in intrafamilial onset and severity suggest environmental factors may also influence underlying susceptibility to the disease.¹⁹⁰ Several environmental toxins have been proposed as causes of ET, including β -carboline alkaloids (e.g., harmine and harmine) and lead, both of which have been found in elevated concentrations in patients with ET compared with normal controls.^{193,194}

Because parkinsonian tremor and ET are the most common forms of tremor observed in practice, it is important to distinguish between the two because the treatments are very different. Diagnostic criteria for ET developed by the Movement Disorder Society are shown in Table 53-8.¹⁹⁵ Tremor should first be identified as either an action or resting tremor. Action tremors include kinetic, postural, and isometric tremors. The defining feature of ET is kinetic tremor of the arms. The tremor can also affect head or voice. Kinetic tremor can be elicited in patients during voluntary movement, such as finger-

Table 53-8 Diagnostic Criteria for Essential Tremor

Inclusion Criteria

Bilateral postural tremor with or without kinetic tremor, involving hands and forearms, that is visible and persistent
Duration >5 yr

Exclusion Criteria

Other abnormal neurological signs (except Froment's sign)
Presence of known causes of increased physiological tremor
Concurrent or recent exposure to tremorogenic drugs or the presence of a drug withdrawal state
Direct or indirect trauma to the nervous system within 3 mo before the onset of tremor
Historical or clinical evidence of psychogenic origins
Convincing evidence of sudden onset or evidence of stepwise deterioration

to-nose test, signing their name, drawing spirals, or drinking water from a cup. Postural tremor occurs during sustained arm extension. Although both types of action tremors (kinetic or postural) can be present in ET and PD, the presence of resting tremor is much more common in PD.¹⁹⁰ Lack of resting tremor and absence of bradykinesia or rigidity in K.H. suggest the tremor is not parkinsonian. She describes interference of her tremor occurring with voluntary movement, such as her ADL and drinking from a cup. Other signs and symptoms that support a diagnosis of ET include her age, family history, large and tremulous handwriting (as opposed to micrographia in PD), and improvement in tremor with alcohol consumption. Table 53-9 summarizes the similarities and differences of ET and parkinsonian tremor.

Several medications and substances are known to be tremorogenic. All patients with tremor should have thorough medication history to rule out these possible causes. Medications commonly implicated include corticosteroids, metoclopramide, valproate, sympathomimetics (e.g. albuterol, amphetamines, pseudoephedrine), SSRI, tricyclic antidepressants, theophylline, and thyroid preparations.¹⁹⁰ In addition, caffeine, tobacco, and chronic alcohol use can cause tremor that resembles ET. K.H. does not report taking any regularly prescribed medications; however, she should be questioned regarding any over-the-counter medication use as well as her caffeine and smoking habits if applicable.

The final step in evaluating K.H.'s tremor should include laboratory analysis to rule out possible medical conditions associated with tremor. If clinical signs suggest the possibility of hyperthyroidism, thyroid function tests should be performed. In patients <40 years of age who present with action tremor, serum ceruloplasmin can be tested to evaluate for possible Wilson's disease.¹⁹⁰ Neuroimaging tests are not useful in the diagnosis and evaluation of ET.

Treatment

28. What therapies are effective in treating essential tremor? How should KH be treated?

Patients with ET who have mild disability that does not cause dysfunction or social embarrassment can go without

Table 53-9 Differentiation of Essential Tremor and Parkinson's Disease

| Characteristic | Essential Tremor | Parkinson's Disease |
|--|-------------------------|------------------------|
| Kinetic tremor in arms, hands, or head | ++ | ++ |
| Hemibody (arm and leg) tremor | 0 | ++ |
| Kinetic tremor > resting tremor | ++ | + |
| Resting tremor > kinetic tremor | 0 | ++ |
| Rigidity or bradykinesia | 0 | ++ |
| Postural instability | 0 | ++ |
| Usual age of onset (yr) | 15–25, 45–55 | 55–65 |
| Symmetry | Bilateral | Unilateral > Bilateral |
| Family history of tremor | +++ | + |
| Response to alcohol | +++ | 0 |
| Response to anticholinergics | 0 | ++ |

| Response to primidone | +++ | 0 |
| Response to propranolol | +++ | + |
| Handwriting analysis | Large, tremulous script | Micrographia |

0, not observed; +, rarely observed; ++, sometimes observed; +++, often observed.

treatment.¹⁹⁶ It is estimated that 15% to 25% of patients with ET will retire prematurely, and 60% will not apply for a job or promotion because of their tremor.¹⁹⁷ Because K.H. is experiencing tremor that is causing both significant functional disability in her occupation and social embarrassment, she should be considered for pharmacotherapy (Table 53-10). It is important to note that, although effective treatments exist, tremor is rarely eliminated completely.¹⁹⁰ Factors predicting lack of response have not been readily identified.¹⁹⁰

Propranolol, a nonselective β -adrenergic receptor blocker, or primidone, an anticonvulsant, are recommended as first-line agents to treat ET.^{196,198} Propranolol is typically effective in doses of at least 120 mg/day, with 45% to 75% of patients reporting benefit.¹⁹⁶ Long-acting propranolol is as effective as the regular-release formulation.¹⁹⁹ Other β_1 -selective blockers such as atenolol and metoprolol, have also been studied, but with mixed findings.²⁰⁰ Propranolol has demonstrated greater efficacy than these B_1 selective agents,²⁰¹ suggesting

Table 53-10 Pharmacotherapy for Essential Tremor

| Drug | Initial Dose | Usual Therapeutic Dose | Adverse Effects |
|------------------------------------|--|----------------------------|--|
| β-Blockers | | | |
| Propranolol | 10 mg QD-BID | 160–320 mg divided QD-BID | Bradycardia, fatigue, hypotension, depression, exercise intolerance |
| Atenolol | 12.5–25 mg QD | 50–150 mg QD | Bradycardia, fatigue, hypotension, exercise intolerance |
| Nadolol | 40 mg QD | 120–240 mg QD | Bradycardia, fatigue, hypotension, exercise intolerance |
| Anticonvulsants | | | |
| Primidone | 12.5 mg QD | 50–750 mg divided QD-TID | Sedation, fatigue, nausea, vomiting, ataxia, dizziness, confusion, vertigo |
| Gabapentin | 300 mg QD | 1,200–3,600 mg divided TID | Nausea, drowsiness, dizziness, unsteadiness |
| Topiramate | 25 mg QD | 200–400 mg divided BID | Appetite suppression, weight loss, paresthesias, concentration difficulties |
| Benzodiazepines | | | |
| Alprazolam | 0.125 mg QD | 0.75–3 mg divided TID | Sedation, fatigue, potential for abuse |
| Clonazepam | 0.25 mg QD | 0.5–6 mg divided QD-BID | Sedation, fatigue, ataxia, dizziness, impaired cognition |
| Miscellaneous | | | |
| Botulinum toxin A | Varies by injection site: 50–100 U/arm for hand tremor; 40–400 U/neck for head tremor; 0.6–15 U/vocal cords for voice tremor; retreat no sooner than every 3 mo (extend as long as possible) | | Hand weakness (with wrist injection); dysphagia, hoarseness, breathiness (with neck or vocal cord injection) |

BID, two times daily; QD, every day; TID, three times daily.

that blockade of β_2 receptors is of importance. β -adrenergic receptor blockers with intrinsic sympathomimetic activity, such as pindolol, appear ineffective in ET.²⁰² Caution should be exercised with propranolol in patients with asthma, congestive heart failure, diabetes mellitus, and atrioventricular block.¹⁹⁶

Several studies have compared propranolol and primidone in ET,^{203,204} and they are considered to have similar efficacy.¹⁹⁸ Primidone is metabolized to a phenobarbital-based metabolite; however, phenobarbital is inferior to primidone in treating ET.²⁰⁵ Acute adverse effects of primidone include nausea, vomiting, and ataxia, which can occur in up to one-quarter of patients often limiting its use.¹⁹⁰ Long-term tolerability of primidone is very good, however, and may actually be superior to propranolol.²⁰⁴ Primidone should be initiated at 12.5 mg/day, administered at bedtime, to reduce the occurrence of acute side effects. It can be titrated gradually as tolerated up to 750 mg/day in divided doses.

Other agents that have demonstrated variable efficacy in ET include gabapentin,²⁰⁶ topiramate,²⁰⁷ and benzodiazepines (specifically, alprazolam²⁰⁸ and clonazepam²⁰⁹). They are generally considered to be less-proven, second-line therapies, however.^{196,198} Adverse effects and potential for abuse (specifically with benzodiazepines) should be considered when an agent is selected.

If oral pharmacotherapy options for ET are not beneficial, intramuscular injections of botulinum toxin A or surgical treatments can be used in selected patients. Targeted botulinum

toxin A injections can reduce hand, head, and voice tremor; however, they are associated with focal weakness of the adjacent areas. Injections in the wrist can cause hand weakness, and dysphagia; hoarseness and breathiness can occur with injections into the neck or vocal cords.¹⁹⁸ Treatment should occur with the lowest dose and the interval should be as long as possible between injections. Deep brain stimulation of the ventral intermediate nucleus of the thalamus or unilateral thalamotomy is highly efficacious in reducing ET.¹⁹⁸ Greater improvement in self-reported measures of function and fewer adverse events make DBS the preferred surgical option of the two.^{196,210}

Because K.H. is otherwise healthy, she is a good candidate for propranolol therapy. Propranolol can be initiated as needed or on a scheduled basis depending on the degree of impairment and desire of the patient. If the decision is made with K.H. to use propranolol on an as-needed basis, she should begin with one-half of a 20-mg tablet administered 30 minutes to 1 hour before the desired effect. The dose can be increased from one-half to two tablets. An example of a situation where this may occur is if she wants to avoid embarrassment with attending a social activity or before certain tasks requiring manual dexterity at work. Given the degree of her impairment, she is probably a better candidate for chronic suppressive therapy with propranolol. In this situation, she can be prescribed 10 mg twice daily and titrated every few days up to 120 to 360 mg/day in divided doses.

Incidence, Prevalence, and Epidemiology

Approximately 10% of the population will experience a seizure at some time. Up to 30% of all seizures are provoked by central nervous system (CNS) disorders or insults (e.g., meningitis, trauma, tumors, and exposure to toxins); these seizures may become recurrent and require chronic treatment with antiepileptic drugs (AED). Reversible conditions such as alcohol withdrawal, fever, and metabolic disturbances may provoke acute, isolated seizures. These seizures are not considered to

be epilepsy and usually do not require long-term AED therapy. Approximately 1% of the general population has epilepsy.¹

Terminology, Classification, and Diagnosis of Epilepsies**Classification of Seizures and Epilepsies**

A seizure is the “clinical manifestation presumed to result from an abnormal and excessive discharge of a set of neurons in the brain. The clinical manifestation consists of sudden and

Table 54-1 International Classification of Epileptic Seizures**Partial Seizure (Local or Focal)****Simple Partial Seizures (Without Impairment of Consciousness)**

- Motor symptoms
- Special sensory or somatosensory symptoms
- Autonomic symptoms

generalized tonic-clonic seizures affect both cerebral hemispheres from the outset. Secondly generalized tonic-clonic seizures begin as either simple or complex partial seizures. The aura described by some patients before a generalized tonic-clonic seizure actually represents an initial partial seizure that spreads to become a secondarily generalized seizure. Identification of secondarily generalized tonic-clonic seizures is important because some AED are more effective at controlling primary generalized seizures than secondarily generalized seizures, and partial seizures are often more difficult to control with AED.⁴⁻⁶

Absence (petit mal) seizures occur primarily in children and often remit during puberty; affected patients may develop a second type of seizure. Absence seizures consist of a brief loss of consciousness, usually lasting several seconds. Simple (typical) absence seizures are not accompanied by motor symptoms; automatisms, muscle twitching, myoclonic jerking, or autonomic manifestations may accompany atypical (complex) absence seizures. Although consciousness is lost, patients do not fall during absence seizures. Patients are unaware of their surroundings and will have no recall of events during the seizure. Consciousness returns immediately when the seizure ends, and postictal confusion is not seen. Differentiation of atypical absence seizures from complex partial seizures may be difficult if only a second-hand account of the episodes is available; identification of a focal abnormality by an electroencephalogram (EEG) often is necessary to identify complex partial seizures. This distinction is important for the proper selection of AED.

Simple partial (focal motor or sensory) seizures are localized in a single cerebral hemisphere or portion of a hemisphere. No loss of consciousness is experienced. Various motor, sensory, or psychic manifestations may occur depending on the area of the brain that is affected. A single part of the body may twitch, or the patient may experience only an unusual sensory experience.

Complex partial (psychomotor or temporal lobe) seizures result from the spread of focal discharges to involve a larger area. Consciousness is impaired and patients may exhibit complex but inappropriate behavior (automatisms) such as lip smacking, picking at clothing, or aimless wandering. A period of brief postictal lethargy or confusion is common.

Epileptic Syndromes

Epilepsy can be classified based on seizure type as shown in Table 54-1. Epilepsy syndromes can be defined on the basis of seizure type as well as cause (if known), precipitating factors, age of onset, characteristic EEG patterns, severity, chronicity, family history, and prognosis. Accurate diagnosis of epilepsy syndromes may better guide clinicians regarding the need for drug therapy, the choice of appropriate medication, and the likelihood of successful treatment.^{1,4,5} Many epilepsy syndromes have been defined; a complete listing is beyond the scope of this chapter. Several are of interest with respect to pharmacotherapy and are described in (Table 54-2).⁵

Diagnosis

Optimal treatment of seizure disorders requires accurate classification (diagnosis) of seizure type and appropriate choice and use of medications. Seizure classification may be straightforward if an adequate history and description of the clinical

transitory abnormal phenomena that may include alterations of consciousness, motor, sensory, autonomic, or psychic events perceived by the patient or observer.”¹ Epilepsy is a “condition characterized by recurrent (≥ 2) epileptic seizures, unprovoked by any immediate identified cause.”¹ The current International Classification of Epileptic Seizures is shown in Table 54-1.^{2,3} Older terms such as “grand mal” and “petit mal” should not be used, because their use may create confusion in the clinical setting. For example, it is common for patients or caregivers to identify any seizure other than a generalized tonic-clonic seizure as a “petit mal” seizure. This labeling may result in the selection of an inappropriate medication.

Generalized tonic-clonic (grand mal) seizures are common. The patient loses consciousness and falls at the onset. Simultaneously, tonic muscle spasms begin and may be accompanied by a cry that results from air being forced through the larynx. Bilateral, repetitive clonic movements follow. After the clonic phase, patients return to consciousness but remain lethargic and may be confused for varying periods of time (postictal state). Urinary incontinence and tongue biting is common. Primary

Table 54-2 Selected Epilepsy Syndromes

| <i>Syndrome</i> | <i>Seizure Patterns and Characteristics</i> | <i>Preferred Antiepileptic Drug (AED) Therapy</i> | <i>Comments</i> |
|---|--|---|---|
| Juvenile myoclonic epilepsy | Myoclonic seizures often precede generalized tonic-clonic seizures. Myoclonic and generalized tonic-clonic episodes on awakening. Absence seizures also common. ↓ sleep, fatigue, and alcohol commonly precipitate seizures. | Valproate. Levetiracetam FDA-approved as adjunct for myoclonic seizures. Phenytoin possibly an adjunct to valproate in resistant cases. Carbamazepine reported to exacerbate seizures in some patients. | 5% to 10% of all epilepsies; 85%–90% response to valproate. Lifelong therapy usually needed. High relapse rate with attempts to discontinue AED therapy. |
| Lennox-Gastaut syndrome | Generalized seizures: atypical absence, atonic/akinetic, myoclonic, and tonic most common. Abnormal interictal EEG with slow spike-wave pattern. Cognitive dysfunction and mental retardation. Status epilepticus common. | Valproate and benzodiazepines may be effective. Lamotrigine and topiramate FDA-approved. Felbamate also may be effective, but potential hematologic toxicity limits use. Poorly responsive to AED. | Oversedation with aggressive AED trials may ↑ seizure frequency. Tolerance to benzodiazepines limits their usefulness. |
| Childhood absence epilepsy (true petit mal) | Typical absences often in clusters of multiple seizures (pyknolepsy). Tonic-clonic seizures in ~40%. Onset usually between ages 4 and 8. Significant genetic component. EEG shows classic 3-Hz spike-wave pattern. | Ethosuximide or valproate. Lamotrigine probably effective. | 80%–90% response rate to AED therapy. Good prognosis for remission. Tonic-clonic seizures may persist. |
| Reflex epilepsy | Tonic-clonic seizures most common. Induced by flicker or patterns (photosensitivity) most commonly. Reading also may precipitate partial seizures affecting the jaw, which may generalize. Some cases involve precipitation of underlying seizures; some seem primary. | AED specific to underlying seizures. Avoidance of precipitating stimuli when possible. Valproate usually effective for cases of spontaneous seizures precipitated by photosensitivity. | Relatively rare; seizures may be precipitated by television or video games. |
| Temporal lobe epilepsy | Complex partial seizures with automatisms. Simple partial seizures (auras) common; secondary generalized seizures occur in 50%. | Carbamazepine, phenytoin, valproate, gabapentin, lamotrigine, topiramate, tiagabine, levetiracetam, oxcarbazepine, zonisamide, pregabalin | Often incompletely controlled with current AED. Emotional stress may precipitate seizures; psychiatric disorders seen with temporal lobe epilepsy; surgical resection can be effective when patient is identified as a good surgical candidate. |

EEG, electroencephalogram; FDA, U.S. Food and Drug Administration.
From references 5, 266–270, with permission.

seizure are available. Physicians often do not observe patients' seizures; thus, family members, teachers, nurses, and others who have frequent direct contact with patients should learn to observe accurately and objectively describe and record these events. The onset, duration, and characteristics of a seizure should be described as completely as possible. Several aspects of the events surrounding a seizure may be especially significant: the patient's behavior before the seizure (e.g., did the patient complain of feeling ill or describe an unusual sensation?), deviation of the eyes or head to one side or localization of convulsive activity to one portion of the body, impaired consciousness, loss of continence, and the patient's behavior after the seizure (e.g., was there any postictal confusion?). In addition, it is helpful if the observer can record the length of the event and how long it took for the patient to return to baseline. The patient and caregivers should have a seizure calendar or diary to record events. Those who observe a seizure should not try to label the seizure but should be encouraged to describe the event fully and objectively.

Accurate seizure diagnosis and identification of the type of epilepsy or epilepsy syndrome also depend on neurologic examination, medical history, and diagnostic techniques, such as EEG, computed tomography (CT), and magnetic resonance

imaging (MRI). The EEG often is critical for identifying specific seizure types. CT scanning may help assess newly diagnosed patients, but MRI is preferred. MRI may locate brain lesions or anatomic defects that are missed by conventional radiographs or CT scans.⁶

Treatment

Early control of epileptic seizures is important because it allows normalization of patients' lives and prevents acute physical harm and long-term morbidity associated with recurrent seizures. In addition, early control of tonic-clonic seizures is associated with a reduced likelihood of seizure recurrence.⁵¹ Early control of epileptic seizures also correlates with successful discontinuation of AED treatment after long-term seizure control.^{7–9}

Nonpharmacologic Treatment of Epilepsy

Alternatives or adjuncts to pharmacotherapy may be helpful in some patients. Surgery is an extremely useful form of treatment in selected patients. Depending on the epilepsy syndrome and procedure performed, up to 90% of patients treated surgically may improve or become seizure free. A study of 80 patients

with medically refractory temporal lobe epilepsy randomized to either surgery or continued medical treatment showed that after 1 year, patients were more likely to be seizure free after surgery.¹⁰ Surgery is advocated as early therapy for some patients with specific epilepsy syndromes, such as mesial temporal sclerosis. Early surgical intervention may prevent or lessen neurologic deterioration and developmental delay.

Dietary modification may be used for patients who cannot tolerate AED or to treat seizures that are not completely responsive to AED. In most circumstances, dietary modification consists of a ketogenic diet. This low-carbohydrate, high-fat diet results in persistent ketosis, which is believed to play a major role in the therapeutic effect. Ketogenic diets are most commonly used and seem to be most beneficial in children; they are also used as adjuncts to ongoing AED treatment.^{11,12}

The vagus nerve stimulator (VNS) is approved for treatment of intractable partial seizures. This device uses electrodes attached around the left branch of the vagus nerve. The electrodes are attached to a programmable stimulator that delivers stimuli on a regular cycling basis; patients can also use “on demand” stimulation at the onset of seizures by placing a magnet next to the subcutaneously implanted stimulator. Approximately 30% to 40% of patients who are so treated have a positive response (50% reduction in seizures).^{13,14} The primary side effect of this device is hoarseness during stimulation; infrequently, this is accompanied by left vocal cord paralysis.

AVOIDANCE OF POTENTIAL SEIZURE PRECIPITANTS

It is impossible to generalize about environmental and lifestyle precipitants of seizure activity in persons with epilepsy. Individual patients or caregivers may identify specific circumstances, such as stress, sleep deprivation, or ingestion of excessive amounts of caffeine or alcohol, which can increase the likelihood of a seizure. Some women experience an increase in the frequency and severity of seizures around the time of menstruation or ovulation. Patients with epilepsy should avoid activities that seem to precipitate seizures; as always, the goal is complete seizure control with as little alteration in quality of life as possible.

Antiepileptic Drug Therapy

Pharmacotherapy is the mainstay of treatment for epilepsy. Therefore, patient education regarding medications and consultation among health care professionals regarding the optimal use of AED are essential to quality patient care. Optimal AED therapy completely controls seizures in 60% to 95% of patients.^{4,15–17} Optimization of drug therapy depends on several factors; with the choice of appropriate AED, individualization of dosing, and adherence being the most important.

CHOICE OF ANTIPILEPTIC DRUG

Many AED have a relatively narrow spectrum of efficacy; therefore, choice of appropriate drug therapy for a specific patient depends on an accurate diagnosis of epilepsy. In addition, toxicity must be considered when selecting an AED. Preferred drugs for specific types of seizures and common epileptic syndromes are listed in Tables 54-2 and 54-3. Although certain drugs are preferred, the identification of the most effective drug for a particular patient may be a process of trial and error; several medication trials may be necessary before

success is achieved. The consensus method was used to analyze expert opinion on treatment of three epilepsy syndromes and status epilepticus.¹⁸ The experts recommended monotherapy first, followed by a second monotherapy agent if the first failed. If the second monotherapy failed, the experts were not in agreement on whether to try a third monotherapy agent or to combine two therapies. The experts recommended epilepsy surgery evaluation after the third failed AED for patients with symptomatic localization-related epilepsies.

To assess the evidence on efficacy, tolerability, and safety of many of the new AED in treating children and adults with new-onset and refractory partial and generalized epilepsies, a panel evaluated the available evidence.^{19,20} They concluded that the AED choice depends on seizure and syndrome type, patient age, concomitant medications, and AED tolerability, safety, and efficacy. The results of these two evidence-based assessments provide guidelines for the use of newer AED in patients with new-onset and refractory epilepsy.

THERAPEUTIC ENDPOINTS

The individual patient's response to AED treatment (i.e., seizure frequency and severity, and symptoms of toxicity) must be the major focus for therapy assessment. In general, the goal of AED treatment is administration of sufficient medication to completely prevent seizures without producing significant toxicity.²¹ Realistically, this goal may be compromised for many patients; it may not be possible to completely prevent seizures without producing intolerable adverse effects. Thus, the therapeutic endpoints achieved can vary among patients; optimization of AED therapy for a specific person depends on tailoring therapy to the patient's needs and lifestyle. It is rarely optimal to administer “standard” or “usual” doses of an AED to a patient or to adjust doses to achieve a “therapeutic blood level” without paying consideration to the effect of the dose or serum concentration on the patient's condition and quality of life. As with many conditions requiring chronic drug therapy, patient participation in developing and evaluating a therapeutic plan is extremely important. Patients should be educated regarding the expected positive and negative effects of their AED therapy, and they must be encouraged to communicate with their health care provider regarding their responses to prescribed AED.

SERUM DRUG CONCENTRATIONS

Relation to Dosage

For some AED, although not all, a good correlation exists between serum concentrations and both therapeutic response and toxicity. For these agents, the wide availability of AED serum concentration determinations has had a significant impact on the treatment of seizure disorders. The correlation between the administered maintenance dose of an AED and the resulting steady-state serum concentration is poor. Administration of “usual therapeutic doses,” even when calculated on the basis of body weight, is equally likely to produce subtherapeutic, therapeutic, or potentially intoxicating serum concentrations. Interindividual variation in hepatic metabolic capacity probably accounts for most of this variability.

Relation to Clinical Response

For selected AED, proper use and interpretation of serum concentrations are important for optimizing treatment regimens in

Table 54-3 Antiepileptic Drugs (AED) Useful for Various Seizure Types^a

| <i>Primary Generalized Tonic-Clonic</i> | <i>Secondarily Generalized Tonic-Clonic</i> | <i>Simple or Complex Partial</i> | <i>Absence</i> | <i>Myoclonic, Atonic/Akinetic</i> |
|---|---|--------------------------------------|--------------------------|---------------------------------------|
| Most Effective With Least Toxicity | | | | |

| Of Little Value | | | | |
| Ethosuximide | Ethosuximide | Ethosuximide | Phenytoin | |
| Trimethadione | Trimethadione | Trimethadione | Carbamazepine | |
| | | | Phenobarbital | |
| | | | Primidone | |

^aDrugs are listed in general order of preference within each category. Recommendations by various authorities may differ, especially regarding the relative place of valproate and the role of phenytoin as a first-line AED. Many authorities now discourage the use of phenobarbital and primidone.

^bThe place of gabapentin, lamotrigine, oxcarbazepine, levetiracetam, topiramate, tiagabine, and zonisamide is yet to be determined. They are placed on this table only to indicate the types of seizures for which they appear to be effective. Much more clinical experience is needed before their roles as possible primary AED are clarified.

^cThe place of felbamate is yet to be determined. It is placed on this table only to indicate the types of seizures for which it appears to be effective. Felbamate has been associated with aplastic anemia and hepatic failure; until a possible causative role is clarified, felbamate cannot be recommended for treatment of epilepsy unless all other, potentially less toxic treatment options have been exhausted.

epilepsy.^{14,22} An individual patient's clinical response to AED treatment must be the major focus for therapy assessment. Neither therapeutic effects nor toxic symptoms are "all or none"; in most situations, there are gradations of efficacy and toxicity. Dosage increases and titration to AED serum concentrations within and occasionally above the "therapeutic range" may significantly improve therapeutic responses without producing significant toxicity.²² Individual patients often differ dramatically in their response to a particular serum drug concentration; therefore, therapeutic serum concentrations should be considered only as guidelines for treatment. Many patients condition may be controlled with serum drug concentrations below the usual therapeutic range.²³ In these patients, dosage adjustment to increase the serum drug concentration is not warranted. In this case, it is better to "treat the patient, not the level."

Interestingly, a recent Cochrane Review found no evidence to indicate that the use of measuring AED concentrations routinely to inform dose adjustments is superior to dose adjustments based on clinical information.²⁴ Only one study fit their evaluation criteria and that was done in patients newly diagnosed with epilepsy treated with a single older AED: carbamazepine, valproate, phenytoin, phenobarbital, or primidone.

The authors do state that their review does not exclude the possibility that AED serum concentration might be useful in special situations or in selected patients.

Indications for Use

Measurement of serum drug concentrations may provide clinically useful information in the following situations:

- Uncontrolled seizures despite administration of greater-than-average doses: Serum concentrations of AED may help distinguish drug resistance from subtherapeutic drug concentrations caused by malabsorption, noncompliance, or rapid metabolism.
- Seizure recurrence in a patient whose seizures were previously controlled: This often is owing to noncompliance with the prescribed medication regimen.
- Documentation of intoxication: In patients who develop signs or symptoms of dose-related AED toxicity, documentation of the dose and serum concentration of the responsible drug is helpful.
- Assessment of patient compliance: Although monitoring AED serum concentrations can be used to assess patient

Table 54-4 Pharmacokinetic Properties of Antiepileptic Drugs

| Drug | Oral Absorption (%) | Half-Life (hr) | Time to Steady State ^a | Dosage Schedule | Usual Therapeutic Serum Concentration | Plasma Protein Binding (%) | Volume of Distribution (L/kg) |
|---------------|----------------------|---|-----------------------------------|---------------------------|---------------------------------------|----------------------------|-------------------------------|
| Carbamazepine | 90–100 | Chronic: 5–25 | 2–4 day | BID to TID | 5–12+ mcg/mL | 75 (50–90) | 0.8–1.6 |
| Ethosuximide | 90–100 | Pediatric: 30 Adult: 60 | 5–10 day | QD (BID) | 40–100 mcg/mL | 0 | 0.7 |
| Gabapentin | 40–60; ↓ with ↑ dose | Normal renal function: 5–9; ↑ with ↓ renal function | Normal renal function: 1–1.5 day | TID to QID (every 6–8 hr) | >2 mcg/mL (proposed) | 0 | ≈0.8 |
| Lamotrigine | 90–100 | Monotherapy: 24–29 Enzyme inducers: 15 Enzyme inhibitor (VPA): 59 | 4–9 day | BID | 4–18 mcg/mL (proposed) | 55 | 0.9–1.2 |
| Levetiracetam | 100 | Normal renal function: 6–8; ↑ with ↓ renal function | Normal renal function: 1–1.5 day | BID | Not determined | <10 | ≈0.7 |
| Oxcarbazepine | 100 | 8–13 | 2–3 day | BID to TID | Not determined | 40 | |
| Phenobarbital | 90–100 | 2–4 day | 8–16 day | QD | 15–40 mcg/mL | 50 | 0.5–0.6 |
| Phenytoin | 90–100 | Varies with dose | 5–30+ day | QD to BID | 10–20 mcg/mL | 95 | 0.5–0.7 |
| Pregabalin | ≥90 | Normal renal function: 6; ↑ with ↓ renal function | 24 hr | BID to TID | Not determined | 0 | 0.5 |
| Tiagabine | 90 | Monotherapy: 7–9 Enzyme inducers: 4–7 | 1–2 day | BID to QID | Not determined | 96 | 1.1 |
| Topiramate | ≥80 | 12–24 | 3–4 day | BID | Not determined | 10–15 | 0.7 |
| Valproate | 100 | 10–16 | 2–3 day | BID to QID | 50–150+ mcg/mL | 90+ | 0.09–0.17 |
| Zonisamide | ≈80 | Monotherapy: ≈60 Enzyme inducers: 27–36 | 2 wk | QD to BID | Not determined | 50–60 | 1.3 |

^aBased on four half-lives. This lag time should allow determination of steady-state serum concentrations within limits of most assay sensitivities.

BID, twice daily; QD, every day; QID, four times daily; VPA, valproic acid.

compliance with therapy, conclusions must be based on comparisons with previous steady-state serum concentrations that reflected reliable intake of a given dose of AED.

- Documentation of desired results from a dose change or other therapeutic maneuver (e.g., administration of a loading dose): When patients are receiving multiple AED, serum concentrations of all drugs should be measured following a change in the dose of one drug because changes in the serum concentration of one drug frequently change the pharmacokinetic disposition of other drugs.
- When precise dosage changes are required: On occasion, small changes in the dose of a drug (e.g., phenytoin) can result in large changes in both the serum concentration and clinical response. In addition, cautious titration of dosage and serum concentration may be necessary to avoid intoxication. Knowledge of the serum drug concentration before the dosage change may allow the clinician to select a more appropriate new maintenance dose.

Frequent, “routine” determinations of serum AED concentrations are costly and not warranted for patients whose clinical status is stable. Clinicians may tend to focus attention on normal variability in serum concentrations rather than on the patient’s clinical status; as a result, unnecessary dosage adjustments may be made to make serum concentrations fit the “normal range.” A plan of action for what the clinician is going to do with the information once it is obtained should be in place before obtaining the sample. Therefore, the results of individual serum concentration determinations must be evaluated

carefully to decide whether a significant, clinically meaningful change has occurred.²⁵

Interpretation of Serum Concentrations

Several factors can alter the relationship between AED serum concentration and the patient’s response to the drug. Whenever a change in serum concentration is apparent, pharmacokinetic factors (Table 54-4) should be considered (along with the patient’s clinical status) before a decision is made to adjust the AED dosage. Laboratory variability can cause minor fluctuations in reported AED serum concentrations. Under the best conditions, reported values for serum concentrations may be within ±10% of “true” values.^{26,27} Therefore, the magnitude of any apparent change must be considered. Therapeutic ranges are not well established for some drugs (e.g., valproate and the newer AED, such as lamotrigine, topiramate, and tiagabine). Published *therapeutic ranges* may have been determined in small numbers of patients or may more accurately represent *average serum concentrations at usual doses*. As an example, many clinicians agree that “pushing” valproate serum concentrations up to 150 to 200 mcg/mL may be beneficial for some patients; these higher concentrations are not consistently associated with specific toxicity symptoms.^{28–31} Nevertheless, most laboratories report 50 to 100 g/mL as a therapeutic range for valproate. Inappropriate sample timing can result in inconsistent and clinically meaningless changes in AED serum concentrations.¹⁴ Generally, serum concentrations of AED should not be measured until a minimum of four to five half-lives have elapsed since initiation of therapy

or a dosage change. Blood samples should be obtained in the morning, before any doses of the AED have been taken; this practice provides reproducible, postabsorptive (i.e., “trough”) serum concentrations. On occasion, especially for rapidly absorbed drugs with short half-lives (e.g., valproate), determination of peak serum concentrations may help assess possible toxic symptoms. Interindividual variability in response to a given serum concentration of medication is common. Excellent therapeutic response or even symptoms of intoxication may be associated with AED serum concentrations that are classified as “subtherapeutic.”³² Active metabolites of AED usually are not measured when serum concentrations are determined.^{27,33} Alterations in the relative proportion of parent drug and active metabolite may result in an apparent alteration in the relationship between the serum concentration of the parent drug and the patient’s response. Binding to serum proteins is significant for some AED (e.g., phenytoin, valproate, tiagabine). Changes in protein binding can result from drug interaction, renal failure, pregnancy, or changes in nutritional status. These changes can alter the usual relationship between the measured total drug concentration (bound and unbound to plasma proteins) and the unbound (pharmacologically active) drug concentration. This change may not be apparent when only total serum concentrations are measured. Determination of serum concentrations of free (i.e., unbound) AED is available from many commercial laboratories; these determinations are expensive and results may not be available for several days. If significant changes in protein binding are suspected, measurement of free concentrations of AED may provide additional information useful for adjustment of doses or interpretation of the patient’s symptoms.^{26,27,33}

MONOTHERAPY VERSUS POLYOTHERAPY

Decades ago, seizure disorders were often treated with multiple AED (polytherapy). A second, third, or even fourth drug was added when seizures were incompletely controlled with a single AED. Evaluation of the effectiveness of polytherapy in recent years has shown little advantage for most patients. Use of a single drug at optimal tolerated serum concentrations produces excellent therapeutic results and minimal side effects in up to 80% of patients. Addition of a second AED significantly improves seizure control in only 10% to 20% of patients.^{34,35} Reduction or elimination of existing polytherapy in patients with longstanding seizure disorders often lessens or eliminates cognitive impairment and other side effects: seizure control actually may improve.^{34,36–39}

Most experts advocate the use of monotherapy (i.e., use of a single AED) whenever possible. Successful monotherapy may require higher-than-usual AED doses or serum concentrations above the upper limit of the usual therapeutic range.^{16,40} Addition of a second drug may be necessary in some patients; however, polytherapy should be reserved for patients with multiple seizure types or for patients in whom first-line AED have failed to control seizures when titrated to maximal tolerated doses.^{16,37} When a new AED is added to a patient’s regimen with the goal of improving seizure control, the existing AED regimen should be scrutinized for continued value. In some cases, a patient’s AED regimen can accumulate drugs that may be unnecessary because they were started and never re-evaluated. Continued vigilance and critical assessment of every drug in a patient’s regimen is important.

Use of polytherapy creates several disadvantages that must be weighed against possible benefits. Seizure control may not significantly improve; in fact, these authors’ experience and information from studies in which patients were converted from polytherapy to monotherapy indicate that even with use of an optimal AED, seizure control may be worsened in some patients by polytherapy regimens.³⁹ Patient expenses for medications and for increased laboratory monitoring may increase significantly with polytherapy. In addition, drug interactions among AED can complicate assessment of the patient’s response and serum concentrations. Patient compliance often is worsened when multiple medications are prescribed, and adverse effects often increase because the side effects of many AED are additive.

Although AED monotherapy is preferred whenever feasible, the recent introduction of several new AED has increased the use of polytherapy.⁴⁰ Owing to limitations on the patient populations used for clinical trials of new drugs (i.e., patients with seizure disorders not completely controlled by previous medications), most new AED are labeled only for use as add-on therapy. Although reports exist on the efficacy of the new AED as monotherapy,^{41–44} only lamotrigine, topiramate, oxcarbazepine, and felbamate are U.S. Food and Drug Administration (FDA) approved for monotherapy. Lamotrigine is indicated for conversion to monotherapy in adults with partial seizures who are receiving treatment with carbamazepine, phenytoin, phenobarbital, primidone, or valproate as the single AED.⁴⁵ Topiramate is approved as initial monotherapy in patients 10 years of age and older with partial-onset or primary generalized tonic-clonic seizures.⁴⁶ Felbamate should be considered (as monotherapy or polytherapy) only when other AED have failed. Other AED will undoubtedly follow with monotherapy indications. At present, data concerning the use of these new drugs as single agents are limited.

DURATION OF THERAPY AND DISCONTINUATION OF ANTIEPILEPTIC DRUGS

A diagnosis of epilepsy may not necessitate lifelong drug therapy. Several long-term studies have examined the prognosis of epilepsy following drug discontinuation; AED therapy may be successfully withdrawn from some patients after a seizure-free period of 2 to 5 years.^{7–9} Seizures recurred in only 12% to 36% of patients who were followed for up to 23 years after AED withdrawal. Therefore, many patients whose epilepsy is completely controlled with medication can stop therapy after a seizure-free period of at least 2 years.

Discontinuation of medications is advantageous for economic, medical, and psychosocial reasons. Costs associated with physician visits, serum concentration determinations, and the medications themselves are eliminated. The risk of adverse effects from long-term medication use is eliminated, and patients can expect fewer lifestyle restrictions. Attempts to withdraw AED therapy are associated with risks, however: reappearance of seizure activity can result in status epilepticus, loss of driving privileges, employment difficulties, or physical injury.

Risk factors for seizure recurrence following discontinuation of AED have been identified in observational studies; complete agreement, however, is not found among studies regarding the nature and importance of specific risk factors. Opinions and data also differ regarding the optimal duration of the seizure-free period before discontinuation of AED is

Table 54-5 Risk Factors Possibly Predicting Seizure Recurrence Following AED Withdrawal

- <2 yr seizure free before withdrawal
- Onset of seizures after age 12
- History of atypical febrile seizures
- Family history of seizures
- >2–6 yr before seizures controlled
- Large number of seizures (>30) before control or total of >100 seizures
- Partial seizures (simple or complex)
- History of absence seizures
- Abnormal EEG persisting throughout treatment
- Slowing on EEG before medication withdrawal
- Organic neurologic disorder
- Moderate to severe mental retardation
- Withdrawal of valproate or phenytoin (higher rate of recurrence than withdrawal of other AED)

AED, antiepileptic drug; EEG, electroencephalogram.
From references 7–9, 47, and 48, with permission.

attempted. Nevertheless, at least some consensus has been reached regarding certain factors that may predict a higher risk of seizure recurrence (Table 54-5).^{7–9,47,48}

In nonemergency situations, AED should be withdrawn slowly; if a patient receives multiple drugs, each drug should be withdrawn separately. Too-rapid withdrawal can result in status epilepticus. Clinical studies of AED discontinuation usually used a 2- to 3-month withdrawal schedule for each drug. The optimal rate of withdrawal of AED has not been identified. One study compared withdrawal of individual drugs over a 6-week and a 9-month period and found no difference in seizure recurrence between the groups.⁴⁹ Another study compared seizure frequencies in patients withdrawn from carbamazepine rapidly (over 4 days) and in patients withdrawn more slowly (over 10 days).⁵⁰ Significantly more generalized tonic-clonic seizures occurred when carbamazepine was withdrawn rapidly; complex partial seizures, however, did not occur at a higher rate with rapid withdrawal. Therefore, withdrawal of each AED over at least 6 weeks would seem to be a safe approach. Gradual withdrawal is recommended even for medications such as phenobarbital that have long half-lives and should theoretically be “self-tapering.” In these authors’ experience, gradual reduction of medications such as phenobarbital is associated with a significantly higher success rate. Appearance of seizures during medication withdrawal is not necessarily an indication for reinstatement of maintenance therapy; many patients who experience seizures during drug withdrawal remain seizure free after complete withdrawal.⁵¹

CLINICAL ASSESSMENT AND TREATMENT OF EPILEPSY

Complex Partial Seizures with Secondary Generalization

Diagnosis

1. A.R. is a 14-year-old, 40-kg, female high school student. A.R. had three febrile seizures when she was 3 years old. She received phenobarbital prophylaxis “off and on,” according to her parents, for about 6 months following her second febrile seizure. Since then, she had no reported seizures until 24 hours before admission. At that time she had a “convulsion” shortly after arriving

at school in the morning. A teacher who witnessed the episode describes her as behaving “oddly” before the seizure. She abruptly got up from her desk and began to walk clumsily toward the door; she bumped into several desks and did not respond to the teacher’s attempts to redirect her back to her seat. After approximately 1 minute of this behavior, she fell to the floor and experienced an apparent generalized tonic-clonic seizure that lasted approximately 90 seconds. During the episode, she was incontinent of urine and was described as “turning kind of blue.” Following this episode, A.R. was transported to the hospital.

On arrival at the hospital, A.R. appeared drowsy and confused. Laboratory studies—a complete blood count (CBC), serum glucose, electrolytes, drug and alcohol screen, and lumbar puncture—were normal. Physical examination and a complete neurologic evaluation were normal. An EEG showed diffuse slowing with focal epileptiform discharges in the left temporal area; it was interpreted as abnormal. There was no history of recent illness or injury, although A.R. had stayed up late several nights recently studying for an examination.

A second seizure occurs in the hospital. The nursing staff’s description of the episode is similar to that provided by the observers at school. After recovery from each episode, A.R. has no memory of events during the seizures; she only remembers a “funny feeling” in her stomach and a “buzzing” in her head before she lost consciousness. She describes having these feelings “a couple of times” in the past; she attributed them to “just getting dizzy” and had not reported them to her parents. After these previous episodes, A.R. described feeling “mixed up” and groggy for a few minutes. What subjective and objective features of A.R.’s seizures are consistent with a diagnosis of complex partial seizures with secondary generalization?

A.R.’s clinical pattern of observed seizure activity (an apparent aura preceding her loss of consciousness), her history of apparent complex partial seizures not accompanied by generalized seizures, and the findings of focal abnormal activity on EEG are all concordant of this diagnosis. Postictal confusion and grogginess are also common after both generalized tonic-clonic and complex partial seizures. Her unusual or inappropriate behavior represents a complex partial seizure that subsequently generalized. The clinical features, accompanied by her EEG findings, also help rule out possible atypical absence seizures, which can be confused with complex partial epileptic syndromes based on only clinical presentation. In both syndromes, patients may briefly appear to lose contact with their surroundings and display automatisms and mild clonic movements during seizure activity. In A.R.’s case, the EEG and the generalized tonic-clonic seizures during her episodes would rule out atypical absence as a likely possibility.

Decision to Use Antiepileptic Drug Therapy

2. What factors should be considered in a decision to treat A.R.’s seizures with AED therapy?

Once a diagnosis of epilepsy is established, the decision to treat the patient with medication is based on the likelihood of recurrence. The need for AED therapy after a single seizure is controversial; however, recurrence of generalized tonic-clonic seizures is less likely if AED therapy is initiated after the first generalized tonic-clonic seizure.⁵² Therefore, at least for this one specific seizure type, early use of AED is supported. Whether this information applies to other types of seizures

is not known. Clinical wisdom, however, holds that “seizures beget seizures,” and most experts advocate early treatment of epilepsy (i.e., after a first or second unprovoked seizure).

In A.R.’s case, the potential benefits of immediate introduction of AED therapy appear to outweigh potential risks. She experienced complex partial seizures followed by secondarily generalized tonic-clonic seizures. Recurrences of seizure activity are likely to result in physical injury, social embarrassment, and interference with her participation in activities typical of a person her age. If her seizures are not controlled, she faces future limitation of her driving privileges and may face barriers to employment. Although AED therapy is associated with risks, they probably are outweighed by the potential benefits.

Choice of Antiepileptic Drug

3. Discuss the AED commonly used for A.R.’s seizure type. Based on the subjective and objective data available, recommend a first-choice AED for A.R. and a plan for initial dosing of this medication.

Many AED would be appropriate choices for A.R.’s complex partial seizures that can secondarily generalize (Table 54-3).^{35,53,54} Some AED are not FDA approved as initial monotherapy. Though valproate (Depakene/Depakote) is effective for treating both generalized and complex partial seizures,⁵⁵ it would not be a good initial choice for this patient owing to the increased risks in a woman of childbearing age (see Women’s Issues section below).

Felbamate (Felbatol), gabapentin (Neurontin), lamotrigine (Lamictal), topiramate (Topamax), tiagabine (Gabitril), levetiracetam (Keppra), oxcarbazepine (Trileptal), zonisamide (Zonegran), and pregabalin (Lyrica) are effective for control of partial seizures with or without secondary generalization. Most experience with these drugs was obtained when they were used as adjunctive agents when previous AED therapies were unsuccessful. Initial clinical trials with these newer medications indicate that several of them may be useful as single agents. As mentioned previously, lamotrigine, oxcarbazepine, and topiramate have monotherapy indications. Most of these more recent medications appear to be safe and are usually well tolerated. The usefulness of felbamate is, however, limited owing to its potential for serious hematologic and hepatic toxicity.

Carbamazepine has several advantages that make it a preferred first-choice agent in the opinion of many clinicians. In comparison with phenytoin, carbamazepine is less sedating and is not associated with dysmorphic effects, such as hirsutism, acne, gingival hyperplasia, and coarsening of facial features. Carbamazepine’s pharmacokinetic profile also makes dosage adjustment easier. In A.R.’s case, the lack of cosmetic side effects may be especially significant because she may be taking medication for many years. In addition, reduced sedation may be important with respect to her school performance.

Carbamazepine Therapy

INITIATION AND DOSAGE

Initiation of treatment with full therapeutic maintenance doses of carbamazepine often causes excessive side effects such as nausea, vomiting, diplopia, and significant sedation. Therefore, carbamazepine therapy should be initiated gradually and patients should be allowed time to acclimate to the effects of the drug. Final dosing requirements are difficult to

anticipate in individual patients. A reasonable starting dosage of carbamazepine for A.R. would be 100 mg twice a day; her dosage could be increased by 100 to 200 mg/day every 7 to 14 days. The rapidity of increases will depend on A.R.’s tolerance for the drug and the frequency of seizures.

HEMATOLOGIC TOXICITY

4. Carbamazepine has been associated with hematologic and hepatic toxicities. What is the incidence and significance of these toxicities? How should A.R. be monitored for them?

Aplastic anemia and agranulocytosis have occurred in association with carbamazepine therapy.⁵⁶ Several cases have been fatal; however, most cases occurred in older patients treated for trigeminal neuralgia. Many patients were receiving other medications, and occasionally the reports were incomplete; thus, assessment of a causal role for carbamazepine is difficult.⁵⁷ Severe blood dyscrasias from carbamazepine seem rare (estimated prevalence of <1/50,000) and have predominantly occurred in nonepileptic patients. The lack of severe hematologic toxicity in various published series and clinical trials in patients with epilepsy has been notable.^{58,59}

Leukopenia is relatively common in patients taking carbamazepine. It is usually mild and often reverses despite continued administration of the drug.⁵⁸ Total leukocyte counts may fall to <4,000 cells/mm³ in some patients, but differentials and platelet and erythrocyte counts remain normal. Symptoms (e.g., fever, sore throat) that might suggest early stages of agranulocytosis do not occur. Carbamazepine-associated hematologic disorders occur independent of drug dosage; thus, these reactions appear to be idiosyncratic.

Routine Hematologic Testing

Laboratory monitoring of A.R.’s hematologic status is recommended during carbamazepine therapy. The likelihood of early detection of aplastic anemia or agranulocytosis through frequent blood counts is low, however, and such monitoring is costly.^{58,60} Because hematologic toxicity from carbamazepine primarily occurs early in therapy, CBC can be obtained before therapy and at monthly intervals during the first 2 to 3 months of therapy; thereafter, a yearly or every-other-year CBC, white blood cell (WBC) count with differential, and platelet count should be sufficient.

HEPATOTOXICITY

Carbamazepine-related liver damage appears to be extremely rare despite its being frequently mentioned as a potential problem and strong warnings are in the package insert.^{61,62} Hepatic adverse reactions are believed to be idiosyncratic or immunologically based. Aggressive laboratory monitoring of liver function tests (LFT) probably is unnecessary.⁶⁰ Alkaline phosphatase and γ -glutamyl-transferase (GGT) concentrations often are elevated in patients taking carbamazepine (and other AED). This is believed to result from hepatic enzyme induction and is not necessarily evidence for hepatic disease.⁶³

In summary, hepatic and hematologic toxicities of carbamazepine are rare. Although potentially serious, they are best monitored on clinical grounds rather than by ongoing, intensive laboratory testing. Patients, families, or caregivers should be aware that the appearance of unusual symptoms (e.g., jaundice,

abdominal pain, excessive bruising and bleeding, or sudden onset of severe sore throat with fever) should be reported to a health care professional. Baseline (pretreatment) determination of A.R.'s hepatic and hematologic status, possibly with monthly follow-up testing for 2 to 3 months, probably will be sufficient.^{59,60} Thereafter, a CBC and a liver function battery should probably be evaluated only every 1 to 2 years, unless signs or symptoms of hepatic or hematologic disorders are observed.

PHARMACOKINETICS AND AUTOINDUCTION OF METABOLISM

5. Over the following 6 weeks, A.R.'s carbamazepine dosage was gradually increased to 400 mg twice daily (BID) (20 mg/kg/day). Until the last dose increase, she had been experiencing one or two complex partial seizures weekly; she had had only one generalized tonic-clonic seizure since her hospitalization. One week following the increase to 20 mg/kg/day, her serum carbamazepine concentration was 9 mcg/mL just before her first dose of the day. No seizures occurred for 4 weeks, and she tolerated the medication well. Subsequent to the 4-week seizure-free period, she again began experiencing one seizure weekly. What factor(s) might be responsible for this reversal of seizure control?

Several factors may account for this change. It is important always to consider the possibility of poor medication adherence when clinical response changes unexpectedly. This should be investigated, and A.R. and her family should be educated regarding the importance of regular medication intake if necessary.

The observed changes in A.R.'s seizure control may also be owing to unique features of carbamazepine pharmacokinetics. Carbamazepine is a potent inducer of hepatic cytochrome P450 (CYP3A4). The drug is also a substrate for this enzyme. As a result, carbamazepine not only stimulates the metabolism of other CYP3A4 substrates but also induces its own metabolism by autoinduction. Carbamazepine's half-life following single acute doses is approximately 35 hours; with chronic dosing, its half-life decreases to 15 to 25 hours. This induction of metabolism may be enhanced by combined administration of carbamazepine and other enzyme-inducing AED; with polytherapy, carbamazepine's half-life may be as short as 6 to 10 hours.²⁷ This increase in clearance necessitates increased doses, increased frequency, or both of carbamazepine administration. Autoinduction of carbamazepine metabolism appears to be related to dose and serum concentration. Approximately 1 month may be required for the autoinduction process to reach completion after each increase in carbamazepine dose.⁶⁴

Assuming that adherence was not the main problem, A.R.'s carbamazepine dose should be increased. The drug's pharmacokinetics are generally linear with respect to acute dosage changes.⁶⁵ A 50% increase in dosage to 1,200 mg/day should re-establish seizure control. Depending on A.R.'s clinical status, further increases in dosage may be necessary.

BIOEQUIVALENCE OF GENERIC DOSAGE FORMS AND EFFECTS OF STORAGE ON BIOEQUIVALENCE

6. A.R.'s dosage was increased to 600 mg BID. Four weeks later, she was still experiencing approximately one complex partial seizure weekly. A repeat trough serum carbamazepine concentration was 6.5 mcg/mL. On questioning, A.R. denied missing doses

of medication, and a tablet count confirmed apparently accurate drug intake. A.R. relates that she experiences some mild nausea following her doses, but she has not vomited. It is noted that her pharmacist has begun substituting generic carbamazepine tablets for the Tegretol that was previously dispensed. What role, if any, might this change in carbamazepine tablet brand have played in the failure of A.R.'s serum concentrations to increase as expected? What other factors might be considered in explaining this situation?

Several manufacturers market generic carbamazepine tablets. Bioavailability data supplied by the manufacturers are based on single-dose or short multiple-dose studies in healthy subjects. Therefore, it is impossible to completely predict the results of a change from Tegretol to generic carbamazepine for maintenance therapy in an individual patient.⁶⁶ Because of variations in amount of drug available from different products, some patients with epilepsy cannot tolerate changes in formulations between brand to generic, generic to generic, or generic to brand.⁶⁷ Changes in seizure control from too little drug or toxicity from too much drug have been reported. Bioavailability data and the author's (R.L.) experience with institutionalized patients with severe seizure disorders suggest that the generic carbamazepine preparations currently on the market may be substituted for Tegretol with little need for dosage adjustment. In A.R.'s case, substitution of generic carbamazepine may be a possible cause for the loss of seizure control. Readjustment of her dose to gain seizure control and consistent use of one manufacturer's product might alleviate this problem.

Three extended-release forms of carbamazepine (Tegretol XR, Carbatrol and Equetro) available and may provide an alternative for A.R. These formulations allow more reliable absorption of drug when administered on a twice-daily dosing schedule. Many patients can better tolerate carbamazepine when these forms are used because large fluctuations in plasma concentrations are avoided. Use of Tegretol XR to avoid three-times-daily or four-times-daily dosing schedules has been shown to increase adherence for many patients.⁶⁸ It is important to counsel patients on the fact that the empty Oros tablet shell from the Tegretol XR dose does not dissolve as it passes through the gastrointestinal (GI) tract, and it may be visible in the stool. Patients need to understand that the carbamazepine has been absorbed, and that this is an empty shell. Tegretol XR tablets lose their extended-release properties when broken or crushed; Carbatrol beads may be emptied onto food or administered via feeding tube.⁶⁹ Equetro is not FDA approved for epilepsy, it is indicated for the treatment of acute manic and mixed episodes associated with bipolar I disorder.

In conclusion, it may be impossible to identify a single cause for the unexpected change in A.R.'s seizure control. Common reasons for loss of seizure control include sleep deprivation, increased stress, acute infection, and medication nonadherence.

Treatment Failure and Alternative Antiepileptic Drugs

7. R.H., a 19-year-old, 64-kg young woman, has experienced simple partial seizures, complex partial seizures, and secondarily generalized tonic-clonic seizures for the past 2 years. She could not tolerate treatment with phenytoin (severe gingival hyperplasia and mental "dullness") or valproate (hair loss, tremor, and a weight gain of 8 kg). In addition, neither phenytoin nor valproate

was dramatically effective in reducing her seizures. She currently receives carbamazepine 600 mg three times daily (TID). Over the past 3 months, while being treated with carbamazepine, she has had approximately five simple partial seizures, three complex partial seizures, and one generalized tonic-clonic seizure. This represents an approximate 30% reduction in her frequency of seizures. She tolerates her present dose of carbamazepine but has experienced significant drowsiness, incoordination, and mental confusion at higher doses. What are possible therapeutic options for R.H.? Evaluate the newer AED and their possible usefulness for R.H.

R.H. is exhibiting a partial response to maximally tolerated doses of carbamazepine. An alteration in her current AED regimen is indicated. She has not tolerated other AED because of side effects. Although valproate is effective for control of partial seizures, it is not considered an alternative in a woman of childbearing age. R.H.'s CNS side effects (e.g., persistent drowsiness) with other AED would make many clinicians reluctant to consider medications such as phenobarbital or primidone as either alternatives or adjunctive agents to her current carbamazepine regimen. Use of one of the newer AED as adjunctive medication may be of value for R.H.

Many new AED marketed in the United States since 1993 for maintenance treatment of epilepsy include the following: felbamate (Felbatol), gabapentin (Neurontin), lamotrigine (Lamictal), levetiracetam (Keppra), oxcarbazepine (Trileptal), topiramate (Topamax), tiagabine (Gabitril), zonisamide (Zonegran) and pregabalin (Lyrica) (Table 54-6).^{70-81,82} Clinical trials for new AED are most often carried out in patients with partial seizures refractory to standard AED. Most of these newer or "second-generation" AED were initially FDA approved as "add-on" or adjunctive treatment in patients with partial seizures with or without secondary generalization. At the time of this writing, oxcarbazepine, felbamate, lamotrigine, and topiramate have FDA-approved monotherapy indications. Also, consensus is that some of these AED may be effective as broad-spectrum agents; for example, lamotrigine appears to be a useful treatment in absence seizures.

SIDE EFFECTS

Common side effects for the newer AED are described in Table 54-6. Most of the newer AED are less sedating than older medications such as phenobarbital or phenytoin. Felbamate causes insomnia and irritability in a significant proportion of treated patients. Other side effects that may be prominent during felbamate therapy include headaches, weight loss, and GI effects, such as nausea, vomiting, and anorexia. Felbamate's usefulness is seriously limited by its association with aplastic anemia and hepatic failure. Some cases of felbamate-associated aplastic anemia and hepatotoxicity were fatal. A conservative estimate of the occurrence rate is 1 case per 2,000 to 5,000 patients treated.⁸³ Too few cases of hepatic failure associated with felbamate therapy have been reported to allow conclusions to be drawn regarding characteristics of this potential adverse effect and risk factors for its development. Routine hematologic studies and LFT should be performed and patients and their families should be fully informed of the potential risks. Written consent is recommended. Patients must be educated about the symptoms of hematologic and hepatic toxicity. Because of the relationship between felbamate therapy

and aplastic anemia and hepatic failure, the place of felbamate in the treatment of epilepsy is uncertain.

Topiramate can cause cognitive disturbances, lethargy, and impaired mental concentration when given in large daily doses (especially in combination with other AED) or when the dosage is titrated too aggressively.⁸⁴ Topiramate has caused nephrolithiasis in approximately 1.5% of treated patients. This adverse effect is believed to be related to inhibition of carbonic anhydrase by topiramate, with resulting increased urinary pH and decreased citrate excretion. Topiramate can also cause dose-related weight loss.

Gabapentin and tiagabine have not been associated with serious side effects; gabapentin has caused weight gain and tiagabine has caused nonspecific dizziness relatively frequently.^{85,86}

Levetiracetam is generally well tolerated with the most common adverse events in clinical trials being asthenia, vertigo, flu-syndrome, headache, rhinitis, and somnolence. The most serious adverse effects are behavioral and are more common in patients with a history of behavioral problems.⁸⁷ Levetiracetam should be used with caution in patients with a history of suicidal ideations.

The most serious adverse effect associated with lamotrigine is skin rash. Rashes occur in approximately 10% of treated patients, usually in the first 8 weeks.⁸⁸ Rashes leading to hospitalization occurred in 1 of 300 adults and 1 of 100 children. Widespread, maculopapular rashes usually appear and may progress to erythema multiforme or toxic epidermal necrolysis. Lamotrigine-related rashes may resolve rapidly when lamotrigine is discontinued. Coadministration of valproate with lamotrigine may increase the likelihood of dermatologic reactions; it is partly for this reason that more conservative dosage titration and lower maintenance doses of lamotrigine are recommended for patients receiving concomitant valproate. Higher starting doses and more rapid dose escalation than those recommended by the manufacturer also increase the risk of skin rash.

Oxcarbazepine, a keto-derivative of carbamazepine, is essentially a prodrug for the monohydroxy active metabolite.⁸⁹ Oxcarbazepine probably causes less frequent, less severe adverse effects compared with carbamazepine, with the exception of hyponatremia. An exception is hyponatremia, which is more common with oxcarbazepine than with carbamazepine. Baseline and periodic serum sodium monitoring is indicated during oxcarbazepine therapy. The most commonly reported side effects of oxcarbazepine in clinical trials include ataxia, dizziness, fatigue, nausea, somnolence, and diplopia.

Zonisamide is a potent broad-spectrum AED.⁹⁰ Zonisamide is a sulfonamide derivative and thus is contraindicated in patients allergic to sulfonamides. The most commonly reported adverse events include ataxia, somnolence, agitation, and anorexia. Kidney stones have developed in 3% to 4% of patients, some of whom had a family history of nephrolithiasis.

Adverse effects of pregabalin are dose-dependent and usually occur within the first 2 weeks of treatment.⁸² Somnolence, dizziness, and ataxia are most common. Pregabalin also appears to be associated with a dose-related weight gain. It should not be discontinued rapidly.

PHARMACOKINETICS

The newer AED have somewhat different pharmacokinetic profiles from those of older agents. They also differ in their

Table 54-6 Drugs Used for the Treatment of Partial and Generalized Tonic-Clonic Seizures

| AED | Regimen | Adverse Effects | Comments |
|---|---|--|---|
| Carbamazepine (Tegretol, Tegretol XR, Carbatrol, Equetro) | Initial 200 mg BID (adults) or 100 mg BID (children) and weekly until therapeutic response or target serum concentrations. Usual maintenance doses 7–15 mg/kg/day in adults; 10–40 mg/kg/day in children. | Sedation, visual disturbance may limit dosage. Severe blood dyscrasias extremely rare. Mild leukopenia more common. Laboratory monitoring of little value. Hepatotoxicity rare. May cause SIADH. Long-term use may cause osteomalacia. | Usually little sedation and minimal interference with cognitive function or behavior. Preferred by most for partial or secondarily generalized seizures. Extended-release products may allow less frequent dosing with fewer peak serum concentration-related side effects. These products may also facilitate adherence. |
| Phenytoin (Dilantin, Phenytek) | Initiate at maintenance dose of 4–5 mg/kg/day (300–400 mg/day). Titrate on basis of clinical response and target serum concentration. 3–4 wk between dose ↑ recommended because of potentially slow accumulation. | Nystagmus, ataxia, sedation may limit dosage. Gum hyperplasia, hirsutism common. Long-term use may cause osteomalacia. Peripheral neuropathy, hypersensitivity with liver damage rare. | Clearance and half-life change with dose. Small ↑ in dose (30 mg capsule) recommended as dose reaches 300 or 400 mg/day. Cautious use of suspension; dose measurement and potential mixing difficulties. IM administration not recommended. Potential precipitation in IV solutions. Fosphenytoin (Cerebyx) recommended for IM and IV use. Due to faster administration rate, admixture compatibility and lower rate of injection site complications. |
| Valproate (Depakene, Depakote, Depakote-ER) | See Table 52-7. | — | — |
| Phenobarbital | Initial 1 mg/kg/day; titrate to therapeutic response. 2–3 wk between dose ↑ | Sedation (chronic), behavior disturbances common, especially in children. Possibly impairs learning and intellectual performance. Long-term use may cause osteomalacia | Considered outmoded for AED therapy in most patients; adverse effects outweigh benefits. IV use for refractory status epilepticus. |
| Pregabalin (Lyrica) | Initial 50 mg BID then titrate to therapeutic response with maximal daily dose at 600 mg/day in BID or TID frequency | Potential side effects include dizziness, blurred vision and weight gain. | At the time of this writing, this is the most recently approved AED. Its place in therapy is emerging. No significant interactions with other AED. Can be useful for patients with concomitant pain disorders. |
| Gabapentin (Neurontin) | Initial 300 mg/day with titration to 900–1,800 mg/day over 1–2 wk. Up to 2,400 mg/day or higher may be needed for some patients. Owing to short half-life, TID or QID dosing recommended. | Sedation, dizziness, and ataxia relatively common with initiation of therapy. Gabapentin therapy usually not associated with prominent side effects. | Primarily excreted unchanged by kidneys. No significant interactions with other AED or other drugs identified to date. Absorption may be dose dependent; fraction absorbed ↓ as size of individual dose ↑ |
| Lamotrigine (Lamictal) | <i>When added to enzyme inducers alone:</i> Initiate at 50 mg QD HS. May start at 50 mg BID. Daily dose can be ↑ by 50–100 mg Q 7–14 days. Usual maintenance doses of 400–500 mg/day. BID dosing may be necessary with enzyme inducer cotherapy. <i>When added to valproate alone:</i> Initiate at 25 mg QOD HS. Daily dose can be ↑ by 25 mg Q 14 days. Usual maintenance doses of 100–200 mg/day. <i>When added to valproate and enzyme inducers:</i> Initiate at 25 mg QOD HS. Daily dose can be ↑ by 25 mg Q 14 days. Usual daily doses of 100–200 mg/day. | Dizziness, diplopia, sedation, ataxia, and blurred vision can be common with initiation of therapy; limit speed of titration. Incidence of serious rash ranges from 0.8–8.0 per 1,000. | Significant ↑ in clearance of lamotrigine when coadministered with enzyme inducers. Significant ↓ in clearance when coadministered with valproate. Slow, gradual titration of dose may reduce risk of skin rash. Hormones can influence clearance. |

(continued)

Table 54-6 Drugs Used for the Treatment of Partial and Generalized Tonic-Clonic Seizures (Continued)

| AED | Regimen | Adverse Effects | Comments |
|------------------------------|---|---|--|
| Tiagabine (Gabitril) | Initial 4 mg/day. ↑ by 4 mg/day at 7 days. Then ↑ daily dose by 4–8 mg Q wk. Maximal recommended dose of 32 mg/day in adolescents or 56 mg/day in adults. BID to QID dosing recommended. | Drowsiness, nervousness, difficulty with concentration or attention, tremor. Nonspecific dizziness described by some patients. | Increased clearance when given with enzyme inducers. TID or QID doses probably needed. Potential for protein-binding displacement interactions with other highly protein bound drugs (e.g., valproate). Significance of protein-binding displacement not known. Substrate for CYP 3A. |
| Topiramate (Topamax) | Initial 50 mg HS. ↑ daily dose by 50 mg Q 7 days. 200–400 mg/day recommended as target dosage range. Larger daily doses associated with increased CNS side effects. BID dosing recommended. | Sedation, dizziness, difficulty concentrating, confusion. May be dose related. Possible weight loss. Weak carbonic anhydrase (CA) inhibitor; may cause or predispose to kidney stones; CA inhibition also possibly related to paresthesias in up to 15%. | Approximately 70% renal elimination. Phenytoin and carbamazepine may reduce topiramate plasma concentrations and potentially increase dosage requirements. Topiramate may cause small ↑ in phenytoin plasma concentration. Advise patients to drink plenty of fluids. May affect oral contraceptives above 200 mg/day. |
| Levetiracetam (Keppra) | Initial 250–500 mg BID. ↑ by 500–1,000 mg/day Q 2 wk. Usual maximal dose is 3,000 mg/day. Doses up to 4,000 mg/day have been used. BID dosing recommended. | Somnolence, dizziness, asthenia are commonly reported. Behavioral symptoms (agitation, emotional lability, hostility, depression, and depersonalization) reported. | No hepatic (CYP450 or UGT) metabolism. 66% excreted unchanged in urine. Less than 10% protein bound. No significant drug interactions reported. |
| Oxcarbazepine (Trileptal) | <i>Monotherapy:</i> Initial 300 mg BID. ↑ weekly up to 1,200 mg/day. Can go up to 2,400 mg/day. <i>Adjunctive therapy:</i> Initial 300 mg BID. ↑ weekly up to 1,200 mg/day. | Dizziness, somnolence, diplopia, nausea, and ataxia are commonly reported. Hyponatremia is described with the administration of this drug; most cases asymptomatic, more common in elderly. A 25% cross-sensitivity reported between oxcarbazepine and carbamazepine. | Parent is a prodrug; the monohydroxy derivative (MHD) is the active component. It is readily converted to MHD via omnipresent cytosolic enzymes. Lacks autoinduction properties. Many years of experience with this drug in Europe before U.S. approval. In doses above 1,200 mg/day, may affect oral contraceptives. |
| Zonisamide (Zonegran) | Initial 100 mg QD. ↑ by 100 mg/day Q 2 wks. General 200–400 mg/day; maximum 600 mg/day. | Somnolence, nausea, ataxia, dizziness, headache, and anorexia are common. Also reported are weight loss, and nephrolithiasis. Serious skin eruptions, oligohidrosis, and hyperthermia have also occurred. | Broad spectrum, long half-life. 35% of dose is excreted unchanged in the urine. Advise patients to drink plenty of fluids. Many years of experience with this drug in Korea and Japan before U.S. approval. |

AED, antiepileptic drugs; BID, twice daily; CNS, central nervous system; GI, gastrointestinal; HS, at bedtime; PE, phenytoin sodium equivalent; QD, every day; QID, four times daily; QOD, every other day; SIADH, syndrome of inappropriate antidiuretic hormone secretion; TID, three times daily.

tendency to interact with other AED. Gabapentin is excreted entirely by the kidneys as unchanged drug and is not significantly bound to plasma protein. Gabapentin has a relatively short half-life and should be administered three times daily.⁹¹

Topiramate has a half-life of approximately 20 hours, which allows twice-daily administration. It is only partially excreted by hepatic metabolism; approximately 70% of the drug is excreted unchanged by the kidneys. Topiramate is minimally protein bound (~10%–15%). When topiramate is coadministered with enzyme-inducing agents, such as carbamazepine, hepatic metabolism is increased and topiramate clearance is increased. This interaction may necessitate titration to somewhat higher doses when topiramate is used with enzyme-inducing drugs. Inconsistently, topiramate can cause a small and often non-significant decrease in phenytoin plasma concentrations.

Tiagabine has a relatively short half-life (4–7 hours). It should be administered at least twice daily.⁹² Concurrently administered enzyme-inducing AED may reduce tiagabine's half-life to 2 to 3 hours and necessitate use of larger daily doses and, possibly, more frequent dosing intervals. Tiagabine is highly protein bound (96%), and it is displaced from protein-binding sites by valproate, salicylate, and naproxen. The clinical significance of these protein-binding interactions is unknown.

Felbamate undergoes both hepatic metabolism and renal excretion as unchanged drug. Phenytoin and carbamazepine induce the hepatic metabolism of felbamate and lower steady-state felbamate concentrations.⁷⁰ Interactions between felbamate and other AED may make therapeutic monitoring difficult. Felbamate reduces the clearance of phenytoin, valproate, and probably phenobarbital; it also reduces the clearance of carbamazepine-10,11-epoxide (CBZ-E) while

apparently increasing the conversion of carbamazepine to the epoxide metabolite.^{93,94} Clinically, this latter effect may create a somewhat paradoxical situation: patients may experience symptoms of carbamazepine intoxication (including increased seizure activity)⁹⁵ with carbamazepine serum concentrations lower than those found before the addition of felbamate. CBZ-E serum concentrations are often elevated in these situations.

Lamotrigine is primarily eliminated by hepatic glucuronidation and excretion of metabolites in the urine. Other AED, such as carbamazepine and phenytoin, induce lamotrigine's hepatic metabolism. When lamotrigine is coadministered with enzyme-inducing drugs, its half-life decreases from approximately 24 hours to 15 hours. Valproate inhibits lamotrigine metabolism, causing increases in half-life and serum concentrations.^{96,97} Patients treated with both lamotrigine and carbamazepine may experience more nausea, drowsiness, and ataxia. Although this interaction has been attributed to lamotrigine-induced increases in serum concentrations of CBZ-E in some patients,⁹⁸ lamotrigine does not consistently produce increases in this metabolite. It appears more likely that this interaction represents a pharmacodynamic interaction between lamotrigine and carbamazepine.⁹⁹

Levetiracetam has a short half-life and is eliminated primarily by renal mechanisms. Dosage reductions are warranted for patients with renal impairment (creatinine clearance <80 mL/minute). The drug has a low potential for interactions with other drugs.¹⁰⁰

Zonisamide has a long half-life and low protein binding. It is eliminated by both liver metabolism and renal excretion. The average half-life of zonisamide is 63 hours, but there is wide interpatient variation. Serum levels of zonisamide are reduced by enzyme-inducing AED.⁹⁰

Oxcarbazepine is a prodrug that is converted to the monohydroxy derivative (MHD), its primary active metabolite. It may cause less hepatic enzyme induction than carbamazepine and may therefore be less likely to interact with other medications. Oxcarbazepine, however, does increase the metabolism of oral contraceptive hormones.¹⁰¹ Because oxcarbazepine probably has a similar mechanism of action to that of carbamazepine, it is unlikely that it would offer significant benefits to R.H. because she has not responded to maximal tolerated doses of carbamazepine.⁸⁹

Pregabalin is excreted entirely by the kidneys as unchanged drug and is not significantly bound to serum proteins. Unlike gabapentin, pregabalin can be administered two or three times daily.⁸²

On the basis of efficacy and side effect characteristics, gabapentin, lamotrigine, topiramate, tiagabine, levetiracetam, zonisamide, or pregabalin could be considered for use as adjunctive therapy for R.H. In young, active patients such as R.H., sedation might prove to be a problem; however, it is not clear that any of these drugs predictably causes more initial or long-term sedation. The short half-lives of gabapentin and tiagabine and the associated need for R.H. to take several doses during the day might decrease her adherence. Therefore, topiramate, lamotrigine, levetiracetam, zonisamide, or pregabalin would be reasonable choices on the basis of convenience.

POTENTIAL THERAPIES

Other AED that may become available in the near future include brivaracetam, remacemide, rufinamide, fluorofelbamate,

and harkoseride.¹⁰² These drugs may become useful as alternatives or adjuncts to established and newer medications in the future.

With advancing technology and knowledge about genes and brain networks, future treatment strategies should move from controlling symptoms of epilepsy with AED to prevention and cure.¹⁰³ For AED-resistant epilepsy, much research is examining the role of multidrug transporters (e.g., P-glycoprotein) at the blood-brain barrier. These proteins may act as a defense mechanism by limiting the accumulation of AED in the brain.¹⁰⁴ Although it has not yet had an impact on the clinical care of patients with epilepsy, pharmacogenetics of AED therapy is continually advancing.¹⁰⁵

Lamotrigine Therapy

INITIATION AND DOSAGE TITRATION

8. R.H. is to be started on lamotrigine as adjunctive therapy to her carbamazepine. Outline a treatment plan for initiating and monitoring therapy for R.H. What should R.H. and her family be told about this medication and how to use it?

Lamotrigine therapy should be initiated in R.H. with slow upward dosage titration to minimize early sedative effects and reduce the likelihood of skin rash. An initial dosage of 50 mg/day given at bedtime is recommended; the daily dose can be increased by 50 mg every 1 to 2 weeks. Because R.H. is currently receiving carbamazepine, induction of liver enzymes is likely to increase her dosage requirements for lamotrigine and allow a less conservative dosage titration. A twice-daily schedule is recommended for maintenance therapy. Usual maintenance dosages of lamotrigine are approximately 300 to 500 mg/day, although there is some experience with dosages of up to 700 mg/day. A patient's ability to tolerate this medication ultimately determines dosage limitations. Onset of side effects (e.g., nausea, diplopia, ataxia, and dizziness) may prevent further dosage increases. Lower initial dosages of lamotrigine (25 mg every other day) with more conservative increases (i.e., by 25 mg/day every 2 weeks) have been recommended for patients who also are receiving valproate. Valproate's inhibition of lamotrigine metabolism results in significantly lower lamotrigine dosage requirements; side effects appear to be much more common with lamotrigine doses >200 mg when it is administered with valproate.

R.H. should be told that she may feel drowsy and possibly experience headache and upset stomach, but that these side effects usually disappear with ongoing therapy. She should contact her physician or other health care professional if severe side effects occur that make it difficult to take the medication; this is especially important if she develops a skin rash.

SIDE EFFECTS AND POSSIBLE INTERACTION WITH CARBAMAZEPINE

9. Two days after her dosage of lamotrigine was increased to 300 mg/day (12 weeks after beginning therapy), R.H. noticed that her vision was blurring; she also complained of feeling dizzy and having difficulty maintaining her balance. Previously, she had experienced only mild, occasional nausea. She had continued to experience seizures at approximately the same frequency she had before the initiation of lamotrigine. Her physician had encouraged her to continue taking the medication and explained that it would take time to increase the dose to possibly effective levels. Her

current carbamazepine serum concentration is essentially unchanged when compared with when she was taking it in monotherapy. Do these new side effects represent treatment failure with lamotrigine? If not, how might these new side effects be managed?

R.H.'s seizure disorder may be unresponsive to lamotrigine therapy, and her side effects may limit further dosage increases. Her current side effects might represent carbamazepine intoxication, lamotrigine side effects, or an interaction between these two medications. Because R.H. tolerated the same carbamazepine dose previously, carbamazepine "intoxication" seems a less likely cause. Assessing the role of lamotrigine as a single agent is difficult. Obtaining a lamotrigine serum concentration to aid in assessing her adverse effects is not likely to be helpful. A usual "therapeutic range" for lamotrigine serum concentrations has not been established. Clinical studies have failed to demonstrate a significant correlation between lamotrigine serum concentrations and either therapeutic or adverse responses.^{106,107} Her symptoms may also be related to an apparent pharmacodynamic interaction between lamotrigine and carbamazepine reported by some authors.⁹⁹ The effects experienced by some patients taking both drugs can be relieved by reducing the carbamazepine dosage. Subsequently, it may be possible to further increase her lamotrigine dosage to improve seizure control. This situation also should be assessed and possibly managed by empirically decreasing R.H.'s carbamazepine dosage by 200 to 400 mg/day and observing the effect on her current symptoms.

Levetiracetam Therapy

INITIATION AND DOSAGE TITRATION

10. R.H.'s carbamazepine dosage was reduced to 1,400 mg/day. After 5 days, her symptoms persisted and her seizure frequency appeared to be increasing. The clinician decides to abandon lamotrigine therapy and institute treatment with levetiracetam. Recommend a plan for initiating R.H.'s levetiracetam treatment.

R.H. previously tolerated and had a better therapeutic response to a higher carbamazepine dose. Therefore, the dosage of carbamazepine should be returned to 1,800 mg/day before levetiracetam therapy is initiated. Little specific information is available to help determine how lamotrigine can be safely discontinued. As a general rule, rapid discontinuation of AED is not recommended in other than emergency situations. Therefore, immediate reduction of R.H.'s lamotrigine dosage to 200 mg/day would seem reasonable. This dosage could then be reduced by 50 to 100 mg every week until lamotrigine was discontinued.

Levetiracetam treatment should be instituted immediately for R.H. because of her continuing seizures. Levetiracetam does not interact with other AED. Therefore, discontinuing lamotrigine during initiation of levetiracetam should not create difficulties in assessing R.H.'s response. Levetiracetam should be initiated at a dosage of 250 to 500 mg two times daily.^{81,100} Although the manufacturer recommends initiating treatment at 500 mg twice daily, patients may better tolerate lower initial doses and more gradual titration.¹⁰⁰ R.H.'s daily levetiracetam dose can be increased by 500 to 1,000 mg every 2 or 3 weeks, according to her tolerance of side effects and her change in seizure frequency. Although the drug reaches steady state quickly, allowing at least 2 weeks for observation before dosage increases may improve patient tolerability and allow for a more

thorough evaluation of therapeutic response. At present, the relationship between serum concentrations of levetiracetam and therapeutic response or symptoms of intoxication is not well defined. Therefore, R.H.'s dose should be titrated to the maximal tolerated amount required to control her seizures. There is limited published experience with levetiracetam dosages as high as 4,000 mg/day.

PATIENT EDUCATION

R.H. should be informed that with levetiracetam she may experience side effects similar to those she had with lamotrigine, but that they are less likely and should be temporary. Much reassurance and encouragement may need to be given along with this information to help ensure that R.H. adheres to her treatment regimen. Many patients become discouraged when multiple trials of medication are necessary and side effects are prominent. They may express feelings of being "guinea pigs" and may become uncooperative with the therapeutic plan.

Phenytoin Therapy

INITIATION AND DOSAGE

11. J.N., an 18-year-old, 88-kg male college student, was diagnosed with epilepsy. He experiences generalized tonic-clonic seizures that last 2 minutes approximately three times monthly. J.N. describes a "churning" feeling in his abdomen before his seizures; this is followed by involuntary right-sided jerking of his upper extremities, during which J.N. is awake and aware of his surroundings. His seizures have been observed and described well both by his family and by nursing staff who cared for him during a brief hospitalization following his first seizure. An EEG showed diffuse slowing with focal epileptiform discharges in the left temporal area; it was interpreted as abnormal. No correctable cause for his seizure disorder was identified despite a thorough workup. He has no other medical conditions and takes no routine medications. He was treated initially with carbamazepine up to 600 mg/day. He could not tolerate the medication because of nausea and diplopia despite relatively low doses. His physician has elected to implement a therapeutic trial of phenytoin for J.N. Recommend an initial dosage. What information should be provided to J.N. about his new medication?

Selecting a nontoxic, therapeutic dose of any AED is difficult without having information about the drug's disposition in the individual patient (i.e., prior dosages and clinical response). Although "average" dosages and resulting serum concentrations for phenytoin often are quoted, interpatient variability is significant. An initial phenytoin dosage of 400 mg/day would be appropriate for J.N. This represents a dosage of approximately 4.5 mg/kg/day. To avoid patient nonadherence because of transient side effects, J.N. could be instructed to take 100 mg in the morning and 100 mg 12 hours later for 1 week. The following week he could take 100 mg in the morning and 200 mg 12 hours later. If he can tolerate this regimen, he could then take 200 mg every 12 hours.

PATIENT EDUCATION

In addition to the name and strength of the medication and instructions for when and how it should be taken, J.N. should be informed that he may experience initial mild sedation from phenytoin. He should be cautioned that symptoms such as blurred or double vision, dysarthria ("thick" tongue), dizziness,

or staggering may indicate that his dosage is too high; he should be instructed to notify his physician, pharmacist, or other health care professional of these symptoms. It is also a good idea to inform patients, at the beginning of therapy, that adjustments of medication dosage and possibly medication changes may be necessary before the medication regimen is stabilized.

ACCUMULATION PHARMACOKINETICS

12. What are the characteristics of phenytoin accumulation pharmacokinetics?

Phenytoin exhibits dose-dependent (Michaelis-Menten or capacity-limited) pharmacokinetics; therefore, the usual pharmacokinetic concepts of “clearance” and “half-life” are meaningless. The apparent half-life of phenytoin changes with the dose and serum concentration. Thus, the time required to reach a new steady state after dose alteration is difficult to predict because it depends on the dose itself and the patient’s pharmacokinetic parameters, V_{\max} and K_m .¹⁰⁸ V_{\max} is a kinetic constant representing the maximal rate of phenytoin elimination from the body. K_m is the Michaelis constant, the serum concentration at which the rate of elimination is 50% of V_{\max} . Values for these parameters vary widely among patients; as a result, patterns of phenytoin accumulation and the time required to achieve steady state also are variable.

Many clinicians assume that phenytoin’s apparent half-life is approximately 24 hours, and they wait 5 to 7 days before assessing the patient’s clinical response and measuring serum phenytoin concentrations. Both clinical studies¹⁰⁹ and model simulations¹¹⁰ using observed values for K_m and V_{\max} indicate that up to 30 days may be required for serum concentrations to reach 90% of the steady state resulting from a dosage of 4 mg/kg/day. Occasionally, such a dose may exceed a patient’s V_{\max} ; the result is extremely high serum phenytoin concentrations, with probable intoxication. If doses sufficient to produce steady-state serum concentrations of 10 to 15 mcg/mL are given, 5 to 30 days may be required to achieve 90% of these concentrations.^{108,111} It is important not assume that steady state has been reached unless widely spaced, serial serum concentrations indicate that accumulation has ceased. Alterations in phenytoin dosage before steady state has been reached can result in significant fluctuations in serum concentrations and the patient’s clinical status. Such situations occur frequently and result in unnecessary confusion and expense. As always, serum concentrations in J.N. must be interpreted in the context of his clinical response.

ORAL LOADING DOSES

13. Would a loading dose be of value for J.N. to reduce the potential delay in achieving a “therapeutic” serum concentration of phenytoin? How large a loading dose should be used, and how should it be administered?

Administration of a loading dose would allow therapeutic serum concentrations of phenytoin to be achieved more rapidly, and more rapid control of J.N.’s seizure activity also would result. Because he is active and pursuing an education, more rapid seizure control may be a significant therapeutic goal. Studies of oral phenytoin loading indicate that doses of approximately 18 mg/kg will achieve serum concentrations approaching the usual therapeutic range after approximately 8 hours in most

patients.^{112,113} Oral loading doses appear to be better tolerated when administered in divided doses over 4 or more hours. GI upset appears to be the most common side effect related to this procedure. Cardiac side effects (e.g., sinus bradycardia, shortened PR intervals) have been observed rarely; they were not related to serum phenytoin concentrations, and their significance is uncertain.¹¹⁰

Oral phenytoin absorption after large doses is unpredictably slow, and it may be less complete than after smaller doses.¹¹⁴ Although potentially therapeutic serum concentrations usually are seen after approximately 8 hours, peak concentrations may not occur for up to 60 hours after administration of large single doses.^{108,110,114} Record et al.¹¹⁵ estimated that 18 mg/kg given in three doses over 6 hours would produce serum concentrations of 13 to 20 mcg/mL 12 hours after completion of loading. No rigorous clinical evaluations of this recommendation are available, although these suggested doses compare well with intravenous (IV) loading regimens. IV loading doses of 18 mg/kg will maintain phenytoin serum concentrations >10 mcg/mL for 24 hours.¹¹⁶

Although administration of an oral loading dose to J.N. is pharmacokinetically sound and has certain therapeutic advantages, practical difficulties in monitoring an ambulatory patient for potential complications may indicate caution in recommending such a procedure. In addition, because J.N. had difficulty tolerating carbamazepine, it may be difficult to justify exposing him to the potential neurologic side effects of a phenytoin loading dose. A more practical approach with a lower risk of complications involves giving one and a half to two times the prescribed maintenance dose for the first 2 or 3 days of treatment. J.N. should be checked for dose-related adverse effects of phenytoin on the day after completion of such a “miniloading” and routinely thereafter.

PHENYTOIN INTOXICATION

14. J.N. was given phenytoin 200 mg AM and 400 mg PM for 3 days. No seizures had occurred, and J.N. experienced no side effects other than mild morning sedation. He was then instructed to take 200 mg every 12 hours. One week later, mild lateral gaze nystagmus was noted, but J.N. had no subjective complaints and remained seizure free. After 3 weeks, J.N. complained of double vision and feeling “drunk” and “unsteady.” Significant nystagmus was present. How should J.N.’s phenytoin dosage be altered?

J.N.’s signs and symptoms indicate mild phenytoin intoxication. Dosage reduction is indicated. Reducing J.N.’s dosage to 360 or 330 mg/day would be reasonable. This dosage reduction can be accomplished using 30-mg phenytoin capsules along with the usual 100-mg capsules. A larger reduction may result in a loss of seizure control. Many clinicians also would have J.N. omit one day’s dose of phenytoin before beginning the new maintenance dosage. This would accelerate the decline in phenytoin serum levels. Following this dosage change, clinical response should be monitored closely. The new maintenance dose may still be excessive; if J.N.’s V_{\max} for phenytoin is low. If this were the case, continued accumulation of drug would occur despite the dosage reduction.¹⁰⁸

INTRAMUSCULAR PHENYTOIN AND FOSPHENYTOIN (PHENYTOIN PRODRUG)

15. S.D. is a 24-year-old, male state hospital patient with a history of complex partial and secondarily generalized tonic-clonic

seizures. Within the past year, his phenytoin formulation was switched from Dilantin Kapseals to phenytoin suspension because S.D. was suspected of “cheeking” his medicines and not swallowing the capsules properly. He has had no seizures in the past 3 months on 275 mg/day of phenytoin suspension. S.D. has now been transferred to the acute medical unit following a 2-day history of anorexia, nausea, occasional vomiting, and abdominal pain accompanied by diarrhea. He is now “nothing per os” (NPO). Intramuscular (IM) fosphenytoin, 275 mg (phenytoin sodium equivalents [PE]) per day, has been ordered. Discuss the use of IM fosphenytoin, and devise a dosage regimen for S.D.

S.D. is a candidate for parenteral administration of his AED. If placement of an IV line for fluid administration is not planned, then IM administration is probably an acceptable approach to treatment. Previously, sodium phenytoin (Dilantin) injection was the only parenteral preparation available for replacement of oral phenytoin. Fosphenytoin sodium (Cerebyx) injection is available, and Dilantin injection has been discontinued. Preparations of sodium phenytoin injection are still available. IM administration of sodium phenytoin is not recommended. Injectable phenytoin is highly alkaline (pH 12) and extremely irritating to tissue. Following IM injection, the drug may precipitate at the injection site because of the change in pH. As a result, phenytoin crystals form a repository or depot from which the drug is slowly absorbed.^{117–119} Often injection site discomfort is noted, although severe muscle damage does not seem to occur.¹¹⁹

Fosphenytoin, a phosphate ester prodrug of phenytoin, is highly water soluble. Its solubility allows this preparation to be administered parenterally without the need for solubilization using propylene glycol or the adjustment of pH to nonphysiologic levels. Therefore, fosphenytoin may be administered either IM or IV with less risk of tissue damage and venous irritation than with parenteral administration of phenytoin.^{120–122} (See later discussion of IV administration of phenytoin and fosphenytoin.) After administration, the prodrug is rapidly absorbed and converted to phenytoin by phosphatase enzymes. Ultimately, the bioavailability of phenytoin from IM fosphenytoin administration is 100%.

Fosphenytoin is available as a solution containing 50 mg PE/mL, where PE equals phenytoin sodium equivalents. By labeling fosphenytoin this way, no dosing adjustments are necessary when converting from phenytoin sodium to fosphenytoin or vice versa. Although the prescriber ordered 275 mg PE, S.D. may be underdosed. His dosage of phenytoin suspension is providing the equivalent of 300 mg/day of sodium phenytoin. Phenytoin suspension and chewable tablets contain free acid, whereas capsules contain sodium phenytoin. Therefore, phenytoin capsule products contain only 92% of the labeled content as phenytoin acid (i.e., a 100-mg sodium phenytoin capsule contains only 92 mg of phenytoin acid). He should receive a 300-mg dose of fosphenytoin daily to fully replace his current dosage of phenytoin suspension.¹²²

Assuming that S.D. will be given 300 mg PE of fosphenytoin daily, he will require a total of 6 mL of this injection given IM. This medication is well tolerated when it is given IM, and S.D.’s full daily dose can probably be given in a single injection site without causing excessive discomfort. Some clinicians report administering IM injections of fosphenytoin as large as 20 mL in a single site without adverse consequences or serious

discomfort.¹²³ It is also possible to divide his daily dosage into two injections given in two different sites, although many patients prefer to receive fewer injections.

ADVERSE EFFECTS

16. M.N., a 10-year-old boy receiving 150 mg/day of phenytoin as chewable tablets, is to be fitted with orthodontic braces. He exhibits moderate gingival hyperplasia resulting in difficulty maintaining oral hygiene and halitosis. Discuss phenytoin-related gingival hyperplasia and management techniques that may be helpful for M.N.

Gingival Hyperplasia

Gum hyperplasia related to phenytoin is common and troublesome. Prevalence is estimated at up to 90%,¹²⁴ depending on the rating system used and the degree of gum change rated as hyperplastic. A realistic prevalence estimate is probably 40% to 50% of treated patients.¹²⁵ Prevalence and incidence rates, however, are misleading because the occurrence and severity of hyperplasia are related to the dose and serum concentration of phenytoin.^{125,126} Gingival hyperplasia is of obvious cosmetic importance. Also, as in M.N., formation of pockets of tissue leads to difficulties with oral hygiene, and severe halitosis may result.

The mechanism of phenytoin-induced gingival hyperplasia is not well understood. The drug is excreted in saliva and saliva phenytoin concentrations and hyperplasia are correlated; however, this correlation may simply reflect higher serum concentrations producing a greater pharmacologic effect. Phenytoin may stimulate gingival mast cells to release heparin and other mediators. These mediators may encourage the synthesis of excessive amounts of new connective tissue by fibroblasts. Local irritation caused by dental plaque and food particles may further stimulate this process. Some patients may be predisposed to gum hyperplasia because they accumulate higher concentrations of phenytoin in gum tissue.^{125,126}

The three approaches to the treatment of existing hyperplasia¹²⁶ are (a) dosage reduction or replacement of phenytoin with an alternative AED, if possible, will permit partial or complete reversal of hyperplasia; (b) surgical gingivectomy will correct the problem temporarily, but hyperplasia eventually recurs; and (c) oral physiotherapy (periodontal treatment) eliminates local irritants and maintains oral hygiene. Because M.N. is to be fitted with braces, oral hygiene will be further complicated. Some form of treatment for existing hyperplasia and prevention of further tissue enlargement is important. Assuming that phenytoin is producing adequate seizure control, a combination of gingivectomy and follow-up periodontal treatment may be the best approach.

Theoretically, the use of chewable phenytoin tablets in M.N. may aggravate hyperplasia. Exposure of the gingiva to high localized concentrations of phenytoin may result from braces holding tablet fragments in close physical contact with gum tissue. The significance of this relationship, however, is questionable. If M.N. can swallow capsules, a change to this dosage form may be beneficial and is usually less expensive. The most appropriate dosage of phenytoin sodium capsules for M.N. would be 160 mg/day. If chewable tablets are used, having M.N. rinse and swallow after each dose may eliminate problems. Use of phenytoin suspension also may be a useful option.

Drug particles, however, may still be retained by the braces, and maintenance of uniform dosage may be more difficult.

Oral hygiene programs appear to reduce the degree and severity of gingival hyperplasia when they are initiated before phenytoin therapy is started.¹²⁶ Patients who are beginning phenytoin therapy should be educated about the role of oral hygiene in diminishing this side effect. The use of dental floss, gum stimulators, and Water Pik-type appliances may be beneficial adjuncts to other oral hygiene techniques.

17. G.R. is a 53-year-old man with primary generalized epilepsy characterized by occasional tonic-clonic seizures. He was started on phenytoin when he was 25 years of age. His dosage of phenytoin was recently reduced from 400 mg/day to 360 mg/day because of symptoms of AED intoxication. Mild confusion, occasional diplopia, ataxia, and lateral gaze nystagmus were present at the 400 mg/day dose. After the dose was reduced to 360 mg/day, his confusion and diplopia decreased significantly. The neurologic evaluation at the lower dose was within normal limits. No seizures occurred during the following 8 weeks. He continued to complain of being mildly “unsteady” on his feet. Because G.R.’s seizures are apparently under complete control, is there any problem maintaining him on this dose of phenytoin?

Neurotoxicity

Patients chronically maintained on intoxicating doses of phenytoin appear to be at some risk for developing irreversible cerebellar damage or peripheral neuropathy. Cerebellar degeneration, resulting in symptoms such as dysarthria, ataxic gait, intention tremor, and muscular hypotonia, is of particular concern; this complication has been observed following episodes of acute phenytoin intoxication.^{127,128} Generalized seizures also can cause cerebellar degeneration secondary to hypoxia. For this reason, the relative importance of phenytoin in the development of this condition is controversial. Nevertheless, cerebellar degeneration has been reported in several patients without hypoxic seizures.^{128,129}

Symptomatic phenytoin-related peripheral neuropathy is rare, although electrophysiologic evidence of impaired neuronal conduction may be found in many patients.^{127,130} Symptomatic patients may complain of paresthesias, muscle weakness, and occasional muscle wasting. Knee and ankle tendon reflexes are absent in 18% of patients on long-term phenytoin therapy; the upper limbs are affected rarely. Although areflexia may be irreversible,¹³¹ electrophysiologic abnormalities may be closely related to excessive serum phenytoin concentrations and are reversible following dosage reduction or discontinuation.¹²⁹

In G.R., the general discomfort of mild phenytoin intoxication and the potential for producing cerebellar degeneration necessitates a therapy alteration. The phenytoin dose should be reduced to 330 mg/day because it may produce adequate seizure control without toxic symptoms. Should seizures recur at this lower dosage, it may be advisable to consider an alternative AED.

ANTIPILEPTIC DRUG IMPACT ON BONE

Some AED have a negative impact on bone density.¹³² Although bone disorders are more common in women, the negative impact of AED on bone is not gender specific. Longer duration of AED therapy and exposure to multiple AED are

thought to be predictors of bone loss. The enzyme-inducing AED (carbamazepine, phenytoin, and phenobarbital) have been associated with bone loss and an increased risk for fracture. Valproate, although not an enzyme inducer, is associated with decreased bone mineral density in children.¹³³ Less is known about the impact of the second-generation AED on bone mineral metabolism, although a recent report suggests lamotrigine has no effect.¹³⁴ Because of the length of phenytoin use, G.R. is at risk. His bone health should be further evaluated by his primary care physician. Minimally, oral calcium and vitamin D supplementation should be implemented. Depending on the outcome of evaluation, a therapy alteration from phenytoin to an AED with less or no effect on bone should be considered.

NEW ONSET SEIZURES IN THE ELDERLY

18. J.R., a 74-year-old man with newly diagnosed partial seizures, is referred to the neurology clinic for evaluation and treatment. The etiology of his new-onset seizures is presumed to be a recent cerebral infarct. His seizures are complex partial seizures where he “blacks out” and loses track of time. He has no history of secondarily generalized tonic-clonic convulsions. He has had three seizures in the last 4 weeks. His last seizure occurred 1 week ago, which resulted in a fall down a flight of stairs. His wife reports that he is more likely to have a seizure if he gets “overtired” or “stressed-out”. He is also being treated for hypertension and diabetes. What options are available for the treatment of J.R.’s epilepsy?

In general, head-to-head comparative studies of AED are rare in patients with epilepsy. Even fewer studies address the comparative efficacy of AED in elderly patients. Two studies, in particular, are important when discussing AED treatment in elderly persons with epilepsy.

Brodie et al.¹³⁵ compared lamotrigine (n = 102) with carbamazepine (n = 48) in elderly patients with newly diagnosed epilepsy via a double-blind, randomized, parallel study. Discontinuation rates because of adverse effects (the primary outcome parameter) were higher for carbamazepine (42%) than for lamotrigine (18%). Using time to first seizure as a measure of efficacy, no differences were found between the two AED, thus allowing the authors to suggest that lamotrigine is “acceptable” as initial treatment in elderly patients with newly diagnosed epilepsy.

More recently, in a randomized, parallel study, carbamazepine (600 mg/day), gabapentin (1,500 mg/day), and lamotrigine (150 mg/day) were compared for efficacy and tolerability in 593 patients >55 years of age (mean age = 72 years).¹³⁶ Although efficacy was similar in all three groups, study termination for adverse events varied between treatment groups. Carbamazepine had the highest termination rate (31%), followed by gabapentin (21.6%), and then lamotrigine (12.1%) ($p = 0.001$). The authors concluded that lamotrigine and gabapentin should be considered as initial therapy for new-onset seizures in older patients with epilepsy.

Evaluating the results from these two studies in elderly patients with epilepsy alone, it would suggest that either gabapentin or lamotrigine would be very good choices for initial treatment of J.R.’s epilepsy. It is noteworthy that neither AED is FDA approved for newly diagnosed epilepsy.

It is also important to consider drug-interaction profile, dosing frequency, and drug costs when selecting AED therapy. Generally, elderly persons take more medicines than younger individuals. For example, the average number of concomitant medications in the study by Rowan et al.¹³⁶ was seven. In J.R.'s case, he is likely to be taking other medicines for diabetes and hypertension. Neither gabapentin, nor lamotrigine cause drug–drug interactions, although lamotrigine is influenced more so than gabapentin by other medicines. When evaluating dosing frequency, gabapentin will probably have to be dosed more frequently than lamotrigine. From a cost perspective, gabapentin is currently available as a generic product; lamotrigine is soon to follow.

ADVERSE EFFECTS

Interestingly, in both of the comparative studies cited above, minimal differences were found in efficacy, but the newer AED showed better tolerability than the older AED. In general, elderly patients not only respond to AED at lower doses and concentrations, but they also develop toxicity symptoms at lower doses than do younger patients. Age-related declines in renal and hepatic function may account for those observations. The pharmacokinetics of most AED have been studied in the elderly and a decrease in clearance is noted as compared with the young.¹³⁷

The impact of AED on cognition is an important issue for all patients with epilepsy and perhaps it is an even greater issue in elderly patients. Martin et al.¹³⁸ evaluated cognitive functioning using a number of standardized measures in 25 older adults with epilepsy (>60 years of age) and compared them with healthy older adults (n = 27). The patients with epilepsy fared worse than their healthy counterparts, especially if they were receiving AED polytherapy. Piazzini et al.¹³⁹ found very similar results in 40 patients >60 years of age compared with 40 controls. Additionally, Bambara et al.¹⁴⁰ reported that 20 older adults (>60 years) with epilepsy demonstrated deficits in their ability to provide informed consent for medical treatment. These authors expressed concern over their patients' medical decision-making abilities.

As evidenced from the study by Rowan et al.¹³⁶ mentioned above, CNS toxicities such as dizziness, unsteady gait, and ataxia are common adverse effects of AED. These symptoms may increase the risk of falls, which are of particular concern in light of the potential negative effects of AED on bone mineral density. In an effort to prospectively compare the impact of AED on balance, Fife et al.¹⁴¹ reported their findings on three AED in patients with epilepsy >50 years of age. Ten patients each on monotherapy with carbamazepine, gabapentin, or lamotrigine underwent extensive testing in this cross-sectional study. The finding was that older epilepsy patients on lamotrigine monotherapy exhibited better scores on select measures of balance as compared with carbamazepine. Although not statistically significant, perhaps owing to a small sample size, gabapentin showed a trend toward better balance scores than carbamazepine.

J.R. and his family should be informed about the benefits and risks associated with each AED and they should also be incorporated into the decision-making. AED therapy in the elderly should follow the “start low and go slow” adage and elderly patients should be monitored for both efficacy (via a

seizure calendar) and toxicity (reporting any intolerable side effects).

Absence Seizures

Choice of Medication and Initiation of Ethosuximide Therapy

19. T.D., a 7-year-old, 25-kg girl, is reported by her teacher to have three or four episodes of “staring” daily. Each spell lasts 5 to 10 seconds. Although no convulsive movements occur, her eyelids appear to flutter during the episodes. She is fully alert afterward. T.D.'s school performance is somewhat below average, despite an IQ of 125. An EEG shows 3/second spike-wave activity. Typical absence epilepsy is diagnosed. Physical examination and laboratory evaluation findings are normal, and no other positive findings are evident on the neurologic examination. What drug should be prescribed for T.D., and how should therapy with this drug be initiated?

Ethosuximide (Zarontin) and valproate are commonly used to treat absence epilepsy in the United States. Both drugs are equally effective. Lamotrigine is also effective and has been recommended as an initial monotherapy agent for treatment of absence epilepsy, although it is not FDA approved for this indication^{17,142–144} (Tables 54-2 and 54-7). Valproate was more efficacious than lamotrigine for treatment of idiopathic generalized seizures (including absence) in the SANAD (Standard and New Antiepileptic Drugs) trial.¹⁴⁵ Trimethadione (Tridione), which is less effective than other agents, is associated with a high rate of neurologic side effects and a risk of hematologic toxicity.¹⁴⁶ At present, most authorities consider ethosuximide the drug of first choice for treatment of absence seizures. In comparison to ethosuximide, valproate is more likely to cause significant nausea and initial drowsiness, and it is more likely to interact with other AED. Valproate usually is reserved for patients whose absence seizures do not respond to ethosuximide.¹⁴⁷ Clonazepam (Klonopin), a benzodiazepine, often is effective for control of absence seizures. Therapy with this drug is limited by prominent CNS side effects (sedation, ataxia, and mood changes) and development of tolerance to its antiepileptic effect after long-term use.¹⁴⁸ Most authorities consider clonazepam a fourth-choice drug for treatment of absence seizures.

T.D. should be started on ethosuximide at a dosage of 15 to 20 mg/kg/day or 250 mg twice daily. The daily dose can be increased by 250 mg every 10 to 14 days as necessary to control seizures. Because the average half-life of ethosuximide in children is ~30 hours, a delay of 10 to 14 days between dosage increments allows ~7 days for achievement of steady state and 7 days for assessment of response.²⁷

PATIENT OR CAREGIVER EDUCATION

Educating T.D. and her parents regarding the importance of regular drug administration is extremely helpful in ensuring successful therapy. Noncompliance is common in patients taking AED, and rapid discontinuation of these drugs (often secondary to noncompliance) may precipitate status epilepticus. The concept that medication controls rather than cures the seizure disorder should be strongly reinforced. It is also critical to inform both the parents and T.D. that a therapeutic response may not occur immediately and that dosage adjustments may

Table 54-7 Common Drugs for the Treatment of Absence Seizures

| AED | Regimen | Adverse Effects | Comments |
|--|---|--|---|
| Valproate (Depakene, Depakote, Depakote ER) | Initial 5–10 mg/kg/day (sprinkle caps or syrup); then ↑ by 5–10 mg/kg/day weekly to therapeutic effect or target serum concentration. Manufacturer's recommended usual maximal dose of 60 mg/kg/day often must be exceeded clinically (especially for patients receiving enzyme-inducing AED) to achieve optimal clinical results. QD dosing recommended for extended-release (ER) product; doses should be 8%–20% higher than non-ER products. | GI upset, hair loss, appetite stimulation, and weight gain common. Tremor may occur. Serious hepatotoxicity extremely rare with monotherapy and in patients >2 yr. | Enteric-coated tablets or capsules or extended release tablets may ↓ GI toxicity. Time to peak serum concentrations delayed for 3–8 hr with enteric coating; longer delay if given with food; serum concentrations must be interpreted carefully. Also effective against primarily generalized tonic-clonic seizures. |
| Lamotrigine (Lamictal) | See Table 54-6 | | |
| Ethosuximide (Zarontin) | Initial 20 mg/kg/day or 250 mg QD or BID; then ↑ by 250 mg/day Q 2 wks to therapeutic effect or target serum concentration. | GI upset and sedation common with large single dose, especially on initiation. Daily divided doses may be necessary despite long half-life. Leukopenia (mild, transient) in up to 7%; serious hematologic toxicity extremely rare. | Parents/patient should be informed that GI effects and sedation may occur but tolerance usually develops. No good evidence it precipitates tonic-clonic seizures. Up to 50% of patients with absence may develop tonic-clonic seizures independent of ethosuximide. |

AED, antiepileptic drug; BID, twice daily; GI, gastrointestinal; QD, every day.

be necessary to establish an effective dose with minimal side effects.

THERAPEUTIC MONITORING

20. What subjective or objective clinical data should be monitored in T.D. for evidence of ethosuximide's therapeutic and adverse effects?

T.D.'s seizure frequency and the side effects she experiences are the primary monitoring parameters. If ethosuximide serum concentrations are used to assist in dosing, 40 to 100 mcg/mL is the usual target range; however, a clearly defined toxicity syndrome does not seem to develop when ethosuximide serum concentrations exceed 100 mcg/mL. Gradual and cautious increases in ethosuximide dosage when serum concentrations are beyond the upper limits of the "usual therapeutic range" may improve response in resistant patients. Although ethosuximide traditionally is administered in divided doses, its long half-life allows successful use of single daily doses for many patients. Clinicians should be alert to acute side effects of nausea and vomiting that are associated with large single doses of ethosuximide; should these occur, divided daily doses may be necessary.²⁷

Laboratory monitoring for idiosyncratic hematologic toxicity from ethosuximide often is recommended. Ethosuximide causes neutropenia in approximately 7% of patients. Although this reaction often is transient even if the drug is continued, rare patients may develop fatal pancytopenia. Presumably, early detection of neutropenia by means of periodic CBC will allow discontinuation of the drug and potential reversal of this adverse effect.¹⁴⁹ These hematologic reactions, however, can occur unpredictably at any time during therapy and often are missed by routine laboratory monitoring. Patient or caregiver education regarding signs and symptoms associated with leukopenia and pancytopenia (e.g., sudden onset of severe sore throat with oral lesions, easy bruisability, increased bleeding ten-

dency) and instructions to consult the physician if these symptoms occur may be more important than laboratory monitoring.⁶⁰

T.D.'s parents should be informed that nausea or sedation may occur with initiation of ethosuximide. Tolerance to these effects usually develops, although temporary dose reductions may be necessary. Subtle degrees of sedation may persist throughout therapy and may not be recognized until the drug has been discontinued and alertness improves.

Generalized Tonic-Clonic Seizures Accompanying Absence Seizures

21. Three months later, T.D.'s absence seizures have been reduced to a frequency of one every 2 weeks with an ethosuximide dosage of 750 mg/day. Her initial drowsiness has almost disappeared, and nausea was alleviated by administering doses with food. She has, however, experienced two tonic-clonic convulsions in the past month. Both seizures were witnessed by her parents and were well described: no auras or signs of focal seizure activity were apparent, and each episode lasted 3 to 4 minutes and apparently consisted of typical tonic-clonic activity. T.D. was incontinent of urine on both occasions, and postictal confusion and drowsiness were significant. Physical examination and laboratory testing showed no abnormalities. A repeat EEG continued to show infrequent 3/second spikes and waves; no abnormal focal discharges were noted. What is the relationship between T.D.'s tonic-clonic seizures and ethosuximide therapy?

It is commonly believed, and often stated in the literature, that ethosuximide may precipitate or worsen tonic-clonic seizures; however, this effect has not been clearly demonstrated. As many as 50% of patients who initially present with absence seizures also develop tonic-clonic seizures.¹⁵⁰ It had been common practice to add phenobarbital or phenytoin to

ethosuximide therapy to prevent this. Livingston et al.¹⁵¹ found that 80.5% of their patients treated with a drug specific for absence seizures developed “grand mal” seizures, whereas only 36% did so while receiving combined therapy. On the other hand, Browne et al.¹⁵⁰ pointed out that a child with absence seizures who has not yet had a tonic-clonic seizure has only a 25% chance of doing so in the future. In addition, routine use of drugs for prophylaxis of tonic-clonic seizures may increase the risk of toxicity and potentially reduce adherence with medication regimens. Sedative drugs, especially phenobarbital, actually may aggravate absence seizures in some patients.¹⁵²

In summary, subsequent generalized tonic-clonic seizures are common in patients who initially develop absence spells. It is not possible to assess the causative role of ethosuximide for this development in T.D.

Assessment Regarding Need for Alteration in Antiepileptic Drug Therapy and Choice of Alternative Antiepileptic Drug

22. What alterations are indicated in T.D.’s drug therapy because of the appearance of generalized tonic-clonic seizures?

Drug therapy for prevention of further tonic-clonic seizures is indicated. Phenobarbital, phenytoin, carbamazepine, or valproate might be considered for use in T.D. Owing to her age and sex, many clinicians would avoid using phenytoin because of its dysmorphic and cosmetic side effects. Phenobarbital can cause sedation and behavioral disturbances (see below) and may aggravate coexisting absence seizures. Carbamazepine is widely used for secondarily generalized tonic-clonic seizures and some cases of primary tonic-clonic seizures in children. It lacks many of the troublesome, common side effects associated with phenobarbital and phenytoin. In young children with primary generalized tonic-clonic seizures, carbamazepine may be preferred over valproate because it is less likely to induce serious hepatotoxicity.¹⁵³ Carbamazepine, however, is not effective for control of absence seizures. Therefore, it is likely that both ethosuximide and carbamazepine would be needed by T.D. Carbamazepine also has been occasionally associated with exacerbation of seizures (including atonic, myoclonic, and absence seizures) in children with mixed seizure disorders who exhibit bilaterally synchronous 2.5- to 3-cycle/second discharges on the EEG.^{154,155} The need for polytherapy and the possible risk of seizure exacerbation make carbamazepine a less attractive treatment option for T.D.

Valproate is effective for controlling both absence and primary generalized tonic-clonic seizures.^{16,54} T.D. appears to have primary generalized tonic-clonic convulsions; focal signs (e.g., unilateral or single limb involvement) were not observed, and focal discharges (e.g., isolated abnormal electrical activity localized to one portion of the brain) were not found on the EEG. Although neither observation completely rules out secondarily generalized tonic-clonic seizures, the likelihood seems low. Therefore, valproate may offer some advantages over carbamazepine in terms of efficacy. In addition, both of T.D.’s seizure types potentially could be controlled with a single medication.

Valproate Therapy

INITIATION AND DOSAGE

23. T.D.’s physician elects to use valproate. The therapeutic goal is control of her seizures with valproate alone. What procedure

should be followed regarding discontinuation of ethosuximide and initiation of valproate?

Techniques used by clinicians to substitute one AED for another depend largely on experience and judgment. Generally, it is best to attain a potentially therapeutic dose of a new medication before attempting to discontinue the previous drug. Serum concentration monitoring may be helpful. Ethosuximide has a relatively long half-life, whereas valproate’s half-life is short. Therefore, if necessary, steady-state serum concentrations of valproate can be established and evaluated rapidly; evaluation of the effect of decreases in the ethosuximide dosage must await the prolonged elimination of this drug. Once a desired valproate dose or serum concentration has been achieved, the ethosuximide dosage can be reduced gradually by 250 mg/day every 2 to 4 weeks.

Valproate should be initiated at 125 to 250 mg twice daily. Valproic acid syrup or capsules or divalproex sodium (Depakote tablets or Depakote Sprinkle capsules) can be used. Divalproex often is preferred because it is enteric coated and may cause fewer GI side effects than valproic acid. Generic formulations of valproic acid capsules are available; they are often tolerated well and are inexpensive. Syrup forms of valproate probably should be avoided unless extremely small doses are required (e.g., infants) or patients cannot swallow. Valproate syrup has an unpleasant taste, and its rapid absorption increases the likelihood of acute, dose-related side effects such as nausea. Lower initial doses are less likely to cause acute side effects (e.g., drowsiness and GI upset). Weekly dosage increases of 5 to 10 mg/kg/day of valproate usually are well tolerated and would be appropriate for T.D. More rapid increases may be desirable if tonic-clonic seizures are occurring frequently. The maximal recommended dosage of valproate is 60 mg/kg/day. Many patients, especially those receiving enzyme-inducing drugs, require higher-than-recommended doses to achieve adequate clinical effect; other patients may respond at much lower doses. Valproate can be titrated in T.D. to produce a “target” serum concentration of approximately 75 mcg/mL. As ethosuximide is withdrawn, the valproate dose can be further adjusted on the basis of seizure frequency and side effects.

DOSAGE FORMS

24. T.D. has been taking valproic acid capsules, 250 mg TID, for 3 weeks. Ethosuximide was discontinued 2 weeks ago; at that time, a valproate serum level just before her morning dose was 68 mcg/mL. She has not experienced generalized tonic-clonic seizures for 6 weeks but continues to have an absence seizure every 2 to 3 weeks. T.D. complains of nausea, epigastric burning pain, and occasional vomiting lasting approximately 1 hour following her doses of valproate. All recent laboratory tests were within normal limits. Administration of the drug with meals is only partially helpful. What alterations can be made in T.D.’s dosing regimen to relieve these symptoms and possibly improve seizure control?

T.D. appears to be a candidate for the use of divalproex (Depakote), an enteric-coated preparation of a complex salt of valproic acid. Capsules containing enteric-coated beads of divalproex (Depakote Sprinkles 125 mg) also are available; the capsule contents can be dispersed in food for administration to children or others who have difficulty swallowing tablets or capsules. In addition, use of the “cap” end of the capsule to measure half of the contents can approximate doses of

62.5 mg. Patients with feeding tubes in place may be given opened Depakote Sprinkles through their feeding tubes; however, patients with certain types of feeding gastrostomies should be assessed frequently for possible leakage at the insertion point. This complication may occur because of adherence of undissolved medication beads to the exterior of the feeding tube. This complication seems more likely when the sprinkle formulation is administered through a *button-type* gastrostomy feeding tube; use of divalproex sprinkles should be avoided in such patients.¹⁵⁶ The beads contained in Depakote Sprinkles may also clog the lumen of smaller-bore feeding tubes.

Administration of divalproex tablets results in delayed rather than prolonged absorption of valproate; therefore, these tablets are not a sustained-release product formulation. When patients are switched from nonenteric-coated formulations to divalproex tablets, the frequency of administration should not be decreased. Divalproex sodium extended release (Depakote ER) is also available. This form of divalproex can be administered as a single daily dose. All older dosage forms of valproate are completely absorbed and can be interconverted at the same total daily dose of medication.^{157,158} Depakote ER, however, is not bioequivalent to other dosage forms of valproate.¹⁵⁹ When equal doses are administered, Depakote ER achieves serum concentrations that are approximately 89% of those produced by other valproate dosage forms. Accordingly, when patients are converted to Depakote ER from other forms of valproate, the manufacturer recommends an increase of 8% to 20% in the administered dose. T.D.'s valproic acid capsules can be replaced with an equal daily dose of divalproex tablets. Divalproex should be administered on a three-times-daily dosing schedule. Alternatively, T.D. could be given 1,000 mg of Depakote ER once daily. The results of this change should be apparent within approximately 1 week. By that time, significant relief from GI side effects should have occurred. It may then be possible to increase the dose of divalproex in an effort to improve control of both absence and generalized tonic-clonic seizures.

PHARMACOKINETICS AND SERUM CONCENTRATION MONITORING

25. Two weeks later, T.D. returns for follow-up. Her GI symptoms have almost completely disappeared. She has been taking divalproex tablets 250 mg with breakfast and lunch and 375 mg with a bedtime snack for the past week. She has had no seizures in the past 2 weeks and complains of no side effects. A valproate serum level before her morning dose today was 117 mcg/mL (considerably higher than her previous valproate level of 68 mcg/mL). The laboratory reports that duplicate determinations of this level agreed within 5 mcg/mL. T.D. denies taking her medication incorrectly; her parents support this, and the tablet count in her prescription bottle is correct. She has taken no other drugs except a multivitamin. How can this disproportionate increase in her valproate serum concentration be explained, and what is its clinical significance? Does valproate exhibit dose-dependent pharmacokinetics?

Changes in valproate serum concentrations of this nature are, in this author's experience (R.L.), relatively common with divalproex. They are probably not the result of saturable, dose-dependent metabolism as is seen with phenytoin; instead, these changes are more readily explained by the absorption characteristics of divalproex tablets. Peak serum concentrations of

valproate after administration of divalproex may be delayed for 3 to 8 hours, and administration of food may further delay absorption.¹⁶⁰ In addition, diurnal fluctuation in both the rate and extent of absorption of divalproex may be significant. Absorption may be reduced by approximately one-third and peak plasma concentrations may be delayed for up to 12 hours for divalproex doses administered in the evening.³³ Twelve to 15 hours probably elapsed between the administration of T.D.'s last dose and blood sampling; therefore, the currently reported blood level may more closely approximate a peak concentration. Previous blood levels, determined while she was receiving rapidly absorbed valproate syrup, are more likely to have been trough concentrations. T.D.'s adherence to her prescribed dosage regimen also may have increased because of the change in dosage form and reduced side effects; her previous serum concentrations may not have reflected administration of the prescribed dose.

Other pharmacokinetic factors may have actually moderated this unusual increase in valproate concentrations. Fluctuation in valproate concentrations occurs throughout the day in a pattern that does not reflect the timing of doses.¹⁶¹ This fluctuation may be partially related to changes in serum concentrations of endogenous fatty acids that displace valproate from protein-binding sites.²⁸ Valproate's hepatic clearance is restrictive (i.e., valproate has a low extraction ratio and its clearance is limited by the free fraction of drug in blood); therefore, protein-binding displacement increases plasma concentration of free drug and clearance. As a result, total serum concentrations decrease. Valproate also exhibits dose dependency in its binding to serum proteins. As concentrations approach 70 to 80 mcg/mL, binding sites on albumin molecules become saturated, and the free fraction of drug in plasma increases.^{27,157} This effect also increases valproate clearance and reduces total serum concentrations. Both of these effects may actually "dampen" the apparent increase in plasma concentrations seen in T.D. When also considering the poorly established "therapeutic range" for this drug, it becomes apparent that monitoring serum concentrations is a less useful tool in valproate therapy than with other AED.^{28,157}

The clinical significance of T.D.'s elevated valproate serum concentrations is minimal. She is not experiencing any symptoms suggestive of valproate toxicity, and it is too soon following the dosage increase to assess the effect of this change on her seizure frequency. Therefore, alteration in her drug therapy is unnecessary at present and might only confuse evaluation of her response to this drug. She should be observed for an additional 4 to 6 weeks to evaluate seizure frequency before further alterations in her dosing regimen are considered. These apparently elevated valproate levels should not discourage further increases in her dosage as long as she is tolerating the medication and such increases are justified on the basis of seizure frequency. This case illustrates what can happen if too much attention is paid to serum concentrations.

HEPATOTOXICITY

26. Two months later, T.D. is taking 375 mg of divalproex TID with meals. She has had no absence seizures for 5 weeks and no generalized tonic-clonic seizures for 10 weeks. Yesterday, her valproate plasma concentration was 132 mcg/mL. In addition, her alanine aminotransferase (ALT) was 32 IU/mL (normal,

6–14) and her aspartate aminotransferase (AST) was 41 IU/mL (normal, 7–17). All other laboratory tests (bilirubin, alkaline phosphatase, lactate dehydrogenase [LDH], prothrombin time, and serum albumin) were normal. T.D.'s LFT have been monitored monthly since she began taking valproate, and they were previously normal. Physical examination was negative for scleral icterus, abdominal pain, or other signs of liver disease. Discuss these laboratory abnormalities and physical findings in relation to possible valproate-induced hepatotoxicity in T.D.

Liver damage related to valproate therapy appears to be caused by accumulation of directly hepatotoxic metabolites of valproate (probably 4-en-valproate) in certain patients.^{162,163} These metabolites may be formed in larger quantities in patients who also receive enzyme-inducing drugs such as phenobarbital. Most cases of fatal hepatotoxicity have occurred in young (<2 years of age) patients with neurologic and metabolic abnormalities who also had severe, difficult-to-control seizures and who were taking multiple AED.^{162–167} It is important to recognize, however, that severe hepatotoxicity is not limited to this population.¹⁶⁸ Liver damage occurs early in therapy and symptomatically resembles fulminant hepatitis with hepatic failure. Patients may experience vomiting, drowsiness, lethargy, anorexia, edema, and jaundice; these symptoms often precede laboratory evidence of hepatic damage. Liver biopsies in affected patients show evidence of hepatic necrosis and steatosis. Laboratory findings consist of dramatic elevations of AST, total bilirubin, and serum ammonia; coagulation disturbances accompanied by prolonged prothrombin times, low fibrinogen concentrations, and thrombocytopenia also may be observed. Death results from hepatic failure or a Reye's-like syndrome.^{163,165,169}

Asymptomatic elevations in liver enzymes (such as those found in T.D.) occur commonly during the first 6 months of treatment with valproate and usually are not associated with severe or potentially fatal valproate-induced hepatotoxicity. These changes in aminotransferase usually disappear without alteration in therapy; in some cases, temporary dosage reduction is followed by normalization of laboratory tests within 4 to 6 weeks.^{163,165} Without systemic symptoms or other signs of significant liver damage, it is unlikely that the laboratory abnormalities observed in T.D. represent severe liver toxicity from valproate. Because T.D. is responding well to valproate therapy, no change in therapy is warranted at this time. Laboratory testing probably can be repeated in 4 to 6 weeks. T.D. and her family should be educated regarding the possible signs and symptoms of valproate-induced liver damage and instructed to consult their physician if these symptoms are noted.

Routine Liver Function Tests

27. What is the usefulness of routinely monitoring LFT in patients receiving valproate?

Serious hepatotoxicity related to valproate therapy is extremely rare. Dreifuss et al.^{163,166} estimated that <0.002% of patients treated with valproate developed fatal hepatotoxicity between 1985 and 1986. This compares with an incidence of 0.01% between 1978 and 1984.¹⁶⁴ The lower recent incidence (despite much wider use of valproate) is attributed to increased valproate monotherapy and reduced use of this drug in high-risk patients such as the very young (Table 54-7). Most cases of fatal hepatotoxicity occur in children <10 years of age. In

children <2 years of age who receive AED polytherapy, the incidence of this complication is 1 in 500 to 1 in 800. Because asymptomatic, apparently benign elevations in liver enzymes are common early in therapy with valproate and symptoms of liver damage often precede laboratory changes, frequent LFT during early valproate therapy are unlikely to detect serious hepatotoxicity.^{60,163–165,170} In addition, this type of laboratory monitoring adds significant cost while providing little benefit for patients. Education of caregivers or patients regarding potential symptoms of hepatotoxicity, with careful observation and follow-up by health care professionals, is recommended as the most effective method for monitoring for this drug-induced illness.

Especially careful monitoring should be provided for predisposed patients (i.e., very young children with associated neurologic abnormalities and those receiving polytherapy). In predisposed patients, significant increases in LFT values that are noted early in therapy may be clinically significant. At the onset of symptoms suggesting this condition, laboratory testing may help confirm its presence. Practitioners who feel compelled to perform frequent laboratory testing for liver dysfunction on the basis of manufacturer's package insert recommendations should be cautious not to overinterpret common, transient, and apparently benign elevations in aminotransferases or ammonia levels.

Acute Repetitive (“Cluster”) Seizures

Rectal Diazepam Gel

28. B.N., a 7-year-old, 28-kg boy, has had seizures since age 3 months. He suffered anoxia at birth. His seizures usually involve initial confusion and disorientation, shortly followed by generalized tonic-clonic convulsive activity. Despite treatment with carbamazepine at maximal tolerated doses and serum concentrations (300 mg TID; 9–11 mcg/mL), he continues to have approximately two seizures monthly. Recent trials of topiramate and tiagabine as additions to his carbamazepine were unsuccessful and caused intolerable sedation and lethargy. During the past year, he has been admitted to the emergency department (ED) five times because of seizure “flurries” consisting of three to six seizures occurring over a period of 12 or fewer hours. While he regains consciousness between these “flurry” seizures, he becomes lethargic. During ED admissions, IV diazepam was administered. This was rapidly successful in terminating seizure activity. B.N.'s mother relates that she usually can identify the onset of seizure flurries; B.N.'s behavior changes and he becomes “clinging” and “whiny” and hyperactive. She also indicates that the initial seizure in a flurry differs from B.N.'s typical episodes. Before the onset of generalized seizure activity, he experiences much briefer periods of confusion. In addition, the generalized seizures are longer and more severe (often with dramatic cyanosis) at the beginning of a “flurry.”

Why is prophylactic or abortive therapy for B.N.'s seizure flurries indicated? What factors about B.N. predict successful use of such treatment, and how can it be administered?

B.N.'s relatively frequent flurries or clusters of seizures are causing him and his family significant difficulty. Frequent ED visits are expensive and frightening for many patients and their families. B.N. continues to experience seizure flurries despite carbamazepine therapy. He responds well to IV diazepam and

has a caregiver who can identify the onset of seizure clusters. His seizure clusters appear to be distinct from the other seizures that he experiences. All of these factors indicate that a trial of home-administered treatment to abort these cluster episodes is likely to be helpful and should be initiated.

Rectal diazepam gel (Diatat) is available for home administration to patients with acute episodes of repetitive seizure activity.¹⁷¹ When diazepam gel is administered rectally, it is absorbed relatively rapidly (peak plasma concentrations occur in approximately 1.5 hours),¹⁷² and is often effective in terminating cluster seizures within 15 or fewer minutes. Use of diazepam rectal gel is recommended only when caregivers can recognize the onset of cluster seizures, which are different from a patient's usual seizure activity, and when the caregivers can be trained to administer the preparation safely and to monitor the patient's response (e.g., respiratory status) following administration. Caregivers should be informed that this preparation is not for as needed (PRN) use with every seizure; it should be used only for identifiable cluster seizures or prolonged seizures. Home use of rectal diazepam may result in significant reduction in the costs of treating these events and may decrease ED visits.¹⁷³

B.N.'s mother should administer rectal diazepam gel at the onset of identifiable cluster seizure activity. A dose of approximately 0.3 mg/kg (10 mg) should be given and repeated, if necessary, within 4 to 12 hours of the first dose. B.N.'s mother should be counseled on the administration of this product and given the patient package insert, which gives complete instructions for the administration of rectal diazepam. After administration, B.N. should be monitored for at least 4 hours to ensure that no respiratory depression or other adverse side effects are occurring and to assess the effect of the medication on his seizures. The most common adverse effect seen with rectal diazepam is somnolence, occasionally accompanied by dizziness and ataxia. Respiratory depression is very uncommon.

Febrile Seizures

Incidence and Classification

29. J.J., a 14-month-old girl, is brought to the ED after having a generalized tonic-clonic convulsion lasting approximately 5 minutes. The episode occurred in association with an upper respiratory infection. On arrival in the ED, her temperature was 39.5°C rectally. She was alert at that time; all laboratory and neurologic findings, including lumbar puncture, were normal. J.J. has no history of neurologic abnormality. Her 7-year-old brother suffers from both absence and generalized tonic-clonic seizures. What is the relationship between febrile seizures and epilepsy? How may J.J.'s convulsion be classified on the basis of the data available?

Up to 5% of children have a febrile seizure between 6 months and 6 years of age.¹⁷⁴ Simple febrile seizures occur with a fever of $\geq 38^{\circ}\text{C}$ in previously normal children <5 years of age. They last <15 minutes and have no focal features. The associated seizure does not arise from CNS pathology. Complex febrile seizures show focal characteristics or are prolonged. The child may or may not have previous neurologic abnormalities. The risk of occurrence of unprovoked afebrile seizures following a febrile seizure is four times greater than in the general population. A family history of afebrile seizures, a complicated initial seizure, and pre-existing neurologic abnor-

malities are risk factors associated with the later development of chronic epilepsy.^{174,175}

J.J.'s seizure appears to be a typical simple febrile seizure that developed in association with her upper respiratory tract infection. The lack of previous neurologic abnormality and normal findings on lumbar puncture and laboratory evaluation help confirm this assessment.

Treatment of Acute Seizure

30. How should J.J.'s febrile seizures be treated?

Because J.J. is not having a seizure at present, AED therapy is not required. Measures to reduce her elevated temperature should be initiated; however, these measures may not reduce the risk of further seizures. Acetaminophen and tepid sponge baths usually are helpful.

If patients experience prolonged or repeated febrile seizures, either diazepam or, less commonly, phenobarbital may be administered.¹⁷⁵ Rectal diazepam gel can be used for this purpose.

Prophylaxis and Choice of Antiepileptic Drug

31. On the basis of the subjective and objective data available for J.J., is AED therapy indicated on a long-term basis? What are the benefits and risks of AED prophylaxis for febrile seizures?

Long-term treatment or prophylaxis with AED for simple febrile seizures is not recommended. Up to 54% of affected patients will have recurrent febrile seizures, and the risk of recurrence is even greater when the first episode occurs before 13 months of age. Nonetheless, recurrent febrile seizures are not associated with brain damage or development of epilepsy.¹⁷⁴ The efficacy of prophylactic AED for prevention of chronic epilepsy following febrile seizures has not been evaluated.¹⁷⁶ Thus, the primary potential benefit of long-term AED therapy would be prevention of recurrent febrile seizures.

Phenobarbital and, occasionally, valproate used to be used as prophylaxis in patients with febrile seizures.¹⁷⁷ A reanalysis of published British trials of both valproate and phenobarbital for febrile seizure prophylaxis found that neither drug was reliably effective.¹⁷⁸ Although phenobarbital had been considered at least partially effective, the high rate of side effects (40%) preclude recommending its use. When the effects on intelligence of phenobarbital versus placebo prophylaxis for febrile seizures in young children were evaluated, IQ scores were significantly lower in children treated with phenobarbital.¹⁷⁹ This effect persisted for at least 6 months after discontinuation of drug therapy. In addition, reduction in the recurrence rate of febrile seizures in children treated with phenobarbital was not statistically significant, although approximately one-third of patients who experienced recurrent febrile seizures were non-compliant with phenobarbital therapy. This study's design and findings have been criticized on the basis of patient selection and "crossing over" of patients from the control group to the study group.¹⁸⁰ Nevertheless, on retesting after 3 to 5 years, phenobarbital-treated children scored significantly lower on the Wide Range Achievement Test. Their mean IQ were 3.71 points lower than those of placebo-treated children, although this difference was not statistically significant. Therefore, phenobarbital has no beneficial effect on preventing febrile seizure recurrence and may adversely affect cognitive function.¹⁸¹

Antiepileptic drug prophylaxis for febrile seizures is probably not warranted for J.J., even though she is at risk for both development of epilepsy and recurrence of febrile seizures. No evidence supports that medication will significantly affect her later development of epilepsy. Phenobarbital's use for this purpose is difficult to justify when considering the risk of learning impairment. In addition, phenobarbital therapy is associated with hyperactivity and behavioral disturbance in up to 75% of children receiving the drug.^{182–184} J.J.'s age places her at higher risk of valproate-related hepatotoxicity, and this risk probably outweighs any potential benefit from treatment with this drug. Close medical follow-up of J.J. is warranted. In addition, her parents should be instructed to institute antipyretic measures (i.e., acetaminophen and tepid sponge baths) at the onset of any febrile illness. Many febrile seizures occur early in the course of an illness before fever is detected¹⁷⁵; nevertheless, vigilance by her parents and early antipyretic therapy may help prevent further febrile seizures. The intermittent administration of oral diazepam (Valium) at the onset of a febrile illness also may be of value. A dosage of 0.33 mg/kg orally given every 8 hours appears to be effective in reducing the recurrence rate of febrile seizures.¹⁸⁵ Diazepam should be initiated as soon as a febrile illness appears and continued until J.J. has been afebrile for 24 hours. Side effects are common when diazepam is used in this manner; approximately one-third of patients will experience ataxia, lethargy, or irritability. These and other common CNS side effects, such as dysarthria and insomnia, may confuse assessment of the condition of children with febrile illnesses.¹⁷⁴

Seizures Secondary to Toxic Exposures: Nerve Gas

32. How likely are seizures to result from exposure to chemical warfare agents such as sarin nerve gas, and how are these seizures treated?

Nerve agents that may be used in chemical warfare or terrorist attacks can cause seizures. These agents include tabun (synonym, GA), sarin (GB), soman (GD), and VX. At normal environmental temperatures, all of these agents except VX are volatile and therefore become “nerve gases.” VX is a viscous liquid. Nerve agents are both lipophilic and hydrophilic and therefore can rapidly penetrate clothing, skin, and mucous membranes and be absorbed systemically.^{186,187} Nerve agents are closely related to organophosphate insecticides, and their toxic effects result from their actions as acetylcholinesterase (AChE) inhibitors. The toxins bind to the active site of AChE and prevent hydrolysis of acetylcholine (ACh). Excessive quantities of ACh then accumulate, causing excessive stimulation of muscarinic and nicotinic receptors. Manifestations of nerve agent exposure can be broadly described as muscarinic (ophthalmic symptoms such as miosis, lacrimation, and blurred vision; respiratory symptoms such as severe rhinorrhea, wheezing, and dyspnea; cardiovascular symptoms such as bradycardia, atrioventricular (A-V) block and hypotension; and GI symptoms such as salivation, nausea, vomiting, and severe diarrhea), nicotinic (cardiovascular symptoms such as tachycardia and hypertension; fasciculation of voluntary muscles; and metabolic symptoms such as hyperglycemia, metabolic acidosis, and hypokalemia), and CNS symptoms (anxiety, agitation, vertigo, ataxia, central respiratory depression, convulsions, and coma). The likelihood and the severity

of CNS toxicity and seizures will depend on the amount of nerve agent and the route of exposure. CNS symptoms are associated with severe exposure to nerve agents. When seizures occur, they are usually generalized; the exact mechanism of seizure induction by these agents has not been identified.¹⁸⁷

Following exposure to nerve agents, early treatment with antidotes may prevent severe toxic manifestations. Large doses of IM atropine (2–6 mg) should be given; dosing is based on respiratory symptoms. Therapeutic endpoints are drying of respiratory secretions and relief of dyspnea.^{186,187} Pralidoxime (Protopam) is an AChE reactivator. This antidote binds nerve agents and removes them from binding sites on AChE. Pralidoxime is useful only if given before the bond between the nerve agent and AChE becomes permanent. This time interval varies from minutes to hours after exposure, depending on the nerve agent.¹⁸⁸ Pralidoxime is a quaternary agent, and it is not clear to what extent it enters the CNS. The effects of pralidoxime are most dramatically seen on skeletal muscle symptoms. Pralidoxime should be given along with the antimuscarinic agent atropine.

Few published data exist regarding the use of anticonvulsant drugs for treatment of nerve agent exposure. It is claimed that early administration of 10 mg IM diazepam may prevent permanent CNS damage in patients with severe nerve agent toxicity.¹⁸⁶ In situations of severe exposure with CNS manifestations and seizures, use of a more rapidly absorbed IM agent such as lorazepam would be expected to produce a more rapid and reliable response; IV administration of diazepam or lorazepam, if feasible, would be more likely to rapidly control seizure activity. If necessary, rectal administration of diazepam gel would be an option (see Question 28).

ANTIEPILEPTIC DRUG INTERACTIONS AND ADVERSE EFFECTS

Carbamazepine–Erythromycin Interaction

33. J.N., a 17-year-old boy, is treated with carbamazepine 600 mg/day for complex partial seizures. His seizures are well controlled with serum carbamazepine concentrations of 8 mcg/mL. He developed an upper respiratory infection, assessed as probable streptococcal pharyngitis. Because J.N. is allergic to penicillin, erythromycin 333 mg TID with meals for 10 days was prescribed. Four days after beginning erythromycin therapy, J.N. complains that, although his upper respiratory symptoms are abating, he is constantly drowsy and is experiencing dizziness and double vision. He also complains of nausea and has vomited once this morning. He receives no other routine medication, although he did take approximately five doses of two tablets of Extra-Strength Tylenol (acetaminophen 500 mg/tablet) during the initial stage of his current illness for fever and general discomfort. What is the relationship between J.N.'s symptoms and the potential interaction between carbamazepine and erythromycin? How might this interaction be further assessed and managed at this point?

Inhibition of CYP3A4 by erythromycin can result in dramatic elevations in carbamazepine serum concentrations and precipitation of intoxication.^{189,190} J.N.'s symptoms are consistent with carbamazepine toxicity, although erythromycin therapy may be contributing to his GI symptoms. Although dramatic elevation of carbamazepine serum concentrations is not

consistently seen, susceptible patients may exhibit a twofold increase in serum levels. Determination of a carbamazepine serum concentration may help confirm probable toxicity and assess the magnitude of the interaction.

Management of this interaction at this point is somewhat difficult; prevention of the interaction by avoiding the use of erythromycin whenever possible is usually the best clinical strategy. Replacement of erythromycin with azithromycin or, possibly, clindamycin should provide adequate antibiotic therapy with no risk of further interaction with carbamazepine. Other macrolide antibiotics (e.g., clarithromycin, triactyloleandomycin, and telithromycin) are likely to cause significant inhibition of carbamazepine metabolism. One or two doses of carbamazepine could be held to allow carbamazepine serum concentrations to decrease to pre-erythromycin levels and correct J.N.'s present intoxication. An alternative approach would be to reduce J.N.'s carbamazepine dose, based on his present serum level, for the duration of erythromycin therapy. This approach may be more difficult to manage; the time required for erythromycin-induced metabolic inhibition to subside when the antibiotic is stopped is unpredictable. With either approach to management of this interaction, J.N.'s clinical status will need to be monitored carefully. Further adjustment of carbamazepine dosage may be required, and repeat serum level determinations may be helpful.

Valproate–Carbamazepine Interaction

34. D.H., a 21-year-old, 84-kg man, was taking carbamazepine 1,400 mg/day (600 mg every AM and 800 mg at bedtime [HS]) for treatment of generalized tonic-clonic seizures. Despite carbamazepine serum concentrations of 14 mcg/mL, he continued to have a seizure every 6 to 8 weeks. Higher serum levels were associated with toxicity symptoms. Valproate (divalproex) was recently added and gradually increased to a dosage of 1,000 mg TID; the therapeutic goal is replacement of carbamazepine with valproate. At this dose, D.H. again experienced symptoms of carbamazepine intoxication (double vision, unsteady gait, and drowsiness), although his carbamazepine serum concentration was 12 mcg/mL. Valproate serum levels were 40 mcg/mL and 43 mcg/mL on two occasions. D.H. has continued to experience seizures at his previous rate. He appears to be adherent with his prescribed medication regimen. How can D.H.'s symptoms and low valproate levels be explained on the basis of an interaction between his two AED?

Difficulty in achieving serum valproate concentrations adequate for improvement in seizure control frequently is encountered in patients who receive concomitant therapy with potent enzyme inducers such as carbamazepine. Clinicians frequently note that it is difficult to administer doses of valproate sufficiently large to achieve desired serum levels under these circumstances.^{27,191} Serum concentrations of valproate in patients receiving carbamazepine may be only approximately 50% of those expected on the basis of single-dose valproate pharmacokinetic studies.

D.H.'s symptoms of carbamazepine intoxication at plasma levels that were previously tolerated suggest possible accumulation of CBZ-10,11-epoxide (CBZ-E). This compound is an active metabolite of carbamazepine. Valproate may inhibit epoxide hydrolase and cause accumulation of CBZ-E sufficient

to exert significant pharmacologic effects, including intoxication. This author (R.L.) has observed a patient receiving both valproate and carbamazepine who developed serum concentrations of CBZ-E equal to the concentration of carbamazepine itself (both compounds were measured at ~12 mcg/mL) and experienced significant intoxication. Determination of the serum concentration of carbamazepine and CBZ-E could help confirm the clinical impression. Unfortunately, the assay for CBZ-E is not readily available in many clinical laboratories.

35. What recommendations can be made for alteration in D.H.'s drug therapy regimen to alleviate the effects of this drug interaction and enhance his therapeutic response to the medication?

On clinical and empiric grounds, D.H.'s dosage of carbamazepine should be reduced; this would seem especially appropriate because the therapeutic goal was replacement of carbamazepine with valproate. Dosage reduction will result in a decrease in serum concentrations of both carbamazepine and CBZ-E and a reduction in symptoms of intoxication. An initial decrease of 10% to 20% (200 mg) of D.H.'s daily carbamazepine dose would be reasonable. Subsequently, his carbamazepine dose can be tapered using reductions of 200 mg every 1 to 2 weeks. During tapering of carbamazepine, D.H. should be monitored carefully for increased seizure activity.

Valproate-Related Thrombocytopenia

36. D.H.'s symptoms abated significantly within 3 days of reduction of his carbamazepine dosage to 1,200 mg/day. A CBZ-E serum concentration was not determined. His carbamazepine dosage was reduced by 200 mg/day in weekly steps, with no increase in seizure activity. A serum valproate concentration after his carbamazepine dosage reached 600 mg/day was 53 mcg/mL. At that time, he had not had a seizure in approximately 6 weeks. A serum valproate concentration was repeated when his carbamazepine dosage reached 200 mg/day and it was 58 mcg/mL. Three weeks following discontinuation of carbamazepine, D.H. noted the onset of tremor affecting his hands and a "fuzzy sensation in my head" accompanied by difficulty concentrating on tasks. His serum valproate concentration was 126 mcg/mL. In addition, a CBC showed a platelet count of 60,000/mm³ cells; no other abnormalities were seen. No bleeding tendencies were noted, and D.H. denied easy bruisability or unusual bleeding. Previous CBC had been normal. Is this pattern of increase in valproate serum concentrations consistent with the loss of carbamazepine-related enzyme induction? What is the relationship between D.H.'s new symptoms, his reduced platelet count, and the elevation in his valproate serum concentration?

[SI unit: 60 × 10⁵/L]

D.H.'s valproate serum concentrations were expected to increase with "deinduction" of hepatic microsomal enzymes while carbamazepine was being discontinued. The pattern and timing of deinduction are not consistently predictable. Although a somewhat linear increase in valproate concentrations might be anticipated as enzyme inducers such as carbamazepine are gradually reduced, it is not unusual for valproate levels to remain relatively constant until 1 to 2 weeks after discontinuation of enzyme inducers.¹⁹¹ Therefore, patients

should be monitored for signs or symptoms of possible valproate intoxication during and for several weeks after such a discontinuation process; clinicians and patients should be aware that dosage adjustment may not be required until the enzyme-inducing drug has been completely discontinued.

D.H.'s new symptoms appear to be consistent with mild to moderate intoxication with valproate. Tremor is a relatively common side effect of valproate that is likely to appear as serum concentrations exceed approximately 80 mcg/mL.²⁷ This side effect may be troublesome for some patients because the tremor is usually an intention tremor, which worsens with physical activity. In most patients, dose reduction will improve or eliminate tremor. Some practitioners counter this side effect with propranolol therapy in doses similar to those used to treat essential tremor.¹⁹² The neurologic symptoms exhibited by D.H. also are typically seen with valproate intoxication. All of these symptoms are reversible with dosage reduction.

Reductions in platelet counts are not rare in patients treated with valproate. Significant thrombocytopenia with bleeding manifestations is extremely uncommon, although measurable changes in platelet function may occur.^{193,194} The mechanism underlying thrombocytopenia is not known; evidence exists for both a dose- or serum concentration-related effect¹⁹⁴ and an immunologic mechanism.¹⁹⁵ Affected patients usually can be continued on valproate therapy at reduced doses without adverse effects. The author (R.L.) has observed two patients who developed significant valproate-related thrombocytopenia without bleeding complications; both cases were associated with dramatic increases in valproate serum concentrations following discontinuation of enzyme-inducing drugs.

Both the neurologic symptoms and thrombocytopenia exhibited by D.H. probably can be corrected by reducing his dose of divalproex. The magnitude of dose reduction should be determined by titration using symptom remission and normalization of his platelet count as endpoints. Periodically rechecking valproate serum concentrations can help establish a safe upper limit dose and serum levels for D.H. Ongoing monitoring also will be important for several weeks because the process of deinduction of hepatic enzymes may not yet be complete. Further dose reductions may be necessary as this process reaches completion and D.H.'s valproate clearance gradually decreases. Reduction of D.H.'s dosage to 2,000 mg/day should approximate serum concentrations between those that were previously subtherapeutic and those that are causing his current adverse effects.

Skin Rash: Hypersensitivity Reactions to Antiepileptic Drugs

37. R.S., a 34-year-old man, has been taking phenytoin 200 mg BID for the past 7 weeks to control complex partial and secondarily generalized tonic-clonic seizures. Seizures began approximately 4 months ago following surgical evacuation of a subdural hematoma. Today he appeared at the walk-in clinic and complained of an "itchy rash" that had begun 2 days ago. He described "feeling lousy" for the past week. On examination he is febrile (38.5°C orally). A maculopapular, scaly, erythematous rash covered his upper extremities and torso, and the mucous membranes of his mouth appeared to be mildly inflamed. Cervi-

cal lymphadenopathy was noted, and the liver was found to be enlarged and tender. R.S. also related that his urine had become very dark in the past 2 days and that his stools were light colored. **What is the significance of R.S.'s skin rash and other signs and symptoms? Are these likely to be related to his phenytoin therapy?**

Skin rash is a relatively common (2%–3% of patients) side effect related to AED therapy. It is most commonly associated with phenytoin, lamotrigine, carbamazepine, and phenobarbital. Most cases are relatively mild, but severely affected patients may develop Stevens-Johnson syndrome or a systemic hypersensitivity syndrome accompanied by severe hepatic damage. In R.S.'s case, signs and symptoms suggesting hepatic involvement accompany the skin rash. Fever, lymphadenopathy, and apparent inflammation of mucous membranes also suggest a hypersensitivity reaction to phenytoin with multisystem involvement and the potential for progression to Stevens-Johnson syndrome. Viral infection (e.g., hepatitis, influenza, infectious mononucleosis) should be considered and ruled out as a possible cause of R.S.'s symptoms before they are attributed to phenytoin therapy.^{124,196–199}

Phenytoin hypersensitivity syndrome is most commonly seen in adults and is more likely to affect blacks.¹⁹⁷ Typically, patients with this syndrome present with complaints of fever, skin rash, and lymphadenopathy during the first 2 months of phenytoin therapy. Hepatomegaly, splenomegaly, jaundice, and bleeding manifestations such as petechial hemorrhage also are relatively common. Laboratory manifestations usually include leukocytosis with eosinophilia, elevated serum bilirubin, and elevated AST and ALT. When a phenytoin hypersensitivity reaction includes significant hepatotoxicity, fatality may occur in as many as 38% of affected patients.¹⁹⁶

A high likelihood exists that R.S. has developed a severe reaction to phenytoin; the clinical manifestations and the timing of their appearance are typical of this reaction. Phenytoin should be discontinued immediately pending diagnostic clarification (i.e., evaluation for other possible causes of his symptoms such as viral illness). R.S. should be hospitalized for further diagnostic evaluation and treatment. Treatment of phenytoin-related hypersensitivity and hepatotoxicity is symptomatic and supportive. Intensive therapy with corticosteroids has commonly been used, although little objective evidence exists for beneficial effects of this treatment. Potential complications of this reaction include sepsis and hepatic failure; these conditions should be treated specifically.

38. R.S. was hospitalized and treated with oral prednisone and topical corticosteroids. Other potential causes for his condition were ruled out, and his signs and symptoms were attributed to phenytoin hypersensitivity. His fever resolved within 5 days; the skin rash became exfoliative but resolved without infectious complications. Laboratory parameters began to normalize after 10 days. While he was hospitalized, R.S. experienced three episodes of generalized seizure activity that were treated with acute administration of IV lorazepam. R.S. was afebrile at the time these episodes occurred. **What information regarding the pathogenesis of phenytoin hypersensitivity and hepatotoxicity can be used to guide selection of an alternative AED for R.S.?**

Further administration of phenytoin to R.S. is contraindicated on the basis of his history of a severe hypersensitivity

reaction to this drug. Readministration of phenytoin is likely to result in rapid recurrence of severe symptoms of this syndrome. Although the mechanism of this reaction is not fully understood, research implicates reactive arene oxide metabolites of phenytoin (and other chemically similar AED) as possible causative agents for hypersensitivity reactions. Affected patients purportedly are predisposed genetically to the development of hypersensitivity, possibly because a relative deficiency of epoxide hydrolase enzymes allows the accumulation of toxic concentrations of reactive epoxide metabolites, which are believed to exert a direct cytotoxic effect and to interact with cellular macromolecules, thereby functioning as haptens that stimulate an immunologic reaction.^{200,201} Carbamazepine, phenytoin, and phenobarbital all are metabolized by similar pathways and converted to reactive arene oxides. It is hypothesized that carbamazepine-induced liver damage also may result from the effects of accumulation of reactive epoxide metabolites; these reactive metabolites differ from the 10,11-epoxide metabolite that accumulates during carbamazepine therapy. For this reason, these drugs potentially cross-react in susceptible patients. Cases of apparent cross-reactivity between phenytoin and phenobarbital or carbamazepine have been documented.^{202–204} In addition, both carbamazepine and phenobarbital can produce hypersensitivity reactions similar to those seen with phenytoin. This potential for cross-reactivity should be considered when an alternative AED is selected for R.S. An analysis of cases of AED-related skin rashes found that the most significant nondrug predictor of skin rash was the occurrence of a rash with another AED.²⁰⁵

Valproate has been suggested as the preferred alternative AED for patients who have developed hypersensitivity reactions to phenytoin.²⁰³ Valproate is not metabolized to arene oxides and also is chemically dissimilar to all other AED. Because valproate often shows good efficacy for complex partial seizures with secondary generalization, it would seem to be a safe and potentially effective alternative AED for R.S. Of the newer AED, lamotrigine should probably be avoided in R.S. because of its likelihood of causing skin rash and apparent hypersensitivity reactions. Oxcarbazepine is potentially an alternative AED for R.S. because it is not metabolized through the arene oxide pathway. Nevertheless, 25% to 30% of patients who develop a rash in response to carbamazepine will also develop a rash with oxcarbazepine.²⁰⁶ Therefore, many clinicians would avoid oxcarbazepine. Topiramate, tiagabine, levetiracetam, gabapentin, pregabalin, or zonisamide could be considered as alternative medications for R.S. These medications appear less likely to cause skin rash or hypersensitivity reactions.^{205,207}

WOMEN'S ISSUES IN EPILEPSY

Although epilepsy affects men and women equally, many health issues are of specific importance to women, such as contraceptive interactions with AED, teratogenicity, pharmacokinetic changes during pregnancy, breast-feeding, menstrual cycle influences on seizure activity (catamenial epilepsy), AED impact on bone, and sexual dysfunction.²⁰⁸ A great need exists to educate both health care professionals and patients about the many complex issues facing women with epilepsy.

For women of child-bearing potential, prepregnancy planning and counseling are important, because significant AED

exposure of the fetus often occurs by the time the pregnancy is confirmed. This is especially important because of the potential for unplanned pregnancies from the AED–contraceptive drug interactions. Prepregnancy counseling also should include the importance of folic acid supplementation and medication adherence. Patients should be informed about the risk of teratogenicity and the importance of prenatal care.

Although complete seizure control is desirable for all patients with epilepsy, it is especially favorable for a woman's seizures to be well controlled before conception. Monotherapy is preferred whenever possible, because the relative risk of birth defects dramatically increases with AED polytherapy.^{209,210} Monotherapy also improves patient adherence. The AED should be given at the lowest effective dose to reduce the possibility of birth defects.²¹¹ The gradual discontinuation of AED may be considered if a woman has been seizure-free for 2 years or longer.

Antiepileptic Drug–Oral Contraceptive Interaction

39. P.Z., a 26-year-old woman, experiences complex partial and secondarily generalized tonic-clonic seizures. She is taking phenytoin 400 mg/day and divalproex 2,000 mg/day. She reports having two or three partial seizures and one generalized seizure every 3 to 4 months. Despite treatment with Lo/Ovral (norgestrel 0.3 mg with ethinyl estradiol 30 mcg), she has just learned she is pregnant. Her last menstrual period was 6 weeks ago. What is the relationship between P.Z.'s apparent contraceptive failure and her antiepileptic drug therapy?

There have been several reports of reduced efficacy of oral contraceptives in patients receiving various AED.^{212,213} These reports describe both breakthrough bleeding and pregnancy. Phenobarbital, phenytoin, carbamazepine, oxcarbazepine, and felbamate have been shown to increase the metabolism of ethinylestradiol and progestogens.²¹⁴ This effect is not associated with valproate, lamotrigine, gabapentin, tiagabine, zonisamide, levetiracetam, or pregabalin.^{82,208,215} Topiramate in polytherapy and at high dosages (200–800 mg/day) appears to have a mild though measurable effect on oral contraceptive pharmacokinetics; apparent clearance of the estrogen component of combined oral contraceptives is increased in patients taking topiramate.²¹⁶ In contrast, topiramate monotherapy in lower dosages (50–200 mg/day) has a lesser impact on the pharmacokinetics of the oral contraceptive.²¹⁷

A different drug interaction exists between oral contraceptives and lamotrigine. It is currently thought that the estrogen component in oral contraceptives increases the clearance of lamotrigine. Lamotrigine concentrations may increase twofold when contraceptive steroids are begun and fall by 50% when contraceptive steroids are discontinued. Changes in lamotrigine levels associated with initiation and discontinuation of contraceptive steroids can result in increased seizure activity in some patients and toxicity in others.²¹⁸ Within a 28-day cycle of oral contraceptives, lamotrigine concentrations decrease during the 21 days of steroid hormone and fairly rapid increases in concentrations during the 'pill-free' week.

A lack of contraceptive efficacy may present as irregular or breakthrough menstrual bleeding. Decreased efficacy is not always associated with breakthrough bleeding, however. Oral contraceptive doses can be increased to compensate for the

effect of an AED.²¹⁹ Estrogens also may exacerbate seizures in some women.²²⁰ Women >35 years of age or those who smoke must consider the risk of thromboembolic complications associated with higher doses of contraceptives. A second contraceptive method (e.g., condoms, intrauterine devices, or spermicide) is recommended to avoid contraceptive failure.²⁰⁷ Tubal ligation is also an alternative.

Assuming P.Z. was taking her contraceptive pills on a regular basis, it is possible that her enzyme-inducing AED (phenytoin) is responsible for their failure. Patients receiving AED should be prospectively informed that this interaction can occur and advised concerning the use of alternative contraceptives (see Chapter 45, Contraception).

Teratogenicity

40. What are the risks of teratogenic effects from P.Z.'s medications? What steps might be taken to minimize these risks?

P.Z.'s child is at a relatively high risk of congenital malformations because of exposure to several potentially teratogenic drugs: estrogen-progestin combination oral contraceptives, valproate and phenytoin (also see Chapter 46, Obstetric Drug Therapy).

Many AED have teratogenic effects.²²¹ Animal data regarding the teratogenic potential of lamotrigine, felbamate, gabapentin, topiramate, tiagabine, levetiracetam, oxcarbazepine, pregabalin, and zonisamide are encouraging, but conclusions regarding the teratogenic potential of these recently marketed AED cannot be made because of limited experience in pregnant women. Controversy has been significantly reduced regarding the relative contributions of parental epilepsy itself, genetic influences, and drug therapy since recent data have shown that the infants of untreated women with epilepsy had fewer abnormalities compared with those born to women with epilepsy who were taking AED.²²² The risk of major congenital malformations (e.g., facial clefts, cardiac septal defects) in children exposed to AED in utero may be as high as two to three times the baseline risk in the general population.²²³ In addition, maternal epilepsy increases the risk of complications of pregnancy, prenatal or postnatal infant mortality, premature birth, and low infant birth weight.

Most AED, with the exception of valproate, are believed to exert their teratogenic effects (and possibly other adverse effects such as hepatotoxicity) partly via reactive epoxide metabolites.²²³ Enhancement of the formation of these metabolites via hepatic enzyme induction (e.g., by carbamazepine or phenobarbital) or inhibition of their breakdown (e.g., through inhibition of epoxide hydrolase by valproate) would increase the risk of teratogenicity. Combined administration of enzyme inducers and valproate (specifically the combination of carbamazepine, phenobarbital, and valproate with or without phenytoin) is associated with an especially high risk of teratogenicity.²²⁴ In addition, each of the present major AED has been associated with congenital malformations when administered alone. Meador et al.²²⁵ have recently provided data from 333 pregnancies in women with epilepsy taking an AED in monotherapy and enrolled in the Neurodevelopmental Effects of Antiepileptic Drugs (NEAD) study. Serious adverse outcomes (major malformations and fetal death) were significantly more likely to occur with exposure to valproate (20.3%),

than with carbamazepine (8.2%), phenytoin (10.7%), or lamotrigine (1%).

The NEAD study included one second-generation AED, lamotrigine. The North American AED Pregnancy Registry recently reported that the risk for a major malformation after first trimester monotherapy exposure to lamotrigine was not increased compared with the risk for the nonexposed control population. The risk for nonsyndromic cleft lip or palate was increased in the babies exposed to lamotrigine,²²⁶ although this has not been identified in other registries.²²⁷ The reason for this incongruence is not known.

In addition to malformations, AED exposure in utero may have an effect on neurodevelopment. An interim analysis of the NEAD study raised concerns about the effects of in utero exposure to valproate on neurodevelopment.²²⁸ It was found that valproate-exposed children have low scores (mean = 85) on the Children's Mental Development Index (MDI), even after controlling for the mother's IQ and seizure type. The MDI scores were significantly lower for children exposed in utero to valproate compared with scores of children exposed to carbamazepine (mean, 94), phenytoin (mean, 90), and lamotrigine (mean, 97) monotherapy.

Several strategies can be used to reduce the potential adverse effects of AED on pregnancy outcomes.^{228,229} If feasible, before conception, seizure control should be optimized using the AED of first choice for the prospective mother's seizure type or epilepsy syndrome. Monotherapy at the lowest effective dose is the goal. Maintenance of adequate folic acid stores before conception and during fetal organogenesis is also important. Folic acid supplementation can reduce the risk of congenital neural tube malformations in infants at risk who are born to women without epilepsy, but folate supplementation does not reliably reduce the teratogenic effects of AED. Nevertheless, supplementation of folic acid (and ensuring adequate folate levels) is recommended. Because about half of pregnancies are unplanned and not evident until weeks after conception, folate supplementation should be routinely given to women of child-bearing age with epilepsy. No study has been conducted to determine the optimal dose of folic acid supplementation in patients taking AED. Clinicians engage in much discussion of this topic, but the current practices are not evidence based. Even though this is the case, P.Z. should start taking 4 mg of folic acid supplementation each day.

Physiologic changes in pregnant women may affect the pharmacokinetics of AED.²⁰⁶ Absorption can be influenced by nausea and vomiting. Hepatic metabolism and renal function both increase during pregnancy. The binding capacity of albumin is decreased during pregnancy, resulting in decreased protein binding for highly bound drugs. Unbound fractions of phenobarbital, phenytoin, and valproate increase with decreased concentrations of albumin.²²⁹⁻²³¹ For drugs predominantly metabolized by the liver with a restrictive clearance (e.g., carbamazepine and valproate), decreased protein binding without changes in intrinsic clearance should result in a decrease in total drug concentrations; unbound drug concentrations should remain unchanged. For drugs with both increased hepatic metabolism and decreased protein binding (e.g., phenytoin and phenobarbital), both total and unbound plasma concentrations decrease, but not necessarily proportionately.

The clearance of lamotrigine increases as pregnancy progresses, presumably related to the impact of estrogen on

lamotrigine metabolism as mentioned above.²³² This alteration in clearance changes immediately postpartum. Preliminary data suggest that oxcarbazepine concentrations may also decrease as pregnancy progresses.²³²

The effects of changes in renal function during pregnancy on AED concentrations are not well known.²³² Renal blood flow and glomerular filtration rate increase during pregnancy. Thus, the pharmacokinetics of drugs that are predominately excreted through the kidneys, such as gabapentin, levetiracetam, and pregabalin, could change during pregnancy.

During pregnancy, serum levels of AED (including free serum levels for highly protein-bound drugs) can be monitored. Dosage adjustments may help to prevent the increase in seizure frequency that is seen in approximately 25% of pregnant women with epilepsy. Because falls and anoxia associated with uncontrolled seizures may increase the risk to the unborn baby, P.Z. should be educated on the value of adherence to her AED regimen.

For P.Z., it can be presumed that significant exposure of the fetus to any teratogenic influence of AED has already occurred. Optimization of seizure control is a primary concern for this woman. Any major alterations in P.Z.'s AED regimen should be made cautiously to avoid precipitating seizures. In addition, she should be instructed to contact the AED pregnancy registry at Massachusetts General Hospital (1-888-233-2334). Information provided to the registry will aid in the ongoing monitoring of outcomes of babies born to mothers taking AED. Reports from this registry have provided risk information on two of the older AED (phenobarbital and valproate). In utero exposure to either of these AED in monotherapy caused a significantly increased incidence of major birth defects compared with controls.

Vitamin K Supplementation

Babies born to women with epilepsy who are taking enzyme-inducing AED are at risk of hemorrhage owing to decreased vitamin K-dependent clotting factors. Although some question the evidence, women taking carbamazepine, phenobarbital, primidone, or phenytoin should receive vitamin K 10 mg orally every day from 36 weeks of gestation until delivery, and babies should also receive vitamin K 1 mg IM at birth.²³³

Breast-Feeding

In a lactating woman who is taking medications, the risk of drug exposure to the infant needs to be weighed against the benefits of breast-feeding.²³⁴ All drugs transfer into milk to some extent. The extent of protein binding of the drug is the most important predictor of drug passage into milk.^{235,236} For the AED, a large intersubject variability in the milk:plasma ratio (M:P) is seen, presumably owing to a difference in volume and composition of the milk. Thus, the M:P ratio is not useful for predicting infant AED exposure. Two recent reviews on AED and breast-feeding are available.^{237,238} For most first-generation AED (carbamazepine, phenytoin, valproic acid), breast-feeding results in negligible AED plasma concentrations in the infants. For the second-generation AED, breast-feeding should be done cautiously and the infant should be monitored for excess AED plasma concentrations and toxicity, if possible. This information should be presented to P.Z. in an

appropriate manner. Once she delivers her baby, re-evaluation and optimization of P.Z.'s AED therapy should occur.

STATUS EPILEPTICUS

Characteristics and Pathophysiology

41. V.S., a 22-year-old, 85-kg man, was recently diagnosed as having idiopathic epilepsy with generalized tonic-clonic seizures. For the past 3 months, he has been treated with 600 mg/day of carbamazepine, which completely eliminated his seizures. His steady-state carbamazepine serum concentration was 10 mcg/mL. While at his parents' home, he had two tonic-clonic seizures, each lasting 3 to 4 minutes. On arrival at the hospital (~30 minutes after the first seizure began), he was noted to be only semiconscious. His blood pressure was 197/104 mmHg, his pulse was 124 beats/minute, respirations were 23 breaths/minute, and his body temperature was 37.5°C rectally. Shortly after his arrival, another generalized tonic-clonic seizure began. How does V.S.'s current condition meet accepted diagnostic criteria for status epilepticus? What risks are associated with status epilepticus?

Status epilepticus (SE) exists if "recurrent seizures occur without complete recovery of consciousness between attacks or virtually continuous seizure activity for >30 minutes, with or without impaired consciousness."²³⁹ Because V.S. has had three seizures within slightly more than 30 minutes and remains unconscious, his present condition meets this definition. V.S. is experiencing generalized convulsive SE; this is the most common type and it is associated with the greatest risk of physical and neurologic damage. SE also may be characterized by non-convulsive seizures that produce a persistent state of impaired consciousness or by partial seizures (motor or sensory) that may not interfere with consciousness.

Uncontrolled, convulsive SE can cause severe metabolic and hemodynamic alterations. V.S.'s vital signs (tachycardia, elevated blood pressure, increased respiratory rate, and elevated body temperature) are typical for a patient in SE. Prolonged, severe muscle contractions and CNS dysfunction from uncontrolled seizure discharges result in hyperthermia, cardiorespiratory collapse, myoglobinuria, renal failure, and neurologic damage. Neurologic damage also may occur with nonconvulsive SE; the neurologic sequelae of SE are related to the excessive electrical activity and resulting alterations in brain metabolism. When seizure activity persists longer than approximately 30 minutes, failure of mechanisms that regulate cerebral blood flow is more likely; this failure accompanies dramatic increases in brain metabolism and demand for glucose and oxygen. Failure to meet the metabolic demands of brain tissue results in accumulation of lactate and cell death. Peripherally, lactate accumulates and serum glucose and electrolytes are altered. After 30 minutes of seizure activity, the body often fails to compensate for increased metabolic demands, and cardiovascular collapse can occur.^{240,241} For these reasons, SE is considered a medical emergency that requires immediate treatment to prevent or lessen both physical and neurologic damage. Mortality in SE may be 20% or higher²³⁹; fatal outcome is often the result of the injury or condition that precipitated SE (e.g., cardiopulmonary arrest, stroke). Long-term neurologic consequences of severe SE may include cognitive impairment,

memory loss, and worsening of seizure disorders. The effect of SE on cognitive function is not clearly established, however; cognitive impairment may result from the neurologic disorder underlying SE rather than from SE itself.²⁴²

General Treatment Measures and Antiepileptic Drug Therapy

42. Describe a general treatment plan for V.S.'s episode of status epilepticus.

The immediate therapeutic concern in V.S. is to ensure ventilation and terminate current seizure activity. If possible, an airway should be placed; however, this may not be possible while he is convulsing. Objects (e.g., spoons, tongue blades) should never be placed into the mouth of a seizing patient. If airway placement is impossible, V.S. should be positioned on his side to allow drainage of saliva and mucus from the mouth and prevent aspiration. An IV line should be established using normal saline, and blood should be obtained for serum chemistries (especially glucose and electrolytes), AED serum concentrations, and toxicology screens. Glucose, 25 g (50 mL of 50% dextrose solution) by IV push should be administered to correct any hypoglycemia, which may be responsible for SE. Glucose administration should be preceded by IV thiamine 100 mg or vitamin B complex to prevent Wernicke's encephalopathy.²³⁹

Intravenous administration of rapidly effective anticonvulsant medication should begin as soon as possible to terminate V.S.'s seizure activity. IM or rectal administration of medication is not recommended in the initial treatment of this condition unless IV access is impossible. IM medications are unlikely to be absorbed sufficiently rapidly to achieve the CNS concentrations needed to terminate status seizures.

43. Which anticonvulsants are available for IV administration? Evaluate the available drugs and recommend a drug, dosage, and regimen for initial treatment of status epilepticus in V.S.

Lorazepam (Ativan), diazepam (Valium), phenytoin (Dilantin), and fosphenytoin (Cerebyx) are the agents most commonly employed as IV therapy in the initial treatment of SE.²⁴³ Phenytoin and fosphenytoin are indicated for treatment of SE, but owing to limitations on their rates of infusion, the onset of their peak effect may be delayed. Therefore, phenytoin or fosphenytoin are usually used following initial treatment with lorazepam or diazepam.

Intravenous sodium valproate (Depacon) is available, but it is not indicated for the treatment of SE. Although the manufacturer only recommends Depacon be administered slowly (<20 mg/minute), it has been administered safely at higher doses and rates.²⁴⁴ Currently, IV valproate is indicated only for use in patients who cannot take oral dosage forms of valproate. An IV form of levetiracetam is now available. This drug also is indicated only for patients who cannot receive oral dosage forms of levetiracetam. Rapid IV administration of levetiracetam has been used, however, in the treatment of SE in Europe.²⁴⁵ IV phenobarbital is usually reserved for SE that does not respond to benzodiazepines and phenytoin.

Four IV regimens for generalized convulsive SE have been directly compared.²⁴⁶ The trial evaluated diazepam (0.15 mg/kg) followed by phenytoin (18 mg/kg), lorazepam (0.1

mg/kg) alone, phenobarbital (15 mg/kg) alone, and phenytoin (18 mg/kg) alone. For initial IV treatment of overt generalized SE, lorazepam was more effective than phenytoin alone. Lorazepam was as effective as the other two regimens, and it was easier to use.

Intravenous administration of either diazepam or lorazepam is usually effective for rapid termination of seizure activity in SE.²⁴⁷ Owing to diazepam's higher lipid solubility, it redistributes from the CNS to peripheral tissues rapidly after administration; this results in a short duration of action (<60 minutes).²⁴⁸ Lorazepam's lower lipid solubility prevents rapid redistribution and accounts for its longer duration of action.²⁴⁸ Lorazepam may be effective for up to 72 hours.^{249,250} Owing to this longer duration, lorazepam is now the preferred benzodiazepine for immediate treatment of SE in many centers.²³⁹ Repeated doses of lorazepam have been associated with development of tachyphylaxis, and lorazepam may be less effective for patients who have received chronic maintenance doses of benzodiazepines.^{251,252} At adequate doses, the onset of antiepileptic activity and efficacy of lorazepam and diazepam are equal.²⁴⁷

Either 0.1 mg/kg of lorazepam at 2 mg/minute or 0.2 mg/kg of diazepam at 5 mg/minute by IV is administered to stop SE.²³⁹ Lorazepam may cause significant venous irritation, and the manufacturer recommends dilution with an equal volume of normal saline solution or water for injection before IV administration. Doses of either lorazepam or diazepam should be repeated after 5 to 10 minutes if seizure activity has not stopped. The efficacy of either drug depends on rapid achievement of high serum and CNS concentrations. Although both diazepam and lorazepam can be administered IM, this route should not be used for treatment of SE because it is unlikely that either drug would achieve serum concentrations necessary for termination of seizure activity. This is especially true for diazepam, which is absorbed slowly and erratically from gluteal IM injection sites.²⁴⁸ Both lorazepam and diazepam are relatively safe drugs. Their primary adverse effects are sedation, hypotension, and respiratory arrest.²⁴⁸ These side effects are usually short-lived and, when adequate facilities are available for assisted ventilation and administration of fluids, they usually can be managed without major risk to the patient. Respiratory depression occurs most commonly in patients who receive multiple IV medications for control of SE.

Intravenous Phenytoin and Fosphenytoin

44. V.S. was given lorazepam 8 mg IV. Seizure activity ceased 5 minutes after the injection was completed. What drug should be administered to V.S. for prolonged control of seizures? Recommend a dose, route, and method of administration.

Continued effective seizure control is important for patients who experience SE. Previously, when diazepam was the benzodiazepine predominantly used for immediate control of SE, a long-acting AED such as phenytoin was routinely administered at the same time to ensure continued suppression of seizure activity. Routine use of phenytoin has been somewhat de-emphasized with increased use of lorazepam²³⁹; lorazepam's apparent longer duration of effect may make routine use of IV phenytoin less necessary. Nevertheless, many

centers still use phenytoin in conjunction with both lorazepam and diazepam.

The availability of fosphenytoin (Cerebyx) for IV administration has provided an additional option for administration of phenytoin in the treatment of SE. Use of this phenytoin prodrug allows more rapid administration of large IV loading doses of phenytoin with less risk of injection site complications and potentially fewer cardiovascular adverse effects. Fosphenytoin itself is inactive; the therapeutic effect results from its conversion to phenytoin.^{121,122} Because fosphenytoin is more expensive, many facilities have been reluctant to place this product on their formularies. Pharmacoeconomic studies, however, seem to indicate that, although it is initially more expensive, fosphenytoin may be more economical because it causes fewer adverse effects than phenytoin.²⁵³ Generic formulations of injectable sodium phenytoin are still available; nevertheless, when the safety profile of fosphenytoin is considered, fosphenytoin may ultimately replace parenteral sodium phenytoin injection.

Phenytoin (administered as either sodium phenytoin injection or as sodium fosphenytoin injection) is presently considered the long-acting anticonvulsant of choice for most patients with generalized convulsive SE.²⁴³ Extensive clinical experience with the use of IV loading doses of phenytoin has established its efficacy and general safety. Phenytoin causes much less sedation and respiratory depression than drugs such as phenobarbital when it is used in conjunction with IV benzodiazepines.²³⁹ V.S.'s maintenance carbamazepine therapy produced moderate serum concentrations and was previously effective. Without obvious precipitating factors such as head trauma, CNS infection, and drug or alcohol abuse, SE, in a patient with a history of epilepsy, most commonly results from poor compliance with maintenance medication. Therefore, IV use of either phenytoin or fosphenytoin is a good choice for re-establishing effective AED therapy for V.S.

LOADING DOSE

Whether or not V.S. has a detectable serum concentration of carbamazepine, he should be given an IV loading dose of either phenytoin (20 mg/kg IV at 50 mg/minute) or fosphenytoin (20 mg/kg PE IV at 150 mg/minute). After administration of either of these loading doses, serum phenytoin concentrations should remain >10 mcg/mL for approximately 24 hours; this will allow time for determination of V.S.'s serum carbamazepine concentration and estimation of an appropriate maintenance dose of oral carbamazepine. In this setting, the use of IV phenytoin or fosphenytoin is a temporary measure. V.S.'s previous positive response to carbamazepine indicates that he should continue to receive this drug as oral maintenance medication.

Intravenous phenytoin can be administered by direct injection into a running IV line. The rate of administration should be no faster than 50 mg/minute to minimize the risk of hypotension and acute cardiac arrhythmias. Cardiovascular status (blood pressure, electrocardiogram) should be monitored closely during administration. Hypotension or electrocardiographic abnormalities usually reverse if the administration of phenytoin is slowed or stopped temporarily. If fosphenytoin is administered, it can be given by either direct IV injection or, after dilution in any suitable IV solution, by infusion at up to 150 mg PE/minute.¹²¹ Absence of propylene glycol as a dilu-

ent renders fosphenytoin potentially less likely than phenytoin to cause cardiovascular adverse effects; however, clear documentation of this effect is lacking. Electrocardiographic and blood pressure monitoring is recommended when this drug is given IV. Pruritus and paresthesias, usually localized to the face and groin, are relatively common side effects during IV fosphenytoin administration. These sensations are not allergic reactions to the medication. Their occurrence is related to the administration rate, and they are reversible with temporary discontinuation or slowing of the injection.¹²¹ These side effects are thought to be related to the phosphate component of fosphenytoin.

INTRAVENOUS INFUSION

45. V.S.'s physician is reluctant to administer this dose of either phenytoin or fosphenytoin by direct IV injection. What are the guidelines for administration of phenytoin and fosphenytoin by IV infusion?

Practical difficulties associated with administration of phenytoin by direct IV push undoubtedly have contributed to its low usage rate. In many hospitals or other facilities, direct IV injections must be administered by a physician, and many physicians would be unwilling to commit the 30 to 45 minutes necessary to administer V.S.'s loading dose at a safe rate. In addition, the rate of direct IV administration is difficult to control, and too-rapid administration resulting in cardiac toxicity is a risk. Although fosphenytoin can be given at a faster injection rate with a lower risk of complications, direct IV administration of this drug still presents practical difficulties.

The compatibility of phenytoin injection with IV solutions has been controversial. Phenytoin's chemical properties (weakly acidic with a pKa of 8 and low water solubility) require that the commercial injectable dosage form of sodium phenytoin be dissolved in a mixture of 40% propylene glycol and 10% alcohol; the pH of the final product is adjusted to approximately 12 with sodium hydroxide. Addition of the preparation to IV fluids dilutes the drug's solvent system and reduces pH. A possible result would be precipitation of free phenytoin. Several studies indicate, however, that phenytoin can be diluted, preferably in small total volumes, with saline solution.^{254,255} Despite the formation of crystals in many solutions, measured phenytoin concentrations are essentially identical to those predicted. Thus, dilution of the required volume of phenytoin injection in approximately 100 to 500 mL of 0.45% or 0.9% saline should provide an appropriate solution for IV administration. An in-line filter of 0.45 to 0.22 micron pore size may be used to prevent the infusion of crystals.²⁵³ The administration rate should be no faster than 50 mg/minute. This method of administration is both safe and effective when the infusion rate is monitored carefully. Burning pain at the IV infusion site, hypotension, and cardiac arrhythmias can occur during the infusion and appear to be related to the infusion rate. Either slowing or temporarily stopping the infusion may relieve these side effects.^{256,257} IV administration of phenytoin is also associated with phlebitis; extravasation has resulted in chemical cellulitis and tissue necrosis.²⁵⁸

Intravenous infusion of fosphenytoin is less troublesome. Fosphenytoin is compatible with virtually all IV fluids because of its high water solubility and the lower pH required

to maintain the drug in solution. Hypotension can occur during fosphenytoin infusion, and cardiovascular status should still be monitored closely. Fosphenytoin should not be infused at a rate >150 mg PE/minute. Injection site complications and phlebitis are significantly less likely with administration of fosphenytoin.¹²⁰

Maintenance Therapy

46. Following administration of IV phenytoin, no further seizures occurred. The laboratory reported that serum chemistries were all normal. The carbamazepine serum concentration was 5 mcg/mL on admission. A serum phenytoin concentration determined 1 hour after administration of the IV loading dose was 24 mcg/mL. How should V.S.'s maintenance AED therapy be altered?

The reduced serum concentration of carbamazepine appears to confirm the role of nonadherence in this episode of SE. As V.S. was previously well controlled on 600 mg/day, this also would be a reasonable maintenance dosage at this time. Administration of maintenance doses should be resumed as soon as V.S. can take oral medication. V.S. should be counseled regarding the importance of taking his medication according to directions.

Alternative Therapies for Refractory Status Epilepticus

47. What other medications are options for treatment of SE that does not respond to benzodiazepines or phenytoin?

Phenobarbital may be useful for treatment of SE if the patient cannot tolerate phenytoin or when seizures continue following administration of appropriate loading doses of phenytoin. Patients who receive phenobarbital after being treated with IV benzodiazepines should be monitored closely for respiratory depression because this effect may be additive. Equip-

ment and personnel to provide ventilatory assistance should be available.²³⁹ Administration of IV phenobarbital can cause hypotension, which may necessitate discontinuation of the drug or the use of pressor agents. An initial dose of 20 mg/kg given IV at a rate no faster than 100 mg/minute is recommended.²³⁹ IM administration of phenobarbital results in slow absorption, and this route of administration is not recommended for treatment of SE.

Pentobarbital or other anesthetic barbiturates are administered for treatment of SE that has not responded to more conservative measures, including phenobarbital. Significant respiratory depression is expected with this therapy; patients will require intubation and mechanical ventilation. In addition, vasopressors, such as dopamine or dobutamine, may be required to control hypotension. Constant EEG monitoring also is required to assess the effect of the drug.

Pentobarbital is given as a loading dose of 5 mg/kg IV and is followed by an IV infusion of 0.5 to 3 mg/kg/hour.²³⁹ The dose and infusion rate are adjusted to produce either a flat or a burst-suppression EEG pattern.²⁵⁹ Most protocols for pentobarbital coma recommend attempts at gradually reducing the dose of medication after 12 to 24 hours of treatment. If clinical or EEG seizure activity recurs, the dose is increased again to produce continued EEG suppression. Pentobarbital coma may be continued for several days in some patients.

Several other drugs have been used for treatment of refractory SE, but experience with these agents is somewhat limited. Midazolam (Versed), a short-acting anesthetic benzodiazepine, has been used by IV infusion.^{260–262} Valproate has been used for treatment of refractory SE. Because no parenteral form of this drug has been available until recently, the syrup form has been administered either rectally or via nasogastric tube. At present, information regarding the IV use of valproate for SE is largely anecdotal.²⁶³ Other drugs that have been used for refractory SE include lidocaine (Xylocaine), general anesthetics (halothane or isoflurane), and propofol.^{243,264,265}

TRANSIENT ISCHEMIC ATTACKS

Cerebrovascular disease is a broad term encompassing many disorders of the blood vessels of the central nervous system (CNS). These disorders result from either inadequate blood flow to the brain (i.e., cerebral ischemia) with subsequent infarction of the involved portion of the CNS or from hemorrhages into the parenchyma or subarachnoid space of the CNS and subsequent neurologic dysfunction. This group of disorders is the third leading cause of deaths among adults in the United States.¹

Definitions**Transient Ischemic Attack**

A transient ischemic attack (TIA) describes the clinical condition in which a patient experiences a temporary focal neurologic deficit such as slurred speech, aphasia, weakness or paralysis of a limb, or blindness. These symptoms appear rapidly and are temporary, lasting <24 hours (usually only 2–15 minutes). The exact clinical presentation depends on the portion of the cerebrovascular tree (e.g., carotid artery, vertebrobasilar artery, or both) affected by diminished or absent blood flow. TIAs frequently result from small clots breaking away from larger, distant blood clots. These emboli are then dissolved by the fibrinolytic system, allowing re-establishment of blood flow and return of neurologic function.

Cerebral Infarction

A cerebral infarction is a permanent neurologic disorder characterized by symptoms similar to a TIA. The patient with a cerebral infarction presents with neurological deficits caused by the death of neurons in a focal area of the brain. The two primary causes of infarction and persistent ischemia are atherosclerosis of cerebral blood vessels, or an embolus to cerebral arteries from a distant clot. Cerebral infarctions can present in three forms: stable, improving, or progressing. A *stable infarction* describes the condition when the neurologic deficit is permanent, will not improve, and will not deteriorate. An *improving infarction* is marked by return of previously lost neurologic function over several days or weeks. A *progressing infarction* is one in which the patient's neurologic status continues to deteriorate following the initial onset of focal deficits.

Cerebral Hemorrhage

Cerebral hemorrhage is a cerebrovascular disorder that involves escape of blood from blood vessels into the brain and its surrounding structures. The leakage of blood causes clinical symptoms similar to those associated with a TIA or infarction. The neurologic dysfunction that is associated with TIAs or cerebral infarction results from the lack of blood flow to a given portion of the brain. In a cerebral hemorrhage, the initial neurologic deficits are due to the direct irritant effects of blood that is in direct contact with brain tissue. Primary causes of a

cerebral hemorrhage include cerebral artery aneurysm, arteriovenous malformation, hypertensive hemorrhage, and trauma.

The terms *apoplexy*, *stroke*, and *paralytic stroke* are commonly used by lay persons to describe a sudden neurologic affliction that usually is related to the cerebral blood supply. The term *stroke* is used to describe a cerebral vascular event when neurologic deficits persist for at least 24 hours.

Epidemiology

Annually, approximately 700,000 individuals in the United States experience a cerebral infarction, and approximately 160,000 will die as a result of the stroke.² Of the 700,000 strokes annually, 500,000 are first-ever strokes and 200,000 are recurrent events.³ Cerebrovascular disease is the third most common cause of death in adults and is one of the more commonly encountered causes of neurologic dysfunction. Nevertheless, this represents a dramatic decrease in the mortality rate of ischemic stroke from 88.8 per 100,000 population in 1950 to 54.3 per 100,000 in 2003. There are important racial and ethnic differences in incidence and mortality rates for ischemic stroke as shown in Table 55-1. The precise reasons for these differences are unclear, but genetic, geographic, dietary, and cultural factors have been considered.⁴ In addition, the incidence of risk factors for stroke such as hypertension, diabetes, and hypercholesterolemia differ between racial groups.⁴

In the United States, ischemic stroke is the most common type of infarction (Fig. 55-1). Atherothrombotic disease of the large cerebral blood vessels is responsible for the majority of cerebral ischemic events and infarctions. Disease of penetrating arteries that are responsible for oxygenation and nutrition of the CNS, thromboembolic causes (e.g., atrial fibrillation), and other causes such as infection or inflammation of arteries are also responsible for ischemic stroke.^{1,2}

There is a strong relationship between the occurrence of TIA and an increased risk for subsequent cerebral infarction.¹ The risk of an ischemic stroke is highest in the first 30 days after a TIA and the risk within 90 days of a TIA is 3% to 17.3%. Additionally, nearly 25% of patients who suffer a TIA will die within a year.¹

Definite risk factors for cerebral infarction are listed in Table 55-2. A key element in the prevention of stroke is the elimi-

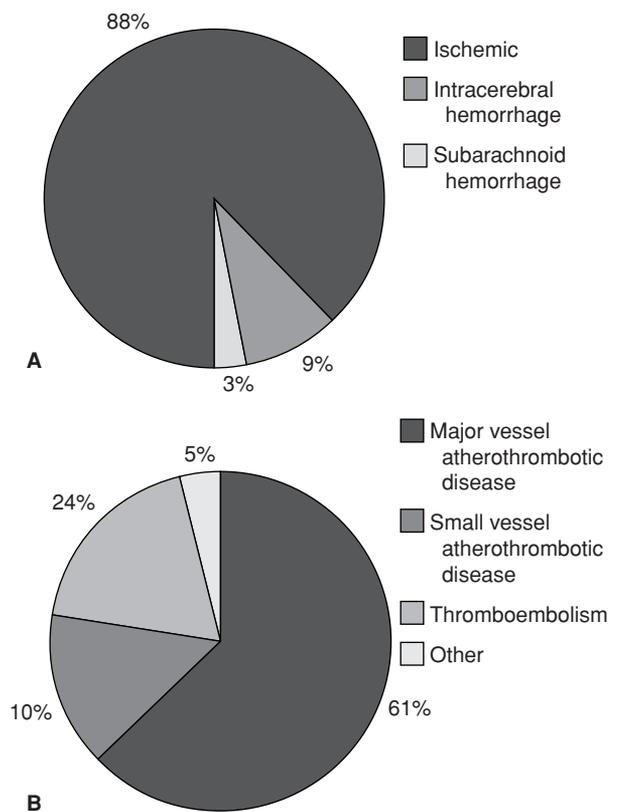

FIGURE 55-1 Etiology of Strokes (A) Causes of All Strokes (B) Causes of Ischemic Strokes

nation or modification of risk factors.^{5,6} The control of risk factors is of primary importance in managing a patient with a TIA or cerebral infarction.

Hemorrhage into the brain accounts for 12% of all strokes in North America. Hypertensive hemorrhage is the most common cause of intracerebral hemorrhages (ICHs), with 46% of ICHs resulting from hypertension.⁷ Subarachnoid hemorrhage is the second most common cause of hemorrhagic stroke and has a mortality rate of approximately 50%. Patients with subarachnoid hemorrhage are usually 20 to 70 years old, and the majority of survivors suffer permanent neurologic deficits. A less common cause of ICH is an arteriovenous malformation (AVM), which is a clump of arteries and veins that are intertwined, resulting in weakened blood vessel walls. AVMs usually result from a congenital defect or trauma.

Pathophysiology

Thrombotic Events

The neurologic sequelae of cerebral ischemia or infarction directly result from an embolic or thrombotic source. A clot may form in the heart, along the wall of a major blood vessel (e.g., aorta, carotid, or basilar artery), or in small arteries penetrating deep into the brain. If the clot is located near the infarction, it is considered to be a thrombus; however, when the clot has migrated to the brain from a distant source, it is considered an embolus. Either can diminish or block blood flow to the affected area of the brain.

Table 55-1 Epidemiology of Stroke by Race or Ethnic Group

| Ethnic/Racial Group | First-ever Age-adjusted Stroke Incidence (per 100,000 people) | Death Rate (per 100,000 people) |
|-----------------------|---|---------------------------------|
| Overall | 208 | 54.3 |
| Black Men | 323 | 78.8 |
| Black Women | 260 | 69.1 |
| White Men | 167 | 51.9 |
| White Women | 138 | 50.5 |
| Hispanic Men | | 44.3 |
| Hispanic Women | | 38.6 |
| Asian Men | | 50.8 |
| Asian Women | | 45.4 |
| Native American Men | | 37.1 |
| Native American Women | | 38 |

Table 55-2 Risk Factors for Ischemic Stroke

| <i>Modifiable</i> | <i>Potentially Modifiable</i> | <i>Nonmodifiable</i> |
|---|--|--|
| Cardiovascular disease (coronary heart disease, heart failure, peripheral arterial disease) | Metabolic syndrome | Age (doubling each 10 years over age 55) |
| Hypertension | Alcohol abuse (≥ 5 drinks daily) | Race (blacks>Hispanics>whites) |
| Cigarette smoking | Hyperhomocysteinemia | Sex (men>women) |
| Diabetes | Drug abuse (e.g., cocaine, amphetamine, methamphetamine) | Low birth weight (<2,500 g) |
| Asymptomatic carotid stenosis | Hypercoagulability (e.g., anticardiolipin, Factor V Leiden, protein C deficiency, protein S deficiency, antithrombin III deficiency) | Family history of stroke (paternal>maternal) |
| Atrial fibrillation | Oral contraceptive use (women 25–44 years old) | |
| Sickle cell disease | Inflammatory processes (e.g., periodontal disease, Cytomegalovirus, <i>Helicobacter pylori</i> seropositive) | |
| Dyslipidemia (high total cholesterol, low HDL) | Acute infection (e.g., respiratory infection, urinary tract infection) | |
| Dietary factors (sodium intake <2,300 mg/day; potassium intake <4,700 mg/day) | CD 40 ligand >3.71 ng/mL in women free of cardiovascular disease | |
| Obesity | IL-18 upper tertile | |
| Physical inactivity | hs-CRP >3 mg/L in women 45 years or older | |
| Postmenopausal hormone therapy (women 50–74 years old) | Migraine headaches | |
| | High Lp(a) | |
| | High Lp-PLA ₂ | |
| | Sleep-disordered breathing | |

Clots, both embolic and thrombotic, affecting the cerebral vasculature are typically arterial in origin and are formed primarily by fibrin. Tissue injury or turbulent blood flow causes the release of adenosine diphosphate (ADP), thrombin, epinephrine, and a variety of other substances to stimulate platelet migration. Exposure of collagen and other subendothelial surfaces of the blood vessel wall cause adhesion of platelets to the damaged vessel wall. As platelets adhere and aggregate, phospholipase is activated, leading to the splitting of arachidonic acid from platelet membrane phospholipid. This begins a cascade of events ultimately ending in the formation of thromboxane A₂ (TXA₂) and prostacyclin. Prostacyclin inhibits platelet aggregation and is a powerful vasodilator, whereas TXA₂ is a potent inducer of platelet release and aggregation. Prostacyclin is formed in and released from arterial and venous walls. TXA₂ is formed in and released from platelets. The delicate balance between the actions of these two compounds controls thrombogenesis. When a clot is formed, it can either embolize to the cerebral vasculature or occlude a cerebral artery.

Inflammatory mechanisms also contribute to the development of ischemia, especially thrombotic lesions. Substances like C-reactive protein, a mediator of inflammation, are elevated in patients with an acute stroke. Inflammation is thought to enhance the development of thrombotic lesions and result in sudden, intermittent occlusion of blood vessels.

Cerebral blood flow in the normal adult brain is 30 to 70 mL/100 g/minute. When a thrombotic or embolic clot partially occludes a cerebral artery, causing a reduction in blood flow to <20 mL/100 g/minute, various compensatory mechanisms are activated. These include vasodilation and increased oxygen extraction. If the artery is further occluded and cerebral blood

flow is reduced to <12 mL/100 g/minute, the affected neurons become sufficiently anoxic to die within minutes (Fig. 55-2).⁸ Rapid re-establishment of blood flow to the ischemic area can delay, prevent, or limit the onset of infarction, improving the outcome of the acute stroke.

Ischemia in the brain usually involves a core or focal region of profound ischemia that results in neuronal death. The extent of this region is dependent on the amount of brain that is perfused directly by the blood vessel that becomes occluded. There is a surrounding area of brain that becomes marginally ischemic with normal function being disrupted. This region of marginal ischemia is frequently called the *ischemic penumbra*. If ischemia continues, neurons in this region will die. However, if normal blood flow is restored quickly, neurons in this area will survive.

**FIGURE 55-2 Physiologic effects of cerebral anoxia.**

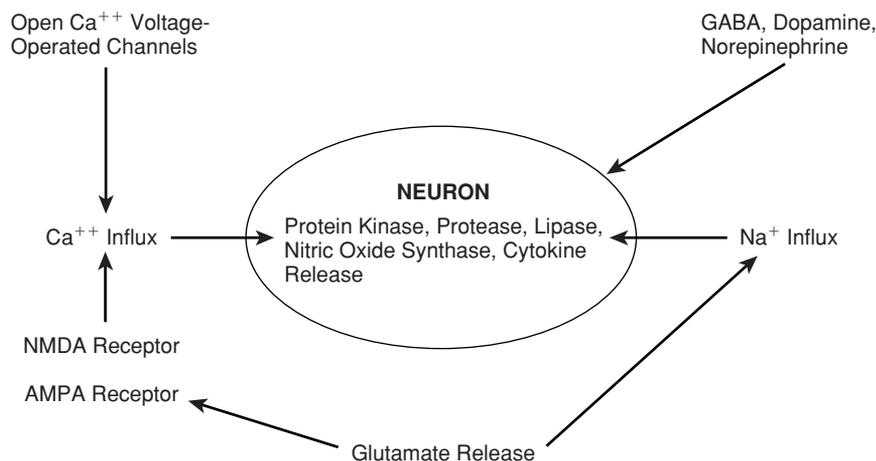

FIGURE 55-3 The effects of membrane depolarization.

When neurons become ischemic, excitatory neurotransmitters are released, causing neurons to rapidly and repeatedly discharge. This compromises the survival of damaged neurons around the area of infarction. Increased neuronal activity results in extreme metabolic demands, disrupts neuronal homeostasis, and synergistically increases the effects of hypoxia. Especially vulnerable to ischemic effects are neurons in the middle layers of the cerebral cortex; portions of the hippocampus (CA-1 and subiculum regions), a structure running parallel to the parahippocampal gyrus; and Purkinje cells in the cerebellum.⁹ There is also a rapid intracellular influx of calcium. Both voltage-dependent and chemical-dependent calcium channels are unable to act as a gate to prevent the movement of calcium, due to depletion of cellular energy sources. Intracellular stores of calcium ions also are disrupted, causing release of calcium into the cytoplasm. Increased concentration of calcium ions enhances phospholipase and protease activity and increased reactive metabolites, such as $-O_2$, $-OH$, and nitric oxide (Fig. 55-3). This eventually causes neuronal death.^{8,9} In addition, lipolysis of cell membranes occurs in the presence of an accumulation of neurotoxic free radicals.

Immediate therapeutic intervention is needed to limit and prevent permanent neurologic damage from these rapidly occurring events.

Embolic Events

The pathophysiology of infarction of brain tissue and neuronal death is similar for both embolic and thrombotic events. However, rather than forming locally in the vasculature of the brain, embolic events result from clots that are formed in distant parts of the body. Portions of these clots may break away and travel through the blood to the brain. When they become lodged in the cerebral vasculature, blood flow will be partially or totally occluded. This occlusion initiates the cascade of ischemic events in the brain and neurons. Disorders like atrial fibrillation, mitral or aortic valve disease, patent foramen ovale, or coagulopathies are associated with formation of clots that may embolize to the brain.

Intracerebral Hemorrhage

Cerebral aneurysms, AVMs, hypertension, and adverse drug reactions are the primary causes of ICH. One type of ICH,

subarachnoid hemorrhage, can result from weakened blood vessel walls (i.e., aneurysms) caused by congenital defects, trauma, infection, and hypertension. Blood slowly leaks from the involved vessel or the aneurysm may rupture suddenly. In this type of hemorrhage, blood typically is released into the subarachnoid space and, depending on the severity of the hemorrhage, into the ventricles of the brain. Direct contact of blood with brain tissue irritates and damages brain cells. Rebleeding, hydrocephalus, and delayed cerebral ischemia frequently occur after the aneurysm ruptures, further worsening the patient's neurologic function.

AVMs due to congenital causes or traumatic injury, and uncontrolled hypertension also can cause devastating intracerebral bleeding. In these patients, blood is usually released directly into the brain parenchyma. In more severe cases blood is released into the surrounding brain structures. ICHs can be the result of adverse reactions to drugs, such as anticoagulants, thrombolytics, and sympathomimetics.

General Treatment Principles

Rapid recognition of stroke symptoms and immediate initiation of treatment are essential to the management of ischemic or hemorrhagic stroke. Appropriate pharmacotherapy of cerebrovascular disease requires a precise diagnosis. It is vital to differentiate between an ischemic stroke and a hemorrhagic stroke, because an inaccurate diagnosis can lead to the use of drugs that may cause severe morbidity or mortality. Interventions to prevent and treat ischemic strokes are directed at reducing risk factors, eliminating or modifying the underlying pathologic process, reducing secondary brain damage, and rehabilitation.

Treatments for ischemic stroke and hemorrhagic stroke vary. In ischemic stroke, treatment involves acute management, chronic management of the effects of the stroke, and prevention of further events. In acute management, the only effective treatment is the use of tPA in combination with supportive measures. Chronic management of the effects of a stroke focus primarily on treating depression, spasticity, possible neurogenic bowel or bladder, and self-care issues. Antiplatelet agents, especially, aspirin, clopidogrel, and aspirin/dipyridamole combination, form the cornerstone of prevention.

In hemorrhagic stroke, the emphasis of treatment is on supportive therapy to maximize neurological function, prevention of further hemorrhagic events, and management of complications. This involves wise management of blood pressure, pulmonary function, fluid and electrolytes, and elimination of drugs that inhibit coagulation. There are no proven direct therapies for hemorrhagic events.

PRIMARY PREVENTION

Lifestyle Modification

1. R.B. is a 60-year-old, 5 feet 6 inches tall, 85-kg woman who is concerned about having a stroke. Her father died from a stroke and her 85-year-old mother has had several episodes diagnosed as TIA. R.B.'s blood pressure is 140–150/90–100 mmHg, and she was recently diagnosed with diabetes mellitus. She does not have a history of TIA or stroke. Additionally, she smoked for 25 years, but has not used tobacco for the past 10 years. Her current medications include lisinopril, metformin, conjugated estrogen/medroxyprogesterone, and acetaminophen. She approaches her pharmacist because of concerns about having a stroke and being “like her parents.” What are the first things she can do to limit her risk of stroke?

Any plan for *primary prevention* (i.e., *orevbtuib* if a first event) of TIA or stroke must address the control or reduction of risk factors (Table 55-3).

For R.B., hypertension is a risk factor that requires immediate attention. Nearly 70% of strokes result from hypertension and blood pressure control is vital for stroke prevention. Both systolic and diastolic hypertension increases the risk of stroke.^{10,11} Adequate control of her blood pressure should reduce R.B.'s risk of stroke by 35% to 44%.¹² Based upon JNC 7 guidelines, R.B.'s blood pressure goal should be <130/80 mmHg due to the additional risk factor of diabetes.¹³ Because she is already receiving lisinopril and her blood pressure is poorly controlled, it is likely that combination therapy is needed. Addition of hydrochlorothiazide 25 mg/day is advisable.⁵

Diabetes is another important risk factor for stroke. In older women, diabetes is a more significant risk factor for stroke than for men.¹⁴ There is controversy regarding the intensity of glucose control that optimally reduces stroke risk. Clearly, good control of diabetes results in better control of hypertension and other risk factors for stroke.¹⁵ Additionally, use of oral hypoglycemics may reduce the risk of stroke through mechanisms other than glycemic control. However, strict control of blood glucose did not reduce the risk of stroke over 9 years in one study.¹⁵ There is evidence that angiotensin converting enzyme inhibitors (ACEI) and angiotensin receptor blockers (ARB) reduce the risk of stroke in diabetics, with or without hypertension.^{16,17} For diabetic patients with at least one additional risk factor for cardiovascular disease, taking a HMG-CoA reductase inhibitor appears to reduce the risk of stroke by approximately 24% even in the absence of hypercholesterolemia.^{18,19} For RB, she should maintain tight control of her diabetes, continue her lisinopril, and start a HMG-CoA reductase inhibitor, such as simvastatin or atorvastatin.

The body mass index (BMI) for R.B. is 30.2, placing her in the obese category. Multiple large studies have demonstrated a direct relationship between increased body weight and an increased risk of stroke.^{20,21} There are no data available to establish the precise effect of weight reduction on reducing the risk of stroke. Data are available to show that an average weight reduction of 5.1 kg results in a reduction in systolic blood pressure of 4.4 mmHg and a reduction in diastolic pressure of 3.6 mmHg.²² In addition to weight loss, a proper diet and exercise are important for controlling risk factors. A diet high in sodium is associated with an increased risk in stroke, whereas a diet high in potassium appears to reduce the risk of stroke.^{23,24} Current recommendations for diet are for sodium intake of ≤ 2.3 g/day and potassium intake of ≥ 4.7 g/day.⁵ Several studies have shown an inverse relationship between physical activity and risk of stroke.^{25,26} At least 30 minutes of moderate intensity exercise daily is recommended.⁵ Based upon these data, R.B. should initiate a weight reduction program that includes a low-sodium and high-potassium diet with an exercise program.

Table 55-3 Primary Prevention of Ischemic Stroke

| Factor | Goal | Recommendation |
|---|--|--|
| Hypertension | Blood Pressure <140/90 mmHg; with diabetes <130/80 | Follow JNC 7 guidelines; after lifestyle modification thiazide-type diuretic, angiotensin converting enzyme inhibitor, or angiotensin receptor blocker |
| Atrial fibrillation | When warfarin is used INR 2–3 | Aspirin 75–325 mg/day or warfarin as determined by the use of the CHADS ₂ score |
| Dyslipidemia Women (>65 years, history of hypertension, hyperlipidemia, diabetes, or 10-year cardiovascular risk $\geq 10\%$) | National Cholesterol Education Program III goals Reduce risk without bleeding complications | Lifestyle modification, HMG CoA reductase inhibitor Aspirin 75–325 mg/day; use the lowest possible dose |
| Cigarette smoke | Elimination of cigarette smoke | Smoking cessation; avoidance of environmental tobacco smoke |
| Physical inactivity Excessive alcohol intake | ≥ 30 minutes daily of moderate intensity activity Moderation | Establish exercise program of aerobic activity ≤ 2 drinks/day for men or ≤ 1 drink/day for nonpregnant women |
| Diet and nutrition | ≤ 2.3 g/day of sodium; ≥ 4.7 g/day of potassium | Institute a diet that is high in fruits and vegetables and low in saturated fats |
| Elevated lipoprotein(a) | Reduction of lipoprotein(a) by $\geq 25\%$ | Niacin 2,000 mg/day as tolerated |

Adapted from reference 5.

Cigarette smoking is an independent risk factor for stroke and potentiates other risk factors. In addition to active smoking, passive inhalation of cigarette smoke also appears to be a risk factor for stroke.²⁷ Smoking cessation does result in a rapid reduction in the risk of stroke, but the risk never returns to levels seen in individuals who have never smoked.²⁸ R.B. should be encouraged to avoid passive smoke and to continue avoiding the use of tobacco.

Previously, treatment guidelines suggested that hormone replacement therapy was at least neutral in its effects on the risk of stroke and perhaps beneficial. However, three subsequent studies have specifically investigated the effect of hormone replacement on stroke risk. The Women's Estrogen for Stroke Trial (WEST) investigated the effect of hormonal therapy on the secondary prevention of stroke.²⁹ In the first 6 months of the study, those randomized to receive estradiol had a significantly higher risk of recurrent stroke and were less likely to recover if they had a stroke. A second study, the Heart and Estrogen/Progestosterone Replacement Study (HERS) evaluated the effect of hormone therapy on the secondary prevention of MI in postmenopausal women.³⁰ In a posthoc analysis, hormone replacement therapy had no effect on stroke risk.³¹ The Women's Health Initiative (WHI) study specifically evaluated the effect of conjugated estrogens and medroxyprogesterone on primary prevention of cardiovascular events, including stroke, in women who were postmenopausal.³² The study was terminated early due to a significant increase in stroke rates and other cardiovascular events in women receiving hormone replacement therapy. Similar findings were seen in a parallel group of women who were surgically postmenopausal.³³ Based upon results from these studies, R.B. should discontinue the conjugated estrogen/medroxyprogesterone product, unless she is taking this medication for a specific reason other than control of menopausal symptoms or prevention of cardiovascular events.

Pharmacotherapy Primary Prevention

2. Are there specific pharmacotherapeutic treatments to reduce the risk of stroke for R.B.?

Aspirin has been carefully investigated for primary prophylaxis of stroke. Although aspirin is recommended in the primary prevention of coronary heart disease, it is not generally recommended for the primary prevention of stroke. In a study of 22,071 male physicians who took 325 mg of aspirin or placebo every other day for 5 years, there was not a reduced incidence of stroke.³⁴ This group of individuals who had no previous history of cerebrovascular disease experienced 217 strokes, 119 in the aspirin group and 98 in the placebo group. In addition, there was an increased risk of cerebrovascular events due to hemorrhage in the aspirin group. Chen et al. reported a meta-analysis of 40,000 patients randomly assigned to aspirin and found a reduction from 47% to 45.8% in death and disability due to stroke.³⁵ Another study considered the role of aspirin for primary stroke prevention in women.³⁶ Women who took one to six aspirin per week had a slightly reduced risk of stroke and a lower risk of large-artery occlusive disease (relative risk, 59%; 95% confidence level (CI), 0.29–0.85, $p = 0.01$). An increased risk of stroke was seen in women who took >7 aspirin weekly and an excess risk of subarachnoid

hemorrhage was seen for those taking >15 aspirin a week. The Women's Health Study also investigated the use of 100 mg/day in asymptomatic women and followed them for 10 years, monitoring for nonfatal cardiovascular events including stroke.³⁷ In this study there was a 17% reduction in the risk for all strokes and a 24% reduction in the risk for ischemic stroke, while there was a nonsignificant increase in the risk for hemorrhage. Women 65 years of age and older at entry into the trial showed the most consistent risk reduction, but hemorrhagic strokes negated some of the benefit. Additionally, women with a history of hypertension, hyperlipidemia, or diabetes, or a 10-year cardiovascular risk of $\geq 10\%$ had the most benefit. Thus, aspirin should only be considered in women who are 65 years or older, or have other important risk factors for stroke. There are very limited data currently available regarding the use of other antiplatelet drugs for primary prevention of stroke.

Although oral anticoagulants are not generally considered safe for primary prevention of stroke, a major exception is patients with atrial fibrillation. These individuals are at risk for an embolic event arising from clot formation in the atrium of the heart. Numerous studies have clearly shown that warfarin prevents embolic cerebrovascular events for patients with non-valvular atrial fibrillation.^{38–42} In these studies, the warfarin dose was adjusted to maintain an INR of 1.5 to 4.5. The Stroke Prevention in Atrial Fibrillation (SPAF) trial included aspirin combined with warfarin in one study arm and indicated that some benefit may be derived by combining antiplatelet agents with anticoagulants.³⁸ A follow-up study was performed and showed no difference between warfarin and aspirin in preventing stroke in atrial fibrillation.⁴² Aspirin can be used as an alternative to warfarin in patients with atrial fibrillation, based upon the CHADS₂ score (Table 55-4).^{5,43,44} Additionally, warfarin may be used in primary prevention of embolic stroke due to a patent foramen ovale.

For R.B., primary prevention of stroke with aspirin 81 mg/day can be considered due to her history of hypertension and diabetes.

SECONDARY PREVENTION AND TRANSIENT ISCHEMIC ATTACKS

Clinical Presentation

3. J.S., a 55-year-old, 5 feet 11 inches tall, 120-kg man, experienced a rapidly progressive paralysis of his right arm and slurred speech yesterday. These symptoms lasted for 15 to 20 minutes and resolved rapidly. His neurologic examination is entirely

Table 55-4 CHADS₂ Score: Primary Stroke Prevention in Atrial Fibrillation

Add points for the following items. If score is <2, aspirin can be considered. If score is ≥ 2 , then warfarin is recommended.

Congestive heart failure = 1 point
Hypertension = 1 point
Age > 75 years = 1 point
Diabetes mellitus = 1 point
Prior stroke or TIA = 2 points

Adapted from references 43 and 44.

normal, and he denies any feeling of weakness. He smokes two packs of cigarettes daily and drinks three to six cans of beer each evening. His physical examination is entirely normal except for a left carotid bruit, which was first noted 2 years ago. His blood pressure (BP) is 165/100 mmHg, and he has a long history of hypertension. His hemoglobin (Hgb) is 16.5 g/dL (normal, 12–16 g/dL), his hematocrit (Hct) is 51% (normal, 42%–52%), and his total serum cholesterol concentration is 275 mg/dL (normal, <200 mg/dL). A Doppler examination of his carotid arteries shows a 90% stenosis on the left and a 40% stenosis on the right. What subjective and objective data in J.S.'s history are consistent with a TIA?

[SI units: Hgb, 165 g/L (normal, 120–160); Hct, 0.51 (normal, 0.42–0.52); cholesterol, 7.11 mmol/L]

A TIA can present with any type of neurologic symptoms. The presentation is determined entirely by the location of the involved arteries and the portion of the brain that they supply. For example, if the affected artery provides circulation to the motor area in the left hemisphere of the brain, the expected result would be impairment of muscle strength on the right side of the body. Symptoms of TIA may include paresis or paralysis of one or more limbs, paraesthesia, slurred speech, blurred vision, blindness (amaurosis fugax), facial droop, dizziness, or difficulty in swallowing (Table 55-5). Patients rarely lose consciousness. Symptoms always resolve within 24 hours, and there is no residual clinical focal neurologic deficit. Most often, the neurologic deficits last for only 2 to 15 minutes, and neurologic function rapidly returns to normal. However, with newer imaging techniques small areas of permanent ischemic damage may be seen, even in the absence of neurologic deficits.

J.S.'s rapid onset of right arm paralysis and slurred speech suggest involvement of the left cerebral cortex. The 15- to 20-minute duration of these symptoms and the entirely normal neurologic examination on the day after these symptoms also are compatible with a TIA. The left carotid bruit heard on physical examination suggests a left-sided process.

Right-sided neurologic deficits generally suggest left-sided cerebral dysfunction because motor and sensory neuronal tracts cross over in the midbrain. Thus, the left hemisphere of the cerebral cortex controls the right or contralateral side of the body. CNS lesions occurring below the midbrain will cause ipsilateral neurologic deficits. Therefore, J.S.'s right arm paralysis suggests a left-sided cerebral lesion above the midbrain.

Risk Factors

4. How can another TIA be prevented?

As with primary prevention, the initial interventions for secondary prevention of stroke are reduction of the risk factors. J.S. has several risk factors for TIA and ischemic stroke (Table 55-2): a smoking history, excessive alcohol consumption, obesity, older age, male gender, hypercholesterolemia, and hypertension. He should be instructed and counseled to change his lifestyle by discontinuing his smoking, limiting his alcohol consumption, reducing his weight, and increasing his physical exercise. Hypoxia and hypercarbia induced by cigarette smoking may have caused his increased hematocrit, and his high serum cholesterol and obesity suggest the need for dietary changes. The goal of a weight control program should be for his body mass index (BMI) to be 18.5–24.9 kg/m², and a waist circumference of <40 inches.⁶ A smoking cessation program, substance abuse program, and consultation with a dietitian should be useful in reducing his risk factors. Additionally, steps should be taken to ensure at least 30 minutes of moderate intensity physical activity for 5 to 7 days of the week.⁶

The goals of antihypertensive therapy should be individualized. A mean blood pressure reduction of approximately 10/5 mmHg has been associated with risk reduction for stroke.⁶ Further reductions may be useful, but in managing his blood pressure all reductions should be gradual. A sudden or dramatic decrease in blood pressure could compromise cerebral perfusion and result in a decreased level of consciousness or cerebral infarction. The degree of his carotid artery stenosis will contribute to the problem of decreased perfusion if the blood pressure is decreased rapidly. A mild degree of hypertension may be temporarily acceptable because of the extent of carotid stenosis. Data are lacking to indicate an optimal treatment regimen, and pharmacotherapy plans should be individualized to the patient. The use of a diuretic or a diuretic combined with an angiotensin converting enzyme inhibitor (ACEI) is supported by available literature.⁶ Initiation of hydrochlorothiazide at a dosage of 12.5 mg/day or a combination of hydrochlorothiazide with an ACEI should be considered.

Reduction of serum cholesterol is important for J.S. The first step in managing his cholesterol is to institute lifestyle and dietary modifications. Several placebo controlled studies have shown that HMG-CoA reductase inhibitors significantly reduce the risk of stroke and TIA.^{45–49} For example, individuals with coronary disease who received pravastatin had a 20% to 40% reduction in the risk of stroke. A study of atorvastatin showed similar risk reductions.⁵⁰ These findings are reinforced by two meta-analyses that reported a 25% to 32% reduction in the risk of stroke.^{51,52} It is known that HMG-CoA reductase inhibitors have anti-inflammatory activity that may influence the development of atherosclerotic plaques and cerebral ischemic processes.^{53–55} Because of these effects of HMG-CoA reductase inhibitors, these drugs should be started following a TIA or stroke even in patients who do not have dyslipidemia.⁵⁶ Targets for managing cholesterol in patients with atherosclerotic disease are a LDL-C of <100 mg/dL or, in extremely high risk patients, a LDL-C of <70 mg/dL.⁶ Niacin or gemfibrozil can be considered for patients with low HDL-C concentrations. Based on these data, J.S. should receive a HMG-CoA reductase

Table 55-5 Symptoms Associated With Transient Ischemic Attacks

| Symptom | Right Carotid | Left Carotid | Vertebrobasilar |
|-------------|---------------|--------------|--------------------|
| Aphasia | Possible | Yes | No |
| Ataxia | No | No | Yes |
| Blindness | Right | Left | Right or left side |
| Clumsiness | Yes | Yes | Yes |
| Diplopia | No | No | Yes |
| Dysarthria | Yes | Yes | No |
| Paralysis | Left side | Right side | Any limb |
| Paresthesia | Left side | Right side | Any limb |
| Vertigo | No | No | Yes |

inhibitor. The benefits of HMG-CoA reductase inhibitors appear to be a class effect, so selection of a specific agent should be based on the individual characteristics of the patient.

Treatment

Goals of Therapy

5. What are the initial and long-term goals in treating J.S.?

The immediate goal is to re-establish adequate blood flow in his diseased cerebral vessels. Longer-range objectives are to prevent reocclusion, decrease the risk of future symptomatic TIAs, and ultimately, prevent a cerebral infarction.⁵⁷

Surgical Interventions

6. What nonpharmacologic interventions might be available to prevent another TIA? What would be the best choice for J.S.?

Various surgical interventions are available to prevent TIA or infarction. These are designed to either remove the source for an embolism or improve circulation to ischemic areas of the brain.

CAROTID ENDARTERECTOMY

Carotid endarterectomy (CEA) is a common surgical procedure for correcting atheromatous lesions responsible for causing a TIA. In this procedure, the carotid artery is surgically exposed, and the atheromatous plaque is excised. Balloon angioplasty and placement of stents also can improve blood flow through a stenosed artery. During this procedure, a catheter with a small, deflated balloon is placed in the stenosed artery and the atherosclerotic lesion is pressed into the arterial wall when the balloon is inflated. A small, plastic tube stent is placed in the artery to prevent the vessel from collapsing at the site of the lesion.

CEA is most effective for patients with an ulcerated lesion or stenotic clot that occludes >70% of blood flow in the ipsilateral carotid artery and who experience symptoms of a TIA or stroke. Use of CEA in these patients may result in a 60% reduction in stroke risk over the subsequent 2 years.⁵⁸ Of six to eight patients treated with CEA, one stroke will be prevented within 2 years.⁵⁹ The use of CEA in other patient groups must be balanced with the risk of the procedure and life expectancy.⁶⁰ CEA is beneficial in patients with 50% to 69% stenosis of the carotid artery.⁶ Surgery should be done within 2 weeks of a TIA or stroke. In other patients, the benefits of CEA are questionable. Generally, CEA is not indicated in patients who have permanent neurologic deficits or total occlusion of the carotid artery.⁵⁸ CEA should be done by a surgeon with <6% morbidity and mortality rates.⁶

Carotid artery angioplasty and stenting (CAS) is another alternative. The initial study of this procedure was halted due to poor outcomes.⁶¹ Subsequently, two studies have shown that CAS is not inferior to CEA, but further study is underway to determine if CAS is more beneficial than CEA.^{62,63} CAS can be used in patients who are not candidates for CEA.

J.S. should undergo CEA for his left carotid lesion as soon as possible. The lesion on the right should be monitored closely for continued progression. If further TIAs occur or the right

carotid stenosis is >60%, he should have a CEA performed on the right carotid artery.

Drug Therapy

ASPIRIN

7. What role does aspirin have in preventing the occurrence of ischemic stroke in patients who have experienced a TIA?

Because platelets play a key role in the formation of atheromatous clots (see Fig. 55-4), various antiplatelet drugs, such as aspirin, sulfapyrazone, dipyridamole, ticlopidine, and clopidogrel have been tried to prevent ischemic strokes. These agents generally work by either preventing the formation of TXA₂ or increasing the concentration of prostacyclin. These actions seek to re-establish the proper balance between these two substances, thus preventing the adhesion and aggregation of platelets (Table 55-6).

Aspirin has been the most widely tested agent for use in preventing TIA and ischemic stroke. It acts primarily by irreversibly inactivating platelet cyclooxygenase.⁶⁴ Inactivation of cyclooxygenase decreases platelet aggregation, prevents release of vasoactive substances, and prolongs the bleeding time. Because binding of cyclooxygenase by the acetyl component of acetylsalicylic acid ([ASA] aspirin) is irreversible and the platelet cannot synthesize new protein, platelet function is altered for the duration of the platelet's life, usually 5 to 7 days. Aspirin's ability to prevent clot formation and subsequent embolic or thrombotic events also can be attributed to an inhibition of TXA₂-mediated vasoconstriction, activation of fibrinolysis, inhibition of synthesis of vitamin K-dependent clotting factors, and inhibition of lipoxigenase pathways.

In addition to its action on platelet cyclooxygenase, high concentrations of aspirin also inhibit prostacyclin synthesis in the walls of blood vessels. Because prostacyclin inhibits platelet aggregation, depletion of prostacyclin could result in an undesirable increase in aggregation of platelets. However, depletion of prostacyclin is not prolonged because the vascular endothelium is able to synthesize new enzymes. Higher dosages of aspirin (1.3 g/day) also may decrease vascular plasminogen activator, thereby enhancing thrombus formation.⁶⁵ Therefore, aspirin should be dosed carefully.

At least 15 randomized trials, with 7 being placebo-controlled, have studied aspirin alone or in combination with other antiplatelet drugs in the prevention of vascular events.^{36,66-70} Patients were enrolled in these studies for as long as 5 years after experiencing a vascular event (i.e., TIA, stroke, unstable angina, or myocardial infarction). Follow-up periods lasted from 1 to 6 years. The incidence of ischemic stroke or TIA ranged from 7% to 23%: the aspirin-treated patients experienced an average 22% decrease in relative risk of a stroke compared with those receiving placebo. In 10 trials that considered only TIA or stroke patients, there was a 24% relative risk reduction in the incidence of nonfatal stroke associated with the use of aspirin.

In initial studies of aspirin in stroke prevention, the positive effects were seen primarily in men. However, the European Stroke Prevention Study and a French study included an equal balance of men and women.^{66,71} In both studies, the risk reduction rate was equal for men and women, indicating that the benefit of aspirin in stroke prevention extends to both sexes.

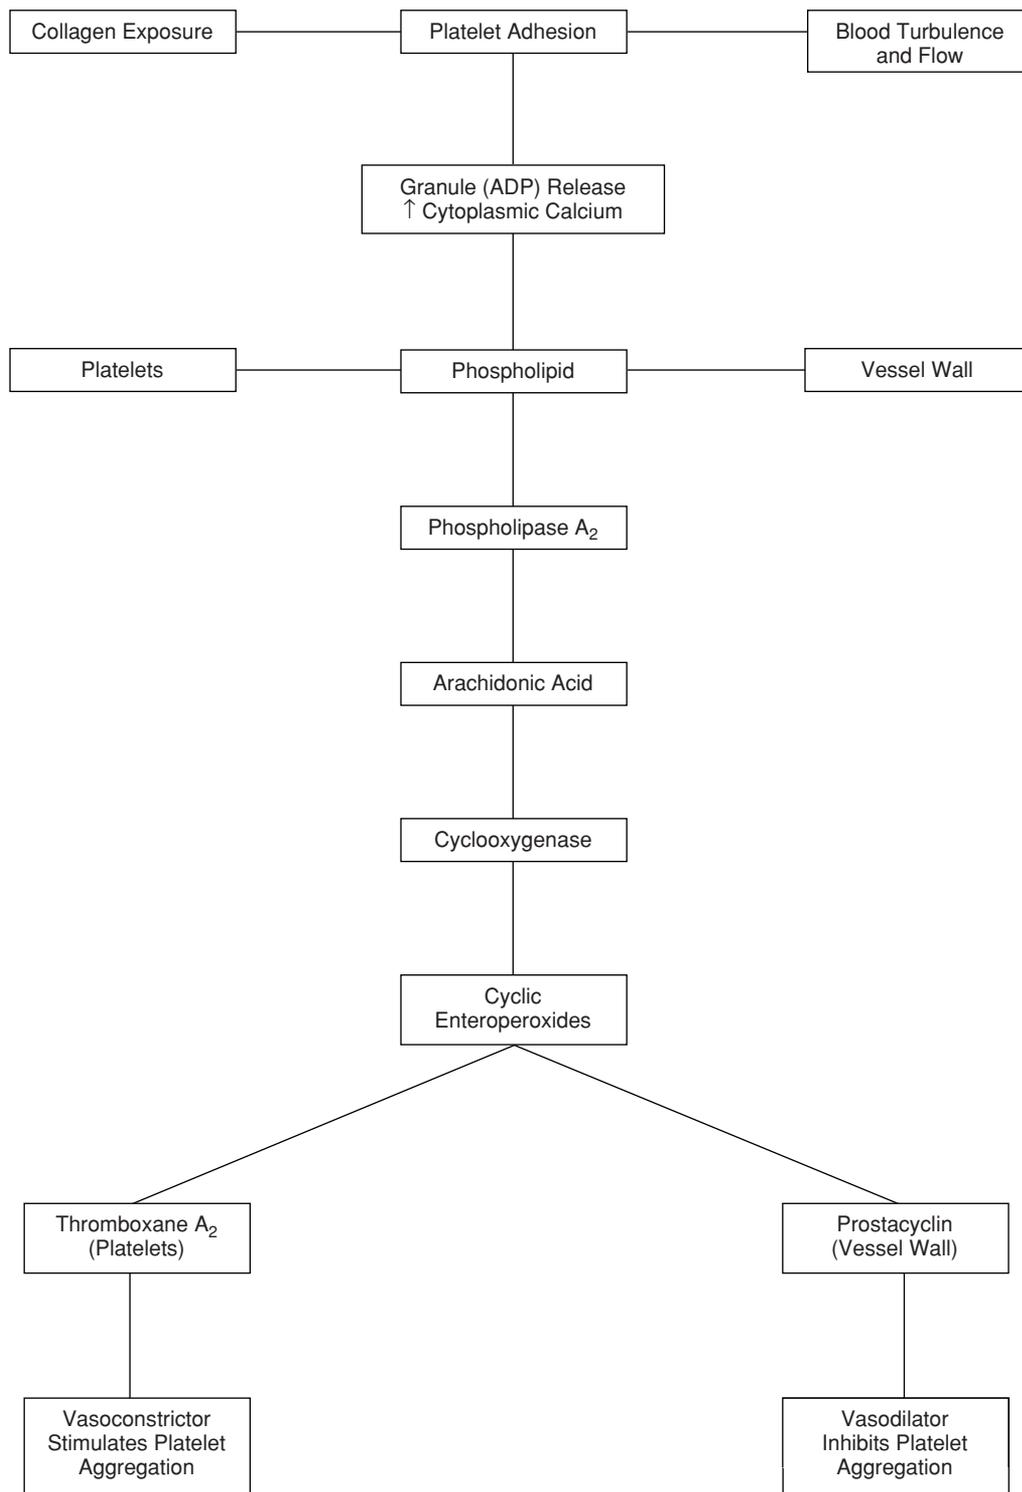

FIGURE 55-4 Arachidonic acid cascade and platelet plug formation.

Aspirin also has been used for prevention of restenosis following CEA. Over the first year after CEA, 25% of patients will redevelop a stenotic lesion, with more than half of these causing a >50% reduction in carotid blood flow.⁷² Stent placement is useful in preventing restenosis. Initial studies indicated that combination therapy with aspirin 325 mg/day and dipyri-

damole 75 mg TID would decrease the rate of restenosis. However, a subsequent randomized, placebo-controlled study using this regimen in post-CEA patients did not substantiate the earlier findings.⁷³ A combination of clopidogrel with aspirin has been shown to reduce postoperative ischemic events.⁷⁴ Stents impregnated with anticoagulants are being evaluated.

Table 55-6 Drugs for Preventing Transient Ischemic Attacks and Ischemic Stroke

| Drug | Action | Dose | Adverse Effects |
|--------------|--|--------------------------------------|-----------------------------------|
| Aspirin | Antiplatelet | 50–1,300 mg/day | Diarrhea, gastric ulcer, GI upset |
| Dipyridamole | Antiplatelet (use in combination with aspirin) | 200 mg sustained release twice daily | GI upset |
| Ticlopidine | Antiplatelet | 500 mg/day | Diarrhea, neutropenia, rash |
| Clopidogrel | Antiplatelet | 75 mg/day | Thrombocytopenia, neutropenia |
| Warfarin | Anticoagulant | Titrate to INR 2–3 | Bleeding, bruising, petechiae |

GI, gastrointestinal; INR, international normalized ratio.

8. What dosage of aspirin should be used for J.S.?

Dosages of aspirin used in clinical trials have ranged from 30 to 1,500 mg/day. In a meta-analysis of placebo-controlled studies comparing 900 to 1,500 mg/day of aspirin with similar studies of 300 to 325 mg/day, there was a 23% reduction in the risk of cerebrovascular events for patients receiving 900 to 1,500 mg/day and a 24% reduction in risk for patients receiving 300 to 325 mg/day.⁶⁸ More direct studies of aspirin dosing have been attempted and have produced conflicting results. A Dutch trial in 3,131 patients showed a 14.7% frequency of nonfatal stroke or nonfatal myocardial infarction in patients receiving 30 mg of aspirin a day and a 15.2% frequency in patients receiving 283 mg of aspirin a day, a nonsignificant difference between these two doses.⁷⁵ The Swedish Aspirin Low-Dose Trial (SALT) showed an 18% reduction in stroke in patients taking 75 mg of aspirin daily compared with placebo.⁷⁶ Helgason et al. compared the effects of 325, 650, 975, and 1,300 mg of aspirin a day in stroke patients.⁷⁷ Platelet aggregation studies were performed to determine the effects of aspirin. Complete suppression of aggregation at a daily dose of 325 mg was achieved in 85 of 107 patients. An additional five patients responded at 650 mg/day, and only one more responded at 975 mg/day. There was no further response at 1,300 mg.

A meta-analysis of all published trials of antiplatelet agents did show that aspirin doses of 75 to 325 mg/day were effective in preventing stroke.⁷⁸ These findings are corroborated by another meta-analysis showing that aspirin of 50 to 1,500 mg/day produced similar risk reductions of 15%.⁷⁹ As aspirin doses increase, so does the risk of gastrointestinal bleeding.⁸⁰

The recommended dose for aspirin is 50 to 975 mg/day. The goal is to use the lowest effective aspirin dosage thereby limiting the risk of gastrointestinal (GI) adverse effects. J.S. should start taking aspirin at a dosage of 50 to 75 mg/day. In the United States, a dose of 81 mg enteric-coated aspirin is usually started.

DIPYRIDAMOLE

9. Should dipyridamole be used alone or in combination with aspirin for J.S.?

Two pharmacologic actions of dipyridamole prompted investigations into its use in preventing TIAs and ischemic stroke. Dipyridamole weakly inhibits platelet aggregation and platelet phosphodiesterase and has potential vasodilating properties through its inhibition of adenosine uptake in vascular smooth muscle.⁶⁴

Two European studies have shown benefit with a combination of aspirin and dipyridamole. In the first study, a com-

bination of aspirin 975 mg/day combined with dipyridamole 225 mg/day was compared to placebo.⁸¹ Results from this study showed that the combination reduced the combined risk of stroke and death by 33% and the risk of stroke by 38%. The Second European Stroke Prevention Study enrolled patients who had experienced a previous stroke or TIA and found that aspirin combined with dipyridamole was more effective than placebo, dipyridamole alone, and aspirin alone.⁸² A sustained-release formulation of dipyridamole was used for this study. A 37% relative-risk reduction was found for the combination treatment, and a 23% relative risk reduction was found for aspirin alone. The dipyridamole dose for this study was 200 mg BID, and the aspirin dose was 25 mg BID. Absolute risk reduction was approximately 1.5% annually. Headache occurred more frequently in patients receiving dipyridamole alone or in combination with aspirin. Bleeding complications were less frequent in patients receiving dipyridamole compared with aspirin alone. As a result of these findings, a combination product of aspirin and dipyridamole is available. The combination of sustained-release dipyridamole and aspirin is an acceptable alternative for secondary prevention of stroke when initial secondary prevention has failed.

TICLOPIDINE

10. What are the risks and benefits of using ticlopidine instead of aspirin in J.S.?

Ticlopidine (Ticlid) is an antiplatelet agent approved only for the prevention of TIA and stroke for patients with a prior cerebral thrombotic event. By inhibiting ADP-induced platelet aggregation, its activity differs from aspirin. A randomized, double-blind, placebo-controlled, multicenter trial, the Canadian American Ticlopidine Study (CATS), shows that ticlopidine significantly reduces the risk of stroke by 33.5%.⁸³ In the Ticlopidine Aspirin Stroke Study Group (TASS), ticlopidine reduced the risk of stroke by 21%.⁸⁴ Neutropenia developed in 1% to 2% of patients on ticlopidine in both the CATS and TASS studies. Severe neutropenia (absolute neutrophil count [ANC] <450/mm³) usually appears in the first 3 months of therapy and is reversible when the drug is discontinued. One episode of neutropenia-associated infection was reported in the CATS study. Because of the rather high potential for this adverse reaction, a complete blood count should be performed at baseline and every 2 weeks for the first 3 months of therapy. Additional data have shown that severe bone marrow depression is fatal in 16% of patients who develop this complication.⁸⁵ Thrombotic thrombocytopenia purpura has also been associated with ticlopidine and proved fatal in 33% of 60 patients.⁸⁶ Additionally, nearly 25% of patient will experience gastrointestinal

adverse events, especially diarrhea, with around 10% requiring discontinuation of ticlopidine.

Ticlopidine is more effective in the secondary prevention of stroke and less likely to cause GI bleeding when compared with aspirin. However, hematologic and gastrointestinal adverse effects severely limit its use.

CLOPIDOGREL

11. Is clopidogrel a reasonable alternative for J.S.?

Clopidogrel (Plavix) is chemically related to ticlopidine and works by inhibiting platelet aggregation induced by ADP. A randomized, double-blind, international trial (Clopidogrel vs. Aspirin in Patients at Risk of Ischaemic Events [CAPRIE]) compared clopidogrel 75 mg/day with aspirin 325 mg/day.⁸⁷ Patients enrolled in the study had a history of atherosclerotic vascular disease manifested by recent ischemic stroke, myocardial infarction, or symptomatic peripheral vascular disease. Using intention-to-treat analysis, a 5.3% risk of an event in patients receiving clopidogrel and a 5.83% risk in patients receiving aspirin was observed. This represents a statistically significant relative risk reduction of 8.7%, favoring clopidogrel. On-treatment analysis showed a relative risk reduction of 9.4%, again in favor of clopidogrel. For patients whose primary condition for entry into CAPRIE was stroke, the relative risk reduction was 7.3%, however this difference was not statistically significant. Patients receiving clopidogrel more frequently experienced rash and diarrhea compared with those receiving aspirin. Patients receiving aspirin were more frequently affected by upper GI distress, intracranial hemorrhage, and GI hemorrhage. Significant reductions in neutrophils occurred in 0.10% of patients on clopidogrel and in 0.17% of patients on aspirin. Some cases of thrombocytopenia purpura are reported in the literature.⁸⁸

Clopidogrel is as effective and safe as aspirin. Clopidogrel is an alternative to aspirin in secondary prevention of stroke.

WARFARIN/ANTICOAGULANTS

12. Is an anticoagulant such as warfarin an alternative instead of aspirin for a patient such as J.S.? What situations make anticoagulants more desirable?

Large randomized trials have compared oral anticoagulants to aspirin in the secondary prevention of stroke and TIA. In one study, aspirin 30 mg/day was compared to oral anticoagulants in doses adjusted to maintain an International Normalized Ratio (INR) between 3.0 and 4.5.⁸⁹ This study was terminated early when the mortality rate due to major bleeding events in the anticoagulant group was double the rate in the aspirin group. In this study, there was no difference between anticoagulants and aspirin in the frequency of stroke. A second study compared warfarin, dosed to maintain the INR between 1.4 and 2.8, and aspirin 325 mg/day.⁹⁰ Results from this study did not demonstrate a significant difference between aspirin and warfarin with regard to the prevention of stroke or major hemorrhagic events. However, minor hemorrhages were significantly more frequent among patients receiving warfarin. A third study was terminated early due to safety concerns in the warfarin arm of the study.⁹¹ The target INR for this study was 2 to 3 in the warfarin arm compared to aspirin. The study was stopped due to significantly higher rates of adverse events in

individuals receiving warfarin and no difference in the risk of stroke. Events including major hemorrhage, myocardial infarction or sudden death, and overall death were increased in those receiving warfarin. Warfarin is not generally recommended for secondary prevention of stroke.

J.S. is clearly at risk for additional TIAs or an ischemic stroke. The most important step in reducing this risk is to change his lifestyle. However, because J.S. has experienced a TIA, he also should be placed on an antiplatelet agent. Aspirin, dipyridamole combined with aspirin, or clopidogrel are acceptable alternatives for J.S. Warfarin is not an acceptable alternative in J.S. for initial, secondary prevention of TIA or stroke. Considering the overall costs of therapy and that he does not have any definite contraindications to aspirin, J.S. should be started on aspirin 81 mg/day. Clopidogrel or a combination of aspirin and dipyridamole can be used if J.S. is unable to tolerate aspirin or he experiences a recurrent TIA or a stroke while taking aspirin (Table 55-6).

Aspirin: Patient Education

13. The physician decides to begin J.S. on aspirin 81 mg/day. How should he be counseled on the use of aspirin? Should J.S. be advised to discontinue aspirin before surgical and dental procedures?

Even low dosages of aspirin may cause gastric erosions and gastric ulcers. J.S. should be instructed to take aspirin with the largest meal of the day, inform his physician of any epigastric pain, and seek medical attention at the first sign of any gastric bleeding (e.g., dark stools). Enteric-coated aspirin may cause less gastric upset than uncoated aspirin formulations.

J.S. should inform all of his healthcare providers, especially his physicians, pharmacist, and dentist, that he is taking aspirin daily. The decision to discontinue aspirin is at the discretion of his physician or dentist. This decision is based on the possibility of bleeding complications from the procedure and the risk of J.S. having a TIA while off aspirin. If aspirin is to be temporarily discontinued, it should be stopped at least 5 to 7 days before the procedure and restarted several days after the procedure.

Combination Antiplatelet Pharmacotherapy

14. Six months later J.S. has another TIA, despite taking aspirin. What is an appropriate intervention to prevent further TIA or stroke?

Possible interventions at this point are to switch to a different antiplatelet therapeutic regimen, to add clopidogrel to aspirin, or to increase the aspirin dose. A major study has compared clopidogrel 75 mg/day to the combination of clopidogrel 75 mg/day and aspirin 75 mg/day.⁹² There was no difference in the risk of recurrent stroke or other cardiovascular outcomes between the groups, but the combination therapy group had a significant increase in life-threatening bleeding. Some individuals may be resistant to aspirin's effects on platelets.⁶⁴ Although poorly understood and studied, aspirin resistance may be due to the presence of extra-platelet sources of thromboxane A₂ and an interaction with over the counter nonsteroidal anti-inflammatory drugs or high levels of circulating 11-dehydro-thromboxane B₂.⁹³⁻⁹⁵ There are no data to suggest that increasing the aspirin dose will overcome possible

resistance to the antiplatelet effects of aspirin, but it is clear that an increased dose of aspirin increases his risk of major bleeding.

Based upon available data, the antiplatelet therapy for J.S. should be switched to clopidogrel monotherapy or the combination product of aspirin with dipyridamole.

CEREBRAL INFARCTION AND ISCHEMIC STROKE

Clinical Presentation and Diagnostic Tests

15. P.C., a 65-year-old man, is admitted through the emergency department (ED) after collapsing to the ground and experiencing a brief loss of consciousness. He regained consciousness by the time he arrived in the ED, 1 hour after the initial event. Both right extremities are flaccid. He is unable to speak but is capable of understanding instructions (i.e., expressive aphasia). Gross ophthalmologic examination indicates right-sided neglect (inability of his eyes to track to the right or acknowledge the right side of his body). His BP is 175/105 mmHg; other vital signs are normal. Laboratory studies are all within normal limits. By the next day, his neurologic status is unchanged and he is diagnosed as having an ischemic stroke. What interventions should be initiated prior to arrival in the ED?

Immediate recognition of and response to stroke symptoms are essential to an optimal outcome. As soon as stroke symptoms are recognized, the emergency medical system should be activated. Emergency medical personnel should be trained to gather important historical information, especially when the symptoms started. Use of a standardized evaluation tool like the Cincinnati Prehospital Stroke Scale or Los Angeles Prehospital Stroke Screen are useful in distinguishing stroke symptoms from other disorders like conversion disorder, hypertensive encephalopathy, hypoglycemia, complicated migraine, or seizures.⁹⁶ General supportive care for respiratory and cardiovascular function should be initiated prior to transporting the patient to the ED. An important key to effectively managing acute stroke patients is to have a well designed evaluation and treatment algorithm that addresses assessment and care of the patient from initial onset of symptoms through rehabilitation (Fig. 55-5).⁹⁶

16. What diagnostic tests and evaluations will be helpful in guiding P.C.'s therapy?

Basic laboratory and diagnostic tests should be quickly performed to exclude noncerebrovascular causes, such as metabolic or toxicologic derangement, or infections for the neurologic compromise that P.C. has experienced. These tests include a routine serum chemistry profile (electrolytes, blood urea nitrogen [BUN], serum creatinine [SrCr], hepatic enzymes, calcium, phosphorus, magnesium, albumin), complete blood count, and toxicology screen. Coagulation studies, including a prothrombin time with INR and partial thromboplastin time (PTT), should be performed to provide baseline values for potential anticoagulation or thrombolytic therapy. In addition, a thorough physical, neurologic, cardiovascular, and mental status examination should be performed. The neurologic examination will allow a localization of the lesion in the CNS. The physical examination should include use of the National Institutes of Health Stroke Scale.⁹⁷ In addition to pro-

viding important information for diagnosis of his neurologic compromise, these tests will provide baseline data for ongoing assessment of P.C.'s progress and recovery.

The etiology of a stroke is difficult to discern based solely on a physical and neurologic examination. As a result, CT or magnetic resonance imaging (MRI) is valuable in the evaluation of these patients. An MRI is preferred to a CT due to its superior tissue contrast, ability to obtain images in multiple planes, absence of artifacts caused by bone, vascular imaging capabilities, absence of ionizing radiation, and safer contrast medium. MRI also allows for a magnetic resonance angiogram to be performed, allowing visualization of the cerebrovasculature and possible identification of the precise location of the thrombus or embolus. Within the first 24 hours of an ischemic stroke, an MRI is clearly more sensitive than a CT. After 48 hours, the MRI and CT are equally effective in detecting ischemic infarcts. The primary disadvantage of the MRI is that it is more sensitive to artifacts and less practical in unstable patients.

P.C. must have either a CT or an MRI before initiation of anticoagulation, thrombolytic agents, or other therapies for stroke. A follow-up CT or MRI in 5 to 7 days is useful to determine the extent of neurologic damage resulting from the ischemic stroke.

Angiographic, Doppler, or sonographic examination of the cerebral vasculature may be helpful in identifying the location of the vascular lesion. These tests usually are performed after the patient has been stabilized, unless angioplasty with stents or use of intra-arterial fibrinolytics are anticipated. A lumbar puncture with collection of cerebrospinal fluid (CSF) for evaluation may be helpful in identifying the presence of blood in the CNS. In the presence of suspected increased intracranial pressure, a lumbar puncture must be avoided because of the potential for tentorial herniation. Tentorial herniation occurs when the ventral half of the midbrain (i.e., the cerebral peduncles) pass through the tentorial notch (i.e., a portion of the dura mater that provides support for the occipital lobe and covers the cerebellum). This causes pressure on blood vessels that supply the cerebral cortex, resulting in restricted blood flow.

Treatment

17. What general treatment interventions should be made for P.C.?

In addition to the general supportive therapy needed for a hospitalized patient, several issues are important to the proper management of a stroke patient. Careful attention should be given to fluid and electrolyte control. Excessive hydration or inadequate sodium supplementation may result in hyponatremia, thereby forcing fluid into neurons to further increase the damage from ischemia. In addition, hyponatremia can produce seizures, which increases the metabolic demand on compromised neurons. Thus, it is advisable to initiate fluid therapy with a solution containing at least 0.45% saline and preferably 0.9% saline.

Attention to body temperature needs to be given. Studies have shown that even small increases in temperature are associated with worse outcomes.^{98,99} Hypothermia is neuroprotective and some studies indicate that even a reduction in body

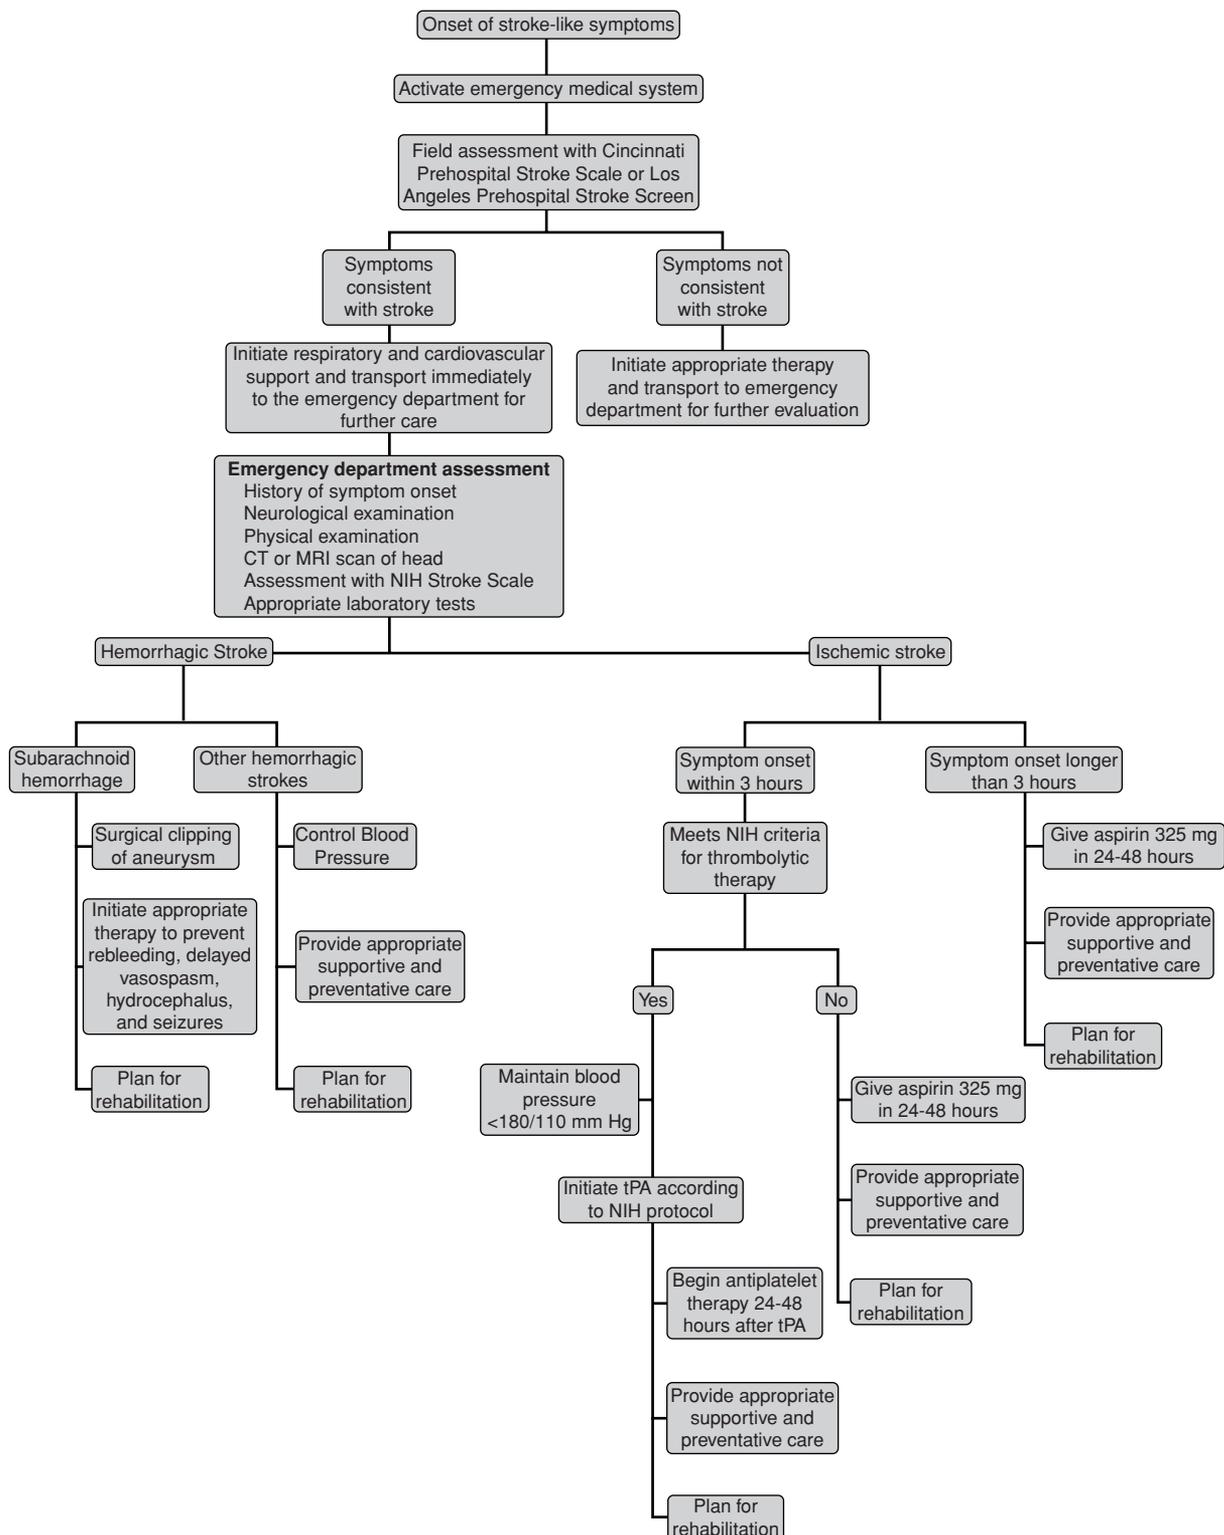

FIGURE 55-5 Treatment algorithm for management of patient with acute stroke-like symptoms (Adapted from Adams HP et al.)

temperature of 0.26°F can be beneficial in stroke patients.^{96,100} Use of antipyretics, like acetaminophen, are advised to maintain normal or slightly subnormal body temperatures.

Another metabolic parameter that must be followed carefully is the serum glucose concentration, because hypergly-

cemia may adversely affect ischemic infarction outcomes. A review of multiple studies on the effects of hyperglycemia in acute stroke concluded that hyperglycemia results in poor outcomes and increased mortality.¹⁰¹ If hyperglycemia is detected, appropriate insulin therapy should be initiated to keep

the serum glucose concentration < 140 mg/dL without causing hypoglycemia.⁹⁶

Caution should be exercised in the acute management of P.C.'s blood pressure. Decreasing the blood pressure too rapidly will compromise cerebral blood flow and expand the region of ischemia and infarction, whereas hypertension will place him at a greater risk for cerebral hemorrhage, especially if a thrombolytic agent is used. However, a study comparing treated and untreated patients who were hypertensive in association with an acute stroke failed to demonstrate any difference in outcomes between the groups.¹⁰² For patients with a systolic blood pressure > 185 mmHg or diastolic blood pressure > 110 mmHg, who are otherwise candidates for intravenous fibrinolytic treatment, labetalol, nitroglycerin paste, or intravenous nicardipine should be used to reduce the blood pressure to these goals prior to starting tPA.⁹⁶ After administration with tPA, blood pressure should be kept below 180/105 mmHg. In other patients, the only consensus on blood pressure control is that treatment is required when pressures exceed 220/120 mmHg.⁹⁶ If there is a clinical deterioration of neurologic function associated with the reduction of blood pressure, the infusion rate of the antihypertensive agent should be slowed or the drug discontinued. Maintenance antihypertensive therapy can then be initiated using an oral agent, such as a calcium channel antagonist or angiotensin-converting enzyme inhibitor.

The general daily needs of the patient should be assessed and provided on an as-needed basis. These include nutrition, urination, defecation, and prevention of decubitus ulcers. Neurologic deficits will compromise the ability of many patients to adequately meet these needs, increasing the necessity for medical assistance.

Two interventions that have been shown to improve outcomes of ischemic stroke are reducing the time to treatment of stroke and admitting patients to specialized stroke care units. Reduction of the time to treatment permits the use of interventions shown only to work within the first 2 hours of a stroke.¹⁰³ In addition, Indredavik et al. have shown that stroke care units significantly improve long-term survival and functionality of patients after a stroke.¹⁰⁴

18. Should anticoagulation or antiplatelet agents be used acutely in P.C.?

Several studies have evaluated the use of anticoagulants and antiplatelet agents in the treatment of acute strokes. However, most of these studies are poorly designed or underpowered to determine the efficacy of these agents. Despite these problems with published studies, many physicians prefer to use anticoagulants or antiplatelets in the management of patients with acute stroke.

Heparin

Duke et al. compared intravenous heparin to placebo in patients with acute partially stable stroke.¹⁰⁵ In this double-blind study, heparin doses were adjusted to maintain the PTT at 1.5 to 2 times control and continued for 7 days. There were no significant differences in death at 7 days, and no differences in functional ability were observed to 1 year following the stroke. At 1 year there was a significantly greater mortality rate in heparin-treated patients. The International Stroke Trial compared aspirin, subcutaneous heparin (5,000 IU or 12,500 IU BID), both and neither treatments for patients with acute

ischemic stroke.¹⁰⁶ There was no reduction of mortality or morbidity for patients receiving either dose of heparin. Heparin use has also been studied in progressing stroke and no benefit was demonstrated with its use.¹⁰⁷ No studies have demonstrated that heparin is useful in mitigating the neurological effects of a stroke.

Heparinoids

Low-molecular-weight heparins and heparinoids have been evaluated in several studies for acute stroke. Two doses of nadroparin were compared to placebo in one randomized, double blind, placebo controlled trial.¹⁰⁸ There were no differences in death rates or functional ability at 3 months between the three treatment arms. However, at 6 months, patients receiving high-dose nadroparin (i.e., 4,100 anti-Xa IU BID) had improved function. A large randomized, placebo controlled trial of dose-adjusted danaparoid, a low-molecular-weight heparinoid, did not demonstrate improvement in danaparoid-treated patients.¹⁰⁹ In addition, no improvements were observed in studies of dalteparin and certoparin.^{110,111} Similar to heparin, low-molecular-weight heparins and heparinoids are not indicated in the acute treatment of stroke.

Aspirin

One study evaluated early administration of aspirin in acute stroke. The Chinese Acute Stroke Trial (CAST) compared 160 mg/day of aspirin administered within 48 hours of the onset of stroke symptoms to placebo.¹¹² Patients who received aspirin had reduced early mortality rates, but there was no difference in the primary endpoint of death or dependency at discharge from the hospital. The IST and the Multicenter Acute Stroke Trial-Italy studies included aspirin arms in their study design. Neither of these studies demonstrated benefit with aspirin.^{106,113} When data from the CAST and IST studies are combined, a slight beneficial effect of aspirin is seen with regard to reducing the risk of early stroke recurrence. Current recommendations are for aspirin 325 mg to be administered within 24 to 48 hours of the onset of stroke symptoms, except when tPA is administered.⁹⁶ If tPA is used, aspirin should not be given until 24 to 48 hours after the tPA infusion.

Glycoprotein IIb/IIIa Inhibitors

Platelet glycoprotein IIb/IIIa inhibitors have also been studied in acute stroke. A placebo controlled Phase II trial of abciximab given within 24 hours of acute stroke showed a trend toward improved functionality in abciximab-treated patients, but the study was not powered to show significance for this outcome.¹¹⁴ In another placebo controlled, Phase II study of patients with acute stroke the direct thrombin inhibitor, argatroban, was associated with statistically significant improvements in neurologic symptoms and daily living activities.¹¹⁵ The number of patients enrolled in this study was small, but the results show promise. Currently, the use of these agents is limited to clinical trials.

Ancrod

Derived from the venom of the Malayan pit viper snake, ancrod cleaves fibrinogen in a way similar to thrombin. Ancrod leads to fibrinolysis soon after its administration and is rarely associated with significant bleeding complications. This low risk of hemorrhagic complications makes ancrod especially attractive

for use in ischemic stroke. The Stroke Treatment with Ancrod Trial (STAT) compared a continuous 72-hour infusion of ancrod dosed to decrease fibrinogen levels to 1.18 to 2.03 mU/L to receive placebo.¹¹⁶ This infusion was followed by 1-hour infusions at approximately 96 and 120 hours after treatment was started. Ancrod infusion rates of 0.167, 0.125, and 0.082 IU/kg/hour were used based on pretreatment fibrinogen concentrations. Significantly more patients treated with ancrod achieved favorable functional status and had fewer disabilities, with no difference in mortality rates. Due to the lack of additional data, the use of ancrod is limited to clinical trials.

19. When might anticoagulants be used in the treatment of acute stroke?

Deep vein thrombosis and pulmonary embolism are common complications in patients following a stroke. The incidence of deep vein thrombosis (DVT) and pulmonary embolus (PE) were reduced in most studies where patients received heparin, low-molecular-weight heparins, or heparinoids.¹¹⁷

Two systematic reviews of the literature in this area resulted in the following recommendations and guidelines^{96,117}:

1. Aspirin 325 mg/day should be initiated within 48 hours of the onset of stroke symptoms, unless tPA is used. If tPA is used, aspirin should not be started until 24 to 48 hours after tPA administration.
2. Heparin, low-molecular-weight heparins, and heparinoids may be considered for prevention of DVT and PE. Use of these agents must be weighed against the risk of hemorrhagic complications.
3. Fixed dose heparin may have some early benefit in the treatment of acute stroke, but this benefit is negated by an increased risk of hemorrhage and is not recommended.
4. Dose-adjusted heparin is associated with increased bleeding complications and is not recommended.
5. Low-molecular-weight heparins and heparinoids at high doses are not recommended in patients with acute stroke.
6. Intravenous heparin, high-dose low-molecular-weight heparins, or heparinoids are not recommended for any subgroup or specific type of stroke.

On the basis of these recommendations, P.C. should receive 325 mg/day of aspirin to be started within 24 to 48 hours of onset of his stroke symptoms, unless tPA is administered. If tPA is used, then aspirin should be started 24 to 48 hours after the tPA infusion. Use of other anticoagulants is not recommended.

Thrombolytics

20. Would thrombolytic agents be useful to treat P.C.'s acute ischemic stroke?

The critical primary event in a thromboembolic stroke is the development of an acute thrombus. Prospective cerebral angiography has demonstrated an arterial occlusion corresponding to the area of acute neurologic deficit in >90% of cases.¹¹⁸ Occlusion of cerebral arteries does not cause complete ischemia because collateral circulation from other arterial sources provides unstable and incomplete circulation to the ischemic region of the brain.¹¹⁹ When blood flow is sustained in the range of 10 to 18 mL/100 g per minute, irreversible cellular damage may occur. Blood flow must be restored quickly after the event. Experimental studies in dogs

and cats have shown that when blood flow is restored within 2 to 3 hours, neurologic deficits are prevented.^{120,121} Thrombolytic agents can reestablish blood flow to ischemic regions of the brain.

A total of five large, placebo-controlled trials using either tPA or streptokinase for acute stroke have been published. In three studies, streptokinase was used as the thrombolytic and all of these studies were terminated early due to high rates of mortality and intracranial hemorrhage associated with streptokinase.^{113,122,123} These trials clearly demonstrate that streptokinase is associated with increased mortality and disability. The rates of intracranial hemorrhage ranged from 6% to 17% for patients receiving streptokinase compared with 0.6% to 3% for patients receiving placebo. In all three trials the mortality rates were significantly greater for patients receiving streptokinase. Streptokinase should not be used for P.C.

Studies with tPA demonstrate some benefit associated its use.^{124,125} The National Institute of Neurological Disorders and Stroke (NINDS) tPA trial and the European Cooperative Acute Stroke Study (ECASS) used different doses, inclusion criteria, and treatment protocols. Both trials showed the benefit of tPA in at least some outcome parameters. In the NINDS tPA study, patients were enrolled using strict inclusion and exclusion criteria (Table 55-7). All patients were within 3 hours of symptom onset and had to undergo a CT scan before enrollment. When enrolled, patients received either tPA 0.9 mg/kg (maximum dose, 90 mg), with 10% of the dose given as a bolus over 1 minute and the remainder infused over 60 minutes, or placebo. Patients were divided into two groups for the purpose of analysis. One group consisted of 291 patients whose early neurologic recovery was assessed 24 hours after enrollment. The second group of 333 patients had neurologic outcomes evaluated at 3 months. In the first group, there was

Table 55-7 Criteria for Alteplase Use in Treatment of Acute Stroke

| Inclusion Criteria | Exclusion Criteria |
|--|--|
| 18 years of age or older | Minor or rapidly improving symptoms |
| Clinical diagnosis of stroke with clinically meaningful neurologic deficit | CT signs of intracranial hemorrhage |
| Clearly defined onset within 180 minutes before treatment | History of intracranial hemorrhage |
| Baseline CT with no evidence of intracranial hemorrhage | Seizure at onset of stroke |
| | Stroke or serious head injury within 3 months |
| | Major surgery or serious trauma within 2 weeks |
| | GI or urinary tract hemorrhage within 3 weeks |
| | Systolic BP >185 mmHg, diastolic BP >110 mmHg |
| | Aggressive treatment to lower BP |
| | Glucose 400 mg/dL |
| | Symptoms of subarachnoid hemorrhage |

BP, blood pressure; CT, computed tomography; GI, gastrointestinal.

no difference in positive responses between patients receiving tPA or placebo. However, a secondary analysis showed that National Institutes of Health Stroke Scale scores were significantly greater at 24 hours for patients receiving tPA. Results in the second group were favorable for tPA. At 3 months, patients who received tPA were 30% more likely to have minimal or no disability and there was an 11% to 13% absolute increase in the number of patients with excellent outcomes. There was a corresponding decrease in the number of patients with severe neurologic impairment or death at 3 months. Improvements associated with tPA were seen across age groups, stroke subtypes, stroke severity, and status of aspirin use before the stroke. Intracranial hemorrhage occurred more frequently among patients receiving tPA (6.4%) than in patients receiving placebo (0.6%). Despite the increased incidence of ICH, outcomes remained better for patients receiving tPA.

For the ECASS I trial, patients with the onset of a stroke were enrolled within 6 hours of the onset of symptoms.¹²⁵ The treatment protocol consisted of IV tPA 1.1 mg/kg (maximum, 100 mg) or placebo. Using intention-to-treat analysis, there was no difference in the primary outcome measures of functionality at 3 months. However, with target population analysis, there was a significant difference favoring tPA. Of tPA-treated patients, 41% had minimal or no disability compared with 29% of placebo-treated patients. A variety of secondary outcome measures favored tPA. There was no difference in 30-day mortality rates, but 19.8% of tPA-treated patients had major parenchymal hemorrhages compared with 6.5% of placebo-treated patients. A more recent trial, ECASS II, used a tPA dose of 0.9 mg/kg and was designed to replicate the NINDS trial.¹²⁶ However, patients were enrolled up to 6 hours after the onset of stroke symptoms. This study found no difference between tPA and placebo. Too few patients were enrolled with stroke symptoms <3 hours to reliably evaluate the influence of this variable on outcome.

The Cochrane Stroke Review Group performed a meta-analysis of 17 thrombolytic trials.¹²⁷ In this analysis, thrombolytic therapy was associated with an excess of early deaths (odds ratio, 1.85; 95% CI, 1.48–2.32) and early symptomatic hemorrhages (odds ratio, 3.53; 95% CI, 2.79–4.45). However, thrombolytic therapy initiated within 6 hours of symptom onset reduced the proportion of patients who were dead or dependent at the end of follow-up (odds ratio, 0.83; 95% CI, 0.73–0.94). Similar results were obtained when the analysis included patients treated within 3 hours of symptom onset (odds ratio, 0.58; 95% CI, 0.46–0.74). About half of the data included in these analyses came from trials of tPA and the results support the use of tPA in the treatment of acute ischemic stroke. This analysis substantiates the use of tPA in the treatment of ischemic stroke.

Several studies have reported the use of intra-arterial thrombolytic therapy. In one trial, patients were randomized to receive either 6 mg of recombinant prourokinase or placebo over 120 minutes.¹²⁸ All patients received IV heparin. Patients who were randomized received treatment at a median of 5.5 hours from symptom onset. Recanalization was significantly greater in the prourokinase group. However, hemorrhagic transformation occurred in 15.4% of prourokinase-treated patients compared with 7.1% of placebo-treated patients. Hemorrhage frequencies and recanalization rates were influenced by heparin dose. A second trial has confirmed these findings, showing sig-

nificantly improved outcomes with intra-arterial prourokinase, despite increased intracranial hemorrhage.¹²⁹ Although useful in major medical centers, intra-arterial prourokinase presents major technical obstacles that limit its use in most emergency departments.

The only study that has clearly shown benefit associated with systemic tPA use for acute stroke is the NINDS tPA trial. If tPA is to be used for acute stroke, the NINDS inclusion and exclusion criteria and treatment protocol should be used.

Because P.C. presented to the ED within 1 hour of the onset of his stroke symptoms, he is a candidate for tPA therapy in accordance with the NINDS study protocol. A thorough history and CT scan must be performed before initiation of tPA to ensure compliance with inclusion and exclusion criteria.

Preservation of CNS Function

Preservation of marginally ischemic regions of the brain is an active area of investigation. Hemodilution, corticosteroids, calcium channel blockers, 21-aminosteroids, NMDA receptor antagonists, lubeluzole, citicoline, anti-intercellular adhesion molecule (ICAM)-1 antibody, clomethiazole, fosphenytoin, piracetam, ebselen, and ganglioside GM-1 are therapeutic interventions that have been studied to retain CNS function in the ischemic penumbra. None of these interventions has been clearly shown to preserve neurologic function. Because the events leading to neuronal death involve numerous pathways, it is possible that a combination of some of these agents will prove to be most effective.

Hemodilution

21. What is the rationale for hemodilution therapy in ischemic stroke? Should this therapeutic approach be recommended for P.C.?

Based on a direct relationship between a lowered hematocrit and decreased blood viscosity, various colloid and crystalloid solutions have been administered to ischemic stroke patients. Initial studies indicated that volume expansion might be useful, but larger trials have not supported the original findings.^{130,131} A more recent trial failed to show any benefit from hemodilution, but found this practice to be as safe as regular hydration therapy.¹³² None of the studies have shown a benefit as measured by a reduction in mortality rates. Hemodilution is not recommended in P.C.'s management.

Corticosteroids

22. Should corticosteroids be used in P.C.?

Corticosteroids have been used to treat stroke on the theory that decreasing edema and swelling of the brain will increase cerebral blood flow to ischemic regions. Dexamethasone (4–20 mg Q 6 hr) was commonly used because it has substantial anti-inflammatory effects without mineralocorticoid activity; however, multiple studies have shown that corticosteroids are ineffective in treating cerebral infarction or hemorrhagic stroke.^{133–138} The lack of efficacy of steroids might be explained by inflammation of dead neurons rather than in marginally ischemic neurons. The use of corticosteroids is relatively contraindicated in these patients because of possible increases in morbidity and mortality.¹³³ Corticosteroids are

ineffective in the treatment of cerebral infarction or hemorrhagic stroke.

Calcium Channel Blockers

23. What is the rationale for using calcium channel blockers in ischemic stroke? Are they indicated for use in P.C.?

Calcium influx into neurons coincides with much of the cellular destruction associated with ischemia. Because calcium influx into the neuron is modulated by both voltage-dependent channels and neurotransmitter-dependent channels, calcium channel blockers that penetrate the CNS could be useful for limiting the neurologic damage associated with an ischemic stroke. In addition, the calcium channel blockers have been shown to increase blood flow into ischemic regions of the brain.

Initial studies of nimodipine for ischemic stroke indicated that treatment positively improved outcomes. A study of 186 patients showed an 8.6% mortality rate in the nimodipine-treated group compared with a 20.4% mortality rate in the placebo-treated group.¹³⁹ Stratification according to gender indicated a significant difference in males but not in females.

Eight other studies failed to substantiate this first study. One study evaluated nimodipine 120 mg/day in a double blind, randomized trial.¹⁴⁰ Based on two stroke rating scales and mortality rates, there was no difference between nimodipine and placebo. Another randomized, double blind, placebo-controlled study of nimodipine showed no improvement with nimodipine.¹⁴¹ A meta-analysis of nimodipine use in 3,719 patients showed a benefit only for patients who were treated with 30 mg Q 6 hr beginning within 12 hours of symptom onset.¹⁴² A second systematic review came to a similar conclusion and effectively ruled out a clinically significant benefit of calcium channel blockers in acute ischemic stroke.¹⁴³

Calcium channel blockers are not indicated in P.C. Their use in subarachnoid hemorrhage is discussed in Question 30.

Stroke Education

24. What information and instruction should be given to P.C. regarding future stroke symptoms?

Early treatment of acute stroke with available or investigational drugs appears to be the most important factor in determining optimal outcome. Nearly every clinical trial demonstrating some benefit of pharmacotherapy for acute stroke has shown the greatest effect for patients who are treated within a few hours of the onset of stroke symptoms. Immediate detection of stroke symptoms and initiation of treatment are imperative. The primary rate-limiting step in diagnosis and provision of medical care is recognition by the patient of stroke symptoms. Every patient who is at increased risk of stroke should be carefully instructed to seek emergent medical attention if they experience any weakness or paralysis, speech impairment, numbness, blurred vision or sudden loss of vision, or altered level of consciousness. These symptoms should be handled with the same urgency as the symptoms of a myocardial infarction. The pharmacist should ensure that P.C. and his caregivers know the symptoms of stroke and understand what to do if they occur.

Complications

25. What complications associated with stroke might P.C. experience?

Agitation, delirium, stupor, coma, cerebral edema, and/or increased intracranial pressure are other symptoms that can be associated with ischemic stroke. These symptoms correlate with the specific blood vessels that are affected, and the development of these complications in P.C. would depend on the progression of his stroke.

Seizures may occur in up to 20% of stroke patients. Pneumonia, pulmonary edema, cardiac arrest, deep vein thrombosis, and arrhythmias commonly are associated with ischemic stroke and should be managed as they occur. In P.C., these may occur soon after his stroke or be related to a rapidly developing neurologic event such as further infarction, hemorrhage, or severe cerebral edema. Pneumonia or deep venous thrombosis are related primarily to inactivity, and the risk of these events will increase the longer P.C. remains immobile.

Stroke patients frequently experience psychologic reactions. The most common psychiatric complication is depression, occurring in 30% to 50% of patients.¹⁴⁵ The severity of depression varies from mild to major depressive episodes. If the depression interferes with recovery and the rehabilitative process, it should be managed with the use of a selective serotonin reuptake inhibitor (SSRI) or other appropriate agent. Severe psychomotor depression may respond to CNS stimulants, such as methylphenidate or dextroamphetamine. Because of P.C.'s hypertension, stimulants only should be used with careful blood pressure monitoring.

Prognosis

26. After 4 days in the hospital, P.C.'s neurologic status is stabilized. Will further neurologic improvements be realized?

Neurologic deficits in stroke patients are not considered stable or fixed until at least 8 to 12 months have elapsed. During this time, neurologic function may return, but rarely to normal. The prognosis following ischemic stroke depends on a variety of factors including age, hypertension, coma, cardiopulmonary complications, hypoxia, and neurogenic hyperventilation. However, infarction of the middle cerebral artery is associated with a poor chance for recovery. Therefore, it is possible that P.C. will experience further neurologic improvement.

Rehabilitation

27. As P.C. enters rehabilitation, what interventions will aid his recovery?

Rehabilitation for P.C. is directed at managing daily functions, enhancing existing neurologic function, and attempting to regain lost function. Considerations for daily functions include activities of daily living and bowel and bladder management through balanced pharmacologic interventions. Efforts should be made to allow P.C. to function independently with activities of daily living and manage the psychologic effects of stroke. Enhancement of current neurologic function and minimizing depression includes elimination of drugs that may

compromise P.C.'s memory and mental function. These include benzodiazepines, major tranquilizers, and sedating antiepileptic drugs.

Spasticity of the affected limb may present a problem for P.C. Because spasticity often is localized to a single limb after ischemic stroke, it frequently responds to regional motor nerve blocks with botulinum toxin. Aggressive physical therapy also is essential to the management of spasticity. Systemic antispasticity agents such as diazepam, baclofen, or dantrolene sodium are not used routinely because of the risk for toxicity. They are used only when spasticity involves multiple parts of the body or is unresponsive to other therapies.

Other less common impediments to P.C.'s recovery include decubitus ulcers, hypercalcemia, and heterotopic ossification (e.g., the laying down and calcification of a bone matrix in muscle surrounding major joints). Prevention through meticulous skin care is the key to the management of pressure ulcers. Mobilizing P.C. as soon as possible after the stroke can prevent hypercalcemia and heterotopic ossification. If necessary, these complications may be treated with etidronate (Didronel).

SUBARACHNOID HEMORRHAGE

Clinical Presentation and Treatment

28. R.A., a 65-year-old woman, suddenly collapsed in the bathroom of her home. An ambulance was immediately called, and on arrival at the ED she had regained consciousness. She complained of a severe headache and kept dropping off to sleep during the examination. Nuchal rigidity (i.e., a stiff and painful neck when flexed) and mild mental confusion with regard to place also were observed. A CT scan demonstrated blood in the subarachnoid space and in her ventricles. A cerebral angiogram demonstrated a posterior communicating artery aneurysm. Electrolytes, coagulation studies, and blood counts were within normal limits. What pharmacotherapy is used for subarachnoid hemorrhage?

R.A.'s neurologic symptoms and the appearance of blood on her CT scan are consistent with a diagnosis of subarachnoid hemorrhage. Unfortunately, there are no direct pharmacotherapeutic interventions that are effective for subarachnoid hemorrhage. Surgical repair and clipping of the aneurysm is the definitive intervention. Pharmacotherapy is directed at preventing or managing complications of SAH (Fig. 55-5).

Complications

29. R.A.'s neurologic status deteriorated approximately 3 days after admission. What complications may be responsible for these changes?

Following the initial hemorrhagic event, there are three major complications that usually are responsible for neurologic changes (Table 55-8). *Rebleeding* from an aneurysm occurs in 20% of patients, usually within the first 48 hours after the initial event. In some cases, rebleeding can happen as long as 14 days later. From 24 hours to weeks after the hemorrhage, *hydrocephalus* (i.e., accumulation of excessive CSF within the ventricular system of the brain) may be caused by blood interrupting CSF flow through the ventricles and reabsorption of CSF through the arachnoid villa. Another 20% to 40% of

Table 55-8 Therapy for Subarachnoid Hemorrhage Complications

| Rebleeding | Hydrocephalus | Delayed Ischemia |
|--|---------------------------------|---|
| Surgical clip | Ventricular drain | Nimodipine 60 mg Q 4 hr for 21 days |
| Aminocaproic acid 5 g loading dose and 1 to 2 g/hr | Ventricular-peritoneal shunt | Hypervolemia PCWP 12–15 mmHg Hypertension Systolic BP 170– 220 mmHg |

BP, blood pressure; PCWP, pulmonary capillary wedge pressure.

patients will develop *delayed cerebral ischemia*, usually within 5 to 12 days following the initial hemorrhage. Delayed ischemia caused by vasospasm of the cerebral vessels is evidenced by development of new neurologic deficits and confirmed by a cerebral angiogram. At least half of these individuals will die or experience permanent neurologic damage. Approximately 5% to 15% of patients have seizures.

30. How should each of these complications (rebleeding, hydrocephalus, vasospasm, seizures) be managed in R.A.? Are calcium channel blockers more effective in treating subarachnoid hemorrhage than ischemic stroke?

Rebleeding

Surgical clipping of the aneurysm is the best method to prevent rebleeding. If early surgery is contraindicated or unavailable, antifibrinolytic therapy with epsilon aminocaproic acid (EACA) may be instituted. EACA blocks the activation of plasminogen and inhibits the action of plasmin on the fibrin clot. EACA enhances hemostasis when fibrinolysis contributes to bleeding and stabilizes the clot that has formed around the ruptured aneurysm. The incidence of rebleeding is decreased from 20% to 30% to 10% to 15% by EACA.^{146,147} However, delayed cerebral ischemia occurs more frequently in patients receiving EACA.¹⁴⁶ It is unclear whether this is a direct effect of EACA or whether more individuals survive to experience delayed cerebral ischemia. EACA usually is given as a 5-g IV bolus followed by a continuous infusion of 1 to 2 g/hour. Dosages can be adjusted to maintain serum concentrations of 200 to 400 mg/mL. R.A. may benefit from receiving EACA as soon as a subarachnoid hemorrhage is diagnosed, and it should be continued until surgical clipping can be performed or for at least 2 weeks after the initial hemorrhage. It is preferable to surgically repair the aneurysm as soon as possible after R.A. is admitted to the hospital.

Hydrocephalus

The only effective treatment for hydrocephalus is surgical intervention. If a CT scan demonstrates hydrocephalus, a ventricular drain should be surgically placed after the aneurysm has been clipped. When hydrocephalus becomes a chronic problem, the drain can be replaced with a permanent ventriculoperitoneal shunt.

Ventriculitis is a common complication of a ventricular drain and is most likely caused by staphylococci or Gram-negative bacteria. Antibiotic therapy for this complication should consist of an IV agent (e.g., chloramphenicol, ceftriaxone, ampicillin, penicillin, vancomycin, ceftazidime, cefuroxime, nafcillin, rifampin) that readily crosses the blood-brain barrier with inflamed meninges. Alternatively, gentamicin and vancomycin can be instilled through the ventricular drains directly to the site of infection.¹⁴⁸ The antibiotic solution is prepared using a preservative-free sterile powder for injection. Gentamicin 4 to 8 mg or vancomycin 5 to 20 mg is instilled once a day. Systemic and intraventricular antibiotics should be continued until three consecutive CSF cultures are free of bacterial growth.

Delayed Cerebral Ischemia (Vasospasm)

The occurrence of delayed cerebral ischemia probably is due to vasospasm of the cerebral blood vessels. Current therapy for delayed ischemia is not optimal and is rather confusing. Volume expansion with normal saline or plasma protein fraction usually is initiated when focal neurologic changes develop, with the goal of maintaining a pulmonary capillary wedge pressure of 15 to 20 mmHg.^{149–152} Some clinicians may institute hypervolemia therapy in anticipation of delayed cerebral ischemia. If the neurologic deficits are not reversed with hypervolemia, systolic blood pressure can be increased to as high as 200 to 220 mmHg using dopamine or norepinephrine. A high systolic pressure allows the brain to redirect flow to ischemic areas, and such therapy is often continued for 7 to 14 days.

CALCIUM CHANNEL BLOCKERS

Nimodipine

Nimodipine also is indicated for the prevention of delayed cerebral ischemia for patients with a subarachnoid hemorrhage. Its mechanisms of action may include preventing cerebral vasospasm that is responsible for delayed ischemia, inhibiting calcium influx into ischemic neurons, or re-establishing cerebrovascular autoregulation (i.e., the ability of the brain to control blood flow in accordance with metabolic needs).

Nimodipine has been administered in clinical studies intravenously, orally, or topically (i.e., direct application to the brain's surface and the cerebral vasculature during surgery). Several studies of nimodipine in subarachnoid hemorrhage have used oral formulations. In these studies, a total

of 1,038 patients were given nimodipine prophylactically according to double-blind, placebo-controlled, randomized protocols.^{153–156} Angiographic improvement was not significantly different in patients treated with nimodipine or placebo, but neurologic outcomes improved significantly in nimodipine-treated patients who presented with a mild to moderately severe subarachnoid hemorrhage. In another study, nimodipine significantly benefited patients with severe hemorrhage. Nimodipine 60 to 90 mg Q 4 hr for 21 days was initiated within the first 96 hours after the original subarachnoid hemorrhage in these patients. No trial has compared the efficacy of nimodipine with hypervolemia therapy and interventions to increase systolic blood pressure. Nimodipine's approved dose is 60 mg PO Q 6 hr.

R.A. should receive nimodipine 60 mg PO Q 4 hr for 21 days, because she was diagnosed within several hours of her subarachnoid hemorrhage.

Seizures

PHENYTOIN

Seizures occur in approximately 9% of patients experiencing a subarachnoid hemorrhage. Only two factors associated with subarachnoid hemorrhage have been identified as predictive of seizures: rebleeding or large amounts of cisternal blood on CT scan.

Phenytoin often is used for seizure prophylaxis. However, no trials have investigated the efficacy of phenytoin in preventing seizure in patients with subarachnoid hemorrhage. The usual dose of phenytoin is 15 to 20 mg/kg administered as an IV bolus at a rate <50 mg/minute. A maintenance dose of 5 to 7 mg/kg/day either orally or intravenously is titrated to maintain steady-state serum concentrations of 10 to 20 mg/mL. Alternatively, fosphenytoin, a phenytoin prodrug, can be administered intravenously or intramuscularly at a loading dose of 15 to 20 mg phenytoin equivalents (PE)/kg and a maintenance dose of 5 to 7 mg PE/kg/day. Infusion rates of fosphenytoin should be <150 mg PE/minute. Maintenance phenytoin usually is continued for 1 to 2 years or longer if the patient experiences seizures. Because there is a 5% to 20% risk of seizures for R.A., she should receive phenytoin prophylactically. Valproic acid (Depacon) and levetiracetam (Keppra) are available in intravenous formulations; however there is little experience with the use of these agents for seizures in the setting of subarachnoid hemorrhage.

APPROACHING THE PROBLEM

The proper selection of antimicrobial therapy is based on several factors. Before initiating therapy, it is important first to clearly establish the presence of an infectious process because several disease states (e.g., malignancy, autoimmune disease) and drugs can mimic infection. Once infection has been documented, its most likely site must be identified. Signs and symptoms (e.g., erythema associated with cellulitis) direct the clinician to the likely source. Because certain pathogens are known to be associated with a specific site of infection, therapy often can be directed against these organisms. Additional laboratory tests, including the Gram stain, serology, and antimicrobial susceptibility testing, generally identify the primary pathogen. Although several antimicrobials potentially can be considered, their spectrum of activity, clinical efficacy, adverse effect profile, pharmacokinetic disposition, and cost considerations ultimately guide the choice of therapy. Once an agent has been selected, the dosage must be based on the size of the patient, site of infection, route of elimination, and other factors.

ESTABLISHING THE PRESENCE OF AN INFECTION

1. R.G., a 63-year-old man in the intensive care unit, underwent emergency resection of his large bowel. He has been intubated throughout his postoperative course. On day 20 of his hospital stay, R.G. suddenly becomes confused; his blood pressure (BP) drops to 70/30 mmHg, with a heart rate of 130 beats/minute. His extremities are cold to the touch, and he presents with circumoral pallor. His temperature increases to 40°C (axillary) and his respiratory rate is 24 breaths/minute. Copious amounts of yellow-green secretions are suctioned from his endotracheal tube.

Physical examination reveals sinus tachycardia with no rubs or murmurs. Rhonchi with decreased breath sounds are observed on auscultation. The abdomen is distended and R.G. complains of new abdominal pain. No bowel sounds can be heard and the stool is guaiac positive. Urine output from the Foley catheter has been 10 mL/hour for the past 2 hours. Erythema is noted around the central venous catheter.

A chest radiograph reveals bilateral lower lobe infiltrates, and urinalysis reveals >50 white blood cells/high-power field

(WBC/HPF), few casts, and a specific gravity of 1.015. Blood, tracheal aspirate, and urine cultures are pending. Other laboratory values include sodium (Na), 131 mEq/L (normal, 135 to 147); potassium (K), 4.1 mEq/L (normal, 3.5 to 5); chloride (Cl), 110 mEq/L (normal, 95–105); CO₂, 16 mEq/L; blood urea nitrogen (BUN), 58 mg/dL (normal, 8–18); creatinine, 3.8 mg/dL (increased from 0.9 mg/dL at admission) (normal, 0.6–1.2); glucose 320 mg/dL (normal, 70–110); serum albumin, 2.1 g/dL (normal, 4–6); hemoglobin (Hgb), 10.3 g/dL; hematocrit (Hct), 33% (normal, 39%–49% [male patients]); WBC count, 15,600/mm³ with bands present; platelets, 40,000/mm³ (normal, 130,000–400,000); prothrombin time (PT), 18 seconds (normal, 10–12); erythrocyte sedimentation rate (ESR), 65 mm/hour (normal, 0–20). Which of R.G.'s signs and symptoms are consistent with infection?

[SI units: Na, 131 mmol/L; K, 4.1 mmol/L; Cl, 110 mmol/L; CO₂, 16 mmol/L; BUN, 20.71 mmol/L of urea; creatinine, 335.92 and 7.56 mmol/L, respectively; glucose, 17.76 mmol/L; albumin, 235.62 mmol/L; Hgb, 103 g/L; Hct, 0.33; WBC, 15.6 × 10⁹; platelets, 40 × 10⁹; ESR 65 mm/hour]

R.G. has numerous signs and symptoms consistent with an infectious process. He has both an increased WBC count (15,600/mm³) and a “shift to the left” (bands are present on the differential). An increased WBC count commonly is observed with infection, particularly with bacterial pathogens. The WBC differential in patients with a bacterial infection often demonstrates a shift to the left (i.e., presence of immature neutrophils), suggesting that the bone marrow is responding to an infectious insult. Infection is not always associated with leukocytosis, however. Overwhelming sepsis can cause a decreased WBC count; some patients become neutropenic secondary to infection. In less acute infection (e.g., uncomplicated urinary tract infection, abscess), the WBC count may remain within the normal range. Because the abscess is a localized

lesion, less bone marrow response would be anticipated; thus, the WBC count may not increase in these patients.

R.G.'s temperature is 40°C by axillary measurement. Fever is a common manifestation of infection, with oral temperatures generally >38°C. Oral and axillary temperatures tend to be approximately 0.4°C lower compared with rectal measurement.¹ As a result, R.G.'s temperature would be expected to be 40.4°C if his temperature had been taken rectally. In general, rectal measurement of temperature is a more reliable determination of fever. Some patients with overwhelming infection, however, may present with hypothermia and temperatures <36°C. Furthermore, patients with localized infections (e.g., uncomplicated urinary tract infection, chronic abscesses) may be afebrile.

The bilateral lower lobe infiltrates on R.G.'s chest radiograph, the presence of copious amounts of yellow-green secretions from his endotracheal tube, and the erythema surrounding his central venous catheter also are compatible with an infectious process. Furthermore, R.G. has the signs and symptoms that also are consistent with sepsis, which are discussed next.

ESTABLISHING THE SEVERITY OF AN INFECTION

2. What signs and symptoms manifested by R.G. are consistent with a serious systemic infection?

The term *sepsis* is used to describe a poorly defined syndrome; however, sepsis generally suggests more systemic infection associated with the presence of pathogenic microorganisms or their toxins in the blood. A uniform system for defining the spectrum of disorders associated with sepsis has been established.²

The pathogenesis of sepsis is complex (Fig. 56-1) and only partially understood.^{2–4} Gram-negative aerobes produce

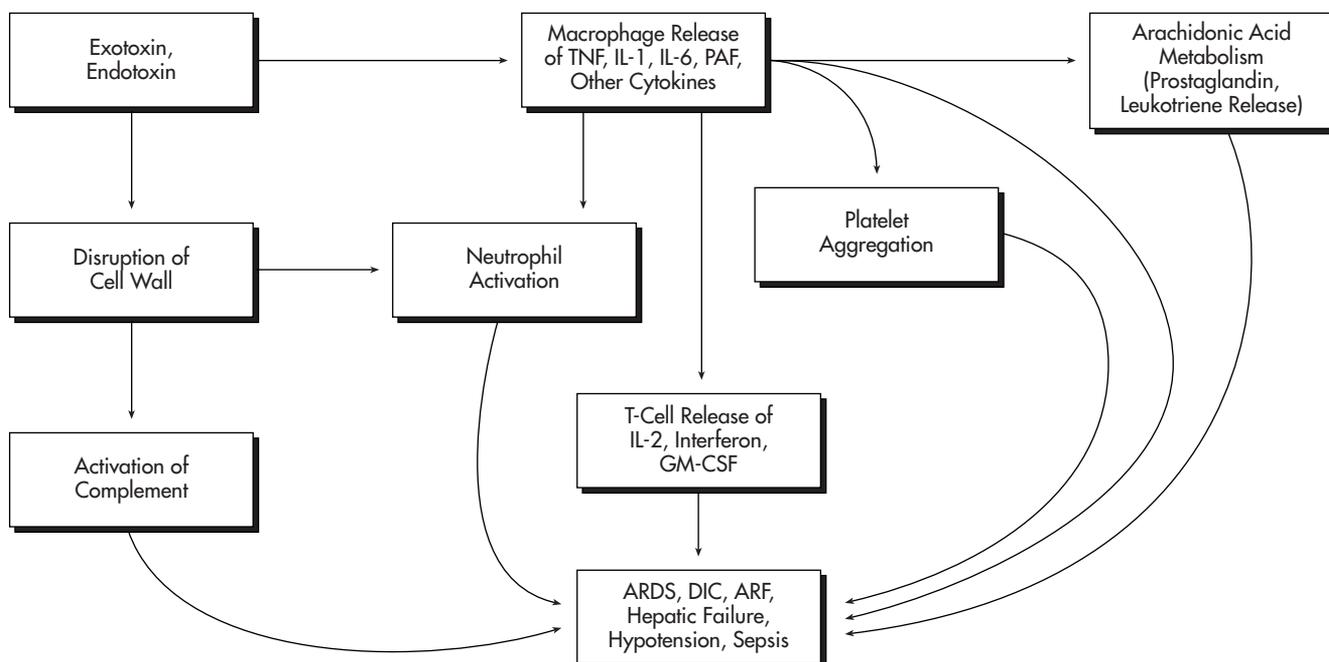

FIGURE 56-1 The sepsis cascade. ARDS, acute respiratory distress syndrome; ARF, acute renal failure; DIC, disseminated intravascular coagulation; GM-CSF, granulocyte-macrophage colony-stimulating factor; IL-1, interleukin-1; IL-6, interleukin-6; PAF, platelet activating factor; TNF, tumor necrosis factor.

endotoxin that results in a cascade of endogenous mediator release, including tumor necrosis factor (TNF), interleukin-1 (IL-1) and interleukin-6 (IL-6), platelet activating factor (PAF), and various other substances, from mononuclear phagocytes and other cells. Although this initial stimulus commonly is associated with gram-negative endotoxin, other substances, including gram-positive exotoxin and fungal cell wall constituents, also may be associated with cytokine release. After release of TNF, IL-1, and PAF, arachidonic acid is metabolized to form leukotrienes, thromboxane A₂, and prostaglandins, particularly prostaglandin E₂ and prostaglandin I₂. IL-1 and IL-6 activate the T cells to produce interferon, IL-2, IL-4, and granulocytemacrophage colony-stimulating factor (GM-CSF). Increased endothelial permeability ensues. Subsequently, the endothelium releases two hemodynamically active substances: endothelium-derived relaxing factor (EDRF) and endothelin-1. Activation of the complement cascade (fragments C3a and C5a) follows with additional vascular abnormalities and neutrophil activation. Other potentially important agents in this cascade include adhesion molecules, kinins, thrombin, myocardial depressant substance, endorphins, and heat shock protein. The net result of this cascade involves several hemodynamic, renal, acid base, and other disorders. Uncontrolled inflammation and coagulation also have an important role in this sepsis cascade.⁴

Hemodynamic Changes

Critically ill patients often have central intravenous (IV) lines in place for measuring cardiac output and systemic vascular resistance (SVR). A normal SVR of 800 to 1,200 dyne.sec.cm⁻⁵ may fall to 500 to 600 dyne.sec.cm⁻⁵ with septic shock because of intense vasodilation. In response to this vasodilation, the heart reflexively increases cardiac output from its normal 4 to 6 L/minute to as much as 11 to 12 L/minute in septic patients. This increase in cardiac output primarily is caused by an increased heart rate; stroke volume is unchanged or decreased because of the hypovolemic state. Although the heart rate is increased on the basis of reflex tachycardia, a chronotropic response also takes place as a result of stress-induced catecholamine release (norepinephrine, epinephrine). Thus, the cardiac output increases in response to arterial vasodilation; however, this increase generally is insufficient to overcome the vasodilatory state, and hypotension ensues. In overwhelming septic shock, myocardial depression results in a decreased cardiac output. The combination of decreased cardiac output and decreased SVR results in hypotension unresponsive to pressors and IV fluids. R.G. has hemodynamic evidence of septic shock. He is hypotensive (BP 70/30 mmHg) and tachycardic (130 beats/minute), presumably in response to significant vasodilation and catecholamine release.

Although vasodilation commonly occurs in sepsis, hemodynamic changes are not equal throughout the vasculature. Some vascular beds constrict, resulting in maldistribution of blood flow. Significant amounts of blood are shunted away from the kidneys, mesentery, and extremities.

Normal urine output of approximately 0.5 to 1.0 mL/kg/hour (30–70 mL/hour for a 70-kg patient) can decrease to <20 mL/hour in sepsis. The urine output for R.G. has decreased to 10 mL/hour, consistent with sepsis-induced perfusion abnormalities. Decreased blood flow to the kidney as well as mediator-induced microvascular failure can cause acute-

tubular necrosis (ATN). R.G.'s uremia (BUN 58 mg/dL) and increased serum creatinine concentration (3.8 mg/dL) are consistent with decreased renal perfusion secondary to sepsis. When sepsis has progressed to septic shock, blood flow to most major organs is decreased. Decreased blood flow to the liver may result in "shock liver," in which liver function tests, including alanine aminotransferase (ALT), aspartate aminotransferase (AST), and alkaline phosphatase, become elevated. The liver function tests for R.G. are not available; however, his serum albumin concentration is low (2.1 g/dL) and his PT of 18 seconds is prolonged. Decreased blood flow to the musculature classically is characterized by cool extremities, and decreased blood flow to the brain can result in decreased mentation. R.G. is confused, his extremities are cold, and the area around his mouth appears pale. All these signs and symptoms provide strong evidence that he is in septic shock.

Cellular Changes

The sepsis syndrome is associated with significant abnormalities in cellular metabolism. Glucose intolerance commonly is observed in sepsis, and patients with previously normal blood glucose levels may experience sudden increases in blood sugar. In some cases, an increase in glucose is one of the first signs of an infectious process. R.G.'s increased blood glucose concentration (320 mg/dL) is, therefore, consistent with sepsis. Other sensitive indicators of sepsis-associated inflammation include the ESR and C-reactive protein, nonspecific tests that are commonly elevated in various inflammatory states, including infection. The ESR or C-reactive protein can be used to follow the progression of infection; currently, R.G.'s ESR is elevated at 65 mm/hour. With appropriate management of infection, the ESR would be expected to decrease; inadequate treatment would be associated with persistent elevation of the ESR and C-reactive protein.

Respiratory Changes

Production of organic acids, such as lactate, increased glycolysis, decreased fractional extraction of oxygen, and abnormal delivery-dependent oxygen consumption are observed.⁴ This increase in lactic acid results in metabolic acidosis, with accompanying decreased serum bicarbonate levels. The lungs normally respond in a compensatory manner with an increased respiratory rate (tachypnea), resulting in an increased elimination of arterial carbon dioxide. R.G.'s acid-base status is consistent with sepsis-associated metabolic acidosis (CO₂ 16 mEq/L) and compensatory respiratory alkalosis (respiratory rate 24 breaths/minutes).

Although not currently present in R.G., a late complication of the above-mentioned sepsis cascade is acute respiratory distress syndrome (ARDS). ARDS initially was described as non-cardiogenic pulmonary edema with severe hypoxemia caused by right-to-left intrapulmonary shunting resulting from atelectasis and edema-filled alveoli. The primary pathophysiology of ARDS is a breakdown in the natural integrity of the alveolar capillary network in the lung.⁵ In the early phase of ARDS, patients have severe alveolar edema with large numbers of inflammatory cells, primarily neutrophils. The chronic phase of ARDS (10–14 days after development of the syndrome) is associated with significant lung destruction. Emphysema, pulmonary vascular obliteration, and fibrosis commonly are

observed. Severe ARDS is associated with arterial oxygen level/fraction of inspired oxygen ($\text{PaO}_2/\text{FiO}_2$) ratios of <100 , low lung compliance, a need for high positive end-expiratory pressure (PEEP), and other respiratory maneuvers. At present, the treatment for this syndrome primarily is supportive, including mechanical ventilation, high inspired oxygen, and PEEP. If patients fail to show improved gas exchange by day 7, the mortality associated with ARDS is high ($>80\%$).⁶ Although R.G. currently does not have ARDS, the severity of his septic episode strongly suggests he may develop this complication in the next few days.

Hematologic Changes

Disseminated intravascular coagulation (DIC) is a well-recognized sequel of sepsis. Huge quantities of clotting factors and platelets are consumed in DIC as widespread clotting takes place throughout the circulatory system. As a result, the PT and the activated partial thromboplastin time (aPTT) are prolonged and the platelet count commonly is decreased in sepsis. Decreased fibrinogen levels and increased fibrin split products generally are diagnostic for DIC. The PT of 18 seconds and the decreased platelet count of $40,000/\text{mm}^3$ in R.G. are consistent with sepsis-induced DIC.

Neurologic Changes

Central nervous system (CNS) changes, including lethargy, disorientation, confusion, and psychosis, predominate in sepsis. Altered mental status is well recognized as a symptom associated with infections of the CNS, such as meningitis and brain abscess. These changes, however, also are common with other sites of sepsis. On day 20 of his hospital stay, R.G. suddenly became confused, his BP dropped, and his heart rate increased. Thus, R.G.'s CNS effects as well as his hematologic, respiratory, hemodynamic, and cellular effects all provide substantial evidence of septic shock.

PROBLEMS IN THE DIAGNOSIS OF AN INFECTION

3. R.G.'s medical history includes temporal arteritis and seizures chronically treated with corticosteroids and phenytoin. Perioperative "stress doses" of hydrocortisone recently were administered because of his surgical procedure. What medications or disease states confuse the diagnosis of infection?

Confabulating Variables

Various factors, including major surgery, acute myocardial infarction, and initiation of corticosteroid therapy are associated with an increased WBC count. Unlike infection, however, a shift to the left does not occur with these disease states. In R.G., the stress dose of hydrocortisone and his recent surgical procedure might have contributed to the increased WBC count. The presence of bands in R.G., however, strongly suggests an infectious process.

Drug Effects

The ability of corticosteroids to mimic or mask infection is noteworthy. Corticosteroids are associated with an increased

WBC count and glucose intolerance when therapy is initiated or when doses are increased. Furthermore, some patients experience corticosteroid-induced mental status changes that may complicate the diagnosis of a septic infection. Although corticosteroids mimic infection, they also have the ability to mask infection. Bowel perforation in a patient with ulcerative colitis would result in significant peritoneal contamination. Concomitant corticosteroids, because of their potent anti-inflammatory effects, may, however, reduce the classic findings of peritonitis. Furthermore, corticosteroids can reduce and sometimes ablate the febrile response. Thus, these corticosteroid-treated patients may be asymptomatic but at great risk for gram-negative septic shock.

Another example of the influence of corticosteroids on the diagnosis of infection relates to neurosurgical procedures. Dexamethasone is a corticosteroid commonly used to reduce the inflammation and swelling associated with neurosurgical procedures. Certain neurosurgical procedures are associated with significant trauma to the meninges; however, the patient often is asymptomatic while receiving high-dose dexamethasone. When the dexamethasone dose is decreased, the patient subsequently may experience classic meningismus, including stiff neck, photophobia, and headache. The lumbar puncture may demonstrate cloudy cerebrospinal fluid (CSF), an elevated WBC count, high CSF protein, and low CSF glucose. Although the signs and symptoms are consistent with infectious meningitis, this disease state is considered aseptic meningitis (i.e., inflammation of the meninges without an infectious origin).⁷ Certain drugs may cause aseptic meningitis, including OKT3,⁸ nonsteroidal anti-inflammatory agents, and sulfonamides.

Fever

Fever also is consistent with autoimmune diseases, such as lupus erythematosus and temporal arteritis.^{9,10} Neoplasms, such as leukemia and lymphoma, also may present with low-grade fevers, similar to those observed in an infectious process. One evaluation of fever of unknown origin (FUO) in community hospitals demonstrated a 25% incidence of FUO caused by cancer.¹⁰ Other diseases associated with fever include sarcoidosis, chronic liver disease, and familial Mediterranean fever. Acute myocardial infarction, pulmonary embolism, and postoperative pulmonary atelectasis are commonly associated with an elevated temperature. Factitious fever or self-induced disease must be considered in certain patients. After infection, autoimmune disease, and malignancy have been ruled out, drug fever should be considered. Drugs, including certain antimicrobials (e.g., amphotericin B) and phenytoin, have been associated with drug fever. Drug fever generally occurs after 7 to 10 days of therapy and resolves within 48 hours of the drug's discontinuation.¹¹ Some clinicians claim that patients with drug fever generally feel "well" and are unaware of their fever. Rechallenge with the offending agent usually results in recurrence of fever within hours of administration. Drug fever should be considered a diagnosis of exclusion, however, and should be considered only after eliminating the presence of other disease states (also see Chapter 4, Anaphylaxis and Drug Allergies).

Neoplasms may be radiographically indistinguishable from an abscess. An example of this dilemma is the differential diagnosis of toxoplasmosis versus lymphoma in patients with

human immunodeficiency virus (HIV) with brain lesions documented by a computed axial tomography scan. One method for diagnosis is to use empiric therapy against *Toxoplasma gondii*. If the lesions are unresponsive to therapy, the presumptive diagnosis of malignancy can be made.

In summary, R.G. has an autoimmune disease, temporal arteritis, which has been associated with fever. Similarly, his corticosteroid administration and phenytoin use may confound the diagnosis of infection. His other signs and symptoms, however, strongly suggest that R.G.'s problems are of an infectious origin.

ESTABLISHING THE SITE OF THE INFECTION

4. What are the most likely sources of R.G.'s infection?

Independent of the presumed site of infection, a blood culture should be drawn to demonstrate the presence of bacteremia. After blood cultures are sampled, a thorough physical examination generally documents the source of infection. Urosepsis, the most common cause of nosocomial infection, may be associated with dysuria, flank pain, and abnormal urinalysis.¹² Tachypnea, increased sputum production, altered

chest radiograph, and hypoxemia may direct the clinician toward a pulmonary source. Evidence for an infected IV line would include pain, erythema, and purulent discharge around the IV catheter. Other potential sites of infection include the peritoneum, pelvis, bone, and CNS.

R.G. is demonstrating several possible sites of infection. The copious production of yellow-green sputum, tachypnea, and the altered chest radiograph suggest the presence of pneumonia. The abdominal pain, absent bowel sounds, and recent surgical procedure, however, require evaluation for an intra-abdominal source.¹³ Lastly, the abnormal urinalysis (>50 WBC/HPF) and the erythema around the central venous catheter suggest other sites of infection.

DETERMINING LIKELY PATHOGENS

5. What are the most likely pathogens associated with R.G.'s infection(s)?

R.G. has several possible sources of infection. The suspected pathogens depend on the presumed site of infection. Table 56-1 provides a classification of infectious organisms (e.g., gram-positive, gram-negative, aerobic, anaerobic),

Table 56-1 Classification of Infectious Organisms

| 1. Bacteria | |
|---|--|
| <i>Aerobic</i> | |
| Gram-positive | |
| <i>Cocci</i> | |
| Streptococci: pneumococcus, viridans streptococci; group A streptococci | |
| <i>Enterococcus</i> | |
| Staphylococci: <i>Staphylococcus aureus</i> , <i>Staphylococcus epidermidis</i> | |
| <i>Rods (bacilli)</i> | |
| <i>Corynebacterium</i> | |
| <i>Listeria</i> | |
| Gram-negative | |
| <i>Cocci</i> | |
| <i>Moraxella</i> | |
| <i>Neisseria (Neisseria meningitidis, Neisseria gonorrhoeae)</i> | |
| <i>Rods (bacilli)</i> | |
| Enterobacteriaceae (<i>Escherichia coli</i> , <i>Klebsiella</i> , <i>Enterobacter</i> , <i>Citrobacter</i> , <i>Proteus</i> , <i>Serratia</i> , <i>Salmonella</i> , <i>Shigella</i> , <i>Morganella</i> , <i>Providencia</i>) | |
| <i>Campylobacter</i> | |
| <i>Pseudomonas</i> | |
| <i>Helicobacter</i> | |
| <i>Haemophilus (coccobacilli morphology)</i> | |
| <i>Legionella</i> | |
| <i>Anaerobic</i> | |
| Gram-positive | |
| <i>Cocci</i> | |
| <i>Peptococcus</i> | |
| <i>Peptostreptococcus</i> | |
| <i>Rods (bacilli)</i> | |
| Clostridia (<i>Clostridium perfringens</i> , <i>Clostridium tetani</i> , <i>Clostridium difficile</i>) | |
| <i>Propionibacterium acnes</i> | |
| Gram-negative | |
| <i>Cocci</i> | |
| None | |
| <i>Rods (bacilli)</i> | |
| Bacteroides (<i>Bacteroides fragilis</i> , <i>Bacteroides melanogenicus</i>) | |
| Fusobacterium | |
| Prevotella | |
| 2. Fungi | |
| <i>Aspergillus, Candida, Coccidioides, Cryptococcus, Histoplasma, Mucor, Tinea, Trichophyton</i> | |
| 3. Viruses | |
| Influenza, hepatitis A, B, C, D, E; human immunodeficiency virus; rubella; herpes; cytomegalovirus; respiratory syncytial virus; Epstein-Barr virus, severe acute respiratory syndrome (SARS) virus | |
| 4. Chlamydiae | |
| <i>Chlamydia trachomatis</i> | |
| <i>Chlamydia psittaci</i> | |
| <i>Chlamydia pneumoniae</i> | |
| Lymphogranuloma venereum (LGV) disease caused by <i>Chlamydia trachomatis</i> of immunotype L1-L3 | |
| 5. Rickettsiae | |
| Rocky Mountain spotted fever, Q fever | |
| Ureaplasma | |
| 6. Mycoplasmas | |
| <i>Mycoplasma pneumoniae, Mycoplasma hominis</i> | |
| 7. Spirochetes | |
| <i>Treponema pallidum, Borrelia burgdorferi</i> (Lyme disease) | |
| 8. Mycobacteria | |
| <i>Mycobacterium tuberculosis</i> | |
| <i>Mycobacterium avium intracellulare</i> | |

Table 56-2 Site of Infection: Suspected Organisms

| Site/Type of Infection | Suspected Organisms |
|--|---|
| 1. Respiratory | |
| Pharyngitis | Viral, group A streptococci |
| Bronchitis, otitis | Viral, <i>Haemophilus influenzae</i> , <i>Streptococcus pneumoniae</i> , <i>Moraxella catarrhalis</i> |
| Acute sinusitis | Viral, <i>Streptococcus pneumoniae</i> , <i>Haemophilus influenzae</i> , <i>Moraxella catarrhalis</i> |
| Chronic sinusitis | Anaerobes, <i>Staphylococcus aureus</i> (as well as suspected organisms associated with acute sinusitis) |
| Epiglottitis | <i>Haemophilus influenzae</i> |
| Pneumonia | |
| <i>Community-Acquired</i> | |
| Normal host | <i>Streptococcus pneumoniae</i> , viral, mycoplasma |
| Aspiration | Normal aerobic and anaerobic mouth flora |
| Pediatrics | <i>Streptococcus pneumoniae</i> , <i>Haemophilus influenzae</i> |
| COAD | <i>Streptococcus pneumoniae</i> , <i>Haemophilus influenzae</i> , <i>Legionella</i> , <i>Chlamydia</i> , <i>Mycoplasma</i> |
| Alcoholic | <i>Streptococcus pneumoniae</i> , <i>Klebsiella</i> |
| <i>Hospital-Acquired</i> | |
| Aspiration | Mouth anaerobes, aerobic gram-negative rods, <i>Staphylococcus aureus</i> |
| Neutropenic | Fungi, aerobic Gram-negative rods, <i>Staphylococcus aureus</i> |
| HIV | Fungi, <i>Pneumocystis</i> , <i>Legionella</i> , <i>Nocardia</i> , <i>Streptococcus pneumoniae</i> , <i>Pseudomonas</i> |
| 2. Urinary Tract | |
| Community-Acquired | <i>Escherichia coli</i> , other gram-negative rods, <i>Staphylococcus aureus</i> , <i>Staphylococcus epidermidis</i> , enterococci |
| Hospital-Acquired | Resistant aerobic Gram-negative rods, enterococci |
| 3. Skin and Soft Tissue | |
| Cellulitis | Group A streptococci, <i>Staphylococcus aureus</i> |
| IV catheter site | <i>Staphylococcus aureus</i> , <i>Staphylococcus epidermidis</i> |
| Surgical wound | <i>Staphylococcus aureus</i> , Gram-negative rods |
| Diabetic ulcer | <i>Staphylococcus aureus</i> , Gram-negative aerobic rods, anaerobes |
| Furuncle | <i>Staphylococcus aureus</i> |
| 4. Intra-abdominal | |
| | <i>Bacteroides fragilis</i> , <i>Escherichia coli</i> , other aerobic Gram-negative rods, enterococci |
| 5. Gastroenteritis | |
| | <i>Salmonella</i> , <i>Shigella</i> , <i>Helicobacter</i> , <i>Campylobacter</i> , <i>Clostridium difficile</i> , amoeba, <i>Giardia</i> , viral, enterotoxigenic-hemorrhagic <i>Escherichia coli</i> |
| 6. Endocarditis | |
| Pre-existing valvular disease | <i>Streptococcus viridans</i> |
| IV drug abuser | <i>Staphylococcus aureus</i> , aerobic Gram-negative rods, enterococci, fungi |
| Prosthetic valve | <i>Staphylococcus epidermidis</i> |
| 7. Osteomyelitis and Septic Arthritis | |
| | <i>Staphylococcus aureus</i> , aerobic Gram-negative rods |
| 8. Meningitis | |
| <2 months | <i>Escherichia coli</i> , group B streptococci, <i>Listeria</i> |
| 2 months–12 years | <i>Streptococcus pneumoniae</i> , <i>Neisseria meningitides</i> , <i>Haemophilus influenzae</i> |
| Adults | <i>Streptococcus pneumoniae</i> , <i>Neisseria meningitides</i> |
| Hospital-acquired | <i>Streptococcus pneumoniae</i> , <i>Neisseria meningitides</i> , aerobic Gram-negative rods |
| Post-neurosurgery | <i>Staphylococcus aureus</i> , aerobic Gram-negative rods |

COAD, chronic obstructive airways disease; IV, intravenous.

and Table 56-2 lists the most likely organisms associated with sites of infection. Determining the most likely infectious agent depends not only on the site of infection but also on host factors. For example, bacterial pneumonia can be caused by various pathogens, including *Streptococcus*

pneumoniae, *Enterobacteriaceae*, and atypical pathogens (e.g., *Legionella pneumophila*).¹⁴ Empiric antimicrobial therapy directed against all the above organisms, however, is unnecessary. Several host factors must be evaluated to streamline therapy against the most likely pathogens. If the pneumonia is

community acquired, *S. pneumoniae*, *Haemophilus influenzae*, *Moraxella catarrhalis*, and “atypical” bacterial pathogens may predominate.¹⁵ In nosocomial (hospital, nursing home) pneumonia, however, gram-negative enterics (e.g., *Escherichia coli*, *Klebsiella* species, *Enterobacter* species, and *Pseudomonas aeruginosa*) become more significant pathogens. If the pneumonia is a result of a gastric aspiration, mouth anaerobes should probably be covered empirically; however, the true pathogenicity of these anaerobes in aspiration pneumonia is not clear. In nosocomial pneumonia, knowledge of the hospital-specific flora is important. If *E. coli* is the most commonly isolated pathogen at a given institution, antimicrobials, such as first- or second-generation cephalosporins, can be used. If *P. aeruginosa* or *Enterobacter cloacae* predominate, then alternative, broader-spectrum therapy is necessary. A thorough evaluation of antimicrobial exposure also is necessary. Recent use of antimicrobials clearly predisposes to subsequent infection caused by resistant gram-negative organisms.

The patient’s age is also an important determinant in the epidemiology of infection. For example, meningitis in a neonate is commonly caused by group B streptococci, *E. coli*, and *Listeria monocytogenes*, whereas these bacteria are uncommon pathogens in normal adults. The presence of concomitant diseases, such as chronic obstructive airways disease (COAD) or alcohol and IV drug abuse, also can help determine the pathogen. For example, patients with COAD-associated pneumonia are more likely to be infected by *S. pneumoniae*, *H. influenzae*, and *M. catarrhalis*. Chronic alcoholics are more likely to have infection caused by enteric gram-negative pathogens, such as *Klebsiella* species.

Immune status is an important predictor of likely pathogens. HIV-positive patients or those receiving cyclosporine (or tacrolimus) and corticosteroids have lymphocyte deficiency-associated infections, including those caused by cytomegalovirus, *Pneumocystis carinii*, atypical mycobacteria, and *Cryptococcus neoformans*. Patients with leukemia and neutropenia are at risk for infection caused by aerobic gram-negative bacilli, including *P. aeruginosa* and fungi.

In R.G., the abdomen, respiratory tract, urinary tract, and IV catheter are all potential sites of infection. Intra-abdominal infection is likely caused by gram-negative enterics and *Bacteroides fragilis*; nosocomial urinary tract infection is usually secondary to aerobic gram-negative rods. R.G.’s pneumonia possibly is caused by gram-negative bacilli, staphylococci, and various other organisms. Furthermore, his use of corticosteroids may predispose him to infection caused by more opportunistic organisms, including *Legionella*, *P. carinii*, and fungi. Lastly, his IV catheter infection suggests infection caused by staphylococci, including *Staphylococcus epidermidis* and *Staphylococcus aureus*.

MICROBIOLOGIC TESTS AND SUSCEPTIBILITY OF ORGANISMS

6. A Gram stain of R.G.’s tracheal aspirate shows gram-negative bacilli. What tests may assist with the identification of the pathogen(s)?

Once the site of infection has been determined and host defense and other epidemiologic factors have been evaluated,

additional tests can be performed to identify the pathogen. Some tests that provide immediate information to guide selection of the initial antimicrobial regimen can be performed. The Gram stain uses crystal violet solution and iodine, which results in bacteria staining gram positive or gram negative; some organisms are gram variable. In addition, the shape of the organism (cocci, bacilli) is readily apparent with the use of the Gram stain. Streptococci and staphylococci are gram-positive cocci, whereas *E. coli*, *E. cloacae*, and *P. aeruginosa* appear as gram-negative bacilli (Table 56-1).¹⁶ If the Gram stain of the tracheal aspirate demonstrates gram-positive cocci in clusters, empiric antistaphylococcal therapy is indicated. In contrast, if the Gram stain shows gram-negative rods, antimicrobials with activity against these pathogens are indicated.

Similar to the Gram stain in bacterial infection, the India ink and potassium hydroxide (KOH) stains are helpful in the identification of certain fungi. The acid-fast bacilli (AFB) stain is critical in the diagnosis of infection caused by *Mycobacterium tuberculosis* or atypical mycobacteria.

In R.G., the Gram stain suggests that antimicrobials active against gram-negative bacilli should be used. Table 56-3 provides a classification of antibacterials (e.g., different generations of cephalosporins). Tables 56-4, 56-5, and 56-6 list in vitro susceptibilities of aerobic gram-positive organisms, gram-negative aerobes, and anaerobic organisms, respectively.

Culture and Susceptibility Testing

Culture and susceptibility testing provides final identification of the pathogen, as well as information regarding the effectiveness of various antimicrobials. Although these tests provide more information than the Gram stain, they generally require 18 to 24 hours to complete. After the pathogen has been identified, Table 56-7 can be used in conjunction with an institution’s specific susceptibility studies to select the most appropriate antimicrobial.

Disk Diffusion

The most widely used tests for bacterial susceptibility are the disk diffusion and the broth dilution methods. The disk diffusion (Kirby-Bauer) technique uses an agar plate on which an inoculum of the organism is placed. After inoculation, several antimicrobial-laden disks are placed on the plate, and evidence of bacterial growth is observed after 18 to 24 hours. If the antimicrobial is active against the pathogen, a zone of growth inhibition is observed around the disk. Based on guidelines provided by the Clinical Laboratory Standards Institute (CLSI), the diameter of inhibition is reported as susceptible, intermediate, or resistant.

Broth Dilution

The broth dilution method involves placing a bacterial inoculum into several tubes or wells filled with broth. Serial dilutions of antimicrobials (e.g., nafcillin 0.5, 1.0, and 2.0 g/mL) are placed in the respective wells. After bacteria are allowed to incubate for 18 to 24 hours, the wells are examined for bacterial growth. If the well is cloudy, bacterial growth has occurred, suggesting resistance to the antimicrobial at that concentration.

As an example, if bacterial growth is observed with *S. aureus* at 0.5 g/mL of nafcillin but not at 1.0 g/mL, then 1.0 g/mL would be considered the minimum inhibitory concentration (MIC) for nafcillin against *S. aureus*.

Similar to the disk diffusion method, the CLSI provides guidelines¹⁷ that also take into account the pharmacokinetic characteristics of an antimicrobial to determine whether the MIC should be reported as susceptible, moderately susceptible, or resistant. MIC interpretations are specific to both the organism and the antimicrobial. For example, ciprofloxacin achieves serum concentrations of 1–4 mcg/mL and ceftriax-

one achieves peak serum concentrations of 100–150 mcg/mL; an MIC of 4 g/mL for *E. coli* would be interpreted as resistant to ciprofloxacin and susceptible to ceftriaxone.

Although these tests provide an accurate assessment of *in vitro* susceptibility, the time delay (18–24 hours) can hinder streamlining of therapy. An alternative efficient but more expensive MIC test is the E test, which uses an antibiotic-laden plastic strip with increasing concentration of a specific antimicrobial from one end to the other. The strip is placed on an agar plate with the actively growing pathogen. Inhibition of growth observed at specific marks on the strip coincides with

Table 56-4 In Vitro Antimicrobial Susceptibility: Aerobic Gram-Positive Cocci

^aNonpneumococcal streptococci.

^bUsually requires combination therapy (e.g., ampicillin and an aminoglycoside) for serious infection.

^cLevofloxacin (gatifloxacin, gemifloxacin, moxifloxacin) is more active than ciprofloxacin against staphylococci and streptococci.

^dActive against *E. faecium* but unpredictable against *E. faecalis*.

^eTGC, cefotaxime, ceftizoxime, ceftriaxone, cefoperazone. Ceftazidime has comparatively inferior antistaphylococcal and antipneumococcal activity. Cefotaxime and ceftriaxone are the most reliable cephalosporins versus *S. pneumoniae*.

^fActive versus vancomycin-resistant *Enterococcus faecium*.

MR, methicillin resistant.

the MIC of the organism. Numerous studies have confirmed that the E test is as effective as traditional susceptibility testing. Some rapid diagnosis culture and susceptibility tests may provide similar information within hours, potentially resulting in more rapid selection of appropriate antimicrobial therapy.

Although susceptibility testing is relatively well standardized for aerobic gram-negative and gram-positive organisms, its utility continues to evolve for anaerobes¹⁸ and fungi.¹⁹ In general, despite improvements in the standardization of testing in anaerobes, most institutions do not routinely perform susceptibility testing for these bacteria. In contrast, susceptibility testing is now available for yeast, and these in vitro data have been demonstrated to predict clinical success in the patient care setting.

The consensus of the CLSI and other experts is that anaerobic isolates from blood, bone, and joint sources, brain abscesses, empyemic fluid, and other body fluids that are normally sterile should be considered for susceptibility testing. Isolates from other sources should be considered for testing

only if the physician believes the test is clearly indicated in the given patient.¹⁸ Although progress has been made in developing a standardized test for determining fungal susceptibility, the primary emphasis has been on the susceptibility of *Candida* species and other yeasts to azoles in oropharyngeal candidiasis. Standardized susceptibility testing for molds recently has been established by the CLSI; however, this testing is rarely performed in the clinical setting.¹⁹

The MIC is the minimum concentration at which an antimicrobial inhibits the growth of the organism; the test does not provide information regarding whether the organism is actually killed. In some disease states (e.g., endocarditis, meningitis), bactericidal therapy may be necessary. The minimum bactericidal concentration (MBC) is the test that can be used to determine the killing activity associated with an antimicrobial. The MBC is determined by taking an aliquot from each clear MIC tube for subculture onto agar plates. The concentration at which no significant bacterial growth is observed on these plates is considered the MBC.

The serum bactericidal test (SBT) occasionally is used as an in vivo test of antimicrobial activity.²⁰ The test may have utility in assessing the treatment of more severe infections, such as endocarditis (see Chapter 59, Endocarditis) and osteomyelitis. A blood sample taken from a patient receiving an antibiotic is serially diluted using Mueller-Hinton broth (e.g., 1:2, 1:4, 1:8, 1:16) and then inoculated with the infecting organism. After 18 to 24 hours, the samples are visually inspected for evidence of bacterial growth. If no growth is observed at dilutions of 1:8

and 1:16 but growth is seen at 1:32 and above, the serum is considered inhibitory at 1:16. Similar to the MIC methodology, the clear tubes define the inhibitory titers; however, it is unknown whether bactericidal concentrations have been achieved. As a result, aliquots of each of the clear tubes are plated onto agar. If significant bacterial growth is observed at 1:16 but not at 1:8 or less, the serum is considered bactericidal at 1:8. The CLSI considers as appropriate “peak,” an SBT of 1:8 to 1:16 and a “trough” SBT of 1:4 to 1:8. Although the SBT provides an

Table 56-7 Antimicrobials of Choice in the Treatment of Bacterial Infection

| Organism | Drug of Choice | Alternatives | Comments |
|--|---|---|---|
| Aerobes | | | |
| <i>Gram-positive cocci</i> <i>Streptococcus pyogenes</i> (group A streptococci) <i>Streptococcus pneumoniae</i> | Penicillin | Clindamycin, macrolide, cephalosporin | Clindamycin is the most reliable alternative for penicillin-allergic patients. |
| | Penicillin, amoxicillin | Macrolide, cephalosporin, doxycycline | Although the incidence of penicillin nonsusceptible pneumococci continues to increase, high-dose penicillin or amoxicillin is active against most of these isolates. Penicillin-resistant pneumococci commonly demonstrate resistance to other agents, including erythromycin, tetracyclines, and cephalosporins. Antipneumococcal quinolones (gemifloxacin, levofloxacin, moxifloxacin), ceftriaxone, cefotaxime, and telithromycin are options for treatment of high-level penicillin-resistant isolates. |
| <i>Enterococcus faecalis</i> | Ampicillin ± gentamicin | Vancomycin gentamicin; daptomycin, linezolid | Most commonly isolated enterococcus (80%–85%). Most reliable antienterococcal agents are ampicillin (penicillin, piperacillin-tazobactam), vancomycin, daptomycin and linezolid. Monotherapy generally inhibits but does not kill the enterococcus. Daptomycin is unique in its bactericidal activity against Enterococci. Aminoglycosides must be added to ampicillin or vancomycin to provide bactericidal activity. Ampicillin resistance and high-level aminoglycoside resistance takes place commonly. Second most common enterococcal organism (10–20%) and is more likely than <i>E. faecalis</i> to be resistant to multiple antimicrobials. Most reliable agents are daptomycin, D/Q and linezolid. Monotherapy generally inhibits but does not kill the enterococcus. Aminoglycosides must be added to cell wall active agents to provide bactericidal activity. Ampicillin and vancomycin resistance is common. Daptomycin, D/Q, and linezolid are drugs of choice for vancomycin-resistant isolates. |
| <i>Enterococcus faecium</i> | Vancomycin ± gentamicin | Daptomycin, dalbopristin/quinupristin (D/Q), linezolid | 10%–15% of isolates inhibited by penicillin. Most isolates susceptible to nafcillin, cephalosporins, trimethoprim-sulfamethoxazole, and clindamycin. First-generation cephalosporins are equal to nafcillin. Most second- and third-generation cephalosporins adequate in the treatment of infection (exceptions include ceftazidime and cefonicid). Methicillin-resistant <i>S. aureus</i> must be treated with vancomycin; however, trimethoprim-sulfamethoxazole, daptomycin, D/Q, linezolid, or minocycline can be used. |
| <i>Staphylococcus aureus</i> (Nafcillin-resistant) | Nafcillin | Cefazolin, vancomycin, clindamycin, trimethoprim-sulfamethoxazole linezolid, trimethoprim-sulfamethoxazole, minocycline, daptomycin | Most isolates are Most isolates are β-lactam-, clindamycin-, and trimethoprim-sulfamethoxazole-resistant. Most reliable agents are vancomycin, daptomycin, D/Q, and linezolid. Rifampin is active and can be used in conjunction with other agents; however, monotherapy with rifampin is associated with development of resistance. |
| | Vancomycin | | |
| <i>Staphylococcus epidermidis</i> (Nafcillin-resistant) | Nafcillin | Cefazolin, vancomycin, clindamycin | |
| | Vancomycin | Daptomycin, linezolid, D/Q | |
| Gram-positive Bacilli | | | |
| Diphtheroids <i>Corynebacterium jeikeium</i> <i>Listeria monocytogenes</i> | Penicillin Vancomycin Ampicillin (± gentamicin) | Cephalosporin Erythromycin, quinolone Trimethoprim-sulfamethoxazole | |

(continued)

Table 56-7 Antimicrobials of Choice in the Treatment of Bacterial Infection (Continued)

| Organism | Drug of Choice | Alternatives | Comments |
|--|---|--|--|
| <i>Gram-negative Cocci</i> <i>Moraxella catarrhalis</i> | Trimethoprim-sulfamethoxazole | Amoxicillin-clavulanic acid, erythromycin, doxycycline, second- or third-generation cephalosporin | |
| <i>Neisseria gonorrhoeae</i> | Cefixime | Ceftriaxone | |
| <i>Neisseria meningitidis</i> | Penicillin | Third-generation cephalosporin | |
| <i>Gram-negative Bacilli</i> <i>Campylobacter fetus</i> | Imipenem | Gentamicin | |
| <i>Campylobacter jejuni</i> | Trimethoprim-sulfamethoxazole | A tetracycline, amoxicillin-clavulanic acid | Not predictably inhibited by most cephalosporins. Imipenem, quinolones, trimethoprim-sulfamethoxazole, cefepime, and aminoglycosides are most active agents. |
| Enterobacter | | Quinolone, imipenem, aminoglycoside | Extended spectrum β -lactamase (ESBL)-producers should be treated with a carbapenem. |
| <i>Escherichia coli</i> | Third-generation cephalosporin | First- or second-generation cephalosporin, gentamicin | |
| <i>Haemophilus influenzae</i> | Third-generation cephalosporin | β -lactamase inhibitor combinations, second-generation cephalosporin, trimethoprim-sulfamethoxazole | |
| <i>Helicobacter pylori</i> | Amoxicillin + clarithromycin + omeprazole | Tetracycline + metronidazole + bismuth subsalicylate | |
| <i>Klebsiella pneumoniae</i> | Third-generation cephalosporin | First- or second-generation cephalosporin, gentamicin, trimethoprim-sulfamethoxazole | Extended spectrum β -lactamase (ESBL)-producers should be treated with a carbapenem. |
| <i>Legionella</i> <i>Proteus mirabilis</i> | Fluoroquinolone Ampicillin | Erythromycin \pm rifampin, doxycycline | |
| Other <i>Proteus</i> | Third-generation cephalosporin | First-generation cephalosporin, trimethoprim-sulfamethoxazole | |
| <i>Pseudomonas aeruginosa</i> | Antipseudomonal penicillin (or ceftazidime \pm) aminoglycoside (or quinolone) | β -lactamase inhibitor combination, aminoglycoside, trimethoprim-sulfamethoxazole | |
| <i>Salmonella typhi</i> <i>Serratia marcescens</i> | Quinolone Third-generation cephalosporin | Quinolone or imipenem \pm aminoglycoside | Most active agents include aminoglycosides, doripenem, imipenem, meropenem, ceftazidime, cefepime, aztreonam and the extended-spectrum penicillins. Monotherapy is adequate for most pseudomonal infections. |
| <i>Shigella</i> <i>Stenotrophomonas maltophilia</i> | Quinolone Trimethoprim-sulfamethoxazole | Ceftriaxone Trimethoprim-sulfamethoxazole, aminoglycoside Trimethoprim-sulfamethoxazole, ampicillin Ceftazidime, minocycline, β -lactamase inhibitor combination (Timentin) | |

| Anaerobes | Metronidazole | β -lactamase inhibitor combinations, penems | Most active agents (95%–100%) include metronidazole, the β -lactamase inhibitor combinations (ampicillin-sulbactam, piperacillin-tazobactam, ticarcillin-clavulanic acid), and penems. Clindamycin, cefoxitin, cefotetan, cefmetazole, ceftizoxime have good activity but not to the degree of metronidazole. Aminoglycosides and aztreonam are inactive. |
|---|--|---|---|
| <i>Bacteroides fragilis</i> | Metronidazole | | |
| <i>Clostridia difficile</i> <i>Fusobacterium</i> | Metronidazole Penicillin | Vancomycin Metronidazole, clindamycin | |
| Other Oropharyngeal | | | |
| <i>Prevotella</i> | β -lactamase inhibitor combination | Metronidazole, clindamycin | |
| <i>Peptostreptococcus</i> | Penicillin | Clindamycin, cephalosporin | Most β -lactams active (exceptions include aztreonam, nafcillin, ceftazidime). |
| Other | | | |
| <i>Actinomyces</i> | | | |
| <i>Actinomyces israelii</i> | Penicillin | Tetracyclines | |
| <i>Nocardia</i> | Trimethoprim-sulfamethoxazole | Amikacin, minocycline, imipenem | |
| <i>Chlamydiae</i> | Doxycycline | | |
| <i>Chlamydia trachomatis</i> | Doxycycline | Azithromycin | |
| <i>Chlamydia pneumoniae</i> | | Azithromycin, clarithromycin | |
| <i>Mycoplasma</i> | | | |
| <i>Mycoplasma pneumoniae</i> | Doxycycline | Azithromycin, clarithromycin | |
| <i>Spirchetes</i> | | | |
| <i>Borrelia burgdorferi</i> | Doxycycline | Ampicillin, second- or third-generation cephalosporin | |
| <i>Treponema pallidum</i> | Penicillin | Doxycycline | |

in vivo test of antibacterial activity, the practical utility of the test is limited.

DETERMINATION OF ISOLATE PATHOGENICITY

7. *Serratia marcescens* grows from a culture of R.G.'s tracheal aspirate, and the decision to treat this organism is based on whether the isolate is a true pathogen. How can the difference between true bacterial infection and colonization or contamination be determined?

A positive culture may represent colonization, contamination, or infection. Colonization indicates that bacteria are present at the site but are not actively causing infection. Poor sampling techniques or inappropriate handling of specimens can result in contamination. Infection, colonization, and contamination might all be applicable to R.G. If a suction catheter was used for a sample of R.G.'s tracheal aspirate, the infecting organism likely would be cultured; however, other flora present in the oropharynx (but not associated with infection) would also appear in the culture medium (colonization). Furthermore, if the sample is not handled aseptically by the clinician or the microbiology laboratory, bacterial contamination is possible.

In summary, culture results do not necessarily identify only the actual pathogens. In R.G., the *Serratia* may be a pathogen, contaminant, or colonizer. Nevertheless, considering the severity of R.G.'s illness, treatment directed against this pathogen is necessary.

ANTIMICROBIAL TOXICITIES

8. In light of the positive culture for *Serratia*, his increased respiratory secretions, and a worsening chest radiograph, R.G.'s lungs are considered a source of infection. Pending susceptibility results, R.G. is started on combination imipenem and gentamicin. Are there equally effective, less toxic options for this patient?

Adverse Effects and Toxicities

Before therapy is started, it is important to elicit an accurate drug and allergy history. When "allergy" has been reported by the patient, it is necessary to determine whether the reaction was intolerance, toxicity, or true allergy (see Chapter 4 Anaphylaxis and Drug Allergies). Table 56-8 lists the most common adverse effects and toxicities associated with antimicrobial therapy. For example, gastric intolerance caused by oral erythromycin is common; however, this adverse effect does not represent an allergic manifestation or toxicity caused by the drug. In R.G.'s case, neither imipenem nor gentamicin is an optimal choice. Imipenem is known to be associated with seizures, particularly in patients with renal failure and in doses in excess of 50 mg/kg/D. Considering R.G.'s acute onset of renal failure and his history of seizures, other carbapenems, such as meropenem, would be preferable. Gentamicin similarly may not be a good choice in R.G. His increased age and changing renal function predispose him to aminoglycoside nephrotoxicity and ototoxicity (cochlear and vestibular).²¹ A reasonable recommendation would be to discontinue imipenem and gentamicin and treat with meropenem with or without a fluoroquinolone.

Concomitant Disease States

Concomitant disease states also should be considered in the selection of therapy. As discussed above, older patients with hearing deficits are poor candidates for potentially ototoxic aminoglycoside therapy. Diabetics or patients with kidney transplants may be better treated with IV fluconazole than nephrotoxic amphotericin B products in candidemia. Patients with a pre-existing seizure history should not receive imipenem if less toxic therapy can be used. In summary, the toxicologic profile must be taken into account in the selection of antimicrobial therapy.

ANTIMICROBIAL COSTS OF THERAPY

9. What factors should be included in calculating the cost of R.G.'s antimicrobial therapy?

The true cost of antimicrobial therapy is difficult to quantitate.²² Although acquisition cost traditionally has been the primary factor in the overall cost of therapy, drug administration labor costs (i.e., nursing and pharmacy) and the use of IV sets, piggyback bags, and infusion control devices must be included in the analysis. As a result, a drug that must be administered several times daily, such as penicillin, will incur increased administration costs compared with one that requires once-a-day dosing.

Some drugs, such as aminoglycosides, are associated with increased laboratory costs (e.g., aminoglycoside serum concentrations, serum creatinine, audiometry) that are not required for other agents,²³ such as the third-generation cephalosporins and quinolones. Similarly, drugs with a high potential for misuse or toxicity can be associated with increased costs because of monitoring (e.g., drug use evaluation, pharmacokinetic monitoring). If meropenem with or without ciprofloxacin had been selected for R.G., this therapy would be expected to be associated with relatively few laboratory costs. The broad spectrum of activity²⁴ and potential for misuse and development of resistance might, however, result in increased monitoring costs and overall cost to society.

Costs that are difficult to quantitate include that of both therapy failure and antimicrobial toxicity. Ineffective or toxic therapy can prolong hospitalization and may require expensive interventions, such as hemodialysis,²³ mechanical ventilation, and intensive care unit admission. The net effect of these latter costs can be significantly greater than the acquisition and administration costs of antimicrobial therapy.

In summary, determining the true cost of antimicrobial therapy is complex. Acquisition cost, IV bags, infusion controllers, and labor must be incorporated into the analysis. Although they are difficult to estimate, other costs, including antibiotic toxicity and failure of therapy, also should be included.

ROUTE OF ADMINISTRATION

10. The *Serratia* was determined to be susceptible to ciprofloxacin. Oral ciprofloxacin was considered for the treatment of R.G.'s presumed *Serratia* pneumonia, but the IV route was prescribed. Why is the oral administration of ciprofloxacin reasonable (or unreasonable) in R.G.?

Table 56-8 Antibiotic Adverse Effects and Toxicities

| Antibiotic | Side Effects | Comments |
|--|---|---|
| <p>β-Lactams, (penicillin, cephalosporins, monobactams, penems)</p> | <p><i>Allergic:</i> anaphylaxis, urticaria, serum sickness, rash, fever</p> | <p>Many patients will have “ampicillin rash” with no cross-reactivity with any other penicillins. Most common in patients with mononucleosis or those receiving allopurinol. Likelihood of IgE-mediated cross-reactivity between penicillins and cephalosporins approximately 37%. Recently documented is minimal cross-reactivity between penicillins and imipenem/meropenem. No IgE cross-reactivity between aztreonam and penicillins.</p> |
| | <p>Diarrhea</p> | <p>Particularly common with ampicillin, Augmentin, ceftriaxone, and cefoperazone. Antibiotic-associated colitis can occur with most antimicrobials</p> |
| | <p><i>Hematologic:</i> anemia, thrombocytopenia, antiplatelet activity, hypotherbinemia</p> | <p>Hemolytic anemia more common with higher doses. Antiplatelet activity (inhibition of platelet aggregation) most common with the antipseudomonal penicillins and high serum levels of other lactams.</p> |
| | <p>Hepatitis or biliary sludging</p> | <p>Hypotherbinemia more often associated with those cephalosporins with the methyltetraazolethiol side chain (cefamandole, cefotetan). Reaction preventable and reversible with vitamin K.</p> |
| | <p>Phlebitis</p> | <p>Most common with oxacillin. Biliary sludging and stones reported with ceftriaxone.</p> |
| | <p>Seizure activity</p> | <p>Associated with high levels of β-lactams, particularly penicillins and imipenem</p> |
| | <p>Potassium load</p> | <p>Penicillin G (K⁺)</p> |
| | <p>Nephritis</p> | <p>Most common with methicillin; however, occasionally reported for most other β-lactams</p> |
| | <p>Neutropenia</p> | <p>Nafcillin</p> |
| | <p>Disulfiram reaction</p> | <p>Associated with cephalosporins with methyltetraazolethiol side chain (cefamandole, cefotetan)</p> |
| | <p>Hypotension, nausea</p> | <p>Associated with fast infusion of imipenem</p> |
| | <p>Nephrotoxicity</p> | <p>Averages 10%–15% incidence. Generally reversible, usually occurs after 5–7 days of therapy. <i>Risk factors:</i> dehydration, age, dose, duration, concurrent nephrotoxins, liver disease.</p> |
| <p>Aminoglycosides (gentamicin, tobramycin, amikacin, netilmicin)</p> | <p>Ototoxicity</p> | <p>1–5% incidence, often irreversible. Both cochlear and vestibular toxicity occur.</p> |
| | <p>Neuromuscular paralysis</p> | <p>Rare, most common with large doses administered via intraperitoneal instillation or in patients with myasthenia gravis</p> |
| <p>Macrolides (erythromycin, azithromycin, clarithromycin)</p> | <p>Nausea, vomiting, “burning” stomach</p> | <p>Oral administration. Azithromycin and clarithromycin associated with less nausea than erythromycin.</p> |
| | <p>Cholestatic jaundice</p> | <p>Reported for all erythromycin salts, most common with estolate</p> |
| | <p>Ototoxicity</p> | <p>Most common with high doses in patients with renal or hepatic failure</p> |
| <p>Clindamycin</p> | <p>Diarrhea</p> | <p>Most common adverse effect. High association with antibiotic-associated colitis.</p> |
| <p>Tetracyclines (including tigeocycline)</p> | <p>Allergic</p> | |
| | <p>Photosensitivity</p> | |
| | <p>Teeth and bone deposition and discoloration</p> | <p>Avoid in pediatrics, pregnancy, and breast-feeding.</p> |
| | <p>GI</p> | <p>Upper GI predominates.</p> |
| | <p>Hepatitis</p> | <p>Primarily in pregnancy or the elderly</p> |
| | <p>Renal (azotemia)</p> | <p>Tetracyclines have antianabolic effect and should be avoided in patients with \downarrow renal function. Less problematic with doxycycline.</p> |
| <p>Vancomycin</p> | <p>Vestibular</p> | <p>Associated with minocycline, particularly high doses</p> |
| | <p>Ototoxicity</p> | <p>Only with receipt of concomitant ototoxins such as aminoglycosides or macrolides</p> |
| | <p>Nephrotoxicity</p> | <p>Nephrotoxic only with high doses or in combination with other nephrotoxins.</p> |
| | <p>Hypotension, flushing</p> | <p>Associated with rapid infusion of vancomycin. More common with increased doses.</p> |
| | <p>Phlebitis</p> | <p>Needs large volume dilution</p> |
| | <p>Phlebitis</p> | <p>Generally requires central line administration</p> |
| | <p>Myalgia</p> | <p>Moderate to severe in many patients</p> |
| | <p>Increased bilirubin</p> | |

(continued)

Table 56-8 Antibiotic Adverse Effects and Toxicities (Continued)

| Antibiotic | Side Effects | Comments |
|--|---|--|
| Daptomycin | Myalgia | Primarily at high doses and reversible |
| Linezolid | Thrombocytopenia, neutropenia, anemia, MAO inhibition, tongue discoloration | |
| Sulfonamides | GI Hepatic Rash Bone marrow Kernicterus | Nausea, diarrhea Cholestatic hepatitis, ↑ incidence in HIV. Exfoliative dermatitis, Stevens-Johnson syndrome. More common in HIV. Neutropenia, thrombocytopenia. More common in HIV. Caused by unbound drug in the neonate. Premature liver cannot conjugate bilirubin. Sulfonamide displaces bilirubin from protein, resulting in excessive free bilirubin and kernicterus. Idiosyncratic irreversible aplastic anemia (rare) Reversible dose-related anemia Caused by inability of neonates to conjugate chloramphenicol |
| Chloramphenicol | Anemia Gray syndrome | |
| Quinolones | GI Prolonged QT Drug interactions CNS Cartilage toxicity Tendonitis or tendon rupture | Nausea, vomiting, diarrhea Moxifloxacin; possibly all quinolones as a class ↓ Oral bioavailability with multivalent cations Altered mental status, confusion, seizures Toxic in animal model. Despite this toxicity, appears safe in children including patients with cystic fibrosis. Common in elderly, renal failure, concomitant glucocorticoids |
| Anti-fungals | | |
| Amphotericin B products | Nephrotoxicity | Common. May depend on patient Na load. Caution with concomitant nephrotoxins (e.g., aminoglycosides, cyclosporine). |
| | Hypokalemia | Predictable. Probably caused by renal tubular excretion of potassium. More common in patients receiving concomitant piperacillin-tazobactam. |
| | Hypomagnesemia | Less commonly observed than hypokalemia |
| | Anemia | Long-term adverse effect. Similar to anemia of chronic disease. |
| Caspofungin, micafungin, anidulofungin | Mild LFT increase with concomitant cyclosporine Anidulofungin is reconstituted with alcohol (about the equivalent of a beer). | |
| Flucytosine | Neutropenia, thrombocytopenia | Secondary to metabolism of flucytosine to fluorouracil. More commonly observed with flucytosine levels >100 mg/mL. More common in patients with HIV. |
| | Hepatitis | Usually moderate ↑ in LFT. Rarely clinical hepatitis. |
| | Drug interactions | ↓ Oral bioavailability of ketoconazole tablet, and itraconazole capsules with ↑ gastric pH. Azoles are CYP450 substrates and also inhibitors of CYP450 3A4 and other CYP isoenzymes |
| Ketoconazole (fluconazole, itraconazole, posaconazole, voriconazole) | Hepatitis Gynecomastia, ↓ libido Visual disturbance | Ranges from mild ↑ in LFT to occasional fatal hepatitis. More common with high-dose ketoconazole (>400 mg/day). Less common with other azoles. Unique to voriconazole, particularly first week of therapy |

Antivirals (excluding antiretrovirals)

| | | |
|-------------|--|---|
| Acyclovir | Phlebitis Renal failure | Caused by poor solubility of IV preparation. Reported in 1–20% of cases. Low solubility of acyclovir associated with renal failure. Dehydrated patients, as well as rapid infusions, predispose to toxicity. |
| Foscarnet | CNS Nephrotoxicity | 1% incidence in AIDS; ↑ Incidence with dose in > 10 mg/kg/day. Occurs in up to 60% of patients. May be prevented with normal saline bolus before dose. Frequent monitoring of renal function imperative. |
| Ganciclovir | Mineral and electrolyte abnormalities | ↑ and ↓ calcium or phosphate may be observed. Hypocalcemia, hypo- and hyperphosphatemia, hypo-magnesemia, hypokalemia. ↑ Risk of cardiomyopathy and seizures. |
| Oseltamavir | Anemia Nausea, vomiting Neutropenia, thrombocytopenia Hepatitis Nausea | Anemia in 33%; usually manageable with transfusions and discontinuation of foscarnet ↑ Incidence in AIDS. ↑ Incidence with doses in excess of 10 mg/kg/day. Usually mild to moderate in LFT |

AIDS, acquired immunodeficiency syndrome; CNS, central nervous system; GI, gastrointestinal; HIV, human immunodeficiency virus; IV, intravenous; LFT, liver function test; MAO, monoamine oxidase; MCV, mean corpuscular volume; Na, sodium.

The proper route of antibiotic administration depends on many factors, including the infection severity, bioavailability, and other patient factors. In patients who appear “septic,” blood flow often is shunted away from the mesentery and extremities, resulting in unreliable bioavailability from the GI tract or muscles. Therefore, hemodynamically unstable patients should receive antimicrobials by the IV route to ensure therapeutic antimicrobial levels. Furthermore, some drug interactions can result in subtherapeutic serum concentrations (e.g., reduced bioavailability associated with concomitant quinolone and antacid administration and the decreased absorption of ketoconazole or itraconazole with concurrent H₂-blocker therapy).

R.G. is clinically septic with a possible *Serratia* pneumonia. Considering his unstable state, the bioavailability of oral ciprofloxacin cannot be guaranteed; thus, he should be treated with IV antimicrobials.

ANTIMICROBIAL DOSING

11. What dose of IV ciprofloxacin should be given to R.G.? What factors must be taken into account in determining a proper antimicrobial dose?

The choice of dosing regimen is based on many factors. Table 56-9 provides a guide for the dosing of more commonly administered antimicrobials. Selection of the appropriate dosage should be based on information that documents the efficacy of the dosage in the treatment of infection. Patient-specific factors, including weight, infection site, and route of elimination, also must be considered in dosage selection. The patient's weight is important, particularly for agents with a low therapeutic index (e.g., aminoglycosides, imipenem, flucytosine); these drugs should be dosed on a mg/kg/day basis. Other agents with a more favorable adverse effect profile, such as cephalosporins, are less likely to require weight-specific dosing.

Site of Infection

The infection site also requires differing dosage requirements. An uncomplicated urinary tract infection requires low antimicrobial doses because of the high urinary drug concentrations that are achieved. In contrast, a more serious systemic infection, such as pyelonephritis, requires increased antimicrobial dosages to achieve therapeutic drug levels in tissue and in serum.

Anatomic and Physiologic Barriers

Anatomic and physiologic barriers also must be considered in evaluating a dosing regimen. For example, penetration into the CNS necessitates high doses to ensure adequate antimicrobial concentrations at the infection site.²⁵ Vitreous humor²⁶ and the prostate gland²⁷ are additional sites in which therapeutic antimicrobial concentrations are more difficult to achieve.

Route of Elimination

Route of elimination must also be considered in the dosage calculation. In general, antimicrobials are eliminated via the kidney or nonrenally (metabolic or biliary). Renal function can be estimated via 24-hour urine collection or with equations

such as the Cockcroft and Gault equation²⁸:

$$\text{Creatinine clearance} = \frac{[(140 - \text{age})^*[\text{weight in kg}]]}{(72 * \text{SrCr})}$$

Several anti-infectives are eliminated renally (Table 56-10). Most β -lactams are eliminated by the kidney. Ceftriaxone, cefoperazone, and most antistaphylococcal penicillins (e.g., nafcillin, oxacillin, dicloxacillin) are eliminated both renally and nonrenally. Aminoglycosides, vancomycin, acyclovir, and ganciclovir are cleared extensively by the kidney. Thus, dosage adjustment is recommended for these drugs in patients with renal failure (Table 56-9 and). Since azithromycin, clindamycin, and metronidazole are primarily eliminated by the liver, no dose reduction is required in renal failure.

Although renal function can be approximated with the use of the Cockcroft and Gault equation (or a similar equation), hepatic function is more difficult to evaluate. No standard liver function test (AST, ALT, alkaline phosphatase) has been demonstrated to correlate well with hepatic drug clearance. Some tests, such as PT and albumin, are markers of hepatic function, but even these tests do not clearly predict drug clearance. Patients receiving hemodialysis or continuous hemofiltration provide additional dosing challenges. Table 56-10 provides dosing recommendations in patients receiving hemodialysis or continuous hemofiltration.

Patient Age

Most dosing information has been derived from a young, relatively healthy patient population, so total drug clearance for several antimicrobials may be decreased in neonatal and geriatric patients. As a result, the age of the patient may be an important factor in the selection of a proper dose.

Fever and Inoculum Effect

The impact of other factors on the selection of an antimicrobial dose is less clear. Fever increases and decreases blood flow to mesenteric, hepatic, and renal organ systems²⁹ and can either increase or decrease drug clearance. Inoculum effect also may be a factor in the selection of a dosing regimen because it is associated with an increase in the MIC of the organism in response to increasing bacterial concentrations.³⁰ For example, piperacillin may demonstrate an MIC of 8.0 g/mL against *P. aeruginosa* at a concentration of 10⁵ colony-forming units/mL (CFU/mL); however, at 10⁹ CFU/mL, the MIC may increase to 32 to 64 g/mL. This phenomenon is well recognized, particularly with β -lactamase-producing bacteria treated with β -lactam antimicrobials. The more stable the antimicrobial is to β -lactamase, the less the influence is the inoculum effect. Aminoglycosides, quinolones, and imipenem appear to be less affected by the inoculum effect than β -lactams. The inoculum effect probably is most relevant in the treatment of a bacterial abscess, in which extremely high concentrations of bacteria would be expected. As a result, antimicrobials that are more susceptible to the inoculum effect may require increased drug dosages for optimal outcome in the treatment of abscesses.

In summary, R.G. normally would be given an IV dosage of ciprofloxacin at 400 mg every 12 hours. His reduced renal function suggests, however, that his dosage should be decreased to 200 to 300 mg every 12 hours.

Table 56-9 University of California San Francisco/Mt. Zion Medical Center Adult Antimicrobial Dosing Guidelines*

Approved by the Antibiotic Advisory Subcommittee (3/13/91) and the Pharmacy and Therapeutics Committee (4/11/91) Rev 2007.

| Drug | CrCl > 50 mL/min | CrCl 10–50 mL/min | CrCl < 10 mL/min (ESRD not on HD) |
|-------------------------|--|---|---|
| Acyclovir | <i>Herpes simplex infections</i> 5 mg/kg/dose Q 8 hr | 5 mg/kg/dose Q 12–24 hr | 2.5 mg/kg Q 24 hr |
| | <i>herpes simplex virus encephalitis/herpes zoster</i> 10 mg/kg/dose Q 8 hr | 10 mg/kg/dose Q 12–24 hr | 5 mg/kg Q 24 hr |
| Amphotericin B | 0.3–1.0 mg/kg Dosage reductions in renal disease are not necessary. Because of the nephrotoxic potential of the drug, reducing the dose or holding the drug in the setting of a rising serum creatinine may be warranted. | No change | No change |
| Ampicillin | 1–2 g Q 4–6 hr | 1–1.5 g Q 6 hr | 1 g Q 8–12 hr |
| Cefazolin | 1–2 g Q 8 hr | 1–2 g Q 12 hr | 0.5–1.0 g Q 24 hr |
| Caspofungin | LD = 70 mg × 1, then 50 mg Q 24 hr | No change | No change |
| Cefepime | ≥60 mL/min 1–2 g Q 12 hr Febrile neutropenia: 2 g Q 8 hr | 30–60 mL/min 1–2 g Q 24 hr | 10–30 mL/min 0.51 g Q 24 hr |
| | | | 0.25–0.5 g Q 24 hr |
| Ceftazidime | 1–2 g Q 8 hr | 1–2 g Q 12–24 hr | 0.5 g Q 24 hr |
| Ceftriaxone | 1 g Q 24 hr | No change | No change |
| | Meningitis: 2 g Q 12 hr | Endocarditis and osteomyelitis: 2 g Q 24 hr | |
| Cefuroxime | 0.75–1.5 g Q 8 hr | 0.75–1.5 g Q 12–24 hr | 0.5 g Q 24 hr |
| Ciprofloxacin | 400 mg Q 12 hr* (500–750 mg PO Q12 hr) | 200–400 mg Q12 hr (250–500 mg PO Q12 hr) | 200 mg Q12 hr (250 mg PO Q12 hr) |
| | The use of every (Q) 12-hour dosing intervals is recommended in ESRD because of the variability in half-life data observed in anephric patients. *Note: Higher doses, increased frequency, or both may be necessary in the treatment of serious pseudomonal infections. | | |
| Clindamycin | 600–900 mg Q 8 hr | No change | No change |
| Ethambutol | 15 mg/kg QD | 7.5–10 mg/kg QD | 5 mg/kg QD |
| Fluconazole | 100–400 mg Q 24 hr | 50–200 mg Q 24 hr | 50–100 mg Q 24 hr |
| Flucytosine (PO) | 12.5–37.5 mg/kg/dose Q 6 hr | 25–50 mL/min 12.5–37.5 mg/kg/dose Q 12 hr | 10–25 mL/min 12.5–37.5 mg/kg/dose Q 24 hr |
| | Steady-state serum 5-FC level measurements are difficult to obtain. However, they may be useful in guiding dosing of 5-FC in anuria. Bone marrow suppression has been associated with 2-hour postdose 5-FC peaks of >100 mg/L. | | |
| Ganciclovir | 30–60 mL/min 5 mg/kg/dose | 50–69 mL/min 2.5 mg/kg/dose Q 12 hr | 10–24 mL/min 0.625–1.25 mg/kg/dose Q 24 hr |
| | | 25–49 mL/min 2.5 mg/kg/dose Q 24 hr | 1.25 mg/kg/dose Q 24 hr |

Gentamicin

5 mg/kg/dose Q 24 hr

The total daily dose of gentamicin can be administered as a single daily dose in patients with normal renal function (CrCl 60 mL/minute). Patients with decreased renal function or abnormal body composition should have their doses adjusted according to the recommendations below. All patients who are anticipated to receive aminoglycosides for ≥7 days should be monitored with gentamicin levels. Peak levels are not useful with this dosing regimen; however, trough levels are recommended and in most cases will be nondetectable.

| | | |
|---------------|---------------|---|
| 40–60 mL/min | 20–40 mL/min | <20 mL/min |
| 1.2–1.5 mg/kg | 1.2–1.5 mg/kg | 2 mg/kg loading dose |
| Q 12 hr | Q 12–24 hr | (consult pharmacy for maintenance dose) |

With traditional dosing of gentamicin, peak (5–8 mg/L) and trough (<2 mg/L) levels are recommended in patients anticipated to receive aminoglycosides for ≥7 days for severe gram-negative infection. Lower doses (1 mg/kg/dose Q 8 hrs) are suggested when aminoglycosides are used synergistically in gram-positive infections. Those patients with CrCl <60 mL/minute, obesity, or increased fluid volume should be monitored with serum gentamicin levels.

| Piperacillin/Tazobactam (Zosyn) | 3.375–4.5 g Q 6–8 hr <i>Pseudomonas</i> : 4.5 g Q 6 hr for CrCl > 20 mL/min | 3.375–4.5 g Q 6–8 hr | 2.25–3.375 g Q 8 hr |
| Pyrazinamide | 20–25 mg/kg/day | No change | No change |
| Rifampin | 600 mg QD | No change | No change |
| Tobramycin | See Gentamicin | See Gentamicin | See Gentamicin |
| TMP-SMX | <i>Systemic GNR infections</i> 10 mg TMP/kg/day divided Q 6–12 hr <i>Pneumocystis carinii pneumonia</i> 15–20 mg TMP/kg/day divided Q 6–12 hr | 5–7.5 mg TMP/kg/day divided Q 12–24 hr 10–15 mg TMP/kg/day divided Q 12–24 hr | 2.5–5.0 mg TMP/kg Q 24 hr 5–10 mg TMP/kg Q 24 hr |
| Voriconazole | LD = 400 mg Q 12 hr × 1 day, then 200 mg Q 12 hr (PO) | No change | No change |
| By mouth (PO) should be used when possible, as oral bioavailability >95%. IV dose: LD = 6 mg/kg/dose Q 12 hr × 1 day, then 4 mg/kg/dose Q 12 hr. The use of IV should be avoided in patients with CrCl <50 mL/min owing to the accumulation of the IV vehicle and it is contraindicated in ESRD. | | | |
| Vancomycin | >60 mL/min 40–60 mL/min 10–15 mg/kg 10–15 mg/kg Q 12 hr Q 12–24 hr | 20–40 mL/min 10–15 mg/kg Q 24–48 hr | 10–20 mL/min <10 mL/min 10–15 mg/kg 10–15 mg/kg Q 4–7 days Q 48–72 hr |
| Vancomycin dosing should be guided by serum level measurements in patients with decreased renal function or abnormal body composition. Peak levels are not recommended. Trough levels (30 minutes before next dose) should be 5–15 mg/L. | | | |
| ^a Doses are those recommended for systemic infections commonly treated with these agents. Infections involving the urinary tract may require lower doses. Infections involving the central nervous system may require higher doses. Estimate of renal function using Cockcroft and Gault equation: CrCl (mL/min) = $\frac{(140 - \text{age}) * \text{Wt (kg)}}{72 * \text{SCr (mg/dL)}}$ (for females multiply by 0.85) | | | |

PHARMACOKINETICS/PHARMACODYNAMICS

12. R.G.'s respiratory status remains unchanged; thus, the ciprofloxacin is discontinued and cefotaxime and gentamicin are started empirically. The use of a constant IV infusion of cefotaxime is being considered in R.G. In addition, the use of single daily dosing of gentamicin is being discussed. What is the rationale for these approaches, and would either be advantageous for R.G.?

β -lactams, such as cefotaxime, are not associated with increased bacterial killing with increasing drug concentrations. Pharmacodynamic activity best correlates with the duration of time that antimicrobial levels are maintained above the MIC.³¹ The animal model suggests that β -lactam antimicrobials should be dosed such that their serum levels exceed the MIC of the pathogen as long as possible.³² This observation appears to be most important in the neutropenic model, in which the use of a constant infusion more reliably inhibits bacterial

^aRecommended doses are for critically ill patients with serious systemic infection. Lower doses may be used for less serious infections.

STANDARD DOSING for the following:
Amphotericin B, Caspofungin, Ceftriaxone, Clindamycin, Erythromycin, Metronidazole, Nafcillin
Please refer to Table 57-9 for additional information.

growth compared with traditional intermittent dosing. An additional benefit of the use of constant infusions of β -lactams is that smaller daily doses appear to be as effective as higher doses administered intermittently. Other than this latter outcome, it is unclear, however, whether constant infusions have any distinct advantages or disadvantages compared with usual dosing of β -lactams. The efficacy of quinolone antimicrobials appears to correlate with the peak plasma concentration to MIC ratio or area under the curve (AUC) to MIC ratio.³³ In light of this pharmacodynamic principle, it is possible that ciprofloxacin was underdosed in this patient, contributing to the therapeutic failure, particularly if the MIC was in the upper range of susceptibility for this agent.

Aminoglycosides traditionally have been administered every 8 to 12 hours to achieve peak serum gentamicin levels of 5 to 8 g/mL to ensure efficacy in the treatment of serious gram-negative infection.^{34,35} Gentamicin troughs of >2 g/mL have been associated with an increased risk for nephrotoxicity.^{35,36} These studies attempting to correlate efficacy and toxicity with serum levels and the association of peaks or troughs with clinical outcomes have been questioned.³⁷ Vancomycin peaks generally have been recommended to be <50 g/mL and troughs 5 to 10 g/mL^{38,39}; however, the validity of these recommendations has also been questioned.⁴⁰

Several antimicrobials (e.g., aminoglycosides) have been associated with a pharmacodynamic phenomenon known as a postantibiotic effect (PAE). PAE is delayed regrowth of bacteria following exposure to an antibiotic^{41,42} (i.e., continued suppression of normal growth in the absence of antibiotic levels above the MIC of the organism). As an example, if *P. aeruginosa* is cultured in broth, it will multiply to a concentration of 10⁹ CFU/mL. If piperacillin is added in a concentration above the MIC for the organism, a reduction in the bacterial concentration is observed. When piperacillin is removed from the broth, immediate bacterial growth takes place. As described, β -lactam antibiotics should be present in concentrations above the MIC to optimize its time-dependent killing. If the above experiment is repeated with gentamicin, a reduction in bacterial CFU is observed. In contrast to that observed with β -lactam antibiotics, if the gentamicin is removed from the system, a lag period of 2 to 6 hours takes place before characteristic bacterial growth occurs. This lag period is defined as the PAE. A PAE also has been observed with quinolones and imipenem against gram-negative organisms. Although most β -lactam antibiotics, such as antipseudomonal penicillins or cephalosporins, do not exhibit PAE with gram-negative organisms, PAE

has been demonstrated with gram-positive pathogens such as *S. aureus*.

Once-Daily Dosing of Aminoglycosides

As a result of PAE and other pharmacodynamic factors, certain antimicrobials may be dosed less frequently. The greatest clinical experience has been with the aminoglycosides in the treatment of gram-negative infection.^{43,44} Earlier data suggested that the maximal aminoglycoside peak level:MIC ratio correlates well with clinical response. Thus, the higher the achievable peak, the greater likelihood of a favorable outcome. Once-daily dosing of aminoglycosides in the treatment of gram-negative infection is as efficacious as traditional multiple daily dosing.⁴⁵

Single daily dosing of aminoglycosides has been investigated primarily in patients with normal renal function, and few critically ill patients have been treated with this nontraditional regimen. Thus, patients in septic shock are not candidates for once-daily dosing. The utility and proper timing of serum aminoglycoside concentrations and association with clinical outcomes are debatable with nontraditional once-daily aminoglycosides.

In summary, the use of a constant IV infusion of cefotaxime is possible in R.G., but the benefit of this mode of administration is not clear. Considering the severity of R.G.'s infection and his elevated creatinine level, he is not a candidate for single daily dosing of aminoglycosides (i.e., 5–6 mg/kg every 24 hours). Independent of the aminoglycoside-associated PAE, his current renal function requires a reduced gentamicin dose to treat his infection.

Antimicrobial Protein Binding

13. Ceftriaxone (Rocephin), rather than cefotaxime (Claforan), is being considered for the treatment of R.G.'s infection. Ceftriaxone is more highly protein bound than cefotaxime. Why is protein binding important in the selection of therapy?

Free (i.e., unbound) rather than total drug levels are best correlated with antimicrobial activity,⁴⁶ and the degree of protein binding may have important clinical consequences in some patients. Chambers et al.⁴⁷ reported treatment failures with the highly protein-bound cefonicid (98% protein bound) in patients with endocarditis caused by *S. aureus*. Despite achievable serum drug concentrations well above the MIC of the

organism, breakthrough bacteremia occurred in three of four patients. Although total drug concentrations greatly exceeded the MIC of the pathogen, free concentrations were consistently below the level necessary to inhibit bacterial growth. Similar experiences have been reported with teicoplanin (98% protein bound).⁴⁸ Thus, clinical cure appears to be more likely if unbound antibiotic concentrations exceed the MIC of the infecting organism. Although ceftriaxone is 85% to 90% protein bound, the free concentrations probably remain far above the MIC of the *Serratia*. Therefore, protein-binding considerations are unlikely to be important in the treatment of R.G.'s infection.

ANTIMICROBIAL FAILURE

Antibiotic-Specific Factors

14. Despite “appropriate” treatment, R.G. is unresponsive to antimicrobial therapy. What antibiotic-specific factors may contribute to “antimicrobial failure”?

Antimicrobials may fail for various reasons, including patient-specific host factors, drug or dosage selection, and concomitant disease states. One of the most common reasons for antimicrobial failure is drug resistance.^{49–51} Several clinically important pathogens have been associated with emergence of resistance over the past decade, including *M. tuberculosis*,⁵² enterococci,⁵³ gram-negative rods,⁵⁴ *S. aureus*,⁵⁵ *S. pneumoniae*,⁵⁶ and others. Of particular concern is the isolation of glycopeptide-resistant *S. aureus*⁵⁵ and vancomycin-tolerant pneumococci.⁵⁷ Considering the common prevalence of these two gram-positive pathogens and the role of vancomycin as the last-line therapy for these organisms, these findings are worrisome. Development of resistance, although less common than initial resistance, may also account for failure to respond to therapy. Cephalosporin-susceptible *E. cloacae* may appear to be susceptible to a cephalosporin; however, β -lactamase production can result in development of resistance to the agent.⁵⁸

Superinfection also may play a role in the unsuccessful treatment of infection. Superinfection is isolation of a new pathogen resistant to the previous antimicrobial regimen. If R.G.'s ceftriaxone-treated *Serratia* pneumonia subsequently worsens and a tracheal aspirate is positive for *P. aeruginosa*, then supercolonization and, perhaps, superinfection has occurred.

Concurrent Therapy

Most infections can be treated with monotherapy (e.g., an *E. coli* wound infection is treatable with a cephalosporin). Some infections, however, require two-drug therapy, including most cases of enterococcal endocarditis and certain *P. aeruginosa* infections. Hilf et al.⁵⁹ studied 200 consecutive patients with *P. aeruginosa* bacteremia and demonstrated a 47% mortality in those receiving monotherapy (antipseudomonal β -lactam or aminoglycoside) versus 27% in those in whom two-drug therapy was used. Thus, monotherapy can contribute to antimicrobial failure in certain infections.

In contrast to these findings, most current investigations do not support the use of two drugs over monotherapy in the treat-

ment of serious gram-negative infection.^{60–62} An exception to this rule is bacteremia caused by *P. aeruginosa* in neutropenic patients.⁶²

If two antimicrobials are used in the treatment of infection, one of three sequelae will result: indifference, synergism, or antagonism.⁶³ Indifference occurs when the antimicrobial effect of drug A plus that of drug B equals the anticipated sum activity of drug A plus drug B. Although numerous definitions exist, synergism generally occurs when the addition of drug A to drug B results in a total antibiotic activity greater than the expected sum of the two agents. Antagonism occurs if the addition of drug A to drug B results in a combined activity less than the sum of drug A plus drug B. An example of antagonism is the combination of imipenem with a less β -lactamase stable β -lactam, such as piperacillin.⁶⁴ Certain organisms, including *P. aeruginosa* and *E. cloacae*, can be induced to produce β -lactamases.⁵¹ If *P. aeruginosa* is exposed to imipenem and piperacillin, the β -lactamase degrades and inactivates piperacillin, and antagonism has resulted. Antagonism is not unique to antibacterials; itraconazole may antagonize amphotericin B in the treatment of certain infections.⁶⁵

Pharmacologic Factors

15. What pharmacologic or pharmaceutical factors may be implicated in failure of therapy?

Subtherapeutic dosing regimens are common, especially for agents with a low therapeutic index, such as the aminoglycosides. For example, a serious gram-negative pneumonitis may not respond to therapy if the achievable peak gentamicin serum levels are only 3 to 4 mcg/mL.³⁴ Considering that only 20% to 30% of the aminoglycoside penetrates into bronchial secretions, only 0.5 to 1.0 mcg/mL may exist at the site of infection,⁶⁶ a level that may be inadequate to treat pneumonia. As another example, the use of an aminoglycoside loading dose is particularly important in patients with renal failure because it may otherwise take several days before a therapeutic level is achieved. Yet another reason for subtherapeutic levels is reduced oral absorption secondary to drug interactions (e.g., ciprofloxacin with antacids or sucralfate).

An emerging problem relates to the use of vancomycin in the treatment of serious methicillin-resistant *S. aureus* infection (MRSA). By CLSI standards, an isolate of MRSA with an MIC of 2 mcg/mL is considered susceptible. Retrospective analyses have, however, demonstrated high failure rate associated with vancomycin in the treatment of MRSA isolates with MIC of 2 mcg/mL.^{67,68} Hidayat et al.⁶⁷ observed that an MIC of 2 mcg/mL was associated with a greater rate of vancomycin nonresponse. Achievement of therapeutic to supratherapeutic vancomycin trough levels had no influence on efficacy.⁶⁷ Similarly, in another retrospective analysis of MRSA bacteremia, investigators noted that a vancomycin MIC of 2 mcg/mL was an independent risk factor for increased mortality.⁶⁸ The pharmacodynamic parameter which serves as the best predictor of vancomycin activity against *S. aureus* is the AUC:MIC ratio, with a value >350 independently associated with success. The probability of attaining this value with isolates with an MIC of 2 mcg/mL is 0%, even when achieving vancomycin trough concentrations of 15 mcg/mL.⁶⁹

The infection site also potentially contributes to antimicrobial failure. Most antimicrobials concentrate in the urine, resulting in therapeutic levels even with low doses. In some infections, such as meningitis, prostatitis, and endophthalmitis, antimicrobial penetration to the site of infection may be inadequate. Agents that have been proved to penetrate into these infected sites are required for a favorable outcome.

Another potential reason for antimicrobial failure is inadequate therapy duration. A woman with a first-time uncomplicated cystitis may respond adequately to a 3-day course of an antibiotic. Patients with recurrent urinary tract infections are not candidates for this therapy, however, and failure would be expected with short-course therapy.

Host Factors

16. What host factors may contribute to the failure of antimicrobial therapy?

Several host factors may limit the ability of an antibiotic to cure infection. Infection of prosthetic material (e.g., IV catheters, prosthetic hip replacement, mechanical cardiac valves, and vascular grafts) is difficult to eradicate without removal of the hardware. In most cases, surgical intervention is necessary. To treat R.G.'s IV catheter infection adequately, removal of his central line probably would be required. Similar to removal of prostheses, large undrained abscesses are difficult, if not impossible, to treat with antimicrobial therapy. These infections generally require surgical drainage for successful outcome.

Diabetic foot ulcer cellulitis may not respond adequately to antimicrobial therapy. Reasons for antimicrobial failure in patients with diabetes include poor wound healing as well as significant peripheral vascular disease that reduces the delivery of antibiotics to the infection site.

Immune status, particularly neutropenia or lymphocytopenia, also affects the outcome in the treatment of infection.

Profoundly neutropenic patients with disseminated *Aspergillus* infections are unlikely to respond to amphotericin B therapy. Similarly, patients with acquired immunodeficiency syndrome (AIDS) who have low CD4 lymphocyte counts cannot eradicate various infections, including cytomegalovirus, atypical mycobacteria, and cryptococci.

Once these factors have been eliminated as causes for antimicrobial failure, noninfectious sources must be ruled out. As discussed, malignancy, autoimmune disease, drug fever, and other diseases must be evaluated.

17. Other than initiation of adequate antimicrobial therapy, what adjunct measures can be considered in this patient with septic shock?

The 2008 Surviving Sepsis Campaign: International Guidelines for Management of Severe Sepsis and Septic Shock consultants developed key recommendations toward the early goal-directed resuscitation of the septic patient. Key recommended adjuncts include administration of broad-spectrum antibiotics within 1 hour of diagnosis of septic shock, administration of either crystalloid or colloid fluid resuscitation, norepinephrine or dopamine to maintain mean arterial pressure ≥ 65 mmHg. In addition, stress-dose steroid therapy can be given in those patients whose blood pressure is poorly responsive to fluid resuscitation and vasopressors. Recombinant activated protein C (rhAPC) is controversial, but may be considered in those patients at high risk of death as documented by Acute Physiology and Chronic Health Evaluation (APACHE) II scores of ≥ 25 or multiple organ failure; however, those patients with severe sepsis and low risk of death, as measured by APACHE II scores of < 25 or one organ failure should not receive rhAPC. Contraindications, including recent major surgery and other bleeding disorders, must also be evaluated before administering rhAPC. Other adjuncts include targeting lower blood glucose levels, stress ulcer prophylaxis, and prevention of DVT in septic patients.⁷⁰

OPTIMIZING SURGICAL ANTIMICROBIAL PROPHYLAXIS 57-06

Prophylactic antibiotics are widely used in surgical procedures and account for substantial antibiotic use in many hospitals.¹ The purpose of surgical antibiotic prophylaxis is to reduce the prevalence of postoperative wound infection (about 5% of surgical cases overall) at or around the surgical site.² Such surgical site infections reportedly increase morbidity and extend the duration of hospitalization by at least 1 week, at an annual cost of up to \$10 billion nationwide.^{3–7} By preventing surgical site infections, prophylactic antimicrobial agents have the potential to decrease patient morbidity and hospitalization costs for many surgical procedures that pose significant risk of infection (e.g., appendectomy); however, the benefits of prophylaxis are controversial, and prophylaxis is not justified for some surgical procedures (e.g., urologic operations in patients with sterile urine).⁸ Consequently, the inappropriate or indiscriminate use of prophylactic antibiotics can increase the risk of drug toxicity, selection of resistant organisms, and costs.

RISK FACTORS FOR INFECTION

The development of postoperative site infection is related to the degree of bacterial contamination during surgery, the virulence of the infecting organism, and host defenses. Risk factors for postoperative site infection can be classified according to operative and environmental factors, and patient characteristics.^{9,10}

Bacterial contamination can occur from exogenous sources (e.g., the operative team, instruments, airborne organisms) or from endogenous sources (e.g., the patient's microflora of the skin, respiratory, genitourinary, or gastrointestinal [GI] tract).^{9,11} Infection control procedures to minimize all sources of bacterial contamination, including patient and surgical team preparation, operative technique, and incision care, are compiled in Centers for Disease Control and Prevention guidelines for surgical site infection.⁹

The risk of postoperative site infection is affected by host factors such as extremes of age, obesity, cigarette smoking, malnutrition, and comorbid states, including diabetes mellitus, remote infection, ischemia, colonization with microorganisms,

and immunosuppressive therapy.^{11,12} In addition, the longer the preoperative hospital stay and the surgical procedure, the greater the likelihood of developing a postoperative wound infection, presumably as a result of nosocomial bacterial acquisition in the former and the greater amount of bacterial contamination occurring over time in the latter.¹¹

Another major risk factor for infection is the skill of the surgeon. In one study,¹³ postoperative wound infection rates were related inversely to the frequency of performing a surgical procedure; thus, hospitals with the highest frequency of surgical procedures have the lowest incidence of postoperative infection.

Based on these risk factors for infection, the decision whether a given patient should receive antimicrobial prophylaxis is multifactorial. Many experts recommend that antimicrobial prophylaxis should be given for surgical procedures (a) with a high rate of infection, (b) involving the implantation of prosthetic materials, or (c) those in which an infection would have catastrophic consequences.¹² A widely used surgical wound classification system to assist in this decision-making process follows.

CLASSIFICATION OF SURGICAL SITE INFECTIONS

From 1960 to 1964, the National Academy of Sciences National Research Council conducted a landmark study of surgical site infections and formulated a widely used standard classification based on the risk of intraoperative bacterial contamination (Table 57-1).¹¹ Current recommendations for surgical prophylaxis pertain to clean surgeries involving implantation of prosthetic material, clean-contaminated surgeries, and select contaminated wounds. Antimicrobial therapy for most contaminated and all dirty surgeries in which infection already is established is considered treatment instead of prophylaxis and is not discussed further in this chapter. Table 57-2 lists suspected pathogens and recommendations for site-specific prophylactic antimicrobial regimens; a detailed examination of clinical trials supporting these recommendations is presented elsewhere.^{8,14}

Table 57-1 National Research Council Wound Classification

| Classification | Criteria | Infection Rate (%) |
|--------------------|---|--------------------|
| Clean | No acute inflammation or entry into GI, respiratory, GU, or biliary tracts; no break in aseptic technique occurs; wounds primarily closed | <5 |
| Clean-contaminated | Elective, controlled opening of GI, respiratory, biliary, or GU tracts without significant spillage; clean wounds with major break in sterile technique | <10 |
| Contaminated | Penetrating trauma (<4-hr old); major technique break or major spillage from GI tract; acute, nonpurulent inflammation | 15–20 |
| Dirty | Penetrating trauma (>4-hr old); purulence or abscess (active infectious process); preoperative perforation of viscera | 30–40 |

GI, gastrointestinal; GU, genitourinary.
From reference 11.

Table 57-2 Suggested Prophylactic Antimicrobial Regimens for Surgical Procedures

| Procedure | Predominant Organism(s) | Antibiotic Regimen (Alternative) | Adult Preoperative IV Dose (Alternative) ^a |
|--|---|---|--|
| Clean | | | |
| Cardiac (all with sternotomy, cardio-pulmonary bypass) | <i>Staphylococcus aureus</i> , <i>Staphylococcus epidermidis</i> | Cefazolin (Vancomycin) | 1 g (1 g) |
| Thoracic | <i>S. aureus</i> , <i>S. epidermidis</i> , gram-negative enterics | Cefazolin (Vancomycin) | 1 g (1 g) |
| Vascular (aortic resection, groin incision, prosthesis) | <i>S. aureus</i> , <i>S. epidermidis</i> , gram-negative enterics | Cefazolin (Vancomycin) | 1 g (1 g) |
| Orthopedic (total joint replacement, internal fixation of fractures) | <i>S. aureus</i> , <i>S. epidermidis</i> | Cefazolin (Vancomycin) | 1 g (1 g) |
| Neurosurgery | <i>S. aureus</i> , <i>S. epidermidis</i> | Cefazolin (Vancomycin) | 1 g (1 g) |
| Clean-Contaminated | | | |
| Head and neck | <i>S. aureus</i> , oral anaerobes, streptococci | Cefazolin (clindamycin-gentamicin) | 2 g (600 mg clindamycin-1.5 mg/kg gentamicin) |
| Gastroduodenal (only for procedures entering stomach) | Gram-negative enterics, <i>S. aureus</i> , mouth flora | Cefazolin | 1 g |
| Colorectal | Gram-negative enterics, anaerobes (<i>Bacteroides fragilis</i>), enterococci | Oral neomycin-erythromycin base (IV Cefoxitin) | 1 g each at 1 PM, 2 PM, and 11 PM day before surgery (1 g) |
| Appendectomy (uncomplicated) | Gram-negative enterics, anaerobes (<i>B. fragilis</i>) | Cefoxitin | 1–2 g |
| Biliary tract (only for high-risk procedures) | Gram-negative enterics, <i>Enterococcus faecalis</i> , <i>Clostridia</i> | Cefazolin | 1 g |
| Cesarean section | Group B streptococci, enterococci, anaerobes, gram-negative enterics | Cefazolin | 2 g after umbilical cord clamped |
| Hysterectomy | Group B streptococci, enterococci, anaerobes, gram-negative enterics | Cefazolin or cefoxitin | 1 g |
| Abortion (only for high-risk in first trimester) | Group B streptococci, enterococci, anaerobes, gram-negative enterics | Aqueous penicillin G (doxycycline) (first trimester) Cefazolin (second trimester) | 2 million units (100 mg PO before and 200 mg PO after) 1 g |
| Genitourinary (only for high-risk procedures) | Gram-negative enterics, enterococci | Ciprofloxacin | 400 mg |

^aCefazolin should be dosed at 2 g in patients >80 kg.

PRINCIPLES OF SURGICAL ANTIMICROBIAL PROPHYLAXIS

Decision to Use Antimicrobial Prophylaxis

1. M.R., a 72-year-old woman, is admitted to the hospital with severe abdominal pain, nausea and vomiting, and temperature of 39.3°C. A diagnosis of acute cholecystitis is made, and M.R. is scheduled for biliary tract surgery (cholecystectomy). Why is antimicrobial prophylaxis warranted for M.R.?

Biliary tract surgery is considered a clean-contaminated procedure and, therefore, carries a risk of surgical wound infection approaching 10% (Tables 57-1 and 57-2). Prophylaxis for biliary tract surgery is limited to “high-risk” procedures, which include obesity, age >70 years, diabetes mellitus, acute cholecystitis, obstructive jaundice, or common duct stones.^{8,12,15} Thus, prophylaxis is warranted in M.R., who falls into at least two high-risk categories (age >70 years and acute cholecystitis).

2. An order for intravenous (IV) cefazolin 1 g on call to the operating room (OR) is written for M.R. Why is this an appropriate (or inappropriate) antibiotic selection?

The selected prophylactic agent should be directed against likely infecting organisms (Table 57-2), but need not eradicate every potential pathogen. Cefazolin has been proved effective for most surgical procedures, including biliary tract surgery, given that the goal of prophylaxis is to decrease bacterial counts below critical levels necessary to cause infection. Broad-spectrum agents, such as third-generation cephalosporins, should be avoided for prophylaxis because they are no more effective than cefazolin and may alter microbial flora, increasing the emergence of microbial resistance to these otherwise valuable agents.

Timing of Antimicrobial Administration

3. Why is the administration time for this antimicrobial appropriate (or inappropriate) for M.R.?

Classic animal studies conducted by Burke¹⁶ and others¹⁷ clearly demonstrated the need for therapeutic antibiotic concentrations in the bloodstream and in vulnerable tissue at the time of wound contamination. Bacteria were most likely to enter the tissue beginning with the initial surgical incision and continuing until the wound was closed; antibiotics administered >3 hours after bacterial contamination were ineffective in minimizing the development of wound infection.^{16,17} This 2- to 3-hour period after the surgical incision was deemed the “effective” or “decisive” period for prophylaxis, when the animal wound was most susceptible to the beneficial effects of the antibiotic. This decisive period for administration of prophylactic antibiotics has been confirmed in humans.^{18,19}

For maximal efficacy, an antibiotic should be present in therapeutic concentrations at the incision site as early as possible during the decisive period and continuing until the wound is closed. Because an antibiotic administered postoperatively cannot achieve therapeutic concentrations during the decisive period, such timing of surgical “prophylaxis” is of no benefit in preventing postoperative wound infections, and infection rates are similar to those in patients who receive no antibiotics.¹⁹

An exception in which postincision administration sometimes is justified is in cesarean sections, because the incidence of endometritis after cesarean section is decreased significantly by postoperative administration of antibiotics.⁸

Based on these study results, prophylactic antibiotics should be administered before the surgical procedure in the OR before the induction of anesthesia.¹⁴ Prophylactic antibiotics are most effective when given during the 1-hour period before the surgical incision is made, and rates of infection increase significantly if antibiotics are administered >1 hour preoperatively or any time postoperatively.^{20,21} If a tourniquet is required, then the entire antibiotic dose should be administered before inflation of the tourniquet.

The “on call” prescribing practice for surgical prophylaxis, as with M.R., has fallen into disfavor because the time between antibiotic administration and the actual incision may exceed 1 hour and, therefore, may result in subtherapeutic antibiotic concentrations during the decisive period.^{14,22} M.R.’s cefazolin should be ordered preoperatively and should be administered in the OR no earlier than 1 hour before the operative procedure.

4. Will M.R. require a second dose of cefazolin during the surgical procedure?

The duration of the surgical procedure and the half-life of the administered antibiotic should be considered when determining whether an additional dose is necessary to maintain adequate antibiotic concentrations at the operative site. Studies have indicated an inverse relationship between the efficacy of short-acting antibiotics and the duration of the surgical procedure; as operative time increases, so does the incidence of postoperative infection.²³ Cefazolin, with a half-life of ~1.8 hours, is effective in a single preoperative dose for most surgical procedures. For procedures lasting >2 hours, or those with major blood loss, additional intraoperative doses should be administered every one to two times the half-life of the drug during the procedure.^{14,23} M.R. should require an additional intraoperative cefazolin dose only if the surgical procedure is prolonged (>3 hours).²³

Route of Administration

5. G.B., a 55-year-old woman recently diagnosed with carcinoma of the large bowel, is admitted to the hospital for an elective colorectal surgical resection; the surgery is expected to last 5 hours. Physical examination reveals a cachectic woman with a 9-kg weight loss over the previous 3 months (current weight, 60 kg). Increased frequency of bowel movements and chronic fatigue are noted; all other systems are normal. Laboratory data include hemoglobin (Hgb), 10.4 g/dL (normal, 11.5–15.5); hematocrit (Hct), 29.7% (normal, 33%–43%); and prothrombin time (PT), 15 secs (normal, 11–13). Stool guaiac is positive. Vital signs are within normal limits. G.B. is taking no medications and has no history of drug allergies. The following orders are written to begin at home on the day before surgery: (a) Clear liquid diet; (b) mechanical bowel cleansing with polyethylene glycol-electrolyte lavage solution (CoLYTE, GoLYTELY); and (c) neomycin sulfate 1 g and erythromycin 1 g PO at 1 PM, 2 PM, and 11 PM. Comment on the appropriateness of the oral route of administration of antibiotic prophylaxis for G.B.

[SI units: Hgb, 104 g/L; Hct, 0.297]

In general, oral administration of surgical antimicrobial prophylaxis is not recommended because of unreliable or poor absorption of oral agents in the anesthetized bowel. Oral agents, however, function effectively as GI decontaminants because high intraluminal drug concentrations are sufficient to decrease bacterial counts.²⁴ The concentration of bacteria in the colon may approach 10^{16} bacteria/mm³ and colorectal procedures, such as the one G.B. will undergo, carry a relatively high risk of postoperative infection. Antimicrobial regimens with activity against the mixture of aerobic and anaerobic bacteria that make up the fecal flora (*Escherichia coli* and other Enterobacteriaceae and *Bacteroides fragilis*) are effective in preventing postoperative wound infections.²⁵

The most widely used oral antimicrobial regimen directed against the fecal flora is 1 g each of the nonabsorbable antibiotics neomycin sulfate (for gram-negative aerobes) and erythromycin base (for anaerobes), given 1 day before surgery at the times indicated for G.B.^{19,25} Mechanical bowel cleansing, such as with polyethylene glycol-electrolyte or sodium phosphate lavage solution, should precede this regimen; the purpose of such bowel purging is to evacuate the colonic contents as completely as possible to decrease colonic bacterial counts. Effective oral alternatives to neomycin plus erythromycin include metronidazole with or without neomycin or with kanamycin, or kanamycin plus erythromycin²⁶; however, clinical situations warranting the use of such alternatives over the well-established neomycin-erythromycin regimen are practically nonexistent. Thus, the regimen selected for G.B. is highly appropriate.

6. The surgical resident has canceled the oral neomycin-erythromycin bowel regimen for G.B. Instead, he orders cefoxitin (Mefoxin) 1 g IV preoperatively. Why is (or is not) this change in therapy an effective and rational choice for G.B.?

Numerous parenteral regimens, specifically with agents that possess both aerobic and anaerobic activity, are effective as surgical prophylaxis in colorectal procedures. The second-generation cephalosporins with significant anaerobic activity (e.g., cefoxitin) are superior to first-generation cephalosporins, which lack sufficient anaerobic activity.²⁷ At present, it is not clear whether oral antimicrobial prophylaxis is superior to parenteral therapy in preventing infection after colorectal surgery.²⁸

Thus, although both IV and oral regimens are effective for prophylaxis before colorectal surgery, the parenteral route of administration, selected because of physician preference, may be less effective.¹² Furthermore, the cefoxitin order for G.B. would be unacceptable if the surgery lasts >3.5 hours (the relatively short half-life of cefoxitin could render G.B. antibiotic-free and predispose her to infection).²⁹ For prolonged procedures (>3 hours) such as anticipated for G.B., an alternative agent with a longer half-life, such as ertapenem, or a second dose of cefoxitin should be considered. Ertapenem has been found to be superior to cefotetan in preventing infection after colorectal surgery.³⁰ This improved efficacy may be because of the long half life or more broad antibacterial activity.³¹ Whereas ertapenem may offer certain advantages as a prophylactic antibiotic, its use in this indication is discouraged by some clinicians. Although unproved, the potential impact of widespread ertapenem utilization on subsequent carbapenem resistance is of concern. The higher acquisition

cost of ertapenem also needs to be considered.¹² Thus, for G.B., the importance and efficacy of established oral prophylactic regimens (plus bowel cleansing) should be stressed to the resident.

7. The surgical resident has reconsidered the cefoxitin order and decided to prescribe both the oral and parenteral prophylactic regimens for G.B. Will the combination significantly reduce the rate of postoperative wound infection compared with either regimen administered singly?

Although the coadministration of both oral and parenteral prophylactic regimens occurs commonly in practice (75% of one survey's respondents),³² data in support of this practice are conflicting.^{26,33} Oral plus parenteral antimicrobial prophylaxis combination is equivalent or superior to either regimen administered alone in reducing infection rates.^{26,33,34} As a result, a combination of oral and parenteral antimicrobial prophylaxis is recommended for colorectal surgery.^{8,12}

Duration of Administration

8. L.G., a 28-year-old man with a history of rheumatic heart disease, has a 12-year history of a heart murmur consistent with mild mitral stenosis and mitral regurgitation. Over the past 4 months his murmur has become much more prominent. In addition, he has developed severe dyspnea with light physical activity and 3+ pitting edema over both lower legs. Physical examination is notable for coarse rales and an S₃ gallop. For the past 6 weeks he has been maintained on digoxin and diuretics without significant relief of his shortness of breath (SOB). The cardiothoracic surgeon recommends mitral valve replacement and orders the following surgical antibiotic prophylaxis regimen: cefazolin 1 g IV preoperatively, then Q 8 hr for 48 hrs. Why is cefazolin the most appropriate antimicrobial for L.G.? Why was prophylaxis ordered for only 48 hrs?

Although the incidence of postoperative wound infection for cardiothoracic procedures is low (<5%), the devastating consequences of a postoperative endocarditis (following valve replacement) and mediastinitis or sternal osteomyelitis (following sternotomy) warrant careful antimicrobial prophylaxis.³⁵⁻⁴⁶ Organisms of concern for cardiothoracic surgery include *Staphylococcus aureus* and *Staphylococcus epidermidis* (Table 57-2); based on these potential pathogens, successful prophylactic regimens include cefazolin (Ancef), cefamandole (Mandol), and cefuroxime (Zinacef). When cefazolin has been compared with cefuroxime or cefamandole, a statistical trend in favor of the second-generation cephalosporins has been noted, and collective wound infection rates were slightly higher in the cefazolin group.³⁷⁻³⁹ In contrast, a comparison of prophylactic cefazolin and cefuroxime in patients having open heart surgery noted a significantly greater incidence of sternal wound infection and mediastinitis in the cefuroxime group.⁴⁰ Furthermore, equal efficacy between the two agents was noted in yet another study.⁴³ In conclusion, cefazolin probably is at least as effective as second-generation cephalosporins; therefore, the choice of agent should be based on an institution's antimicrobial susceptibility and cost data. Hospital-specific antimicrobial resistance patterns are especially important in determining the incidence of methicillin-resistant *S. aureus* (MRSA) or methicillin-resistant

S. epidermidis (MRSE) surgical site infection rates is important, although evidence does not support the use of vancomycin at large in hospitals with high prevalence.⁴⁷ Vancomycin is the drug of choice for prophylaxis in patients known to be colonized with such organisms.^{14,47}

Meta-analyses of the use of prophylactic antibiotics in cardiac surgery demonstrated no significant differences in the rate of surgical site infection between first- and second-generation cephalosporins and between β -lactams and glycopeptides.^{41,46,48} Thus, the cefazolin prophylaxis selected for L.G. is acceptable, provided the patient is not colonized with MRSA or MRSE.

With regard to duration, the shortest effective prophylactic course of antibiotics should be used (i.e., single dose preoperatively or not more than 24 hours postoperatively for most procedures).⁴⁵ Postoperative doses after wound closure are usually not required and may increase the risk of resistance. Single-dose prophylaxis, a viable option for many surgical procedures (see Question 9), is controversial for cardiac procedures.⁴⁹ In practice, cardiothoracic antimicrobial prophylaxis often is continued 48 hours after surgery,¹² as in L.G. No benefit is seen to prolonging prophylaxis to >48 hours, and such use should be discouraged. The duration of antimicrobial prophylaxis ordered for L.G. is appropriate.

9. G.J., a 27-year-old woman, is admitted to the obstetrics unit at term with her first pregnancy. She is scheduled for a cesarean section because the baby is breech. Cefazolin 1 g IV to be administered after the cord is clamped and Q 8 hr for 24 hrs is ordered. Why is this surgical prophylaxis inappropriate?

As noted previously, the shortest effective duration of prophylaxis is desired. In the past, 5- or 6-day antimicrobial regimens were used for cesarean section, but 24-hour regimens have since been proved as effective as these longer regimens.⁵⁰ Faro et al.⁵⁰ demonstrated that a single 2-g dose of cefazolin was superior to either a single 1-g dose or to a three-dose, 1-g prophylactic regimen. Others have noted similar results (i.e., a single cefazolin dose administered after the umbilical cord is clamped seems to be sufficient in preventing postoperative wound infections in cesarean section).^{51–53} Single-dose prophylaxis is less costly⁵⁴ and minimizes the development of bacterial resistance.⁵⁵ Thus, G.J. should receive a single 2-g dose of cefazolin after the cord has been clamped, without the three additional doses.

Single-dose prophylaxis also is effective in a variety of GI tract, orthopedic, and gynecologic procedures.²³ A single dose of an antibiotic with a short half-life, however, may provide insufficient antimicrobial coverage during a prolonged surgical procedure, and repeated intraoperative dosing or selection of an agent with a longer half-life is recommended when the duration of surgery is long.¹⁴

Signs of Surgical Site Infection

10. G.J. is discharged on the fifth hospital day and instructed to observe her incision site carefully for signs of infection. What are the typical signs of site infection? What is the typical time course for signs of site infection to become manifest?

Most surgical site infections involve the incision site and are defined as either *superficial* (involving the skin and subcu-

taneous fat) or *deep incisional* (involving fascia and muscle). Typically, an infected incision site wound is red, inflamed, and purulent. The purulent drainage should be cultured to identify the causative pathogen and to direct antimicrobial therapy. Empiric therapy directed against the most likely pathogens should be instituted while awaiting culture and sensitivity test results. Although most incision site infections are clinically apparent shortly after surgery (within 30 days), some deep-seated infections present indolently over weeks to months, by which time an abscess may have developed.¹¹ When implants are involved, infections occurring up to a year after surgery may be related to the operation.⁵⁶

Selection of an Antimicrobial Agent

11. L.T., a 46-year-old woman, has a recent history of abnormal uterine bleeding and vaginal discharge. Endometrial biopsy is positive for squamous cell carcinoma. Invasive disease is not evident. The diagnosis is carcinoma in situ, and a vaginal hysterectomy is scheduled. What would be a good surgical prophylaxis antimicrobial regimen for L.T.?

The selection of a prophylactic regimen should incorporate such factors as the agent's microbiologic activity against the most likely potential pathogens encountered during the surgical procedure (Table 57-2), pharmacokinetic characteristics (e.g., half-life), inherent toxicity, potential to promote the emergence of resistant strains of bacteria, and cost.

The usefulness of antimicrobial prophylaxis in vaginal hysterectomies is well established and is directed against vaginal microflora, including gram-positive and gram-negative aerobes and anaerobes (Table 57-2). The narrowest-spectrum agent that is efficacious is desired, given that the goal of prophylaxis is not to eradicate every potential pathogen, but to reduce bacterial counts below a critical level necessary to cause infection. Cefazolin has been proved to be an effective prophylactic agent for vaginal hysterectomy when compared with broad-spectrum agents such as ceftriaxone (Rocephin).⁵⁷ This indicates that a broader-spectrum agent with anaerobic activity (which cefazolin lacks) is unwarranted.

Similar to vaginal hysterectomy, cefazolin and numerous agents have been documented to reduce the incidence of postoperative surgical infection via the abdominal approach.^{58,59} As with vaginal hysterectomy, most trials have not documented significant differences between first- and second-generation cephalosporins.⁵⁸ In contrast, Hemsell et al.⁶⁰ observed a significantly higher incidence of major postoperative surgical infections in patients receiving the first-generation agent cefazolin when compared with cefotetan. Cefazolin exhibits a favorable toxicity profile and has a relatively long half-life (~1.8 hours) such that a single dose has proven prophylactic efficacy.⁵⁷ Cefazolin also is considerably less expensive than broader-spectrum agents and is currently recommended by the American College of Obstetricians and Gynecologists.⁶¹ Although it has a broader spectrum of coverage, a single dose of cefoxitin would also be an appropriate choice for this patient.

12. Because cefoxitin has an increased spectrum of activity against the anaerobe *B. fragilis*, it is being considered as an alternative to cefazolin prophylaxis for L.T. Comment on the appropriateness of this proposed change in prophylaxis.

The second- and third-generation cephalosporins and ampicillin-sulbactam generally are not more effective than the first-generation cephalosporins for surgical prophylaxis in vaginal hysterectomy or gastroduodenal, biliary, and clean surgical procedures.⁸ One clear exception to these findings is in the prevention of infection after colorectal procedures and perhaps hysterectomy. Several investigations have documented the failure of first-generation agents when used as prophylaxis in colorectal procedures, probably a consequence of their weak anaerobic coverage.²⁷ As stated previously, second- and third-generation agents and ampicillin-sulbactam generally are no more efficacious than cefazolin and should not be used for surgical prophylaxis in most procedures. Cefoxitin, however, would be a reasonable choice in colorectal surgery or hysterectomy. Considering that this patient is having a hysterectomy, either cefazolin or cefoxitin is appropriate.

13. S.N., a 57-year-old woman with rheumatoid arthritis and degenerative joint disease, has been admitted for total hip arthroplasty. She had an anaphylactic reaction to penicillin in the past. What should be prescribed for S.N. for surgical prophylaxis?

Cefazolin is the preferred prophylactic agent for most clean procedures, including cardiac, vascular, and orthopedic procedures⁸ (Table 57-2). Although the risk of cefazolin cross-allergenicity to penicillin is minimal, S.N. experienced a significant penicillin allergy (hives, SOB); therefore, an alternative prophylactic agent definitely is appropriate. The organisms most likely to cause postoperative infection after total hip replacement are *S. aureus* and *S. epidermidis* (Table 57-2). Nafcillin, cefazolin, and vancomycin possess excellent activity against *S. aureus*, however, the β -lactams have only marginal activity against *S. epidermidis*. Regardless, nafcillin clearly must be avoided because of the penicillin allergy. Thus, the preferred agent for S.N. is vancomycin.

Preoperative vancomycin 1 g should be administered IV slowly, over at least 60 minutes. This slow rate of infusion is necessary to reduce the risk of infusion-related hypotension, which poses a particular danger during anesthesia induction and has been reported to cause cardiac arrest.⁶²

14. B.K., an 18-year-old woman, complains of severe acute abdominal pain and nausea; the pain is localized to the periumbilical region. B.K. has a temperature of 39.5°C. After initial examination by her pediatrician, she is admitted to the hospital with presumed appendicitis and an exploratory laparotomy is scheduled. What surgical antimicrobial prophylaxis should be ordered for B.K.?

As with colorectal surgery, the most likely infecting organisms in appendectomy are *Bacteroides* species and gram-negative enterics (Table 57-2). On surgical inspection, if the appendix appears normal (uninflamed, without perforation), then antimicrobial prophylaxis is unnecessary.⁶³ If the appendix is inflamed without perforation, a single preoperative antibiotic dose is necessary. If the appendix is perforated or gangrenous (complicated), infection is already established and postoperative treatment is warranted. The status of the appendix, however, cannot be determined before surgery; therefore, all patients should receive at least one dose of an appropriate antibiotic preoperatively.⁶⁴ After surgical inspection of the appendix, the need for postoperative antibiotic therapy can be determined.

Based on the pathogens likely to be encountered, an antimicrobial agent with both aerobic and anaerobic activity is desired for surgical prophylaxis in this situation. Consequently, cefoxitin (Mefoxin), ceftizoxime (Cefizox), or cefotaxime (Claforan) are acceptable choices for prophylaxis.⁶⁵

Risks of Indiscriminate Antimicrobial Use

15. On surgical exploration, B.K. was found to have uncomplicated (nonperforated, nongangrenous) appendicitis; however, cefoxitin therapy was continued for 3 days for unclear reasons. What are the risks of indiscriminate use of antimicrobials for surgical prophylaxis?

The risks of indiscriminate use of antimicrobials to a given patient include the potential for adverse effects and superinfection. The administration of any β -lactam agent poses the risk of a hypersensitivity reaction, and many antibiotics, including cefoxitin, such as in B.K., are known to predispose patients to *Clostridium difficile*-associated disease. The risk of developing this superinfection increases with duration of antibiotic exposure.⁶⁶ Avoiding unnecessary initial and prolonged exposure may help reduce the risk to patients of contracting this emerging disease and its associated complications.⁶⁷ In addition, widespread or prolonged use of antimicrobial agents increases the potential for the development or selection of resistant organisms in a given patient or other patients who may acquire a pathogen nosocomially.⁶⁸

OPTIMIZING SURGICAL ANTIMICROBIAL PROPHYLAXIS

Antibiotic control strategies have improved the appropriate use of antimicrobial agents for surgical prophylaxis. The implementation of an automatic stop-order policy for surgical prophylaxis has reduced the duration of antimicrobial prophylaxis dramatically. These stop-order policies can be printed directly onto an antibiotic order form.⁶⁹ Reviewing the process can help improve antibiotic appropriateness and timing of administration. This was achieved in one study by redesign of the process and education of medical staff by a multidisciplinary quality-improvement team and it resulted in substantial cost avoidance.⁷⁰ In a second study, a multidisciplinary team generated electronic quick orders allowing for a computer-enhanced decision-making process and developed an antibiotic administration protocol. Appropriate antibiotics administered increased from 78% to 94%, timely administration improved from 51% to 98%, and clean wound infection rate decreased from 2.7% to 1.4%.⁷¹

In collaboration with other health care providers, the pharmacy department of health care organizations is responsible for optimizing the timing, choice, and duration of antimicrobial surgical prophylaxis.⁷² Education of surgical, anesthesia, and nursing staff, supported by hospital policy changes initiated by pharmacists improved appropriate timing from 68% to 97% and resulted in significant cost avoidance.⁷² More recently, a quality improvement approach developed by a national collaborative involving multidisciplinary teams achieved a decrease in the surgical infection rate from 2.3% to 1.7% over a 1-year period.^{14,73} Postdischarge surveillance can also help in reducing surgical site infections.⁷⁴

The pharmacotherapy of central nervous system (CNS) infections presents a tremendous challenge to the clinician. CNS infections often are caused by virulent pathogens. These infections occur in an area of the body in which antibiotic penetration often is limited and where host defenses are absent or inadequate. Thus, morbidity and mortality from infections of the CNS remain high despite the availability of highly potent, bactericidal antibiotics. In a review of 493 adult patients treated for bacterial meningitis at the Massachusetts General Hospital between 1962 and 1988, the mortality rates were 25% and 35% for community-acquired and hospital-acquired cases, respectively.¹ The overall case fatality rate of 25% did not change significantly over the 27-year period of the study. Although eradication of bacteria is essential, it is only one of the variables that affect mortality from CNS infections. In an attempt to improve morbidity and mortality statistics, the pathophysiologic mechanisms of CNS infections continue to be further scrutinized.^{2–4} In addition, the beneficial effects of corticosteroids in bacterial meningitis continue to be evaluated.⁵

A number of infectious processes can occur within the CNS (e.g., meningitis, encephalitis, meningoencephalitis, brain ab-

cess, subdural empyema, and epidural abscess).^{6,7} In addition, prosthetic devices placed into the CNS (e.g., cerebrospinal fluid [CSF] shunts for management of hydrocephalus) often are complicated by infection.⁸ Many etiologic agents are capable of inducing CNS infections, including bacteria, viruses, fungi, and certain parasites. This chapter focuses primarily on bacterial infections of the CNS, with an emphasis on the pharmacotherapy of bacterial meningitis and brain abscess. (Also see Chapter 69, Pharmacotherapy of Human Immunodeficiency Virus Infection, and Chapter 70, Opportunistic Infection in HIV-Infected Patients, for presentations pertaining to CNS infections in these populations.)

REVIEW OF CENTRAL NERVOUS SYSTEM

Anatomy and Physiology

Meninges

Proper therapy of CNS infections first requires an understanding of the anatomic and physiologic characteristics of this region. The brain and spinal cord are ensheathed by a protective covering known as the meninges and suspended in CSF, which

acts as a “shock absorber” to outside trauma.^{9,10} The meninges consist of three layers of fibrous tissue: the *pia mater*, *arachnoid*, and *dura mater*. The *pia mater*, the innermost layer of the meninges, is a thin, delicate membrane that closely adheres to the contours of the brain. Separating the *pia mater* from the more loosely enclosed arachnoid membrane is the subarachnoid space, where the CSF resides. The *pia mater* and arachnoid, known collectively as the *leptomeninges*, lie interior to the *dura mater*, a tough outer membrane that adheres to the periosteum and vertebral column.^{9,11} *Meningitis* is a term describing inflammation (often the result of infection) of the subarachnoid space, whereas *subdural empyema* refers to a collection of purulent material (pus) in the region separating the *dura* and arachnoid.^{7,9} Abscesses also can form outside the dural space (epidural abscess), often with devastating consequences.⁷

Cerebrospinal Fluid

The CSF is produced and secreted by the choroid plexus in the lateral ventricles and, to a lesser extent, by the choroid plexuses within the third and fourth ventricles.^{10,12} The choroid plexus is histologically similar to the renal tubules and removes organic acids (including penicillins) from the CSF via active transport mechanisms. These transport processes can be inhibited by probenecid (Benemid) administration.¹² CSF flows unidirectionally from the lateral ventricles through the foramina of the third and fourth ventricles into the subarachnoid space, then over the cerebral hemispheres and downward into the spinal canal. CSF is absorbed through villous projections (arachnoid villi) into veins, primarily the cerebral venous sinuses.^{10,12} About 550 mL/day of CSF is produced, with complete exchange occurring every 3 to 4 hours.^{10,12} The flow of CSF is unidirectional from the ventricles to the intralumbar space. Therefore, intrathecal injection of antibiotics results in little, if any, antibiotic reaching the cerebral ventricles.^{13,14} This unidirectional flow of CSF presents a problem because ventriculitis commonly occurs in conjunction with bacterial meningitis. Direct intraventricular instillation of antibiotics, usually by means of a reservoir, is preferable in the setting of ventriculitis (see Question 21).^{13,14}

In adults, children, and infants the volume of CSF is approximately 150 mL, 60 to 100 mL, and 40 to 60 mL, respectively.^{10,12} Knowledge of approximate CSF volume facilitates estimation of the CSF concentration of a drug subsequent to intrathecal administration. For example, administration of gentamicin 5 mg (5,000 mcg) intrathecally should result in a CSF concentration of roughly 33 mcg/mL in an adult shortly after administration.

The composition of CSF differs from other physiologic fluids. The pH of CSF is slightly acidic (normal pH, 7.3) and, with the exception of chloride ion, electrolyte concentrations are slightly less than those in serum.^{10,12} Under normal conditions, the protein concentration in CSF is <50 mg/dL, CSF glucose values are approximately 60% those of plasma, and few if any white blood cells (WBC) are present (<5 cells/mm³).^{10,12} When the meninges become inflamed (i.e., in meningitis), the composition of the CSF is altered. In particular, the protein concentration in the CSF increases, and the glucose concentration in the CSF usually declines with meningitis. Therefore, careful evaluation of CSF chemistries is useful when establishing a diagnosis of meningitis.

Blood–Brain Barrier

The blood–brain barrier plays a crucial role in protecting the brain and maintaining homeostasis within the CNS.^{10,15,16} Actually, two distinct barriers exist within the brain: the blood–CSF barrier and the blood–brain barrier.^{15,16} The blood–CSF barrier is located in the choroid plexus and circumventricular organs (e.g., area postrema) and is characterized morphologically by fenestrated (porous) capillaries (Fig. 58-1).¹⁵ This arrangement allows proteins and other molecules (including antibiotics) to pass freely into the immediate interstitial space. Diffusion of substances into the CSF is restricted by tightly fused ependymal cells lining the ventricular side of the choroid plexus (Fig. 58-1).¹⁵ Cerebral capillary endothelial cells make up the blood–brain barrier, which separates blood from the interstitial fluid of the brain. Unlike capillaries in other areas of the body, the capillary endothelia of the brain are packed closely together, forming tight junctions that in effect produce a barrier physiologically similar to a continuous lipid bilayer.¹⁵

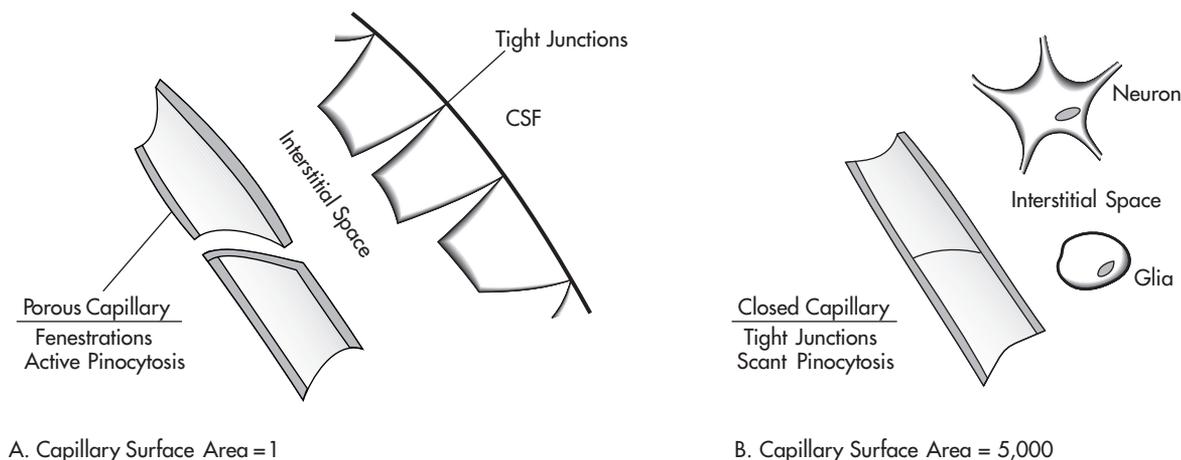

FIGURE 58-1 The two membrane barrier systems in the central nervous system: the blood–CSF barrier (left) and the blood–brain barrier. (From Partridge WM, et al. Blood–brain barrier: interface between internal medicine and the brain. *Ann Intern Med* 1986;105:82, with permission.)

The surface area of the blood–brain barrier is >5,000 times greater than that of the blood–CSF barrier; thus, the blood–brain barrier plays a more important role in protecting the brain and regulating its chemical composition.^{12,15} Many antimicrobials traverse the blood–brain barrier with difficulty, particularly agents having low lipid solubility (see the following discussion).¹⁶

MENINGITIS

Meningitis is the most common type of CNS infection. The signs and symptoms associated with bacterial meningitis usually are acute in onset, evolving over a few hours.⁶ Prompt recognition and early institution of therapy are essential to ensuring beneficial outcomes. In contrast, a diverse group of infectious (e.g., viruses, fungi, and mycobacteria) and non-infectious (e.g., chemical irritants) agents produce a meningitic picture often of a less acute or chronic nature.¹⁷ On occasion, such “aseptic” causes can produce signs and symptoms nearly indistinguishable from those of acute bacterial meningitis.^{6,17} Drugs that can induce aseptic meningitis include trimethoprim-sulfamethoxazole (TMP-SMX), the antirejection monoclonal antibody muromonab (OKT3), azathioprine, and nonsteroidal anti-inflammatory drugs (NSAID) such as ibuprofen, naproxen, and sulindac.¹⁸

Microbiology

The bacterial causes of meningitis correlate well with age and underlying conditions, such as head trauma or recent neurosurgery (Table 58-1).^{19–22} Generally, meningitis is a disease of the very young and very old: most cases occur in children <2 years of age and in elderly adults.^{19,20}

Neonates (infants <1 months) are at an especially high risk of developing meningitis. Meningitis in neonates most often is caused by group B streptococci (*Streptococcus agalactiae*) or coliform organisms such as *Escherichia coli*.^{19,20,23} These highly virulent pathogens usually are acquired during passage through the birth canal or from the hospital environment and are associated with significant morbidity and mortality, particularly in premature infants.^{19,20,23} Case fatality rates of >20% and 30% have been reported for meningitis caused by group B streptococci and gram-negative bacilli, respectively.¹⁹ *Listeria monocytogenes* is another important and often overlooked pathogen in neonates.^{19,20,24} Because *L. monocytogenes* is resistant to many antimicrobial agents, including third-generation cephalosporins, selection of initial (empiric) therapy in neonates must be approached with this pathogen in mind.²⁴

Infants >1 month of age and children <4 years of age are at the highest risk for meningitis. Dramatic changes have occurred in the epidemiology of bacterial meningitis in this age group over the past several years. Historically, in this age group, the disease was caused predominantly by three pathogens: *Haemophilus influenzae*, *Streptococcus pneumoniae*, and *Neisseria meningitidis*.^{19,20} Up to 45% of all cases of meningitis in the United States before 1985 were caused by *H. influenzae* type b (Hib).²⁰ From 1987 through 1997, however, Hib meningitis cases in children <5 years of age decreased by 97%.^{25,26} This reduction in *H. influenzae*-induced meningitis correlates with the widespread vaccination of children against invasive

Table 58-1 Microbiology of Bacterial Meningitis

| Age Group or Predisposing Condition | Most Likely Organisms ^a |
|--|--|
| Neonates (<1 mo) | Group B streptococcus (<i>Streptococcus agalactiae</i>), <i>Escherichia coli</i> , and other gram-negative bacilli (<i>Klebsiella</i> , <i>Serratia</i> species), <i>Listeria monocytogenes</i> |
| Infants and children (2–23 mos) | <i>Streptococcus pneumoniae</i> , <i>Neisseria meningitidis</i> , <i>S. agalactiae</i> , <i>Haemophilus influenzae</i> , ^b <i>E. coli</i> |
| Children and adults (2–50 yrs) | <i>N. meningitidis</i> , <i>S. pneumoniae</i> |
| Adults (>50 yr) | <i>S. pneumoniae</i> , <i>N. meningitidis</i> , <i>L. monocytogenes</i> , <i>E. coli</i> , <i>Klebsiella</i> species, and other gram-negative bacilli, |
| Postneurosurgical | <i>Staphylococcus aureus</i> , gram-negative bacilli (e.g., <i>E. coli</i> , <i>Klebsiella</i> * species, <i>Pseudomonas aeruginosa</i>), <i>Staphylococcus epidermidis</i> ^c |
| Closed head trauma | <i>S. pneumoniae</i> , <i>H. influenzae</i> , group A β -hemolytic streptococci |
| Penetrating trauma | <i>S. aureus</i> , <i>S. epidermidis</i> , gram-negative bacilli (e.g., <i>E. coli</i> , <i>Klebsiella</i> * species, <i>P. aeruginosa</i>) |
| Presence of risk factor (alcoholism and altered immune status) | <i>S. pneumoniae</i> , <i>L. monocytogenes</i> , <i>H. influenzae</i> , <i>N. meningitidis</i> |

^aOrganisms listed in descending order of frequency.

^bNeed to consider this pathogen only in children not vaccinated with Hib.

^cMost commonly seen in association with prosthetic devices (e.g., cerebrospinal fluid shunts).

H. influenzae disease with the Hib polysaccharide–protein conjugate vaccines. Invasive *H. influenzae* infection now is considered a vaccine-preventable disease in the United States as well as in other countries, highlighting the importance of vaccinating children against Hib invasive disease.²⁷ Further follow-up from 1998 to 2000 indicates that the incidence of Hib has remained extremely low. One of the national health objectives in *Healthy People 2010* is to reduce the incidence of Hib to zero.²⁶ In addition, widespread vaccination has caused a shift in the age distribution of bacterial meningitis. Before the Hib vaccine was available, more than two-thirds of cases occurred in children <5 years of age. With the dramatic reduction of Hib cases in this age group, most cases now are observed in adults.^{27,28}

In adults and children who have received the conjugated Hib vaccine, community-acquired meningitis most often is caused by *S. pneumoniae* (the pneumococcus) and *N. meningitidis* (the meningococcus).^{4,19,20} Meningococci more commonly are implicated in individuals ages 5 to 30 years, whereas pneumococci are the predominant pathogens in adults >30 years of age.¹⁹ In the past several years, meningococcal meningitis has been occurring in clusters within the general population with increased frequency. The observed clusters, defined as two or more cases of the same serogroup that are closer in time or

space than expected, usually occur in secondary schools or university settings.²⁸

Traditionally, pneumococci and meningococci have been highly susceptible to penicillin G (minimum inhibitory concentration [MIC] <0.1 mcg/mL). Pneumococcal strains showing intermediate penicillin resistance (MIC 0.1 to 1.0 mcg/mL) and high resistance (MIC \geq 2.0 mcg/mL), however, are a problem in many areas of the world, including the United States. Penicillin-resistant pneumococci are of particular concern in relation to meningitis because there is the additional challenge of delivering adequate levels to the site of infection, the CSF.^{2,29} Optimal therapy for resistant pneumococci is controversial and is discussed in greater detail in Question 14.

The elderly also are susceptible to developing meningitis, and the infection-related mortality in this population often is higher than in other age groups.^{19,20,30} For example, the case-fatality rate for pneumococcal meningitis is 5% in children <5 years of age but 19% to 37% in adults.^{20,31} Patients of advanced age are most susceptible to meningitis from pneumococci and meningococci. Enteric gram-negative bacilli (e.g., *E. coli*, *Klebsiella pneumoniae*) also are occasionally isolated.^{19,20,30} Furthermore, *L. monocytogenes* is a problem pathogen in the elderly, especially in immunocompromised patients.^{19,20,24,30,32}

Meningitis after neurosurgical procedures or open trauma to the head most often is caused by enteric gram-negative bacilli (predominantly *E. coli* and *K. pneumoniae*) and, to a lesser extent, staphylococci, particularly *Staphylococcus aureus*.^{1,21,32} Meningitis that occurs after neurosurgery is occasionally caused by resistant pathogens, such as *Enterobacter* species and *Pseudomonas aeruginosa*, often with devastating consequences.^{21,33–35} In addition, patients requiring ventriculostomy or placement of CSF shunts can develop infections of these prosthetic devices by coagulase-negative staphylococci (e.g., *S. epidermidis*) or diphtheroids.^{8,21} Closed head trauma, particularly when associated with CSF rhinorrhea or otorrhea, can lead to pneumococcal meningitis or, to a lesser extent, *H. influenzae* meningitis.²¹

Pathogenesis and Pathophysiology

The steps leading to the development of meningitis and the underlying pathophysiologic processes involved have become more clearly understood in the past few years.^{2,4} In general, meningitis can develop from *hematogenous* spread of organisms (the most common mechanism), by *contiguous* spread from a parameningeal focus (e.g., sinusitis or otitis media), or by direct bacterial *inoculation*, as occurs with head trauma or neurosurgery.

The list of pathogens causing bacterial meningitis is relatively short because only bacteria possessing certain virulence factors are capable of invading the meninges. Specifically, the presence of a polysaccharide capsule and other cell surface structures (e.g., pili) are necessary for bacteria to evade host defenses and gain entry into the subarachnoid space.^{2–4} Once in the CSF, virulence factors contained within the cell wall (e.g., lipopolysaccharide or endotoxin in the case of *H. influenzae*) initiate a complex cascade of events culminating in neurologic damage.^{2,3} These cell wall substances trigger the release of various cytokines, which act as mediators of the inflammatory response.^{2–4}

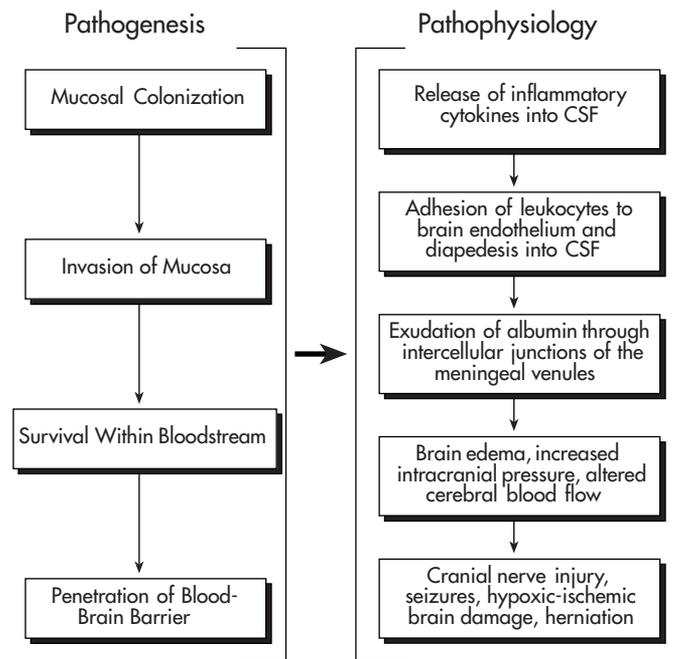

FIGURE 58-2 Summary of the pathogenesis and pathophysiology of bacterial meningitis. (Adapted from Quagliarello VJ, et al. New perspectives on bacterial meningitis. *Clin Infect Dis* 1993;17:603; and Quagliarello VJ, et al. Bacterial meningitis: pathogenesis, pathophysiology, and progress. *N Engl J Med* 1992;327:864, with permission.)

Colonization of mucosal surfaces is a necessary first step in the pathogenesis of meningitis (Fig. 58-2).^{3,4} The polysaccharide capsule and pili or fimbriae on the bacterial cell surface allow attachment to oropharyngeal or nasopharyngeal mucosa.^{2–4} Secretion of protease enzymes that neutralize the protective activity of mucosal IgA and intrinsic resistance to ciliary clearance mechanisms allow meningeal pathogens to adhere to, and penetrate through, the epithelial surface and enter the intravascular space.³ The presence of a capsule prevents binding by the alternative complement pathway and prolongs survival within the bloodstream.^{3,4} Eventually, organisms multiply to sufficient numbers that allow invasion of the blood–brain barrier. The exact mechanism by which bacteria invade the blood–brain barrier is not well understood. Bacteria, however, probably adhere to cerebral capillary endothelia or perhaps the epithelium of the choroid plexus.^{3,4}

Once bacteria gain entry into the CSF, host defenses are inadequate to contain the infection, and bacteria replicate rapidly. Humoral immunity (both complement and immunoglobulin) essentially is absent within the CSF.^{2–4} In addition, opsonic activity in CSF is negligible, and although leukocytosis ensues shortly after bacterial invasion, phagocytosis also is inefficient.^{3,4} Therefore, this relative immunodeficiency state necessitates the initiation of bactericidal therapy.²

Inflammation of the meninges is initiated by contents within the bacterial cell wall.^{2–4} Specifically, gram-negative bacteria possess lipopolysaccharide, or endotoxin, and gram-positive bacteria contain teichoic acid in their cell walls. Release of lipopolysaccharide (or teichoic acid) induces the production and secretion of inflammatory cytokines such as interleukin-1 (IL-1), interleukin-6 (IL-6), prostaglandin E₂, and tumor

necrosis factor (TNF) from astrocytes, endothelial cells, and circulating monocytes.^{3,4} These cytokines play an essential role in promoting the adherence of leukocytes to cerebral capillary endothelial cells, and they also facilitate the migration of leukocytes into the CSF.^{2,3} On attachment to brain endothelium, leukocytes release toxic oxygen products that damage endothelial cells. This increases pinocytotic activity, widens tight junctions, and eventually increases blood–brain barrier permeability (Fig. 58-2).^{2–4}

Inflammation of the blood–brain barrier allows the influx of albumin and, consequently, vasogenic cerebral edema.^{2,3} The brain edema combined with obstruction of CSF outflow increases intracranial pressure and alters cerebral blood flow.³ Altered cerebral blood flow is a problem because it often is coupled with a loss of cerebrovascular autoregulation. Hyperperfusion or hypoperfusion of the brain secondary to increases or decreases in systemic blood pressure, respectively, ultimately can result in neuronal injury, cerebral ischemia, and irreversible brain damage.³ The use of adjunctive corticosteroids in certain patient populations can substantially reduce inflammation and the subsequent neurologic sequelae of meningitis.^{2,5}

The inflammatory response in meningitis also can be aggravated by some antibiotics, notably the penicillins and cephalosporins.^{2,35} When the β -lactam antibiotics lyse bacterial cell walls, large amounts of cell wall products are liberated early in the course of disease, and these contents of bacterial cell walls amplify the inflammatory response.³⁵ The long-term benefits of β -lactam therapy far outweigh such transient detrimental effects. The use of less rapidly bacteriolytic agents, however, may be theoretically advantageous.² The proinflammatory effect of β -lactam antibiotics is attenuated by concomitant corticosteroid therapy.^{2,5}

Neurologic sequelae develop in one-third to one-half of patients with bacterial meningitis.^{31,36–38} The type and severity of neurologic complications vary with the specific infecting organism, the severity of the infection, and the susceptibility of the host. In children, pneumococcal meningitis carries the highest risk of permanent neurologic sequelae, particularly sensorineural hearing loss.^{6,38} In a long-term prospective study of 185 children with acute bacterial meningitis, permanent hearing loss occurred in 6%, 10.5%, and 31% of children with meningitis caused by *H. influenzae*, *N. meningitidis*, and *S. pneumoniae*, respectively.³⁸ Although seizures are fairly common on initial presentation, long-term epilepsy occurs in approximately 7% of patients.³⁶ Other important long-term complications include spastic paraparesis, behavioral disorders, and learning deficits.³⁶

Diagnosis and Clinical Features

Clinical and Laboratory Features of Bacterial Meningitis

1. S.C., a 5-year-old boy, is brought to the emergency department (ED) by his mother, who says her son has a temperature of 39°C, is irritable and lethargic, and has a rash. S.C. was in his usual state of good health until last night, when he awoke crying. When she went to investigate, her son began to stiffen up and rock back and forth in his bed. Because he was unarousable, S.C.'s mother rushed him to the hospital. S.C.'s medical history is non-contributory except for an allergy to amoxicillin described as a skin rash. S.C., his mother and father, and his 7-year-old brother

recently moved to the United States. S.C.'s vaccination history currently is unknown. S.C. and his brother currently attend a community day care center.

On physical examination, S.C. was in marked distress, with a temperature of 40 °C, blood pressure (BP) of 90/60 mmHg, and a respiratory rate of 32 breaths/minute. His weight on admission was 20 kg. Neurologic examination showed evidence of nuchal rigidity; he was lethargic and difficult to arouse. Brudzinski's and Kernig's signs were positive. On head, eyes, ears, nose, and throat examination, S.C. demonstrated photophobia (he squinted severely when the examiner shined a light in his eyes), but no evidence was noted of papilledema. A petechial rash was visible on his extremities. The remainder of S.C.'s examination was essentially normal.

Blood drawn for laboratory tests revealed sodium (Na), 128 mEq/L (normal, 135–145); potassium (K), 3.2 mEq/L (normal, 3.5–5); chloride (Cl), 100 mEq/L (normal, 95–105); bicarbonate (HCO₃), 25 mEq/L (normal, 22–28); blood urea nitrogen (BUN), 16 mg/dL (normal, 8–18); serum creatinine (SrCr), 0.6 mg/dL (normal, 0.6–1.2); and serum glucose, 80 mg/dL (normal, 70–110). The WBC count was 18,000 cells/mm³ with 95% polymorphonuclear (PMN) cells (normal, 54%–62%); the hemoglobin (Hgb), hematocrit (Hct), and platelet count all were within normal limits.

What clinical and laboratory features does S.C. display that are suggestive of meningitis?

[SI units: Na, 128 mmol/L; K, 3.2 mmol/L; Cl, 100 mmol/L; 25, mmol/L; BUN, 5.7 mmol/L; SrCr, 53.04 μ mol/L; serum glucose, 4.44 mmol/L; WBC count, 18 $\times 10^9$ /L]

S.C.'s presentation contains many features typical of acute bacterial meningitis. For example, the boy was in good health until he awoke at night confused and disoriented. When symptoms present abruptly and evolve quickly over a period of several hours, an acute bacterial process is a strong possibility.^{39,40} S.C. has several predisposing factors for the development of meningitis: young age, an unknown vaccination history, and day care exposure.^{1,37}

The clinical features of bacterial meningitis are summarized in Table 58-2.^{1,6,21,39,40} The most common symptoms include the triad of fever, stiff neck (nuchal rigidity), and altered mental status.^{1,6,39} When all three of these features are present, as is S.C.'s case, meningitis should be strongly suspected. Other less common signs and symptoms include headache, photophobia (unusual intolerance to light), and focal neurologic deficits, including cranial nerve palsies.^{1,6,39,40} A positive Brudzinski's sign (reflex flexion of the hips and knees produced on flexion

^b Symptoms seen in infants with meningitis.

of the neck when lying in the recumbent position), and Kernig's sign (pain on extension of the hamstrings when lying supine with the thighs perpendicular to the trunk) provide physical evidence of meningeal irritation.⁴¹ Brudzinski's and Kernig's signs both were positive in S.C. Seizures occur on initial presentation in 15% to 30% of patients and may be focal or generalized.^{1,6,36} The presence of seizures or a severely depressed mental status (i.e., obtundation or coma) generally is associated with a poorer prognosis.^{1,6,36} Headache, nausea, vomiting, photophobia, and papilledema on eye examination all suggest increased intracranial pressure.^{6,39,40} When these symptoms or focal neurologic deficits are present, a computed tomographic (CT) scan is recommended before lumbar puncture to rule out an intracranial mass.^{6,39,40} Although controversial, brain herniation can occur when lumbar puncture is performed in such patients because of the pressure changes induced within the cranial vault.⁴²

As is clearly evident, S.C. has many of the clinical features associated with acute bacterial meningitis. High fever, stiff neck, altered mentation, photophobia, and positive Kernig's and Brudzinski's signs all are consistent with bacterial meningitis. Furthermore, the low blood pressure (hypotension) and increased respiratory rate are characteristic findings in severe, life-threatening types of bacterial infection (e.g., septic shock, meningitis) and are likely the result of endotoxin release.

The signs and symptoms of meningitis in the very young and very old differ from those in older children and adults.^{6,23,30,37} In neonates, signs of meningeal irritation may be absent; fever, irritability, and poor feeding are often the only symptoms manifested.^{6,23} Fullness of the fontanel in infants also may reflect the increased intracranial pressure that occurs with meningitis.^{6,38} Because S.C. is 5 years of age, accurate assessment of his mental status is challenging. Irritability (crying), as was manifested by S.C., is an important finding that suggests an altered mental status.

In elderly patients, many of the classic signs of meningeal irritation are absent as well, and the disease presentation can be subtler.^{6,30,39} Therefore, given the grave consequences of a misdiagnosis, clinicians caring for infants and elderly patients must have a particularly high index of suspicion for meningitis.

Laboratory evaluation of meningitis should include serum chemistries and a hemogram as well as a detailed examination of the CSF.^{6,12,39} The peripheral WBC count often is markedly elevated in acute bacterial meningitis, usually with a left shift evident on the differential. This finding, however, is nonspecific and occurs in many acute inflammatory and infectious diseases. S.C. has a marked leukocytosis with a predominance of PMN cells on the differential. A low serum sodium value, which is present in S.C., reflects the syndrome of inappropriate secretion of antidiuretic hormone (SIADH), a frequent complication of acute bacterial meningitis.^{4,6} SIADH is an important finding in meningitis because it worsens cerebral edema.^{4,6}

The abrupt onset of S.C.'s clinical symptoms is consistent with an acute bacterial process rather than a fungal or viral etiology. Given his age (5 years) and the community-acquired nature of the infection, the most likely pathogens for his meningitis are *H. influenzae*, *N. meningitidis*, and *S. pneumoniae*. The presence of maculopapular lesions argues for *N. meningitidis* as the causative pathogen because this is a common finding in cases of meningococemia or meningococcal meningitis.³ To make an accurate clinical and microbiologic diagnosis in

S.C., it is necessary to obtain CSF for analysis. Thus, a lumbar puncture is required as soon as possible.

Cerebrospinal Fluid Examination

2. The resident in the ED performs a lumbar puncture, which yielded the following: opening pressure, 300 mm CSF (normal, <20); CSF glucose, 20 mg/dL (normal, 60% of plasma glucose); protein, 250 mg/dL (normal, <50); WBC count, 1,200 cells/mm³ (normal, <5), with 90% PMN, 4% monohistiocytes, and 6% lymphocytes. The CSF red blood cell (RBC) count was 50/mm³. A stat gram's stain of CSF revealed numerous WBC but no organisms. CSF, blood, and urine cultures are pending. What CSF findings in S.C. are consistent with a diagnosis of bacterial meningitis?

[SI units: CSF glucose, 1.1 mmol/L; protein, 2.5 g/L; WBC count, 1,200 × 10⁶ cells/L; RBC count, 5 × 10⁶/L]

Careful examination of the CSF is essential to confirm the diagnosis of meningitis.¹⁰ Table 58-3 compares the typical findings in CSF obtained from patients with acute bacterial meningitis with those seen with fungal or viral causes.^{6,17,39} In acute bacterial meningitis, the CSF is purulent, containing numerous WBC (usually >500 cells/mm³) with a predominance of PMN, and often is turbid.^{12,39} CSF protein nearly always is elevated, usually >100 mg/dL, and the CSF glucose concentration is low, either <50 mg/dL or <50% of a simultaneously obtained serum glucose value.^{10,13} In contrast, CSF obtained in viral and fungal cases of meningitis usually is clear and characterized by a much lower WBC count (<100 cells/mm³), with a mononuclear or lymphocyte predominance.^{17,39} Although the CSF protein concentration often is elevated, it may be normal.¹⁷ A variable effect is observed with CSF glucose.¹⁷

Microbiologic Evaluation

Microbiologic evaluation should include examination of CSF by Gram stain and culture as well as cultures obtained from other potential sites of infection (e.g., blood, sputum, urine).^{6,39} Gram stain of the CSF is positive in >50% of acute bacterial meningitis cases and is an extremely useful test to help direct initial (empiric) antimicrobial therapy.^{6,10,39} The presence of organisms on smear is indicative of a high bacterial inoculum (i.e., inoculum >10⁵ colony-forming units/mL) and is associated with more fulminant disease.² The absence of organisms on Gram stain by no means rules out infection but does make selection of empiric therapy more difficult.

S.C. has a negative Gram stain, which may be the result of previous antibiotic therapy or the early detection of disease. Given the negative CSF Gram stain result, S.C. must

Table 58-3 CSF Findings in Various Types of Meningitis

| Microbial Etiology | WBC Count (cells/mm ³) | Predominant Cell Type | Protein | Glucose |
|--------------------|------------------------------------|-----------------------|----------|----------|
| Bacterial | >500 | PMN | Elevated | – |
| Fungal | 10–500 | MN | Elevated | Variable |
| Viral | 10–200 | PMN or MN | Variable | Normal |

CSF, cerebrospinal fluid; MN, mononuclear cells; PMN, polymorphonuclear neutrophils; WBC, white blood cell.

receive antibacterial therapy sufficiently broad to cover all pathogens associated with meningitis in his age group until the results from his CSF culture are available (usually within 24 to 48 hours). The CSF culture nearly always is positive in purulent meningitis, and the presence of any organism in this normally sterile fluid must always be taken seriously.^{6,39,43} In a few instances, particularly when prior antibiotic therapy has been given, CSF cultures are negative in a patient who clearly appears to have meningitis.^{10,37,43} In this setting, newer diagnostic tests, such as latex particle agglutination, which reliably detect antigens of *H. influenzae*, *S. pneumoniae*, *N. meningitidis*, *E. coli* (K-1 capsular antigen), and group B streptococci in CSF, are available. Latex particle agglutination should be considered for S.C., especially if his cultures fail to yield any growth. Finally, results from cultures of other sites, such as the blood, urine, and sputum (when appropriate), can yield very useful microbiologic information.^{39,43}

The CSF findings in S.C. also strongly support the diagnosis of bacterial meningitis. He has a markedly elevated opening CSF pressure, CSF leukocytosis (with a predominance of PMN), an elevated CSF protein concentration, and a depressed CSF glucose value. A few RBC are present in the CSF, which suggests contamination with peripheral blood caused by the traumatic nature of the lumbar puncture. Precise identification of the offending organism is not possible until CSF culture results are available.

Treatment Principles

Prompt institution of appropriate antimicrobial therapy is essential when treating meningitis.³⁹ Delay in antibiotic administration is associated with increased morbidity and mortality.⁴⁴ When choosing antimicrobial therapy, a number of factors must be considered. First, the antibiotics selected must penetrate adequately into the CSF.^{13,16,45} In addition, the regimen chosen must have potent activity against known or suspected pathogens and exert a bactericidal effect.^{16,42–44}

Antimicrobial Penetration Into the Cerebrospinal Fluid

In cases of purulent meningitis, the amount of bacteria in the CSF often is much higher than the standard inoculum ($\sim 10^5$ colony-forming units per milliliter) used in routine antimicrobial susceptibility testing.^{16,46} As a result, extrapolation of in vitro sensitivity results to clinical efficacy is difficult, particularly for antimicrobials susceptible to an inoculum effect (i.e., an increase in the MIC with an increase in inoculum size). Cefuroxime (Zinacef), for example, is affected by an inoculum effect against *H. influenzae*, and extended-spectrum penicillins (e.g., piperacillin and mezlocillin) are affected similarly by enteric gram-negative bacilli.^{16,47} In addition, some antimicrobials (e.g., aminoglycosides, fluoroquinolones) have reduced bactericidal activity in the acidic milieu of purulent CSF.^{16,45,48,49} For example, gentamicin has a minimum bactericidal concentration (MBC) of 1 mcg/mL against *E. coli* at a pH of 7.35, and a decrease in the pH to 7.0 results in an eightfold increase in MBC.⁴⁹ This may partially explain why aminoglycoside therapy for gram-negative bacillary meningitis is suboptimal, even when direct intrathecal therapy is given.^{32,35} The ability of antimicrobials to penetrate into CSF is affected by lipid solubility, degree of ionization, molecular weight, protein binding, and susceptibil-

Table 58-4 CSF Penetration Characteristics of Various Antimicrobials

Very Good^a

Chloramphenicol, metronidazole, TMP-SMX, linezolid

Good^b

Penicillins: Penicillin G, ampicillin, nafcillin, piperacillin, ticarcillin
Other β -lactams: Aztreonam, clavulanic acid, imipenem, meropenem, sulbactam
Cephalosporins: Cefepime, cefotaxime, cefazidime, ceftizoxime, ceftriaxone, cefuroxime
Fluoroquinolones: Ciprofloxacin
Other agents: Rifampin

Fair to Poor^c

Aminoglycosides: Amikacin, gentamicin, tobramycin
Other agents: Azithromycin, clarithromycin, clindamycin, erythromycin, vancomycin, daptomycin

^a Penetrate CSF well regardless of meningeal inflammation.

^b Adequate CSF penetration achieved when the meninges are inflamed.

^c Penetration often inadequate even when the meninges are inflamed.

CSF, cerebrospinal fluid; TMP-SMX, trimethoprim-sulfamethoxazole.

ity to active transport systems operative within the choroid plexus.^{13,16,46,50} In general, the penetration of most antibiotics into the CSF is increased when the meninges are inflamed. Although the optimal degree of CSF penetration has not been elucidated entirely, experiments in the rabbit meningitis model indicate that bactericidal effects are maximal when CSF antibiotic concentrations exceed the MBC of the infecting pathogen by 10- to 30-fold.^{16,45,51} Antimicrobial penetration into CSF is most commonly reported as a ratio of CSF to serum antimicrobial levels. Table 58-4 summarizes the CSF penetration characteristics of various antimicrobials during acute bacterial meningitis.^{13,14,45,51,52} Chloramphenicol, metronidazole, and trimethoprim are highly lipophilic compounds and penetrate into the CSF extremely well, achieving high concentrations even when meningeal inflammation is absent.^{13,45,53} Rifampin also has good CSF penetration; because of this, it often is combined with vancomycin to treat coagulase-negative staphylococcal infections in the CNS.^{8,45,53} Because β -lactams and aminoglycosides usually are ionized at physiologic pH, they are more polar and do not penetrate into the CSF as well. β -Lactams penetrate poorly when the meninges are intact, but when the meninges are inflamed, most penicillins and the third-generation cephalosporins achieve CSF concentrations sufficient to treat meningitis ($\sim 10\%$ – 30% of simultaneously obtained serum concentrations).^{13,45,50,52,53} An additional factor working against maintenance of therapeutic concentrations of β -lactams in the CSF is the active transport system of the choroid plexus, which pumps these organic acids out of the CSF.¹⁶ Carbapenems, namely meropenem, attain CSF levels that are 10% to 40% of serum levels.⁵¹

The aminoglycosides have a low therapeutic index, and adequate CSF concentrations are difficult to achieve with intravenous (IV) dosing alone without risking significant toxicity.^{14,45} Furthermore, the acidic nature of purulent CSF

Table 58-5 Empiric Therapy for Bacterial Meningitis

| Age Group or Predisposing Condition | Recommended Therapy | Alternative Therapy |
|--|---|-----------------------------------|
| Neonates (<1 mo) | Ampicillin + cefotaxime | Ampicillin + gentamicin |
| Infants and children (1–23 mos) | Cefotaxime or ceftriaxone + vancomycin | Vancomycin + rifampin + aztreonam |
| Older children and adults (2–50 yr) | Cefotaxime or ceftriaxone + vancomycin | Vancomycin + rifampin + aztreonam |
| Elderly (>50 yr) | Ampicillin, cefotaxime, or ceftriaxone + vancomycin | Vancomycin + TMP-SMX + aztreonam |
| Postneurosurgical | Vancomycin + ceftazidime | Vancomycin + ceftazidime |
| Closed head trauma | Cefotaxime or ceftriaxone + vancomycin | Vancomycin + rifampin + aztreonam |
| Penetrating head trauma | Vancomycin + ceftazidime | Vancomycin + ceftazidime |
| Presence of risk factor (alcoholism and altered immune status) | Vancomycin + ceftriaxone or cefotaxime + ampicillin | Vancomycin + TMP-SMX + aztreonam |

reduces the antimicrobial activity of the aminoglycosides.⁴⁹ Thus, when aminoglycoside therapy is initiated for adults with CNS infections, concomitant intrathecal therapy is required.^{14,54} Direct instillation of aminoglycosides into the ventricles is preferred, but this approach requires the surgical insertion of a reservoir (e.g., Ommaya reservoir), which often is not possible, particularly in the early stages of bacterial meningitis.^{16,45} Thus, at the very least, patients requiring aminoglycosides for meningitis should receive daily intralumbar injections until clinical improvement is seen and CSF cultures are sterilized.^{14,16}

The degree of serum protein binding correlates well with the extent of CSF penetration.^{16,50} Ceftriaxone is highly bound to serum proteins and, thus, they are more confined to the intravascular space and not as readily available for CSF penetration as cefotaxime and ceftazidime, which are protein bound to a lesser extent. Ceftriaxone achieves sustained, reliable bactericidal activity within the CSF despite its high protein binding.^{45,52} Ceftriaxone has been used successfully to treat meningitis in both children and adults for many years.^{5,52,55}

Vancomycin and polymyxin B do not diffuse well across the blood–CSF barrier, primarily because of their large molecular size.^{13,16,45,53} Therapeutic concentrations in the CSF (up to 22% of serum concentrations) are attained with systemic vancomycin therapy when the meninges are inflamed. In selected circumstances, however, concomitant intralumbar or intraventricular therapy also may be necessary.^{8,45} The commonly prescribed antimicrobials, clindamycin and erythromycin, penetrate the CSF poorly,^{13,45,53} and they have limited usefulness because of their bacteriostatic mode of action.

Finally, fluoroquinolones, such as ciprofloxacin and ofloxacin, penetrate reasonably well into the CSF on a percentage basis (~20%–30%); however, the concentrations attained are fairly low (≤ 1 mcg/mL) when standard doses are administered.^{45,48} Given the potential neurotoxicity and the limited amount of clinical data, the quinolones have limited use in treating meningitis.

Empiric Therapy for Childhood Meningitis

3. A detailed medication and vaccination history reveals that S.C. and his brother appropriately received vaccination for Hib when they were 2 months of age. What constitutes appropriate empiric therapy for childhood meningitis? Which antibiotic would be appropriate for S.C.? What dose and route of administration should be used?

Because results from culture and sensitivity testing of CSF will not be available for >24 hours, empiric therapy must be instituted promptly to provide coverage of potential pathogens. The initial antimicrobial regimen should take into consideration the patient's age, any predisposing conditions that might make the patient vulnerable to increased morbidity and mortality, results from the CSF Gram stain, history of allergy, and the presence of organ dysfunction. Table 58-5 gives recommendations for empiric antimicrobial therapy for acute bacterial meningitis.^{4,6,20,22,39,40,54–56}

S.C. is 5 years of age and has a negative CSF Gram stain. Therefore, therapy with a third-generation cephalosporin, such as ceftriaxone (Rocephin) or cefotaxime (Claforan), is preferred. Either of these two agents will provide excellent coverage of the most likely pathogens in this age group (*S. pneumoniae* and *N. meningitidis*).^{19,20,56} Of these two pathogens, S.C.'s rash suggests that *N. meningitidis* is likely.³⁹ *H. influenzae* is not very likely because he was vaccinated against Hib. Thus, initiation of ceftriaxone would be appropriate for S.C. at this time.

Use of a cephalosporin in this case is appropriate even though S.C. may be allergic to amoxicillin (history of skin rash). Patients with penicillin allergy carry a 5% to 12% risk of cross-reactivity when cephalosporins are prescribed.⁵⁷ In this setting, the type of reaction to penicillin is important to consider.⁵⁷ Patients with a history of accelerated hypersensitivity reactions (e.g., hives, shortness of breath [SOB], or anaphylaxis) to penicillins should not be given cephalosporins because the risk of cross-reactivity is too high. Conversely, a benign skin rash would not contraindicate use of a cephalosporin. If S.C. had experienced an accelerated reaction to penicillin, vancomycin plus aztreonam would be the best alternative choice (Table 58-5).^{4,6,22}

Dosing Considerations

In general, therapy of meningitis requires the use of high dosages of antimicrobials administered by the IV route. Table 58-6 lists the recommended dosing regimens for the treatment of CNS infections.^{4,6,8,14,54,56,58}

S.C. should receive ceftriaxone in a dosage of 100 mg/kg/day given in one or two doses.^{6,55,56} A ceftriaxone regimen of 1,000 mg IV Q 12 hours is reasonable for S.C. The elimination half-life of ceftriaxone is long (usually 6–8 hours), and once-daily dosing is feasible. Many clinicians, however, prefer to administer ceftriaxone on a twice-daily schedule^{4,56} because most published trials used the twice-daily regimen

Table 58-6 Suggested Antibiotic Dosing Regimens for Treatment of Central Nervous System Infections

| Antibiotic | Daily Dose ^a | | | Dosing Interval (hr) | |
|------------------------|----------------------------|---------------------------|--|----------------------|-----------------|
| | Neonates ^b | Children | Adults | Neonates | Children/Adults |
| Penicillins | | | | | |
| Ampicillin | 100–200 mg/kg | 200–300 mg/kg | 12 g | 8–12 | 4–6 |
| Nafcillin | 100–150 mg/kg | 150–200 mg/kg | 12 g | 8–12 | 4–6 |
| Penicillin G | 0.1–0.2 million units/kg | 0.15–0.2 million units/kg | 20–24 million units | 8–12 | 4–6 |
| Meropenem | 20 mg/kg | 120 mg/kg | 6 g | 8–12 | 8 |
| Cephalosporins | | | | | |
| Cefotaxime | 100–150 mg/kg | 200–300 mg/kg | 12 g | 9–12 | 4–6 |
| Ceftizoxime | 100–150 mg/kg | 200 mg/kg | 12 g | 8–12 | 6–8 |
| Ceftriaxone | NR | 100 mg/kg | 4 g | — | 12–24 |
| Cefazidime | 100–150 mg/kg | 150–200 mg/kg | 8–12 g | 8–12 | 6–8 |
| Cefepime | 100 mg/kg | 150 mg/kg | 6 g | 1–2 | 8 |
| Aminoglycosides | | | | | |
| Gentamicin | 5–7.5 mg/kg ^{d,e} | — | 5–6 mg/kg ^{d,e} | 12 | 8–12 |
| Tobramycin | 5–7.5 mg/kg ^{d,e} | — | 5–6 mg/kg ^{d,e} | 12 | 8–12 |
| Amikacin | 15–30 mg/kg ^{d,e} | — | 15–25 mg/kg ^{d,e} | 12 | 8–12 |
| Chloramphenicol | NR | 75–100 mg/kg | 4–6 g | — | 6 |
| Metronidazole | — | 30 mg/kg | 1.5–2 g | — | 6–8 |
| TMP-SMX | — | 12–15 mg/kg ^f | 12–15 mg/kg ^f | — | 8 |
| Vancomycin | 20–30 mg/kg | 40–60 mg/kg ^g | 2–3 g ^g or 20–30 mg/kg ^g | 12 | 8–12 |

^aRecommended daily dose when renal and hepatic functions are normal.
^bInfants <1 month of age; lower end of dosage range applies to neonates <7 days of age.
^cConcurrent intraventricular doses of 5–10 mg (gentamicin, tobramycin), or 20 mg (amikacin) often required when treating gram-negative bacillary meningitis.
^dDose should be individualized based on serum level monitoring.
^eConcurrent intraventricular therapy not recommended for neonatal meningitis.
^fDose is based on the trimethoprim component.
^gConcurrent intraventricular doses of 5–20 mg recommended if response to intravenous therapy is inadequate.
 NR, not recommended.

and such a schedule reduces the potential for prolonged periods of subtherapeutic CSF concentrations if a dose is delayed or missed.⁴ Nevertheless, the U.S. Food and Drug Administration (FDA) has approved the use of the once-daily dosing regimen of ceftriaxone for treatment of pediatric meningitis.⁵⁹

Adjunctive Corticosteroid Therapy

4. What is the rationale for adjunctive corticosteroid therapy in acute bacterial meningitis, and would it be appropriate for S.C.? How should dexamethasone be dosed and monitored for S.C.?

Corticosteroids, particularly dexamethasone, can reduce cerebral edema and lower intracranial pressure.⁶⁰ Before 1988, however, studies that evaluated the efficacy of corticosteroids in bacterial meningitis failed to demonstrate any beneficial effects.^{61,62} These studies were not designed very well, and importantly, hearing loss was not a routinely monitored complication. Given the recent elucidation of the pathophysiologic mechanisms of meningeal inflammation and the important role of cytokine mediators in this process, attention has been refocused on adjunctive corticosteroid therapy for meningitis.

The rationale for steroid therapy in meningitis stems from the fact that steroids reduce the synthesis and release of the

proinflammatory cytokines TNF- α and IL-1 β from monocytes and astrocytes.^{3–5} These two cytokines play a central role in initiating the cascade of events that lead to neuronal tissue damage and neurologic sequelae. Early use of steroids now has been shown in several studies to reduce neurologic complications, particularly sensorineural hearing loss.^{5,63–66}

Despite these studies, controversy remains regarding the efficacy and safety of adjunctive dexamethasone therapy in the treatment of bacterial meningitis. Several prospective placebo-controlled, randomized trials have demonstrated that adjunctive dexamethasone therapy significantly reduces audiologic and neurologic sequelae in children >2 months of age. *H. influenzae*, however, was the causative pathogen in most of these meningitis cases, whereas the number of children with streptococcal and meningococcal meningitis in these trials was small.^{5,63–67} As previously mentioned, the number of Hib cases has decreased dramatically in recent years and the rate of resistant streptococci has increased, making the data from these trials difficult to apply to other pathogens. In one small study, 29 of 56 children were randomized to receive dexamethasone for the management of pneumococcal meningitis.⁶⁸ Few audiologic and neurologic sequelae were observed in the dexamethasone-treated group compared with the placebo group, but the difference did not reach statistical significance.⁶⁸

Other studies have demonstrated the critical importance of the timing of dexamethasone dosing with respect to antimicrobial therapy. Significant differences in outcome have been observed when dexamethasone was given only before or at the time of administration of the first dose of parenteral antibiotic, as opposed to several hours after antibiotic administration.^{5,67}

A meta-analysis by McIntyre et al.⁵ was designed to address important issues regarding the concomitant use of dexamethasone, including the value of dexamethasone for organisms other than Hib, the importance of the nature and timing of antibiotic therapy, the effect of dexamethasone on neurologic deficits other than hearing loss, and the frequency of adverse events. Eleven randomized studies published between 1988 through 1996 were eligible for this analysis. One of the most significant findings of this analysis was that the administration of dexamethasone significantly reduced severe hearing loss in Hib meningitis. In pneumococcal meningitis, severe hearing loss was reduced in patients who received dexamethasone early (with or before parenteral antibiotics).⁵ Significant variation was seen in hearing loss, depending on the causative pathogen. In patients with meningococcal meningitis, only 1 child of 61 randomized to dexamethasone and none of the 50 controls had severe hearing loss. Although the efficacy of shorter treatment duration has not been extensively studied, similar outcomes were observed with 2 versus 4 days of therapy. Although not statistically significant, a trend was noted toward less gastrointestinal (GI) bleeding in patients who were treated for only 2 days compared with patients who received 4 days of therapy (0.8% vs. 3.0%, respectively).⁵

These studies, taken together, provide convincing evidence for the beneficial effects of adjunctive dexamethasone therapy. The risks associated with short-term steroid therapy are low and are far outweighed by the benefit of a reduction in neurologic complications. Therefore, children with bacterial meningitis should receive concomitant dexamethasone therapy.^{2,4,63}

Thus, S.C. should receive dexamethasone therapy, 0.15 mg/kg/dose given IV Q 6 hours for 2 to 4 days. For S.C., who is 20 kg, this would be 3 mg Q 6 h, with the first dexamethasone dose given 15 minutes before initiating ceftriaxone therapy.

The benefit of corticosteroid therapy in adults has recently been studied in a prospective, randomized, double-blind multicenter trial.⁶⁹ A total of 301 patients with acute bacterial meningitis were randomized to receive dexamethasone or placebo 15 to 20 minutes before or with the first dose of antibiotic every 6 hours for 4 days. Dexamethasone reduced the risk of unfavorable outcome, defined as a Glasgow Coma Scale score of 1 to 4 at 8 weeks (relative risk, 0.59; $P = 0.03$), and of death (relative risk, 0.48; $P = 0.04$). Among the patients with pneumococcal meningitis, 26% in the dexamethasone group and 52% in the placebo group had unfavorable outcomes (relative risk, 0.5; $P = 0.06$). Although this was not statistically significant, patients with pneumococcal meningitis appeared to receive the most benefit from steroids. Neither GI bleeding nor other adverse effects were increased in the dexamethasone group.

In addition, in a recent Cochrane review of this topic,⁷⁰ treatment with corticosteroids was associated with reduced mortality and neurologic sequelae in adults. Regardless of the pathogen or clinical severity of illness, dexamethasone should be continued for 4 days in patients with bacterial

meningitis.^{31,70,71} For such patients, the risk of neurologic complications is much greater than the potential for adverse drug effects. In some adults, such as those with septic shock and adrenal insufficiency with suspected meningitis, adjunctive dexamethasone may be harmful, however.³¹ The data evaluating patients with septic shock and meningitis are lacking, therefore, dexamethasone cannot be recommended. Although the use of low doses of hydrocortisone 50 mg every 6 hours or fludrocortisone 50 mcg daily seems reasonable.³¹

Potential adverse effects associated with dexamethasone include GI bleeding, mental status changes (e.g., euphoria or encephalopathy), increases in blood glucose, and possibly elevations in blood pressure.^{5,60–65} For S.C., the complete blood count (CBC), serum chemistries, and stool guaiac should be monitored daily while he is receiving dexamethasone. He also should be questioned about possible GI upset and assessed for changes in mental status (e.g., confusion, combativeness). Given the short duration of corticosteroid therapy, dexamethasone can be discontinued abruptly without tapering after 2 days.

Effect on Central Nervous System Penetration of Antibiotics

Another important issue to consider is whether dexamethasone, a potent anti-inflammatory agent, reduces the ability of some antimicrobials (e.g., the β -lactams) to penetrate across the blood–brain barrier into CSF. Because CSF penetration of the penicillins, cephalosporins, and other β -lactams is greatest when the meninges are inflamed, a hypothetical concern is that concomitant dexamethasone may reduce CSF concentrations of these agents, resulting in reduced efficacy. Data to support or refute this hypothesis are limited. In animal models of pneumococcal meningitis, vancomycin penetration into the CSF was reduced in dexamethasone-treated animals compared with animals not treated with steroids.^{72–74} Unlike vancomycin, ceftriaxone penetration was not reduced in these animal models. Decreased bactericidal activity, however, was reported with cephalosporin- and penicillin-resistant *S. pneumoniae* isolates. Furthermore, only the combination of ceftriaxone and rifampin sterilized the CSF when dexamethasone was given in cases of highly resistant strains of *S. pneumoniae*.⁷³ In another cephalosporin-resistant pneumococcal meningitis animal model, dexamethasone did not decrease ceftriaxone levels in the CSF, but concomitant use of dexamethasone resulted in a higher number of failures owing to decreased bacterial killing and bactericidal effect.⁷⁵ Although McIntyre et al. did not directly measure antibiotic concentrations in the CSF, they did not observe any significant differences in CSF bactericidal activity (a test in which CSF is serially diluted and tested for activity against the infecting pathogen) in steroid-treated versus placebo-treated children.⁵ Furthermore, children given dexamethasone had similar, if not better, clinical responses (e.g., shorter duration of fever) than placebo controls,⁵ and the rate of CSF sterilization did not differ.^{5,63,65} A recent study evaluated vancomycin levels in CSF in 14 adult patients receiving adjunctive corticosteroids to treat pneumococcal meningitis.⁷⁶ Vancomycin was administered by continuous infusion at 60 mg/kg/day. In this small observational study, vancomycin concentrations in the CSF were therapeutic even in the setting of dexamethasone.⁷⁶ Therefore, based on current evidence, vancomycin penetration into CSF does not appear to be reduced by dexamethasone administration

in children, but decreased penetration of vancomycin is observed in adults.^{67,72,73} In a rabbit meningitis model, the coadministration of dexamethasone and vancomycin resulted in 29% less penetration of vancomycin into the CSF. By increasing the daily dose of vancomycin in these rabbits, therapeutic CSF levels were achieved, however, suggesting that giving larger daily doses of vancomycin circumvents the steroid effect on CNS penetration.⁷⁷ Currently, it is unknown whether the decreased penetration of antibiotics secondary to dexamethasone administration is of clinical significance, especially in this era of penicillin- and cephalosporin-resistant pneumococcal isolates.^{51,67} In adults receiving concomitant dexamethasone, experts suggest using the combination of ceftriaxone, vancomycin, and rifampin.^{46,67}

Neisseria meningitidis Meningitis

Definitive Therapy

5. Twenty-four hours after admission, S.C.'s culture results from his blood and CSF samples are available. The CSF culture is growing * *N. meningitidis* (penicillin MIC 0.06), also present in both of the two collected blood cultures. What modification in S.C.'s antimicrobial therapy is necessary at this time?

Once culture and sensitivity results become available, definitive therapy can be instituted, often with a single agent (Table 58-7).^{4,6,33–35,56} As suspected, S.C.'s CSF culture is positive for *N. meningitidis*. Cefuroxime, a second-generation cephalosporin, also has activity against *N. meningitidis*. How-

ever, cefuroxime is less effective for meningitis than third-generation cephalosporins.^{78,79} In a prospective, randomized trial involving 106 children with acute bacterial meningitis, 12% of the patients receiving cefuroxime had positive CSF cultures after 18 to 24 hours versus 2% of those who received ceftriaxone ($p = 0.11$), and 17% of cefuroxime-treated patients developed moderate to severe hearing loss compared with only 4% of those receiving ceftriaxone ($p = 0.05$).⁷⁸ Nearly identical findings to these also were noted in a retrospective analysis of four comparative trials of children treated with cefuroxime (159 patients) and ceftriaxone (174 patients) for bacterial meningitis.⁷⁹ The reason for the inferiority of cefuroxime relative to ceftriaxone most likely is related to reduced potency and the presence of an inoculum effect (described earlier).⁴⁷

Because *N. meningitidis* is susceptible to penicillin and ampicillin currently, penicillin is the drug of choice. However, S.C.'s questionable history of amoxicillin rash makes the use of penicillin worrisome, and therapy previously begun with ceftriaxone should be continued.

Monitoring Therapy

6. What subjective and objective data should be monitored to evaluate the efficacy and toxicity of treatment of patients with meningitis, and what specifically should be monitored in S.C.?

Monitoring of patients with meningitis is similar in many respects to monitoring patients with other infectious diseases. Clinical signs and symptoms attributable to the disease, such as fever, altered mental status, and stiff neck, need to be checked

Table 58-7 Definitive Therapy for Bacterial Meningitis

| Pathogen | Recommended Treatment | Alternative Agents |
|---|---|--|
| <i>Haemophilus influenzae</i> | | |
| β-Lactamase-negative | Ampicillin | Cefotaxime or ceftriaxone |
| β-Lactamase-positive | Cefotaxime or ceftriaxone | Chloramphenicol |
| <i>Neisseria meningitidis</i> | Penicillin G or ampicillin | Cefotaxime or ceftriaxone or chloramphenicol |
| | Penicillin-sensitive ^a : Penicillin G or ampicillin | |
| <i>Streptococcus pneumoniae</i> | Intermediately penicillin-resistant ^d : Vancomycin + cefotaxime or ceftriaxone ^e | Cefotaxime or ceftriaxone or chloramphenicol |
| | Highly penicillin-resistant ^d : Vancomycin + cefotaxime or ceftriaxone ^d ± rifampin | Cefotaxime or ceftriaxone and rifampin |
| <i>Streptococcus agalactiae</i> | Penicillin G or ampicillin + gentamicin | Cefotaxime or ceftriaxone and rifampin |
| <i>Listeria monocytogenes</i> | Ampicillin ± gentamicin | TMP-SMX |
| Enterobacteriaceae | | |
| <i>Escherichia coli</i> , <i>Klebsiella</i> species | Cefotaxime or ceftriaxone | Cefepime + gentamicin ^b |
| <i>Enterobacter</i> , <i>Serratia</i> species | TMP-SMX | Cefepime + gentamicin, ^b or ciprofloxacin, ^c or meropenem, cefepime ^c |
| <i>Pseudomonas aeruginosa</i> | Ceftazidime + tobramycin ^b | Cefepime + tobramycin, or ciprofloxacin, ^c meropenem |
| <i>Staphylococcus aureus</i> | | |
| Methicillin-susceptible (MSSA) | Nafcillin or oxacillin | Vancomycin ^b |
| Methicillin-resistant (MRSA) | Vancomycin ^c ± rifampin | TMP-SMX ^c ± rifampin |
| <i>Staphylococcus epidermidis</i> | Vancomycin ^b ± rifampin | TMP-SMX ^c ± rifampin |

^aPenicillin-sensitive strains defined as having MIC ≤0.1 mcg/mL; intermediately resistant strains MIC >0.1–1.0 mcg/mL; highly resistant strains MIC ≥2.0 mcg/mL.

^bConcomitant intrathecal therapy often required for optimal response.

^cLimited experience or efficacy data for the agent against with this pathogen.

^dCheck cefotaxime or ceftriaxone if MIC ≤0.5; then susceptible in CSF isolates.

MIC, minimum inhibitory concentration; TMP-SMX, trimethoprim-sulfamethoxazole.

periodically throughout the day and monitored for resolution. S.C.'s temperature and mental status should be assessed at least four times a day. Accurate assessment of S.C.'s mental status can be difficult because of his young age. Thus, his baseline level of mental status should be evaluated (e.g., whether he is awake and alert, or lethargic and difficult to arouse). If awake and alert, S.C. should be observed for irritability, because this often is the only sign of altered mentation. Questions can be used to assess his orientation: Does he know where he is? Does he know his name? Can he recognize his mother or other family members? In general, signs of clinical improvement should be evident within 24 to 48 hours for most uncomplicated cases of acute bacterial meningitis,^{5,6,39,78} and the corticosteroid therapy that S.C. is receiving may accelerate the clinical response.^{5,64}

Laboratory tests should be monitored as well. A CBC with differential, serum electrolytes (e.g., Na, K, Cl, HCO₃), blood glucose, and renal function tests (e.g., BUN, SrCr) should be performed daily. Abnormal electrolyte results may require more frequent monitoring. Laboratory abnormalities, such as leukocytosis and hyponatremia, may take longer to normalize than clinical symptoms. If S.C. develops severe SIADH, as manifested by serum sodium values up to 120 mEq/L with altered mental status or seizures, fluid restriction and short-term (i.e., 6–12 hours) IV administration of 3% sodium chloride may be necessary.

Cerebrospinal fluid chemistries usually normalize after several days, although CSF protein may remain elevated for a week or more.^{6,39} With effective therapy, the CSF culture usually is sterile after about 18 to 24 hours of therapy.^{5,64,78} Delays in CSF sterilization are associated with a higher propensity for neurologic complications.^{4,35} If S.C. responds to therapy in a straightforward manner, he need not have a repeat lumbar puncture. If the response is inadequate, as evidenced by persistent fever or deteriorating mental status, S.C. will require a repeat lumbar puncture to re-examine the CSF parameters.^{6,39}

In addition to monitoring the therapeutic response, side effects of the antimicrobial regimen also need to be assessed frequently. Meningitis requires high-dose therapy, making the likelihood of adverse effects much greater. Currently, S.C. is being treated with ceftriaxone, a cephalosporin antibiotic. The adverse effects most often associated with ceftriaxone include hypersensitivity reactions, mild pain and phlebitis at the injection site, and GI complaints.⁸⁰ S.C. should be observed for the formation of an antibiotic-related skin rash or evidence of an accelerated allergic reaction (e.g., hives, wheezing). The IV catheter site should be observed daily for redness, tenderness, or pain on palpation of the vein. S.C. should be watched closely for loose stools or diarrhea. Although diarrhea is a common side effect of most antimicrobials, this adverse effect is more likely to occur with ceftriaxone because approximately 40% to 50% of the dose is excreted unchanged into the bile. Mild diarrhea, which usually does not require discontinuation of therapy, occurs in 23% to 41% of children receiving ceftriaxone for meningitis therapy.^{55,78} Less common but of concern is the potential for antibiotic-associated colitis.^{80,81} If S.C. experiences diarrhea that is persistent, accompanied by fever and abdominal cramping, a stool sample should be tested for *Clostridium difficile* toxin. If positive, oral antibiotic therapy, preferably with metronidazole, should correct the problem (see Chapter 62, Infectious Diarrhea).

Ceftriaxone-Induced Biliary Pseudolithiasis

7. After 5 days of treatment, the nurse caring for S.C. notes that his appetite is markedly diminished, and he complains of an upset stomach. S.C. was afebrile and alert and oriented, but abdominal examination revealed “guarding,” with pain localized in the right upper quadrant area. Laboratory data at this time are WBC count, 6,000 cells/mm³ (normal, 3,200–9,800); Hgb, 12.5 g/dL (normal, 14–19); Hct, 34% (normal, 39%–49%); platelets, 120,000/mm³ (normal, 130,000 to 400,000); Na, 135 mEq/L; K, 3.6 mEq/L; Cl, 98 mEq/L; aspartate aminotransferase (AST), 35 U/L (normal, 0–35); alanine aminotransferase (ALT), 33 U/L (normal, 0–3.5); alkaline phosphatase, 110 MU/dL (normal, 30–120); total bilirubin, 1.2 mg/dL (normal, 0.1–1.0); and amylase 70 U/L. A stool guaiac is negative. What are possible causes of S.C.'s abdominal discomfort?

[SI units: WBC count, 6×10^9 cells/L; Hgb, 125 g/L; Hct, 0.34; platelets, 120×10^9 /L; Na, 135 mmol/L; K, 3.6 mmol/L; Cl, 98 mmol/L; AST, 33 U/L; ALT, 33 U/L; alkaline phosphatase, 110 U/L; total bilirubin, 20.5 μ mol/L; amylase, 70 U/L]

A number of possible causes exist for S.C.'s abdominal discomfort. His corticosteroid therapy may have caused acute GI bleeding. This is unlikely because the dexamethasone was discontinued 3 days ago and S.C.'s hemoglobin and hematocrit values are in the low-normal range. The negative stool guaiac result also argues strongly against a GI bleed. Acute pancreatitis is unlikely given the normal amylase result. Viral or drug-induced hepatitis is another possibility but also is unlikely given his normal AST, ALT, and bilirubin results. An intra-abdominal infection also is possible, but this is improbable because he is afebrile and has a normal WBC count. Other causes, such as acute cholecystitis or appendicitis, require further diagnostic evaluation.

8. An abdominal ultrasound reveals sludge in the gallbladder. What is the significance of this finding in S.C., and how should this abnormality be managed?

The abnormality on S.C.'s abdominal ultrasound explains his right upper quadrant pain. S.C. has what appears to be a condition known as biliary pseudolithiasis (i.e., biliary “sludging”). Biliary sludging can occur in conditions of gallbladder hypomotility (e.g., recent surgery, burns, total parenteral nutrition) and, in some instances, can be drug induced. S.C. has been receiving ceftriaxone for treatment of his meningitis, and this drug can cause biliary pseudolithiasis.^{82–85}

Antibiotic-associated biliary pseudolithiasis is seen almost exclusively with ceftriaxone.⁸⁰ The predominance of biliary excretion that occurs with ceftriaxone results in very high concentrations of the drug in gallbladder bile.⁸² In selected circumstances, the biliary concentration of ceftriaxone may exceed solubility limits, resulting in formation of a fine, granular precipitate (i.e., sludge),⁸² which differs in composition and ultrasound features from true gallstones.^{78,83} The precipitate is composed of a ceftriaxone–calcium complex, the formation of which is dose dependent.^{82,84} Given the high dosages required for meningitis therapy, it is not surprising that this adverse effect has occurred in S.C.^{78,83} In the comparative randomized trial between ceftriaxone and cefuroxime cited previously,

evidence of biliary pseudolithiasis on abdominal ultrasonography was observed in 16 of 35 (46%) patients who received ceftriaxone and in none of 35 patients receiving cefuroxime.⁷⁸ Pseudolithiasis usually appears 3 to 10 days following the start of therapy and, in most instances, it is clinically asymptomatic. Symptoms similar to acute cholecystitis are evident in some individuals and include nausea with or without vomiting and abdominal right upper quadrant pain. Although he has not vomited yet, S.C.'s symptoms fit this description. Approximately 10% to 20% of patients with evidence of biliary sludging on ultrasound are symptomatic.^{83,85}

Prompt recognition of this adverse effect and discontinuation of ceftriaxone therapy are required to effectively manage biliary pseudolithiasis. Before this complication was recognized, a few patients underwent cholecystectomies, but this intervention is rarely necessary because the condition nearly always is reversible. Once S.C.'s ceftriaxone is discontinued, the condition should resolve gradually over a period of weeks to months; the clinical symptoms should disappear within a few days.^{83,85} Cefotaxime can be substituted for ceftriaxone; cefotaxime is not associated with biliary complications, and the efficacy of these two agents is equivalent.^{64,80} For S.C., the cefotaxime dosage would be 1,000 mg IV every 6 hours (Table 58-6).

Duration of Therapy

9. What is the recommended duration of antimicrobial therapy for *N. meningitidis* meningitis, and for how long should S.C. be treated?

The optimal duration of therapy for meningitis is difficult to ascertain because few trials have been designed to address this issue.⁸⁶ Although general guidelines exist, the decision to discontinue therapy should be individualized based on the response to therapy, the presence of complicating factors (e.g., immunosuppression), and the specific causative pathogen. Table 58-8 lists the recommended treatment durations for uncomplicated cases of bacterial meningitis according to the specific pathogen.^{6,22,56,58,86} Patients such as S.C. with meningitis caused by *N. meningitidis* should be treated for 7 days.^{22,79} Complicated cases, such as those with delayed CSF sterilization, require therapy for longer periods (up to 2 weeks or more).

S.C. had been responding well to the ceftriaxone therapy, and if he continues to respond well to the cefotaxime regimen outlined previously, there is no need for additional oral antibiotics when he is discharged from the hospital. An oral second- or third-generation cephalosporin cannot be recommended in the treatment of meningitis because insufficient concentrations

are achieved in the CSF. S.C. should be watched carefully for a possible relapse (e.g., the reappearance of signs and symptoms of meningitis), which would require readmission to the hospital for further evaluation and IV antibiotic therapy.

Prevention of *Neisseria meningitidis* Meningitis

10. S.C. is ready to be discharged home. How can the potential spread of meningococcal disease be prevented in persons with whom S.C. has contact?

CHEMOPROPHYLAXIS OF CLOSE CONTACTS

Despite an excellent response to therapy, S.C. still may harbor *N. meningitidis* in his nasopharynx and could transmit this organism to individuals with whom he has close contact.^{88,89} Therefore, chemoprophylaxis to reduce nasopharyngeal carriage of *N. meningitidis* is indicated for S.C. and his close contacts.^{87,89} In this context, close contacts are defined as individuals who frequently sleep and eat in the same dwelling with an index case: a household member, day care center contacts, and any person directly exposed to the patient's oral secretions (e.g., boyfriend or girlfriend, mouth-to-mouth resuscitation, or endotracheal intubation).^{87,89} The potential for a close contact to become infected with *N. meningitidis* is 500 to 800 times greater than for the total population.⁸⁷ S.C.'s 7-year-old brother, who is at risk for invasive *N. meningitidis* disease, should receive chemoprophylaxis. Also, the children at the day care center or close contacts at the hospital who have been caring for S.C. may benefit from chemoprophylaxis. Because the risk of secondary disease is greatest within 2 to 5 days after exposure to the index case, chemoprophylaxis should be instituted as soon as possible and ideally within 24 hours.⁸⁷ Administering chemoprophylaxis 14 days or more after identification of the index case is probably of little value. The most frequently used regimen to reduce nasopharyngeal carriage of *N. meningitidis* for children > 1 month is rifampin, given once daily in a dosage of 10 mg/kg/day for 2 days.^{87,89} A suspension containing 10 mg/mL of rifampin (which requires extemporaneous compounding) is available; 20 mL will provide a 200-mg dose. The index patient should also receive prophylaxis if he or she was treated with penicillin or chloramphenicol as soon as he or she is able to tolerate oral medications. Because S.C. is receiving ceftriaxone, he does not need chemoprophylaxis. For adult close contacts, rifampin 600 mg twice a day for 2 days should be administered. Thus, S.C.'s brother, parents, and day care contacts should be treated with appropriate doses of rifampin as soon as he is diagnosed. Alternative chemoprophylactic regimens shown to be effective for reducing nasopharyngeal carriage of *N. meningitidis* are ceftriaxone 250 mg or 125 mg intramuscularly in adults and children, respectively, and ciprofloxacin 500 mg orally as a single dose in adults. Because rifampin is not recommended for pregnant women, ceftriaxone would be a viable alternative.^{87,89}

Prevention of *Haemophilus influenzae* Type b Meningitis

HIB VACCINATION RECOMMENDATIONS

11. S.C. and his brother were vaccinated for Hib. Are these vaccinations now routinely recommended?

Yes. S.C. appropriately received one of the Hib protein conjugate vaccines when he was 2 months of age.⁹¹ Given the tremendous success that conjugated Hib vaccines have had on

Table 58-8 Duration of Therapy for Bacterial Meningitis

| Etiology | Duration of Therapy (0 days) |
|--|------------------------------|
| <i>Haemophilus influenzae</i> | 7 |
| <i>N. meningitidis</i> | 7 |
| <i>Streptococcus pneumoniae</i> | 10–14 |
| Group B streptococci (<i>Streptococcus agalactiae</i>) | 14–21 |
| <i>Listeria monocytogenes</i> | 14–21 |
| Gram-negative bacilli | 21 |

Table 58-9 Recommended Vaccination Schedule for *Haemophilus influenzae* Protein Conjugated Vaccines

| Vaccine (Trade Name) | Schedule | | | | |
|----------------------|----------|----------|----------|-----------|-----------|
| | 2 Months | 4 Months | 6 Months | 12 Months | 15 Months |
| HbOC (HibTITER) | Dose 1 | Dose 2 | Dose 3 | — | Booster |
| PRP-T (ActHIB) | Dose 1 | Dose 2 | Dose 3 | — | Booster |
| PRP-OMP (PedvaxHIB) | Dose 1 | Dose 2 | — | Booster | — |

reducing the incidence of Hib meningitis in the United States, all children >2 months of age should receive the vaccination series with one of the three commercially available products.⁹¹ HbOC (HibTITER) is a product that links polyribosylribitol phosphate (PRP), the antigen derived from Hib purified capsular polysaccharide, with a carrier protein (CRM₁₉₇) derived from a mutated variant of the diphtheria toxin protein, whereas PRP-OMP (PedvaxHIB) links PRP with the outer membrane complex protein of *N. meningitidis*.^{87,90} The third product, PRP-T (ActHIB), is a PRP–tetanus toxoid conjugate. The linkage of PRP with a carrier protein is necessary to elicit an adequate immune response in children <15 months of age.^{87,91} HbOC and PRP-OMP have been licensed since 1988 and 1989, respectively. In 1990, both products received FDA approval for use in infants 2 months of age or older. PRP-T was approved for use in infants 2 months of age or older by the FDA in early 1993. All three of these conjugate vaccines are equally effective.^{25,26,90,91} Table 58-9 outlines the vaccination schedule for HbOC, PRP-OMP, and PRP-T as recommended by the Centers for Disease Control and Prevention Advisory Committee on Immunization Practices.⁹⁰ In general, the vaccines are well tolerated; fever, redness, and swelling at the injection site are the most common adverse effects and occur in <4% of patients.^{26,89,91}

Neisseria meningitidis VACCINATION RECOMMENDATIONS

12. A 21-year-old college student who lives in a dormitory dies of *N. meningitidis* meningitis. Two additional cases are diagnosed in students living in the same dormitory. Should all individuals living in the dormitory be vaccinated? What are the current recommendations for the use of meningococcal vaccine?

Neisseria meningitidis is responsible for causing both outbreaks (clusters of cases) as well as epidemics. Currently, two meningococcal vaccines are available in the United States. MPSV4 or Menomune, a quadrivalent (Men A,C,Y,W-135) polysaccharide vaccine, has been available for over 25 years and is approved for all age groups. Meningococcal conjugate vaccine (MCV4 or Menactra) was approved in January 2005 for use in persons 11 to 55 years of age. Unlike MPSV4, the new vaccine elicits a more durable initial antibody response and it will also reduce nasopharyngeal carriage. Meningococci serogroups A, B, and C are responsible for causing >90% of cases. After vaccination, protective levels of antibody are usually achieved within 7 to 10 days. Neither vaccine has activity against meningococci serogroup B.^{87–89}

With the advantages of the second vaccine, the Advisory Committee on Immunization Practices (ACIP) of the CDC extensively revised its recommendations for use of meningococcal vaccines. ACIP recommends routine vaccination of young

adolescents (age 11 to 12 years) with MCV4.⁸⁹ If persons have not received the vaccine before entering high school, ACIP recommends vaccination before high-school entry. By 2008, all adolescents, beginning at the age of 11 years, will have routine vaccination with MCV4. In addition, routine vaccination with meningococcal vaccine is recommended for college freshman living in dormitories and for other populations at increased risk (i.e., military recruits, travelers to areas in which meningococcal disease is hyperendemic or epidemic, microbiologists who are routinely exposed to meningococcal isolates, patients with anatomic or functional asplenia and patients with terminal complement deficiency).^{88,89} Therefore, all students living in the dormitory should be vaccinated. Other college students may elect to receive vaccination as well.

Streptococcus pneumoniae Meningitis

Clinical Features, Predisposing Factors, and Diagnosis

13. A.L., a 58-year-old man with a long history of alcohol abuse, is admitted to the ED febrile and unresponsive. Over the past several days, A.L. has experienced intermittent episodes of fever, chills, SOB, and a worsening productive cough. A friend visiting A.L. called 911 when he could not arouse him. A.L.'s medical records indicate that he has hypertension, adult-onset diabetes mellitus, peptic ulcer disease (PUD), and chronic obstructive airways disease (COAD). A splenectomy was performed 10 years ago after trauma to the abdomen. A.L. is divorced and lives alone in a low-income apartment. He has no known drug allergies. His records show him to be a smoker for >30 years. Current medications include hydrochlorothiazide 50 mg QOD, sustained-release theophylline (Theo-Dur) 300 mg PO TID, glipizide 5 mg PO BID, famotidine 20 mg PO HS, and ciprofloxacin 250 mg PO BID PRN for cough and increased sputum production.

On admission to the ED, A.L. had a temperature of 40°C, BP of 90/50 mmHg, and pulse and respiratory rates of 115 beats/minute and 25 breaths/min, respectively. His weight is 59 kg. A.L. was unresponsive but withdrew all extremities to painful stimuli. His pupils were equal and sluggishly reactive to light; papilledema and evidence of meningismus were present. Wheezes and crackles were heard throughout both lung fields, with dense consolidation noted in the left lower lobe. The remainder of his physical examination was noncontributory.

Stat laboratory tests revealed a WBC count of 18,000 cells/mm³ (normal, 3,200–9,800), with 80% PMN, 15% bands, 3% lymphocytes, and 2% basophils; Hgb and Hct of 10.5 g/dL (normal, 14–18) and 34% (normal, 39–49%), respectively; and a platelet count of 250,000/mm³ (normal, 130,000–400,000). Serum chemistries were significant for K, 3.0 mEq/L (normal, 3.5–5.0); glucose, 250 mg/dL (normal, 70–110); AST and ALT, 190 mg/dL (normal, 0–35) and 140 mg/dL (normal, 0–3.5), respectively; BUN,

35 mg/dL (normal, 8–18); and SrCr, 2.4 mg/dL (normal, 0.6–1.2). The prothrombin time was high-normal, and albumin was 3.1 mg/dL (normal, 4–6). A stat blood alcohol level of 100 mg/dL was reported, and a urine toxicology screen was negative. A.L.'s serum theophylline concentration was 18 mg/dL. Stool guaiac was positive.

A CT scan showed no evidence of mass lesions or cerebral hematoma. Lumbar puncture yielded CSF opening pressure, 200 mmHg (normal, <20); protein, 120 mg/dL (normal, <50); glucose, 100 mg/dL (normal, 60% of plasma glucose); WBC count, 8,500 cells/mm³ (normal, <5 cells/mm³), 92% PMN, 4% mononuclear cells, and 4% lymphocytes; and RBC count, 400/mm³. Gram-positive, lancet-shaped diplococci were visible on CSF Gram stain. In addition, a sputum Gram stain revealed numerous WBC, few epithelial cells, and numerous gram-positive cocci in pairs and in short chains. Blood, CSF, urine, and sputum cultures are pending.

What are the clinical and laboratory features of pneumococcal meningitis? What features of pneumococcal meningitis are present in A.L.?

[SI units: WBC count, 18×10^9 cells/L with 0.8 PMN, 0.15 bands, 0.03 lymphocytes, and 0.02 basophils; Hgb, 105 g/L; platelets, 250×10^9 /L; K, 3.0 mmol/L; glucose, 13.9 mmol/L; BUN, 12.5 mmol/L urea; SrCr, 212 mmol/L; glucose, 5.5 mmol/L; WBC count, $8,500 \times 10^6$ cells/L; RBC count, 400×10^6 /L]

A.L. presents to the ED with many signs and symptoms suggestive of pneumococcal meningitis. He is 56 years of age, and *S. pneumoniae* is the most common bacterial etiology for meningitis in adults >30 years of age (Table 58-1).^{19,20} As is evidenced by A.L.'s presentation, invasive pneumococcal disease often is associated with significant morbidity, and mortality rates remain high.²⁰ Over the past several years, the incidence of *S. pneumoniae* meningitis in the United States has consistently ranged between 1.2 and 2.8 cases per 100,000 population per year.^{19,20,25} Predisposing factors to invasive pneumococcal disease include advanced age, alcoholism, chronic pulmonary disease, and sickle cell disease.^{6,39,87} In addition, individuals infected with the human immunodeficiency virus (HIV), those with Hodgkin's disease, and patients who have undergone kidney, liver, or bone marrow transplantation also appear to be at higher risk.^{6,88,92,93} Patients with CSF otorrhea or rhinorrhea induced by closed head trauma or neurosurgical procedures are more susceptible to develop pneumococcal meningitis as well.^{20,87,93}

A.L. has many predisposing factors for pneumococcal meningitis. He has a low socioeconomic status, smokes, has a long history of alcohol abuse, has had a splenectomy, and has diabetes and COAD. Underlying COAD is an important predisposing factor in that chronic colonization with pneumococci occurs in such patients. Intermittent use of ciprofloxacin by A.L. for acute exacerbations of COAD is unjustified. The poor activity of this antibiotic against *S. pneumoniae* is likely to select out this organism for infection. Furthermore, ciprofloxacin can increase serum theophylline concentrations by inhibiting its metabolism, another important reason why this agent is not a good therapeutic choice for productive cough in A.L.⁹⁴

A diagnosis of pneumococcal meningitis in A.L. is supported by the high fever, stiff neck (meningismus), and altered mental status. He is unresponsive, which is a definite nega-

tive prognostic factor.^{1,6} Results from CSF chemistries and microbiologic analysis are highly suggestive of pneumococcal meningitis. A.L. has an elevated opening CSF pressure and a markedly elevated CSF protein and WBC count with a predominance of neutrophils on differential examination. The normal CSF glucose level (100 g/dL) is misleading because A.L. is diabetic. The calculated ratio of CSF-to-serum glucose for A.L. is <50%, which is consistent with acute bacterial meningitis (Table 58-3). The presence of gram-positive, lancet-shaped diplococci in pairs on the CSF Gram stain strongly supports the diagnosis of pneumococcal disease. The signs and symptoms of pneumococcal pneumonia (cough, SOB, increased sputum production, and pulmonary consolidation) as well as the sputum Gram stain result also lend support to a diagnosis of invasive pneumococcal infection.

Empiric Therapy in Adults

14. What empiric therapy is appropriate for A.L. at this time?

Resistance among pneumococci to penicillin G has become an important concern worldwide and in the United States.^{2,29,96} For this reason, susceptibility testing should be performed on all pneumococcal isolates obtained from sterile sites (e.g., blood, CSF).^{2,95} For treatment of meningitis caused by strains intermediately resistant to penicillin, ceftriaxone and cefotaxime are the most useful agents because many of these isolates retain cephalosporin sensitivity.^{2,8,95} Management of invasive pneumococcal infections in sites other than CSF (e.g., lungs, bloodstream) usually can be accomplished by increasing the dose of penicillin G to 20 to 24 million units/day. This approach is not possible with meningitis caused by intermediately resistant strains because further increases in the penicillin dose are likely to produce unacceptable neurotoxicity. Vancomycin and chloramphenicol are potential options, but relapses and clinical failures have been reported with both of these agents when given alone.^{95,96,97} Many penicillin-resistant pneumococcal isolates also are resistant to chloramphenicol (defined as an MIC >4 mcg/mL), and even against susceptible isolates, chloramphenicol may fail to elicit a bactericidal effect.² Third-generation cephalosporins cannot be relied on for treatment of meningitis caused by strains fully resistant to penicillin (MIC ≥ 2.0 mcg/mL) because reduced cephalosporin sensitivity often occurs (MIC range from 2–8 mcg/mL to both cefotaxime and ceftriaxone). *S. pneumoniae* strains in CSF with MIC >0.5 mcg/mL to cefotaxime or ceftriaxone are considered resistant.⁹⁸ Reduced activity of ceftriaxone and cefotaxime against penicillin-resistant pneumococci affects the therapeutic ratio achieved in CSF and is the likely explanation for reports of clinical failure.⁹⁵ Optimal therapy for fully penicillin-resistant pneumococcal meningitis is unclear. Vancomycin alone in high dosage (3–4 g/day in adults) has been suggested.^{2,95,96} The combination of vancomycin and ceftriaxone was superior to either agent given alone in a rabbit model of penicillin-resistant pneumococcal meningitis.⁹⁹ Ceftriaxone or vancomycin combined with rifampin also may be superior to either drug given alone.^{95,96} Animal data suggest that the use of rifampin reduces early mortality in pneumococcal meningitis by reducing the release of proinflammatory bacterial cell components.¹⁰⁰ Thus, until more information is available, the combination of ceftriaxone or cefotaxime with vancomycin

represents the most reasonable approach to empiric therapy for potential penicillin-resistant pneumococcal meningitis.

Until culture and susceptibility results are available, the recommended antibiotic in this situation is ceftriaxone 2 g given IV Q 12 h and vancomycin 500 mg given IV Q 12 h. A.L. weighs 59 kg, and because his renal function is not normal (SrCr, 2.4 mg/dL; creatinine clearance, 30 mL/minute), a dosage adjustment was made. (See Question 23 for vancomycin dosing in CNS infections.)

Corticosteroid Therapy for Adult Meningitis

15. Should A.L. receive corticosteroid therapy in addition to his antibiotic therapy?

The issue of adjunctive corticosteroid therapy for A.L. needs to be addressed. As previously stated, the efficacy of dexamethasone in adults with meningitis has recently been studied.⁶⁹ Clearly, A.L. presents with profoundly altered mental status, and his signs and symptoms are consistent with a fulminant course of disease. Given that he is unarousable, hypotensive, and tachycardic, A.L. likely will be admitted to the intensive care unit. Thus, his age, underlying medical problems, likely streptococcal meningitis, and deteriorating clinical status all point to a poor prognosis and argue for the use of adjunctive dexamethasone. On the other hand, A.L. is diabetic and has an elevated glucose concentration. He also has PUD, which may be active given that he is anemic and has a positive stool guaiac result. High-dose dexamethasone therapy may cloud A.L.'s sensorium, making mental status assessment even more difficult. Although each of these issues is a concern, none appears to be so critical as to preclude the use of corticosteroids.⁶⁹ Therefore, dexamethasone given in a dosage of 10 mg IV Q 6 h could be instituted before starting ceftriaxone therapy and continued for up to 4 days, provided that the diagnosis of bacterial meningitis is confirmed. If corticosteroids are administered, the addition of rifampin to ceftriaxone is recommended.⁴⁶ To control blood glucose, a sliding-scale dosing schedule of regular insulin is recommended. A.L.'s PUD should be properly worked up and treated if necessary.

Treatment of Penicillin-Susceptible Pneumococcal Meningitis

16. Results from A.L.'s CSF, blood, and sputum cultures are available and are positive for *S. pneumoniae* at each site. Sensitivity testing in CSF revealed an MIC of 0.06 mcg/mL to penicillin, 0.25 mcg/mL to cefotaxime and ceftriaxone, 0.25 mcg/mL to vancomycin, and 8 mcg/mL to chloramphenicol. What therapy is indicated for A.L.?

A.L. has become infected with a strain of *S. pneumoniae* that is susceptible to penicillin G (Table 58-5).^{4,6,39} The dosage usually is 20 to 24 million units/day in adults with normal renal function (Table 58-6). A.L. has renal impairment, however, which means he should receive a reduced penicillin dosage. One of the most useful methods for calculating the dose of penicillin G when renal function is compromised is the following equation¹⁰¹:

$$\text{Dose (in million units/days)} = (\text{Calculated creatinine clearance}/7) + 3.2$$

This equation should be used only when the calculated creatinine clearance is <40 mL/minute.¹⁰¹ For A.L., who has a

calculated creatinine clearance of 30 mL/minute (according to the method of Cockcroft and Gault), the daily dose would be approximately 8 million units, or 2 million units Q 6 hours. This revised regimen should provide penicillin serum concentrations similar to those achieved with high-dose therapy when kidney function is normal. Failure to adjust the dosage appropriately is equivalent to providing massive doses of penicillin, which may result in hyperkalemia (if the potassium-containing preparation is used), seizures, and encephalopathy.¹⁰¹

In patients unable to tolerate penicillin G, the best alternatives are ceftriaxone or cefotaxime (Table 58-5).^{4,6} First-generation cephalosporins (e.g., cefazolin) have good activity against pneumococci, but their limited CSF penetration makes these agents poor choices for therapy.^{45,52} Conversely, the third-generation agent, ceftazidime, penetrates well into CSF, but its usefulness is limited by reduced activity against pneumococci in comparison to other third-generation agents.^{50,52} Cefuroxime also has good pneumococcal activity but, as previously mentioned, is inferior to ceftriaxone and cefotaxime.⁷⁸ Vancomycin has more limited and variable CSF penetration.^{45,102} Therefore, vancomycin should be reserved for situations in which there is bacterial resistance or penicillin intolerance. TMP-SMX has excellent CSF penetration characteristics but is not active against many strains of *S. pneumoniae*. Limited experience exists with this product for the treatment of pneumococcal meningitis, however.^{45,103}

Prevention of Meningitis

17. Should A.L. have received pneumococcal vaccine? How effective is vaccination in preventing invasive pneumococcal disease?

Yes, he should receive this vaccine. The pneumococcal vaccine (Pneumovax 23, Pnu-Immune 23) provides protection against invasive pneumococcal disease.^{87,89,93} The vaccine is composed of purified capsular polysaccharide antigens of 23 serotypes of *S. pneumoniae*, which are responsible for causing approximately 88% of the bacteremic pneumococcal disease in the United States.^{87,93} Individuals such as A.L. who are at high risk for pneumococcal infection should be given the vaccine. Persons with chronic cardiopulmonary diseases, diabetes, alcoholism, cirrhosis, CSF leaks, and asplenia, and those >65 years of age should be vaccinated with the pneumococcal vaccine.⁹³ Immunocompromised patients, such as those with Hodgkin's disease, lymphoma, multiple myeloma, and chronic renal failure; patients who have undergone organ transplantation and HIV-infected individuals also are at high risk for pneumococcal disease and should receive the vaccine.⁹³ Immunocompromised patients, however, often fail to mount a sufficient immune response to the vaccine to fully protect them against infection.^{87,93,104} Patients with asymptomatic HIV disease respond more favorably to the vaccine than those with advanced acquired immunodeficiency syndrome (AIDS).¹⁰⁴ The antibody response in children <2 years of age also is poor or absent, and the vaccine is not recommended for these young children.⁸⁷

Thus, given his underlying medical condition (splenectomy) and history of alcoholism, A.L. should receive the pneumococcal vaccine. A single dose is all that is required; subsequent doses may be necessary in ≥5 years.

Gram-Negative Bacillary Meningitis

18. R.R., a 40-year-old, 80-kg man, is admitted to the hospital for a cervical laminectomy with vertebral fusion. His surgical procedure was complicated by a dural tear. On the third postoperative day, drainage at his surgical excision site was noted, and R.R. was febrile to 38.2°C. A Gram stain of the drainage revealed few gram-positive cocci and moderate gram-negative bacilli. Therapy with IV cefazolin 1 g Q 8 h was begun. The following morning, R.R. was oriented to person, place, and time, but he was slightly obtunded and had a temperature of 40°C. Neck stiffness could not be assessed because of his recent surgery. A magnetic resonance imaging (MRI) scan of the head and neck was negative, and lumbar puncture yielded a CSF WBC count of 3,000 cells/mm³ (normal, <5 cells/mm³), with 95% PMN; glucose of 20 mg/dL (normal, 60% of plasma glucose); and protein of 280 mg/dL (normal, <50). CSF Gram stain showed numerous gram-negative rods. What important clinical and laboratory features of gram-negative bacillary meningitis are manifested in R.R.?

[SI units: WBC count, 3×10^9 cells/L; glucose, 1.11 mmol/L; protein, 2.8 g/L]

Epidemiology

R.R. has developed gram-negative meningitis as a complication of his recent neurosurgical procedure. Although gram-negative bacilli do not cause meningitis nearly as often as *H. influenzae*, *S. pneumoniae*, and *N. meningitidis*, they remain important pathogens in both the community and hospital setting.^{1,19,20,32,35,58} During an 8-year period covering 1972 to 1979, 158 cases of gram-negative bacillary meningitis were reported to the New York City Health Department, or approximately 20 cases per year for the population of 8 million.³² Of 493 episodes of meningitis occurring over a 27-year period (1962–1988) at the Massachusetts General Hospital, enteric gram-negative bacilli accounted for 33% of all nosocomial episodes and 3% of community-acquired cases.¹ Historically, mortality rates from gram-negative bacillary meningitis have been extremely high, ranging from 40% to 70%. With the availability of newer antimicrobials such as third-generation cephalosporins, fatalities have declined to <40%.^{19,32,35,58} Increasing resistance among certain gram-negative bacilli, such as *Enterobacter* species and *P. aeruginosa*, presents a therapeutic dilemma in that mortality associated with these pathogens is high and therapeutic options are fewer.^{33,34}

Predisposing Factors

Individuals at greatest risk for gram-negative bacillary meningitis include neonates, the elderly, debilitated individuals, patients with open trauma to the head, and individuals such as R.R. undergoing neurosurgical procedures.^{19–21,32,58} Although meningitis is a rare complication of clean neurosurgical procedures (e.g., craniotomy, laminectomy), the consequences can be devastating when it does happen.^{1,21,105}

Microbiology

Escherichia coli and *K. pneumoniae* are the most common gram-negative bacteria causing meningitis and they represent about two-thirds of all cases.^{35,58,105} *E. coli* is the most common gram-negative cause of neonatal meningitis, whereas *K. pneumoniae* is isolated more often in the adult population.^{23,35,58,105} The remaining one-third of cases are divided evenly among

Proteus, *Serratia*, *Enterobacter*, and *Salmonella* species, *P. aeruginosa*, and other less common bacilli.^{35,58,105}

Clinical Features

In general, clinical laboratory features of gram-negative bacillary meningitis are similar to other types of bacterial meningitis.^{23,39,58,98} Because of high virulence, gram-negative bacillary meningitis often is a fulminant, rapidly progressive disease. An exception to this rule is meningitis after neurosurgery.²¹ As is evidenced by R.R.'s clinical presentation, postneurosurgical gram-negative bacillary meningitis can present in a more subtle fashion. In such patients, many of the symptoms of meningitis (e.g., altered mental status, stiff neck) are masked by underlying neurologic disease. Thus, a high index of suspicion is warranted in the postsurgical setting. In addition to gram-negative bacilli, staphylococci also are associated with postneurosurgical meningitis.²¹ The presence of what looks like staphylococci on R.R.'s wound drainage fluid is of concern, but the abundance of gram-negative rods on his CSF Gram stain supports the latter as being the most likely causative pathogen.

Treatment of Gram-Negative Bacillary Meningitis

19. What would be appropriate therapy for gram-negative bacillary meningitis in R.R.?

Fewer choices are available for treatment of gram-negative bacillary meningitis than for other meningitides. Ampicillin is active against only *E. coli*, *P. mirabilis*, and *Salmonella* species, but its low potency and a high likelihood of resistance severely limit its use.^{35,58,105} Chloramphenicol has mediocre gram-negative activity (except against *P. aeruginosa*), but it is only bacteriostatic in activity against enteric bacilli.³⁵ Chloramphenicol treatment of gram-negative bacillary meningitis historically has been associated with excessively high mortality.^{32,35,58,105} Aminoglycosides are limited by their inability to achieve therapeutic CSF concentrations, as well as reduced activity in the acidic milieu of purulent CSF.^{14,16,35,54} Intrathecal administration will produce therapeutic CSF concentrations, but repeated administration often is complicated by painful arachnoiditis. Even with this approach, mortality rates are high (>40%).^{14,58} Unlike intrathecal administration, lumbar injections will not result in therapeutic CSF concentrations in the ventricle. Extended-spectrum penicillins (e.g., piperacillin) are active against most gram-negative rods but require combination therapy with aminoglycosides for optimal results.⁵⁸ The third-generation cephalosporins represent by far the most useful group of agents for treating gram-negative bacillary meningitis, given their high potency against many enteric gram-negative bacilli and good CSF penetration. Experience with these agents spanning over a decade has resulted in the third-generation cephalosporins becoming the drugs of choice for gram-negative bacillary meningitis.^{4,35,106}

Empiric therapy for R.R. should include an antipseudomonal β -lactam such as cefepime (Table 58-5).^{4,21,56} Cefepime has excellent activity against *E. coli* and *K. pneumoniae* and is active against other enteric gram-negative bacilli as well.^{35,106} (Table 58-7). Resistance to third-generation cephalosporins among species of *Enterobacter*, *Citrobacter*, and *Serratia* is so problematic that these drugs cannot be

relied on for the treatment of meningitis caused by these pathogens.^{33–35,107,108} With this in mind, therapy of gram-negative meningitis in situations in which resistance is more likely to be encountered (e.g., nosocomial or postneurosurgical meningitis) also may include an aminoglycoside based on susceptibility results. Of the third-generation cephalosporins currently available, the most experience has been accumulated with cefotaxime; success rates are >80% for treatment of gram-negative bacillary meningitis caused by *E. coli* or *K. pneumoniae*.^{35,106,108} Ceftriaxone has comparable efficacy to cefotaxime and is considered a good alternative.³⁵ Ceftizoxime penetrates CSF to about the same extent as cefotaxime and has virtually the same spectrum of activity, but published experience with this agent is limited.^{35,109} Nonetheless, no compelling evidence suggests that ceftizoxime is inferior to cefotaxime or ceftriaxone.

For R.R., cefazolin should be discontinued, and treatment with cefepime (2 g IV Q 8 h) should be instituted. The choice of cefepime for empiric therapy is appropriate while waiting for results from culture and sensitivity testing. Until these results are available, combination therapy with cefotaxime and an aminoglycoside (gentamicin) is not unreasonable. The dosage of IV gentamicin should be designed to achieve high peak serum concentrations (i.e., >6 mcg/mL) while maintaining trough concentrations <2 mcg/mL (Table 58-6). If intrathecal administration is indicated based on culture and susceptibility data, a 5- to 10-mg intrathecal dose of gentamicin also may be administered daily until clinical improvement is noted.^{13,14,58} Gentamicin is commercially available in a 2-mg/mL, preservative-free solution for intrathecal use. The most practical way to provide intrathecal gentamicin to R.R. is by performing a lumbar puncture each day and administering the drug by intralumbar injection. This also will allow daily sampling of CSF for cultures and chemistries. Although intraventricular administration of gentamicin is ideal, insertion of a ventricular reservoir (e.g., Ommaya reservoir) is not appropriate at this time because R.R. has just had major spinal surgery, and it is not clear yet whether prolonged therapy is required.

It is important to make the distinction between aminoglycoside therapy for gram-negative bacillary meningitis in neonates versus adults. In adults, results from clinical trials support the use of combined IV and intrathecal therapy for reasons described previously.^{35,58} In neonates, however, combined intraventricular and IV gentamicin produces higher mortality rates than IV gentamicin alone.¹¹⁰ The reason for the poor clinical outcomes associated with direct instillation of gentamicin into ventricular fluid is unclear. Initially, the increased mortality was attributed to increased trauma related to repeated insertion of the intrathecal needle into the infant's fontanel. More recent evidence suggests that the direct intraventricular injection of aminoglycoside can cause an abrupt release of inflammatory cytokines (TNF and IL-1) from mononuclear cells that could have led to enhanced neurologic sequelae.¹¹¹ Whatever the reason, intraventricular and intrathecal therapy should not be given to neonates with gram-negative bacillary meningitis (Tables 58-5 and 58-6)⁵⁶ without due consideration of this increased risk.

Treatment of *Enterobacter* Meningitis

20. Culture results from R.R.'s wound drainage and CSF both are positive for *Enterobacter cloacae*. Sensitivity data reveal re-

sistance to ceftriaxone, cefepime, ceftazidime, piperacillin, aztreonam, and chloramphenicol. Drugs to which the isolate is sensitive include imipenem, TMP-SMX, gentamicin, tobramycin, and ciprofloxacin. What alteration in antimicrobial therapy is most appropriate for R.R. at this time?

Treatment of meningitis caused by *Enterobacter* and related species (e.g., *Serratia*, *Citrobacter* species) presents a challenge in that resistance is encountered more commonly.^{33,35,106} Furthermore, some isolates that are sensitive to third-generation cephalosporins can become resistant during therapy by virtue of possessing inducible, type I β -lactamases.³³ Thus, in contrast to gram-negative bacillary meningitis caused by *E. coli* and *Klebsiella* species, alternative therapies are needed when treating meningitis caused by *Enterobacter*, *Serratia*, *Citrobacter*, and *Pseudomonas* species. Based on the sensitivity profile of R.R.'s infecting strain, it is apparent that an extended-spectrum penicillin (e.g., piperacillin) would not be appropriate. Aztreonam, a monobactam antibiotic with good CSF penetration and gram-negative activity comparable to ceftazidime, also is inactive against R.R.'s infecting strain.¹¹² The isolate is sensitive to imipenem, but the higher propensity for seizures compared with other β -lactams (including penicillin G) argues against its use in R.R.^{113–115} Meropenem is not considered to be epileptogenic and is an alternative to imipenem for meningitis.^{67,116} Clinical trials have evaluated the efficacy and safety of meropenem versus cefotaxime in the treatment of meningitis in children. Clinical outcomes were similar among the patients randomized to either group, and the incidence of seizures was similar in the treatment groups.^{116,117} Ciprofloxacin, a fluoroquinolone antibiotic, offers the attractive features of excellent in vitro potency against gram-negative bacilli (including *Enterobacter* and *Pseudomonas* species).^{48,118} Experience with ciprofloxacin in meningitis is limited, however, and achievable CSF levels are relatively low despite reasonable CSF penetration.⁴⁸ Furthermore, fluoroquinolones are associated with adverse CNS effects, including the potential to cause seizures.¹¹⁹ Because limited clinical data exist on the use of meropenem and fluoroquinolones in adults, these agents should be reserved for the treatment of multiresistant isolates.^{46,67} TMP-SMX has excellent activity against most gram-negative bacteria, with the exception of *P. aeruginosa*, and penetrates into the CSF especially well.^{46,53,103}

Thus, after consideration of the aforementioned options, TMP-SMX appears to be the best choice of therapy for R.R. Cefepime should be discontinued and therapy started with TMP-SMX 15 mg/kg/day (based on the trimethoprim component) given IV in three divided doses.^{4,58,103} For R.R., this would be a dosage of 400 mg (trimethoprim component) Q 8 h. Because of poor aqueous solubility, IV TMP-SMX must be prepared such that each 80 mg (5 mL) of TMP-SMX injectable solution is diluted with 75 to 125 mL of 5% dextrose in water. For R.R., 400 mg of TMP-SMX would be administered in approximately 500 mL of D₅W and each dose infused over 1 hour. Whether or not to discontinue gentamicin in R.R. at this time is less clear. Although no data demonstrate superiority of TMP-SMX combined with aminoglycosides over TMP-SMX alone, in vitro evidence is found of synergy, which may be of theoretic advantage.¹²⁰

A review of antibiotic therapy for *Enterobacter* meningitis supports the contention that TMP-SMX is the most useful therapy currently available.³³ Although the study was

uncontrolled and retrospective in design, infection was cured in all 7 patients receiving TMP-SMX, compared with 21 of 32 (65%) patients treated solely with third-generation cephalosporins. In all 11 instances of clinical failure, resistance developed during therapy.³³ In an earlier report describing TMP-SMX treatment of bacterial meningitis, including eight cases of gram-negative bacillary meningitis caused by organisms known to be moderately susceptible to third-generation cephalosporins, clinical and bacteriologic cures were observed in all instances (two cases each of *E. cloacae*, *Serratia marcescens*, and *C. diversus*; one case each of *Proteus vulgaris* and *Morganella morganii*).¹⁰³ In contrast, TMP-SMX therapy failed to cure six cases of gram-negative bacillary meningitis caused by *E. coli* (four cases) and *K. pneumoniae* (two cases) despite documented sensitivity to the drug combination. Thus, TMP-SMX appears to be most useful for treatment of gram-negative bacillary meningitis caused by organisms that are only moderately susceptible to third-generation agents, whereas cefotaxime and ceftriaxone remain the drugs of choice for meningitis caused by *E. coli* and *K. pneumoniae* (Table 58-7).

Duration of Therapy

The optimal duration of therapy for gram-negative bacillary meningitis has not been clearly established. Because of the high mortality and morbidity associated with these pathogens and the reduced susceptibility of enteric pathogens to antimicrobial agents, 21 days has been suggested (Table 58-8).^{46,56,58} Although R.R. does not appear to have a fulminant case of gram-negative meningitis, a 21-day course of therapy is recommended with close follow-up.

Staphylococcus epidermidis Meningitis/Ventriculitis

Clinical Presentation of CSF Shunt Infections

21. T.A., a 21-year-old woman with a history of congenital hydrocephalus, is admitted to the neurosurgery unit for worsening mental status and fever. T.A. has a history of multiple revisions and placements of intraventricular shunts for control of hydrocephalus. Currently, she has a ventriculoperitoneal (VP) shunt, which was placed 1 month ago and previously had been functioning normally. Over the past few days, T.A. has developed worsening obtundation, stiff neck, and a temperature of 39.5°C. A CT scan performed today reveals enlarged ventricles consistent with acute hydrocephalus.

T.A.'s medical history is noncontributory except for a seizure disorder for which she takes phenytoin 400 mg PO QHS. She also takes Lo-Ovral for birth control. T.A. is allergic to sulfa drugs (severe skin rash). Her weight on admission is 60 kg.

Laboratory analysis was significant for a WBC count of 14,000 cells/mm³ (normal, 3,200–9,800), with a differential of 85% PMN and 10% lymphocytes; BUN and SrCr values were within the normal range at 19 mg/dL and 0.9 mg/dL, respectively.

A tap of T.A.'s shunt was performed, and the ventricular fluid was notable for total protein of 150 mg/dL (normal, <50), glucose of 40 mg/dL (normal, 60% of serum glucose), and a WBC count of 200 cells/mm³ (normal, <5 cells/mm³), with 85% PMNs and 10% lymphocytes. Gram stain of the ventricular fluid showed numerous gram-positive cocci in clusters. What are the subjective and objective findings of CSF shunt infections, and what manifestations of this type of infection are present in T.A.?

[SI units: WBC count, 14 × 10⁹ cells/L with 0.85 PMN and 0.1 lymphocytes; BUN, 6.8 mmol/L urea; SrCr, 80 μmol/L; total protein, 1.0 g/L; glucose, 2.2 mmol/L; WBC count, 200 × 10⁶ cells/L with 0.85 PMN and 0.1 lymphocytes]

T.A. appears to have meningitis with ventriculitis secondary to infection of her VP shunt. The most important way to manage hydrocephalus involves the use of devices that divert (shunt) CSF from the cerebral ventricles to other areas of the body such as the peritoneum (VP shunts) or atrium (VA shunts).^{8,121,122} This approach alleviates increased CSF pressure and substantially reduces morbidity and mortality.^{121,122} Infection of these devices, however, is a common cause of shunt malfunction, as seen in T.A. The reported incidence of CSF shunt infections varies from 2% to 39% (usually between 10% and 11%) and depends on patient factors, surgical technique, and the type and duration of the procedure performed (i.e., shunt revision versus placement of a new device).^{121,122} T.A., who has been hydrocephalic since birth and has a history of multiple shunt procedures, is at high risk for such an infection.

Clinical symptoms associated with infected CSF shunts vary widely from asymptomatic colonization to fulminant ventriculitis with meningitis.^{121–123} Fever is common and, in many instances, is the only presenting symptom.¹²¹ CSF findings also are slightly different in shunt infection compared with acute meningitis: the WBC count usually is not as elevated, the decrease in CSF glucose is less pronounced, and the protein value may be normal or slightly elevated.^{121,122} CSF culture is positive in most patients not receiving concurrent antibiotics.^{123,124} T.A.'s clinical presentation, CSF findings, and radiographic evidence of hydrocephalus are highly suggestive of a VP shunt infection. She is febrile and has altered mental status. The presence of a stiff neck strongly suggests meningeal involvement. Evaluation of T.A.'s ventricular fluid reveals a slightly elevated WBC count, with a predominance of polymorphonuclear neutrophils, an elevated protein concentration, and a slightly lower than normal glucose concentration.

Skin microflora are the most common causes for CSF shunt infections.^{121–124} Staphylococci account for 75% of all cases, with two-thirds of these caused by coagulase-negative staphylococci (usually *S. epidermidis*) and one-third by *S. aureus*.^{123,124} Other less common pathogens include diphtheroids, enterococci, and *Propionibacterium acnes* (an anaerobic diphtheroid). Enteric gram-negative bacilli are responsible for a small percentage of cases; these cases usually occur when the distal end of the shunt is inserted improperly into the peritoneal cavity.^{123,124} The gram-positive cocci in clusters on Gram stain of T.A.'s CSF strongly suggest a staphylococcal shunt infection. Determining the coagulase status of the isolate will allow differentiation between *S. aureus* and *S. epidermidis*.

Treatment of CSF Shunt Infections

22. Culture and sensitivity tests of T.A.'s ventricular fluid are positive for *S. epidermidis*. The isolate is resistant to nafcillin but sensitive to vancomycin, rifampin, and TMP-SMX. How should T.A.'s CSF shunt infection be treated?

For T.A.'s CSF shunt infection to be optimally treated, a combined medical and surgical approach is required.^{117,118,125} Antibiotic therapy directed against the causative organism, although essential, often is inadequate by itself. On average, antibiotic therapy by itself produces cure rates of <40%.¹²⁴ In contrast, antibiotic therapy plus surgical removal of the infected

device produces clinical cure rates of >80%.¹²⁴ Because many patients cannot tolerate the complete removal of their shunt for long, externalization of the distal end of the shunt, or shunt removal and placement of an external drainage device, often is necessary during systemic antibiotic therapy. The presence of an externalized device permits sequential sampling of ventricular fluid and also provides a convenient way to administer antibiotic intraventricularly (see the following discussion).

GLYCOLALYX

Although *S. epidermidis* is not as virulent a pathogen as *S. aureus*, it is extremely difficult to eradicate this organism from prosthetic devices such as CSF shunts. This is because many strains of *S. epidermidis* produce a mucous film or slime layer known as *glycocalyx*, which allows the staphylococci to adhere tightly to the Silastic shunt material, protecting them against phagocytosis.^{126,127} As expected, antibiotic failures are much more likely with slime-producing strains of *S. epidermidis*.

Vancomycin is the drug of choice for treatment of shunt infections caused by *S. epidermidis* and should be instituted immediately in T.A.^{8,121,127} This is because a high percentage (>60%) of coagulase-negative staphylococci are resistant to methicillin (e.g., methicillin-resistant *S. epidermidis* [MRSE]). Furthermore, methicillin-resistant staphylococci (both methicillin-resistant *S. aureus* [MRSA] and MRSE) also are resistant to cephalosporins. T.A.'s isolate also is sensitive to TMP-SMX, as is the case with many strains of MRSE (and also MRSA),⁸ and it must be avoided because T.A. is allergic to this drug combination. Although many staphylococcal isolates (both *S. epidermidis* and *S. aureus*) are susceptible to rifampin, monotherapy with this drug is not recommended because of rapid emergence of resistance. Combination therapy with vancomycin and rifampin may be synergistic and sometimes is used.

VANCOMYCIN THERAPY

23. What would be an appropriate dosage of vancomycin therapy in T.A.? What subjective or objective data should be monitored to evaluate the efficacy and toxicity of the treatment?

Vancomycin therapy for T.A.'s CSF shunt infection requires the use of higher than usual doses, which is true for the treatment of other types of staphylococcal CNS infections as well.^{8,56,128} For adults such as T.A., vancomycin dosages of 20 to 30 mg/kg/day to a maximum of 2 g/day have been suggested. Even higher dosages, however, may be required in patients with fulminant disease (Table 58-6).^{8,56,96,128} For children with meningitis or infected shunts, the recommended dosage of vancomycin is 40 to 60 mg/kg/day, given IV in two to four divided doses (Table 58-6).^{8,56} Although specific recommendations are lacking, it is reasonable to target serum trough concentrations of vancomycin toward the higher end of the target range (i.e., ~15 to 20 mcg/mL). With an every-12-hour dosing schedule, peak serum levels will approach or possibly exceed 40 mcg/mL. It is unlikely, however, that peak serum concentrations of >60 mcg/mL will be observed. Although the potential for toxicity may be greater, higher than usual vancomycin serum concentrations are warranted to ensure adequate penetration into the CSF.^{96,128}

T.A., who weighs 60 kg, should be started on a vancomycin regimen of 1 g IV Q 12 h (~30 mg/kg/day) because her renal function is normal. Alternatively, the dose could be calculated using population estimates of vancomycin pharmacokinetic parameters to achieve a trough serum concentration of 15 mcg/mL. In either case, trough serum concentrations should be obtained at steady-state to assess whether the initial dosing regimen is adequate.

Anecdotal evidence suggests that very high dosages of vancomycin (≥ 3 g/day in adults with normal renal function) are associated with an increased risk of ototoxicity.^{96,129} This observation is difficult to verify because hearing loss also is a potential sequelae of meningitis. High-dose vancomycin therapy also has a greater likelihood of inducing the "red man syndrome."^{130,131} This adverse effect, manifested by flushing and pruritus, with or without hypotension, is related directly to the amount of drug infused over a given period of time.¹³⁰ It usually can be avoided or minimized by infusing vancomycin doses of 1,000 mg in ≥ 250 mL of solution (either D₅W or normal saline) over at least 1 hour. If red man syndrome is observed, slowing the infusion rate often ameliorates symptoms.¹³⁰ Pretreatment with antihistamines (diphenhydramine or hydroxyzine) may also minimize the reaction because the proposed mechanism partially involves histamine release.¹³¹

Another consideration for T.A. is the addition of rifampin to her vancomycin regimen. This is based on the excellent staphylococcal activity of rifampin, its good CSF penetration, and the potential for synergy between these two agents.^{8,121} Whether rifampin plus vancomycin is superior to vancomycin alone has not been determined. For T.A., it is best to avoid rifampin because evidence supporting its efficacy is weak, and she currently is taking phenytoin and birth control pills. Rifampin is a potent inducer of hepatic microsomal enzymes, which can lower serum phenytoin concentrations (possibly resulting in seizure activity) and increase the possibility of an unplanned pregnancy (from reduced effectiveness of the birth control pill).

Intraventricular and Intravenous Dosing of Vancomycin

24. Should T.A. receive intraventricular vancomycin? If so, what would be an appropriate dosage?

T.A. has a long history of hydrocephalus and will require placement of an external drainage device after removal of her VP shunt. This makes intraventricular administration of vancomycin possible, and such treatment should be instituted promptly. The dosages used in the literature vary from 5 to 20 mg/day. Experts recommend 20 mg/day of intraventricular vancomycin; therefore, an intraventricular vancomycin dosage of 20 mg/day is recommended for T.A. Also, serial (daily) cultures of CSF are recommended to monitor her response to therapy. Some authors suggest adjusting intraventricular vancomycin doses to achieve trough CSF vancomycin concentrations of at least 5 mcg/mL or CSF bactericidal activity of at least 1:8 against the infecting strain.^{8,121} Until more information is available, monitoring serial CSF trough concentrations is more appropriate than CSF bactericidal titers, and serial trough levels should be obtained in T.A. To summarize, T.A. should receive combined IV and intraventricular vancomycin therapy as described previously. Therapy should be continued for at least 10

days after sterilization of her ventricular fluid is documented, at which time a new VP shunt can be placed.^{121,124,132}

In contrast to T.A.'s situation, vancomycin therapy for patients with staphylococcal meningitis not associated with a CSF shunt or indwelling ventricular catheter is more problematic. Because of this, therapy often is instituted with IV vancomycin alone.^{96,128} Intrathecal vancomycin, although preferable, requires either daily lumbar puncture (for intralumbar therapy) or surgical placement of an intraventricular reservoir. If the response to therapy is inadequate within the first 24 to 48 hours, the addition of intrathecal vancomycin therapy (5 to 20 mg/day) is recommended.^{96,128} In fulminant cases of staphylococcal meningitis, however, intrathecal vancomycin should be instituted as quickly as possible (i.e., with the first lumbar puncture) to optimize the response to therapy.

BRAIN ABSCESS

Epidemiology

Although not nearly as common as meningitis, abscesses of the brain parenchyma (brain abscess) remain an important type of CNS infection. The incidence of brain abscess has not varied since the preantibiotic era and is estimated to account for 1 in 10,000 hospital admissions.¹³³ On a busy neurosurgical service, 4 to 10 cases a year typically are seen.^{133,134} For reasons that are not entirely clear, men are more likely to develop abscesses within the brain than women.^{133,135} Brain abscess can occur at any age, but the median age is 30 to 40 years, with approximately 25% of cases occurring in children.^{133,136,137}

Despite advances in antimicrobial therapy over the past several decades, mortality rates from brain abscess has remained above 40% until just recently. Developments in imaging techniques (e.g., CT and MRI scanning), which allow early recognition of abscesses and the ability to serially monitor the radiographic response to antimicrobial therapy, have had the most profound impact on reducing morbidity and mortality from brain abscess.^{133,134,138} In a review of 102 cases of bacterial abscesses occurring over a 17-year period, mortality was 41% in the period before 1975 (pre-CT scan era), compared with 6% during 1975 to 1986, when CT scanning became routinely available.¹³⁴ With the combined medical and surgical approach

currently recommended, mortality rates continue to average <10%.^{133,134,138}

Predisposing Factors

Brain abscesses most commonly arise from a contiguous suppurative source of infection (e.g., sinusitis, otitis, mastoiditis, or dental infections).^{133,135,139} In the United States, abscesses occurring as a complication of sinusitis are more common than abscesses arising from otitic or dental sources.¹³³ The formation of a single abscess cavity usually is found when infection develops from a contiguous source. In addition, the abscess nearly always is formed in close proximity to the primary focus of infection (Table 58-10).^{133,139} For example, abscesses of sinusitic origin more commonly involve the frontal lobe, whereas otitic infections often lead to temporal lobe abscess formation.¹³⁹ Brain abscess also occurs as a consequence of metastatic spread of organisms from a primary site of infection (e.g., lung abscess, endocarditis, osteomyelitis, pelvic, and intra-abdominal infections).^{129,131} In children, cyanotic congenital heart disease is a common predisposing factor for brain abscess.^{136,137} Multiple abscesses suggest a metastatic source of infection.¹³³ As with meningitis, brain abscess occurs as an infrequent complication of head trauma or neurosurgery.^{11,133,139} No identifiable source (cryptogenic abscess) is detected in as many as 30% of cases.^{133,139}

Staging

Once an intracranial focus of infection is established, the evolution of brain abscess involves two distinct stages: cerebritis and capsule formation.^{136,138} The cerebritis stage evolves gradually over the first 9 to 10 days of infection and is characterized by an area of marked inflammatory infiltrate that contains a necrotic center surrounded by an area of cerebral edema.^{136,138} Capsule formation occurs about 10 to 14 days after the initiation of infection, and once formed, the capsule continues to thicken over a period of weeks.^{136,138} The stage of abscess development has important implications for therapy. Although it is best to wait until the capsule is fully formed before attempting any type of surgical intervention, antimicrobial therapy alone may resolve the infection if discovered in the early cerebritis stage.¹³⁸

Table 58-10 Predisposing Conditions, Microbiology, and Recommended Therapy for Bacterial Brain Abscess

| Predisposing Condition | Usual Location of Abscess | Most Likely Organisms | Recommended Therapy |
|-----------------------------|-----------------------------|--|--|
| Contiguous Site | | | |
| Otitic infection | Temporal lobe or cerebellum | Streptococci (anaerobic and aerobic), <i>Bacteroides fragilis</i> , gram-negative bacilli | Penicillin G + metronidazole + cefotaxime or ceftriaxone |
| Sinusitis | Frontal lobe | Streptococci (predominantly), <i>Bacteroides</i> species, gram-negative bacilli, <i>Staphylococcus aureus</i> , <i>Haemophilus</i> species | Penicillin G + metronidazole + cefotaxime or ceftriaxone |
| Dental infection | Frontal lobe | <i>Fusobacteria</i> species, <i>Bacteroides</i> species, and streptococci | Penicillin G + metronidazole |
| Primary Infection | | | |
| Head trauma or neurosurgery | Related to site of wound | Gram-negative bacilli, staphylococci, streptococci, diphtheroids | Vancomycin + ceftazidime |

Microbiology

The microbiology of brain abscess is distinctly different from that of meningitis. Streptococci are implicated in 60% to 70% of cases and include anaerobic as well as microaerophilic streptococci of the *S. milleri* group.^{133,139,140} Other anaerobes, particularly *Bacteroides* species (including *B. fragilis*) and *Prevotella* species, are found in up to 40% of cases, usually in mixed culture.^{133,139} In recent years, staphylococci appear to be decreasing and enteric gram-negative bacteria increasing as etiologic agents of bacterial brain abscess.¹²³ Although somewhat imprecise, a reasonable correlation exists between the various predisposing conditions and the microbiologic etiology of brain abscess (Table 58-10).^{133,135,137,138}

In the immunocompromised patient, a diverse group of microorganisms can induce abscesses within the brain. In patients with AIDS, *Toxoplasma gondii* is by far the most common infectious cause of focal brain lesions.¹⁴¹ Transplant recipients and those receiving immunosuppressive therapy are susceptible to infection from *Nocardia* species.¹⁴² In Mexico and other Central American countries, cysticercosis remains a common cause of intracerebral infection.¹⁴³

Clinical and Radiologic Features

25. L.Y., a 40-year-old man, is brought to the ED by a friend. L.Y. complains of severe headache, fever, weakness in his left arm and leg, and increasing drowsiness. Over the past week, L.Y. has suffered from headaches, which have gradually worsened in intensity, and from intermittent episodes of fever. Despite getting plenty of sleep, L.Y. has been feeling increasingly drowsy over the past several days. When he noticed weakness in his left arm and difficulty concentrating this morning, he called a friend and asked to be taken in for evaluation.

L.Y. has a history of chronic sinusitis that has been treated with a variety of oral antibiotics. His last episode of sinusitis, which occurred about 1 month ago, was treated with a 10-day course of cephalexin. He denies any nausea or vomiting and has not experienced any seizures in the recent past. L.Y. was tested for HIV 6 months ago, and the result of his antibody test was negative. He takes no current medications, denies smoking and use of recreational drugs, and drinks alcohol only on social occasions a few times a month. L.Y. has no known drug allergies.

Physical examination reveals L.Y. to be in mild distress, with a temperature of 38.2°C. He is slightly lethargic and is oriented to person and place but not time (0 × 2). The strength in L.Y.'s left arm is 3/5; the strength in his left leg is 4/5. The remainder of his neurologic examination is grossly normal. L.Y. described moderate pain on palpation of his frontal sinuses, and a purulent discharge is noted.

Laboratory evaluation shows a WBC count of 8,000 cells/mm³ (normal, 3,200–9,800), with 70% PMN, 25% lymphocytes, and 5% monocytes; Hgb, Hct, platelets, and serum chemistries are within normal limits; and his BUN and SrCr are 16 mg/dL (normal, 8 to 18) and 1.2 mg/dL (normal, 0.6 to 1.2), respectively. L.Y.'s erythrocyte sedimentation rate (ESR) is 40 mm/hour (normal, 0 to 20).

A CT scan with contrast dye reveals a right frontal ring-enhancing lesion with a small amount of surrounding cerebral edema. L.Y. is admitted to the neurosurgery unit for further eval-

uation and treatment. What clinical signs and symptoms does L.Y. display that are suggestive of bacterial brain abscess? How can brain abscess be diagnosed in L.Y.?

[SI units: WBC count, 8×10^9 cells/L with 0.7 PMN, 0.25 lymphocytes, and 0.05 monocytes; Hgb, 145 g/L; Hct, 0.4; platelets, 120×10^9 /L; BUN, 5.7 mmol/L urea; SrCr, 106.1 μ mol/L; ESR 40 mm/hr]

L.Y. has presented to the ED with many signs and symptoms suggestive of bacterial brain abscess. He is 40 years of age and a man, both of which place him in a group with the highest likelihood of having a brain abscess. In contrast to the diffuse nature of meningitis, brain abscess presents as a focal neurologic process.^{133,134} Notable in L.Y.'s presentation is left-sided (arm and leg) weakness. Symptoms of brain abscess range in severity from indolent to fulminant and, in most patients, the duration of symptoms at the time of presentation is ≤ 2 weeks.^{133,134,136} Headache is the most common symptom of brain abscess, occurring in approximately 70% of cases. L.Y.'s clinical manifestations have become gradually worse over the past week, and his worsening headaches, increasing drowsiness, and difficulty in concentrating all are consistent with bacterial brain abscess.

L.Y. presents with the classic triad of fever, headache, and focal neurologic deficits. Although this triad should always be looked for, fewer than half of patients with confirmed bacterial brain abscess present in this manner.^{133,134,135} The absence of fever does not rule out infection because fever is found in $<50\%$ of patients.^{133,134} Focal neurologic deficits are present in approximately 50% of patients and vary in nature and severity in relation to the location and size of the abscess and surrounding cerebral edema.^{133,134,137} Although L.Y. does not have a history of seizure activity, approximately one-third of patients experience partial seizures that often become generalized.^{133,137} Papilledema and nuchal rigidity occur in $\leq 25\%$ of cases and often are not useful in confirming the diagnosis. Symptoms associated with a contiguous focus of infection should always be sought and, in some situations, they may dominate the clinical picture.^{133,134} L.Y. has a history of sinus infection, and the pain on palpation of his sinuses coupled with the purulent sinus drainage suggests active infection at this site.

As can be seen from L.Y.'s test results, laboratory evaluation usually is not very helpful when diagnosing brain abscess. L.Y. does not have a peripheral leukocytosis, but he does have an elevated ESR. A normal peripheral WBC count is not unusual in patients with intracranial suppuration. The ESR often is elevated in brain abscess, but this test is nonspecific and only indirectly supports the diagnosis.

L.Y. did not have a lumbar puncture because this procedure is contraindicated for diagnosing brain abscess.^{42,133,134} The diagnostic yield from CSF is low because chemistries (e.g., protein, glucose, WBC) usually are normal and culture of the CSF in patients with brain abscess is unlikely to yield the causative pathogen. More important, performing a lumbar puncture in patients with space-occupying lesions of the brain can produce cerebral herniation as a consequence of the shifting pressure gradient induced within the cranial vault after insertion of the lumbar puncture needle.⁴²

Of paramount importance is the abnormality detected on the CT scan of L.Y.'s brain. When dye is injected before the CT

scan, brain abscesses will appear to “ring enhance.” Furthermore, cerebral edema can be identified as a variable hypodense region immediately surrounding the abscess cavity. As stated earlier, CT and MRI scanning techniques have revolutionized the diagnosis and treatment of brain abscess.^{133,134,138} The superiority of CT versus MRI is unclear. MRI, however, is more sensitive in detecting cerebritis than CT, and it can be helpful in ruling out (or ruling in) an abscess when the CT scan is negative.^{133,138} Assessment of the size and location of the lesion is possible with both techniques, which is invaluable in deciding which surgical intervention is indicated. In addition, serial radiographic studies can be used to evaluate antimicrobial response over time.^{134,138} In general, a good correlation exists between the clinical and radiologic response to therapy of bacterial brain abscess.

Treatment

26. How should L.Y.’s brain abscess be treated?

Surgical Techniques
