The rational use of medications in neonates depends on an appreciation of both the physiological immaturity and the developmental maturation that influence neonatal drug disposition and pharmacologic effects. Much progress has been made to decrease neonatal mortality and improve survival of more premature and lower-birth-weight newborns. Neonates, particularly those of extremely low birth-weights, pose a pharmacotherapeutic challenge to the clinician. The alterations of body composition, weight, size, as well as physiological and pharmacokinetic parameters that occur with normal growth and maturation during the first few months of life are greater than at any other time. Although the amount of neonatal drug information is increasing, the overall lack of well-designed pharmacokinetic and pharmacodynamic studies still hinders the clinical use of many drugs in this population. This is especially true for newborns of the lowest birth-weights (<750 g).

The term *therapeutic orphans*,¹ which was coined more than 30 years ago to describe the lack of medications labeled for use in children, unfortunately still is applicable today.² Although the number of medications under development for children has significantly increased over recent years, 71% of new molecular entities approved by the U.S. Food and Drug Administration (FDA) do not have pediatric drug labeling.³ In addition, practical issues (e.g., technical problems of drug delivery, a lack of suitable dosage formulations) further complicate neonatal pharmacotherapeutics.

This pediatric dilemma led to the passage of the FDA Modernization Act of 1997.⁴ This federal legislation offered incentives (in the form of a 6-month drug patent extension) to pharmaceutical companies to conduct pediatric research. The Best Pharmaceuticals for Children Act of 2002 reauthorizes the use of these incentives and provides a process to increase pediatric studies for medications that are no longer “on patent.”⁵ In addition, this law specifically includes neonates as a population that should be studied. These and other regulations, plus the establishment of the Pediatric Pharmacology Research Unit Network by the National Institutes of Child Health and Human Development,³ will increase pediatric drug studies, enhance the neonatal labeling of medications, and lead to more rationale use of medications in neonates. Until that time, the clinical use of drugs in neonates presents unique therapeutic challenges for the clinician.

Terminology

An understanding of common neonatal terminology is important because every newborn is evaluated and classified at birth according to birth-weight, gestational age, and intrauterine growth status. These factors influence patient outcome and long-term prognosis.⁶ Common neonatal terminology is listed in Table 94-1. Pharmacokinetic parameters, pharmacodynamics, and dosing recommendations often are specified according to these terms.

Neonatal Monitoring Parameters

Many pharmacotherapeutic monitoring parameters used in adults also are used in neonates; however, normal values for neonates may differ from those in adults. The monitoring of pharmacotherapy in neonates must take into account these differences. For example, neonates have higher heart rates (HR)

Table 94-1 Common Neonatal Terminology^{6,8}

| Term | Definition |
|---------------------------------|--|
| Gestational age | <i>By dates:</i> The number of weeks from the onset of the mother's last menstrual period until birth <i>By examination:</i> Assessment of gestational maturity by physical and neuromuscular examination; gestational age estimates the time from conception until birth |
| Postnatal age | Chronologic age after birth |
| Postconceptional age | Gestational age plus postnatal age |
| Corrected age | Postconceptional age in weeks minus 40; represents postnatal age if neonate had been born at term (40 weeks' gestational age) |
| Preterm | <38 weeks' gestational age at birth |
| Term | 38–42 weeks' gestational age at birth |
| Post-term | ≥43 weeks' gestational age at birth |
| Extremely low-birth-weight | Birth-weight <1 kg |
| Very low-birth-weight | Birth-weight <1.5 kg |
| Low birth-weight | Birth-weight <2.5 kg |
| Small for gestational age | Birth-weight <10th percentile for gestational age |
| Appropriate for gestational age | Birth-weight between 10th and 90th percentiles for gestational age |
| Large for gestational age | Birth-weight >90th percentile for gestational age |

and respiratory rates (RR) and lower blood pressures (BP) compared with adults. Appropriate texts should be consulted for neonatal normal values when providing comprehensive pharmacy care.^{7,8}

The physiological transitions from intrauterine to extrauterine life can influence disease states and drug disposition. For example, the change from fetal to adult circulation results in an increase in perfusion of organs that are responsible for the elimination of drugs. The developmental changes in absorption, distribution, metabolism, and excretion affect drug disposition and, ultimately, neonatal drug dosing. This chapter focuses on applied therapeutics for common neonatal disease states and the safe and effective use of drugs in the neonate.

NEONATAL PHARMACOKINETICS

Drug Absorption

Gastrointestinal Absorption

Numerous developmental factors (e.g., gastric acidity, gastric emptying time, intestinal integrity and motility, bacterial colonization) can influence the absorption of enterally administered drugs during the neonatal period. Neonates, especially preterm newborns, have a decreased capacity to secrete gastric acid compared with adults.⁹ This relative lack of gastric acid output may be referred to as relative achlorhydria or hypochlorhydria. Although the exact maturational pattern of gastric acid secretion needs more clarity, a biphasic pattern in term infants usually is described. At birth, the pH of gastric contents is neutral owing to the presence of residual amniotic fluid. (Amniotic fluid is swallowed regularly during intrauterine life.) In term infants, acid output begins within minutes after birth and gastric

pH decreases to 1.5 to 3 within a few hours. Gastric acidity then decreases (pH increases) over the next 10 days; subsequently, basal acid output gradually rises. The maturational pattern of acid secretion in term infants is different in preterm neonates. Gastric acid rarely is present in the fetal stomach before 32 weeks' gestation, and the early decrease in gastric pH usually is not seen or may be delayed in preterm neonates. Hypochlorhydria with a basal pH above 4.0 is present in approximately 20% of preterm neonates 1 to 2 weeks of age. After 6 weeks of life, gastric pH falls to below 4.¹⁰ Although gastric acid production correlates with postnatal age, extrauterine factors (e.g., initiation of enteral feedings) seem to be responsible for the stimulation of gastric acid output.¹⁰ In general, gastric acidity is lower during the neonatal period, and adult values for maximal acid output are not reached until 2 years of age.^{9,11}

Gastric and duodenal pH affect drug ionization and absorption.^{11,12} Generally, an acidic environment favors absorption of acidic drugs because these drugs will be un-ionized and, therefore, more lipid soluble. Basic drugs, however, are mostly ionized in an acid environment. As a result, basic drugs in an acidic environment are hydrophilic and less well absorbed. Likewise, an acidic drug in an alkaline environment is also primarily in the ionized form and less well absorbed. Therefore, the hypochlorhydria (relatively alkaline gastric pH) in neonates can result in decreased bioavailability of acidic drugs (e.g., phenobarbital, phenytoin), as well as increased bioavailability of weakly basic drugs or acid-labile drugs (e.g., penicillin, ampicillin, erythromycin) compared with that in adults.^{11,13}

Gastric emptying time plays an important role in both the rate and the degree of drug absorption because most drugs are absorbed in the small intestine. During the neonatal period, gastric emptying time can be prolonged by up to 6 to 8 hours and may not attain adult values until 6 to 8 months of age.¹¹ The rate of gastric emptying is affected by gestational age, disease states, and dietary intake. Prematurity, respiratory distress syndrome (RDS), congenital heart disease, and ingestion of long-chain fatty acids prolong gastric emptying time. The rate of gastric emptying is increased with consumption of human milk and hypocaloric feedings, but is unaffected by osmolality and posture. A prolonged gastric emptying time can delay drug absorption, resulting in a longer time to reach maximal serum drug concentrations and a decrease in the peak concentration.

Small intestine motility is irregular in both neonates and young infants,¹³ making it difficult to predict the time for peak absorption or the extent of absorption of enterally administered drugs. In addition, the immature or altered permeability of the intestinal mucosa, which can result in increased drug absorption, actually may be more important than both gastric emptying time and intestinal motility.¹⁴ Osmolality also can influence gastrointestinal (GI) tract integrity and absorption, particularly in preterm infants.¹³ Enteral administration of drugs or solutions with high osmolalities can destroy GI tract integrity and increase the risk of necrotizing enterocolitis (NEC) in neonates.

Drug absorption in the neonate also can be affected by other factors. For example, the reduced rate of bile acid synthesis and pancreatic secretions in preterm neonates may decrease the absorption of fat-soluble vitamins D and E.^{12,13,15} Absorption of these vitamins may be reduced further by cholestasis,

and water-soluble forms of these vitamins may be necessary. Short-bowel syndrome (which may occur as a result of NEC) may decrease the intestinal surface area available for drug absorption and result in decreased drug bioavailability. Changes in bacterial colonization of the GI tract during the neonatal period can influence the fate of conjugated forms of drugs excreted in bile. The high activity of β -glucuronidase in the neonatal intestinal lumen results in hydrolysis of drug glucuronide conjugates and potentially alters the disposition of the parent drug or its metabolite.^{11,13}

During the neonatal period, drugs such as phenobarbital, digoxin, and sulfonamides are absorbed at a slower, rate but the total amount absorbed is similar to that of older children.¹⁴ In contrast, the total absorption of drugs such as phenytoin, acetaminophen, carbamazepine, and rifampin is decreased in neonates.^{11,13,15}

Rectal Absorption

The routine use of the rectum for administration of drugs (e.g., aminophylline) has been discouraged because of erratic drug absorption and toxicities.¹³ With the proper drug and dosage formulation, however, the rectum can be an important alternative route for drug administration, with rapid and efficient absorption.^{11,13} For example, rectal administration of diazepam solution for injection produces serum concentrations similar to those from intravenous (IV) administration.¹⁶ This route is therapeutically important in the neonate with seizure activity in whom rapid IV access is not available.

Intramuscular Absorption

Many physiological factors, as well as physicochemical characteristics of drugs, influence intramuscular (IM) absorption.¹¹⁻¹³ During the first few days of life, both the rate and the amount of IM absorption may be reduced owing to the relatively decreased muscle blood flow, higher percentage of water in muscle mass, and diminished strength of muscular contractions.¹¹ The amount of both muscle and subcutaneous tissue in the newborn is directly proportional to gestational age. The low muscle mass to total body mass ratio in neonates can result in decreased absorption of a drug administered IM because absorption is influenced by the surface area of the muscle that comes into contact with the injected medication. In addition, the degree of muscle activity, which directly affects the rate of drug absorption from both IM and subcutaneous injections, can be greatly decreased in the severely ill, immobile, or paralyzed neonate.¹¹⁻¹³ Adequate perfusion of the injection site also is required for systemic absorption to occur. Blood supply to muscles can be compromised in the critically ill neonate with low cardiac output or hypotensive states such as patent ductus arteriosus (PDA), sepsis, or RDS.^{12,17} Drugs that more commonly may be administered IM to neonates include vitamin K, aminoglycosides, phenobarbital, and penicillins.^{8,12}

Percutaneous Absorption

Percutaneous absorption is increased in neonates (especially in preterm newborns) because of decreased thickness of the stratum corneum, increased skin hydration, and increased ratio of surface area per kilogram body weight.¹¹⁻¹³ Because the epidermis is barely present before 34 weeks' gestational age, preterm newborns (especially those <2 weeks' postnatal age) are at greatest risk for percutaneous drug absorption. After 2 to

N/A, not available; $t_{1/2}$, half-life; Vd, volume of distribution.

3 weeks' postnatal age, the epidermis of the preterm newborn histologically matures to that seen at term.¹⁸ Although the epidermis of a term neonate is functionally intact, the epidermis continues to develop through 4 months of age. The newborn's ratio of skin surface area to body weight is approximately three times that of an adult. Therefore, for the same percutaneous dose, a neonate absorbs three times more drug per kilogram than an adult. In addition, occlusive dressings or an interruption in the integrity of the skin (e.g., abrasion) increases the amount of drug absorbed percutaneously. Various toxicities have been described in neonates after topical administration of iodine, hexachlorophene, boric acid, salicylic acid, alcohol, epinephrine, corticosteroids, and triple antibiotic (Bacitracin, neomycin, polymyxin B) spray.¹⁸

The increased percutaneous absorption of drugs in preterm newborns has potential therapeutic implications.¹⁸ For example, transdermal theophylline, administered as a gel with an occlusive dressing, produces therapeutic serum concentrations in preterm newborns who are 30 weeks or less gestational age and 20 days or less postnatal age. Clinical application of transdermal drug delivery in preterm newborns seems promising and may avoid problems associated with other routes of administration. However, transdermal drug delivery is limited by the normal maturation of the epidermis, and drug absorption decreases with increasing postnatal age and in newborns older than 32 weeks' gestational age.¹⁸

Drug Distribution

Drug distribution—the process of drug partition among various body organs, fluids, and tissues—depends on pH, composition and size of body compartments (e.g., total body water, intracellular and extracellular water, and adipose tissue mass), protein binding, membrane permeability, and hemodynamic factors such as cardiac output and regional blood flow.¹⁹

Water Compartments

Total body water, as a percentage of body weight, is increased in the newborn (especially the preterm neonate) and decreases with increasing age. The total body water of a preterm, 1-kg newborn is 80% and that of a term newborn is 75%. These values are much higher than those of a 3-month old (60%) or an adult (55%).²⁰ Newborns also have an increase in extracel-

lular water as a percentage of body weight, and an increase in the extracellular water to intracellular water ratio. Extracellular water decreases from approximately 40% at term to approximately 20% at 3 months of age.²⁰ The higher total body water and extracellular water in newborns typically result in larger volumes of distribution (Vd) for water-soluble drugs (Table 94-2).^{8,12,21,22} In addition, the Vd for water-soluble drugs that distribute to the extracellular water compartment (e.g., gentamicin) roughly parallels extracellular water as a percentage of body weight. Because the Vd in newborns usually is larger for water-soluble drugs, larger mg/kg loading doses of these agents are needed in neonates, particularly preterm newborns, to achieve initial drug concentrations similar to that of an adult. As the neonate grows and matures, total body water and extracellular water decrease, causing the Vd for water-soluble drugs and therefore mg/kg loading doses to decrease with increasing age.

Adipose Tissue

Compared with the adult, the neonate has much less adipose tissue. A preterm newborn is composed of only 1% to 2% fat, whereas a term neonate is approximately 15% fat.²⁰ Neonatal adipose tissue also contains more water. The decreased amount of adipose tissue and the higher water content in the newborn may decrease the Vd for fat-soluble drugs (e.g., diazepam). Because of the smaller Vd for fat-soluble or lipophilic drugs, smaller mg/kg loading doses should be administered in neonates.

Protein Binding

In general, neonatal protein binding of drugs is decreased compared with adults (Table 94-2). The decrease in plasma protein binding is a result of several factors, including a lower concentration of binding proteins (e.g., albumin, lipoproteins, α_1 -acid glycoprotein, and β -globulins); the presence of fetal albumin, which has decreased affinity for drugs; a lower plasma pH, which can decrease protein binding of acidic drugs; and the presence of endogenous substances (e.g., bilirubin and free fatty acids) or transplacentally acquired interfering substances (e.g., hormones and pharmacologic agents) that can compete for protein-binding sites.^{11,23} Decreased protein binding (increased free fraction) has been described in neonates for many drugs (e.g., ampicillin, carbamazepine, diazepam,

lidocaine, penicillin, phenobarbital, phenytoin, propranolol, salicylic acid, sulfonamides, theophylline).^{11,12,23} Total plasma protein concentration, as well as the affinity of albumin for acidic drugs, increases with age and approaches adult values at 10 to 12 months of age.¹² Therefore, as the newborn grows and matures, protein binding also increases.

A decrease in protein binding may result in an increased V_d, increased free (unbound) fraction, or increased free concentration of a drug. Drugs that have an increased V_d may require larger mg/kg loading doses in neonates to attain the same total serum concentration as that of an adult. However, for a given total serum concentration, the increased free fraction results in a higher free concentration. The increased free concentration may result in increased therapeutic or toxic effects. For example, protein binding of theophylline in term newborns (36%) is decreased compared with adults (56%).²⁴ The commonly accepted total theophylline serum concentration of 10 to 20 mcg/mL in adults produces free theophylline serum concentrations of 4.4 to 8.8 mcg/mL in adults but 6.4 to 12.8 mcg/mL in newborns (i.e., approximately 1.5 times the adult free concentrations). Pharmacologic and toxic effects of drugs are related to the free concentration (i.e., the amount of drug that can pass through membranes and reach the receptor). Therefore, the total theophylline serum concentration range used in adults (10–20 mcg/mL) could result in toxicities if applied to the neonatal population. In neonates, a total theophylline serum concentration of approximately 7 to 14 mcg/mL would produce free concentrations comparable with those seen with total concentrations of 10 to 20 mcg/mL in adults.²⁴ Likewise, the decreased protein binding of phenytoin in neonates and resultant increased free fraction suggests that total phenytoin therapeutic serum concentrations in newborns should be 8 to 15 mcg/mL rather than the 10 to 20 mcg/mL as accepted in adults.

Decreased protein binding also may be a result of endogenous or exogenous substances displacing highly protein-bound drugs from protein-binding sites. Higher concentrations of free fatty acids in neonates may be responsible for the decreased protein binding of diazepam, propranolol, salicylates, and valproic acid.²³ In addition, bilirubin can displace acidic drugs (e.g., phenytoin) from albumin-binding sites. A positive correlation between total bilirubin concentrations and free fraction of phenytoin has been described. Unbound phenytoin was reported as 11% in normal newborns, but approximately 20% in neonates when bilirubin concentrations were 20 mg/dL.²⁵

Some drugs (e.g., sulfonamides) or free fatty acids can displace bilirubin from albumin-binding sites, facilitating the deposition of unconjugated bilirubin in the brain. This condition, known as *kernicterus* or *bilirubin encephalopathy*, may produce neurologic injury and cell death and is frequently fatal. Survivors experience central hearing loss, ataxia, and choreoathetosis.²⁶ The displacement of bilirubin from albumin-binding sites depends on several factors, including pH, the affinity of albumin for the drug and bilirubin, and the individual molar concentrations of the drug, bilirubin, and albumin. Preterm newborns may be at an increased risk for bilirubin displacement because of lower albumin concentrations, decreased albumin affinity for bilirubin, lower pH, and higher bilirubin concentrations (secondary to overproduction or decreased hepatic glucuronide conjugation). To displace bilirubin, a specific molar concentration of a drug is

necessary to occupy a critical portion of the reserve albumin. Generally, if the molar concentration of a drug is much lower than the molar concentration of albumin, displacement of bilirubin from albumin-binding sites is unlikely.^{12,27} For example, highly protein-bound drugs such as furosemide, indomethacin, and cardiac glycosides can be administered to neonates without fear of displacing bilirubin from albumin (even though some of them are potent displacers of bilirubin) because they achieve low plasma concentrations.¹² In contrast, ceftriaxone can significantly displace bilirubin off albumin-binding sites and therefore should be avoided in the presence of hyperbilirubinemia.^{28,29} Sulfonamides are associated with the development of kernicterus, and therefore generally are avoided in infants younger than 2 months of age. However, not all sulfonamides have the same ability to displace bilirubin. Therapeutic concentrations of trimethoprim-sulfamethoxazole do not alter albumin's capacity to bind bilirubin, and this drug occasionally is used in neonates if no reasonable alternative antibiotic exists.³⁰

Other Factors

Decreased skeletal muscle mass and alterations in tissue affinity, membrane permeability, and hemodynamics also can influence drug distribution in neonates. The increased permeability of the central nervous system (CNS) to certain lipophilic drugs, such as phenytoin, may be due to the composition of the immature brain (lower myelin content) and the higher cerebral blood flow as compared with adults.¹¹ The increased permeability of drugs into neonatal tissues, such as the CNS or red blood cells (e.g., digoxin, theophylline), also may contribute to the increased V_d observed in newborns.¹⁹

Metabolism

Most drugs are lipophilic and require biotransformation into more water-soluble substances before they can become inactivated and eliminated from the body. Biotransformation (metabolism) of drugs is catalyzed by specific enzymes. Drug-metabolizing enzyme activity is ultimately determined by an individual's underlying genetic makeup (pharmacogenetics); however, it is also greatly influenced by developmental and environmental factors. Thus, the clinically observed rate of enzyme activity and metabolism of a specific drug depends on a patient's genetic constitution, age, development, race, and gender; environmental and nutritional influences; and concomitant drug exposure and disease states.³¹ Although biotransformation may take place at various sites (e.g., plasma, skin, GI tract, lungs, and kidney), it typically occurs in the liver with subsequent elimination of metabolites via the kidneys, lungs, or biliary tract. Hepatic biotransformation may include phase I (oxidation, reduction, hydrolysis, and demethylation) and phase II reactions (conjugation with sulfate, glucuronide, glycine, glutathione, and hippurate; acetylation; and methylation).³² In general, hepatic metabolism is reduced in the neonate because of decreases in hepatic blood flow, cellular uptake of drugs, hepatic enzyme capacity, and biliary excretion. Hepatocellular uptake and intrahepatic transport of drugs may be decreased at birth because of reduced concentrations of the hepatocyte acceptor proteins Y and Z. This may result in decreased hepatic clearance for capacity-limited drugs (i.e., drugs with low extraction ratios and low intrinsic clearance).^{11,12} Concentrations

of acceptor proteins significantly increase during the first 10 days of life.^{12,32}

Phase I Biotransformation Reactions

Phase I biotransformation reactions are significantly reduced in the newborn, but increase with both gestational and postnatal age.¹¹ Maturation of enzyme activity (phases I and II) occurs at different ages for different metabolic pathways, may be regulated by endogenous hormones (e.g., growth hormone or corticosteroids), and may be substrate specific. The development of isoenzymes, presence of endogenous competitive substrates, and in utero or postnatal induction of hepatic enzymes may alter the maturation of drug metabolism.

The major group of enzymes responsible for phase I biotransformation reactions are the cytochromes P450.³³ Cytochrome P450 enzymes catalyze the biotransformation of many lipophilic drugs and endogenous substances. These enzymes are actually a “superfamily” of heme-containing proteins that exist as many different isoforms (i.e., isoenzymes). Cytochrome P450 isoenzyme nomenclature uses the root symbol CYP, followed in order by (a) an Arabic number to denote the gene family, (b) an upper case letter to designate a subfamily of highly related genes, and (c) another Arabic number to identify the individual isoenzyme within the subfamily. Seventeen human CYP gene families have been described. The most important gene families involved in human drug metabolism include CYP1, CYP2, and CYP3.³⁴ Table 94-3 lists important drug-metabolizing enzymes, their known developmental pattern, and important neonatal substrates.³³ Isoenzymes can catalyze more than one type of biotransformation reaction, and the metabolism of certain drugs may be catalyzed by more than one isoenzyme. For example, CYP1A2 catalyzes the 3-demethylation and 8-hydroxylation of theophylline. However, theophylline 8-hydroxylation may also be catalyzed by CYP2E1 and CYP3A4. In preterm and newborn infants with low CYP1A2 activity, the contribution to 8-hydroxylation by CYP2E1 and CYP3A4 may become important. However, in

general, decreased isoenzyme activity results in decreased drug clearance. Clinical examples of decreased drug metabolism in neonates according to specific phase I biotransformation reactions are described in the following sections.

Oxidation

In term newborns, activity of cytochrome P450 enzymes and NADPH-cytochrome-C-reductase is approximately 50% of the adult value.³⁵ This decreased oxidative capacity results in a reduced clearance of some drugs (e.g., diazepam, phenobarbital, phenytoin, valproic acid, theophylline, indomethacin, and metronidazole), particularly in the first few weeks of life.^{11,32} Compared with other enzyme systems, maturation of oxidative reactions occurs rapidly after birth. For example, in term newborns hydroxylation of phenytoin and phenobarbital matures as early as 2 to 4 weeks' postnatal age.³² In preterm infants, however, the rapid postnatal maturation of hydroxylation is delayed. Hydroxylation of theophylline is related primarily to postconceptional age (PCA) and approaches adult values by 40 weeks' PCA.³⁶ In general, oxidative biotransformation pathways have one-third to one-half the adult activity at birth but increase to two to five times that of an adult by 1 year postnatal age.

Hydrolysis

Hepatic and plasma esterase activity is reduced in neonates, especially preterm newborns, and reaches adult values within 10 to 12 months.¹¹ The decreased esterase activity results in reduced elimination of ester anesthetics such as procaine, tetracaine, and cocaine. This may explain the increased effects and cardiorespiratory depression seen in newborns exposed to local anesthetics.

Demethylation

The dealkylation pathway for some drugs (e.g., diazepam and lidocaine) may be less impaired than the hydroxylation pathway at birth.¹¹ In contrast, the *N*-demethylation pathways of theophylline are greatly reduced in comparison with

Table 94-3 Important Neonatal Phase I Drug-Metabolizing Enzymes, Substrates, and Known Developmental Patterns

| Enzyme | Neonatal Substrates | Known Developmental Pattern |
|-------------------|--|---|
| CYP1A2 | Acetaminophen, caffeine, theophylline, warfarin | Not present to an appreciable extent in human fetal liver. Adult levels reached by 4 months of age and may be exceeded in children 1–2 years of age. Activity slowly declines to adult levels, which are attained at the conclusion of puberty. Gender differences in activity are possible during puberty. |
| CYP2C9 CYP2C19 | Phenytoin, S-warfarin; Diazepam, phenytoin, propranolol | Not apparent in fetal liver. Inferential data using phenytoin disposition as a nonspecific pharmacologic probe suggest low activity in first week of life, with adult activity reached by 6 months of age. Peak activity (as reflected by average values for V_{max} , which are 1.5- to 1.8-fold adult values) may be reached at 3–4 years of age and declines to adult values at the conclusion of puberty. |
| CYP2D6 | Captopril, codeine, propranolol | Low to absent in fetal liver but uniformly present at 1 week of postnatal age. Poor activity (approximately 20% of that in adults) at 1 month of postnatal age. Adult competence attained by approximately 3–5 years of age. |
| CYP3A4 | Acetaminophen, alfentanil, carbamazepine, cisapride, diazepam, erythromycin, lidocaine, midazolam, theophylline, verapamil, R-warfarin | Low activity in the first month of life, with approach toward adult levels by 6–12 months of postnatal age. Pharmacokinetic data for CYP3A4 substrates suggest that adult activity may be exceeded between 1 and 4 years of age. Activity then progressively declines, reaching adult levels at the conclusion of puberty. |
| CYP3A7 | Dehydroepiandrosterone sulfate, ethinylestradiol, triazolam | Functional activity in fetus is approximately 30%–75% of adult levels of CYP3A7. |

Table 94-4 Important Neonatal Phase II Drug-Metabolizing Enzymes, Substrates, and Known Developmental Patterns

| Enzyme | Neonatal Substrates | Known Developmental Pattern |
|--------------------------------------|---|--|
| <i>N</i> -acetyltransferase-2 (NAT2) | Caffeine, clonazepam, hydralazine, procainamide, sulfamethoxazole | Some fetal activity present by 16 weeks. Virtually 100% of infants between birth and 2 months of age exhibit the slow metabolizer phenotype. Adult phenotype distribution reached by 4–6 months of postnatal age, with adult activity present by approximately 1–3 years of age. |
| Thiopurine methyltransferase | Azathioprine, mercaptopurine, thioguanine | Levels in fetal liver are approximately 30% of those in adult liver. In newborn infants, activity is approximately 50% higher than in adults, with a phenotype distribution that parallels that in adults. In Korean children, adult activity appears at approximately 7–9 years of age. |
| Glucuronosyltransferase (UGT) | Acetaminophen, chloramphenicol, morphine, valproic acid | Ontogeny is isoform specific as reflected by pharmacokinetic data for certain pharmacologic substrates (e.g., acetaminophen or chloramphenicol). In general, adult activity as reflected from pharmacokinetic data seems to be achieved by 6–18 months of age. |
| Sulfotransferase | Acetaminophen, bile acids, chloramphenicol, cholesterol, dopamine, polyethylene glycols | Ontogeny (based on pharmacokinetic studies) seems to be more rapid than that for UGT; however, it is substrate specific. Activity for some isoforms (e.g., that are responsible for acetaminophen metabolism) may exceed adult levels during infancy and early childhood. |

Modified with permission from reference 33.

hydroxylation.³⁶ Maturation of theophylline *N*-demethylation occurs at 55 weeks' PCA and lags behind the maturation of the oxidation pathways seen at 40 weeks' PCA. Despite the earlier maturation of theophylline hydroxylation, theophylline clearance is not increased significantly until the *N*-demethylation pathway matures.³⁶ Clearances of other drugs such as diazepam, morphine, and meperidine also are affected by low *N*-demethylation activity.

Phase II Reactions

Most phase II reactions are decreased in the newborn (Table 94-4).³³ Sulfation, however, is more developed than other conjugation reactions because sulfotransferase activity may approximate adult values at birth (e.g., estrogen sulfotransferase).³² Methylation also is functional at birth, as demonstrated by the ability of both term and preterm newborns to methylate theophylline to caffeine. Methyltransferase activity is known to be present even in the fetus because methylation is required for synthesis of pulmonary surfactant. In contrast, acetylation of sulfonamides via *N*-acetyltransferase 2 is decreased in neonates, especially preterm newborns.³² Other drugs such as hydralazine that are eliminated via acetylation have decreased hepatic clearance in the neonate. In fact, almost all infants younger than 2 months of age are phenotypically slow acetylators. This is in contrast to 50% of 4- to 7.5-month-old infants and 62% of 7.5- to 11-month-old infants being phenotypically fast acetylators.³³

Glucuronide Conjugation

Uridine diphosphate–glucuronosyltransferase (UGT) activity is significantly reduced at birth and generally reaches adult levels by 6 to 18 months of age.³³ However, at least ten different UGT isoforms exist, and adult levels of UGT metabolism may be reached at different ages for different substrates (drugs).³⁷ As a result of the decreased UGT activity, metabolism is significantly decreased in the neonate for compounds that undergo glucuronidation (e.g., chloramphenicol, morphine, lorazepam, corticosteroids, bilirubin, and trichloroethanol [the active metabolite of chloral hydrate]). Toxic effects of these

agents may be seen unless doses are decreased appropriately. Reduced glucuronidation with resultant accumulation of chloramphenicol was responsible for the toxic symptoms of the “gray baby syndrome” (cardiovascular collapse and shock).

The effects of decreased glucuronidation may not be as dramatic for drugs that have alternate metabolic pathways because a shift to a more mature pathway may occur. For example, in neonates, the decreased glucuronidation of acetaminophen is partially offset by an increase in acetaminophen-sulfate conjugation. This change to sulfation only partially compensates for decreased glucuronidation because acetaminophen half-life is still prolonged in the newborn.¹²

Glycine Conjugation

Glycine conjugation is decreased in newborns, but increases to adult levels by approximately 8 weeks of age. In adults, benzyl alcohol (a preservative) is converted to benzoic acid (benzoate), which then is detoxified in the liver through conjugation with glycine to form hippuric acid. Because neonates have a decreased capacity to conjugate *p*-amino benzoate and benzoate with glycine, benzoic acid can accumulate in newborns given excess benzyl alcohol or benzoic acid.³⁸ Accumulation of benzoic acid results in the “gaspings syndrome,” which consists of multiple organ system failure, severe metabolic acidosis, and gasping respirations. This potentially fatal syndrome is associated with cumulative benzyl alcohol doses of 99 mg/kg or higher in preterm neonates.³⁹ As recommended by the FDA, drugs containing the preservatives benzyl alcohol or benzoic acid should not be used in neonates.⁴⁰ The use of preservative-free IV solutions, diluents, and medications is advised.

Induction of Enzymes

Maturation of hepatic enzymes can be influenced by in utero or postnatal exposure to enzyme-inducing agents.³² Neonatal enzymes may have a faster and greater response to inducing agents compared with adults. Hydroxylation and glucuronidation pathways are especially affected.¹¹ For example, the plasma half-life of diazepam is 40 to 100 hours in preterm neonates and 20 to 45 hours in term neonates, but only 11 to

18 hours in neonates briefly exposed to the enzyme-inducing drug, phenobarbital.^{41,42} This shortened diazepam half-life is a result of an increase in the hydroxylation and conjugation pathways. Because phenobarbital can induce uridine diphosphate-UGT (and therefore glucuronide conjugation), it sometimes is used to treat neonatal unconjugated hyperbilirubinemia. Antenatal corticosteroid administration, which commonly is used to promote fetal lung maturation, also can induce postnatal metabolism of both theophylline and metronidazole.¹¹

Other Effects

Decreased cardiac output, respiratory distress, decreased liver perfusion, or hypoxia may further decrease neonatal hepatic enzymatic activity.¹¹ Decreased phenobarbital clearance has been demonstrated in asphyxiated neonates.⁴³

Renal Elimination

Glomerular filtration, tubular secretion, and tubular reabsorption are decreased in preterm and term newborns compared with adults. Because most drugs and metabolites are eliminated renally, clearance generally is decreased in neonates. As a result, maintenance doses of drugs that are eliminated renally must be decreased. Although overall renal function increases with age, the maturational rates of individual physiological functions vary. For example, glomerular filtration matures several months before tubular secretion, and factors increasing tubular reabsorption mature after tubular secretion. Because renal elimination depends on the balance of filtration, secretion, and reabsorption, predictions of renal clearance of drugs eliminated by more than one of these mechanisms may be difficult in the maturing neonate.

Glomerular Filtration

At birth, the glomerular filtration rate (GFR) is significantly decreased. The GFR for term newborns is 2 to 4 mL/minute, or approximately 10 to 20 mL/minute/1.73 m². For preterm newborns, GFR is only 0.7 to 0.8 mL/minute or approximately 0.5% of an adult.⁴⁴ In term newborns, GFR increases markedly after birth, doubling by 1 to 2 weeks' postnatal age. Despite the continued increase postnatally, GFR is only 50 mL/minute/1.73 m² at 2.5 weeks' postnatal age⁴⁵ and does not reach adult values until 3 to 5 months' postnatal age.

In preterm neonates, postnatal development of GFR is delayed and a lower GFR persists beyond the first few months of life, especially in very low-birth-weight (VLBW) newborns \leq 30 weeks' gestational age. Even at a corrected postnatal age of 9 months (i.e., 18 months' PCA), GFR is significantly decreased in VLBW infants compared with term infants of the same PCA.⁴⁵ Although the exact age at which GFR matures in VLBW infants is not known, a normal GFR should not be assumed in older preterm infants even up to 1 to 2 years postnatal age.

Serum creatinine (SrCr) concentrations in all neonates are elevated at birth, reflecting maternal concentrations. In healthy newborns more than 30 weeks' gestational age, SrCr steadily decreases throughout the first week of life to approximately 0.4 mg/dL. SrCr concentrations in VLBW infants born at 30 weeks' or less gestational age are significantly higher than their term counterparts, even at a corrected postnatal age of 9 months.⁴⁵

Table 94-5 Gentamicin Dosing Guidelines for Neonates and Infants^{a,b}

| Age | Weight | Dosing Regimen |
|-------------------|---------------|---------------------------|
| GA <38 wk | <1000 g | 3.5 mg/kg/dose Q 24 hr |
| PNA 0–4 wk | <1200 g | 2.5 mg/kg/dose Q 18–24 hr |
| PNA \leq 7 days | \geq 1200 g | 2.5 mg/kg/dose Q 12 hr |
| PNA > 7 days | 1200–2000 g | 2.5 mg/kg/dose Q 8–12 hr |
| PNA > 7 days | >2000 g | 2.5 mg/kg/dose Q 8 hr |

^aTraditional dosing; see Question 33, Dosage and Route of Administration section for discussion of extended-interval aminoglycoside dosing
^bGA, gestational age; PNA, postnatal age

Clearance of drugs primarily eliminated by glomerular filtration (e.g., digoxin, vancomycin, and the aminoglycosides) is well correlated with GFR. Therefore, maturation of GFR must be considered when developing dosing guidelines for these medications. For example, both vancomycin clearance and gentamicin clearance correlate with postnatal age, weight, and creatinine clearance, as well as PCA.^{46–50} Therefore, guidelines that incorporate these patient factors are more likely to result in therapeutic serum concentrations in the developing neonate.^{8,51,52} An example of neonatal gentamicin dosing guidelines⁸ that are used commonly is given in Table 94-5.

Other conditions such as asphyxia, decreased cardiac output, renal disease, or indomethacin therapy may further decrease GFR and drug clearance during the perinatal period.^{53–55} The hypoxia, hypercarbia, hypotension, and decreased cardiac output that occur during asphyxia cause significant decreases in GFR. In addition, compensatory mechanisms such as an increased formation of renovascular constricting prostaglandins may aggravate this condition further.⁴⁴ Therefore, dosage regimens of renally eliminated drugs should be empirically decreased in severely asphyxiated neonates. Dosage reduction before the initiation of indomethacin therapy also is necessary because significant elevations of aminoglycoside and digoxin serum concentrations have resulted with concomitant indomethacin therapy.^{54,55} For example, a 50% dosage reduction of digoxin is recommended in preterm infants receiving indomethacin.⁵⁵

In contrast, an increase in dosage may be required for drugs (e.g., thiazide and loop diuretics) that depend on GFR for sufficient intraluminal concentrations and pharmacologic effect. A diminished diuretic response may be seen in preterm neonates, particularly during the first month of life. Because furosemide is less dependent on GFR, it is the preferred diuretic in neonates.

Tubular Secretion

Tubular secretion is approximately 20% to 30% of adult values at birth and matures more slowly than GFR. Despite a doubling over the first 7 days of life, tubular secretion does not reach adult values until 30 to 40 weeks' postnatal age. By 1 year of age, tubular secretion is 10 times higher than at birth.^{11,12} Therefore, in neonates, a decreased clearance is seen for drugs that are eliminated by proximal tubular secretion (e.g., furosemide, penicillins, thiazides, atropine, and morphine). Tubular secretion, however, can be enhanced in the immature kidney

after continued exposure to certain drugs. Substrate stimulation of tubular secretory pathways and subsequent increases in elimination (and therefore dosing requirements) have been reported for penicillin, ampicillin, and dicloxacillin.^{12,56}

Tubular Reabsorption

Tubular reabsorption, a passive process that is concentration dependent, is decreased in the neonate owing to the decreased GFR and reduced filtrate load.¹¹ The low urinary pH seen in neonates results in an increase in reabsorption of weak acids (decreased clearance) and a decrease in reabsorption of weak bases. In addition, the normal diurnal variation in urine pH is not present until 2 years postnatal age.¹¹

Clinical Relevance to Dosing

Decreased enzyme activity and renal function in neonates result in a decreased clearance and prolonged half-life for many drugs (Table 94-2). Because drug clearance determines the maintenance dose, mg/kg/day dosages must be reduced in neonates, particularly preterm neonates, to avoid toxicities. As biotransformation reactions and renal function mature, daily dosages subsequently must be increased with age to prevent subtherapeutic concentrations. Because of these dynamic changes, periodic clinical assessment and therapeutic drug monitoring are extremely important in neonates.

RESPIRATORY DISTRESS SYNDROME

RDS is a major cause of morbidity and mortality in preterm neonates, affecting approximately 50,000 infants in the United States each year.⁵⁷ This clinical syndrome is characterized by respiratory failure with atelectasis, hypoxemia, decreased lung compliance, small airway epithelial damage, and pulmonary edema. The principle cause of RDS is pulmonary surfactant deficiency. Pulmonary surfactant decreases the surface tension at the air/fluid interface in the alveoli and prevents alveolar collapse. Surfactant also facilitates the clearance of pulmonary fluid, prevents pulmonary edema, and stabilizes alveoli during aeration. At birth, the clearance of residual fetal lung fluid is accompanied by an increase in pulmonary blood flow, which facilitates the transition from fetal to adult circulation.^{58,59}

In the fetus, endogenous cortisol stimulates the synthesis and secretion of pulmonary surfactant at 30 to 32 weeks' gestational age.⁶⁰ However, sufficient amounts of pulmonary surfactant for normal lung function are not present before 34 to 36 weeks' gestation.⁶¹ Therefore, the incidence and severity of RDS increase as gestational age decreases. RDS occurs in <20% to 30% of neonates born at 30 to 31 weeks' gestational age, but in 50% of neonates born at 26 to 28 weeks' gestational age.⁵⁸

Without adequate amounts of surfactant, the surface tension within the alveoli is so great that the alveoli collapse (atelectasis), resulting in poor gas exchange (e.g., hypoxemia, hypercapnia). Low lung compliance also results and large inspiratory pressures are needed to aerate the lungs. Unfortunately, the extremely compliant neonatal chest wall makes it difficult to create the large negative inspiratory pressures necessary to open the alveoli. This results in an increased work of breathing and alterations of ventilation and perfusion (V/Q mismatch).^{58,59}

Aeration of the surfactant-deficient lung also results in the cyclic collapse and distention of bronchioles with resultant bronchiolar epithelial injury and necrosis. This epithelial

damage causes pulmonary edema by allowing fluid and proteins to leak from the intravascular space into the air spaces and interstitium of the lung. The necrotic epithelial debris and proteins then form fibrous hyaline membranes.⁵⁹ Hyaline membranes and pulmonary edema further impair gas exchange. The term *hyaline membrane disease* has been used to describe the presence of these fibrous membranes. However, because hyaline membrane disease is not specific to surfactant deficiency, the term *respiratory distress syndrome* (RDS) is preferred.

The inadequate oxygenation and ventilation and increased work of breathing caused by RDS may result in the need for assisted positive-pressure ventilation. Complications of RDS may be related to mechanical ventilation and include pulmonary barotrauma (e.g., pneumothorax, pulmonary interstitial emphysema [PIE]), intraventricular hemorrhage (IVH), PDA, retinopathy of prematurity (ROP), and chronic lung disease or bronchopulmonary dysplasia (BPD).⁵⁹ (Also see Bronchopulmonary Dysplasia.)

Clinical Presentation

1. L.D., an 800-g male, was precipitously born at 27 weeks' gestational age to a 38-year-old gravida 6 para 5 female. Apgar scores were 5 at 1 minute, and 7 at 5 minutes. One hour after birth, L.D. seems cyanotic and has retracting respirations with grunting and nasal flaring. HR is 160 beats/minute and RR is 65 breaths/minute. An arterial blood gas (ABG) on 100% oxygen by nasal cannula is as follows: pH, 7.26; PCO₂, 50 mmHg; PO₂, 53 mmHg; and base deficit, 7. Arterial to alveolar oxygen tension ratio (a/A) is <0.2. L.D. is intubated immediately and placed on positive-pressure–assisted ventilation. A catheter is inserted in his umbilical artery for frequent ABG monitoring, and an umbilical vein catheter is inserted for central venous access. L.D.'s chest radiographic shows moderate hyaline membrane disease. Ampicillin 50 mg/kg Q 12 hours and gentamicin 3.5 mg/kg Q 24 hours are ordered IV to rule out sepsis. What risk factors does L.D. have for RDS? What signs and laboratory data are consistent with RDS?

[SI units: PCO₂, 6.67 kPa; PO₂, 7.1 kPa]

L.D.'s risk factors for RDS are prematurity and male gender. Other risk factors include gestational diabetes, cesarean section with no labor, second-born twins, perinatal asphyxia, and maternofetal hemorrhage.^{58,59,62} Clinical signs and laboratory data consistent with RDS in L.D. include tachypnea (RR, 65 breaths/minute); cyanosis, retracting respirations, grunting, nasal flaring, hypoxemia (PO₂, 53 mmHg); hypercapnia (PCO₂, 50 mmHg); and a mixed respiratory and metabolic acidosis.^{58,59,62} Clinical manifestations classically present within the first 6 hours of life.⁶²

Tachypnea, the first sign of respiratory distress, is an attempt to compensate for the inadequate ventilation, hypercapnia, and acidosis. L.D.'s retracting respirations (the use of intercostal, subcostal, suprasternal, or sternal accessory muscles) reflect the increased work of breathing necessary to maintain ventilation. His nasal flaring decreases resistance during inspiration and increases oxygenation. Grunting is the result of forceful exhalation against a partially closed glottis in an effort to prolong expiration and maximize oxygenation. Grunting also increases intrathoracic pressure during expiration in an attempt to stabilize the alveoli and prevent atelectasis. L.D.'s cyanosis,

hypoxemia, hypercapnia, and mixed respiratory and metabolic acidosis are consequences of inadequate oxygenation and poor ventilation and are consistent with RDS.^{58,59}

Prevention

2. What maternal treatment might have prevented RDS in L.D.?

RDS may be prevented if pregnancy can be prolonged long enough for fetal lungs to mature, or if production of pulmonary surfactant can be accelerated in utero. Premature labor can be suppressed pharmacologically with drugs that inhibit uterine contractions (tocolytic agents), such as the β -adrenergic agonists (e.g., ritodrine, terbutaline), prostaglandin inhibitors (e.g., indomethacin), calcium channel blockers (e.g., nifedipine), and magnesium sulfate.^{63,64} (See Chapter 46.)

Maternal administration of glucocorticoids can accelerate fetal lung maturation and decrease the incidence and severity of RDS. L.D.'s mother should have been considered a candidate for antenatal corticosteroids, unless immediate delivery was anticipated. In a meta-analysis of 15 antenatal maternal corticosteroid trials with more than 3,400 participants, corticosteroids significantly reduced RDS, NEC, IVH, and neonatal death, regardless of the infant's gender and race. Furthermore, there was no evidence of an increased incidence of fetal, neonatal, or maternal infection, or fetal death associated with the use of antenatal steroids. The incidence of BPD, however, was not affected, and the decrease in RDS was not significant for newborns greater than 34 weeks' gestational age.⁶⁵

A consensus panel formed by the National Institutes of Health (NIH) evaluated the use of antenatal corticosteroids for fetal lung maturation.⁶⁴ This panel recommended administration of antenatal steroids in all pregnant women at high risk for premature delivery. Many centers repeated the course of steroids every 7 days until 34 weeks' gestation because the effects of antenatal steroids had not been shown to last beyond 7 days. Although the potential benefits and risks of repeated courses were unknown at the time, multiple-course antenatal steroids became widespread, with usage ranging from 85% to 98%.⁶⁶ Subsequently, a decrease in birth-weight and head circumference, and an increase in neonatal sepsis and death have been associated with multiple-course antenatal steroids.^{67,68} Investigation by a second NIH consensus panel resulted in a recommendation that a single course of antenatal corticosteroids be considered for all pregnant women between 24 and 34 weeks gestation who are at risk of preterm delivery within 7 days; repeat courses of antenatal steroids are not routinely recommended and should be reserved for patients enrolled in randomized controlled trials.⁶⁹

Since the second NIH consensus panel in 2000, three large randomized controlled trials of single versus repeat courses of antenatal corticosteroids reported conflicting results.⁷⁰⁻⁷² The issue of repeat courses of antenatal steroids remains controversial. Not all trials found significant decreases in the incidence of RDS and chronic lung disease with repeat courses. A significant decrease in other neonatal morbidities (e.g., PDA, pneumothorax, surfactant use, and the need for oxygen therapy, continuous positive airway pressure, mechanical ventilation, and pressor or volume support) was found in at least one, but not all trials. However, birth-weight and head circumference were significantly decreased and severe IVH was significantly

increased with repeat steroid courses in at least one trial. Sepsis and death were not increased with repeat courses.

Despite numerous clinical trials, the appropriate number and timing of repeat courses of antenatal corticosteroids and the risk to benefit ratio are still unknown. Repeat courses might benefit neonates of extreme prematurity because a significant decrease in composite neonatal morbidity was noted in one clinical trial for neonates born less than 28 weeks' gestational age.⁷⁰ A randomized clinical trial known as the "Multiple courses of antenatal corticosteroids for preterm birth (MACS)" is currently underway to investigate if a longer interval between repeat courses will maintain efficacy while decreasing composite neonatal morbidity.

Betamethasone injection 12 mg IM Q 24 hours for two doses or dexamethasone injection 6 mg IM Q 12 hours for four doses are the only two NIH-recommended regimens to accelerate lung maturation.^{64,69} Fetal lung maturity can be assessed by measuring certain components (e.g., lecithin, sphingomyelin) of lung surfactant in amniotic fluid. A ratio of lecithin to sphingomyelin greater than 2 indicates functionally mature fetal lungs and a decreased risk for RDS.⁵⁹ Although both betamethasone and dexamethasone decrease the incidence of RDS, only betamethasone decreases neonatal mortality and the risk for periventricular leukomalacia (PVL).^{73,74} Multiple courses of dexamethasone (compared with betamethasone) have been associated with an increased risk for PVL, IVH, ROP, and neurodevelopmental abnormalities.⁷⁵ Therefore, betamethasone seems to be the preferred agent.

Maternal administration of glucocorticoids increases the production of fibroblast-pneumocyte factor, which stimulates the biosynthesis of surfactant in type II pneumocytes. This mimics the physiological response of fetal lungs to the increased cortisol production that normally begins at 30 to 32 weeks' gestation.⁶⁰ Certain obstetric conditions can stress the fetus and stimulate adrenal activity and corticosteroid release in utero, thereby enhancing fetal lung maturity. For example, an unusually low incidence of RDS occurs in neonates born prematurely to mothers with hypertension, infection, cardiovascular disease, hemoglobinopathies, heroin addiction, premature rupture of membranes >48 hours, and decreased placental function.^{59,61} Antenatal steroids also improve postnatal responsiveness to exogenous surfactant administration.^{62,64,76} Administration of thyrotropin-releasing hormone (TRH) in combination with antenatal steroids was initially thought to enhance fetal lung maturation, decrease the incidence of RDS, and decrease the incidence of BPD. Unfortunately, in a meta-analysis, prenatal TRH increased neonatal ventilation usage, lowered 5-minute Apgar scores, and was associated with poorer 12-month outcomes.^{64,77} Therefore, antenatal use of TRH cannot be recommended.

Treatment

Surfactant Therapy

3. What treatments should be initiated for L.D.?

Before L.D. is treated for RDS, other causes of respiratory distress must be ruled out. For example, infections, (particularly group B streptococcal sepsis or pneumonia), often present with respiratory distress. Because it is difficult to distinguish between RDS and infection, all infants with severe RDS should receive antibiotics. L.D. was started empirically on antibiotics,

and a complete evaluation of possible sepsis should be performed.

Exogenous surfactant should be administered intratracheally to L.D. as soon as possible. Until the late 1980s, oxygen supplementation, mechanical ventilation, fluid restriction, and supportive care were the general treatment measures for RDS. Presently, RDS primarily is considered a consequence of surfactant deficiency; therefore, the administration of exogenous surfactant should decrease the severity of RDS and the risk of death.⁷⁸

Human surfactant is synthesized and secreted by type II alveolar epithelial cells of the lung. It contains 80% phospholipids, 8% neutral lipids, and 12% proteins.⁷⁹ The major surface-active component is dipalmitoylphosphatidylcholine (DPPC), also known as *colfosceril* or *lecithin*. However, this phospholipid slowly adsorbs to the air/fluid interface in the alveoli. Other phospholipids (e.g., phosphatidylcholine, phosphatidylglycerol), and four surfactant apoproteins (SP-A, SP-B, SP-C, and SP-D) enhance spreadability and surface adsorption.^{61,76,80} Adsorption and surface spreading of the surfactant in the alveoli are important determinants of surface-tension activity. SP-A and SP-D both play a role in immune regulation and providing host defense. SP-A may also help to regulate alveolar surfactant reuptake and metabolism.⁶¹ SP-B and SP-C are the two most important apoproteins responsible for promoting adsorption and surface spreading of the surfactant in the alveoli to form a phospholipid monolayer.⁷⁹

Natural surfactants are derived from bovine or porcine lung-lipid or lavage extracts, or from human amniotic fluid. Modified natural surfactants are lung-lipid extracts supplemented with phospholipids or other components.⁷⁶ Currently, three surfactant products are commercially available for clinical use in the United States: beractant (Survanta) is a modified natural surfactant, and both calfactant (Infasurf) and poractant alfa (Curosurf) are natural surfactants. Colfosceril palmitate (Exosurf), a synthetic surfactant without a protein analog, is no longer available for clinical use. Beractant and calfactant are FDA-approved for the prevention (i.e., prophylaxis) of RDS, and all three products are approved for the treatment (i.e., rescue therapy) of RDS.⁸¹⁻⁸³ Lucinactant (Surfaxin), a new synthetic surfactant that contains a protein analogue, is awaiting FDA approval for the treatment and prevention of RDS.⁷⁹

Beractant is prepared by mincing bovine lung, which contains lung surfactant and phospholipids from lung cells. During the extraction process, cholesterol is removed and synthetic DPPC is added to improve surface activity. Surfactant apoprotein B (SP-B), which is thought to be the most critical protein for surfactant activity, is removed with cholesterol. As a result, beractant contains only trace amounts of SP-B (<0.5% of total protein). Ninety-nine percent of the protein in beractant is SP-C.^{84,85}

In contrast, calfactant is extracted from washings of newborn calves' lungs; therefore it contains fewer contaminating lung cell components. Forty percent of the protein in calfactant is SP-B and 60% is SP-C. Poractant alfa is extracted from washings of pigs' lungs and is purified by liquid gel chromatography to remove neutralized lipids such as cholesterol. As with calfactant, no synthetic DPPC is added to poractant alfa.⁸⁶ It is composed of 99% lipids and 1% apoproteins (SP-B [30%] and SP-C [70%]). Neither beractant, calfactant, nor poractant alfa contain SP-A (refer to Table 94-6 for comparisons).⁸¹⁻⁸³

PHARMACOLOGIC AND LONG-TERM EFFECTS

4. What are the effects of exogenously administered surfactant in RDS?

Oxygenation and lung compliance rapidly and markedly improve after the administration of surfactant. Supplemental oxygen and mechanical ventilation can be reduced significantly. The increased lung compliance and decreased need for high inspiratory pressures result in a dramatic decrease in the incidence of pneumothorax and PIE. Survival in treated infants increases by approximately 40% regardless of birth-weight or gestational age, and neonatal mortality from RDS is decreased to approximately 20%.⁷⁸ Other complications of RDS such as severe BPD, IVH, and PDA have not been decreased consistently with surfactant therapy. Although the severity of ROP was decreased with the use of exogenous surfactants, overall incidence is unchanged.⁷⁸

NUMBER OF DOSES

5. At 2 hours of age, 4 mL/kg of beractant was administered to L.D. intratracheally. Within 1 hour, oxygenation improved and the FiO_2 was weaned from 100% to 80%. Six hours later, the ABGs revealed the following: pH, 7.36; PCO_2 , 45 mmHg; PO_2 , 80 mmHg; base deficit, 2; and O_2 saturation of 94% on the following ventilator settings: FiO_2 , 0.73; intermittent mechanical ventilation (IMV), 40; peak inspiratory pressure (PIP), 18; and positive end-expiratory pressure (PEEP), +3. The a/A ratio is <0.2. Should another dose of beractant be administered?

[SI units: PCO_2 , 6.0 kPa; PO_2 , 10.7 kPa]

The response to a single dose of surfactant usually is transient; thus, more than one dose is needed. Response to surfactant therapy can be variable, especially in preterm newborns weighing less than 750 g.⁷⁶ Reasons for nonresponse include surfactant inhibition by proteins that have leaked into the alveolar spaces, inactivation of surfactant by inflammatory mediators (free oxygen radicals, proteases), presence of conditions that can decrease surfactant effectiveness (e.g., pulmonary edema), or poor delivery of surfactant to the alveoli (owing to atelectasis). The degree of responsiveness to surfactant also decreases with increasing postnatal age.^{76,85}

Although the indications for subsequent doses of surfactant have varied in investigational studies, persistence of respiratory failure is the major clinical indicator for retreatment. A second dose of beractant should be given to L.D. because he still requires mechanical ventilation with relatively high inspiratory pressures and supplemental oxygen ($FiO_2 \geq 0.3$) to maintain an arterial $PO_2 \geq 50$ mmHg and oxygen saturation of 90%. Furthermore, an a/A ratio of <0.2 is an indication for repeat dosing.⁷⁸ In meta-analyses, the incidence of neonatal death and pneumothorax is reduced by multiple surfactant doses; however, other large trials have not reported additional benefits with more than two doses of calfactant.^{87,88} In practice, despite these conflicting findings, most infants receive an average of two surfactant doses.

PROPHYLACTIC ADMINISTRATION AND TREATMENT OF RESPIRATORY DISTRESS SYNDROME

6. Could prophylactic administration of surfactant have prevented RDS in L.D.?

Prophylactic administration (i.e., at the time of delivery within 30 minutes after birth) of surfactant may reduce the

Table 94-6 Comparison of Currently Marketed Surfactant Products⁸¹⁻⁸³

| Variable | <i>Calfactant (Infasurf)</i> | <i>Poractant α (Curosurf)</i> | <i>Beractant (Surfacta)</i> |

incidence and severity of RDS, but does not always prevent the disease.⁷⁸ Theoretically, the first dose of surfactant should be given before the newborn's first breath or before positive-pressure ventilation.^{78,85} This would avoid the early lung injury in RDS that can interfere with surfactant distribution, bioavailability, and effectiveness.⁷⁶ This strategy, however, increases the cost of care because newborns who might never develop RDS would be intubated and treated unnecessarily.^{62,76,87} In

addition, delivery room treatment may interfere with resuscitation and stabilization of the neonate.⁸⁵

In a Cochrane meta-analysis, prophylactic administration of surfactant to infants at high risk for developing RDS was associated with significant decreases in the risk of pneumothorax, PIE, death and the combined variable of BPD or death, compared to rescue treatment.⁸⁹ Although these results are promising, the exact criteria to clinically determine "high-risk"

newborns who should receive prophylactic surfactant therapy is still unclear. Additionally, a clinical study has not compared prophylactic use of surfactant to early therapy.

Exogenous surfactant also can be administered “early” (i.e., at 2 hours of age) to treat RDS, or immediately upon diagnosis of RDS as “rescue” therapy. In another Cochrane meta-analysis, mortality, pneumothorax, PIE, and BPD were significantly reduced among neonates receiving early therapy compared with rescue therapy.⁹⁰

In summary, surfactant treatment should be administered as soon as clinical signs of RDS appear.⁹⁰ Early therapy avoids progression of the disease and the potential for decreased surfactant effectiveness. Prophylactic administration in the delivery room should be reserved for extremely premature neonates who are at the highest risk for RDS.^{78,85}

COMPLICATIONS

7. What complications of surfactant treatment is L.D. at risk of developing?

The most common adverse effects of surfactant therapy are related to the method of administration.⁸⁵ Surfactant is administered directly into the lungs via the endotracheal tube (ETT) by using a catheter or a side-port adapter connected to the ETT. During administration, bradycardia and oxygen desaturation may develop secondary to vagal stimulation and airway obstruction.^{81–83,85} These adverse events might require temporary discontinuation of surfactant administration and increased ventilator support. Mucous plugging with obstruction, BP changes, and altered electroencephalogram (EEG) tracings also can occur.⁸⁵ Airway obstruction can be decreased by delivering surfactant as a continuous intratracheal infusion over 10 to 20 minutes via an infusion pump.⁹¹

Surfactant therapy may increase the risk of pulmonary hemorrhage. Although the exact mechanism is unknown, surfactant may increase pulmonary blood flow through the ductus arteriosus, increase pulmonary microvascular pressures, and cause hemorrhagic pulmonary edema.⁷⁸ The benefits of surfactant therapy, however, far outweigh the increased risk of pulmonary hemorrhage.

Neonates who are given surfactant can be at greater risk for apnea that requires methylxanthine treatment. Surfactant-treated neonates can be weaned from ventilator support sooner and, therefore, might display apnea more easily.⁷⁸ Individual trials with natural surfactants have suggested an increased incidence of sepsis and NEC, but most studies have not validated these findings.⁷⁸ No difference in the incidence of NEC or apnea treated with methylxanthines was noted between calfactant and beractant.⁸⁴

PRODUCT SELECTION

8. Are there any advantages of one surfactant product over the other?

Not enough data exist to label one commercially available product superior to the other. Although several studies have compared two products, no study has compared all three commercially available surfactant products. Currently, three comparative trials of commercially available natural and modified natural surfactants exist.^{84,86,92} In the first randomized, double-blind trial of calfactant and beractant, calfactant-treated infants required significantly less supplemental oxygen and mean air-

way pressures (MAP) during the acute phase of respiratory distress.⁸⁴ However, the duration of mechanical ventilation and the use of supplemental oxygen for the rest of the hospital stay were not significantly different between the two groups. The number of infants requiring four doses of surfactant was significantly less in the calfactant-treated group. In addition, the calfactant group also had a longer dosing interval, indicating that calfactant may have a longer duration of effect. The incidence of death, BPD, and secondary outcomes, including pneumothorax, were not significantly different between the two groups.⁸⁴

The second clinical trial of calfactant versus beractant compared the immediate changes in lung compliance after treatment in infants <37 weeks gestational age with RDS.⁹² There was no difference in pulmonary compliance at 1 hour after surfactant administration between the two treated groups. However, calfactant-treated infants had a significant decrease in FiO_2 and MAP at 1 hr after treatment and required fewer doses compared to the beractant-treated infants (2 versus 4, respectively). No significant differences in the incidence of death, BPD, PIE, pneumothorax, PDA, sepsis, or pneumonia were found between the two groups.

In the third randomized trial of poractant alfa and beractant, poractant alfa-treated infants required significantly less supplemental oxygen and mechanical ventilation than infants treated with beractant during the acute phase of RDS.⁸⁶ These improvements were significant for up to 24 hours after treatment. Pneumothorax tended to be higher in the beractant-treated infants (5 of 40 versus 2 of 33); however, a significant difference was not detected because of the small sample size. The overall duration of mechanical ventilation and total time of oxygen therapy, mortality, the incidence of BPD, and other secondary outcomes were not significantly different between the two groups.

Based on these three comparative trials, the natural surfactants (calfactant and poractant alfa) seem to have a longer duration of effect and require less supplemental oxygen and MAP than the modified natural surfactant, Survanta, (Beractant). The incidence of BPD, death, and other secondary outcomes are not different between natural and modified natural surfactants. A new synthetic surfactant, lucinactant, contains both phospholipids and a high concentration of recombinant proteins designed to mimic human SP-B and has approvable status from the FDA for the prevention of RDS. A recent Phase III, multicenter, randomized, controlled trial compared the efficacy and safety of poractant alfa and lucinactant in the prevention of RDS in very premature infants at high risk for RDS.⁹³ There were no significant differences in the incidence of BPD, overall mortality, and the number of doses required per infant. Further comparative trials are needed to better determine if other clinical advantages of surfactant products exist.

Surfactant should be administered by qualified physicians with the presence of nursing and respiratory therapy personnel.⁹⁴ Neonates receiving beractant or poractant alfa need to be disconnected from the ventilator before surfactant administration.^{81,83} As a result, clinicians transiently increase both FiO_2 and peak inspiratory pressures before disconnecting the ventilator. These higher settings and interruption from the ventilator may be avoided, however, if beractant is given through a neonatal suction valve. This method is equally effective, simpler, and possibly safer than methods with ventilator disconnection.⁹⁵ Calfactant, on the other hand, has

the advantage of flexible administration techniques. It can be administered intratracheally via a catheter passed through the ETT with brief interruptions in ventilation (as with beractant and poractant alfa) or via a side-port adapter into the ETT without disconnecting the ventilator.⁸²

Because beractant, calfactant, and poractant alfa are all derived from natural sources, they contain proteins that are potentially antigenic. Thus, theoretically, they may cause an immunologic response. However, there are no reports of beractant-, calfactant-, or poractant alfa-induced hypersensitivity reactions.⁷⁸ Surfactant products are expensive and are commercially available only in single-use vials; two vial sizes are available for each product (Table 94-6). The current availability of a second size vial may make these products more cost effective.⁹⁶

Diuretics

9. What is the role of diuretics in the management of RDS?

The therapeutic role of diuretics in RDS is controversial. In the natural course of RDS, an abrupt diuresis (urine output >80% of fluid intake) occurs within the first 48 to 72 hours of life. This diuresis is followed by an improvement in pulmonary function, which is thought to be due to a decrease of alveolar or interstitial pulmonary fluid. Before surfactant was commercially available, neonates who did not have this diuresis (or had it after 72 hours) were more likely to develop BPD.

ROUTINE USE

Routine early administration of furosemide to pharmacologically mimic the natural course of RDS may facilitate diuresis and weaning from mechanical ventilation. Although diuretics do not decrease the incidence of BPD or mortality, infants receiving early (prophylactic) therapy of furosemide had a greater increase in urine output, decrease in ventilator MAPs, and improvement in oxygenation compared with infants not receiving furosemide.⁶² However, infants receiving prophylactic furosemide had hemodynamic instability and a greater postnatal weight loss. Furthermore, long-term use of furosemide can result in hypercalciuria, renal calcifications, and other electrolyte imbalances (e.g., hyponatremia, hypochloremia, and hypokalemia).⁶² Finally, treatment with furosemide may promote patency of the ductus arteriosus, which may further worsen pulmonary edema.⁹⁷ Therefore, routine administration of diuretics in RDS is not indicated.⁶²

SELECTIVE USE

Because pulmonary edema is present in RDS, furosemide occasionally is administered to enhance lung fluid elimination and decrease pulmonary edema. If L.D. had signs of pulmonary edema with compromised pulmonary function (e.g., hypoxemia and hypercapnia), furosemide 1 mg/kg IV push could be given.

BRONCHOPULMONARY DYSPLASIA

Definition and Incidence

10. J.T. is an 80-day-old, 2-kg, female ex-preemie born at 25 weeks' gestation. Her medical history includes RDS, episodes of sepsis and pneumonia, and chronic parenteral hyperalimentation. J.T. has also failed extubation numerous times and is cur-

rently requiring mechanical ventilation with an FiO_2 of 0.5. Current vital signs are as follows: RR, 60 breaths/minute; HR, 150 beats/minute; BP, 80/55 mmHg; O_2 saturation, 90%. On physical examination, J.T. has intercostal and subcostal retractions, shallow breathing, and an expiratory wheeze. Bilateral diffuse haziness with lung hyperinflation, focal emphysema (with bleb formation), atelectasis, and irregular fibrous streaks are seen on chest radiograph. J.T. is currently receiving enteral feedings with a standard preterm 20-cal/oz formula at 40 mL Q 3 hr. Based on these findings, the diagnosis of BPD is made. What risk factors for BPD does J.T. have? What is the pathogenesis of BPD? What clinical signs and laboratory evidence of BPD are apparent in J.T.?

BPD (also known as chronic lung disease) is the most common form of chronic pulmonary disease in infants. The disease develops in newborns who require supplemental oxygen and positive-pressure ventilation for RDS or other primary lung disorders. A severity-based definition of BPD has been developed by the National Institute of Child Health and Human Development.⁹⁸ For infants born <32 weeks' gestational age, assessment of BPD is performed at 36 weeks' PCA or at the time of discharge. Mild BPD is defined as a need for supplemental O_2 >21% for ≥ 28 days but not at 36 weeks' PCA or discharge; moderate BPD as a need for supplemental O_2 ≥ 28 days plus treatment with <30% O_2 at 36 weeks' PCA or discharge; and severe BPD as a need for supplemental O_2 ≥ 28 days plus treatment with $\geq 30\%$ O_2 and/or positive pressure at 36 weeks' PCA or discharge. For infants born ≥ 32 weeks gestational age, the above definitions are different only in that assessments are conducted at 56 days of life rather than 36 weeks' PCA.⁹⁸ BPD is a significant cause of infant morbidity and mortality. Approximately 7,500 new cases of BPD occur in the United States each year.⁹⁹ The incidence of BPD is inversely related to gestational age and birth-weight. Infants with birth-weights $\leq 1,000$ g have as high as a 77% risk of developing BPD compared with a 7% risk in infants with birth-weights >1,250 g.¹⁰⁰ J.T. has two of the most important risk factors for BPD, low birth-weight and decreased gestational age. She is also at risk for BPD owing to mechanical ventilation, oxygen toxicity, and fluid excess (160 mL/kg/day). Other risk factors include male gender, white ethnicity, and persistent PDA.¹⁰¹

Pathogenesis and Clinical Manifestations

The cause of BPD seems to be multifactorial. Lung immaturity, surfactant deficiency, oxygen toxicity, barotrauma/volutrauma, and inflammation all play important roles. Premature infants, especially those <26 weeks' gestation, are at a higher risk for BPD owing to lung immaturity.¹⁰² Surfactant deficiency (which causes severe RDS) and the immature parenchymal structure of the lung and chest wall contribute to the development of BPD. Oxygen therapy, which causes a release of free oxygen radicals, is directly associated with the pathogenesis of BPD. Prolonged exposure to high oxygen concentrations and free oxygen radicals causes tissue damage, alveolar-capillary leaks, and atelectasis with resultant impaired gas exchange and pulmonary edema.¹⁰² This may lead to the chronic pulmonary fibrotic changes seen in infants with BPD. In term infants, the lungs contain antioxidant enzymes that help to protect the lung from damage produced by free oxygen radicals. However, in preterm infants, the concentration of antioxidant enzymes

may be low or absent. Therefore, premature infants are more susceptible to develop BPD than term infants.

Barotrauma secondary to positive-pressure ventilation is also a major factor in the pathogenesis of BPD, independent of oxygen toxicity.¹⁰² Barotrauma is caused by repetitive distention of the terminal airways during mechanical ventilation. This results in disruption of the epithelium and an increase in capillary permeability to proteinaceous fluid. The severity of lung injury is related to the amount of positive peak pressure used. Volutrauma is also involved in the pathogenesis of BPD and is caused by high tidal volume ventilation and overdistention. Volutrauma may be due to unusually high peak inflation pressures compared with lung compliance. The combined iatrogenic insults of oxygen toxicity and barotrauma/volutrauma, both inflicted on an immature lung over a period of time, can worsen lung damage.

The inflammatory process in the lung is activated by oxygen toxicity, barotrauma/volutrauma, or other injury. This results in the attraction and activation of leukocytes (e.g., neutrophils, macrophages), which may cause further release of inflammatory mediators, elastase, and collagenase.⁹⁹ Elevated levels of elastase and collagenase can destroy the elastin and collagen framework of the lung. α_1 -Proteinase inhibitor, a major defense against elastase activity, may be inactivated by free oxygen radicals. Therefore, the combined elevated levels of elastase and the decreased activity of α_1 -proteinase inhibitor may enhance lung injury and lead to the development of BPD. Infants who are going to develop BPD also have elevated levels of cytokines such as platelet-activating factor, leukotrienes, tumor necrosis factor, and fibronectin.¹⁰² These agents, combined with the activated leukocytes, cause significant lung damage with breakdown of capillary endothelial integrity and capillary leakage. Furthermore, the increased fibronectin levels found in tracheal aspirate samples of infants with early BPD may predispose them to develop pulmonary fibrosis.¹⁰²

Infection and nutrient deficiency may also play a role in the pathogenesis of BPD. Pathogens such as *Ureaplasma*, *Chlamydia*, or cytomegalovirus (CMV) may cause chronic infection and contribute to the development of BPD. Studies have shown direct correlations between *Ureaplasma* colonization and the presence of BPD.¹⁰² Deficiencies in nutrients such as vitamin A (retinol) or trace elements such as zinc, copper, and selenium (which are integral components of the antioxidant enzyme structure), may also play a role in the pathogenesis of BPD.

BPD is characterized by tachypnea with shallow breathing, intercostal and subcostal retractions, and expiratory wheezing as demonstrated in J.T. Other signs and symptoms include rales, rhonchi, cough, airflow obstruction, airway hyperreactivity, increased mucus production, hypoxemia, and hypercarbia.⁹⁹ J.T.'s chest radiograph shows evidence of BPD, including focal emphysema (with bleb formation), atelectasis, bilateral diffuse haziness (interstitial thickening) with increased expansion of the lungs (hyperinflation), and irregular fibrous streaks. Mucous plugging, sepsis, and pneumonia can also develop in BPD infants on chronic mechanical ventilation. Infants with severe BPD eventually develop cardiovascular complications such as pulmonary hypertension, cor pulmonale, systemic hypertension, and left ventricular hypertrophy. In addition to chronic respiratory and cardiovascular complications, infants with BPD have significant growth, nutritional, and neurodevelopmental problems.

Management

11. What nonpharmacologic and therapeutic agents should be used to manage BPD in J.T.?

The medical management of infants with BPD includes supplemental oxygen therapy, mechanical ventilation, fluid restriction, nutritional management, and various pharmacologic interventions. Supplemental oxygen administered via mechanical ventilation, continuous positive airway pressure, or nasal cannula should be provided to maintain an oxygen saturation of 88% to 92% and prevent hypoxemia.¹⁰³ Fluids should be restricted to 120 to 130 mL/kg/day to prevent congestive heart disease and pulmonary edema. Because infants with BPD have a 25% increase in caloric expenditure (owing to the increased work of breathing), hypercaloric formulas (e.g., 24 or 27 cal/oz) may be used to optimize calories while restricting fluid intake.⁹⁹ If this increased energy is not provided, infants are at risk for developing a catabolic state that places them at higher risk for developing BPD (inadequate nutrition may potentiate the toxic effects of oxygen toxicity and barotrauma). The goal of nutritional therapy is to produce weight gains of 10 to 30 g/day, which can usually be accomplished by providing 140 to 160 kcal/kg/day.^{99,102} If infants do not tolerate enteral feedings, parenteral alimentation should be substituted until the GI tract becomes more functional. Because J.T. is on a 20-cal/oz formula, switching her to a hypercaloric formula (i.e., 24 or 27 cal/oz) would help to optimize her weight gain. Her fluids should be restricted to 240 to 260 mL/day (120–130 mL/kg/day).

Pharmacologic Therapy

The treatment of BPD consists of multiple-drug therapy, which includes diuretics, bronchodilators, and corticosteroids. Despite the advancement of drug therapy, none of these drugs has been shown to reverse pulmonary damage in infants with BPD. Instead, they are used primarily to reduce clinical symptoms and to improve lung function. Pharmacologic therapy and dosage regimens for the management of BPD are shown in Table 94-7.^{8,99,101,103–105}

Diuretics

Infants with BPD are particularly prone to pulmonary edema from cardiogenic and noncardiogenic factors. Left ventricular failure may superimpose the already existing right ventricular failure. Pulmonary vascular permeability is increased because of the disruption of the alveolar-capillary unit and causes an increased amount of fluid in the interstitium. Although the precise mechanism in the treatment of BPD is unknown, diuretics help to reduce interstitial lung water. In addition, diuretics lower pulmonary vascular resistance and improve gas exchange, thereby, reducing oxygen requirements. Among the diuretics available, furosemide is the drug of choice because of its potent diuretic effect. It acts by blocking the reabsorption of chloride in the ascending loop of Henle. In addition, it increases lymphatic flow and plasma oncotic pressure and decreases pulmonary interstitial edema. In several studies, the use of furosemide in infants with BPD was associated with short-term improvement in lung compliance and oxygenation, decreased total pulmonary resistance, and facilitation in ventilator weaning.^{99,106} However, a more recent meta-analysis did not support all of these findings. The chronic use of furosemide

Table 94-7 Pharmacologic Management of Bronchopulmonary Dysplasia^{8,99,101,103-105}

| <i>Drug Therapy</i> | <i>Dosage Regimen</i> |
|---|--|
| Diuretics | |
| Chlorothiazide | <i>Neonates and infants <6 months:</i> PO: 20–40 mg/kg/day in two divided doses; maximum dose: 375 mg/day <i>Infants >6 months:</i> PO: 20 mg/kg/day in two divided doses; maximum dose: 1 g/day |
| Furosemide | PO: 1–4 mg/kg/dose 1–2 times/day IV: 1–2 mg/kg/dose Q 12–24 hr <i>Nebulized:</i> 1 mg/kg/dose diluted to a final volume of 2 mL with NS (use IV form) |
| Hydrochlorothiazide/Spironolactone | PO: 1–2 mg/kg/dose Q 12 hr (dose based on hydrochlorothiazide) |
| Systemic Bronchodilators | |
| Caffeine citrate | <i>Loading dose:</i> 20 mg/kg (10 mg/kg as caffeine base) IV over 30 min <i>Maintenance dose:</i> 5 mg/kg/dose (2.5 mg/kg/dose as caffeine base) Q 24 hr; start 24 hr after loading dose; may administer IV (over 10 min) or PO |
| Theophylline | <i>Loading dose:</i> 5 mg/kg IV or PO <i>Maintenance dose:</i> 2–3 mg/kg/dose Q 8–12 hr IV or PO |
| Inhaled Bronchodilators | |
| Albuterol | 0.03–0.06 mL/kg/dose of 0.5% solution (0.15–0.3 mg/kg/dose) diluted to 1–2 mL NS; give via nebulization Q 2–6 hr or PRN; minimum dose: 0.25 mL (1.25 mg); maximum dose: 1 mL (5 mg) |
| Cromolyn sodium | 20 mg (2 mL) via nebulization Q 6–8 hr; may need up to 2–4 weeks for response to occur |
| Ipratropium bromide | <i>Neonates:</i> 0.125 mL/kg/dose of 0.02% solution (25 mcg/kg/dose) diluted to 2–2.5 mL NS; give via nebulization Q 8 hr <i>Infants:</i> 0.625–1.25 mL of 0.02% solution (125–250 mcg/dose) diluted to 2–2.5 mL NS; give via nebulization Q 8 hr |
| Metaproterenol | 0.01–0.02 mL/kg/dose of 5% solution (0.5–1 mg/kg) diluted to 1.5–2 mL NS; give via nebulization Q 4–6 hr or PRN; minimum dose: 0.1 mL (5 mg); maximum dose: 0.3 mL (15 mg) |
| IV, intravenous; NS, normal saline; PO, oral; PRN, as needed. | |

in infants >3 weeks old with BPD was associated with significant improvements in oxygenation and lung compliance only.¹⁰⁷ The effects of furosemide on the duration of oxygen requirement and mechanical ventilation, length of hospital stay, mortality, and the incidence of BPD could not be assessed owing to limited data. In addition to questionable clinical outcome, furosemide can have significant adverse effects. Chronic furosemide use can result in increased urinary losses of chloride, potassium, and sodium, and may result in hypochloremia, hypokalemia, and hyponatremia. Furthermore, volume depletion, hypercalciuria, nephrocalcinosis, osteopenia, and ototoxicity may also occur.⁹⁹ Excessive fluid loss or hypochloremia may result in metabolic alkalosis and worsen respiratory acidosis. Some of these adverse effects may be reduced by using alternate-day furosemide therapy or nebulized furosemide.^{106,108} Both of these regimens were not associated with electrolyte imbalances and were shown to significantly increase lung compliance and decrease pulmonary resistance.¹⁰⁶ In summary, because of the limited efficacy data and potential adverse effects, the use of furosemide for the management of BPD cannot be routinely recommended.

Thiazide diuretics (e.g., hydrochlorothiazide) in combination with a potassium-sparing diuretic (e.g., spironolactone) can improve lung function and decrease oxygen requirements with increased diuresis.^{99,106} Although less potent than furosemide, the combination of these two diuretics can reduce the incidence of hypokalemia commonly associated with loop

or thiazide diuretics. Adverse effects commonly seen with a combination of a thiazide and spironolactone include hyponatremia, hyperkalemia or hypokalemia, hypercalciuria, hyperuricemia, hyperglycemia, azotemia, and hypomagnesia.⁹⁹ Various diuretics and dosage regimens are listed in Table 94-7.

Generally, infants with BPD who are treated with diuretics are started on furosemide, but are changed to a combination diuretic (spironolactone/hydrochlorothiazide) if long-term treatment is needed to avoid adverse effects. Suggested indications for initiating furosemide therapy include (a) 1-week-old infants with early BPD and ventilator dependency, (b) infants with stable BPD who significantly worsen owing to fluid overload, (c) infants with chronic BPD who do not improve, and (d) infants requiring an increased fluid intake to provide adequate calories.¹⁰²

Because J.T. has chronic BPD and is not improving (i.e., she has not been able to be weaned off the ventilator), furosemide 1 mg/kg Q 12 hours should be initiated. J.T. should be monitored for electrolyte disturbances while on furosemide. Electrolyte supplements such as potassium chloride or sodium chloride may be required to prevent hypokalemia, hyponatremia, and hypochloremia.

12. J.T. is started on furosemide 2 mg Q 12 hours. One week later, she still requires high ventilatory settings and is unable to be weaned from the ventilator. What other therapeutic agents may be considered to treat J.T.'s BPD?

Systemic Bronchodilators

Methylxanthines (theophylline, caffeine) have been used extensively in infants with BPD because of a direct bronchodilating effect. Methylxanthines can also improve diaphragmatic and skeletal muscle contractility and act as mild diuretics (see the Apnea of Prematurity section). Improvement in skeletal muscle contractility may improve functional residual capacity, which can help to facilitate ventilator weaning. Both theophylline and caffeine reduce pulmonary resistance and increase lung compliance.⁹⁹ Unfortunately, most studies in infants with BPD have only evaluated the short-term benefits of methylxanthines in improving lung function; long-term outcome studies are needed. The early use of caffeine to treat apnea of prematurity has recently been shown to decrease the incidence of BPD compared with placebo.¹⁰⁹

If J.T. is started on theophylline, a loading dose of 5 mg/kg followed by a maintenance dose of 2 mg/kg every 8 hours is recommended (Table 94-7). J.T. should be monitored for adverse effects, including tachycardia, gastroesophageal reflux, vomiting, diarrhea, agitation, and seizures. Caffeine may be preferred because it has fewer side effects and a wider therapeutic index. However, caution should be taken to ensure that the dosing reflects the salt form of the caffeine prescribed (e.g., caffeine base or caffeine citrate).¹⁰⁵ Therapeutic serum concentrations for theophylline and caffeine are not well defined for BPD. However, most clinicians target the upper range cited for apnea of prematurity (see the Apnea of Prematurity section).

Inhaled Bronchodilators

Infants in the early stages of BPD generally have airway hyperactivity and smooth muscle hypertrophy. They are also at higher risk for bronchoconstriction owing to increased airway resistance secondary to hypoxia. Therefore, the use of bronchodilators may be helpful in these infants. β_2 -Agonists such as albuterol or metaproterenol have been shown to provide short-term improvements (duration, 4 hours) in lung compliance and pulmonary resistance owing to bronchial smooth muscle relaxation.^{99,110} However, inhaled bronchodilators are not effective in all infants with BPD. Infants in the late stages of BPD may have severe pulmonary damage and fibrotic changes. Only half of these infants demonstrate a decrease in pulmonary resistance after albuterol therapy.¹¹¹ Although β_2 -agonists are more potent bronchodilators than theophylline or caffeine, their adverse effect profile, which includes cardiovascular side effects (e.g., tachycardia, hypertension), limit their use. In addition, tolerance may develop with prolonged administration.⁹⁹ Therefore, inhaled bronchodilators should be reserved for infants who clearly demonstrate improvements during therapy. Currently, there are no well-designed studies evaluating the chronic use of inhaled bronchodilators for the treatment of BPD. Further studies evaluating the efficacy and safety of long-term inhaled bronchodilator therapy are needed.

Inhaled anticholinergics such as ipratropium bromide have produced short-term benefits (duration, ~4 hours) in infants with BPD by improving pulmonary function.¹¹² These drugs work by preventing the action of acetylcholine at the muscarinic cholinergic receptor site, thereby interfering with vagally mediated bronchoconstriction. Anticholinergics relax bronchial smooth muscle and decrease mucus secretion. Inhaled anticholinergics are generally reserved for infants who fail or are intolerant to albuterol, or as an adjunct to albuterol

if clinical improvement is not seen.⁹⁹ The combined therapy of albuterol and ipratropium may be more effective than either drug alone.^{99,112} The adverse effect profile of ipratropium is minimal because the drug is poorly absorbed.

Cromolyn prevents the release of inflammatory mediators from mast cells. In randomized trials, cromolyn has not been shown to prevent BPD or to decrease mortality.¹¹³ Because of the lack of evidence supporting the role of cromolyn for the prevention of BPD, its use is not recommended. Further studies evaluating different dosage regimens and mode of delivery of cromolyn are required.

A major problem with inhaled bronchodilators is their method of administration and drug delivery. Inhaled bronchodilators can be given by jet or ultrasonic nebulization or via a metered-dose inhaler.¹⁰⁶ For ventilator-dependent infants receiving metered-dose inhalers, the metered-dose inhaler is connected to an adapter that is attached to the ventilator circuit and ETT. Metered-dose inhalers can also be given through bag ventilation via the ETT. For nonventilated infants, the metered-dose inhaler can be given using a spacer/AeroChamber and a face mask.

Compared with metered-dose inhalers, nebulization of inhaled bronchodilators has several disadvantages. Loss or inefficient delivery of drug and cooling of the inspired oxygen mixture may occur with nebulization. In several studies in neonates, metered-dose inhalers with a spacer provided more efficient delivery of inhaled bronchodilators and greater improvements in oxygenation and ventilation; smaller doses and a shorter treatment time were also used.^{114,115} In addition, metered-dose inhalers are less expensive than nebulization. Therefore, the use of metered-dose inhalers with an appropriate spacing device is preferred for most infants. Various products and dosage regimens can be found in Table 94-7.

Corticosteroids

Corticosteroids, particularly dexamethasone, have been used extensively for the prevention and treatment of BPD. Mechanisms of action of corticosteroids include (a) reduction of polymorphonuclear leukocyte migration to the lung, (b) reduction of lung inflammation, (c) inhibition of prostaglandin, leukotriene, tumor necrosis factor, and interleukin synthesis, (d) reduction of elastase production, (e) stimulation of surfactant synthesis, (f) reduction of vascular permeability and pulmonary edema, (g) enhancement of β -adrenergic receptor activity, (h) reduction of pulmonary fibronectin (which can reduce the risk of interstitial fibrosis), and (i) stimulation of serum retinol concentrations.^{99,106,116} Treatment with dexamethasone (initiated ~7 days of life) in infants with documented BPD or with clinical signs and chest radiograph findings consistent with BPD reduces the release of inflammatory mediators, improves pulmonary mechanics and clinical status, facilitates weaning from mechanical ventilation, and decreases the duration of oxygen therapy.^{99,102,106,116-118} In most studies, dexamethasone therapy did not significantly reduce the duration of hospitalization or improve survival in infants with BPD.^{99,106,116,118,119}

Systemic dexamethasone is associated with many serious short-term adverse effects, including hyperglycemia, increased BP, hypertrophic cardiomyopathy, GI bleeding, intestinal perforation, pituitary-adrenal suppression, bone demineralization, poor weight gain, and increased risk of infection.^{99,102,106,116}

Serious long-term adverse effects have also been identified in preterm infants who receive systemic corticosteroids. Two reviews (which assessed infants at ~1 year) reported an increase in the incidence of cerebral palsy, neurodevelopmental delay, and motor dysfunction in preterm infants who received systemic steroids for the prevention and treatment of BPD.^{120,121}

The American Academy of Pediatrics does not recommend the use of steroids for the prevention and treatment of BPD in preterm infants because of short- and long-term adverse effects.¹²² Systemic corticosteroids should be reserved for preterm neonates enrolled in randomized, double-blind, controlled trials; long-term neurodevelopmental assessment is highly encouraged. In general, the clinical use of systemic steroids should be limited to exceptional circumstances (e.g., an infant on maximal ventilatory and oxygen support) where the benefits may outweigh the risks. The American Academy of Pediatrics advises that parents should be fully informed about the short- and long-term adverse effects of systemic corticosteroids.¹²²

Subsequent to the last American Academy of Pediatrics recommendation, several randomized trials have evaluated different corticosteroids and dosing regimens for the prevention and treatment of BPD, in an attempt to minimize adverse effects while maintaining efficacy. A recent placebo-controlled trial of low-dose dexamethasone administered to ventilator-dependent very preterm (gestational age <28 weeks) or extremely low-birth-weight infants (birth-weight <1,000 g) after 1 week of life (median age, 4 weeks) reported a decrease in ventilator settings, improvement in oxygenation, and higher percentage of extubation in the dexamethasone-treated infants.¹²³ However, the incidence of BPD and mortality were not different between groups. Short-term adverse effects such as hypertension, hyperglycemia, and intestinal perforation were not found. A 2-year follow-up to this study reported no significant differences in the incidence of cerebral palsy, blindness, deafness, developmental delay, and mortality between the two groups.¹²⁴ However, the number of patients followed was too small to provide definitive evidence.

Hydrocortisone has also been used for the prevention and treatment of BPD in several clinical trials.^{125–128} In a retrospective study, hydrocortisone was as effective as dexamethasone in decreasing supplemental oxygen requirements but produced fewer adverse effects.¹²⁵ However, a prospective placebo-controlled trial found no effect of hydrocortisone on survival without BPD or mortality. In addition, an increase in spontaneous GI perforation was found in the hydrocortisone-treated group resulting in an early termination of the study.¹²⁶ Long-term adverse effects (e.g., cerebral palsy, neurodevelopmental impairment) have been reported to be similar between hydrocortisone and placebo or nontreated groups.^{125,127,128} Based on these clinical findings, a lower dose and a shorter duration of therapy using either dexamethasone or hydrocortisone for the prevention and treatment of BPD may be considered in extremely high-risk ventilated infants. A delay of treatment until >7 days postnatal age may decrease the risk of adverse neurologic outcomes such as cerebral palsy. Some centers have delayed treatment until the infant reaches a postnatal age of >14 days. One currently recommended dosing regimen is dexamethasone 0.2 mg/kg/day in two divided doses for 3 days followed by 0.1 mg/kg/day for 3 days and then 0.05 mg/kg/day for 3 days.¹²⁹

Inhaled steroids such as beclomethasone dipropionate, flunisolide, fluticasone, and budesonide have also been used for the treatment and prevention of BPD.^{102,106} Infants receiving inhaled steroids for the treatment of BPD may have reduced oxygen requirements and duration of mechanical ventilation, and improvement in lung mechanics.^{102,106,122} However, the onset of clinical improvements may be delayed compared with systemic steroids. In contrast, the preventative use of inhaled steroids has not been shown to decrease the incidence of BPD or the duration of mechanical ventilation and oxygen therapy; however, the use of systemic steroid may be decreased.^{110,130} Two meta-analyses assessing comparative trials of inhaled versus systemic steroids found no significant differences in mortality or the incidence of BPD.^{131,132} The use of early inhaled steroids (for prevention of BPD) was associated with increased duration of mechanical ventilation and oxygenation. Adverse effects of inhaled steroids reported in BPD infants are less common than with systemic steroids.^{129,131,132} These include mild adrenal suppression, bronchospasm, tongue hypertrophy, and oral candidiasis.¹³³ High-dose inhaled fluticasone (500 mcg Q 12 hours for 2 weeks) has also been associated with moderately severe pituitary-adrenal suppression in VLBW infants.¹³⁴ The infant's mouth should be cleaned after each use of inhaled steroid to minimize complications such as oral thrush. As with inhaled bronchodilators, administration is a therapeutic problem with these medications. The amount of drug delivered to the infant can vary from 0.02% (by jet nebulizer) to 14.2% (by metered-dose inhaler with an aerochamber).¹¹⁶ Further studies evaluating the optimal dose, duration of therapy, route of administration, time of initiation, most appropriate preparation, and long-term adverse effects of corticosteroids are needed before inhaled steroids can be routinely recommended.

Long-Term Sequelae

13. Six months have passed, and J.T. is now 6 months old (corrected age), weighs 5 kg, and ready for discharge. Over the past several months, ventilation requirements slowly decreased and J.T. was eventually extubated. However, she still requires supplemental oxygen at an F_{iO_2} of 30%, 1/8 L/minute via nasal cannula to maintain an oxygen saturation of 88% to 92%. Discharge medications include multivitamins with iron 0.5 mL Q 12 hours; spironolactone/hydrochlorothiazide suspension, 5 mg Q 12 hours; sodium chloride solution, 2 mEq Q 8 hours; nebulized albuterol (0.5% solution), 0.25 mL Q 6 hours; and fluticasone metered-dose inhaler (44 mcg per actuation), 2 puffs Q 12 hours. What are the long-term complications of BPD that can be expected in J.T.?

Infants with BPD have little pulmonary reserve and, therefore, are at higher risk for developing frequent respiratory exacerbations. BPD places J.T. at risk for recurrent infections of the lower respiratory tract and she may require frequent hospitalizations during the first year for bronchiolitis and pneumonia.¹⁰³ Approximately 50% of all children with severe BPD require hospitalization for respiratory exacerbations during the first year of life.¹⁰³ Respiratory syncytial virus is a common cause of respiratory distress (airway obstruction, mucus plugging, and airway edema) and recurrent atelectasis. With time, most preterm survivors with BPD have an improvement in pulmonary function owing to lung growth; however, many continue to have airway hyperreactivity. Infants with severe

BPD can also develop pulmonary hypertension, cor pulmonale, systemic hypertension, and left ventricular hypertrophy.

In addition to pulmonary and cardiovascular complications, J.T. may be at risk for developing bone demineralization and rickets. VLBW infants are born with inadequate stores of vitamin D. In general, these premature infants may not receive an adequate intake of vitamin D, either parenterally or through their diet. Most VLBW infants require prolonged parenteral nutrition, which may cause cholestasis or hepatic failure. Prolonged cholestasis or chronic hepatic congestion owing to heart failure may cause malabsorption of calcium and vitamin D. In addition, furosemide may exacerbate calcium deficiencies by causing hypercalciuria. These combined factors may result in bone demineralization and rickets. Infants with BPD usually have a high catabolism and increased oxygen consumption due to an increased work of breathing and chronic hypoxia. Inadequate nutritional support may negatively affect weight gain, growth, and long-term outcome of BPD.

Neurologic and developmental abnormalities such as learning disabilities, speech delays, vision and hearing impairment, and poor attention span can also occur in infants with BPD.¹⁰⁰ BPD itself is not an independent risk factor for neurologic abnormality; related factors include birth-weight, gestational age, and socioeconomic status.^{99,102} Long-term follow-up evaluations at 1 to 8 years of age in infants previously treated with dexamethasone revealed an increase in neurodevelopmental abnormalities such as cerebral palsy and decreased school performance.^{102,120,125,135} However, it is not known if these abnormalities were due to an adverse effect of dexamethasone on brain development or to an improved survival of infants who may already be at risk for developing these abnormalities. Recent studies assessing the long-term follow-up of infants treated with low-dose or delayed use of dexamethasone (i.e., initiated at >7 days of age), did not find an increase risk of developmental delay or cerebral palsy.^{124,129} Hydrocortisone may offer an advantage over dexamethasone, because increases in neurodevelopmental abnormalities were not observed in infants followed up at 2 to 8 years of age.^{127,128}

Mortality rates for infants with severe BPD range from 30% to 40%.¹⁰⁴ Approximately 80% of deaths associated with BPD occur during initial hospitalization and are from respiratory failure, sepsis, pneumonia, cor pulmonale, and congestive heart failure.¹⁰⁴

Prevention

14. What preventive measures could have been used to decrease the incidence of BPD in J.T.?

Prevention of prematurity and other etiologic factors of RDS is the most effective means of preventing BPD. The administration of antenatal steroids to mothers before delivery decreases the incidence of RDS and, potentially, BPD. Exogenous surfactant therapy also reduces the incidence of RDS, but not the incidence of BPD. Early administration of dexamethasone (initiated <96 hours of life) in preterm infants reduces pulmonary inflammation and lung injury, decreases the incidence of BPD and oxygen requirements, improves lung function, and facilitates weaning from the ventilator.^{99,116,119} However, early dexamethasone therapy has also been associated with an increased risk of infection, GI bleeding, intestinal perforation, hyper-

trophic cardiomyopathy, growth failure, and, of greatest concern, neurologic impairment and cerebral palsy.¹¹⁹ A follow-up study at school age reported significant decreases in motor skills and coordination, lower IQ scores, and clinically significant disabilities in the dexamethasone-treated children.¹³⁵ Early dexamethasone therapy is not recommended for routine use because of the inconsistent improvements in outcome and mortality, and the lack of long-term follow-up data.¹²² Clinicians should weigh the potential benefits versus the risks of early dexamethasone therapy for the prevention of BPD.

One of the causes of BPD can be vitamin A deficiency, which can predispose infants to BPD owing to impaired lung healing, increased susceptibility to infection and loss of cilia, and decreased number of alveoli.^{136,137} Premature infants, especially VLBW infants, are at greatest risk owing to low body stores, inadequate intake during feedings, and decreased enteral absorption of vitamin A. In a meta-analysis evaluating various dosing regimens of IM vitamin A, mortality or oxygen requirement was reduced significantly at 1 month of life.¹³⁷ In addition, a significant reduction in oxygen requirements at 36 weeks PCA was observed in infants with a birth-weight <1,000 g. Administration of oral vitamin A 5,000 IU/day did not decrease the incidence of BPD, perhaps because of inadequate dose or poor oral absorption.¹³⁸ Vitamin A seems to be a relatively safe drug; the incidence of adverse effects was similar between treated and control groups.¹³⁷ Despite the beneficial findings of IM vitamin A, further studies evaluating the efficacy, safety, and optimal dosage regimen of vitamin A for the prevention of BPD are needed before routine use can be recommended.

Optimization of nutritional support may also help to prevent the development of BPD because proper nutrition helps to promote lung maturation, growth, and repair. Excessive fluid administration should be avoided because it may lead to BPD. Fluid restriction decreases both the incidence of BPD and mortality.¹⁰⁶ In addition, the early use of high-frequency ventilation in infants may decrease the severity and incidence of BPD.⁹⁹

PATENT DUCTUS ARTERIOSUS

Pathogenesis

Several major differences between adult and fetal circulation exist. To understand the pathophysiology and clinical manifestations of PDA, fetal circulation and the cardiovascular changes that occur at birth are reviewed.

Fetal Circulatory Anatomy

The fetus has three unique circulatory structures that differ from the adult: (a) the ductus venosus, which permits blood to bypass the liver; (b) the foramen ovale, which allows blood to pass from the right atrium into the left atrium; and (c) the ductus arteriosus, the structure that connects the pulmonary artery to the descending aorta and allows blood to bypass the lungs (Fig. 94-1).¹³⁹

In addition to these structural differences, vascular resistance and pressure play important roles in determining the pathway of fetal circulation. For example, the relative hypoxia that occurs in utero causes pulmonary vasoconstriction. Pulmonary vasoconstriction, along with compression of pulmonary blood

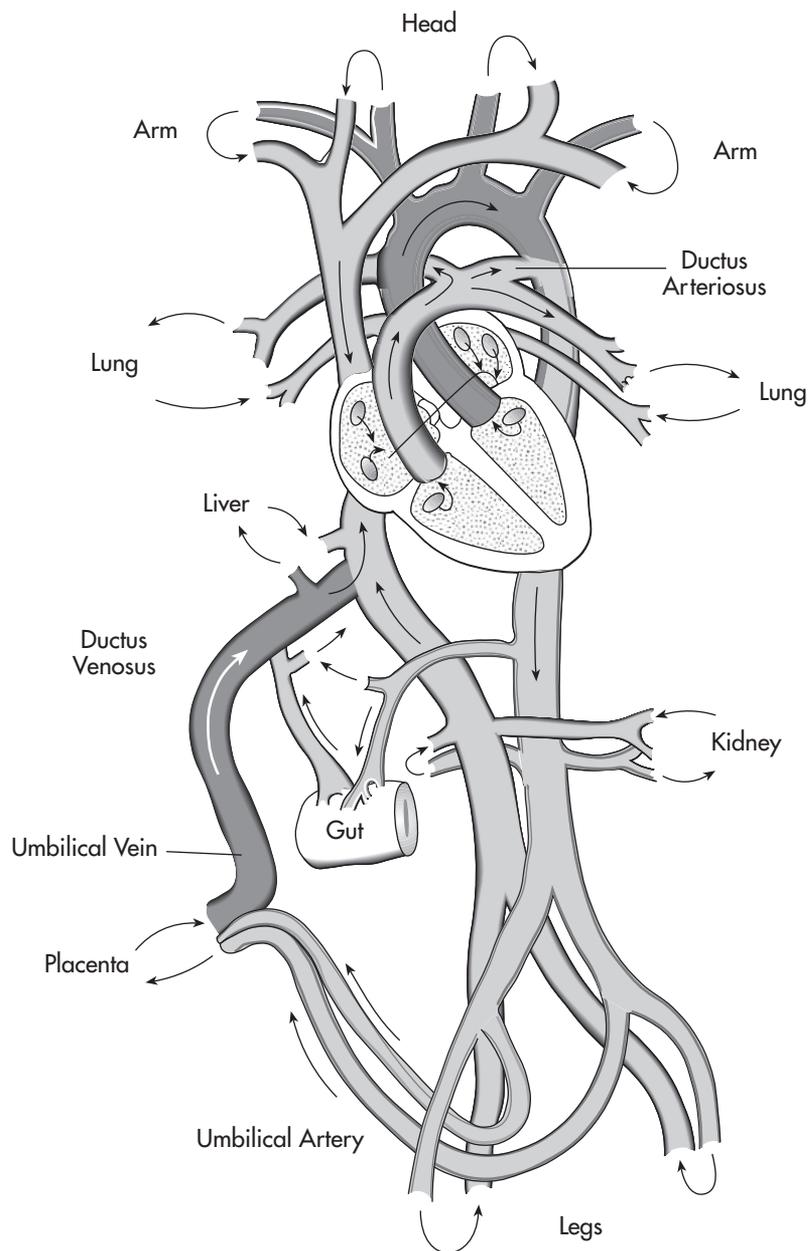

FIGURE 94-1 Fetal circulation. (Modified with permission from Bernstein D. The fetal to neonatal circulatory transition: the fetal circulation. In: Kliegman RM et al., eds. *Nelson Textbook of Pediatrics*, 18th Ed. Philadelphia: Saunders Elsevier; 2007;1855.)

vessels by unexpanded fetal lung mass, results in a high pulmonary vascular resistance and decreased pulmonary blood flow. This decreased pulmonary blood flow is acceptable in utero because the lungs essentially are nonfunctional. Large amounts of blood, however, must be pumped through the placenta where gas exchange occurs.

Fetal Circulation

Maximally oxygenated blood (PO_2 , 30–35 mmHg) flows from the placenta to the fetus through the umbilical vein (Fig. 94-1). Approximately 50% of the umbilical venous blood is shunted away from the liver through the ductus venosus and directed into the inferior vena cava. Blood from the inferior vena cava and superior vena cava then enters the right atrium. Most of the

blood from the inferior vena cava, which is well oxygenated, is directed in a straight pathway across the right atrium through the foramen ovale directly into the left atrium. It then enters the left ventricle through the mitral valve and is pumped into the vessels of the head and forelimbs. Thus, the fetal brain is preferentially perfused with blood containing a higher amount of oxygen. Deoxygenated blood returning from the head region via the superior vena cava enters the right atrium and is directed through the tricuspid valve into the right ventricle, where it then is pumped into the pulmonary artery. Most of this blood is diverted through the ductus arteriosus into the descending aorta and then through the two umbilical arteries to the placenta. A small percentage of the blood flows to the lower extremities and then is returned to the heart via the inferior vena cava.¹³⁹

Changes at Birth

At birth, major circulatory changes result from umbilical cord clamping, aeration and expansion of the lungs, and an increase in arterial PO_2 . These changes are important in the transition from fetal to adult circulation. When the umbilical cord is clamped, blood flow decreases through the ductus venosus, which closes within 3 to 7 days. Clamping of the umbilical cord also results in a twofold increase in systemic vascular resistance. This increase in systemic vascular resistance increases aortic, left ventricular and atrial pressures and cardiac output. Pulmonary pressures and blood flow also change. After the neonate's first breath, the lungs expand, oxygenation improves, and pulmonary vascular resistance immediately drops. This increases pulmonary blood flow, causing a decrease in pulmonary artery, right ventricle, and right atrium pressures.¹³⁹

If hypoxia occurs after delivery, pulmonary vasoconstriction results and the neonate may develop pulmonary hypertension with a persistence of fetal circulation. This is termed persistent pulmonary hypertension of the newborn or persistent fetal circulation. Oxygenation of these neonates is extremely difficult because of the pulmonary vasoconstriction and resultant decreased pulmonary blood flow. Systemic alkalization (through hyperventilation and the use of sodium bicarbonate) and inotropic support often are necessary.¹³⁹ Severe cases may require extracorporeal membrane oxygenation.

Closure of the Foramen Ovale

Because of the decreased right atrium pressure and increased left atrium pressure that occur after birth, blood attempts to flow down the pressure gradient from the left atrium through the foramen ovale into the right atrium. This is in the opposite direction from what occurs in fetal life. The small, valvelike flap that lies over the foramen ovale on the left side of the atrial septum closes over the foramen ovale opening when the pressure in the left atrium exceeds the pressure in the right atrium. Closure of this flap prevents further flow through the foramen ovale. As long as the pressure in the left atrium is higher than the right atrium, the foramen ovale remains functionally closed, until it closes anatomically.

Closure of the Ductus Arteriosus

Closure of the ductus arteriosus is more complex and depends on many factors. In utero, patency of the ductus arteriosus is maintained through the combined vasodilatory effects of a low PO_2 and high concentrations of prostaglandins, particularly prostaglandin E_2 (PGE_2).¹⁴⁰ Prostacyclin also plays a role in maintaining ductal patency.^{140,141} After birth, the smooth muscles of the ductus arteriosus constrict as arterial oxygenation increases and concentrations of placentally derived prostaglandins, particularly PGE_2 , decrease.¹⁴¹ In utero, the PO_2 of the ductal blood is 18 to 28 mmHg, whereas after birth in a term neonate, it is approximately 100 mmHg. Normally, the ductus arteriosus of a term neonate functionally closes within the first few days of life (i.e., in 82% of infants within 48 hours of life and in 100% of infants within 96 hours of life).¹⁴⁰ Anatomical closure of the ductus occurs within 2 to 3 weeks of life.¹⁴¹ When the ductus arteriosus fails to close, it is called *patent ductus arteriosus (PDA)*. In a term neonate, a PDA beyond the first few days of life generally is permanent. It usually is secondary to an anatomical defect in the wall of the ductus arteriosus and requires surgical ligation. In contrast, a

PDA in a preterm neonate may persist for weeks and still close spontaneously.

When a PDA is present, the direction and amount of shunting through this opening are determined by the pressure between the systemic and pulmonary circulation. Usually, blood flows from the aorta into the pulmonary circulation. Because systemic vascular resistance and aortic pressure are increased, and pulmonary vascular resistance and pulmonary artery pressure are decreased after birth, blood pumped from the left ventricle into the aorta flows from the aorta (a high-pressure area) through the PDA and into the pulmonary artery (a lower-pressure area). This flow is called *left-to-right shunting* and is in contrast to the right-to-left shunting that occurs through the PDA during fetal life.

Although the persistence of a PDA is pathological, it is necessary for the survival of patients with cyanotic congenital heart disease while awaiting corrective or palliative cardiac surgery. These patients have congenital cardiac defects that depend on the ductus arteriosus to maintain cardiac output and systemic perfusion (e.g., coarctation of the aorta, aortic stenosis, and hypoplastic left heart syndrome) or to provide pulmonary blood flow and maintain systemic oxygenation (e.g., pulmonary artery atresia or severe stenosis and tricuspid atresia). Patency of the ductus arteriosus can be maintained pharmacologically with a continuous infusion of alprostadil (PGE_1). The initial starting dose of PGE_1 is 0.05 to 0.1 mcg/kg/minute and may be increased every 15 to 30 minutes up to 0.2 mcg/kg/minute until achievement of clinical response. Infusion doses up to 0.4 mcg/kg/minute have also been used by several centers. PGE_1 infusion should be reduced to the lowest effective dose once patency of the ductus arteriosus is achieved.^{8,142}

Clinical Presentation

15. T.S. is a 750-g female who was born at 25 weeks' gestational age to a 22-year-old gravida 2 para 1 female. One hour after birth, T.S. developed symptoms of RDS and two doses of beractant were given within the first 24 hours of life. After the second dose of beractant, T.S.'s respiratory function greatly improved and no further doses of beractant were required. On the third day of life, the nurse noticed that T.S. had tachycardia, a systolic murmur, a hyperactive precordium, and a widened pulse pressure. Her lungs sounded "wet." In addition, the nurse noted that T.S.'s combined IV fluid rates total 160 mL/kg/day instead of the desired fluid intake of 120 mL/kg/day. Current vital signs are as follows: HR, 190 beats/minute; RR, 65 breaths/minute; BP, 55/23 mmHg; and O_2 saturation, 89%. ABGs include pH, 7.22; PCO_2 , 55 mmHg; PO_2 , 77 mmHg; and base deficit, 10. Ventilator support is increased to compensate for T.S.'s deteriorating respiratory status. Echocardiography is performed and shows a moderate-size PDA with significant left-to-right shunting. The chest radiograph shows pulmonary edema and an enlarged heart. What risk factors for PDA does T.S. have?

[SI units: PCO_2 , 7.33 kPa; PO_2 , 10.3 kPa]

T.S. has two major risk factors for developing a symptomatic PDA: prematurity and RDS. The occurrence of a PDA is inversely proportional to gestational age and birth-weight. The incidence of PDA is approximately 45% in premature infants

with a birth-weight of <1,750 g but can be as high as 80% in premature infants with a birth-weight of <1,200 g.¹⁴¹ In contrast, the incidence of PDA in term infants is only 0.04%.¹⁴⁰ Preterm neonates are at a higher risk for PDA than term newborns because the smooth muscle of the immature ductus is more sensitive to the dilatory effects of prostaglandins and less sensitive to the constrictive effects of increased oxygen tension. In addition, circulating concentrations of PGE₂ are often elevated in premature infants owing to the decreased pulmonary metabolism of prostaglandins.¹⁴⁰ These factors contribute to the delayed closure of the ductus arteriosus in premature infants. With advanced gestation, the ductus is less responsive to the relaxant effects of prostaglandins and is more sensitive to the constricting effects of oxygen.^{140,143}

RDS also increases the risk for PDA. Exogenous surfactant, especially prophylactic use, also may increase the risk of symptomatic PDA.^{143,144} PDA can further complicate the course of RDS.^{143,145} T.S.'s course is typical of a preterm neonate with resolving RDS. T.S.'s pulmonary function improved after surfactant administration. Consequently, pulmonary vascular resistance decreased and the degree of left-to-right shunting across the ductus arteriosus increased, causing a deterioration in respiratory status. In addition, the excess fluid that T.S. received is an iatrogenic factor that may have increased the shunting across the PDA, aggravating the degree of pulmonary congestion.¹⁴³

16. How is T.S.'s presentation consistent with that of PDA?

T.S.'s clinical presentation is due to the increased pulmonary blood flow, decreased systemic perfusion, and left ventricular volume overload that resulted from the shunting of left ventricular cardiac output through the PDA into the lungs. To compensate for the inadequate peripheral perfusion, HR increases. This results in an increase in cardiac output and a greater left-to-right shunt through the PDA, creating a vicious cycle. The widened pulse pressure (the difference between systolic and diastolic pressures, 32 mmHg) is a result of diversion of aortic blood flow through the PDA, which is causing the bounding pulses. The systolic murmur, which is not always present, is the result of turbulent blood flow through the ductus arteriosus occurring as the pulmonary vascular resistance decreases. Tachycardia, hyperactive precordium, and a continuous murmur are results of the left-to-right shunting through the ductus arteriosus during systole.¹⁴¹

17. What are the potential complications of this hemodynamically significant PDA in T.S.?

The increased pulmonary blood flow and resultant pulmonary edema will worsen T.S.'s respiratory disease and increase the need for ventilatory support. The higher ventilatory settings (increase in MAP and FiO₂) place T.S. at risk for developing BPD. If the PDA is left untreated, T.S. may develop congestive heart failure secondary to an increased left ventricular end-diastolic volume. A hemodynamically significant PDA also places T.S. at risk for IVH and NEC.¹⁴³

Treatment

18. How should PDA be managed in T.S.?

The initial medical management for T.S.'s symptomatic PDA is supportive care, which includes fluid management (e.g.,

fluid restriction and diuretic therapy), correction of anemia, and treatment of hypoxia and acidosis. Although excessive fluid administration may increase the risk of PDA, fluid restriction alone is unlikely to result in ductal closure. T.S.'s fluid intake should be restricted to 100 to 120 mL/kg/day (approximately 80% of total fluid maintenance requirements) to avoid worsening of her pulmonary edema and to prevent congestive heart failure.^{141,143} Furosemide 1 mg/kg IV push should also be given to T.S. immediately to treat her pulmonary edema (see Question 9). In addition to fluid management, correction of anemia is important. Low concentrations of hemoglobin result in an increased cardiac output, which may worsen the infant's cardiac function. Anemia not only increases the demand of left ventricular output to ensure adequate oxygen delivery to the tissues, but may also increase the magnitude of the left-to-right shunt by decreasing the resistance of blood flow through the pulmonary vascular bed.¹⁴³ Maintaining a hematocrit level of >40% to 45% is often recommended.¹⁴¹ Because of T.S.'s gestational age, birth-weight, and size of PDA, it is unlikely that she will respond to these general measures alone. Therefore, T.S. requires treatment with indomethacin. Indomethacin nonspecifically inhibits prostaglandin synthesis, thereby eliminating the vasodilator effects of the PGE series on the ductus arteriosus. Unfortunately, not every infant who is treated with indomethacin responds with constriction of the ductus arteriosus; therefore, surgical ligation of the PDA may be required for T.S. Ligation generally is reserved for neonates who do not respond to indomethacin therapy or those in whom indomethacin therapy is contraindicated (see Question 20).¹⁴³

Indomethacin

19. What is the dose of indomethacin and what route should be used for its administration?

The treatment of choice for T.S. is pharmacologic therapy with IV indomethacin; enteral indomethacin is less effective. This reduced effectiveness may be due to the formulation of the suspension and decreased, erratic, enteral absorption.¹⁴⁶

A large interpatient variability of indomethacin pharmacokinetics occurs in preterm neonates. Serum concentrations do not correlate consistently with therapeutic or adverse effects.¹⁴⁶ Furthermore, the optimal therapeutic serum concentration is not yet defined. Although many dosage regimens have been reported, dosing guidelines from the National Collaborative Study are commonly used.¹⁴⁵ Three indomethacin doses are given in 12- to 24-hour intervals, with the first dose equal to 0.2 mg/kg IV in all neonates. Because indomethacin clearance is directly proportional to postnatal age, the second and third doses are determined by postnatal age at initiation of indomethacin therapy.¹⁴¹ If onset of treatment was at less than 2 days postnatal age, neonates receive 0.1 mg/kg/dose; if initiation of therapy occurred at 2 to 7 days postnatal age, neonates receive 0.2 mg/kg/dose; and if therapy began more than 7 days postnatal age, neonates receive 0.25 mg/kg/dose. Second and third doses are administered at 12- to 24-hour intervals. No specific guidelines exist regarding which patients receive every-12-hour versus every-24-hour dosing; however, the individual dosing interval generally is determined by the neonate's urine output.¹⁴¹ If urine output remains >1 mL/kg/hour after an indomethacin dose, then the next dose may be given in 12 hours.

If urine output is <1 mL/kg/hour but >0.6 mL/kg/hour, then the dosing interval may be extended to 24 hours.

Other indomethacin dosing regimens have been evaluated more recently for the treatment of PDA in preterm infants. An initial dose of 0.2 mg/kg followed by either 0.1 or 0.2 mg/kg for two doses at 12- to 24-hour intervals has been used. In a study measuring serum concentrations, higher doses of indomethacin were required in older neonates (>10 days post-natal age).¹⁴⁷ This may be due to an increased indomethacin clearance in these infants. Because rapid IV administration of indomethacin can vasoconstrict the mesenteric arteries and renal vascular beds, longer infusion rates of 20 to 30 minutes are recommended. Continuous infusion of indomethacin seems to further decrease the adverse effects, but additional studies are needed.¹⁴³

Response to indomethacin therapy can be determined by assessing the clinical signs of PDA such as tachycardia, widened pulse pressure, bounding pulses, heart murmur, and the ability to wean ventilator support. In certain cases, echocardiography may be performed to confirm closure of a PDA.

MONITORING THERAPY

20. What clinical and laboratory data should be monitored during T.S.'s indomethacin therapy?

Before initiating indomethacin therapy, T.S. should receive an echocardiogram to rule out ductal-dependent congenital heart disease and to confirm the presence of a PDA. In addition, a SrCr and blood urea nitrogen (BUN) should be obtained from T.S. before indomethacin therapy because nephrotoxicity is the most common adverse effect. Infants receiving indomethacin can develop transient oliguria with increased SrCr. This occurs as a result of indomethacin-induced decreases in renal blood flow and GFR.¹⁴⁵ Dilutional hyponatremia may occur secondary to either decreased urine output or decreased free water diuresis owing to increased antidiuretic hormone activity.¹⁴² Treatment of hyponatremia should be aimed at decreasing free water intake through fluid restriction rather than by sodium supplementation. Typically, renal function normalizes within 72 hours after the last dose of indomethacin.¹⁴² In general, indomethacin therapy is contraindicated in neonates with renal failure, urine output <0.6 mL/kg/hour, or SrCr ≥ 1.8 mg/dL.¹⁴⁵ Although furosemide has been reported to decrease indomethacin-induced nephrotoxicity without affecting PDA, more studies are needed to confirm these findings.¹⁴⁸ In addition, serum concentrations of aminoglycosides, digoxin, and other renally eliminated drugs should be monitored carefully. Indomethacin therapy may decrease renal drug clearance and cause accumulation of these agents.¹⁴⁹

A platelet count should also be obtained from T.S. before therapy because indomethacin may decrease platelet aggregation. Thrombocytopenia (platelet count, $<50,000/\text{mm}^3$) is a contraindication to indomethacin therapy.^{142,145} In cases of thrombocytopenia, indomethacin may be withheld temporarily until platelets can be transfused. Other potential contraindications to indomethacin therapy include active bleeding and clinical evidence of NEC because GI bleeding, perforation, and NEC have been reported with indomethacin use.¹⁴³ These GI effects may be related to decreases in intestinal blood flow usually seen with rapid IV infusions. Grades II to IV IVH also are frequently quoted as contraindications to indomethacin ther-

apy; however, indomethacin treatment probably is not associated with progression of IVH. In fact, prophylactic treatment with indomethacin may be associated with a decrease in the incidence of severe IVH (grades III and IV).^{143,144}

Ibuprofen

Because of the adverse effects of indomethacin, other prostaglandin inhibitors such as ibuprofen have been studied for the closure of the ductus arteriosus. Results indicate that ibuprofen is as effective as indomethacin and causes significantly less of a decrease in renal, mesenteric, and cerebral blood flow.¹⁵⁰ In studies comparing ibuprofen to indomethacin, ibuprofen was less likely to cause adverse effects on renal function (e.g., oliguria). The incidence of NEC or IVH were similar for both of these drugs.^{151,152} However, one recent meta-analysis found that ibuprofen may increase the risk of developing chronic lung disease (BPD).¹⁵³ Thus, until further studies are conducted, many clinicians still consider indomethacin the drug of choice. Ibuprofen may be preferred in select patients who have or are at increased risk for decreased renal function. IV ibuprofen lysine is commercially available in the United States. The initial dose is 10 mg/kg followed by two doses of 5 mg/kg given at 24-hour intervals. If urinary output decreases to <0.6 mL/kg/hour, the second or third doses should be held.⁸

21. When is the best time to initiate indomethacin for symptomatic treatment of PDA?

Conflicting data exist on when to initiate indomethacin therapy for the treatment of symptomatic PDA. Some centers may opt to treat within the first 2 to 3 days of life (early symptomatic PDA) when infants initially present with clinical signs of PDA (i.e., murmur, widened pulse pressures, tachycardia). Others may not treat until clinical signs of congestive heart failure are present (late symptomatic PDA; 7–10 days of life).¹⁴⁴ Both indomethacin treatment strategies (early and late) significantly decrease the incidence of PDA, but both cause significant transient reduction of urine output and SrCr elevation. In some studies, infants receiving early treatment of indomethacin had significant reductions in the incidence of BPD and NEC and the need for surgical ligation.¹⁴⁴ In contrast, one study found that final PDA closure rates and the need for surgical ligation were comparable in early versus late indomethacin-treated neonates. In fact, spontaneous closure was observed in 43% of the late treatment group, which may indicate unnecessary treatment in the early group. In addition, renal adverse effects and ventilatory requirements were higher in the infants treated early.¹⁵⁴ Thus, early administration of indomethacin should not be used routinely.

RECURRENCE

22. T.S. completes a course of indomethacin 0.16 mg IV Q 12 hours \times 3 doses. The physicians were able to decrease T.S.'s ventilator support within the first 12 to 24 hours after starting indomethacin treatment. After 3 to 4 days of gradual and consistent ventilator weaning, the ventilator settings could not be decreased further. Over the next 2 to 3 days, T.S.'s respiratory status deteriorates and she requires increased ventilator support. T.S. now has tachycardia, a widened pulse pressure, bounding pulses, and a hyperactive precordium. Repeat echocardiogram shows a small-to-moderate PDA. Current data include the following:

BUN, 10 mg/dL; SrCr, 1.1 mg/dL; sodium (Na), 134 mEq/L; potassium (K), 4.9 mEq/L; chloride (Cl), 97 mEq/L; urine output, 2.3 mL/kg/hour; fluid intake, 130 mL/kg/day; and platelets, 180,000/mm³. Why did PDA recur in T.S.?

[SI units: BUN, 3.6 mmol/L of urea; SrCr, 97.2 mmol/L; Na, 134 mmol/L; K, 4.9 mmol/L; Cl, 97 mmol/L; platelets, 180 × 10⁹/L]

Successful closure of the PDA with indomethacin occurs in 70% to 90% of infants; however, ductal reopening or recurrence can occur in 20% to 35% of infants who initially respond to indomethacin.^{140,155} Recurrence of PDA occurs especially in lower birth-weight infants.¹⁵⁵ Several reasons might explain T.S.'s transient response to indomethacin. Recurrence of PDA is inversely proportional to gestational age; the incidence of ductal reopening is significantly higher in infants ≤26 weeks' gestational age compared with infants born ≥27 weeks' gestation (37% versus 11%, respectively).¹⁵⁶ The higher recurrence in younger gestational age neonates may be due to resumption of PGE₂ production after indomethacin serum concentrations decline and heightened sensitivity of the immature ductus arteriosus to the dilating effects of PGE.^{143,155} This is particularly important in ventilator-dependent patients such as T.S. because mechanical ventilation increases circulating vasodilating prostaglandins.¹⁴⁰ Furthermore, the rate of ductal reopening is independent of indomethacin serum concentrations, but seems to be related to the timing of indomethacin therapy, postnatal age, and the amount of fluid intake 24 hours before indomethacin treatment.¹⁵⁶ The rate of recurrence is lower in infants who were treated with indomethacin within the first 48 hours of life compared with those receiving treatment after 7 days of life.¹⁴³ Because anatomical closure of a PDA may be delayed for a couple of weeks, it is not surprising that the ductus arteriosus reopened in T.S. after her initial response to indomethacin.¹⁴³

Although controversial, prolonged indomethacin therapy may prevent recurrences and allow for permanent closure of the ductus arteriosus. Several prolonged treatment regimens have been successful in preventing ductal reopening.^{143,155} One such regimen (indomethacin 0.2 mg/kg/dose IV Q 12 hours × 3 doses, followed by 0.2 mg/kg/dose Q 24 hours × 5 doses) was able to significantly decrease the recurrence of PDA in neonates <1,500 g from 47% to 10% without increasing toxicity. The need for surgical ligation also was decreased significantly.¹⁵⁵ However, some studies report an increased mortality in infants receiving prolonged therapy (seven doses) compared with those receiving the short course (three doses).¹⁴³ Furthermore, other investigators found a significantly higher PDA closure rate in the short-course group (initial, 0.2 mg/kg then 0.1 mg/kg for two doses, each given at 12-hour intervals). The prolonged course (0.1 mg/kg/dose Q 24 hours × 7 doses) had a higher incidence of NEC and urea retention, and a longer duration of oxygen therapy.¹⁵⁷ Therefore, the optimal duration of indomethacin therapy and dosing regimen need to be identified.

23. Should indomethacin be given to T.S. again? Can future recurrences be prevented?

T.S. remains ventilator dependent and is at increased risk for developing BPD. Because she has no contraindications to indomethacin therapy, a second course should be given. To prevent further recurrences, an additional five doses of indomethacin (0.1–0.2 mg/kg/dose Q 24 hours) may be given to

T.S. after she completes the standard three-dose regimen.^{155,157} If the PDA fails to respond to this prolonged regimen or if it recurs again after an initial response, and T.S. remains ventilator dependent, surgical ligation most likely will be required to permanently close the PDA.

PROPHYLACTIC ADMINISTRATION

24. Could prophylactic indomethacin have prevented the development of a symptomatic PDA?

Prophylactic indomethacin therapy is defined as the administration of indomethacin to infants who have echocardiographic evidence but no clinical signs of PDA. Only 40% of infants with severe RDS and echocardiographic evidence of PDA during the first day of life go on to develop a hemodynamically significant PDA. Therefore, 60% of infants would be treated unnecessarily if prophylactic indomethacin was given on day 1 of life.¹⁴³ Prophylactic use of indomethacin for the prevention of PDA significantly decreases the incidence of PDA and IVH (grades III and IV)^{144,158} and the need for surgical ligation.¹⁴⁴ Unfortunately, most studies have not been able to show that prophylactic ductal closure with indomethacin decreases the incidence of death, BPD, or NEC.^{144,158} In fact, infants receiving prophylactic therapy had a higher incidence of NEC (when studies were evaluated individually),¹⁵⁸ oliguria, and elevated SrCr.^{144,158} Therefore, routine prophylactic administration is not warranted. Preterm neonates, particularly those at high risk for developing a large PDA (e.g., extremely low-birth-weight neonates), should be treated as soon as clinical signs appear.

Prophylactic ibuprofen therapy (administered at <24 hours of life) can significantly increase ductal closure rate without increasing IVH, NEC, or mortality or decreasing renal function.^{159,160} However, one study that utilized IV ibuprofen buffered with *tris*-hydroxymethyl-aminomethane (THAM) was terminated early because of three cases of severe hypoxemia and pulmonary hypertension that occurred in ibuprofen-treated infants.¹⁵⁹ Early administration of ibuprofen (i.e., <6 hours of life in this study versus <24 hours of life in other studies) may have prevented the decrease in pulmonary vascular resistance that normally occurs shortly after birth. However, other studies that administered ibuprofen early have not reported this adverse effect.¹⁶¹ Another explanation is that the THAM-buffered solution allowed the ibuprofen to precipitate, causing microembolization of the lungs with resultant pulmonary hypertension. Although this is a plausible explanation, a case of pulmonary hypertension was reported in Europe after administration of L-lysine ibuprofen.¹⁶² Additional studies are needed before routine use of prophylactic ibuprofen therapy can be recommended.

NECROTIZING ENTEROCOLITIS

Pathogenesis and Classification

25. C.D., an 11-day-old female neonate, was born at 28 weeks' gestational age with a birth-weight of 908 g. Her postnatal course has been complicated by RDS, sepsis, and PDA for which she required intubation and mechanical ventilation, two doses of betactant, a 7-day course of ampicillin and gentamicin, and indomethacin. Enteral feedings with a standard preterm 24-cal/oz formula were started on day 7 of life at 5 mL Q 3 hours (44 mL/kg/

day). Feedings were increased by 5 mL/feed on days 8 through 10 to 20 mL/feed Q 3 hours on day 10 of life (176 mL/kg/day). This morning, C.D. developed a distended abdomen, bloody stools, multiple episodes of apnea that required reintubation and assisted ventilation, and metabolic acidosis. ABG results revealed the following: pH, 7.20; Pco₂, 47 mmHg; and PO₂, 55 mmHg. An abdominal radiograph revealed pneumatosis intestinalis (the presence of gas in the intestinal submucosa). C.D. is to take nothing by mouth (NPO), and gentamicin 3.5 mg/kg IV infusion Q 24 hours and ampicillin 50 mg/kg IV push Q 12 hours are restarted. What clinical signs of NEC does C.D. have? What is the pathogenesis of NEC and what risk factors for NEC does C.D. have?

NEC, a type of acute intestinal necrosis, is the most common life-threatening nonrespiratory condition, affecting 1,200 to 9,600 newborns in the United States each year.¹⁶³ The rate of hospitalization associated with NEC is 1.1 per 1,000 live births.¹⁶⁴ Approximately 62% to 94% of NEC occurs in premature infants; however, NEC can infrequently occur in full-term neonates.^{163,165} NEC occurs in 3% to 15% of neonatal intensive care unit (ICU) admissions and has a mortality rate of 25% to 30%; approximately 25% of survivors develop long-term complications.^{165,166} The age of onset of NEC is inversely related to gestational age and birth-weight; the greater the gestational age of the infant at birth, the sooner the onset of NEC. Although NEC is less common in term infants, it usually develops within 3 to 4 days of age. In contrast, infants born at ~30 weeks' gestation develop NEC at a mean postnatal age of 20 days. Thus, preterm infants are at a risk for NEC for a longer period of time.^{163,166} Although C.D. is extremely premature, she developed NEC early (at 11 days of age), most likely due to the aggressive advancement of feedings (see following discussion).

C.D. has several clinical signs of NEC, including abdominal distention, bloody stools, apnea, metabolic acidosis, and pneumatosis intestinalis on abdominal radiograph. Gastric retention of feedings, respiratory distress, occult blood in stools, lethargy, temperature instability, thrombocytopenia, and neutropenia also may occur. NEC may progress to bowel perforation, peritonitis, sepsis, disseminated intravascular coagulopathy (DIC), and shock. On an abdominal radiograph, the presence of gas in the intestinal mucosa or in the portal venous system is diagnostic of NEC, and free air in the abdomen is observed with bowel perforation. Although these radiographic findings confirm the diagnosis of NEC, a lag time may occur between the initial clinical signs of NEC and radiologic confirmation.¹⁶⁵

NEC can evolve slowly over a period of 24 to 48 hours, from a clinically benign course to an advanced stage of shock, peritonitis, and widespread intestinal necrosis. Although NEC can affect any part of the GI tract, most of the disease is confined to the ileum and colon.¹⁶⁷ A staging system, which categorizes severity according to systemic, intestinal, and radiologic signs, has been developed to permit a more consistent evaluation and treatment of patients.¹⁶⁸ Stages IA and IB NEC include neonates and infants with suspected disease or "rule out" NEC. These patients may have mild GI problems such as emesis and increased gastric residuals, temperature instability, apnea, bright red blood from rectum, or a mild ileus. Infants with stages IIA and IIB have definite NEC and usually present with abdominal distention, bloody stools, and the pres-

ence of pneumatosis intestinalis on radiograph. Infants in stage IIB NEC may also develop metabolic acidosis and thrombocytopenia. C.D.'s presentation is most consistent with stage IIB NEC. Infants with stages IIIA and IIIB (advanced disease) are severely ill with clinical signs, including peritonitis, ascites, shock, severe metabolic and respiratory acidosis, and DIC. Those with stage IIIB have intestinal perforation.

The exact pathogenesis of NEC is unknown, but seems to be multifactorial. Most likely, NEC results from the effects of intestinal bacteria and other factors on injured intestinal mucosa (Fig. 94-2). Inflammatory mediators such as platelet-activating factor, tumor necrosis factor- α , interleukin-1 β , and interleukin-8 may also contribute to mucosal damage.¹⁶⁹ The neonatal intestinal mucosa is prone to injury for the following reasons: (a) increased permeability to potentially harmful substances, such as bacteria and proteins; (b) decreased immunologic host defenses, including low concentrations of IgA in intestinal mucosa; and (c) decreased nonimmunologic defenses, such as decreased concentrations of proteases and gastric acid. In addition, numerous factors (both prenatal and postnatal) can cause injury to the neonatal intestinal mucosa and increase the risk for NEC.¹⁶⁷ Prenatal maternal factors include eclampsia, prolonged rupture of membranes, fetal distress, maternal cocaine use, and cesarean section. Postnatal factors include prematurity, low birth-weight, ischemia/hypoxemia, asphyxia, hypotension, respiratory distress, apnea, malnutrition, infection, hemodynamically significant PDA, congenital GI anomalies, cyanotic heart disease, toxins, hyperosmolar substances (e.g., feedings, medications), rapid advancement of enteral feedings, exchange transfusions, and the presence of umbilical catheters.^{166-168,170} Medications such as corticosteroids, indomethacin, and H₂-blockers significantly increase the incidence of NEC in VLBW infants.^{171,172} However, the most significant clinical risk factor for NEC is prematurity.^{163,168}

C.D. has several risks for developing NEC, which include prematurity (gestational age of 28 weeks), extremely low birth-weight (908 g), history of infection, and RDS requiring mechanical ventilation. Furthermore, C.D. not only was given a hyperosmolar formula (24 cal/oz instead of 20 cal/oz), but her feedings were advanced aggressively. These two factors may also contribute to the development of NEC. Approximately 90% to 95% of infants with NEC have received enteral feedings, although NEC also occurs in infants who have never been fed.¹⁷³ Enteral feedings (breast-milk or formulas) serve as substrates for bacterial proliferation in the gut. As a result, reducing substances, organic acids, and hydrogen gas are produced by bacterial fermentation of these nutrients. Although studies have shown that rapid advancements in the volume of feeds (30 mL/kg/day versus 15–20 mL/kg/day) were associated with an increased risk of NEC, more recent studies report that infants advanced at rate of 30 mL/kg/day reach full enteral intake and regain birth-weight significantly earlier than infants advanced at 15 or 20 mL/kg/day without increasing the risk of NEC.^{174,175} Similarly, older studies reported that early initiation of feeds might increase the risk of NEC; however, more recent studies have failed to confirm these findings.¹⁷⁶ Thus, feedings should be increased by 10 to 20 mL/kg/day; however, advancement >20 mL/kg/day (up to 30 mL/kg/day) may enable infants to reach full feeds and regain birth-weight faster without increasing the risk of NEC. C.D. was started at a much higher initial feeding volume (44 mL/kg/day) and aggressively

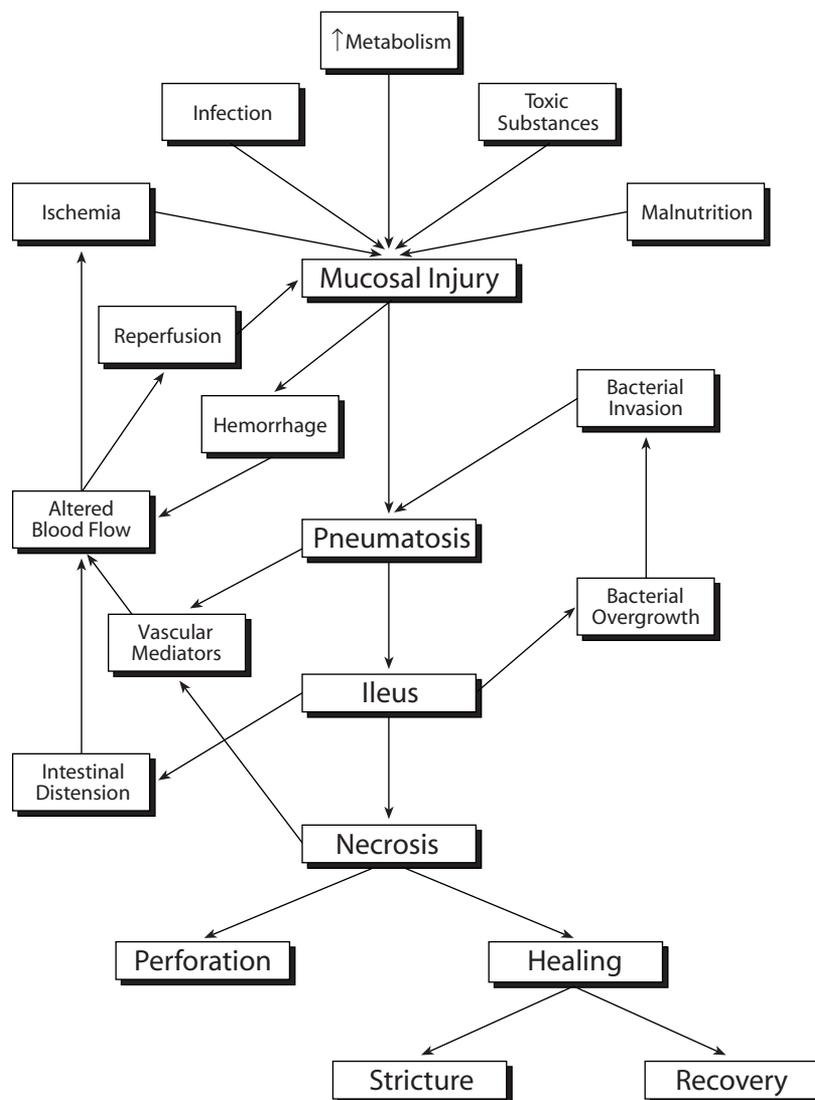

FIGURE 94-2 Necrotizing enterocolitis (NEC). This schematic is a composite of the theories about factors believed to be involved in the pathogenesis of NEC. The progression of this disease is denoted in large type. The factors believed to initiate or propagate the disease process are in smaller type. (Reproduced with permission from Crouse DT. Necrotizing enterocolitis. In: Pomerance JJ, Richardson CJ, eds. *Neonatology for the Clinician*. Norwalk, CT: Appleton & Lange; 1993:364.)

increased by 44 mL/kg/day. If C.D. were appropriately fed, she would have reached full feedings in 7 to 14 days instead of 4 days. Last, the presence of PDA and the use of indomethacin for the treatment of PDA may also have contributed to NEC in C.D. Her PDA or the use of indomethacin may have decreased mesenteric blood flow with resultant ischemia and intestinal mucosal injury.¹⁶⁶

Treatment

General Management

26. How should C.D. be managed?

Significant abdominal distention may compromise respiratory function and blood flow to the intestines. Therefore, as soon as NEC is suspected, feedings should be stopped immediately and an orogastric tube with low intermittent suction

placed to decompress the abdomen. C.D.'s vital signs and abdominal circumference should be closely monitored for disease progression. A complete blood count (CBC) and platelet count should be obtained frequently to monitor for neutropenia and thrombocytopenia. Blood, urine, and stool cultures should be obtained, and parenteral antibiotics should be started as soon as possible; 20% to 30% of infants with NEC have associated bacteremia. In infants with stage I NEC, antibiotic therapy is usually given for 3 days pending culture results and clinical signs. Once the diagnosis of NEC is ruled out, antibiotics may be discontinued.¹⁶⁸ Enteral feedings can then be initiated slowly. However, if the diagnosis of NEC is made, antibiotics are continued and parenteral nutrition is initiated at that time. Infants require 7 to 14 days of bowel rest (NPO). The length of antibiotic therapy and bowel rest in infants with documented NEC (stages II or III) is determined by the severity of systemic illness (e.g., metabolic acidosis, thrombocytopenia). C.D. has stage

IIB disease and needs to be NPO for at least 10 to 14 days; she requires total parenteral nutrition during that time. Infants with stage III disease may also require fluid resuscitation, administration of inotropic agents such as dopamine and dobutamine, and surgical intervention, especially for those with perforated NEC.¹⁶⁶ In a recent, randomized, controlled trial, significant differences were not noted in survival rate, duration of hospitalization, and dependence on parenteral nutrition (assessed 90 days postoperatively) between primary peritoneal drainage versus laparotomy with bowel resection in preterm infants with perforated NEC.¹⁷⁷

Antibiotics

27. C.D. just completed a 7-day course of ampicillin and gentamicin. Is it appropriate to restart these antibiotics?

The selection of antibiotics for NEC depends on the common micro-organisms observed in an individual neonatal unit and their sensitivities. Many organisms have been implicated in NEC, including Enterobacteriaceae (e.g., *Escherichia coli*, *Klebsiella* species), *Pseudomonas*, *Staphylococcus aureus* (in rare cases, methicillin resistant), *Staphylococcus epidermidis*, *Clostridium*, enteroviruses, and rotaviruses.^{165,168,170} For most cases of NEC, treatment with a broad-spectrum penicillin, such as ampicillin, and an aminoglycoside (e.g., gentamicin) is appropriate.

However, in some nurseries, *S. epidermidis* is the most common cause of neonatal nosocomial infections. Increases in *S. epidermidis*-associated NEC also have been reported. Therefore, vancomycin and an aminoglycoside may be used as routine treatment in some nurseries or in specific patients at risk for *Staphylococcus* infections (e.g., neonates with central catheters or prolonged ICU stays). Vancomycin may be more appropriate than ampicillin because vancomycin has coverage against methicillin-resistant *S. epidermidis*, as well as enterococcal and streptococcal species. Because C.D. has been hospitalized for longer than 1 week, vancomycin and gentamicin may be more appropriate, especially if her neonatal ICU has a high incidence of staphylococcal nosocomial infections. C.D. should be treated with parenteral antibiotics for 10 to 14 days.

Other antibiotic combinations used to treat NEC include cefotaxime and vancomycin, and cefotaxime and ampicillin. The combination of cefotaxime and vancomycin has been shown to prevent severe peritonitis and death in <2,200-g birth-weight neonates with NEC, whereas gentamicin and ampicillin have not. Suppression of aerobic fecal flora by the combination of cefotaxime and vancomycin, but not by ampicillin and gentamicin, may explain these findings.¹⁷⁸

28. The neonatologist would like to give gentamicin 2.5 mg/kg via the orogastric tube Q 12 hours in addition to parenteral antibiotics. Is there any added benefit to adding enteral gentamicin to the current parenteral antibiotic regimen?

Enteral administration of aminoglycosides does not prevent or change the course of NEC or prevent GI perforation in infants with NEC. In addition, enteral aminoglycosides can be absorbed systemically in neonates with NEC, via the inflamed intestinal mucosa.¹⁶⁸ Systemic absorption may significantly increase the serum concentrations of concomitantly administered parenteral aminoglycosides. Therefore, routine enteral administration of antibiotics such as gentamicin is not war-

ranted for C.D. In select patients and during NEC epidemics, however, prophylactic administration of enteral aminoglycoside antibiotics or vancomycin decreases the incidence of NEC. Unfortunately, prophylactic use of these antibiotics has been associated with the emergence of resistant organisms, which limits their systemic use.¹⁷⁹ Systemic absorption of enterally administered vancomycin also can occur through inflamed intestinal mucosa.

ADDITIONAL ANTIBIOTICS

29. Two days later, C.D. develops peritonitis with ascites, hypotension, metabolic acidosis, neutropenia, and DIC. IV fluids and dopamine are administered for the hypotension, fresh frozen plasma and whole blood are given to treat the coagulopathy, and morphine 0.05 mg/kg IV push Q 4 hours PRN is started for pain control. Free air in the abdomen is observed on abdominal radiograph. Blood and urine cultures have had no growth for 48 hours. What additional antimicrobial coverage should be provided?

Peritonitis secondary to intestinal perforation may be polymicrobial, involving both aerobes and anaerobes. Therefore, an antimicrobial agent with anaerobic activity should be added to C.D.'s current regimen.¹⁶⁶ The two most commonly used agents are clindamycin and metronidazole. Empiric anaerobic coverage in the treatment of NEC without perforation is controversial.¹⁶⁵ Routine use of clindamycin in the treatment of NEC has not decreased the incidence of intestinal gangrene or perforation. In addition, it has been associated with an increased incidence of abdominal strictures.¹⁸⁰

Complications/Prognosis

30. C.D. is taken urgently to the operating room and 10 cm of necrotic ileum is removed along with the ileocecal valve. What long-term nutritional problems is C.D. likely to develop?

The most common postoperative complications of NEC are intestinal strictures (14%–32%) and short-bowel syndrome (~10%).¹⁸¹ C.D. is at risk of developing short-bowel syndrome, a condition of malabsorption and malnutrition that results from surgical removal of a significant portion of the small intestine. The most important factors that determine short-bowel syndrome are the length of the remaining small intestine and the presence of the ileocecal valve. Because C.D. has had a majority of her ileum and her ileocecal valve removed, she most likely will suffer from short-bowel syndrome.

Because the terminal ileum is an important site for absorption of vitamins, trace minerals, and nutrients, C.D. will be at risk for decreased absorption of these substances. C.D. also will have a faster GI transit time and diarrhea because her ileocecal valve was removed. (The ileocecal valve plays a major role in controlling intestinal transit time.) Absorption of enterally administered medications also may be decreased in patients with short-bowel syndrome. As C.D. starts to receive most of her nutrition enterally, she should be monitored for fat malabsorption and other nutritional deficiencies (e.g., deficiencies in vitamins A, B₁₂, D, E, and K), and supplemented accordingly.¹⁸²

Owing to advances in earlier diagnosis and aggressive treatment, 56% of VLBW infants and 72% of infants with

birth-weight $\geq 1,000$ g with NEC survive.¹⁸³ However, infants with NEC are significantly more likely to have neurodevelopmental impairment (e.g., cerebral palsy); those requiring surgical management are at higher risk.¹⁸⁴

Prevention

31. What could have been done to prevent NEC in C.D.?

Several interventions may decrease the incidence of NEC. Enteral feedings in preterm infants can be withheld for several weeks and parenteral nutrition initiated. Intestinal priming or trophic feeding (i.e., using a small amount of full-strength formula or breast-milk to stimulate GI mucosal development) in addition to parenteral nutrition can improve feeding tolerance and increase GI motility.^{185,186} Because breast-milk provides antibodies, growth factors, and cellular immune factors, it may reduce the incidence of NEC. In fact, NEC was six to ten times less common among infants fed human milk exclusively than in those fed formula alone and three times less common in those fed a combination of human milk and formula than in those fed formula alone.¹⁸⁷ In contrast, the use of hyperosmolar formulas or medications can cause osmotic injury to the bowel and may result in NEC. Maternal steroids (commonly used to accelerate fetal lung maturation) can decrease the incidence of NEC due to a maturational effect on the microvillous membranes. Strict infection control measures, such as preventing fecal and oral spread of bacterial pathogens after epidemic outbreaks, also decrease the incidence of NEC.¹⁷⁰

Probiotics

Probiotics are live, nonpathogenic microbial preparations that colonize the intestine and have a beneficial effect on the health of the host.¹⁸⁸ Probiotic micro-organisms commonly used are strains of *Lactobacillus* and *Bifidobacterium*. Enteral administration of probiotics has been shown to significantly decrease the risk of NEC and death and shorten the time to full feedings in VLBW infants.¹⁸⁹ One major concern is that exposing immunologically immature VLBW infants to probiotics may potentially increase the risk for infections. However, in a recent meta-analysis, no significant risk of sepsis was noted in infants treated with probiotics.¹⁸⁹ Currently, there is no strong evidence to recommend a specific type of probiotic (species, strains, single or combined, live or killed), the timing, dosage, or duration of therapy. In addition, the long-term effects of probiotics for the prevention of NEC in VLBW infants are unknown. Further clinical studies addressing these issues are needed.

NEONATAL SEPSIS AND MENINGITIS

Pathogenesis and Clinical Presentation

32. J.E., a 28-week gestation, 850-g male, was born to a mother with prolonged rupture of membranes (>72 hours). The newborn's mother is febrile with a white blood cell (WBC) count of $20 \times 10^3/\text{mm}^3$ and differential of 70% segmented neutrophils, 20% bands, 7% lymphocytes, and 3% monocytes. J.E. had Apgar scores of 4 at 1 minute and 3 at 5 minutes after birth. Mechanical ventilation was instituted and J.E. was admitted to the neonatal ICU. Vital signs upon admission were as follows: HR,

190 beats/minute; temperature, 35.8°C; and BP, 56/33 mmHg. Blood and urine cultures are pending. Significant laboratory data include the following: WBC 2,400 cells/mm³ with a differential of 25% segmented neutrophils, 15% bands, 45% lymphocytes, 10% monocytes, 4% eosinophils, and 1% basophils; platelets, 45,000/mm³; and C-reactive protein (CRP), 5 mg/dL. What is the etiology and pathogenesis of neonatal sepsis? What risk factors for sepsis does J.E. have? What clinical signs and laboratory evidence of sepsis are apparent in J.E.?

[SI units: WBC, $2,400 \times 10^6$ cells/L with 0.25 neutrophils, 0.15 bands, 0.45 lymphocytes, and 0.1 monocytes; platelets, 45×10^9 /L]

Bacterial sepsis significantly contributes to neonatal morbidity and mortality. Neonates, especially preterm newborns, are at increased risk for infections and should be considered immunocompromised. The neonate's decreased immune function (e.g., immature function of neutrophils, lower amounts of immunoglobulin) also results in a reduced ability to localize infections. Once a tissue site becomes infected, bacteria can spread easily, resulting in disseminated disease. In addition, the lack of opsonic antibodies in preterm infants such as J.E. increases the susceptibility to infections caused by bacteria with polysaccharide capsules (e.g., group B streptococcus, *E. coli*, *Hemophilus influenzae* type B).¹⁹⁰

The incidence of neonatal sepsis varies from 6 to 9 cases per 1,000 live births, but is higher among low-birth-weight neonates.¹⁹¹ In VLBW infants with prolonged hospitalization, the incidence increases to 110 to 320 per 1,000.¹⁹² Risk factors (as demonstrated in J.E.) include prematurity, low birth-weight, male gender, and predisposing maternal conditions (e.g., prolonged rupture of membranes, maternal fever, elevated maternal WBC or left shift, chorioamnionitis, and urinary tract infection).^{193,194} Despite treatment, mortality rates for neonatal sepsis can be as high as 30% to 50%, with the highest mortality observed in newborns $<1,500$ g.^{195,196} Meningitis occurs as a complication of bacterial sepsis in 10% to 30% of septic neonates^{195,196} and has a mortality rate of 20% to 50% depending on the pathogen.¹⁹³

Common Pathogens

The fetal environment within the amniotic membranes is normally sterile until the onset of labor and delivery. Once the membranes are ruptured, the infant may be at risk for colonization of micro-organisms from the maternal genital tract. Many of these organisms do not cause infection in the mother, but may be detrimental to the infant. Early onset neonatal sepsis (sepsis that presents during the first 5–7 days of life) usually is caused by organisms acquired from the maternal genital tract. The most common pathogens found in early-onset neonatal sepsis are group B streptococcus (50%) and *E. coli* (20%). Other primary pathogens include *Listeria monocytogenes*, *Enterococcus*, and other Gram-negative bacilli (e.g., *H. influenzae*, *Klebsiella pneumoniae*). Late-onset sepsis (sepsis presenting after 5–7 days postnatal age) usually is caused by these primary organisms or by nosocomial pathogens, such as coagulase-negative staphylococci (CONS), particularly *S. epidermidis*, *S. aureus*, *Pseudomonas* species, anaerobes, and *Candida* species.^{195,197} The major risk factor for nosocomial septicemia is the presence of IV catheters (umbilical and central).¹⁹⁸ Other risk factors include low birth-weight, prolonged hospital stay, prior antibiotic use, parenteral

hyperalimentation, lipid emulsion, invasive procedures, and the presence of other indwelling devices (e.g., ETTs, ventriculoperitoneal shunts).^{192,193}

Over the past two decades, CONS such as *S. epidermidis*, have emerged as the most common pathogen for late-onset neonatal nosocomial septicemia, causing 55% to 58% of cases.^{198,199} This emergence is most likely due to the increased survival of extremely premature neonates with a resultant prolonged hospital stay and an increase in the associated risks of infection (i.e., placement of umbilical and central venous catheters and arterial lines, use of hyperalimentation and intralipid). More disturbing, however, is the reported persistence of coagulase-negative staphylococcal bacteremia, despite appropriate treatment in low-birth-weight neonates without central venous catheters.²⁰⁰

Neonatal sepsis may present with nonspecific or subtle signs, especially in VLBW infants.¹⁹³ The most common signs are poor feeding, temperature instability, lethargy, or apnea.^{193,196} Other signs of neonatal sepsis include glucose instability (hypoglycemia or hyperglycemia), tachycardia, dyspnea or cyanosis, tachypnea, diarrhea, vomiting, feeding intolerance, abdominal distension, metabolic acidosis, and abnormal WBC.¹⁹³ Clinical signs and laboratory evidence of neonatal sepsis observed in J.E. include tachycardia (HR, 190 beats/minute), hypothermia (temperature 35.8°C), leukopenia (WBC, $2.4 \times 10^3/\text{mm}^3$), neutropenia (absolute neutrophil count of $960/\text{mm}^3$), a left shift in the differential (i.e., an immature-to-total neutrophil ratio [I/T] of 0.38), thrombocytopenia (platelets, $45,000/\text{mm}^3$), and an elevated CRP (5 mg/dL). Hypothermia is more common than fever in neonatal sepsis, especially in preterm newborns. However, if fever is present, it is strongly associated with bacterial infection. Neutropenia, especially with a left shift (as seen in J.E.) can be a sign of WBC depletion from bone marrow owing to overwhelming sepsis. An elevated WBC also can indicate a neonatal infection, but may be less specific.¹⁹⁴ The I/T ratio, defined as band forms plus any earlier cells divided by the total neutrophil count (including early cells), has been shown to be useful in diagnosing neonatal sepsis. An I/T ratio of <0.3 is normal.¹⁹⁴ CRP, an acute phase reactant protein associated with tissue injury in response to an inflammatory process, may also be included as part of a sepsis workup. A CRP level >1 mg/dL indicates inflammation and possible infection.¹⁹⁴ Late signs of neonatal infection include jaundice, hepatosplenomegaly, and petechiae.¹⁹³ A bulging fontanel, posturing, or seizures indicate meningitis, although these CNS signs are not always present when meningitis exists.

Bacterial meningitis should always be considered in infants with neonatal sepsis. The definitive diagnostic method for bacterial meningitis is lumbar puncture. Lumbar puncture should be performed in infants with a positive blood culture, abnormal neurologic signs, an elevated WBC or left shift, or the presence of bacterial antigen in the urine.²⁰¹ The cerebrospinal fluid (CSF) should be tested with a Gram stain, cell counts with differential, glucose and protein levels, and bacterial culture. Neonatal CSF cell counts are difficult to interpret because values may overlap with normal neonatal values. The diagnosis of neonatal sepsis is confirmed by isolation of the pathogen from blood, urine, CSF, or other body sites. Latex agglutination tests that detect antigens (e.g., bacterial cell wall fragments) of group B streptococcus, *E. coli*, *S. pneumonia*, *N. meningitidis*,

and *H. influenzae* type B in body fluids can facilitate a prompt diagnosis, especially in patients who previously were treated with antibiotics.²⁰²

Treatment of Sepsis

Antibiotic Selection

33. What antibiotic regimen should be prescribed for J.E.?

Empiric treatment with appropriate IV antibiotics must be initiated immediately in J.E. Significant morbidity or fatality would occur if antibiotics were withheld until a diagnosis was confirmed by culture results (in 24–72 hours). This is especially true in patients in whom meningitis is suspected. The initial empiric antibiotic treatment of choice for early onset neonatal sepsis and meningitis is ampicillin plus an aminoglycoside. These antibiotics are used because they (a) are bactericidal against the common neonatal pathogens; (b) penetrate into the CNS; (c) are relatively safe; and (d) have proven clinical efficacy. If group B streptococcus is suspected, antibiotic therapy should be switched to high-dose penicillin G. Penicillin is preferred over ampicillin because of its higher activity against group B streptococcus.¹⁹⁷

Therefore, ampicillin 45 mg Q 12 hours IV plus an aminoglycoside (e.g., gentamicin 3 mg Q 24 hours IV) should be started in J.E. for suspected neonatal sepsis and possible meningitis. Meningitic doses of ampicillin should be used in J.E. until meningitis can be ruled out. Ampicillin is active against group B streptococci, group D streptococci, *Listeria*, and most strains of *E. coli*. Aminoglycoside antibiotics (e.g., gentamicin or tobramycin) usually are active against gram-negative bacilli. In addition, aminoglycosides may provide synergy with ampicillin against *Listeria* and group B streptococci.¹⁹⁴ Selection of the specific aminoglycoside should be determined by antibiotic resistance patterns within the neonatal ICU. Amikacin should be reserved for gram-negative organisms resistant to gentamicin and tobramycin. Aminoglycoside regimens need to be designed to achieve safe and therapeutic serum concentrations (gentamicin and tobramycin peak 6–8 mcg/mL, trough <2 mcg/mL; amikacin peaks 20–30 mcg/mL, troughs <10 mcg/mL).^{8,49}

In some nurseries, a third-generation cephalosporin (e.g., cefotaxime [Claforan] or ceftriaxone [Rocephin]), instead of an aminoglycoside, is added to ampicillin for initial empiric treatment of early-onset neonatal sepsis and meningitis.¹⁹⁷ The spectrum of activity of these third-generation cephalosporins includes many gram-negative organisms and group B streptococci. However, third-generation cephalosporins do not have sufficient activity against *Listeria* or group D streptococci. Therefore, these agents must be used in combination with ampicillin for empiric neonatal therapy. As mentioned, ceftriaxone should be avoided in neonates with hyperbilirubinemia owing to bilirubin displacement from albumin-binding sites. Ceftriaxone has also been associated with sludging in the gallbladder and cholestasis.⁸ In addition, calcium-ceftriaxone precipitates have been found in the lungs and kidneys of neonates when ceftriaxone was administered with calcium-containing solutions. Several fatalities have been reported; ceftriaxone should not be administered within 48 hours of calcium-containing solutions or products.⁸ Hence, cefotaxime is the preferred cephalosporin for neonatal use.

The third-generation cephalosporins have advantages over the aminoglycosides, including better CNS penetration, the elimination of serum concentration measurements, and less nephrotoxicity. However, these cephalosporins do not significantly improve clinical or microbiological endpoints compared with the standard ampicillin and gentamicin regimen. Furthermore, extensive use of the third-generation cephalosporins in neonatal ICUs may lead to rapid emergence of resistant gram-negative bacilli (e.g., *Enterobacter cloacae*, *Pseudomonas aeruginosa*, and *Serratia* species) and vancomycin resistance in enterococci. In contrast, gentamicin has not been associated with rapid development of these resistant strains.¹⁹⁷ Thus, combinations such as ampicillin and cefotaxime should be reserved for the following situations: (a) neonatal ICUs where aminoglycoside resistance to Gram-negative enteric bacilli is of concern, (b) neonatal ICUs where serum concentrations of aminoglycosides cannot be measured, and (c) specific neonates in whom aminoglycoside therapy could be of concern (e.g., neonates with known renal failure).¹⁹⁷

Therapy for late-onset sepsis or meningitis is directed toward nosocomial pathogens plus the primary pathogens of early-onset infection (see Question 32). Selection of initial antibiotic therapy should consider the specific neonatal ICU's nosocomial pathogen and antibiotic resistance patterns, as well as the neonate's risk factors, clinical condition, and previous antibiotic therapy.²⁰³ CONS is now the most common pathogen of late-onset neonatal nosocomial septicemia. Because of the high incidence of methicillin-resistant CONS (as high as 80% in some neonatal ICUs),²⁰³ vancomycin has been used as the drug of choice for empiric therapy for suspected late-onset neonatal sepsis. However, widespread use of vancomycin has led to the emergence of vancomycin-resistant enterococci. Therefore, the routine use of vancomycin as empiric therapy for nosocomial neonatal sepsis should be discouraged. In two retrospective studies, the highly selective use of vancomycin for neonatal CONS septicemia results in low morbidity and mortality, while significantly reducing vancomycin use.^{199,204} Guidelines for the selective use of vancomycin should be tailored according to individual neonatal ICU's nosocomial pathogens, susceptibility patterns, and patient risk factors, clinical condition, and antibiotic history. Therefore, if J.E. had a central venous catheter and presented with a late-onset sepsis, initial antibiotic therapy should include an aminoglycoside (for gram-negative coverage) plus either an antistaphylococcal penicillin (e.g., nafcillin, methicillin) or vancomycin (for activity against *S. aureus* and *S. epidermidis*). Vancomycin is used in place of the antistaphylococcal penicillin in neonatal units with methicillin-resistant *S. aureus* and for selective use to cover *S. epidermidis* (a CONS) as outlined.^{197,203}

Linezolid, a new oxazolidinone, has activity against staphylococci, streptococci, and enterococci. This drug has been approved by the FDA for treatment of gram-positive infections in neonatal and pediatric patients and is available as IV and oral formulations. A study comparing linezolid with vancomycin for the treatment of resistant gram-positive infections in neonates reported no significant difference in overall clinical cure rate between the linezolid-treated (84%) and the vancomycin-treated groups (77%). About 60% of these infections were due to CONS with similar eradication rates between groups (linezolid 88% versus vancomycin 100%). Linezolid was well-tolerated and had fewer drug-related ad-

verse events than vancomycin.²⁰⁵ Because of limited studies in term and preterm neonates, linezolid should be reserved for those infants who failed or are intolerant to vancomycin therapy for the treatment of staphylococcal infections. If *Pseudomonas* infection is suspected, an antipseudomonal penicillin (e.g., piperacillin, ticarcillin, mezlocillin) combined with an aminoglycoside should be used for their synergistic bacterial activity.

For systemic fungal infections, amphotericin B (with or without flucytosine) is considered the initial treatment of choice.¹⁹⁶ Because of the high incidence of *Candida* species colonization (up to 60%) with up to 20% progressing to invasive fungal infections in VLBW infants, prophylactic antifungal agents may be used to prevent candida colonization and infection in these infants. In a multicenter randomized trial, prophylactic fluconazole in preterm neonates significantly decreased the incidence of fungal colonization and invasive fungal disease in the fluconazole-treated infants compared to placebo.²⁰⁶ Overall mortality, adverse events and emergence of resistant candida species were similar in both groups. Despite these findings, routine use of prophylactic antifungal therapy is not recommended and should be reserved for those units with high incidence of fungal infections. Because uncommon organisms are not suspected in J.E., the regimen of ampicillin 45 mg IV Q 12 hours plus gentamicin 3 mg IV Q 24 hours is appropriate.

Dosage and Route of Administration

Dosage regimens for the antimicrobial agents commonly used in neonates^{8,51,52,207,208} are listed in Tables 94-5 and 94-8. Dosing guidelines for tobramycin and netilmicin are the same as gentamicin (Table 94-5). The IV route is preferred for treatment of all septic neonates. If the IV route is not available, the IM route can be used in neonates with sufficient muscle mass, adequate peripheral perfusion, and a normal, stable coagulation status. Oral administration almost never is used in serious neonatal infections because GI drug absorption is extremely variable at this age. Meningitic doses of antibiotics should be used for the treatment of any seriously ill neonate until meningitis is excluded by negative CSF cultures.

Extended-interval aminoglycoside dosing (also known as once-daily dosing or single-daily dosing) has been widely used in the adult population. Aminoglycoside antibiotics display concentration-dependent killing of bacteria. Rationale for the use of extended-interval aminoglycoside dosing include: (a) enhancement of bacterial killing by providing a higher peak serum concentration to minimal inhibitory concentration ratio, (b) provision of a prolonged postantibiotic effect, and (c) minimization of adaptive postexposure microbial resistance.²⁰⁹ In meta-analyses of clinical studies in adults, extended-interval aminoglycoside dosing seems to have similar efficacy, without increased toxicity, compared with traditional multiple daily dosing.²¹⁰ In addition, extended-interval aminoglycoside dosing can reduce costs associated with drug wastage, administration time, and therapeutic monitoring.²¹¹

Because of these beneficial effects, the use of extended-interval aminoglycoside dosing has been studied in the pediatric population. Most studies have included term or near-term newborns (i.e., gestational age ≥ 34 weeks).²⁰⁹ As expected, the use of extended-interval aminoglycoside dosing resulted in higher peak and lower trough serum concentrations in

Table 94-8 Antimicrobial Dosage Regimens for Neonates: Dosages and Intervals of Administration

| Drug | Weight < 1,200 g ⁵² | Weight 1,200–2,000 g | | Weight > 2,000 g | |
|--|--------------------------------|-------------------------------|-------------------------------|-------------------------------|-------------------------------|
| | 0–4 Weeks ^a (mg/kg) | 0–7 Days ^a (mg/kg) | > 7 Days ^a (mg/kg) | 0–7 Days ^a (mg/kg) | > 7 Days ^a (mg/kg) |

these neonates compared with traditional multiple-daily dosing. However, neonatal studies have not established optimal regimens to achieve the best peak serum concentration to minimal inhibitory concentration ratio. A meta-analysis in neonates > 32 weeks' gestation confirmed these findings and reported no nephrotoxicity or ototoxicity in either group.²¹² Several clinical trials have evaluated the use of once-daily dosing of gentamicin in preterm infants < 32 weeks' gestation; however, these studies evaluated serum gentamicin concentrations and potential adverse effects and not clinical efficacy or cure rates.^{213–215} Furthermore, most studies in neonates used extended-interval aminoglycoside dosing for short periods of time, for example, during the workup to rule out neonatal sepsis (i.e., 72-hour duration). Studies included only a few neonates, who received extended-interval aminoglycoside dosing to actually treat documented neonatal infections. Other neonatal-specific factors, such as the neonate's immature immune function and a potential decreased postantibiotic effect, have not been adequately addressed. Therefore, large, well-designed studies evaluating the clinical efficacy and safety of extended-interval aminoglycoside dosing for the treatment of gram-negative infections in neonates are required before routine use can be recommended.

Once a pathogen is isolated, the antimicrobial susceptibilities should be evaluated and the drug therapy modified appro-

priately. Blood, CSF, or urine cultures should be repeated to document bacterial sterilization after 24 to 48 hours of appropriate therapy. J.E. should be evaluated carefully for the development of serious bacterial complications such as meningitis, osteomyelitis, abscess formation, or endocarditis.

Duration of Therapy

As long as there is no evidence of meningitis or other focal infection (e.g., abscess formation), the duration of therapy for most systemic bacterial infections is 7 to 10 days (or approximately 5–7 days after significant clinical improvement). Antibiotic therapy may need to be continued for 14 to 21 days if the neonate's clinical response is slow or if multiple organ systems are involved.¹⁹⁶ If cultures are negative at 72 hours and the infant does not have any clinical or laboratory signs of sepsis, antibiotics can be discontinued. In neonates presenting with signs of severe infection followed by improvement after initiation of antibiotics, therapy may be continued despite negative cultures.

Treatment of Meningitis

34. How should J.E. be treated if meningitis is suspected?

Antibiotic Selection

The major pathogens causing neonatal sepsis also are the primary pathogens that cause neonatal meningitis. Seventy-five percent of neonatal meningitis is caused by group B streptococcus and *E. coli*; *L. monocytogenes* is the third most common organism.¹⁹⁶ Initial empiric antibiotic therapy of choice consists of ampicillin plus an aminoglycoside.¹⁹³ Ampicillin plus a third-generation cephalosporin (cefotaxime or ceftriaxone) may be used empirically for early-onset neonatal meningitis in situations as outlined previously for early-onset neonatal sepsis (see Question 33). In addition, because of their greater CSF penetration compared with the aminoglycosides, the combination of a third-generation cephalosporin with ampicillin may be preferred when the CSF Gram's stain indicates a gram-negative infection. Initial empiric antibiotic treatment of late-onset meningitis should follow guidelines similar to those for late-onset sepsis with consideration of nosocomial as well as primary pathogens (see Question 33). As with neonatal sepsis, once an organism is recovered from the CSF, the most appropriate antibiotic is selected based on susceptibility.

Duration of Therapy

If CSF cultures are positive, repeat CSF cultures should be obtained daily or every other day in J.E. to document when the CSF becomes sterilized. The duration of therapy for neonatal meningitis depends on the clinical response and duration of positive CSF cultures after therapy is initiated. Appropriate antibiotics should be continued for a minimum of 14 days after the CSF is sterilized. This is equivalent to a duration of antibiotic therapy for a minimum of 21 days for gram-negative organisms and at least 14 days for gram-positive pathogens.^{193,196,216} As a general rule, it takes longer to sterilize the CSF of neonates infected by gram-negative enteric bacilli (72 hours) than those infected by gram-positive bacteria (36–48 hours).¹⁹³ Although surgical placement of a ventricular reservoir for intraventricular administration of an antibiotic (usually an aminoglycoside) has been used to treat meningitis not responding to IV antimicrobial therapy, the Neonatal Meningitis Cooperative Study group reported no beneficial effect of this method of administration in infants with gram-negative meningitis. In fact, infants treated with intraventricular gentamicin had a threefold increase in mortality rate compared with infants treated solely on IV antibiotics^{196,217} (see Chapter 58).

Intravenous Immune Globulin

35. On day 2 of life, J.E.'s blood culture is reported as positive for group B streptococcus. His current vital signs are as follows: HR, 135 beats/minute; temperature, 37°C; and BP, 59/40 mmHg. Laboratory data include the following: WBC, 7,000 cells/mm³ with a differential of 53% segmented neutrophils, 15% bands, 25% lymphocytes, and 7% monocytes; platelets, 100,000/mm³. J.E.'s ventilatory settings are slightly improved. What is the role of IV immune globulin (IVIG) in a patient like J.E.?

[SI units: WBC, 7,000 × 10⁶ cells/L with 0.53 neutrophils, 0.15 bands, 0.25 lymphocytes, and 0.07 monocytes; platelets, 100 × 10⁹/L]

Rationale

Neonatal humoral immunity is provided primarily by transplacental transport of maternal immunoglobulin (Ig)G to the fetus. Active transfer starts at 17 weeks' gestation and increases with

gestational age. By 33 weeks' gestation, fetal IgG levels are equal to maternal IgG.²¹⁸ Neonates born before 33 weeks' gestation have very low IgG concentrations. In addition, because of the neonate's poor antibody response to antigenic stimuli, these low concentrations of IgG can decrease further during the first few weeks of life.²¹⁹ Low IgG concentrations, as well as a lack of micro-organism-specific antibodies, and opsonic antibody activity against the polysaccharide capsules of certain bacteria (i.e., group B streptococcus, *E. coli*, and *H. influenzae*) significantly contribute to the neonate's increased susceptibility to infections.²¹⁹ Exogenous administration of IVIG may correct low IgG serum concentrations and improve neonatal host defenses. Therefore, administration of IVIG has been proposed for the prevention and treatment of neonatal infections.

Efficacy

The efficacy of IVIG as an adjunct to antimicrobial therapy for the prevention and treatment of neonatal sepsis has been assessed in numerous studies. However, comparisons between studies are difficult because of differences in study design, sample size, dosage regimens (dose and duration of therapy), specific product used, pathogen-specific antibodies, lot-to-lot variability, inclusion criteria, and outcome measures. In addition, studies assessing IVIG for treatment of neonatal sepsis differ in the specific infecting organism and the rates and severity of infection.¹⁹⁰ Despite these differences, several meta-analyses have been conducted to try to summarize the data evaluating the effectiveness of IVIG for prophylaxis and treatment of neonatal sepsis.

An early evaluation of published articles assessing prophylaxis of IVIG concluded that its effectiveness depended on the pathogen-specific antibody activity of the individual product used. Other evaluations have found encouraging results or no clear evidence of benefit for preterm infants.¹⁹⁰ In a recent systematic review of 19 studies (representing approximately 5,000 preterm infants) prophylactic IVIG was associated with a significant, but very small reduction in sepsis (3%) and serious infections (4%). However, NEC, IVH, length of hospital stay, and mortality were not significantly affected.²²⁰ Therefore, the use of prophylactic IVIG is of marginal clinical benefit and thus cannot be routinely recommended.

Few studies have evaluated IVIG as adjunctive treatment with antibiotics for treatment of neonatal sepsis. In a Cochrane review of 13 studies of suspected or proven infections in >500 neonates, IVIG treatment was associated with reductions in length of hospitalization (for term infants) and mortality. However, the reduction in mortality for clinically suspected infections was of borderline significance.²²¹ Owing to the lack of power of this meta-analysis, further studies are needed to determine the effectiveness of IVIG for the treatment of suspected or proven neonatal infections. Clinically, the routine use of IVIG for suspected or proven infections cannot be recommended. IVIG can be considered for select patients with proven infections.

Large, well-designed, prospective studies are required to determine the optimal IVIG dosage regimen, including dose per kilogram, number of doses, and timing of treatment. Studies of the cost-effectiveness of IVIG are also needed. Unlabeled or low concentrations of antibodies against the primary pathogens of neonatal sepsis may limit the use of commercial IVIG preparations. However, the use of preselected lots of IVIG that possess antibodies against specific neonatal pathogens may be

of benefit. Other immunologic agents, such as monoclonal antibodies and hyperimmune immunoglobulin preparations, may be more effective and currently are being investigated.

Initiation of Therapy

At this time, routine use of IVIG for all newborns to prevent or treat neonatal sepsis is not indicated.^{190,219} However, treatment with IVIG should be considered in septic neonates who are not responding to standard antibiotic treatment and supportive care.¹⁹⁰ Because J.E. has responded to antibiotic therapy, as evidenced by his improvement in vital signs, WBC, differential, platelet count, and ventilatory settings, IVIG would not be indicated.

Dosing, Administration, and Adverse Effects

36. IVIG 500 mg/kg IV push weekly for four doses has been ordered for J.E. because of prescriber preference. How should IVIG be administered and what should be monitored for adverse effects?

The optimal dose of IVIG has not been established. The National Institute of Child Health and Human Development study used prophylactic doses of 900 mg/kg for neonates 501 to 1,000 g and 700 mg/kg for neonates 1,001 to 1,500 g to attain IgG serum concentrations of 700 mg/dL.²²² Doses were repeated every 2 weeks. Trough concentrations after the first dose were ≥ 700 mg/dL in approximately 50% of the neonates. Only 13% of neonates had all trough concentrations at or above the target concentration during the study period.²²² These findings suggest that the clinical use of these doses or even slightly higher doses would be adequate. However, the optimal total IgG serum concentration for treatment or prophylaxis of neonatal sepsis has not been established. In addition, the amount of specific immunoglobulins directed against the primary neonatal pathogens may be more important. Although many dosing regimens have been studied,^{190,219,222} doses of 500 to 1,000 mg/kg are commonly used. Some institutions repeat treatment every 2 weeks.¹⁹⁰ Doses $> 1,000$ mg/kg may not be more effective and may have toxic effects. Suppression of opsonophagocytosis and decreased bacterial clearance have been reported with high-dose IVIG in neonatal animal models.²²³

Although the dose of IVIG prescribed for J.E. is reasonable, IVIG should never be administered via IV push. Rapid IV administration may result in significant adverse effects. Administration rates for IVIG are product specific and most neonatal doses should be infused IV over 2 to 6 hours. Because anaphylaxis can occur, slower initial infusion rates are recommended. In this case, the specific IVIG product used in J.E.'s neonatal ICU should be identified, and an appropriate text⁸ or the package insert should be consulted for proper administration rates. Neonates receiving IVIG should be monitored routinely for adverse effects such as tachycardia, dyspnea, hypotension, hypertension, fever, flushing, irritability, tremors, restlessness, and emesis.²²² These reactions may be related to the rate of infusion and generally resolve when the infusion rate is decreased or when the infusion is discontinued temporarily. In the National Institute of Child Health and Human Development study, the overall rate of NEC in the IVIG group (12%) was not statistically higher than in the control group (9.5%). However, a significantly greater number of NEC cases occurred during Phase 2 of the study in the IVIG group (12%) compared with placebo (8.3%).²²² Therefore, because of the potential associ-

ation with NEC, indiscriminate use of IVIG is not warranted. Other adverse effects may be identified as neonatal investigations continue with IVIG use.

CONGENITAL INFECTIONS

TORCH Titers

37. S.Y., a 2,000-g girl, was born at 34 weeks' gestational age by vaginal delivery. She was born at another institution and transferred to your hospital on day 3 of life. S.Y.'s birth was complicated by prolonged rupture of membranes (> 72 hours), a difficult labor and delivery, and fetal distress requiring a fetal scalp monitor. On physical examination, S.Y. is an extremely irritable newborn with RR of 60 breaths/minute. Several vesicular skin lesions located on the scalp and around the eyes are noted. Conjunctivitis also is present. S.Y. is placed on supplemental oxygen and ABGs are obtained. Blood, CSF, and urine were cultured for bacteria and fungus and S.Y. was started on ampicillin 100 mg IV Q 12 hours and gentamicin 5 mg IV Q 12 hours to rule out sepsis. Antimicrobial therapy will not be altered until culture results are available. What other tests and/or information are needed for S.Y. at this time?

Certain bacteria, viruses, and protozoa can cause fetal infections that may result in fetal death, congenital anomalies, serious CNS sequelae, intrauterine growth retardation, or preterm birth.²²⁴ The primary organisms that cause these infections can be remembered by the acronym, TORCH: *toxoplasmosis; other* (i.e., syphilis, gonorrhea, hepatitis B, listeria); *rubella; cytomegalovirus; herpes simplex*. Because of the potential severity of these diseases, newborns who display any signs of infection (e.g., irritability, fever, thrombocytopenia, hepatosplenomegaly) need to be evaluated for these intrauterine and perinatally acquired infections. The diagnosis of each of these infections should be considered separately. A complete infectious disease workup should include specific antibody titer measurements to the suspected organisms rather than sending a single serum sample for TORCH titer measurement.²²⁴

Primary clinical manifestations and treatment^{8,224-228} for selected congenital infections are listed in Table 94-9. The clinical signs of these infections may overlap, and concurrent infection with two or more micro-organisms is possible. The detection of congenital infections often is difficult because many neonates are asymptomatic at birth. Therefore, prenatal maternal screening and accurate evaluation of maternal history for risk factors are very important. Other organisms that can cause congenitally acquired infections include human immunodeficiency virus (HIV), human parvovirus, varicella-zoster virus, and measles virus.²²⁴

When congenital infections are suspected, appropriate diagnostic tests for each suspected organism should be performed. Viral cultures of the urine, oropharynx, nasopharynx, stool, and conjunctiva and a complete maternal history along with the results of recent maternal vaginal cultures also should be obtained.²²⁴ Measurements of IgM levels specific for each possible organism under consideration are also recommended. S.Y. has signs of a congenital infection (respiratory distress, skin rash, and conjunctivitis). Because of the nature of S.Y.'s skin rash (i.e., vesicular), infection with the herpes simplex virus (HSV) should be highly suspected. Skin vesicles, conjunctiva, oropharynx, nasopharynx, rectum, urine, and CSF

Table 94-9 Selected Congenital and Perinatal Infections in the Neonate^{8,224–228}

| Organism | Primary Clinical Manifestations | Treatment of Proven or Highly Probable Disease |
|---|--|---|
| Herpes simplex ^{a,b} | Cutaneous vesicles, keratoconjunctivitis, microcephaly, CNS infection, hepatitis, pneumonitis, prematurity, respiratory distress, sepsis, convulsion, chorioretinitis | <i>Acyclovir</i> : 20 mg/kg Q 8 hr IV × 14–21 days <i>Ocular Involvement</i> : Acyclovir IV plus topical therapy: 1–2% trifluridine, 1% iododeoxyuridine, or 3% vidarabine |
| Toxoplasmosis | Chorioretinitis, ventriculomegaly, microcephaly, hydrocephaly, intracranial calcifications, ascites, hepatosplenomegaly, lymphadenopathy, jaundice, anemia, mental retardation | Sulfadiazine 100 mg/kg/day in two divided doses PO for 1 year and pyrimethamine 2 mg/kg/day × 2 days then 1 mg/kg/day for 2–6 months then 1 mg/kg QOD to complete 1 year of therapy and folic acid (leucovorin) 5–10 mg 3 times/week × 1 year |
| <i>Treponema pallidum</i> ^d | <i>Early</i> : Osteochondritis, periostitis, hepatosplenomegaly, skin rash (maculopapular or vesiculobullous), rhinitis, meningitis, IUGR, jaundice, hepatitis, anemia, thrombocytopenia, chorioretinitis <i>Late</i> : Hutchinson's triad (interstitial keratitis, VIIIth-nerve deafness, Hutchinson's teeth), mental retardation, hydrocephalus, saddle nose, mulberry molars | Aqueous crystalline penicillin G × 10–14 days IV (preferred) or IM: ≤ 7 days postnatal age: 50,000 U/kg Q 12 hr > 7 days postnatal age: 50,000 U/kg Q 8 hr OR Procaine penicillin G 50,000 U/kg/day IM Q 24 hr × 10–14 days |
| Hepatitis B ^c | Prematurity; usually asymptomatic; long-term effects include chronic hepatitis, cirrhosis, liver failure, hepatocellular carcinoma | <i>Perinatal exposure (maternal HbsAg-positive)</i> : HBIG 0.5 mL IM and hepatitis B vaccine IM (different IM sites) within 12 hours after birth; repeat hepatitis B vaccine at 1 and 6 months |
| Rubella | <i>Early</i> : IUGR, retinopathy, hypotonia, hepatosplenomegaly, thrombocytopenic purpura, bone lesions, cardiac effects <i>Late</i> : Hearing loss, mental retardation, diabetes <i>Rare</i> : Myocarditis, glaucoma, microcephaly, hepatitis, anemia | Supportive care |
| Cytomegalovirus | Petechiae, hepatosplenomegaly, jaundice, prematurity, IUGR, increased liver enzymes, hyperbilirubinemia, anemia, thrombocytopenia, interstitial pneumonitis, microcephaly, chorioretinitis, intracranial calcifications <i>Late</i> : Hearing loss, mental retardation, learning and motor abnormalities, visual disturbances | IV ganciclovir (optimal dose and duration not established; preliminary data suggests doses of 15 mg/kg/day divided Q 12 hr) |
| <i>Neisseria gonorrhoeae</i> ^d | Ophthalmia neonatorum, scalp abscess, sepsis, arthritis, meningitis, endocarditis | <i>Nondisseminated (including ophthalmia neonatorum)</i> : Ceftriaxone 25–50 mg/kg IV or IM × 1 (maximum dose: 125 mg); alternative for ophthalmic neonatorum: cefotaxime 100 mg/kg IM or IV × 1; use saline eye irrigations for ophthalmia neonatorum <i>Disseminated</i> : Ceftriaxone 25–50 mg/kg IV or IM Q 24 hr; cefotaxime 25–50 mg/kg IV or IM Q 12 hr Duration of therapy: • Arthritis or septicemia: 7 days • Meningitis: 10–14 days Use cefotaxime if hyperbilirubinemic |

^a See Chapter 65.^b See Chapter 72.^c See Chapter 73.

CNS, central nervous system; HBIG, hepatitis B immune globulin; HbsAg, hepatitis B surface antigen; IM, intramuscular; IUGR, intrauterine growth retardation; IV, intravenous; QOD, every other day.

should be cultured for HSV and other organisms known to cause congenital infections. Rapid diagnostic testing using tissue scrapings from vesicles and fluorescein-conjugated monoclonal HSV antibody can also be performed. Other appropriate tests for the diagnosis and workup of suspected congenital infections also should be performed (e.g., liver enzymes, prothrombin time, partial thromboplastin time, EEG, computed tomography scan [CT], or magnetic resonance imaging [MRI]).²²⁴

Congenital Herpes

38. Upon investigation, it is discovered that S.Y.'s mother has genital herpes. This infection is her first known genital HSV

episode and was accompanied by fever and headache. S.Y.'s mother had herpes genital lesions present during the vaginal delivery of S.Y. What are risk factors for HSV infection in S.Y.? What interventions could have lowered S.Y.'s risk for HSV?

The incidence of neonatal HSV infection is approximately 1 in 3,200 live births (i.e., ~1,500 estimated new cases each year) in the United States.^{229,230} Neonatal HSV may be acquired in utero by either transplacental or ascending vaginal and cervical infections, perinatally via passage through a birth canal with active herpes lesions, or postnatally.²³⁰ Most congenital HSV infections (85%) are acquired during passage through the birth canal in the intrapartum period; 5% are acquired in utero and 10% postnatally through close contact.²³⁰ Ascending infections are more likely to occur with prolonged rupture

of membranes. Factors that increased the risk of HSV in S.Y. include primary maternal infection during delivery, prolonged rupture of membranes, presence of active lesions at vaginal birth, and use of a fetal scalp monitor during active herpes infection.^{229,231} The most important of these risk factors is primary maternal genital HSV infection at the time of delivery. Neonates born vaginally to these women are ten times more likely to develop HSV infections than neonates born vaginally to women with recurrent HSV infection (33%–50% risk of HSV versus 3%–5%).²²⁸ Identification of newborns at high risk for HSV is difficult, however, because most women who give birth to HSV-infected neonates have asymptomatic or unrecognized HSV infection at the time of delivery. These women also have negative histories for HSV genital infection.

In women with active genital herpes lesions, delivery by cesarean section can reduce the newborn's exposure to HSV lesions by sevenfold and thereby decrease the risk of perinatal transmission.²²⁹ Prolonged rupture of membranes, however, can lessen the protective effect of cesarean delivery by increasing the risk of an ascending HSV infection. Therefore, cesarean section cannot prevent all cases of neonatal HSV. In fact, as many as 33% of infants with congenital HSV infection are delivered by cesarean section.²³¹ In S.Y.'s case, delivery by cesarean section may have decreased S.Y.'s risk for HSV infection, especially if performed before or shortly (within 4–6 hours) after rupture of the membranes.²³¹

Treatment

39. Cultures for HSV and other organisms have been obtained from S.Y. as described in Question 37. Why should therapy be initiated before culture results are available?

Neonatal HSV infections can result in significant morbidity and mortality. Given S.Y.'s signs of infection and risk factors, she should be treated as a case of probable HSV infection until culture results confirm the diagnosis. Three patterns of neonatal HSV infection can occur: (a) disseminated infection (multiple organ involvement) with or without encephalitis; (b) localized CNS infection; and (c) localized infection of the skin, eyes, or mouth (SEM). Approximately 25% to 30% of newborns are symptomatic on the first day of life. Most infants present with SEM disease; however, 60% progress to disseminated disease or CNS infection.²³⁰ S.Y. has several signs of disseminated infection, including irritability, respiratory distress, and skin vesicles. Other signs of disseminated disease include seizures, coagulopathy, jaundice, and shock. Symptoms of CNS infection include temperature instability, irritability, lethargy, poor feeding, bulging fontanel, tremors, and seizures. The onset of illness in neonates with disseminated or SEM disease is at 10 to 12 days of life, whereas those with CNS disease usually present at 16 to 19 days.²³⁰ Morbidity and mortality for neonatal HSV infections are extremely high if left untreated, but can be decreased with appropriate treatment. Even with treatment, disseminated infections have the worst prognosis with a mortality rate of 29%.²³⁰ The mortality rate for CNS disease with treatment is 4% and approximately two-thirds of these infants will have neurologic abnormalities. Mortality from SEM disease is essentially zero; less than 2% have developmental delays. Early treatment also is important because it can halt the progression of less severe SEM infections to more severe forms (i.e., encephalitis and disseminated

disease). However, early diagnosis of infection is difficult and treatment is often delayed because the initial symptoms of the disease are often nonspecific.

IV acyclovir, the antiviral of choice for the treatment of neonatal HSV infection, can improve the outcome of neonatal herpes.²²⁸ The recommended acyclovir dose is 60 mg/kg/day in three divided doses, given intravenously for 14 days for those with SEM disease and 21 days for CNS or disseminated HSV disease.²²⁸ Because acyclovir is primarily excreted via the kidneys, the dose must be reduced in neonates with renal dysfunction (e.g., SrCr >0.8 mg/dL). These neonates should receive 20 mg/kg/dose administered every 12 to 24 hours, depending on SrCr.²³² S.Y. should receive acyclovir 40 mg IV Q 8 hours (60 mg/kg/day) for 21 days plus topical antiviral ophthalmic therapy (Table 94-9). Some experts recommend repeating lumbar puncture at the completion of IV acyclovir therapy in all patients with CNS involvement to document virologic clearance from the CSF.²³⁰ Treatment should be continued for those who remain HSV polymerase chain reaction positive (PCR) until their PCR becomes negative. Liver enzymes, SrCr, BUN, and CBC should be monitored for adverse effects of acyclovir. Phlebitis at the injection site also may occur.⁸

Recurrence of mucocutaneous HSV is common and is associated with neurologic sequelae if it occurs more than three times during the first 6 months of life.²²⁸ In a small, Phase I/II trial, oral acyclovir suppressive therapy (300 mg/m²/dose TID for 6 months), initiated after completion of 10 days of acyclovir treatment for neonatal SEM disease, prevented cutaneous recurrences of HSV.²³³ However, approximately 50% of the infants developed neutropenia while receiving suppressive acyclovir therapy. Furthermore, HSV encephalitis has been reported in a preterm infant who was receiving suppressive oral acyclovir therapy.²³⁴ The benefits and risk associated with suppressive therapy are unclear and therefore, routine use of oral acyclovir suppressive therapy is not recommended. A larger study comparing different acyclovir suppressive dosage regimens and the effects on neurologic outcome of infants is needed.

Other Congenital Infections

Toxoplasmosis

Congenital toxoplasmosis, an infection caused by the protozoan organism, *Toxoplasma gondii*, usually results from maternal ingestion of uncooked meat or contact with infected cats. In the United States, 400 to 4,000 cases of congenital toxoplasma infection are reported yearly.²³⁵ The only mode of human-to-human transmission is transplacental. The rate of transmission to the infant is highest (60%) if the disease is acquired during the third trimester of pregnancy. However, if infection occurs earlier in gestation, the infant develops a more severe form of infection. Most newborns infected with *T. gondii* are asymptomatic. The most common manifestation of *T. gondii* infection in neonates is chorioretinitis. These infants may develop permanent visual loss.²³⁵ Other clinical symptoms are listed in Table 94-9. Maternal treatment with spiramycin (currently investigational in the United States) or pyrimethamine with sulfadiazine can be administered to the infected mother to help reduce vertical transmission of *T. gondii*. If the diagnosis of an in utero toxoplasmosis infection is made, treatment of

both the mother and the fetus reduces the sequelae in the infant. Because pyrimethamine is teratogenic, it cannot be used during the first trimester. Treatment of neonatal toxoplasmosis includes pyrimethamine, sulfadiazine, and folic acid (leucovorin). Folic acid is given to decrease potential hematologic toxic effects of pyrimethamine.²³⁵

Syphilis

Syphilis is caused by a spirochete, *Treponema pallidum*, and can be acquired by direct contact with ulcerative, denuded lesions of the mucous membranes or skin of the infected person. Vertical transmission of congenital syphilis can either occur transplacentally or during delivery by contact of the newborn with genital lesions. In fact, the rate of transmission can be as high as 100% during the secondary stage of the disease.²²⁸ The incidence of congenital syphilis in the United States has decreased from 107 per 100,000 live births in 1991 to 11.2 cases per 100,000 live births in 2002.²³⁶ Forty percent of pregnancies in women with untreated early syphilis result in spontaneous abortion, stillbirth, nonimmune hydrops, premature delivery, and perinatal death.²²⁸ Clinical manifestations of congenital syphilis are divided into two syndromes, early (occurring before 2 years of life) and late (occurring after 2 years). The most classic presentations of congenital syphilis are bone lesions, hepatosplenomegaly, erythematous maculopapular rash (primarily on the hands and feet), and rhinitis (“snuffles”). Other clinical manifestations are listed in Table 94-9. Parenteral penicillin G is the preferred treatment and is the only drug that has documented efficacy for the treatment of congenital syphilis. IV penicillin G is preferred over IM penicillin G procaine owing to higher CSF concentrations; however, both are considered adequate treatment for congenital syphilis. If more than 1 day of therapy is missed, the entire course must be restarted.²²⁸

Hepatitis B Virus

Unlike other congenital infections (e.g., toxoplasmosis, syphilis), hepatitis B virus (HBV) infection is rarely transmitted transplacentally, especially if infection occurs during the first or second trimesters. However, the rate of transmission can be as high as 60% if infection occurs in the third trimester.²²⁷ Most infants with HBV are infected around the time of birth as a consequence of exposure to maternal HBV-positive genital tract secretions and blood.^{227,237} Newborns with HBV infection are usually asymptomatic initially, but the majority (90%) can become chronic carriers of hepatitis B surface antigen. Many of these infants develop long-term sequelae such as chronic hepatitis, cirrhosis, and hepatocellular carcinoma. Neonatal chronic carrier rates of HBV can be significantly decreased to 0% to 14% with the combined use of hepatitis B vaccination and hepatitis B immune globulin.²²⁷ Owing to these beneficial effects, the Centers for Disease Control and Prevention recommends that all newborn infants should be immunized with hepatitis B vaccination regardless of the mothers' hepatitis status (see Chapter 95).

Rubella

Rubella was a common viral illness affecting humans; however, with the advent of vaccines, the prevalence of rubella has significantly decreased. The virus crosses the placenta and infects the fetus, resulting in spontaneous abortion, stillbirth, or birth defects known as congenital rubella syndrome

(CRS). The rate of congenital infection is highest during the first trimester (80%), but transmission can also occur at any time of pregnancy.²²⁵ CRS is characterized by hearing loss, cataracts, and congenital heart disease (primarily PDA and pulmonary artery stenosis); intrauterine growth retardation also commonly occurs. Other clinical findings of CRS are listed in Table 94-9. In a 20-year follow-up study, ocular disease (i.e., cataracts, retinopathy, glaucoma) was found to affect approximately 80% of infants with CRS.²²⁵ Currently, there are no effective antiviral medications for the treatment of CRS; therefore, it is important to provide universal immunization with rubella vaccination to all children.²²⁸

Cytomegalovirus Infection

CMV is the most common cause of congenital infection, affecting approximately 40,000 infants each year.²³⁸ Transmission of CMV can occur transplacentally at any stage of pregnancy or during delivery. The rate of transmission from the mother to the fetus is much higher in mothers with primary CMV infection (50%) than in those with recurrent infection (0.5%–2%).²³⁹ CMV infection can also be transmitted through breast-milk or close contact.²³⁹ Approximately 10% of infants with CMV infection are symptomatic at birth (i.e., 90% are asymptomatic). The most common manifestations of CMV infection in symptomatic infants <2 weeks of age are petechiae, hepatosplenomegaly, jaundice, and prematurity.²³⁹ Mortality rates in severely affected infants can be as high as 20%, and most infants surviving the infection have permanent damage, such as visual deficits, hearing loss, seizure disorders, and learning and motor disabilities.^{238,239} Currently, there is no proven effective antiviral therapy for congenital CMV infection. Ganciclovir has been used to treat infants with symptomatic CMV infection²³⁹; however, it must be administered intravenously and has been associated with severe adverse effects (e.g., neutropenia, anemia, thrombocytopenia).⁸ In addition, the optimal dose and duration of ganciclovir treatment remains unknown. Therefore, routine use of ganciclovir is not recommended.²²⁸ In preliminary findings, oral valganciclovir may be a promising alternative; however, further studies are needed.²⁴⁰

APNEA

Pathogenesis

Apnea in neonates is a life-threatening condition that occurs more frequently in premature newborns and newborns of lower birth-weights. Only 7% of infants 34 to 35 weeks' gestational age have apnea.²⁴¹ In contrast, the incidence of apnea has been reported to be 78% in infants 26 to 27 weeks' gestational age and 84% in infants with birth-weights <1,000 g.²⁴¹ Although several definitions exist,^{242,243} clinically significant apnea may be defined as cessation of breathing for ≥ 15 seconds, or less if accompanied by bradycardia (HR <100 beats/minute), significant hypoxemia, or cyanosis.^{244–246} Pallor or hypotonia also may occur.

In neonates, apnea may be caused by a severe underlying illness, drugs, or prematurity itself (Fig. 94-3). Appropriate patient history, physical examination, and laboratory tests must be evaluated to rule out other causes of apnea before the diagnosis of apnea of prematurity can be made.^{244,245} It is especially important to rule out sepsis before apnea of prematurity

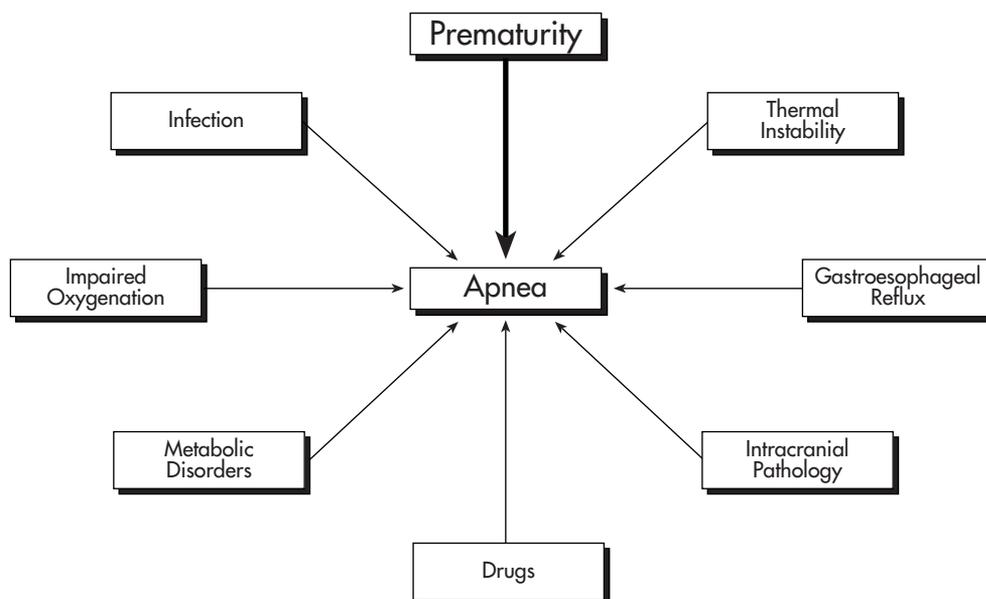

FIGURE 94-3 Causes of apnea in the neonate. (Reproduced with permission from Martin RJ et al. Pathogenesis of apnea in preterm infants. *J Pediatr* 1986;109:738.)

is presumed. If an etiology other than prematurity is identified, therapy would be directed toward that specific cause. For example, antibiotics are used to treat neonatal sepsis with secondary apnea.

Apnea of prematurity is classified into three types: central, obstructive, and mixed. Approximately 40% of apneic episodes are of central origin (i.e., no respiratory effort), 10% are due to obstruction, and 50% are due to both (i.e., mixed events).²⁴⁷ Although these terms imply separate mechanisms, obstruction/airway closure may be important in all three types (even “central”).²⁴¹ Treatment of apnea of prematurity includes the use of supplemental oxygen, gentle tactile stimulation, environmental temperature control, oscillation water beds, methylxanthines, nasal continuous positive airway pressure, and positive-pressure ventilation.^{244,245}

Treatment

Methylxanthines

40. S.M., a premature male newborn of 29 weeks’ gestational age, had a birth-weight of 995 g. On day 2 of life, he develops seven episodes of apnea followed by bradycardia with HR as low as 85 beats/minute. These episodes last 20 to 30 seconds and require administration of oxygen and tactile stimulation. Three prolonged episodes required bag-and-mask ventilation. Between apneic spells, the newborn seems well; physical examination and laboratory tests are normal for gestational age. Appropriate cultures are drawn for a septic workup and ampicillin and gentamicin are initiated. The decision is made to begin aminophylline. What is the rationale for the use of methylxanthines in apnea of prematurity and what dosing considerations must be addressed?

RATIONALE

Methylxanthine therapy generally is initiated for apnea of prematurity when apneic episodes are frequent (e.g., more than three episodes), prolonged (e.g., duration >20–30 seconds),

or severe in nature (e.g., accompanied by significant bradycardia or cyanosis) or are not controlled by nonpharmacologic means (e.g., gentle tactile stimulation, environmental temperature control, or oscillation water beds). This infant’s apneic episodes are frequent, prolonged, and severe, and therefore require pharmacologic intervention.

Methylxanthines, specifically theophylline and caffeine, are widely accepted as the initial pharmacologic approach for the treatment of idiopathic apnea of prematurity.²⁴⁵ These agents decrease apneic episodes via both central and peripheral effects. Methylxanthines stimulate the medullary respiratory center and increase receptor responsiveness to carbon dioxide. This results in an increase in respiratory drive and minute ventilation.²⁴⁵ Central stimulatory effects may be mediated by adenosine receptor blockade. Adenosine is a known inhibitor of respiration, and both theophylline and caffeine competitively inhibit adenosine at the receptor level.²⁴⁸ Other central effects, such as alteration of sleep–wake patterns, also may be important.²⁴⁹ Peripherally, methylxanthines increase diaphragmatic contractility, decrease diaphragmatic fatigue, and improve respiratory muscle contraction.^{250,251} In addition, methylxanthines increase catecholamine release and metabolic rate. This may improve cardiac output and oxygenation, lessen hypoxic episodes, and decrease apneic spells.

DOSING CONSIDERATIONS

Several developmental pharmacokinetic and pharmacodynamic factors need to be considered when dosing theophylline in neonates. Protein binding of theophylline is decreased in term newborns (36%) compared with adults (65%).²⁴ The decreased protein binding along with an increased tissue distribution results in a larger Vd of theophylline in neonates (Table 94-2). This larger Vd results in larger loading-dose requirements to attain similar serum concentrations.

Theophylline clearance in preterm newborns (17.6 mL/hour/kg) is much slower than that observed in young children 1 to 4 years of age (100 mL/hour/kg).²⁴ As a result, smaller

theophylline maintenance doses are required in neonates. Theophylline clearance increases dramatically during the first year of life, approaching adult values at 55 weeks' PCA.³⁶ Theophylline clearance and therefore maintenance doses increase with increasing PCA. Adjustment of maintenance doses is especially important in infants 40 to 50 weeks' PCA when the greatest maturational changes in theophylline clearance occur.³⁶

In adults, theophylline is eliminated primarily via hepatic metabolism by C-8 oxidation to 1,3-methyluric acid (39% of a dose) and by *N*-demethylation to 3-methylxanthine (16%) and 1-methyluric acid (20%).²⁵² Small amounts of theophylline are eliminated unchanged in the urine (13%) and 6% of the dose is *N*-methylated to caffeine.^{252,253} In contrast, the primary route of theophylline elimination in neonates is renal excretion of unchanged drug (55%).³⁶ Hepatic metabolism of theophylline (especially *N*-demethylation) is decreased in the neonate. Lower amounts of theophylline are eliminated by C-8 oxidation to 1,3-methyluric acid (24%) and by *N*-demethylation to 3-methylxanthine (1.4%) and 1-methyluric acid (8.2%).³⁶ As in adults, theophylline is methylated to caffeine in the neonate. The neonate's decreased demethylation pathway, however, results in a decrease in caffeine elimination and significant serum caffeine accumulation. On average, serum caffeine concentrations can be 40% of the serum theophylline concentration.³⁶ The theophylline-derived caffeine may contribute to the pharmacologic and toxic effects seen in neonates receiving theophylline. After 50 weeks' PCA, the theophylline-derived serum caffeine concentrations become insignificant.

The generally accepted therapeutic range of theophylline for apnea of prematurity is 6 to 12 mcg/mL. This range is lower than that which is normally accepted for the treatment of asthma (10–20 mcg/mL) for several reasons: (a) the higher free fraction of theophylline found in neonates results in a higher free concentration at any given total concentration; (b) there is a significant accumulation of the unmeasured active metabolite, caffeine; and (c) a different mechanism of action for theophylline is being exploited for apnea (i.e., central stimulation versus bronchodilation for asthma). Although some neonates may respond to theophylline serum concentrations as low as 2.8 mcg/mL,²⁴⁹ most require concentrations in the generally accepted therapeutic range.²⁵⁴

DOSING AND ADMINISTRATION

Although oral aminophylline and theophylline are considered to be well absorbed in the neonate, many neonates initially have feeding problems when apnea and bradycardia are present. Therefore, S.M. should initially receive IV therapy, and an oral nonalcoholic solution can be used when S.M. is stable and tolerating oral feedings. It should be remembered that, depending on the specific product used, aminophylline is 80% to 85% theophylline.

An aminophylline IV loading dose of 6 to 7 mg/kg (4.8–5.6 mg/kg of theophylline) produces theophylline levels of approximately 6.4 to 7.5 mcg/mL. Most centers use initial maintenance doses of aminophylline in the range of 1 to 2 mg/kg/dose given Q 8 to 12 hours, with the lower doses in this range used in younger, more premature infants. For IV administration in neonates, aminophylline should be diluted to 1 mg/mL and infused over 20 to 30 minutes.⁸ An aminophylline maintenance dose for S.M. of 1.5 mg/kg/dose Q 8 hours should

produce steady-state theophylline serum concentrations in the midtherapeutic range. Lower doses for S.M., as recommended by the FDA guidelines (theophylline 1 mg/kg Q 12 hours for preterm neonates <24 days postnatal age),²⁵⁵ result in serum concentrations below 5 mcg/mL in most infants less than 40 weeks' PCA.²⁵⁶ Concomitant drug therapy and disease states (e.g., hepatic or renal dysfunction) also should be taken into consideration when selecting initial theophylline doses.

41. S.M. was given aminophylline 6 mg (6 mg/kg of aminophylline, 4.8 mg/kg theophylline) as an IV loading dose over 20 minutes. Maintenance doses of 1.5 mg Q 8 hours have been ordered. Describe your pharmacotherapeutic monitoring plan for S.M. Include monitoring parameters for efficacy and toxicity and duration of therapy.

The goal of methylxanthine therapy in the treatment of apnea of prematurity is to decrease the number of episodes of apnea and bradycardia. Continuous monitoring of HR and RR is required for proper evaluation. The time, duration, and severity of episodes, activity of the infant, and any necessary intervention performed should be documented. Relationships between the apneic episodes and the feeding schedule and volume of feeds, as well as the dosing schedule of theophylline (e.g., trough), should be examined.

Apnea of prematurity usually resolves by 37 weeks' PCA; however, it may persist in some infants up to or beyond 40 weeks' PCA.²⁵⁷ In general, the younger the gestational age of the infant at birth, the older the PCA at cessation of apnea. Apnea of prematurity frequently persists beyond 36 weeks' PCA in infants born at 28 weeks' gestational age or less, and persists beyond 40 weeks' PCA in 22% of infants born at 24 weeks' gestational age.²⁵⁷ Therefore, methylxanthine therapy usually is discontinued at 35 to 37 weeks' PCA provided that the infant has not been having apneic spells.²⁴⁵ Infants requiring therapy for longer periods of time may be discharged home on methylxanthines with apnea monitors.

Toxicities noted in neonates include tachycardia, agitation, irritability, hyperglycemia, feeding intolerance, gastroesophageal reflux, and emesis or occasional spitting up of food. Tachycardia is the most common toxicity and usually responds to a downward adjustment of the theophylline dose. Tachycardia may persist for 1 to 3 days after dosage reductions owing to the decreased elimination of theophylline-derived caffeine. Seizures also have been reported with accidental overdoses. Methylxanthine toxicity can be minimized with careful dosing and appropriate monitoring of serum concentrations. Serum theophylline concentrations should be monitored 72 hours after initiation of therapy or after a change in dosage. Serum concentrations of theophylline also should be measured if the infant experiences an increase in the number of apneic episodes, signs or symptoms of toxicity, or a significant increase in weight. In asymptomatic neonates, once steady-state levels are obtained, theophylline concentrations may be monitored every 2 weeks.

42. S.M. now is 3 weeks old (32 weeks' PCA) and weighs 1,100 g. His septic workup was negative. Currently, S.M. has several apneic spells per day, which respond to tactile stimulation; his apneic episodes have not required ventilatory assistance. S.M. receives 1 mg aminophylline IV Q 8 hours, and his trough theophylline level this morning was 5.7 mcg/mL. The medical team is considering switching S.M.'s theophylline therapy to caffeine because

of possible improved benefits. How does caffeine compare with theophylline with regard to its pharmacokinetics, efficacy, and toxicity? What treatment should be selected?

PHARMACOKINETICS

The plasma clearance of caffeine is considerably lower and the half-life is extremely prolonged in the premature newborn (Table 94-2). The low clearance is a reflection of the decreased neonatal hepatic metabolism and a resultant dependence of elimination on the slow urinary excretion. In the preterm neonate, the amount of caffeine excreted unchanged in the urine is 85%, compared with <2% in adults. Adult urinary metabolite patterns are seen by 7 to 9 months of age.²⁵⁸ The half-life of caffeine decreases with increasing PCA²⁵⁹ and plasma clearance reaches adult levels after 3 to 4.5 months of life.²⁶⁰ As a result of the maturational changes, doses usually need to be adjusted after 38 weeks' PCA and dosing intervals need to be shortened to 8 hours after 50 weeks' PCA.²⁵⁹

EFFICACY, TOXICITY, AND DOSING

Comparative studies have found similar efficacy for theophylline and caffeine in the control of apnea of prematurity.²⁶¹ Caffeine, however, may have some advantages over theophylline, including a wider therapeutic index. Adverse effects such as tachycardia, CNS excitation, and feeding intolerance are reported more frequently with theophylline than with caffeine. The prolonged half-life of caffeine in premature neonates results in less fluctuation in plasma concentrations and permits the use of a 24-hour dosing interval. Because the half-life is prolonged and dosing requirements do not change quickly over time, caffeine serum concentrations can be monitored less frequently. Loading doses of 10 mg/kg of caffeine base (20 mg/kg of caffeine citrate), followed 24 hours later by maintenance doses of 2.5 mg/kg (5 mg/kg caffeine citrate) given daily maintain plasma caffeine concentrations in the therapeutic range (5–20 mcg/mL). Loading doses of caffeine citrate are recommended to be given IV over 30 minutes using a syringe infusion pump. Maintenance doses can be administered IV over 10 minutes or given orally.¹⁰⁵ Because of the longer half-life, infants receiving caffeine must be monitored for a longer period of time (e.g., for 7–10 days) for adverse effects if toxicities occur and for efficacy once the medication is discontinued. Another disadvantage of caffeine is its high cost. Although infants who are unresponsive to theophylline may respond to caffeine,²⁶² S.M.'s theophylline therapy presently is not optimized; his serum concentration is <6 mcg/mL. S.M. seems to have partially responded to theophylline and may benefit from an increase in the dose with resultant therapeutic serum concentrations. S.M.'s aminophylline dose should be increased to 1.5 mg every 8 hours to achieve serum concentrations of approximately 8 mcg/mL. Caffeine may have several advantages over theophylline. Now that a preservative-free caffeine citrate product is available in the United States,¹⁰⁵ its use is increasing. It is important to remember that another IV caffeine product is marketed in the United States as the sodium benzoate salt. Benzoic acid has been associated with the gasping syndrome and also may displace bilirubin from albumin-binding sites.^{39,40} Because of these toxicities, the caffeine sodium benzoate product should not be used in neonates.

The short- and long-term safety and efficacy of caffeine to treat apnea of prematurity in VLBW infants was studied in

a large, randomized, placebo-controlled trial.^{109,263} Caffeine significantly decreased the frequency of BPD.¹⁰⁹ Infants who received caffeine were able to have positive airway pressure discontinued 1 week sooner than those receiving placebo. Although caffeine reduced weight gain, the effect was only temporary (during the first 3 weeks of therapy). No significant short-term effects of caffeine on death rates, ultrasonographic signs of brain injury, or NEC were identified. In a follow-up study at 18 to 21 months' corrected age, caffeine significantly improved the rates of survival without neurodevelopmental disability; no difference in death rates were observed between caffeine and placebo, but the incidence of cerebral palsy and cognitive delay were both decreased in infants receiving caffeine.²⁶³

Other Agents

43. S.M.'s dose of theophylline has been optimized and theophylline serum concentrations now are 12.4 mcg/mL. S.M. continues to have apneic episodes. What other pharmacologic agents can be used?

Doxapram, an analeptic agent, has been shown to be as effective as theophylline for the treatment of apnea of prematurity.^{264,265} Because of the limited number of investigations and uncertain side effects, however, doxapram should be restricted to patients who are refractory to methylxanthine therapy. In addition, the IV preparation commercially available in the United States contains 0.9% benzyl alcohol and should be used with caution. Although doses are not well defined, a loading dose of 2.5 to 3 mg/kg given IV over 15 to 30 minutes followed by a 1 mg/kg/hr continuous infusion has been recommended. Doses may be increased by 0.5 mg/kg/hour increments to a maximum dose of 2.5 mg/kg/hour. Lower doses have been used in infants receiving concomitant methylxanthine therapy with approximately 50% responding to IV doxapram doses of 0.5 mg/kg/hour.²⁶⁶ A few studies have administered doxapram enterally; however, bioavailability in preterm newborns is not well defined²⁶⁷ and routine use of oral doxapram cannot be recommended.²⁶⁸ Side effects associated with doxapram include cardiovascular problems such as increased BP (usually with doses > 1.5 mg/kg/hour)²⁶⁶ and second-degree atrioventricular heart block with prolonged QT interval²⁶⁹; GI disturbances such as abdominal distention, regurgitation, increased gastric residuals, and vomiting; and CNS adverse effects such as increased agitation, excessive crying, jitteriness, irritability, disturbed sleep, and seizures. Further studies of doxapram are needed to better delineate its adverse effects and to help define its safety and efficacy for the treatment of apnea of prematurity.

PERIVENTRICULAR–INTRAVENTRICULAR HEMORRHAGE

Pathogenesis

44. M.C., a 3-day-old male infant, was born at 28 weeks' gestation with a birth-weight of 980 g. He was intubated shortly after birth for respiratory distress and last night developed a pneumothorax. This morning, M.C. required a blood transfusion because of a significant drop in hematocrit. Hypotension, hypotonia, and decreased responsiveness now are noted on physical examination. An ultrasound of the infant's head was ordered

to confirm the suspicion of an intraventricular bleed. What factors are associated with an increased risk for the development of periventricular–intraventricular hemorrhage (PV-IVH)?

PV-IVH is a significant cause of death among premature newborns and is one of the most common serious neurologic injuries that occurs during the neonatal period. The incidence and severity of PV-IVH is inversely related to gestational age, with the highest frequency occurring in the most immature neonates.²⁷⁰ PV-IVH occurs in approximately 3% of healthy, term newborns, in >20% of premature newborns <1,500 g birth-weight, and in >60% of preterm infants <700 g birth-weight.^{271,272}

The most common site of origin of the hemorrhage is the periventricular germinal matrix, a highly vascularized cellular region that contains neuronal precursor cells. This vascular network, which is prominent at 26 to 34 weeks' gestational age, contains poorly supported blood vessels that are fragile and vulnerable to injury.²⁷⁰ Most factors associated with an increased risk of PV-IVH alter cerebral blood flow or arterial BP, which results in damage to these vessels. M.C. has two risk factors that are strongly associated with PV-IVH: prematurity and acute respiratory failure requiring mechanical ventilation.²⁷⁰ Other associated risk factors include pneumothorax (which M.C. also has), hypotension, hypertension, hypoxia, hypercapnia, asphyxia, acidosis, rapid volume expansion, coagulation defects, infusion of hyperosmolar substances (e.g., sodium bicarbonate), hypernatremia, hyperglycemia, seizures, PDA, heparin use, tracheal suctioning, and inadvertent noxious stimulation.^{270–273} The use of low-dose heparin in umbilical catheter infusions (1 unit/mL) may not increase the risk of PV-IVH, but larger studies are required.²⁷⁴

Common signs and symptoms of PV-IVH include hypotension, hypotonia, a drop in hematocrit, and a decrease in responsiveness as illustrated by M.C. Apnea, oculomotor disturbances, areflexia, tonic posturing, flaccid quadriplegia, seizures, and death also may occur.²⁷⁵ Prognosis for normal neurologic development in survivors depends on location and severity of the bleed. Mild hemorrhages (grade I, isolated germinal matrix hemorrhage; grade II, hemorrhage extending into normal-size ventricles) have a better prognosis, but may result in cognitive deficits such as reading disabilities or other learning problems. Approximately 10% of infants with mild hemorrhages develop a major disability, such as spastic diplegia. Infants with moderate (grade III, hemorrhage extending into enlarged ventricles) or severe hemorrhages (grade IV, intraparenchymal hemorrhage) do worse with an increase in major motor (e.g., spastic hemiparesis, quadriplegia) and intellectual deficits. Infants with moderate and severe bleeds also are more likely to develop posthemorrhagic hydrocephalus and seizure activity. Those with severe hemorrhage have a higher mortality rate.²⁷⁰

Treatment

45. How is PV-IVH managed and what therapies have been investigated to prevent PV-IVH?

Management and prevention of PV-IVH include the reduction or elimination of known risk factors. Because prematurity is a major risk factor, prevention of premature birth is the most effective way to eliminate PV-IVH. However, antenatal tocolytic agents such as maternal β -sympathomimetics and indomethacin have been shown to increase the incidence

of IVH in infants.^{272,273} Other antenatal pharmacologic agents (magnesium sulfate, phenobarbital, vitamin K, and corticosteroids) have been investigated to reduce PV-IVH, but only antenatal corticosteroids are currently recommended.^{64,270,272,273}

Antenatal maternal corticosteroids significantly reduce the incidence and severity of PV-IVH (as well as the incidence of RDS and infant mortality).^{64,272} Corticosteroids may prevent PV-IVH by stabilizing or promoting maturation of the endothelium of the fragile blood vessels of the germinal matrix.^{270,273} Because even partial courses of maternal corticosteroids are beneficial, M.C. may have benefited from prompt treatment of his mother with corticosteroids as soon as the risk for preterm delivery was identified (see Respiratory Distress Syndrome section).^{64,271,273}

To prevent PV-IVH after birth, wide variations in BP and cerebral blood flow, abnormalities in serum osmolality and blood gases, and noxious stimulations should be avoided. Several postnatal pharmacologic agents, including phenobarbital, indomethacin, ibuprofen, ethamsylate, vitamin E, and pancuronium have been investigated for the prevention of PV-IVH.²⁷⁰ At present, none are widely accepted for routine use in newborn infants. Of the agents studied, low-dose indomethacin offers the best potential for PV-IVH prophylaxis.^{272,276} A multicenter, randomized, placebo-controlled trial using indomethacin (0.1 mg/kg/dose IV at 6–12 hours after birth and every 24 hours for two additional doses) significantly lowered the incidence and severity of IVH in neonates of weighing 600 to 1,250 g at birth.²⁷⁶ Postnatal low-dose indomethacin therapy also significantly lowered the incidence of IVH in infants whose mothers received antenatal corticosteroid therapy.²⁷⁷

Indomethacin, a cyclo-oxygenase inhibitor, may prevent IVH by reducing the synthesis of vasodilating prostanoids and prostaglandins. This results in a decrease in baseline cerebral blood flow and changes in cerebral blood flow modulation. Inhibition of cyclo-oxygenase also may decrease formation of harmful free radicals. Because indomethacin lowers cerebral blood flow, concerns about increased risks of cerebral ischemic injury and neurodevelopmental handicaps exist. One follow-up study conducted at 36 months of corrected age showed that low-dose indomethacin did not result in any adverse cognitive or motor outcomes.²⁷⁷ Although this seems promising, further long-term follow-up investigations are needed before the use of low-dose indomethacin in premature infants can be recommended universally.^{271,273}

In animal studies, ibuprofen enhances cerebral blood flow autoregulation and may offer neuroprotection after oxidative stress.¹⁵² However, in clinical trials, IV ibuprofen did not prevent IVH. In two placebo-controlled double-blind, randomized studies of early administration of ibuprofen (within 6 hours after birth), ibuprofen did not reduce the frequency of IVH (grades II–IV).^{161,278} In addition, comparative trials of ibuprofen and indomethacin for the treatment of PDA did not find significant differences in the incidence IVH.¹⁵³ Thus, ibuprofen has no proven effect on IVH risk and cannot be recommended.

NEONATAL SEIZURES

Pathogenesis and Diagnosis

46. F.H., a term female newborn (weight 3.5 kg), has a history of perinatal asphyxia. Apgar scores were 2 and 4 at 1 and 5 minutes,

respectively. Forty-eight hours after birth, F.H. begins to have rhythmic clonic twitching of the right hand, repetitive chewing movements, fluttering of the eyelids, and occasional pendular movements of the extremities that resemble swimming motions. What interventions should be initiated immediately for F.H.?

Seizure activity may be difficult to recognize in the term or premature neonate. Because of the immaturity of the cortex, neonatal seizures rarely are generalized tonic-clonic events, but can be clonic (focal or multifocal), tonic (focal or generalized), myoclonic (focal, multifocal, or generalized), or subtle in nature.²⁷⁹ Subtle seizures include activities such as abnormal oral-buccal-lingual movements; ocular movements; swimming, pedaling, or stepping movements; and occasionally apnea.²⁷⁵ In addition, autonomic nervous system signs such as changes in HR, BP, respirations, skin color, oxygenation, salivation, or pupil size may occur.²⁸⁰ Clinical neonatal seizures may or may not be associated with EEG changes.²⁸⁰

Neonatal seizure activity is a common manifestation of a life-threatening underlying neurologic process (Table 94-10);

therefore, initial efforts may not include antiepileptic drug therapy. Definitive treatment is directed toward specific identified etiologies. The acute evaluation of neonatal seizures includes assessment of the infant's airway, breathing, and circulation and a review of the infant's history, physical examination, and laboratory studies. Every neonate with seizure activity should have a bedside determination of glucose; laboratory determinations of serum electrolytes, including sodium, BUN, glucose, calcium (Ca), and magnesium (Mg); blood gases; bilirubin; and an infectious disease workup, including CBC with platelets, blood culture, urine culture, lumbar puncture with CSF analysis (cell count, protein, glucose), and CSF culture.^{275,279} Treatment with antiepileptic drugs is indicated after correction of known electrolyte abnormalities. Antiepileptic drug therapy can be initiated (after correction of hypoglycemia) while laboratory test results are pending.

If these tests do not reveal any abnormalities, an EEG, metabolic disease workup (e.g., serum ammonia, lactate, pyruvate; serum and urine amino and organic acids), and screening of blood and urine for drugs can be performed.^{275,279,280}

Intrauterine infections associated with congenital neurologic abnormalities and seizures can be identified by obtainment of TORCH titers (see Question 37). Cranial ultrasounds, CT scans, and MRIs may be obtained to identify infarcts, hemorrhages, calcifications, or cerebral malformations that may cause seizure activity.^{275,281}

47. The physician assesses F.H. as having adequate ventilation and circulation. She establishes an IV line and sends blood samples for electrolytes, Ca, and Mg. A Chemstrip reveals a blood glucose of 20 mg/dL. What is your assessment and recommendation at this time?

Hypoglycemia seems to be the cause of F.H.'s seizure activity. Hypoxic ischemic encephalopathy (secondary to asphyxia), however, is the most common cause of neonatal seizures. Hypoxic ischemic encephalopathy can be associated with metabolic abnormalities such as hypoglycemia, hypocalcemia, and hyponatremia (owing to inappropriate secretion of antidiuretic hormone). Hypocalcemia may also be accompanied by hypomagnesemia.²⁸⁰ Hypoglycemia is defined as a whole blood glucose <20 mg/dL for premature infants and <30 mg/dL for term infants during the first 72 hours of life and <40 mg/dL for any neonate after 72 hours of age. In clinical practice, however, a glucose <40 mg/dL in a neonate of any age would be treated.²⁸²

F.H. should receive an IV bolus dose of 7 to 14 mL (2–4 mL/kg) of dextrose 10% (200–400 mg/kg) given over 2 to 3 minutes, followed by a continuous infusion of dextrose 10% at an initial dose of 12.6 to 16.8 mL/hour (6–8 mg/kg/minute or 3.6–4.8 mL/kg/hour).²⁸¹ Serum glucose levels should be monitored, and the dextrose infusion should be titrated as needed. If hypoglycemia persists, possible causes such as islet tumor of the pancreas, adrenal insufficiency, and inborn errors of metabolism should be investigated. Corticosteroids, glucagon, and diazoxide have been used to treat persistent hypoglycemia.²⁸²

Treatment of Hypocalcemia and Hypomagnesemia

48. The physician administers 10 mL (1 g) of 10% dextrose solution IV and starts an IV infusion of glucose at 8 mg/kg/min. A repeat Chemstrip reveals a blood glucose of 80 mg/dL, but F.H. continues to have seizure activity. F.H.'s laboratory results come back with the following results: Na, 137 mEq/L; K, 4.3 mEq/L; CO₂, 22 mEq/L; Cl, 104 mEq/L; BUN, 7 mg/dL; SrCr, 0.7 mg/dL; glucose, 25 mg/dL; Mg, 1.0 mEq/L; and Ca, 5 mg/dL. What should be done next to control F.H.'s seizures?

[SI units: Na, 137 mmol/L; K, 4.3 mmol/L; CO₂, 22 mmol/L; Cl, 104 mmol/L; BUN, 2.5 mmol/L of urea; SrCr, 61.9 μmol/L; glucose, 1.4 mmol/L; Mg, 0.5 mmol/L; Ca, 1.25 mmol/L]

F.H. also has hypocalcemia and hypomagnesemia, both of which may cause seizure activity. Neonatal hypocalcemia is defined as a serum calcium <7.5 mg/dL in preterm and <8 mg/dL in term infants²⁸⁰ or an ionized serum calcium <3 mg/dL.²⁸¹ Hypomagnesemia (defined as a serum magnesium <1.5 mEq/L) is rare but may coexist with hypocalcemia. Hypomagnesemia should be suspected when hypocalcemia cannot be corrected despite large doses of calcium.²⁸³

F.H. should receive calcium gluconate 700 mg (200 mg/kg) given slowly intravenously as a 10% solution²⁸⁰ and magnesium sulfate 25 to 50 mg/kg/dose (0.2–0.4 mEq/kg/dose) IM as a 50% solution or intravenously as a dilute solution (maximum concentration, 100 mg/mL) administered over 2 to 4 hours.⁸ Doses of calcium gluconate and magnesium sulfate may be repeated based on serum determinations. If IV calcium is administered too quickly, vasodilation, hypotension, bradycardia, and cardiac arrhythmias may occur. Calcium gluconate may be administered intravenously at a maximum rate of 50 mg/min while monitoring HR, BP, and electrocardiogram (ECG).⁸ To avoid IV extravasation with resultant severe dermal necrosis, calcium salts should be administered through a properly working IV line, and the IV site should be monitored for signs of infiltration.

Treatment With Antiepileptic Drugs

49. Despite normalization of her laboratory tests, F.H. continues to have seizure activity. Phenobarbital 35 mg IV push over 1 minute is administered. Ten minutes later, F.H. continues to have intermittent seizure activity. Describe a pharmacotherapeutic plan to control F.H.'s seizure activity.

Phenobarbital is the initial antiepileptic drug of choice for neonatal seizures; phenytoin and lorazepam usually are considered the second and third drugs of choice.²⁸⁴ Because of the large Vd of phenobarbital in neonates (approximately 1 L/kg), large initial loading doses of 20 mg/kg are required to produce therapeutic serum concentrations (Table 94-11). Because F.H. received only a 10-mg/kg dose (35 mg) of phenobarbital, an additional 10 mg/kg should be given now. Phenobarbital should be administered IV at a rate of ≤1 mg/kg/minute,⁸ so a 35-mg dose should be given over at least 10 minutes, not over 1 minute. Rapid administration of phenobarbital may cause respiratory depression, apnea, or hypotension. If F.H. continues to have seizure activity after a total phenobarbital loading dose of 20 mg/kg, additional 5- to 10-mg/kg loading doses may be given every 15 to 20 minutes as needed up to a total loading dose of 40 mg/kg. Ventilatory support may be required when using these higher doses, and serum phenobarbital concentrations should be monitored. Phenobarbital's therapeutic effect of controlling neonatal seizures plateaus at serum concentrations of 40 mcg/mL; adverse effects increase at higher serum concentrations.²⁸⁵

If seizure activity is not controlled in F.H. (despite optimal phenobarbital loading doses), a phenytoin loading dose of 70 mg (20 mg/kg) should be administered IV at a rate ≤0.5 mg/kg/minute.^{8,279} Rapid IV administration of phenytoin may cause cardiac arrhythmias, bradycardia, or hypotension. Phenytoin also may cause severe damage to tissues if extravasation occurs. Therefore, BP, HR, ECG, and the IV site of infusion should be monitored. Recently, fosphenytoin, the diphosphate ester salt of phenytoin, became available in the United States for IV and IM use in adults.⁸ Fosphenytoin is a water-soluble prodrug of phenytoin that undergoes conversion by plasma and tissue esterases to phenytoin, phosphate, and formaldehyde. Fosphenytoin has several advantages over phenytoin. Because of its greater water solubility, the IV preparation does not contain propylene glycol, and thus fosphenytoin may have fewer cardiovascular adverse effects associated

Table 94-11 Pharmacotherapy of Neonatal Seizures^{a8}

| Drug | Loading Dose | Maintenance Dose | Therapeutic Concentration |
|---------------|---|--|---------------------------|
| Phenobarbital | IV: Initial: 20 mg/kg then 5–10 mg/kg Q 15–20 min if needed until total load of 40 mg/kg | IV PO: Initial: Premature: 3 mg/kg/day Term: 4 mg/kg/day May need to ↑ to 4–5 mg/kg/day by 2–4 weeks of therapy | 20–40 mcg/mL |
| Phenytoin | IV: 15–20 mg/kg | IV: Initial: 5 mg/kg/day May need to ↑ to ≥10 mg/kg/day by 2–4 weeks of therapy | 8–15 mcg/mL |
| Lorazepam | IV: 0.05–0.1 mg/kg | May repeat doses if needed Q 10–15 min | |
| Diazepam | IV: 0.1–0.3 mg/kg | May repeat doses if needed Q 10–15 min | |
| Midazolam | IV: Initial bolus dose of 0.15 mg/kg has been used in some studies; however, for safety reasons, this bolus dose should not be given if the neonate has received an IV dose of a benzodiazepine | IV continuous infusion: Initial: 0.05 mg/kg/hr; ↑ by 0.025 mg/kg/hr increments; usual maximum 0.4 mg/kg/hr; some studies reported neonates who required doses up to 1 mg/kg/hr | |
| Pyridoxine | IV: 50–100 mg | IV PO: 20–50 mg/day; ↑ dose PRN with age | |
| Valproic acid | PO: 20 mg/kg | PO: 10 mg/kg/dose Q 12 hr | 40–50 mcg/mL |

^aSee text for comments on appropriate IV administration and monitoring. IV, intravenous; PO, oral.

with IV administration. Unlike phenytoin, fosphenytoin's more neutral pH also allows for IM administration. Unfortunately, appropriate clinical studies of fosphenytoin in neonates have not yet been conducted. Unanswered concerns about the neonatal handling of formaldehyde also exist. Currently, routine use of fosphenytoin in neonates cannot be recommended. Studies assessing the safety, efficacy, and optimal dosing are needed.

Lorazepam or diazepam may be used to treat F.H.'s seizures if they are unresponsive to phenobarbital and phenytoin.^{286,287} Although lorazepam offers the advantage of a longer duration of effect than diazepam, the use of either agent (especially in combination with phenobarbital) may cause respiratory and CNS depression. RR, BP, and HR should be monitored. Both IV preparations contain propylene glycol and benzyl alcohol. Although these substances have been reported to cause toxicities in newborns, the actual amount administered when using appropriate benzodiazepine doses is minimal and should not pose a significant risk.²⁸⁶ Doses of lorazepam should be diluted with an equal volume of D₅W, normal saline, or sterile water for injection before IV use and administered slowly over 2 to 5 minutes. The relatively high concentration of diazepam injection (which results in <0.1-mL doses) and its physical incompatibility with most diluents, make it impractical to use in small neonates. As a result, lorazepam has become the preferred benzodiazepine in many neonatal ICUs.

If seizure activity continues in F.H., continuous IV infusion of midazolam, or oral levetiracetam should be considered.^{280,288–290} An IV formulation of levetiracetam is commercially available in the United States. Although not approved for use in neonates, some neonatal centers use the oral dosing recommendations for the IV formulation because the two forms are bioequivalent.⁸ However, the optimal neonatal dose of levetiracetam has not been established. Neonatal case reports have used doses from studies in pediatric patients.²⁹⁰ Given that levetiracetam is primarily excreted via the kidney (66% of a dose is excreted as unchanged drug in the urine) and that the renal function of neonates is decreased compared with older infants, prudence dictates using conservative dose titration and close monitoring of adverse effects. Oral carba-

mazepine, primidone, lamotrigine, or valproic acid (IV, oral) have also been used to treat neonatal seizures in limited numbers of patients.^{279,291,292} Because the risk of valproic acid-associated hepatotoxicity is higher for patients <2 years of age, this drug is not a preferred agent for use in neonates.⁸ IV pyridoxine should be considered when seizure activity persists. Pyridoxine is a cofactor required for the synthesis of the inhibitory neurotransmitter γ -aminobutyric acid (GABA). Patients with pyridoxine dependency require higher amounts of pyridoxine for proper GABA synthesis. Pyridoxine dependency is a rare disorder, but should be considered in neonates with seizure activity unresponsive to antiepileptic drug therapy. Lifelong supplementation of pyridoxine is required in these patients.²⁸⁰

Antiepileptic Drug Maintenance Doses

50. F.H.'s seizure activity stopped after receiving a total loading dose of 105 mg of phenobarbital and 70 mg of phenytoin. A serum phenobarbital concentration of 35 mcg/mL and a phenytoin concentration of 17 mcg/mL were measured 1 hour after the phenytoin loading dose (2 hours after the last phenobarbital loading dose). How should maintenance doses of antiepileptic drugs be instituted in F.H.?

It is not surprising that F.H. required both phenobarbital and phenytoin to control her seizures. Although phenobarbital and phenytoin are equally effective, neonatal seizures are controlled in fewer than 50% of neonates with either agent alone. When both agents are used together, neonatal seizures are controlled in approximately 60% of neonates.²⁹³

F.H. should be placed on maintenance doses of both phenobarbital and phenytoin because both drugs were needed to control her seizure activity. Because the half-life of phenobarbital is prolonged in neonates (about 100–150 hours), maintenance doses can be instituted 24 hours after the loading dose at 3 to 4 mg/kg/day^{280,294} as a single daily dose (Table 94-11). Although this newborn is term, she should receive a lower dose of phenobarbital (2.5–3 mg/kg/day) because of her history of asphyxia. Asphyxiated neonates have impaired phenobarbital

clearance and therefore require lower maintenance doses than nonasphyxiated neonates to achieve similar phenobarbital serum concentrations.⁴³ Maintenance doses of phenytoin (3–4 mg/kg/day given in divided doses Q 12 hours) may be initiated 12 to 24 hours after the loading dose. Serum concentrations of these agents should be monitored periodically because maintenance dose requirements increase over time (usually by week 2–4 of therapy).²⁹⁴ This may be due to a normal maturation of hepatic enzyme systems with age or induction of P450 enzymes. In neonates, oral phenytoin is poorly absorbed and should be avoided in the acute setting. A routine 25% increase in the dose is needed when converting IV phenytoin to oral to attain similar serum concentrations. In addition, after 2 to 4 weeks of age, dosing intervals of every 8 hours may be needed.

The optimal duration of anticonvulsant treatment of neonatal seizures has not been clearly established. Typically, anticonvulsants are continued for approximately 6 months in neonates with persistently abnormal neurologic examinations. Because of the potential long-term toxicities of these medications and the low risk of seizure recurrence, anticonvulsants are generally discontinued before discharge if the neonate's neurologic examination and EEG are normal.²⁹⁵ However, the duration of anticonvulsant medications should be individualized.

NEONATAL ABSTINENCE SYNDROME

A disturbing incidence of maternal substance abuse and associated obstetric and neonatal complications exists.^{296,297} Drugs such as alcohol, opiates, barbiturates, and benzodiazepines readily cross the placenta and may induce fetal dependency. In addition to the neonatal abstinence syndrome (NAS), other problems seen in infants of addicted mothers must be recognized to optimize patient care. In utero exposure to drugs of abuse may have serious short- and long-term consequences on fetal growth, physiological functions, and neurologic development. The use of cocaine during pregnancy may cause complications such as fetal distress, preterm labor, spontaneous abortion, abruptio placentae, stillbirths, or congenital malformations and may place the infant at a higher risk for IVH and NEC.^{296,298} Intrauterine growth retardation and sudden infant death syndrome have been associated with heroin, methadone, and cocaine abuse during pregnancy.^{296,297} Neonatal systolic hypertension, abnormal thyroid function, hyperbilirubinemia, thrombocytosis, and increased platelet aggregation have been reported with maternal methadone use.²⁹⁶ The increase of polydrug abuse during pregnancy also may complicate treatment.

Although environmental, familial, and neonatal coexisting factors (such as prematurity and low birth-weight) need to be considered, investigations assessing neurobehavioral development suggest that drug-exposed infants may be at a greater risk for certain learning, developmental, and behavioral problems.²⁹⁶ For example, infants born to narcotic-dependent mothers may have later difficulties with short-term memory, attention, concentration, and general processing of perception. Delayed language development has been noted for methadone- and cocaine-exposed infants. Hyperactivity, aggressiveness, impulsiveness, uncontrollable temper, and other behavioral problems have been reported in follow-up studies of infants of drug-dependent mothers.²⁹⁶ Investigations that control for confounding factors are needed to fully assess the long-term

neurobehavioral outcomes of drug-exposed infants and the long-term effects of currently recommended therapies.²⁹⁹

Adverse neonatal effects from the maternal use of selective serotonin reuptake inhibitors (SSRIs) during pregnancy have been reported. First trimester exposure to SSRIs may increase the risk of congenital cardiovascular malformations; antenatal exposure to paroxetine has been associated with an increased risk of cardiac defects (e.g., ventricular or atrial septal defects).^{300,301} Late pregnancy SSRI exposure is associated with an increased risk for persistent pulmonary hypertension of the newborn and the neonatal behavioral syndrome.^{302,303} This syndrome includes respiratory distress, tremors, jitteriness, increased muscle tone, feeding difficulties, seizures, and temperature instability. However, it is unknown whether these symptoms are due to toxic effects of SSRIs or drug withdrawal.³⁰² To help reduce the incidence of neonatal behavioral syndrome, physicians should try to taper maternal SSRIs in late pregnancy. Unfortunately, it is unknown whether tapering of SSRIs in high-risk patients could complicate labor and delivery. Therefore, it is important to assess the risks and benefits and use SSRIs with caution during pregnancy.

Clinical Presentation

51. A.K., a 38-week gestation, 2,000-g, small-for-gestational-age female, was born to a gravida 3 para 2 mother with a history of frequent heroin use during pregnancy. A.K.'s mother was enrolled in a methadone maintenance program 1 month ago, and her last dose of methadone was 12 hours before delivery. On further questioning, A.K.'s mother admits to the continued use of heroin and occasional use of crack cocaine. Her last "fix" was 3 hours before delivery. On the first day of life, A.K. became restless, irritable, and tachypneic, and displayed spontaneous tremors and a high-pitched cry. A.K. developed vomiting and diarrhea on day 2 of life after starting feedings with a standard formula. Although A.K. frequently suckled on her fist, she was not able to suckle properly while feeding. A.K.'s drug screen was positive for cocaine, opiates, and methadone. What clinical symptoms of NAS does A.K. demonstrate? How do the onset, severity, and duration of NAS vary with various commonly abused substances?

Symptoms of drug withdrawal occur in 30% of infants exposed to SSRIs in utero and 50% to 90% of infants born to narcotic-dependent mothers, with a higher incidence for methadone (70%–90%) compared with heroin (50%–75%).^{296,304} NAS is a generalized disorder characterized by CNS hyperirritability (e.g., hyperactivity, irritability, high-pitched or prolonged cry, hyperreflexia, fist sucking, abnormal sleep pattern, tremor, myoclonic jerks, and rarely, seizures), respiratory difficulties (e.g., stuffy nose, rhinorrhea, respiratory distress, tachypnea, respiratory alkalosis, and apnea), GI dysfunction (e.g., regurgitation, drooling, vomiting, diarrhea, hyperphagia, uncoordinated suck and swallow reflex, and poor feeding), and vague autonomic symptoms (e.g., sneezing, yawning, hiccups, sweating, lacrimation, hyperthermia or hypothermia, and skin mottling).^{296,297,299}

The onset, severity, and duration of NAS may be influenced by many factors, including the specific drug(s) abused, duration of drug exposure, timing and amount of the mother's last dose before delivery, elimination of the drug by the infant, and the gestational age of the infant at birth.^{297–299,305} Preterm

infants display a less severe abstinence syndrome compared with term infants, possibly because of their CNS immaturity or a decreased total in utero drug exposure.³⁰⁶ Neonatal methadone withdrawal may be more severe than heroin withdrawal and is associated with a higher incidence of seizures (10%–20%).²⁹⁶ Withdrawal from non-narcotic drugs usually is less severe, but can also be associated with seizures.³⁰⁷ Typically, the cocaine-exposed newborn is hypertonic when alert, irritable, and tremulous. Infants may display decreased interactive behavior, disorganized sleeping and feeding patterns, abnormal cry patterns, seizures, and may be intermittently lethargic. These symptoms are considered to be signs of cocaine toxicity rather than withdrawal.^{297,307}

The onset of narcotic drug withdrawal ranges from minutes after delivery to 2 weeks of age, with most symptoms appearing within 72 hours.^{297–299} Withdrawal from methadone, however, may be delayed in some infants, with symptoms presenting as late as 2 to 4 weeks of age.^{296,298} Similarly, symptoms of barbiturate withdrawal can appear as late as 10 to 14 days.^{298,299,305} The long elimination half-life of these abused substances contributes to the delayed onset of drug withdrawal (and possibly a greater duration of symptoms). Major symptoms of opiate withdrawal usually continue for 2 to 3 weeks, but subacute signs may persist for 2 to 6 months.^{297–299,307} In mild cases, significant symptoms may subside within a week. The onset of SSRI withdrawal ranges from birth to 3 weeks of life with duration ranging from 2 days to 2 weeks.³⁰² Maternal polydrug abuse, as seen in A.K., may result in biphasic patterns or recurrence of abstinence syndrome.²⁹⁹

A.K.'s presentation is consistent with neonatal narcotic abstinence syndrome. However, clinical manifestations of NAS are similar to other serious neonatal diseases. Disorders such as infection (sepsis, meningitis), metabolic abnormalities (hypoglycemia, hypocalcemia, hypomagnesemia, hypothermia), endocrine dysfunction (adrenal insufficiency, hyperthyroidism), and CNS abnormalities (hemorrhage and anoxia) must be ruled out before specific neonatal abstinence therapy is begun.^{297,307} Failure to recognize and treat these diseases would have dire consequences for A.K. A.K. also may be at risk for hepatitis and sexually transmitted diseases, including the HIV. Therefore, an accurate maternal history or testing also should be performed.

Treatment

52. What initial therapy is recommended for A.K.'s narcotic withdrawal symptoms?

Supportive Care

Because pharmacologic therapy may prolong A.K.'s hospital stay or expose her to unnecessary adverse effects, initial treatment should include nonpharmacologic measures directed at decreasing sensory stimulation. Provision of a quiet, dark, warm environment, gentle handling, and swaddling can be beneficial. Use of a pacifier for non-nutritive, excessive sucking also may help. Hypercaloric formulas (24 cal/oz) should be given as frequent small feedings to supply the additional calories that these infants require (150–250 cal/kg/day).³⁰⁷ Changes in severity of symptoms, vital signs, sleeping and feeding patterns, and weight loss or gain should be monitored.

Successful management of 40% to 50% of symptomatic infants can be accomplished with supportive care alone.²⁹⁷ In addition, most infants who are exposed to cocaine as the primary drug of abuse can be managed successfully without pharmacologic intervention.²⁹⁷ Although most infants exposed to SSRIs require no pharmacologic treatment, some infants may benefit from supportive care measures that are commonly used to treat infants with neonatal opioid withdrawal. However, this intervention has not been evaluated in a controlled trials. Infants who have severe signs of SSRI-related withdrawal/toxicity may require pharmacologic therapy including anticonvulsants, fluid replacement, and respiratory support.³⁰⁶

Monitoring and Indications for Pharmacologic Treatment

An abstinence scoring system (e.g., Finnegan) should be used to more objectively assess symptoms of withdrawal and the need for pharmacologic treatment or dosage adjustment. The abstinence scoring sheet lists common signs and symptoms of neonatal opiate withdrawal. The infant is monitored and a number score that indicates severity is assigned to each observed symptom. A “total score” is calculated for each 2- or 4-hour observation period and is used to initiate, increase, decrease, or discontinue pharmacologic therapy.²⁹⁷ Standardized scoring systems currently are used for all neonates regardless of gestational age; however, studies suggest the need for development of specific scoring systems for preterm newborns.³⁰⁶ In addition, the scoring systems have not been validated for nonopioid drug exposure. Also, a potential for bias and subjectivity may affect the scores and thresholds for treatment. In general, indications for pharmacologic treatment include seizures; excessive weight loss or dehydration owing to diarrhea, vomiting, or poor feeding; severe hyperactivity, irritability, tremors, or tachypnea that interferes with feeding; inability to sleep; and significant hypothermia or hyperthermia.^{296,307} If the Finnegan scoring system is used, pharmacologic treatment is generally initiated when the average of three scores is higher than 7.²⁹⁸

A.K. should be monitored closely and, if her symptoms are not controlled with supportive care, pharmacologic therapy is indicated. Pharmacologic therapy is needed in approximately 30% to 91% of infants with NAS.³⁰⁶ The most common agents used to treat neonatal narcotic or CNS depressant withdrawal are phenobarbital, paregoric (camphorated tincture of opium), diluted tincture of opium, and diazepam. The choice of agent depends on the specific nursery, the predominant symptoms displayed, and the substance of abuse. For example, diazepam is the preferred agent in neonatal withdrawal from maternal benzodiazepine abuse. Doses of these agents should be initiated at lower amounts and titrated upward to a dose that controls withdrawal symptoms but does not produce toxicity. Once A.K. is symptom free for 3 to 5 days, the dose should be decreased gradually by 10% to 20% of the dose every 2 to 3 days with close patient monitoring.²⁹⁸ The goals of pharmacologic therapy are to control the symptoms of withdrawal and wean the patient completely off therapy.

53. A.K.'s laboratory tests were within normal limits and other diseases have been ruled out. Her symptoms have worsened despite supportive care and pharmacologic therapy for NAS is initiated. Phenobarbital was started on day 3 of life with an IV dose of 10 mg Q 12 hours for four doses, followed by 3 mg Q 8 hours. This morning's phenobarbital serum concentration was 27 mcg/mL.

A.K. is less irritable today (day 6 of life) and no longer tachypneic. Her tremors have decreased significantly and she no longer has a high-pitched cry. She continues to have significant diarrhea and is feeding poorly. A.K. has not gained weight in the past 4 days. Evaluate A.K.'s therapy. What are your recommendations?

Phenobarbital

Phenobarbital is the drug of choice for NAS due to non-narcotic (e.g., barbiturate, alcohol) and polydrug abuse^{297,298,305} and because it is a second-line agent for treatment of seizures due to withdrawal. Phenobarbital is effective in approximately 50% of neonates exposed to methadone in utero, but it is effective in approximately 90% of infants exposed to multiple drugs in utero.³⁰⁷ Phenobarbital is especially useful (as demonstrated in A.K.) for controlling symptoms of CNS hyperirritability.²⁹⁷ GI symptoms of withdrawal, however, do not respond well to phenobarbital. A.K. received the proper phenobarbital total loading dose (20 mg/kg) and maintenance therapy (4.5 mg/kg/day). Although generally reserved for more symptomatic patients, a loading dose of phenobarbital may decrease the duration of treatment when phenobarbital is used as a single agent.²⁹⁸ The recommended loading dose is 15 to 20 mg/kg and can be given as a single dose or in divided doses.³⁰⁵ A single IV, IM, or oral loading dose may be given when rapid control of symptoms is desired. However, single loading doses may be associated with CNS and respiratory depression (e.g., sedation, apnea, or an increase in periodic breathing). Maintenance doses range from 2 to 6 mg/kg/day.²⁹⁷ Doses should be adjusted according to symptoms, and serum concentrations should be monitored to avoid toxicity. High dosages of phenobarbital may result in oversedation and impairment of the suck reflex. Other disadvantages of phenobarbital include development of tolerance to the sedative effects, induction of drug metabolism, and oral availability as an elixir containing 14% to 25% alcohol.^{305,307} The therapeutic serum concentration for control of withdrawal symptoms has not been clearly identified; however, 20 to 30 mcg/mL has been suggested.^{299,305} Although A.K.'s serum phenobarbital concentration is within the normal range, she continues to have diarrhea and has not gained weight. Because GI symptoms do not respond well to phenobarbital, an alternative agent (preferably a narcotic) should be selected.

Narcotic Agents

Because paregoric (0.4 mg/mL anhydrous morphine), tincture of opium (10 mg/mL morphine), morphine, and methadone are narcotics, they may have a physiological advantage over non-narcotics in the treatment of neonatal opiate withdrawal syndrome.^{298,299,306} In addition, the constipating side effects of narcotics may be advantageous when diarrhea is part of the withdrawal symptoms. Although any narcotic theoretically could be used, most studies assessing opioid treatment have used paregoric. Paregoric is easy to administer and controls withdrawal symptoms in 90% of infants. In comparative studies, paregoric improved sucking coordination, nutrient ingestion, and weight gain better than diazepam or phenobarbital. Infants treated with paregoric also may have a lower incidence of seizure episodes than those treated with phenobarbital or diazepam. Unfortunately, large doses of paregoric often are needed and the duration of treatment usually is longer than with other agents.^{297,307} In addition to opium alkaloids, paregoric contains unwarranted compounds such as antispasmod-

ics (noscapine, papaverine), camphor (a CNS stimulant that is eliminated slowly), high concentrations of alcohol (44%–46%), anise oil, benzoic acid, and glycerine. Because some of these substances may have adverse effects on the newborn, a 25-fold dilution of tincture of opium with water (final concentration 0.4 mg/mL morphine) now is preferred.³⁰⁷ The dilution of tincture of opium is free of unnecessary ingredients and has a lower alcohol concentration. It is stable for 2 weeks after dilution.³⁰⁵ For term infants, the dose of paregoric (or a 25-fold dilution of tincture of opium) is 0.1 mL/kg or 2 drops/kg (0.04 mg/kg morphine)³⁰⁷ given orally with feedings every 3 to 4 hours until control of withdrawal symptoms. A.K.'s dose may be initiated at 0.2 mL/dose (or 4 drops/dose) and titrated upward as needed by 0.1 mL/kg/dose every 3 to 4 hours until withdrawal symptoms are controlled. Once symptoms are controlled for 3 to 5 days, the dosage can be tapered gradually (keeping the same dosing interval).³⁰⁷ A.K. also should be monitored for signs of overtreatment such as hypotonia, lethargy, irregular respirations, and bradycardia.²⁹⁷

Oral morphine (in concentrations of 2 and 4 mg/mL) may be a preferred agent when treating NAS due to opioid withdrawal. Oral morphine preparations contain less alcohol than paregoric and do not contain unwanted additives. In addition, medication errors may occur during the dilution and dosing of tincture of opium. Parenteral morphine has been used in infants to treat narcotic withdrawal seizures²⁹⁸ and vasomotor collapse secondary to heroin withdrawal.³⁰⁷ Parenteral morphine, however, may contain sodium bisulfite and phenol, substances that have been associated with adverse effects in newborns when given at higher doses.³⁰⁷ Parenteral morphine may be used if A.K. is unable to take oral medications and a narcotic agent is desired. Methadone also may be used, but the prolonged elimination half-life (26 hours) makes tapering the dosage difficult. Initial methadone doses of 0.05 to 0.1 mg/kg given every 6 hours are recommended. Doses may be increased by 0.05 mg/kg/dose until control of withdrawal symptoms. Methadone can be administered every 12 to 24 hours once signs of withdrawal are controlled and can be discontinued once doses are weaned down to 0.05 mg/kg/day.³⁰⁷

Diazepam, Chlorpromazine, and Clonidine

Diazepam (0.3–0.5 mg/kg Q 8 hours) has been used to control the CNS hyperactivity associated with neonatal narcotic withdrawal symptoms.²⁹⁶ However, diazepam may be less effective than paregoric or phenobarbital in treating symptoms of NAS. Adverse effects, which may be related to prolonged elimination and accumulation of diazepam and metabolites, can limit the drug's usefulness (e.g., depression of the suck reflex, sedation, late-onset seizures, and bradycardia).^{298,299} In addition, the parenteral formulation contains substances (benzyl alcohol, sodium benzoate, ethanol, propylene glycol) known to cause problems in the newborn (see Question 49).³⁰⁷

Chlorpromazine (0.5–0.7 mg/kg Q 6 hours) controls the CNS and GI symptoms of neonatal withdrawal.²⁹⁹ Disadvantages of chlorpromazine include a wide spectrum of pharmacologic effects such as cerebellar dysfunction, decreased seizure threshold, prolonged elimination in the neonate (half-life, 3 days), hypothermia, hematologic problems such as eosinophilia, and lack of long-term studies on behavioral outcomes.^{299,307} As a result, chlorpromazine rarely is used to treat NAS.

Clonidine is commonly used in adults to treat narcotic withdrawal symptoms. One pilot study in neonates ($n = 7$) used oral clonidine at an initial single dose of 0.5 to 1 mcg/kg. Doses were then increased slowly over 1 to 2 days to 3 to 5 mcg/kg/day divided every 4 to 6 hours.³⁰⁸ Clonidine controlled most neonatal methadone withdrawal symptoms except for poor sleeping. Hypotension and other cardiac adverse effects did not occur. Transient mild metabolic acidosis, however, was reported in two patients. Mean duration of clonidine treatment (13 days) was shorter than phenobarbital treatment (27 days) in a retrospective comparative group. Further clinical trials are needed before clonidine can be routinely recommended for treatment of NAS.

A.K. should receive long-term follow-up to monitor for potential developmental problems. Because A.K. is at risk for recurrence of drug withdrawal, her parents should receive information on recognition of symptoms. Her parents need instructions on how to care for this drug-exposed infant as well as counseling for drug addiction.

SEDATION AND PARALYSIS DURING VENTILATION

Pharmacology and Monitoring Parameters

54. M.M., a 42-week-gestation (post-term), 3,500-g male, is born with a history of meconium-stained amniotic fluid. At birth, meconium was removed by suction from M.M.'s nose and mouth. M.M. was tachypneic (RR, 80 breaths/minute) and cyanotic and had decreased peripheral perfusion. His Apgar score at 1 minute was 5. M.M. was intubated shortly after delivery and his trachea was suctioned to remove meconium. Immediate ABGs, obtained while M.M. was intubated and ventilated with an Ambu bag at 60 breaths/minute and 100% oxygen, revealed the following: pH, 7.18; P_{CO_2} , 55 mmHg; and PO_2 , 50 mmHg. M.M.'s clinical condition and ABG results (acidosis, increased P_{CO_2} , and hypoxia) were consistent with persistent pulmonary hypertension of the newborn and appropriate tests confirmed the diagnosis. He currently is receiving mechanical ventilation using hyperoxia and hyperventilation to achieve a target P_{CO_2} of 30 mmHg and pH of 7.5. M.M. had been "fighting the ventilator" and pancuronium bromide 0.35 mg IV every 30 to 60 minutes as needed for spontaneous movement was initiated. M.M.'s other medications are ampicillin and gentamicin to rule out sepsis, and dopamine, dobutamine, and sodium bicarbonate for his persistent pulmonary hypertension of the newborn. After evaluating M.M.'s paralysis therapy, what medications should be started immediately for him?

[SI units: P_{CO_2} , 7.33 kPa, 4.0 kPa, respectively; PO_2 , 6.7 kPa]

Neonates with severe lung disease (e.g., RDS, persistent pulmonary hypertension of the newborn, pneumonia) may require mechanical ventilation with high ventilatory settings (high rates or pressures). Ineffective mechanical ventilation results when neonates fight the ventilator (i.e., spontaneously breathe asynchronously or out of phase with mechanical ventilation). Advancements in ventilator technology (e.g., synchronized ventilation or patient-triggered ventilation) may help to decrease asynchronized breathing. However, sedation generally is indicated when high ventilator settings are used or when patients fight the ventilator after ventilator adjustments. Paralysis usually is reserved for cases when sedation alone does

not improve the effectiveness of mechanical ventilation. Typically, paralysis is required in severely ill, hypoxic neonates such as M.M. Paralysis increases chest wall compliance and allows for adequate oxygenation and ventilation.^{309,310} It also decreases oxygen consumption, improves blood gases, and may decrease the risk for pneumothorax.^{309,311} In addition, paralysis of neonates with persistent pulmonary hypertension of the newborn (like M.M.) indirectly decreases right-to-left shunting through the ductus arteriosus and foramen ovale and results in increased oxygenation.³¹²

Pancuronium bromide causes skeletal muscle paralysis by competitively blocking acetylcholine at postsynaptic nicotinic cholinergic receptors located on the muscle fiber (motor endplate) of the neuromuscular junction.^{311,313} At normal clinical doses, pancuronium has minimal ganglionic blocking effects and possesses little histamine-releasing activity.^{311,313} Onset of effect occurs within minutes and duration, which typically lasts 30 to 60 minutes after a single dose, increases with incremental dosing. Like pancuronium, vecuronium is also a nondepolarizing neuromuscular blocking agent commonly used in neonates.⁸ Each agent may offer certain advantages in specific neonatal patients. Pancuronium is primarily eliminated via the kidneys (60%). Thus, without a dosage adjustment, patients with decreased renal function have a prolongation of pancuronium's neuromuscular blocking effect. Vecuronium, however, is excreted primarily via biliary elimination (50%) and, therefore, dosage reduction in hepatic (but not renal) dysfunction is required. Many neonatal centers prefer vecuronium because a dosage adjustment is not needed in patients with renal dysfunction. M.M.'s dose of pancuronium is appropriate. Pancuronium and vecuronium can be dosed at 0.05 to 0.1 mg/kg every 30 to 60 minutes IV as needed for spontaneous movement. Some neonates require a continuous infusion, using doses of either agent of 0.02 to 0.05 mg/kg/hour. Many factors (e.g., serum electrolytes, acid-base balance, concomitant medications) can affect the duration of action of neuromuscular blocking agents and dosage needs to be individualized.⁸

The greatest danger of using any neuromuscular blocking agent is inadvertent disconnection from the ventilator with resultant apnea. When paralytic agents are initiated, adjustments in ventilator settings usually are required to avoid hypoventilation. Clinically important adverse effects include tachycardia and fluid retention with significant edema.^{311,314} Although pancuronium usually does not have a significant effect on BP,³¹⁴ hypertension³¹⁵ and occasional reports of hypotension³¹⁶ (usually in marginally hypovolemic neonates) have been reported. Ventilatory settings, blood gases, spontaneous movements, daily weights, fluid intake and output, HR, and BP should be monitored. If tachycardia becomes serious, another nondepolarizing neuromuscular blocking agent with fewer cardiovascular effects, such as vecuronium, can be used.

Paralysis, as well as intubation and mechanical ventilation, may be extremely stressful to the neonate. Neuromuscular blocking agents do not possess any analgesic, sedative, or amnesic effects.^{311,313} Therefore, sedation therapy should be instituted as soon as possible in M.M. Neonates and even premature newborns have the anatomical structures and physiological capacity to sense pain.^{317,318} Because clinical symptoms of pain may go undetected in paralyzed neonates, a sedative/analgesic such as morphine may be preferred for

sedation. In fact, preliminary data suggest that poor neurologic outcomes may occur less frequently in mechanically ventilated neonates who receive continuous low-dose morphine infusions compared with those who receive infusions of midazolam or placebo.³¹⁹ In addition, administration of analgesics for painful procedures may be easily forgotten when neonates are sedated with nonanalgesics such as phenobarbital, benzodiazepines, or chloral hydrate. Because paralysis masks the clinical symptoms of seizures,³¹¹ M.M. should be monitored carefully for rhythmic fluctuations in HR, BP, ECG, and oxygenation. These rhythmic changes may indicate seizure activity in a paralyzed neonate and, if observed, EEG testing is indicated.³²⁰ The EEG also may be monitored in paralyzed newborns who are at high risk for seizure activity (e.g., asphyxiated neonates). Alternatively, some clinicians advocate routine sedation with phenobarbital (rather than morphine), which also would treat any clinically inapparent seizure activity.

Morphine usually is administered by slow IV push over 1 to 2 minutes at initial doses of 0.05 to 0.1 mg/kg every 2 to 4 hours.³²¹ The dose is then titrated according to clinical symptoms. A continuous morphine infusion may be preferred for patients with persistent pulmonary hypertension or in infants requiring intermittent morphine doses every 2 hours or less. Clinically, a bolus infusion of 0.05 mg/kg can be given, followed by a continuous infusion at an initial dose of 0.02 mg/kg/hour (20 mcg/kg/hour). The infusion should be carefully titrated. Morphine clearance in neonates, especially premature neonates, is greatly reduced but increases with PCA.³²² Adverse effects of morphine include hypotension, decreased GI motility, respiratory depression, tolerance, and physiological dependence with prolonged use. The use of morphine in neonates may be limited by histamine release and the development of hypotension.

Fentanyl, a synthetic opiate with less histamine-releasing activity and fewer cardiovascular effects, may be used as an alternative agent. Fentanyl is 50 to 100 times more potent than morphine, but has a shorter duration of action and therefore usually is administered by continuous IV infusion (0.5–2 mcg/kg/hour).^{8,323} Continuous infusion of fentanyl, however, may be associated with a greater development of tolerance and physical dependence compared with intermittent morphine administration.^{324,325} Continuous fentanyl infusions of 5 and 9 or more days have been associated with a >50% and a 100% chance, respectively, of developing withdrawal symptoms,³²⁶ and withdrawal has been reported after as few as 3 days.³²⁷

At this time, recommendations for M.M. should include the addition of morphine as a sedative agent (initial bolus infusion of 0.18 mg, followed by a continuous infusion starting at 0.07 mg/hr [70 mcg/hour]) and an ocular lubricant to prevent corneal abrasions. Neuromuscular blocking agents prevent blinking, and corneal abrasions may occur. Because tolerance to opiates develops, the morphine dose needs to be increased with continued use. Determination of adequate sedation is difficult in paralyzed infants, but increases in HR and BP or decreases in oxygenation may indicate inadequate sedation. M.M. may also require additional sedation/anxiolytic therapy with benzodiazepines such as lorazepam or midazolam. Diazepam is not a preferred agent for sedation in neonates owing to its long half-life and accumulation of its active metabolite (*N*-desmethyldiazepam).

Drug/Disease Interactions

55. Morphine and an ocular lubricant (as an ophthalmic ointment applied to both eyes Q 6 hours PRN) were added to M.M.'s therapy. On day 2 of life, M.M. continues on mechanical ventilation with hyperoxia and hyperventilation. His ABG is pH, 7.5; PCO₂, 30 mmHg; and PO₂, 55 mmHg. M.M. continues to receive IV ampicillin, gentamicin, dopamine, dobutamine, sodium bicarbonate, and pancuronium. What factors may influence the neuromuscular blocking effect of pancuronium in M.M.? What adjustments to his dosing schedule should be made?

[SI units: PCO₂, 4.0 kPa; PO₂, 7.33 kPa]

Both alkalosis and gentamicin may potentiate the neuromuscular blocking effects of pancuronium in M.M.³¹¹ Although alkalosis may potentiate and acidosis may antagonize the effects of pancuronium, the opposite effects have been reported with vecuronium.³¹¹ Pancuronium already is being dosed in M.M. on an “as-needed” basis. Monitoring for spontaneous movement should continue, and a longer required dosing interval may be noted. If gentamicin then is discontinued or pH is normalized, the duration of effect may shorten. Other factors such as electrolyte status, disease states, and other medications may influence the pharmacodynamics of neuromuscular blocking agents.³¹¹ For instance, renal or hepatic impairment (such as cholestasis) may result in accumulation of drug or active metabolite (3-hydroxypancuronium) and a prolonged effect.

Toxicity

56. Sodium bicarbonate, dobutamine, and dopamine were discontinued on day 3 of life. On day 4 of life, M.M.'s antibiotics were discontinued after culture results ruled out infection. On Friday (day 5 of life), pancuronium was discontinued and M.M. remained intubated. Concerns about morphine “addiction” resulted in the discontinuation of morphine and the initiation of chloral hydrate 250 mg NG Q 4 hours for sedation. On Monday morning, M.M. was noted to have severe lethargy, decreased deep tendon reflexes, and respiratory depression requiring an increase in ventilator settings. Bowel sounds were absent and M.M. had marked abdominal distention. Is M.M. experiencing prolonged paralysis from pancuronium? What is your assessment of this situation?

Administration of opiates for sedation or analgesia does not cause addiction.³²⁸ The term “addiction” should be used only to describe complex behavioral patterns characterized by a preoccupation with obtainment of a drug (drug-seeking behavior) and compulsive drug use. Prolonged administration of opiates may cause tolerance (i.e., a decreased effect after repeated administration of the original dosage or an increasing dosage requirement to attain the original effect) or physical dependence. Physical dependence requires the continued administration of a medication to prevent symptoms of withdrawal. Although symptoms of withdrawal may occur when opiates are discontinued, careful weaning of the opiate and appropriate monitoring of symptoms using an abstinence scoring method lessen withdrawal severity. Opioids may be weaned in <72 hours when low to moderate doses have been used for <1 week. Typically, the dose is decreased by 25% to 50% initially (and by 20% subsequently) every 6 to 8 hours. If opioids are used for >1 week, smaller decreases in doses, a longer

total weaning time, and conversion to an oral agent usually are required.³²⁸ In M.M.'s case, IV morphine could have been continued for sedation or an appropriate oral agent could have been used if normal bowel function was apparent.

Disuse atrophy, muscle weakness, joint contractures, and prolonged paralysis have been reported after discontinuing neuromuscular blocking agents.³¹¹ Prolonged neuromuscular blockade may be more common in patients with renal or hepatic dysfunction or with the use of continuous infusion, prolonged therapy, or certain concomitant medications. In particular, prolonged paralysis may be seen after discontinuation of steroidal based neuromuscular blocking agents (e.g., pancuronium, vecuronium) when these agents have been administered with corticosteroids.³²⁹ In this case, M.M. did not have any apparent renal or hepatic disease, was treated with intermittent "as-needed" doses, received short-term paralysis, and did not receive corticosteroids. Therefore, M.M. would be at a low risk for developing prolonged paralysis after discontinuation of pancuronium.

The most likely cause of M.M.'s current symptoms is chloral hydrate intoxication. The recommended initial dose of chloral hydrate for prolonged sedation in neonates is 10 to 30 mg/kg/dose given every 6 to 8 hours on an as-needed basis.³³⁰ Although some clinicians recommend 20 to 40 mg/kg/dose every 4 to 6 hours as needed (80–240 mg/kg/day),³²¹ toxicity has been reported in a term infant with persistent pulmonary hypertension of the newborn receiving doses of 44 to 50 mg/kg every 6 hours (176–200 mg/kg/day).³³⁰ M.M. received approximately 70 mg/kg/dose every 4 hours around the clock for 3 days.

Chloral hydrate is metabolized quickly in erythrocytes and the liver by alcohol dehydrogenase to trichloroethanol, an active metabolite. Trichloroethanol is metabolized to trichloroacetate and to trichloroethanol glucuronide in the liver and renally eliminated. The conversion of chloral hydrate to trichloroethanol may not be as rapid in neonates,³³¹ and both chloral hydrate and trichloroethanol may be responsible for the sedative effects seen in neonates.³³² The parent drug (chloral hydrate) may be responsible for the immediate short-term sedative effects, whereas trichloroethanol may be responsible for long-term effects. The short duration of sedation (2 hours) necessitates frequent repeated dosing that unfortunately results in accumulation of the active metabolite, trichloroethanol, and toxic effects. The half-life of trichloroethanol is prolonged in preterm (40 hours) and term neonates (28 hours).³³¹ Because trichloroethanol may accumulate, chloral hydrate should be used only on an as-needed basis for long-term sedation in neonates. The lower end of the recommended dosage range should be used for preterm newborns, and all neonates, especially those who require frequent repeated doses, should be monitored for toxic effects.

Toxicities of chloral hydrate include CNS, respiratory, and myocardial depression; gastric irritation; adynamic ileus; cardiac arrhythmias; hypotension; renal impairment; bladder atony; and direct hyperbilirubinemia.³³⁰ Although M.M. is showing signs of CNS depression (lethargy, decreased deep tendon reflexes), respiratory depression (increased ventilator settings), and GI effects (absent bowel sounds, abdominal distention), a physical examination and appropriate laboratory tests should be performed to identify other known toxicities (e.g., serum BUN and SrCr to detect renal impairment). In addition, other causes of M.M.'s current condition also should

be ruled out (e.g., sepsis, meningitis, intracranial hemorrhage, metabolic disorder). Chloral hydrate should be discontinued and trichloroethanol serum concentrations determined, if available. Supportive care should be given and severe toxicities may require exchange transfusions.³³⁰

USE AND ADMINISTRATION OF MEDICATIONS

Drug Formulation Problems

57. What problems are encountered with the use of commercially available medications in the neonate?

The lack of appropriate enteral and parenteral formulations results in many unique problems of drug use and administration in the neonatal population.

Lack of Nonsolid Enteral Dosage Formulations

Many drugs used in neonates and infants are not commercially available in an enteral liquid dosage form, including acetazolamide, captopril, enalapril, rifampin, spironolactone/hydrochlorothiazide, and ursodiol. For some medications, such as sodium chloride, the liquid injectable form can be given enterally. Otherwise, extemporaneous powder formulations or liquid preparations must be made from the solid dosage forms.^{8,333}

Little information exists regarding the preparation and stability of extemporaneous formulations.³³⁴ Formulations intended for neonates should limit the use of pharmaceutical adjuvants, unnecessary ingredients (e.g., flavoring agents for drugs administered via nasogastric tubes), and other substances that would increase osmolality.

Inappropriate Concentrations

Most drugs are formulated for use in the adult population. As a result, the available concentrations of liquid formulations result in appropriate volumes for adult doses, but extremely small volumes for the doses required by neonates. Frequently, these volumes are too small to accurately measure (i.e., <0.1 mL). Therefore, dilutions of commercially available injections (e.g., aminophylline, digoxin, morphine, phenobarbital) are necessary to accurately measure the small doses required by neonates. Proper diluents and dilutional techniques must be ensured because inappropriate dilutions are a common source of potentially fatal medication errors (Table 94-12).^{321,335} In addition, the sterility and stability of these diluted injections need to be documented before being used in neonates.³³⁴

Hypertonicity

In the neonate, parenteral and enteral administration of hypertonic medications may result in severe adverse effects.^{336,337} NEC and IVH have been associated with IV administration of hyperosmolar drugs, such as radiographic contrast media or sodium bicarbonate. Infusions of hypertonic medications directly into the umbilical or portal vein have resulted in severe hepatic injury. In addition, enteral administration of hyperosmolar medications and feedings have been associated with NEC.^{336,337} Therefore, appropriate dilutions of hypertonic medications should be made before administration to neonates.

Pharmaceutical Adjuvants

Ingredients used for the enhancement of bioavailability, stability, taste, or appearance of medications can cause adverse

Table 94-12 Potential Errors in Drug Administration Techniques**Factors Involving Drug (Dose) Preparation**

Inappropriate dilutions
 Similarity in appearance of dose units
 Loss of potentially large amounts of drug dose in the dead space of a syringe or infusion Y site
 Unsuitable drug formulations for administration
 Unlabeled or undesirable ingredients in dosage forms
 Undesirable drug concentrations and/or osmolalities
 Errors in interpreting drug orders and/or dose calculations

Factors Involving IV Drug Administration

Loss of drug consequent to routine changing of IV sets
 Reduction in serum concentrations for drugs with rapid plasma clearance that are infused slowly
 Extreme ↑ in plasma concentrations consequent to rapid infusion of drugs with small central compartment Vd
 Delayed infusion of total dose when IV line is not flushed
 Inadvertent admixture of drugs by the manual IV retrograde method
 Large distance between the site of drug infusion into an IV line and the insertion of the line into the patient
 Potential loss of large-volume doses in the overflow syringe with the IV retrograde technique
 Possible loss of drug because of binding to IV tubing
 Use of large intraluminal diameter tubing for small patients
 Infiltrations not detected by pump alarms
 Infusion of multiple medications/fluids at different rates by means of a common “hub”
 Oscillations in fluid/dose rate of potent medications infused with piston-type pumps

Factors Involving Other Routes of Drug Administration

Loss of delivery (NG tube dead space) or from oral cavity
 Leakage of drug from IM or SC injection site
 Expulsion of drug from the rectum
 Misapplication to external sites (i.e., ophthalmic ointment in young infants)

IM, intramuscular; IV, intravenous; NG, nasogastric; SC, subcutaneous; Vd, volume of distribution.

effects in neonates.³³⁸ Preservatives such as benzyl alcohol or methylparaben may displace bilirubin from albumin-binding sites.²³ Benzyl alcohol also may cause the potentially fatal “gassing syndrome” (see the Neonatal Pharmacokinetics, Metabolism section). Propylene glycol, a solubilizing agent, may cause several toxicities in neonates, including hyperosmolality, lactic acidosis, seizures, CNS and respiratory depression, hypotension, and arrhythmias.³³⁸ Emulsifiers, such as Polysorbate 20 and Polysorbate 80, have been associated with hypotension, renal dysfunction, hepatotoxicity, and death in low-birth-weight infants.³³⁹ Sorbitol, a poorly absorbed sweetener, may cause osmotic diarrhea, intestinal gas, bloating, and abdominal pain when administered enterally in large doses. A report of sorbitol-induced pneumatosis intestinalis in a child underscores the serious consequence of receiving multiple liquid medications containing sorbitol.³⁴⁰ Unfortunately, these unde-

sired substances are currently not required by law to be listed in the package insert of oral medications.³³⁸ The safety of pharmaceutical adjuvants should be examined thoroughly before these substances are used in the neonatal population. In addition, further studies are required to identify other pharmaceutical ingredients that may be potentially toxic to the neonate.

Drug Administration

58. D.S., a 4-day-old female neonate born at 30 weeks' gestational age with a current weight of 1,200 g, has a birth history of prolonged rupture of membranes and a difficult delivery. Her current problems include rule out sepsis and apnea of prematurity. D.S. receives the following: ampicillin, 60 mg IV Buretrol Q 12 hours at 2 am and 2 pm (100 mg/kg/day); gentamicin, 3.6 mg IV Buretrol Q 24 hours at 7 am (3 mg/kg/day); aminophylline, 1.2 mg IV Buretrol Q 12 hours at 10 am and 10 pm (2 mg/kg/day); and dextrose, 5% NaCl 0.2% with KCl 1.8 mEq/day and calcium gluconate 250 mg/day at 6 mL/hr. Gentamicin serum concentrations were obtained today (day 4 of antibiotic therapy) and reported as a trough of 1.2 mcg/mL at 6:50 am and a peak of 2.8 mcg/mL at 8 am. Using standard pharmacokinetic equations you calculate a Kd of 0.037 hr⁻¹, half-life of 18.7 hours, and Vd of 1.8 L/kg. What should be done next for D.S.?

Serum concentrations of aminoglycosides and other drugs can be affected significantly by the IV drug delivery system.^{341,342} The low IV infusion rates required by neonates significantly delay drug delivery, especially if medications are administered via volumetric chamber devices (e.g., Buretrol or Metriset) or via the Y-site injection port distal to the patient. Even when factors such as injection site, infusion rate, drug volume, and tubing diameter are considered, actual drug delivery may be delayed up to 2 hours using volumetric chamber devices.³⁴¹ If aminoglycosides are administered by Y-site injection, peak concentrations can be decreased by a mean of 2.5 mcg/mL and delayed by 1.5 hours compared with IV syringe pump administration.³⁴³ Trough concentrations, however, are not significantly affected. As a result of inappropriate administration methods, a larger Vd and prolonged half-life would be calculated, as demonstrated in D.S.

D.S.'s unbelievably large Vd should lead to suspicion of the method of drug administration. At this time, no dosage change can be recommended for D.S. Serum aminoglycoside concentrations should be repeated after an appropriate IV administration method is instituted. This method should include the use of a neonatal syringe pump, low-volume IV tubing, and drug injection into the port most proximal to the neonate.^{341,342}

Other potential neonatal IV drug administration errors are listed in Table 94-12. Additional problems include significant overdoses resulting from the unintended delivery of residual drug from the hub or needle of syringes (i.e., dead spaces), and underdosages due to trapping of medications in IV filters.^{321,335} In addition, the neonate's limited ability to tolerate excess fluid prohibits drug delivery via IV riders or “piggybacks,” which significantly increase fluid administration. Neonates also require special IV rates of drug infusion (i.e., mg/kg/minute) to avoid significant adverse effects. Appropriate references should be consulted for drug-specific methods and rates of infusion, appropriate final concentrations, and other special neonatal considerations.⁸

PEDIATRIC IMMUNIZATIONS FOR IMMUNOCOMPROMISED PATIENTS 95-12

The use of immunizations to control common childhood infectious diseases has been one of the most important medical developments to date. Children are now routinely immunized against 13 infectious diseases.¹ Immunization rates are at an all-time high in the United States with >80% of children 3 years of age receiving all the recommended vaccines. As a result, cases of diphtheria, tetanus, mumps, measles, rubella, polio, and *Haemophilus influenzae type b* are at record-low levels. Despite the overall high rates of immunization coverage, however, only 9% of infants 24 months of age have received all the vaccines at the recommended ages,² thus putting infants at risk for disease. The need for timely immunization administration is key to preventing disease resurgences.² As the incidence of vaccine-preventable disease continues to decrease, however, parents are becoming less aware of the significance and severity of the diseases that could be prevented. This, along with the parental concerns regarding vaccine safety, may jeopardize the vaccination coverage achievements. Health care providers play a vital role in clarifying misconceptions and educating parents and health care practitioners about the importance of proper and complete immunizations. Any contact with a pediatric patient represents an opportunity to promote immunization. Every medication history should include a complete immunization history, and the child's vaccination card should be used to detect any deficiency in immunization status.^{3,4-6}

GUIDELINES

Schedule for Immunizations

1. K.C., a 2-month-old baby girl, is brought to the clinic for a scheduled well-baby visit. K.C.'s mother inquires about immunizations for her daughter. What are the current recommendations for immunizing pediatric patients? When should these immunizations be given to K.C.?

The goal of pediatric immunization is to prevent specific infectious diseases and their sequelae. For maximal effective-

ness, a vaccine must be administered to the susceptible population before anyone has been exposed to the pathogen. The age at which immunizations are administered to specific individuals depends, however, on several factors (e.g., age-specific risks of the disease, risks of complications, presence of maternal antibodies transferred through the placenta, maturity of the immune system). Usually, immunizations are administered at the youngest age that the child is able to develop an adequate antibody response.

The recommended childhood and adolescent immunization schedules (Fig. 95-1)⁷ are reviewed annually in *Morbidity and Mortality Weekly Reports* by the Centers for Disease Control and Prevention (CDC) and are available on-line through their website. The minimal immunization requirements for entry into public schools and daycare centers, however, vary with each state and the departments of health of individual states need to be consulted for these guidelines.

Immunization schedules can be adjusted to meet individual needs and may begin at any time of the year. Vaccines should not be administered at time intervals shorter than those recommended to allow for maximal immune responses before the administration of subsequent doses.³ A CDC administration schedule for immunizations of children and adolescents who begin their immunizations late or who are >1 month behind schedule in their immunizations, and recommendations for minimal intervals between doses for the administration of various vaccines are depicted in Figure 95-2.⁷ An interruption or delay in the recommended schedule does not interfere with the final immunity gained.

Contraindications

2. K.C. was exposed to a viral upper respiratory tract infection a few days before her scheduled well-baby visit. What immunizations should K.C. receive at this visit, or should her immunizations be delayed?

Recommended Immunization Schedule for Persons Aged 0–6 Years—UNITED STATES • 2007

| Vaccine ▼ | Age ► | Birth | 1 month | 2 months | 4 months | 6 months | 12 months | 15 months | 18 months | 19–23 months | 2–3 years | 4–6 years |
|---|-------|-------|---------|----------------|----------|------------------|--------------------|-----------|----------------|--------------|-------------|-----------|
| Hepatitis B ¹ | | HepB | HepB | see footnote 1 | | | HepB | | | | HepB Series | |
| Rotavirus ² | | | | Rota | Rota | Rota | | | | | | |
| Diphtheria, Tetanus, Pertussis ³ | | | | DTaP | DTaP | DTaP | | | DTaP | | | DTaP |
| Haemophilus influenzae type b ⁴ | | | | Hib | Hib | Hib ⁴ | Hib | | | Hib | | |

| Meningococcal ¹⁰ | | | | | | | | | | | | MPSV4 |

Range of recommended ages

Catch-up immunization

Certain high-risk groups

This schedule indicates the recommended ages for routine administration of currently licensed childhood vaccines, as of December 1, 2006, for children aged 0–6 years. Additional information is available at <http://www.cdc.gov/nip/recs/child-schedule.htm>. Any dose not administered at the recommended age should be administered at any subsequent visit, when indicated and feasible. Additional vaccines may be licensed and recommended during the year. Licensed combination vaccines may be used whenever any components of the combination are indicated and

other components of the vaccine are not contraindicated and if approved by the Food and Drug Administration for that dose of the series. Providers should consult the respective Advisory Committee on Immunization Practices statement for detailed recommendations. Clinically significant adverse events that follow immunization should be reported to the Vaccine Adverse Event Reporting System (VAERS). Guidance about how to obtain and complete a VAERS form is available at <http://www.vaers.hhs.gov> or by telephone, 800-822-7967.

Range of recommended ages

Catch-up immunization

Certain high-risk groups

This schedule indicates the recommended ages for routine administration of currently licensed childhood vaccines, as of December 1, 2006, for children aged 7–18 years. Additional information is available at <http://www.cdc.gov/nip/recs/child-schedule.htm>. Any dose not administered at the recommended age should be administered at any subsequent visit, when indicated and feasible. Additional vaccines may be licensed and recommended during the year. Licensed combination vaccines may be used whenever any components of the combination are indicated and other components

of the vaccine are not contraindicated and if approved by the Food and Drug Administration for that dose of the series. Providers should consult the respective Advisory Committee on Immunization Practices statement for detailed recommendations. Clinically significant adverse events that follow immunization should be reported to the Vaccine Adverse Event Reporting System (VAERS). Guidance about how to obtain and complete a VAERS form is available at <http://www.vaers.hhs.gov> or by telephone, 800-822-7967.

Catch-up Immunization Schedule UNITED STATES • 2007

for Persons Aged 4 Months–18 Years Who Start Late or Who Are More Than 1 Month Behind

The table below provides catch-up schedules and minimum intervals between doses for children whose vaccinations have been delayed. A vaccine series does not need to be restarted, regardless of the time that has elapsed between doses. Use the section appropriate for the child's age.

| CATCH-UP SCHEDULE FOR PERSONS AGED 4 MONTHS–6 YEARS | | | | | |
|---|------------------------|--|--|--|-----------------------|
| Vaccine | Minimum Age for Dose 1 | Minimum Interval Between Doses | | | |
| | | Dose 1 to Dose 2 | Dose 2 to Dose 3 | Dose 3 to Dose 4 | Dose 4 to Dose 5 |
| Hepatitis B ¹ | Birth | 4 weeks | 8 weeks (and 16 weeks after first dose) | | |
| Rotavirus ² | 6 wks | 4 weeks | 4 weeks | | |
| Diphtheria, Tetanus, Pertussis ³ | 6 wks | 4 weeks | 4 weeks | 6 months | 6 months ³ |
| <i>Haemophilus influenzae</i> type b ⁴ | 6 wks | 4 weeks if first dose administered at age <12 months 8 weeks (as final dose) if first dose administered at age 12–14 months No further doses needed if first dose administered at age ≥15 months | 4 weeks ⁴ if current age <12 months 8 weeks (as final dose) ⁴ if current age ≥12 months and second dose administered at age <15 months No further doses needed if previous dose administered at age ≥15 months | 8 weeks (as final dose) This dose only necessary for children aged 12 months–5 years who received 3 doses before age 12 months | |
| Pneumococcal ⁵ | 6 wks | 4 weeks if first dose administered at age <12 months and current age <24 months 8 weeks (as final dose) if first dose administered at age ≥12 months or current age 24–59 months No further doses needed for healthy children if first dose administered at age ≥24 months | 4 weeks if current age <12 months 8 weeks (as final dose) if current age ≥12 months No further doses needed for healthy children if previous dose administered at age ≥24 months | 8 weeks (as final dose) This dose only necessary for children aged 12 months–5 years who received 3 doses before age 12 months | |
| Inactivated Poliovirus ⁶ | 6 wks | 4 weeks | 4 weeks | 4 weeks ⁶ | |
| Measles, Mumps, Rubella ⁷ | 12 mos | 4 weeks | | | |
| Varicella ⁸ | 12 mos | 3 months | | | |
| Hepatitis A ⁹ | 12 mos | 6 months | | | |
| CATCH-UP SCHEDULE FOR PERSONS AGED 7–18 YEARS | | | | | |
| Tetanus, Diphtheria/ Tetanus, Diphtheria, Pertussis ¹⁰ | 7 yrs ¹⁰ | 4 weeks | 8 weeks if first dose administered at age <12 months 6 months if first dose administered at age ≥12 months | 6 months if first dose administered at age <12 months | |
| Human Papillomavirus ¹¹ | 9 yrs | 4 weeks | 12 weeks | | |
| Hepatitis A ⁹ | 12 mos | 6 months | | | |
| Hepatitis B ¹ | Birth | 4 weeks | 8 weeks (and 16 weeks after first dose) | | |
| Inactivated Poliovirus ⁶ | 6 wks | 4 weeks | 4 weeks | 4 weeks ⁶ | |
| Measles, Mumps, Rubella ⁷ | 12 mos | 4 weeks | | | |
| Varicella ⁸ | 12 mos | 4 weeks if first dose administered at age ≥13 years 3 months if first dose administered at age <13 years | | | |

FIGURE 95-2 Catch-Up Immunization Schedule. The reader should refer to the links above or go to www.cdc.gov/mmwr and follow the appropriate links to obtain further information on immunization guidelines which are updated annually and to view the detailed footnotes indicated in these tables.

Misconceptions about contraindications and precautions for immunization often result in missed opportunities to provide needed immunizations. Acute, severe febrile illness; history of anaphylaxis to the vaccine or vaccine components; and history of a severe reaction to an immunization are clear contraindications to immunizations. Immunizations, however, should not be delayed in a child who has a minor illness (e.g., upper respiratory tract infection, otitis media, diarrhea) even in the presence of a low-grade fever. A family history of seizures, allergies, and sudden infant death syndrome are not contraindications for immunizations. Immunization of a child with a history of anaphylaxis to a vaccine or vaccine component should be withheld until the child has undergone desensitization.³ Preterm infants should begin to receive routine immunizations based on their chronological age for all vaccines, although initiation of the hepatitis B series should begin at 1 month of age.⁸

Allergic reaction to previous exposure to vaccine components, immunosuppression (e.g., immunosuppressive therapy, immunodeficiencies), encephalopathy, recent administra-

tion of blood products, and pregnancy (although the risk in pregnancy is largely theoretic) are contraindications to live-attenuated virus or live-bacterial vaccines. Pooled blood products (e.g., immunoglobulins, packed red blood cells, platelet transfusions) can impair the immune response to a live vaccine because these products contain antibodies, which can prevent an infant's immune system from mounting an adequate response. The impairment of an immune response to an immunization varies, depending on the type and amount of blood product administered and immunizations may need to be delayed for up to 12 months if pooled blood products have been administered recently.³ With any question about immune response, antibody titers can be obtained to determine if a patient needs to be reimmunized.³

Because K.C. does not have any contraindications, she can continue her active immunization series at this visit. She should receive her first doses of diphtheria, tetanus, acellular pertussis (DTaP), *H. influenzae type b* (Hib), inactivated polio (IPV), hepatitis B, conjugated pneumococcal, and rotavirus vaccines.

Adverse Effects

3. K.C.'s mother is very concerned about the potential adverse effects of vaccines. How should parents evaluate the balance between the benefits and the risks of immunizations?

Immunizations have had a dramatic impact on several once common childhood infections. For example, smallpox has been eradicated from the world, polio is moving toward global eradication, and invasive *H. influenzae type b* disease among children has declined 95%.⁹ Vaccines, however, have potential side effects that often cause concern for parents.

Adverse reactions to inactivated vaccines include pain at the injection site (also see Question 4) and fever within 48 to 72 hours of administration. In contrast, adverse effects from live-attenuated vaccines occur 7 to 10 days after immunization, after the virus has replicated and the immune system has responded. Adverse reactions to live-attenuated vaccines mimic the symptoms of disease. Transient rash occurs in 5% of patients receiving measles, mumps, rubella (MMR) immunizations, and a mild varicella-like rash (median of five lesions) occurs in fewer than 5% of patients receiving the varicella vaccine. Syncope, usually occurring within 30 minutes of immunization, has been reported.¹⁰ Although anaphylactic reactions to vaccines are rare, an allergic reaction may occur as a result of specific allergy to the vaccine itself or to trace components in the vaccine (e.g., preservatives, antibiotics). Children with egg allergy can receive vaccines produced in chick-embryo-fibroblast tissue culture (e.g., MMR) because the risk for serious reaction to these vaccines in egg-allergic children is very low.^{11–13} MMR should be used cautiously in individuals with a history of a severe reaction to gelatin, which is a stabilizer in the MMR vaccine. Trace amounts of streptomycin, bacitracin, and neomycin are present in oral polio virus vaccine (OPV), IPV, and MMR; therefore, these vaccines should not be administered to individuals with a history of an anaphylactic reaction to these antibiotics.¹⁴

Overall, vaccinations are safe, especially when compared with the risks of the diseases that these vaccines prevent, and the safety of immunizations are scrutinized continually. In response to concerns about vaccine safety, the National Vaccine Injury Compensation Act mandated an ongoing review of evidence regarding the possible adverse effects of vaccines and established a no-fault injury compensation program for selected vaccines.^{9,14,15}

COMMON PARENT CONCERNS

4. K.C.'s mother is very concerned about the pain associated with immunization and the number of injections K.C. is to receive at each office visit. How can the pain associated with immunization injections be minimized? Can immunizations be given together in the same syringe to lessen the number of injections?

The pain associated with injection of immunizations is typically brief and often more upsetting for the parent than the child. The need for multiple injections can result, however, in an unhappy baby, especially by the third or fourth injection. Administration of an oral sucrose solution during the injection may help alleviate pain.^{16,17} Topical anesthetics containing prilocaine and lidocaine can reduce pain and crying associated

with immunization; however, high cost and the time required between application and injection have limited the use of these agents. More importantly, the use of topical anesthetics does not seem to modify the fear of injection or post-immunization discomfort.¹⁸

Ideally, pediatricians and parents would like to be able to deliver all needed vaccines with the fewest number of injections; however, admixing various vaccines in the same syringe is strongly discouraged. Commercially prepared combinations of immunizations (e.g., DTaP with Hib; DTaP with hepatitis B [HepB] and IPV; HepB with Hib) are available to reduce the number of injections and can be used after 6 weeks of age.¹⁹ It is preferred that the same manufacturer of acellular pertussis vaccines be used for the first three doses to ensure adequate immune responses. The recommended number of injections of a specific antigen is acceptable if a commercially available combination vaccine will reduce the number of injections.¹⁹ If combination products are not used, the vaccines should be administered at different sites. If more than one injection must be administered in the same limb, the thigh is the preferred location because of the greater muscle mass.³

5. Some opponents to immunizations have raised the questions of whether immunizations can cause autism or weaken a child's immune system. What is the basis for these concerns?

Some parents are concerned that the MMR vaccine, in particular, might cause autism. Because of a rise in the prevalence of autism and the development of autistic symptoms around the time of vaccination, some suggested that MMR vaccination might cause autism.^{20,21} Multiple epidemiologic studies, however, have shown no correlation between vaccination and the development of autism.^{22–25}

In a National Network for Immunization Information Steering Committee survey, 25% of parents believe that administering “too many” immunizations at one time can weaken a child's immune system.²⁴ While children now receive at least 20 immunizations by 2 years of age, the number of antigens to which they are exposed is far less than children received in the 1980s. Only an estimated 0.1% of the immune system would be affected if 11 immunizations are given simultaneously.²⁴ Current studies do not support the hypothesis that multiple immunizations weaken the immune system.²⁵

HEPATITIS B

6. K.C.'s mother was hepatitis B-surface antigen (HBsAg) negative before delivery, and her baby received Engerix-B shortly after birth. When should K.C. receive her next immunization for hepatitis B?

Hepatitis B virus (HBV) can be transmitted via exposure to contaminated blood (e.g., blood products, on medical instruments, on nonsterilized needles used in intravenous drug abuse or tattooing), exposure to body fluids (e.g., sexual intercourse), and transplacentally from an HBsAg-positive mother. The prevention of HBV maternal transmission to an infant is essential because acute disease can progress to a chronic carrier state, which can lead to chronic liver disease and primary hepatocellular carcinoma. Children acquiring HBV infection before 5 years of age are at an especially high risk of developing chronic infection.²⁶ All pregnant women should be tested for

HBsAg and infants born to HBsAg-positive mothers should receive their first vaccine dose within 12 hours of birth.²⁷ The vaccination of infants born to HBsAg-negative mothers may be delayed only in rare circumstances and in accordance with appropriate documentation. Subsequent vaccine doses should be administered at age 1 to 2 months if the mother is HBsAg negative and again at age 6 months. Hepatitis B immunoglobulin (HBIG) should be administered as soon as possible for infants born to HBsAg-positive mothers. If the mother's HBsAg status is unknown, the infant should be also immunized within 12 hours of birth. Infants born to HBsAg-negative mothers should begin their immunization series before hospital discharge. All unimmunized children should receive HBV vaccine as soon as they are identified.²⁷

Two hepatitis B (HepB) vaccines are currently available for use in the United States. Recombivax-HBTM and Engerix-BTM are yeast-derived recombinant vaccines administered as a three-dose series. Adolescents and adults also should follow a three-dose schedule at 0, 1, and 6 months apart. As an option, adolescents may receive a two-dose schedule of the adult formulation of Recombivax-HB.⁷ Patients on dialysis and other immunocompromised patients may require a fourth dose if the anti-HBs level is <10 mIU/mL 2 months after the third dose.²⁸ Antibody screening following immunization is only recommended in high-risk groups. HBV vaccine is combined with *Haemophilus influenzae* type b vaccine in Comvax. PEDIARIX is a combination of DTaP, hepatitis B, and IPV. Monovalent vaccines are preferred for the initial vaccination; however, combination vaccines can be used to complete the series after 6 weeks of age.^{7,19}

K.C.'s immunization against hepatitis B at birth was appropriate based on current national guidelines, and HBIG was not needed because her mother is HBsAg negative. K.C. can receive her subsequent doses of HBV vaccine according to the schedule in Table 95-1. Either formulation can be used because the immune response from an immunization series using different vaccines is comparable to that of a full series using a single vaccine.^{3,19}

ROTAVIRUS

7. J.M., a 24-year-old mother, presents her 2-month-old infant to receive immunizations. She is concerned about the administration of the RotaTeq vaccine because the infant's grandmother is undergoing chemotherapy for breast cancer and she is concerned that the vaccine may put her mother at risk for infection as well as "bowel problems" for her baby.

Rotavirus is a major cause of gastroenteritis and subsequent dehydration in the United States. Almost all children in the United States will develop rotavirus gastroenteritis within the first 5 years of their lives and up to 50% of hospitalizations secondary to gastroenteritis in children are caused by rotavirus infection.^{29,30} The American Academy of Pediatrics and CDC currently recommend the routine immunization of infants with RotaTeq, a live-attenuated, pentavalent oral vaccine against rotavirus.⁷ This immunization regimen calls for a three-dose series at 2, 4, and 6 months, with the initial vaccination at 6 to 12 weeks of age and repeat doses at 4- to 10-week intervals. Rotavirus immunization should not be initiated for infants >12 weeks of age and should not be administered af-

ter age 32 weeks. Although immunization against rotavirus does not prevent all future episodes of rotavirus infection, it can reduce significantly the severity of infections and reduce hospitalization rates.

Because the rotavirus vaccine is a live-attenuated vaccine and infants can shed the virus for up to 1 week after administration, the immunocompromised person (the grandmother) should avoid contact with the infant's feces and adhere to good handwashing procedures, particularly during the first week after vaccine administration.²⁹ Although an immunized infant can spread the rotavirus to an immunocompromised person, the risk is believed to be small relative to the benefits and risks to the immunocompromised individual. Rotavirus immunization of infants under this circumstance still is strongly encouraged.²⁹ The immunization of infants, who themselves are immunocompromised, is more controversial: rotavirus immunization in this circumstance remains with the medical practitioner to discuss risks and benefits with the infant's parents.

The routine implementation of a rotavirus immunization policy was halted a few months after implementation because of an increased rate of intussusception. Intussusception, a form of bowel obstruction, can occur either spontaneously or after natural rotavirus infections in an infant. In postmarketing studies, an increased incidence of intussusception was noted with the RotaShield vaccine, which was subsequently withdrawn from the market. Studies with the new RotaTeq vaccine did not find an increased risk of intussusception; however, reports of intussusception around the time of immunization have been documented.^{29,30} At present, the number of cases of intussusception in rotavirus-immunized children is not more than is expected to occur naturally; therefore, the CDC continues to support routine immunization.³¹ After rotavirus immunization, infants should be observed for signs and symptoms of intussusception (constipation, diarrhea, bloody stools, abdominal pain).

PERTUSSIS

Pertussis ("whooping cough"), an infectious disease caused by *Bordetella pertussis*, is characterized by a paroxysmal cough with a whooplike, high-pitched inspiratory noise, vomiting, and lymphocytosis. It is a highly communicable infection, which can affect 90% of infants and young children in non-immunized households, and it can be associated with serious sequelae, particularly in young infants. An estimated 0.3% to 14% of patients with pertussis experience encephalopathy, 0.6% to 2% have permanent neurologic damage, and about 0.1 to 4% die.³² This serious childhood infection has been mitigated with the availability of a pertussis vaccine, which commonly is administered in combination with diphtheria and tetanus vaccines (i.e., DTP). The efficacy of the DTP vaccines against pertussis after primary immunization (three doses) is greater than 80%.³³ Protection increases to 90% after the last booster (age 4–6 years) and then decreases over the next 12 years, after which protection is minimal.³⁴

Despite the availability of an effective vaccine and a high rate of vaccine coverage, reports of pertussis continue to rise.³⁵ Decreased immunity in adolescents and adults is believed to contribute to this problem. About 12% of adult patients with a cough lasting >2 weeks have pertussis.³⁶ Although the illness is typically mild in adults and adolescents, they serve as a

source of transmission to unprotected infants. This has led to the development and recommendation of pertussis booster vaccines for adolescents and adults.³⁷

The association of serious adverse events with whole-cell pertussis vaccine generated considerable controversy on whether the risk-to-benefit ratio was sufficient to warrant routine immunization. As a result, vaccines containing whole-cell pertussis have been withdrawn and replaced with acellular pertussis. Despite a much more favorable adverse effect profile, the DTaP vaccine is contraindicated in any child experiencing an anaphylactic reaction or encephalopathy within 7 days of immunization with DTaP when these symptoms cannot be attributed to another cause.³³ In addition, careful consideration of subsequent doses should be given to infants experiencing a temperature of 105°F (not resulting from another cause) or persistent, inconsolable crying lasting >3 hours within 48 hours after the administration of a pertussis-containing vaccine.³³ The pertussis component of the DTaP vaccine should be eliminated (i.e., continue vaccination with DT) in any child experiencing collapse or a hypotonic-hyporesponsive episode. If an evolving neurologic disorder is present, pertussis immunization should be deferred until the neurologic problem has been fully evaluated. Pre-existing, stable neurologic conditions (e.g., well-controlled seizures) are not contraindications because the benefits of pertussis immunization outweigh the risks. A family history of seizures or other central nervous system (CNS) disorder is not a contraindication.

The recommended schedule for DTaP immunization is shown in Figure 95-1. Acetaminophen or ibuprofen should be administered at regular intervals for 24 hours after immunization to minimize the possibility of postvaccination fever and pain associated with the local reaction.

Three DTaP vaccines (Infanrix, Tripedia, and Daptacel) are approved for the primary vaccination series. The combination product of DTaP-HepB-IPV (PEDIARIX) is also approved for the primary vaccination series, whereas the combination vaccine DTaP-HIB (TriHIBit) is approved for the 15- to 18-month vaccination. If possible, the same DTaP product should be used for all five doses because the immunity, safety, and efficacy associated with the interchanging of different DTaP vaccines are unknown.^{3,19} If the product information is unknown or unavailable from prior vaccinations, however, any licensed DTaP vaccine can be used to complete the vaccination series.^{3,10,19} Two pertussis vaccine (Tdap) formulations (BOOSTRIX and ADACEL) have been U.S. Food and Drug Administration (FDA) approved for use as a booster dose for children 11 to 18 years of age. This dose should be given at least 5 years from a previous DTaP or Td dose.³⁷

POLIO

Polio, an infectious disease caused by a highly contagious enterovirus, can strike at any age, but primarily affects children younger than 3 years of age (>50% of cases). The three identified serotypes of poliovirus are transmitted person to person by direct fecal-oral contact or indirect exposure to infectious saliva, feces, or contaminated water. After household exposure, 90% of susceptible contacts become infected. The poliovirus enters through the mouth and then multiplies in the throat and intestines. Once established in the intestines, poliovirus can

enter the bloodstream and invade the CNS. As it multiplies, the virus destroys nerve cells, which cannot be regenerated. As a result, muscles no longer function because of the lack of electrical stimuli from affected nerve cells and paralysis is permanent. The muscles of the legs are affected more often than arm muscles; however, when trunk muscles and muscles of the thorax and abdomen are affected, quadriplegia can be the result. The polio virus also can attack the motor neurons of the brainstem and, thereby, cause difficulty in speaking, swallowing, and breathing.

Immunity to polio can be achieved following natural infection with poliovirus; however, infection by one serotype of the poliovirus does not protect an individual against infection from the other two serotypes. Immunity also can be achieved through immunization, and the development of effective vaccines to prevent paralytic polio was one of the major medical breakthroughs of the 20th century. Since the advent of the trivalent OPV and IPV, the incidence of paralytic poliomyelitis has been reduced dramatically. Inspired by the success of the smallpox initiative, a global poliomyelitis eradication initiative has been inaugurated by the World Health Assembly. As a result of exclusive use of OPV, the Americas, Europe, and the western Pacific regions have been certified free of indigenous wild poliomyelitis. The resurgence of polio, however, can be affected by religious, economic, or political factors (e.g., Africa, Middle East), and the possibility for importation of wild virus still exists unless worldwide eradication is achieved. To prevent a polio epidemic in the United States, high levels of immunization for children during the first year of life are essential.

8. K.C.'s mother is surprised when the nurse brings in a polio injection because her son received an oral form of the vaccine when he was a baby. Why is KC receiving a different form of polio vaccine than her older brother received?

Until recently, the OPV or Sabin vaccine has been the vaccine of choice in the United States. Its advantages include low cost and ease of administration. OPV induces lifelong immunity similar to that observed after natural infection. In addition, OPV provides a high level of gut immunity, thus preventing the carrier state. Finally, the fecal shedding of vaccine virus after Sabin vaccine administration is an effective way to immunize or boost the pre-existing immunity in close contacts.³⁸ Despite these benefits, OPV carries the risk of vaccine-associated paralytic polio (VAPP), especially after the first dose. In the United States, 8 to 10 cases of VAPP occur each year. The current overall rate of paralytic disease is approximately 1 case per 2.4 million doses distributed, or 1 case per 1.4 million doses for immunologically normal children receiving OPV for the first dose.³⁹ The risk of VAPP is greater for immunocompromised patients, especially those with B-lymphocyte disorders (e.g., agammaglobulinemia, hypogammaglobulinemia).⁴⁰

In contrast to OPV, the Salk vaccine (IPV) has not been associated with VAPP or other reactions. Enhanced-potency IPV (IPOL, POLIOVAX), with an improved immunogenic response, has been available in the United States since 1987.⁴¹ IPV provides the same systemic immunity as OPV. IPV also induces some immunity of the gastrointestinal tract mucosa, however, less than OPV.⁴² Intestinal immunity improves when

two doses of OPV follow the first two doses of IPV.⁴³ IPV is administered only by injection, however.

Considerable debate has raged over which immunization, OPV or IPV, should be used in the United States. OPV is necessary for global eradication and should be used in countries endemic for poliovirus. Because of the reduced threat of wild poliovirus, however, the risks associated with OPV have become less acceptable. In 1997, the Advisory Committee on Immunization Practices (ACIP) provided three options for poliovirus vaccination: sequential use of IPV and OPV, OPV alone, and IPV alone.⁴⁴ In 1999, as the global polio initiative progressed and the likelihood of importing wild polio into the United States greatly decreased, the ACIP modified the polio vaccination recommendations to include only an all-IPV schedule. Based on these revised recommendations, all children will receive four doses of IPV (ages 2 months, 4 months, 6 to 18 months, and 4 to 6 years).⁴⁵ Currently, OPV may be used only in special circumstances, such as vaccination to control outbreaks of paralytic polio, unvaccinated children traveling in <4 weeks to areas endemic for polio, and children of parents who reject the number of vaccine injections (these children should receive IPV for the first two doses followed by OPV for doses three and four).⁴⁵ This revised strategy provides protection against poliomyelitis while minimizing the possibility of VAPP among OPV recipients as well as household and community contacts. IPV is the only poliovirus vaccine that should be used in patients with an immunodeficiency disorder, those receiving immunosuppressive chemotherapy, or children living with a person who is known or suspected to have these conditions.

9. A 28-year-old patient is planning extensive travels through the African continent and is concerned about polio because she had not been immunized as a child. What would be a prudent immunization schedule for her if her trip includes travel to a polio-endemic area?

Routine poliovirus vaccination of persons older than 18 years of age is not necessary in the United States because U.S. residents are at minimal risk of exposure. Vaccination, however, should be considered for adults at high risk of polio exposure (e.g., travel to an area endemic for polio, close contact with children who will be receiving OPV, close contact with patients who may be excreting wild polioviruses, work that requires handling poliovirus specimens). IPV is the vaccine of choice because it has not been associated with VAPP and adults have a higher incidence of VAPP than do children. Ideally, nonimmunized persons anticipating exposure should receive two doses of IPV, administered 4 to 8 weeks apart followed by a third dose 6 to 12 months later. If exposure is likely in <8 weeks, two doses of IPV should be administered at least 4 weeks apart.⁴⁵ If this patient's travel must be undertaken on short notice, the patient and physician must weigh the risk of OPV use against the risk of infection abroad. Adults who have completed a primary series of OPV or IPV can receive another dose of OPV or IPV before travel.^{39,45} In domestic outbreaks of polio, OPV is routinely given to adult contacts because the risk of natural disease is much greater than the risk of paralysis from OPV. Pregnancy is not a contraindication to OPV immunization when protection is needed (i.e., during an epidemic).

HAEMOPHILUS INFLUENZAE TYPE b

Haemophilus influenzae type b (Hib) was the most common cause of bacterial meningitis and a leading cause of serious, systemic bacterial diseases in children <5 years of age until an effective vaccine was added to the routine immunization schedule.^{46–48} The mortality rate associated with Hib meningitis was approximately 5%, with neurologic sequelae observed in 25% to 35% of survivors.^{49,50} Epiglottitis, cellulitis, septic arthritis, osteomyelitis, pericarditis, and pneumonia also were commonly caused by *H. influenzae*. Although *H. influenzae* is commonly associated with otitis media and respiratory tract infections, type b strains account for only 5% to 10%.⁵¹

10. K.C. will be attending day care. Which of the available Hib immunizations should be administered to K.C.?

The first Hib polysaccharide vaccine could elicit an adequate immune response in children >2 years of age; however, in children 18 to 23 months of age, the immune response was only partial and a booster dose was required at 24 months of age.^{52,53} The polysaccharide vaccine was replaced by conjugate Hib vaccines to improve the immune response in younger children. It has led to a 95% reduction in the incidence of Hib disease in children <5 years of age.⁹ The four currently available Hib polysaccharide conjugate vaccines (HbCV) are as follows: Hib diphtheria toxoid conjugate vaccine or PRP-D (ProHIBiT), Hib meningococcal protein conjugate vaccine or PRP-OMP (PedvaxHIB), Hib tetanus toxoid conjugate vaccine or PRP-T (ActHIB, OmniHIB), and Hib diphtheria CRM197 protein conjugate vaccine or HbOC (HibTITER).⁹ As with the original polysaccharide vaccine, immunogenicity of the conjugate vaccines are age dependent (i.e., older children have an improved immune response).^{49,54} These four conjugated vaccines have been approved for use in infants, the group at greatest risk for *H. influenzae* infection.^{55,56} The HbCV immunization series requires a priming series followed by a booster dose at 12 to 18 months. PRP-OMP (PedvaxHIB) follows a slightly different priming series schedule compared with the other HbCV; the primary series is administered at 2 and 4 months of age in contrast to the schedule of 2, 4, and 6 months' primary series for the other vaccines. Ideally, the primary series should be completed with the same HbCV; however, data support the interchangeability of the products for the priming and booster doses.⁵⁷ If PRP-OMP (PedvaxHIB) is used in a priming series with another HbCV, the number of doses necessary to complete the series for the other product should be administered.⁵⁷ K.C. could be immunized with any of these four Hib immunizations.

The number of doses of HbCV vaccine needed in older infants and children depends on their age at presentation. Children who begin HbCV at 7 to 11 months of age should receive a primary series of two doses of an HbOC-, PRP-T-, or PRP-OMP-containing vaccine followed by a booster dose at 12 to 18 months of age administered at least 2 months after the previous dose. Children ages 12 to 15 months should receive a primary series of one dose followed by a booster dose 2 months later. If a child reaches 15 months of age without receiving HbCV, only one dose is necessary. HbCV is not indicated in children >5 years of age unless special circumstances place a child at an increased risk of infection.^{55,58} The ACIP suggests

considering immunization of children >5 years of age who have functional asplenia, sickle cell anemia, or human immunodeficiency virus (HIV) infection. Although the combination vaccine TETRAMUNE (DTwP-Hib) is available to reduce the number of injections, it is preferred to utilize an acellular form of pertussis for childhood immunization.

Availability of HbCV for infants and children has dramatically reduced the incidence of invasive Hib infections. K.C. should start her primary series with an HbCV approved for young infants.

VARICELLA VACCINE

11. A working mother of two children has learned of a case of chickenpox at their elementary school. Her children are 7 and 10 years of age, respectively, and have both been previously immunized with the varicella vaccine. Will her children be protected from a breakthrough infection or would additional immunization be indicated?

Varivax, a live attenuated vaccine against varicella-zoster (chickenpox), is the first herpesvirus vaccine to be widely tested in healthy and high-risk children and adults.^{59–61} Chickenpox is a highly contagious, mild childhood disease in healthy children, but it can be severe and even fatal, especially in the immunocompromised patient. Unusual complications (e.g., severe bacterial superinfections, Reye's syndrome, encephalopathies) are worth preventing with an immunization program. Before the vaccine was available, approximately 4 million cases of chickenpox were reported annually, with 4,000 to 9,000 hospitalizations and 100 deaths. Historically, 55% of varicella-related deaths occur in adults, many of whom are infected by exposure to unvaccinated preschool-aged children with typical cases of varicella.⁶² Although most children with chickenpox have a self-limited disease lasting 4 to 5 days, many direct and indirect costs are involved. Direct costs include non-prescription and prescription (e.g., acyclovir) medications used to treat the illness, whereas indirect costs are those associated with missed work to be home to care for an ill child.⁶³

Previously, a single dose of the vaccine was recommended for children 12 months to 12 years of age who lacked a reliable history of varicella infection: two injections 4 to 8 weeks apart were recommended for children >13 years of age.⁶⁴ Although the vaccine was effective in preventing severe cases of chickenpox, the single-dose immunization of children resulted in only 85% efficacy in preventing disease overall.⁶⁵ Despite high vaccine coverage rates, outbreaks of breakthrough varicella continued to occur. As a result, current guidelines recommend a two-dose series for all children.^{7,65} The current immunization schedule recommends administration of the first varicella vaccine dose at 12 to 15 months of age, followed by the second dose at 4 to 6 years of age. For persons 7 to 13 years of age who have not received varicella vaccine, two doses of varicella vaccine should be administered at least 3 months apart. For persons >13 years of age, administer two doses of varicella vaccine at least 4 weeks apart. The varicella vaccine may be given to healthy varicella-susceptible children, such as those described in this case who already have been exposed. Chickenpox can be prevented if varicella vaccine is administered within 3 days of exposure, and might be prevented if administered within 5 days.⁶⁶ If the exposure does not cause infection, the vaccination

will provide protection for future exposures. In this case, this parent's 7- and 10-year-old children should receive a second dose of varicella vaccine, and if administered within 5 days of exposure, it can prevent a break-through infection. If her children also are in need of their second dose of MMR vaccine, the quadrivalent combination vaccine ProQuad (MMRV) containing measles, mumps, rubella, and varicella antigens, can be used because it can be interchanged with the single entity vaccines.⁶⁵

The most common adverse effect associated with varicella vaccine administration is rash. Transmission of the virus from the vaccine has been documented in only 3 of 15 million doses administered, all of which occurred in the presence of a vesicular rash after vaccination.⁶⁴ Salicylates should not be used for 6 weeks after administration of the varicella vaccine because of its association with Reye's syndrome: non-salicylate analgesics can be used.

Although varicella vaccine might not entirely prevent the occurrence of chickenpox in the immunocompromised patient, it can modify the disease. In the National Institutes of Health's Collaborative Varicella Vaccine Study, a seroconversion rate of only 85% was observed after a single dose in adults, compared with 95% in healthy children and 90% in children with leukemia.⁶⁷ Varicella vaccine is generally not recommended in children who have cellular immunodeficiencies, but it can be used in those with impaired humoral immunity.⁶⁴ The vaccine should be avoided in children with symptomatic HIV, but may be considered in asymptomatic or mildly symptomatic patients.⁶⁴ Although the vaccine is not licensed for routine use in children with acute lymphocytic leukemia, immunization is available for patients enrolled in specific research protocols.

12. What is the recommended dosage and role of varicella zoster immune globulin (VZIG) in children who have been exposed to chickenpox?

Prepared from plasma of healthy volunteer donors with high varicella-zoster virus (VZV) titers, VZIG can decrease the incidence of varicella in selected individuals. It is not useful for treatment of varicella or herpes zoster. VZIG, distributed by the American Red Cross, can prevent clinical varicella if administered within 72 to 96 hours of exposure. Direct contact with an infected person or continuous household exposure carries the greatest risk of infection.

Varicella zoster immune globulin is recommended for individuals at high risk for serious complications following exposure to varicella. Those at risk include immunocompromised children or adults (e.g., acquired or congenital immunodeficiency, immunosuppressive therapy, cancer) and premature infants <28 weeks' gestation or <1,000 g at birth. Pregnant women, who have not had chickenpox, are at high risk of severe varicella complications (e.g., disseminated infection, pneumonia, death) and should receive VZIG within 72 hours of exposure to varicella. Neonates born to women with symptoms of varicella within 5 days before, or 2 days after, delivery should receive VZIG regardless of whether the mother received VZIG.

Varicella zoster immune globulin is administered intramuscularly at a dose of 125 U/10 kg of body weight up to a maximum of 625 U. The minimal dose is 125 U, and fractional doses are not recommended. Protection is thought to last approximately 3 weeks. To limit the need for VZIG in the hospital

setting, all susceptible personnel (including health profession students) should be immunized with varicella virus vaccine.⁶⁸

MEASLES/MUMPS/RUBELLA

13. At 15 months, K.C. (Question 1) is scheduled to receive her MMR (a combination vaccine containing live attenuated measles, mumps, and rubella viruses). K.C.'s mother, who has never received MMR, is pregnant with her third child. Should K.C.'s immunization be delayed because of her mother's pregnancy? Should K.C.'s mother be immunized?

Measles, a highly contagious and common disease of childhood historically, often is associated with symptoms, such as high fever, rash, cough, rhinitis, and conjunctivitis. Complications, although uncommon, can include pneumonia and encephalitis. Live-attenuated measles virus vaccine produces a benign infection that is thought to produce lifelong immunity. Despite the availability of the vaccine, measles is responsible for approximately 10% of deaths among children <5 years of age in developing countries. The United States is currently in its third attempt to eliminate measles infection. The most significant decrease in the incidence of measles occurred when U.S. children were required to receive the vaccine before entering school.⁶⁹ During the 1985–1988 epidemic, most measles transmission occurred in areas with 95% immunization rates, thereby, indicating that some children fail to respond adequately to the initial vaccine dose.⁷⁰ In addition, up to 47% of reported cases of measles in the United States result from international importation; the remaining cases result from outbreaks in school-age children who did not receive a second dose of the vaccine.⁷¹

The first dose of the MMR vaccine should be administered in children 12 to 15 months of age, and followed by a second dose of MMR at entrance to grade school (age 4 to 6 years).^{7,72} The combination vaccine MMRV (ProQuad) should be administered when both MMR and varicella vaccinations are required.^{7,72} During an epidemic outbreak, infants can be immunized at 6 to 9 months of age with single-antigen measles, followed by a dose of MMR at 12 months of age, and a dose of MMR at 4 to 6 years of age; older children should receive an additional vaccine dose.^{69,73} Adults should receive a second dose of MMR if they were born between 1963 and 1967, previously vaccinated with killed measles vaccine, are students in postsecondary institutions, work in health care facilities, travel internationally, or were recently exposed to a measles outbreak.⁷⁴ Persons born after 1968 should receive one dose of a measles-containing vaccine.^{75,76}

Mumps immunization remains controversial in childhood because mumps illness in children rarely produces complications. Meningoencephalitis generally is a benign meningitis, and postinfectious encephalitis, a serious complication, is extremely rare (1 of 6,000). Deafness, commonly considered a risk of mumps, occurs rarely (1 of 15,000) and usually is unilateral. Orchitis, another complication, affects adult men. Mumps vaccination at 12 to 15 months of age may not protect male children into their adult years. Although administration of a second dose of MMR at age 4 to 6 years may provide longer protection, current immunization practices are aimed at eliminating the mumps virus from the pool of young children, thereby, minimizing the exposure of nonimmunized adults.^{72,76}

Tuberculin-skin testing, when necessary, should be performed before, simultaneously with, or 6 weeks after administration of mumps vaccine because the vaccine can temporarily suppress the skin reaction to the tuberculin.

Rubella, another historically common childhood infection, often is misdiagnosed because its signs and symptoms (e.g., postauricular and suboccipital lymphadenopathy, arthralgia, transient erythematous rash, low-grade fever) vary widely. The most significant consequences of rubella occur in pregnant women (e.g., abortions, miscarriages, still births, fetal anomalies), especially when rubella infection occurs during the first trimester. Preventing congenital rubella through elimination of the viral pool is the primary objective of rubella immunization programs because about 10% to 20% of women of child-bearing age have not acquired natural immunity.

Live-rubella virus vaccination is recommended for all children at 12 to 15 months of age.⁷² Immunization or rubella antibody titer screening of women at premarital examinations and postpartum also is recommended. Women of childbearing age receiving the rubella vaccine should use contraception for at least 28 days after immunization.⁷⁷ Antibody titers should be measured 3 months after immunization to evaluate antibody response in individuals who have received blood products or immunoglobulin within 8 weeks of immunization because the latter may inhibit antibody stimulation.^{78,79}

Before reformulation of the rubella vaccine in 1979, rubella immunization in women who were unknowingly pregnant, resulted in congenital rubella infection in about 10% of fetuses. The current RA27/3 vaccine has reduced dramatically the risk of fetal infection.^{73,80} Data from the U.S. Rubella Vaccine in Pregnancy Registry and the UK National Congenital Rubella Surveillance Programme found no evidence of congenital rubella syndrome in 680 women who were inadvertently administered rubella vaccine 3 months before or during pregnancy.⁷⁷ Current recommendations are to avoid pregnancy for 28 days following vaccination with a rubella-containing vaccine because of the theoretic risk of contracting disease from the vaccine.⁷⁷

K.C.'s mother should have rubella antibody titers measured. If she does not have natural immunity to rubella, she should receive MMR postpartum. Because the vaccine presents no risk to nonimmunized close contacts, K.C. should receive MMR vaccination at this visit.

TETANUS TOXOID AND RABIES VACCINE

14. A.R., a 9-year-old boy, presents to the emergency department 3 hours after being bitten by a neighbor's dog. He has two deep lacerations and one puncture wound on his right hand. The wounds are cleaned and he is given amoxicillin-clavulanic acid. The neighbor claims that the dog has been vaccinated against rabies but has no proof. The county health department is notified, and the dog is placed in quarantine. A.R.'s immunizations are up to date (verified by card) and his last tetanus shot (DTP) was 4 years ago. Should A.R. receive tetanus immunoglobulin (TIG) or tetanus toxoid (Td)? What is the role of rabies immunoglobulin (RIG) and rabies vaccine in animal bites?

Tetanus (lockjaw) is a highly fatal, noncommunicable disease that is most notably manifested by generalized, board-like muscular rigidity. It results from wounds (including animal

bites) infected by *Clostridium tetani*, an anaerobic, gram-positive rod that exists in nature as an extremely resistant spore. Prophylaxis can be achieved by actively stimulating antibody formation against the toxin by immunization with Td. Passive immunity can be achieved by administering TIG. Because A.R.'s immunizations are up to date and <5 years have elapsed since his last dose of Td, he does not need to receive Td or TIG.^{81,82}

Rabies is an important concern in any patient presenting with an animal bite. Wild animals serve as reservoirs for rabies and may infect domestic animals. All wild animals should be considered rabid until such is proved otherwise. In the United States, domestic dogs and cats have a low incidence of rabies, but must be quarantined for 7 to 10 days and monitored for signs and symptoms of rabies unless proof of vaccination is available.

Infection with rabies virus produces an acute illness with rapid, progressive encephalitis. Once the onset of symptoms occurs, the prognosis is extremely poor; therefore, emphasis is placed on prevention. Following exposure, rabies prophylaxis includes passive immunization with RIG (20 U/kg) as soon as possible and active immunization with rabies vaccine on days 0, 3, 7, 14, and 28.^{83,84} Because the dog that attacked A.R. was a family pet and in good health, A.R. does not need to receive rabies prophylaxis at this time. Postexposure prophylaxis will need to be initiated immediately if the dog develops any sign of rabies.⁸²⁻⁸⁷

PNEUMOCOCCUS

15. The pneumococcal, influenza, and hepatitis A vaccines have been added to the pediatric immunization schedule. What is the role of the pneumococcal and influenza vaccines in children? Should all children receive these vaccines?

Streptococcus pneumoniae (pneumococcus) is responsible for meningitis, pneumonia, and otitis media.⁸⁸ Children <2 years of age and adults >65 years are at highest risk for developing pneumococcal infections. The risk for disseminated pneumococcal infections is increased by some underlying medical conditions (heart failure, chronic obstructive pulmonary diseases), chronic liver disease (e.g., cirrhosis), functional or anatomic asplenia (e.g., sickle cell disease, splenectomy), and acquired or inherited immunosuppressive conditions (e.g., HIV, cancer, immunosuppressive therapy). *S. pneumoniae* is a common pathogen in children with HIV, often presenting as one of the first manifestations of HIV infection.

Two pneumococcal vaccines are available: the original polysaccharide vaccine (Pneumovax) and the conjugate-pneumococcal vaccine (Prevnar). Pneumovax contains 23 purified capsular-polysaccharide antigens of *S. pneumoniae*. Antibody response to the Pneumovax is inconsistent in children <2 years of age, and the antigens included in Pneumovax protect against strains that typically cause adult disease. The conjugate pneumococcal vaccine (Prevnar) improves immunogenicity and efficacy in infants and toddlers. This vaccine protects against the seven strains of pneumococcus that cause 80% of all pneumococcal invasive disease in children <6 years of age. The ACIP recommends giving the conjugate vaccine to all children <24 months of age to prevent invasive pneumococcal disease (e.g., meningitis, pneumonia); and to any child <5 years of age who is at high risk of pneumococcal disease.⁸⁸ The

polysaccharide vaccine is recommended as a supplement to the conjugate vaccine for some high-risk children (e.g., sickle cell anemia).⁸⁸

Immunocompromised patients typically have an unreliable response to vaccines, but because of the potential benefits, the pneumococcal vaccines should be administered. Some studies have found transient elevation of plasma HIV levels after pneumococcal vaccination, although this has not been associated with decreased patient survival.^{89,90} To maintain immunity, revaccination with the 23-valent polysaccharide vaccine is recommended after 3 years in high-risk children <10 years of age and after 5 years in older patients.

HEPATITIS A

Viral hepatitis can be caused by at least six hepatotropic viruses (identified by letters A through G) and can present as either an acute or chronic illness (see Chapter 73, Viral Hepatitis). Typically, the course of hepatitis A includes an incubation phase, an acute hepatitis phase, and a convalescent phase. Symptoms often include fever, malaise, anorexia, nausea, abdominal discomfort, and jaundice. Clinical illness typically lasts 1 to 2 months. More than 70% of older children and adults have symptomatic infection, but just as many children <6 years of age are asymptomatic. Asymptomatic children serve as a source of infection, especially for household or other close contacts.

About one-third of hepatitis A cases occur in children <5 years of age.⁹¹ Among all reported cases, the most common source of infection is household or sexual contact, followed by day care attendance or employment, international travel, and food or waterborne outbreak.

The ACIP had previously (1987-1997) recommended routine vaccination of children 2 years of age and older in communities with an average incidence of >20 cases per 100,000 population.⁹² Rates of disease in these areas has dramatically decreased to at or below rates in areas where vaccination was not recommended; therefore, the ACIP now recommends routine vaccination for all persons >1 year of age.⁹³ Vaccination programs targeting toddlers and young children are important because children are often asymptomatic and unwittingly transmit the virus to adolescents and adults. In addition, data suggest a "herd effect" when vaccination of children is widespread.⁹⁴ A program aimed exclusively at toddlers in an endemic area reduced the prevalence of hepatitis A by >90%, not only in the 2- to 4-year-old vaccine recipients, but in all age groups.

Havrix and Vaqta, two hepatitis A vaccines with adult and pediatric formulations, are indicated for adults and children 1 year of age or older. Two doses are recommended, the second dose should be administered 6 to 18 months after the initial dose, depending on the formulation (see Chapter 73: Viral Hepatitis). The pediatric formulations of each product are indicated for those 1 to 18 years of age and contain half the antigen of adult formulations. Twinrix, a combination hepatitis A and B vaccine, is indicated in individuals >18 years of age on a three-dose schedule.

INFLUENZA

The influenza vaccine is currently recommended for anyone older than 6 months of age who is at increased risk for

complications secondary to influenza. The American Academy of Pediatrics and the CDC also recommend that healthy children 6 to 59 months of age receive the influenza vaccine. This age recommendation was recently expanded from children 6 to 23 months of age because although children <24 months of age have increased hospitalization rates, healthy children from 24 to 59 months of age also experience significant morbidity resulting in increased use of health care resources.⁹⁵ Additional target groups for the influenza vaccine include the following⁹⁶:

- Any household contact or caregiver of high-risk individuals or children <5 year of age
- People 50 or more years of age
- Residents of chronic care facilities
- Adults and children with chronic pulmonary or cardiovascular disorders, diabetes mellitus, renal dysfunction, hemoglobinopathies, or immunosuppression
- Children <18 years of age receiving aspirin therapy (because of an increased risk of Reye's syndrome after influenza)
- Adults and children who have any condition predisposing to respiratory complications, such as aspiration
- Women who will be pregnant during the influenza season
- Household members and care providers in close contact with high-risk patients

Each year, the influenza vaccine includes three inactivated influenza-18 virus strains (usually, two type A and one type B) thought to be circulating in the United States during the upcoming winter. The vaccine is available as both a split- and whole-virus preparation. The split-virus vaccine is used in children <12 years of age to decrease the likelihood of a febrile reaction. Immunocompetent children and young adults typically develop high postvaccination antibody titers. Elderly patients and some people with chronic disorders have lower antibody titers and may remain susceptible to influenza despite vaccination.⁹⁶

Influenza vaccine should be administered annually for adequate protection. Children <9 years of age require two doses of the vaccine administered 1 month apart to achieve adequate antibody response. If these children received influenza vaccination in a previous season, however, only one dose is required. One dose of the vaccine is indicated for individuals >9 years of age. Influenza vaccine contains a small amount of egg protein and historically has been contraindicated in patients with a severe egg allergy. Evidence indicates, however, that even patients with severe egg allergies can safely receive the influenza vaccine.^{97,98}

A live, attenuated trivalent intranasal influenza vaccine (FluMist) is available for use in healthy, nonpregnant patients 5 to 49 years of age. After administration, recipients become infected with attenuated virus strains, which stimulate both local IgA and circulating IgG antibodies.⁹⁹⁻¹⁰² Live vaccine may be especially useful for healthy individuals, including health care workers, during periods when supply of inactivated vaccine may be low, potentially increasing availability of the inactivated product for those unable to receive the live vaccine. Individuals should not receive the live vaccine if any of the following apply⁹⁵:

- Age <5 years
- Moderate to severe illness
- Received another live vaccine within 4 weeks

- Severe allergy to eggs
- Currently taking salicylates
- Known or suspected immunodeficiency
- History of Guillain-Barré syndrome
- Asthma or reactive airway disease or other condition conferring high risk of severe influenza

Although the health and economic benefits of protecting targeted groups of adults from influenza are well documented, the cost-effectiveness of routine immunization for children is not known at this time.

ADOLESCENT IMMUNIZATIONS

Meningococcus

16. J.C. is a 12-year-old girl who presents for a check-up with her pediatrician. In discussion, it is found that her cousin attends a university where an outbreak of meningococcal disease recently occurred. What are current recommendations for children and adolescents regarding administration of meningococcal vaccine?

Until recently, the ACIP has recommended meningococcal vaccination for special populations, such as travelers to endemic areas, those with certain immunodeficiencies (i.e., terminal complement deficiency), those with functional or anatomic asplenia, and laboratory personnel who may come in contact with aerosolized meningococcus.¹⁰³ With the use of the *H. influenzae type b* and pneumococcal conjugate vaccines, however, *Neisseria meningitidis* has become a more prominent cause of bacterial meningitis.

The two available meningococcal vaccines, a polysaccharide preparation and a conjugated vaccine, cover the serotypes A, C, Y, and W-135 of *N. meningitidis*. The polysaccharide preparation (Menomune), or MPS4, is indicated for persons 2 to 10 years of age with the risk factors mentioned above. It is important to note that polysaccharide vaccines such as this only stimulate B-lymphocytes, not T-lymphocytes, and thus do not produce a memory response. As a result, the effectiveness wanes over time. In addition, nasopharyngeal colonization of meningococcus is not reduced, so person-to-person transmission continues, blocking the development of herd immunity.¹⁰³

The conjugate vaccine (Menactra), or MCV4, is indicated for individuals 11 to 55 years of age. ACIP recommends administration of this vaccine to all persons at 11 to 12 years of age (or at high school entry if there is no history of vaccination) and to unvaccinated college freshmen residing in dormitories.¹⁰³

Adverse effects (e.g., fever, headache, chills, malaise, and arthralgias) from both vaccines are similar and relatively rare; however, in October 2006, the CDC and FDA issued a warning regarding the potential for increased risk of Guillain Barré syndrome in patients receiving the conjugate vaccine. Over a 16-month period beginning in June of 2005, 15 cases were reported in the 11- to 19-year age group, and 2 cases in those >20 years of age. All patients recovered. Despite this apparent small increased risk of Guillain Barré syndrome, current recommendations remain the same, but monitoring of this development will continue.¹⁰⁴ At this time, J.C. should receive the MCV4 vaccine.

Human papilloma Virus (HPV)

17. What is the role of the HPV vaccine and who should be targeted for immunization?

The human papilloma virus (HPV), a virus that commonly infects the genital tract, is primarily transmitted by sexual contact. Infection with HPV has been associated with cervical cancer as well as other anogenital cancers, anogenital warts, and recurrent respiratory papillomatosis.^{105,106} Acute infections with HPV typically resolve without clinical complications within 1 year; however, 10% to 15% of infections remain persistent and pose a risk of invasive cervical carcinoma and other anogenital carcinomas.¹⁰⁶ Although not all HPV infections cause cervical cancer, almost all (99%) of cervical cancer in women is associated with a previous HPV infection.^{105,106} Two strains of HPV, HPV 16 and 18, have been associated with 70% to 80% of what are referred to as “high grade” or precancerous cervical lesions^{105,106} and are the targets of the currently marketed HPV vaccine (Gardasil). The vaccine also protects against HPV strains 6 and 11, which have been associated with >90% of all genital warts and 10% of “low grade” or low risk cervical lesions. Infection with one strain of HPV does not prevent infection from other strains; thus, repeated infections can occur through one’s lifetime¹⁰⁶ and those with prior HPV infections benefit from immunization as well.

Routine vaccination with the HPV vaccine is recommended for female patients at 11 to 12 years of age.¹⁰⁵ Vaccination at this age attempts to achieve an immune response before the sexual debut¹⁰⁵ and involves a three-dose series administered at intervals of 0, 2, and 6 months.^{105,107} The vaccine can also be administered from 9 to 26 years of age.¹⁰⁵ Immunization against HPV is 90% effective in reducing persistent HPV infections and 100% effective in preventing HPV-related diseases, such as genital warts or lesions.^{105–107}

The mandatory requirement for immunization against HPV is controversial and debated in many state legislatures because of ethical and social concerns. The CDC and AAP recommend immunization for adolescent females, regardless of current sexual activity, to decrease the lifetime risk of cervical cancer and to protect against infection when the time comes that an individual chooses to become sexual active.

PEDIATRIC IMMUNIZATIONS FOR IMMUNOCOMPROMISED PATIENTS

18. B.R., a 15-month-old boy who is HIV positive, lives with foster parents taking care of two other immunocompromised children. He is taking zidovudine 180 mg/m² PO QID, didanosine 120 mg/m² PO BID, trimethoprim-sulfamethoxazole (TMP-SMX) 75 mg/m² PO BID three times weekly, and intravenous immunoglobulin (IVIG) 400 mg/kg once monthly. His recent CD4 T-lymphocyte counts were 976 g/L (23%). Currently, he is asymptomatic and has not received any immunizations. What immunizations are recommended for immunocompromised children and their close contacts?

tomatic and has not received any immunizations. What immunizations are recommended for immunocompromised children and their close contacts?

Immunocompromised children (e.g., those with acquired or congenital immunodeficiencies, leukemia, lymphoma, generalized malignancies, and those receiving cancer chemotherapy or other immunosuppressive agents) should be immunized with all of the regularly scheduled inactivated vaccines, although an adequate immune response cannot be guaranteed. Previously, vaccination of these children with live-attenuated virus vaccines was deemed to be contraindicated because of possible infection from uncontrolled viral replication; however, the risk of disease often outweighs the risk of vaccination. Patients receiving high-dose corticosteroids (>2 mg/kg/day of prednisone or its equivalent) for >2 weeks; however, should not receive live-attenuated vaccines for at least 3 months after the discontinuation of the corticosteroid.³ In patients infected with HIV, transient increased viremia from immune activation is of concern and has been reported in adults so infected after a booster dose of Td, although the clinical significance is unclear.^{3,108}

The MMR vaccine, a live-virus vaccine, should not be administered to severely immunocompromised patients.^{3,109} Because the risk of developing illness from the vaccine is low, MMR can be administered to patients with HIV who are not severely immunocompromised (as determined by age-appropriate CD4 lymphocyte counts and percentage).^{3,75,110} Response to the vaccine declines as HIV progresses; therefore, susceptible individuals should be vaccinated as soon after diagnosis as possible.⁷⁵ Infants infected with HIV should be vaccinated at 12 months of age with a second dose administered 1 month later rather than waiting to give the booster dose at 5 years of age. Immunization of children who are asymptomatic and mildly symptomatic HIV infected against varicella should be considered⁶⁴; however, varicella vaccine continues to be contraindicated in patients with cellular immunodeficiencies.³

Although B.R.’s ability to mount an antibody response cannot be determined, he should receive all inactivated vaccines as scheduled, including pneumococcal and influenza vaccinations. Because he is asymptomatic and has an adequate CD4 lymphocyte count for his age, varicella and MMR vaccines also should be considered. His monthly administration of IVIG, however, may compromise his ability to respond to the MMR and varicella vaccines.^{75,111} If B.R. is exposed to chickenpox or measles, passive prophylaxis with VZIG and IG, respectively, should be instituted if it has been >3 weeks since his last dose of IVIG. Specific recommendations for immunization of children with varying degrees of immunodeficiency are available from the CDC.^{3,111}

OVERVIEW

Infectious diseases account for the vast majority of annual visits to the pediatrician. Acute febrile illnesses, either viral or bacterial, occur in children on average six to eight times a year. For this reason, the management of pediatric infectious diseases remains a significant component of care.

Several host and microbial factors contribute to the relatively high incidence of infectious diseases in pediatric patients. Deficiencies in both cellular and humoral immunity have been described in the immediate newborn period as well as in the first several years of life. Concentrations of all the immunoglobulins (IgG, IgM, IgD, IgE, and IgA) are diminished at birth, particularly in the premature neonate. Although some IgG is transferred to the newborn from the mother via the placenta, this is generally a short-lived effect that dissipates during the first year of life. Deficits in complement and C-reactive protein (CRP) decrease opsonization, and the phagocytic and intracellular killing functions of neutrophils and macrophages are depressed. The microbial naivety of children also has a significant impact on their ability to fight infection. Potential pathogens are able to colonize and cause clinical infection more readily in newborns and infants because the full complement of normal flora bacteria has not been fully developed. Children begin acquiring their own immunity to organisms by becoming exposed to antigens, developing an immune response, and generating lasting memory immunity cells.

Children are increasingly exposed to potential pathogens at an earlier age, placing them at greater risk of infection. Societal and family reliance upon formal or informal child

care arrangements is more prevalent often exceeding 20 to 30 hours per week of outside care in groupings of children larger than six.⁴ As a result, more children are attending day care and school environments, where they are more likely to come in contact with an infected child or caregiver.¹

The age of the child and the site of infection, implicate different potential pathogens; however, there is significant overlap. *Streptococcus pneumoniae*, *Moraxella catarrhalis*, and *Hemophilus influenzae* are the most common pathogens. Antimicrobial therapy in pediatric patients almost always includes an agent that is active against these organisms, especially when the organism is unknown. Many different viruses cause respiratory infections in children, but these are not cultured clinically because treatments are not readily available.

OTITIS MEDIA

Otitis media, an inflammation of the middle ear, is one of the most common childhood illnesses. Acute otitis often has been treated with an antibiotic, despite controversial evidence in support of the routine use of antibiotics for this condition.² About a decade ago, about half of all prescriptions written for children in the United States were for the treatment of otitis media; however, more recent data from the Centers for the Disease Control and Prevention note a 42% reduction in the number of ambulatory visits and antibiotic prescriptions for acute otitis media (AOM) in children younger than 2 years over a 7-year period.³ These decreases probably can be attributed to increased immunizations with the seven-valent

pneumococcal conjugate vaccine and more appropriate use of antibiotics.

The middle ear is the anatomical location of the hearing apparatus. It is separated from the outer ear canal by the tympanic membrane (eardrum) and drains into the nasopharynx via the Eustachian tubes. The presence of a dull, red, bulging, tympanic membrane that shows no movement during insufflation (application of slight changes in air pressure in the ear canal) on otoscopic examination is diagnostic of AOM. Otitis media peaks between 6 months and 3 years of age and is thought to be most likely due to Eustachian tube obstruction and secondarily to the decreased immunocompetence present in young children. Eustachian tube dysfunction has been associated with upper respiratory tract infections (URIs) and allergies.^{4–6} Some children may have three or four infections per year, whereas others suffer from continuous chronic otitis media for prolonged periods (>3 months). Viruses cause many otitis media infections alone or together with bacteria⁷; however, it is difficult to distinguish viral from bacterial etiology based solely on clinical presentation and otoscopic examination.

Clinical Presentation

1. T.T., a 20-month-old male, is seen in the urgent care clinic with a fever that began about a day and a half ago. He is pulling on his right earlobe, has purulent nasal drainage, and a moderately wet cough. His temperature currently is 101.2°F. He has had a runny nose and cough for 4 days and the daycare center director called to bring this to the attention of T.T.'s mother. He has had several episodes of wheezing over the last 5 months, which now is considered to be asthma by his pediatrician. He now uses a nebulizer (PulmoAide) at home when needed. As a result of this diagnosis, T.T.'s father has discontinued his smoking of cigars in the house. T.T.'s immunizations are up to date. According to his mother, T.T. had experienced one case of otitis media when he was 8 months old, which responded to amoxicillin; another one at 15 months of age after a bout of the flu; and has had two URIs. What is the relationship between T.T.'s URI and a potential bacterial infection? Why should (or should not) he be treated with medications?

The need for restraint in managing URIs with medications in pediatric patients is increasingly advocated, especially because of recent scientific panel evaluations. Although cold symptom control medications (e.g., decongestants, antihistamines) have been widely used, the U.S. Food and Drug Administration (FDA) recommends avoidance of their usage in children younger than 6 years of age because of the potential for significant adverse effects (see Chapter 93). In addition, the treatment of URIs with antimicrobials should be individualized for specific situations and should be prescribed judiciously.

Avoidance of antibiotic management of viral URIs is critical in efforts to limit the clonal expansion and spread of antibacterial-resistant organisms. Parents (or guardians) often have expectations of antibiotic treatments when their child is brought to a clinician for evaluation, and clinicians often presume such expectations.⁸ In videotaped encounters with 38 pediatricians, 64% of parents of children who were experiencing cold symptoms expected an antibiotic to be prescribed. In addition, 22% of the physicians perceived that the child's parents wanted antibiotics, resulting in more than a 32% increase in

the likelihood of inappropriate prescribing. When information about bacterial resistance, antibiotic use, and nonantibiotic alternatives to treatment were offered by the physician, parental demands for antibiotic treatment from the physician were decreased. In contrast, perceived school or daycare pressures for antibiotic therapy increased parental demands for antimicrobial treatment from the physician. Low socioeconomic status of the parents also contributed to a greater likelihood of inappropriate prescribing.⁹

The relationship between antibiotic utilization and subsequent development of microbial resistance is complex; however, this relationship has been supported by large multinational data as well as by data from individual patient cohorts.¹⁰ The temporal onset, and offset, of antibiotic-resistance selection pressure for *S. pneumoniae* and *H. influenzae* have been noted in cohorts of children exposed to β -lactam antibiotics.¹¹ Increases in the mean inhibitory concentrations (MICs) associated with enhancement of resistance mechanisms that are chromosomally mediated, or mediated via mobile-exchange elements (and temporally correlated to antibacterial usage) have been demonstrated for both of these pathogens. Clonal dissemination of resistant organisms is more likely in close contact or overcrowded environments (e.g., daycare centers, homes with multiple siblings). Although the diagnostic distinction between viral and bacterial URI can be difficult, clinicians, nevertheless, need to utilize appropriate diagnostic criteria to minimize the indiscriminate use of antibiotics.

Some success already has been achieved in reducing the burden of antibiotic use in pediatric patients in outpatient and emergency room settings.¹² More specifically, the use of antibiotics for URIs in emergency rooms decreased from 55% in 1993 to 35% in 2004,¹³ and a greater percentage of decrease in antibiotic use was noted in patients who are white, from the southern states in the United States, or who were dwelling in nonurban areas.¹⁴ Ongoing applied vigilance has been advocated and standards have been developed to minimize the misuse of antibiotics for viral URIs. In 2004, the National Committee for Quality Assurance initiated Health Plan Employer Data and Information Set (HEDIS) measures to be used as benchmarks for a variety of chronic and acute disease states, including appropriate testing and treatment of pharyngitis and URIs in children and adolescents. These newly instituted benchmarks are significant because individual states and large health plans use HEDIS measures to optimize diagnosis, treatment, and resource utilization, and as a component of pay-for-performance incentives. The need for HEDIS measures was supported by data that antibiotics were prescribed for 51.2% of office visits for URIs out of 69,936 Pennsylvania Medicaid recipients, and for 44.9% of the 20,213 children younger than 5 years.¹³ Moreover, 77.3% of these patients received the antibiotic on the same day as the index URI. The URI diagnosis of acute bronchitis drove prescribing of antibiotics about threefold more than that for the common cold. Amoxicillin and advanced-generation macrolides were most often prescribed.

The concern for inappropriate use of antibiotics for viral URIs, however, is juxtaposed with the well-recognized relationship between viral infections, either concurrent with, or as a prelude to, bacterial infection. In an evaluation of 709 URI episodes over a 1-year period in 198 children 6 to 35 months of age, 35% of episodes were complicated by AOM. The adjusted

odds ratio of AOM was 1.8, 2.2, and 1.9 for *S. pneumoniae*, *H. influenzae*, and *M. catarrhalis* isolates, respectively, compared with no bacteria isolated at the time of the URI (after controlling for breast-feeding, daycare center attendance, and cigarette smoke exposure).¹⁵ The odds ratio was 2.6 if two or more of these pathogens were found. Similarly, an AOM complication rate of 33% was noted in a longitudinal study that followed a cohort of families through a winter season using weekly pneumatic otoscopy.⁷ In this latter study, intrafamilial transmission of coldlike illnesses was an associated risk factor.⁹

T.T. has had an URI for several days and has a clinical indication of an AOM with new onset of fever and ear pulling. This child's physical examination should be directed toward the proper middle ear examination, and possible initiation of antimicrobial therapy that depends on the nature of the otitis media.

Diagnostic Findings

2. Further examination, including pneumatic otoscopy, reveals bulging and red tympanic membranes in both ears (right greater than left). Upon injecting air, the child cries more intensely; the left tympanic membrane is somewhat mobile, but the right is not. T.T. is sent home with a provisional diagnosis of AOM. Antibiotics were not prescribed, and the patient's parent was instructed to observe the patient for the next 48-hours. What diagnostic findings of otitis media are evident in T.T.?

The diagnostic distinction between AOM and otitis media with effusion (OME) is one of the first steps in the determination of whether antibiotic use is appropriate. The judicious use of antibiotics in children initially was recommended by the American Academy of Pediatrics (AAP) in 1996, with an emphasis on reducing antibiotic use both for the treatment of OME and for the prophylaxis of recurrent otitis. AOM features rapid onset of acute illness (i.e., fever, irritability, otalgia) along with signs of middle ear inflammation and effusion. In contrast, OME features signs of middle ear inflammation and effusion in the absence of acute illness. T.T.'s fever, irritability, otalgia, and red, bulging tympanic membranes (Table 96-1) are consistent with a diagnosis of AOM.

Otosopic findings of middle ear disease use the color, anatomical position and mobility of the tympanic membrane to establish the presence of AOM. Meta-analysis suggests that tympanic membrane findings of distinct redness (likelihood ratio [LR] = 8.4), bulging (LR = 51), and distinctly impaired mobility (LR = 31) are the most important diagnostic indicators of AOM.⁸ In addition, criteria for the otologic diagnosis of AOM utilizing pneumatic otoscopy have been established (Table 96-1). Yet, despite these clinical and otoscopic hallmarks (similar to those reemphasized by the AAP and American Academy of Family Practitioners (AAFP) in their joint 2004 guidelines), the application of these diagnostic criteria in clinical trials has been inconsistent. Only 17 and 20 of 88 studies from 1994 through 2005 utilized all three AAP and Hoberman criteria (i.e., rapid onset, middle ear effusion, erythema, otalgia), respectively.¹⁶ The prime concern is that lack of diagnostic stringency, in combination with a high spontaneous resolution rate, can contribute to the conclusion of a good cure rate, even though a relatively microbiologically ineffec-

Table 96-1 Diagnostic Criteria for Acute Otitis Media¹⁶

American Academy of Pediatrics and the American Academy of Family Practitioners (AP/AAFP) Subcommittee on Management of Acute Otitis Media

A diagnosis of AOM requires a history of recent, usually acute, onset of signs and symptoms of middle ear inflammation and effusion in the presence of either distinct erythema of the tympanic membrane or distinct otalgia (discomfort clearly referable to the ear that results in interference with, or precludes, normal activity or sleep). The presence of middle ear effusion can be present as bulging of the tympanic membrane, limited or absent mobility of the tympanic membrane, air–fluid level behind the tympanic membrane, or otorrhea.

Consensus Recommendations

A diagnosis of otitis media can be established if purulent otorrhea of <24 hours (not otitis externa), or if two of four tympanic membrane abnormalities (i.e., middle ear effusion) are present as: (a) Marked decrease or absent mobility; (b) Yellow/white discoloration; (c) Opacification (other than from scarring); (d) Air–fluid interfaces

WITH

One indicator of inflammation as: (a) New ear pain (\pm unaccustomed ear pulling); (b) Marked tympanic membrane redness; or (c) bulging tympanic membrane

tive antibiotic was used.¹⁷ These factors create difficulty in evaluating and comparing antibiotics within and between therapeutic trials. Despite apparently large numbers of patients, the clinical trials using endpoints without culture evidence often lack sufficient statistical discriminating power. Studies in which tympanocentesis is used to screen patients with bacterial AOM, and trials where tympanocentesis is done on entry and at 3 to 5 days of antibiotic therapy (i.e., double tympanocentesis), require fewer patients to statistically discriminate between superior and inferior antibiotics.

Viral infection of the middle ear can occur in 30% to 40% of cases in the absence of bacteria, and cannot easily be discriminated from bacterial disease. Moreover, the spontaneous resolution rate for AOM is suggested to be high (somewhat organism dependent; lower with pneumococcus). Therefore, a concern for indiscriminant antibiotic prescribing is logical, as the number needed to treat to cure one case of AOM or to prevent complications is high.

Immediate versus Delayed Treatment

3. Why is the recommendation of a short period of observation for T.T. more appropriate (or less appropriate) than the initiation of antibiotics when the diagnosis already has been established?

The wait-and-see or safety-net prescription approach to treatment has been utilized in several respiratory tract infections. The underlying assumption of this strategy is based on the expectation that the likelihood of a spontaneous resolution of an infection is deemed to be highly likely. In these situations, an antibiotic prescription is issued, but the parent is instructed not to fill the prescription unless the respiratory infection persists or worsens over the ensuing 2 to 3 days. This practice has been applied to AOM with favorable acceptance by parents and clinicians, and about two-thirds of the time the prescription has not been filled.¹⁸ This strategy, however, may not be applicable

Table 96-2 Nonqualifiers for Delayed Prescription for Acute Otitis Media

- Symptoms suggestive of AOM for >48 hours.
- Antibiotic therapy within past 7 days for any reason.
- Infant ≤6 months of age.
- Toxic-appearing child.
- Tympanic membrane perforation or impending perforation.
- Tympanostomy tubes.
- Hearing impairment.
- Chronic condition that may impede the child's immunity or ability to clear the infection.
- Another episode of AOM within the past 3 months.
- Coexisting bacterial infection.
- Family unable to access prompt medical follow-up if child deteriorates.
- The child's parent/guardian cannot gain an acceptable understanding of the protocol (according to the parent/guardian or the clinician).

to the majority of patients with otitis media. In a randomized study of 776 children who presented to an emergency room with AOM, 64% of the children were excluded from participating because of clinical or other discretionary reasons. The remaining children included for randomization were older (i.e., 3.2 vs. 2.3 years of age for the exclusions) and predominantly (84%) had unilateral disease, thereby, suggesting milder infection in a less vulnerable age group. The 38% of the wait-and-see group who eventually filled the antibiotic prescription at the parents' discretion had statistically longer periods of pain and fever, requiring more symptom-relieving medications, and experienced more episodes of vomiting.^{18a} Therefore, although the delayed treatment strategy, with caregiver acceptance, can successfully reduce antibiotic use in children with AOM, care must be taken in appropriate patient selection, diagnosis, and follow-up. Criteria for the exclusion of children who could participate in a delayed treatment plan are listed in Table 96-2.

More precision in defining demographic and clinical predictors of patients with AOM who would most benefit from antibiotic therapy is a continuing focus of clinical studies. In recent studies, children younger than 2 years or those with bilateral disease generally experience longer periods of fever and pain, and generally do not experience spontaneous resolution of AOM if antibiotic therapy is delayed or not given. In one study of 824 untreated children with AOM, approximately 70% of children younger than 2 years with bilateral disease, and 60% of those with unilateral disease, would continue to experience ear pain and/or fever for 2 days after diagnosis. In comparison, only 40% of those older than 2 years with unilateral or bilateral disease, in this same study, would have these symptoms still present at 2 days.^{18a} Given that children over than 2 years of age with AOM account for 60% of all visits to an emergency department, and because more than 50% of these patients are prescribed antibiotics,¹⁹ these age-specific criteria and clinical findings help to identify patients who would benefit from prompt antibiotic treatment and those who would benefit from a strategy involving delayed treatment. The successful application of these criteria (i.e., age specificity, clinical findings) can help to reduce inappropriate antibiotic use and decrease the development of microbial resistance to antibiotics.

Laterality (i.e., unilateral or bilateral ear involvement) is an additional variable in the selection of patients to receive prompt treatment, rather than delayed treatment, because patients with

bilateral ear involvement experience more severe disease.^{20,21} Bilateral disease also correlates with younger age²¹ and the presence of *H. influenzae* as the primary pathogen^{20,21}; therefore, the selection of an antibiotic that is effective against this organism would be an important consideration for treating children younger than 2 years, and those with bilateral disease. In addition, otitis-prone children, children enrolled in a daycare facility, and children with more severe signs and symptoms are candidates for early antimicrobial therapy. In T.T.'s case, age, recurrent fever, bilateral middle ear inflammation, and 4 days of URI symptoms preclude watchful waiting, and prompt antibiotic therapy would have been more appropriate.

Risk Factors

4. What are risk factors for the development of AOM in T.T.?

T.T.'s gender puts him at greater risk for the development of otitis because infections of the middle ear occur with greater prevalence in boys.²² His attendance in a daycare facility also is a risk factor because it subjects him to greater risk of viral and bacterial-communicable infections (e.g., AOM), and especially to the acquisition and dissemination of antibiotic-resistant organisms. T.T.'s atopy (asthma), can contribute to altered local immunity, especially in the handling of non-typeable *H. influenzae*. Another risk factor is that T.T., at 15 months of age, experienced a previous episode of AOM after a bout of influenza. The association of the flu with AOM does decrease subsequent to influenza vaccination in infants.²³ T.T.'s father has discontinued his cigar smoking in the house. Nevertheless, passive exposure to cigarettes has been related to increases in URIs, AOM, and OME in children. The use of a pacifier, being fed in a horizontal position or by bottle propping, or being breast-fed for fewer than 6 months are other risk factors for otitis; however, information about these details were not solicited during the taking of the medical history. Anatomical factors such as craniofacial malformation, adenoids, and horizontal Eustachian tube–middle ear disposition (infants and American Indian and Eskimo ethnicities) can increase risk. Winter or early spring season, siblings with URIs, household overcrowding, and exposure to pollutants are additional risk factors for AOM.⁹ Recurrence has also been associated with recent antibiotic use (≤3 months), and this temporal relationship convenes added risk of reinfection or relapse with resistant pathogens. Lack of influenza and conjugate pneumococcal vaccine inoculations can be considered risk factors in light of the reductions of AOM incidence when the vaccinations are provided. In addition to clinical and demographic risk factors, genetic susceptibility via overrepresentation of polymorphisms in genes coding for proinflammatory cytokines (e.g., interleukin [IL]-6, IL-10, and tumor necrosis factor- α)^{24,25} have been associated with an otitis-prone state, and may contribute to lower capsular-antibody response after antipneumococcal vaccination. In summary, T.T. has a number of risk factors for AOM (gender, age, attendance at daycare, asthma, history of AOM).

Pathogens

The majority of cases of AOM are caused by *S. pneumoniae*, *H. influenzae*, and *M. catarrhalis*. Regional, seasonal, and

clinical variances of the pathogen and its resistance pattern are recognized, but a priori determination of the organism without benefit of a tympanocentesis and culture is difficult. A proposed clinical scoring system based on severity of symptoms (temperature, irritability, ear tugging) and otoscopic signs (redness, bulging) can statistically differentiate tympanocentesis-proven bacterial AOM from culture-negative disease.²⁶ This clinical scoring system can associate the benefits of antibiotics in reducing severity scores, but it cannot identify the responsible bacterial pathogen. In a study of 929 tympanocentesis-proven cases of AOM caused by the three major pathogens, a higher percentage of children with high fever correlated with infection by *S. pneumoniae*; however, more than half of the patients did not experience any fever. There was no difference in other signs and symptoms within the three groups, except for the known relationship of the conjunctivitis–otitis syndrome and *H. influenzae*.²⁷

5. T.T. returns to the pediatrician’s office with a temperature of 103°F and severe conjunctival injection. He has continued to pull on his right ear and cries when trying to be put to sleep. What is the likely organism in addressing the empiric treatment T.T. should receive?

The likely organism for T.T. is *H. influenzae* for several reasons. As mentioned, bilateral disease has been associated with *H. influenzae* more than with the other pathogens,^{20,21} and the conjunctivitis is indicative of AOM with *H. influenzae*. Additionally, because T.T. most likely already would have been immunized with all four doses of conjugate pneumococcal vaccine (Prevnar), infection with *H. influenzae* is more likely than with pneumococcus. Since the addition of the conjugate pneumococcal vaccine to the childhood immunization schedule, *H. influenzae* has been more commonly associated with AOM, with 57% of these middle ear isolates expressing β -lactamase.²⁸ Finally, the presence of asthma could loosely reflect the relationship of atopy and OME,²⁹ and that could, in turn, influence the development of persistent and recurrent bacterial AOM. *H. influenzae* was the most isolated pathogen in a large study of patients who underwent tympanostomy tube placement.³⁰ In other patients, recent treatment with amoxicillin could select for early relapse or reinfection with *H. influenzae*.³¹

Although *H. influenzae* is the most likely causative organism, the pathogen could still be pneumococcus, which likely would be amoxicillin resistant. Although the pneumococcal vaccine has reduced the prevalence of *S. pneumoniae*–associated AOM by a third, non–vaccine-susceptible serotypes of pneumococci have been observed to be increased in AOM. Serotype 19A in particular, which is not handled well by the conjugate pneumococcal vaccine, might become more prevalent in AOM, and the inherent penicillin resistance of this serotype can be troubling.³² *M. catarrhalis*, which accounts for 5% to 20% of AOM episodes, is another pathogen that may not have been eradicated by prior treatment with amoxicillin because 90% to 100% of these isolates are β -lactamase producers. Fortunately, high spontaneous resolution rates are associated with *M. catarrhalis* AOM. Group A streptococci are less of a concern in T.T. because of the absence of concomitant sore throat symptoms. Nevertheless, group A streptococci are implicated in 3% to 5% of all AOM cases, and are associated

with older age and a higher risk of mastoiditis.³³ Staphylococci can be the pathogenic organism in recurrent infections, and methicillin-resistant strains have been identified in recurrent and chronic infection, as well as in patients with otorrhea from tympanostomy tubes.³⁴ Additionally, trends toward greater isolation of staphylococcus in the postpneumococcal vaccine era have been associated with the development of mastoiditis and sinusitis.^{35,36}

6. When would tympanocentesis have a role in establishing the microbiologic etiology of T.T.’s AOM?

Tympanocentesis can be useful, but seldom is indicated for first-time or infrequent middle ear infections. In the absence of an organism to be obtained in another way, direct access to the infected body fluid is important, particularly in the face of repeated or relapsing infection. Results from culture and sensitivity testing could be especially useful, for example, when a clinician is faced with the consideration of using an antibiotic such as clindamycin for highly penicillin-resistant pneumococcus (given its absence of coverage for *H. influenzae* and *M. catarrhalis*), or whether a macrolide might be more acceptable. Tympanocentesis would be more urgent in a young infant with otitis, particularly in the presence of concurrent signs of sepsis; other organisms (including enteric gram-negative rods) could be the otitis-producing pathogens. Tympanocentesis can be of benefit not only for diagnostic purposes, but also for the benefits associated with drainage of infected middle-ear fluid.

Treatment

Empiric Antibiotic Selection

7. What empiric antibiotic therapy should be initiated for T.T.? What are some of the selection/dosing issues involved in treatment selection?

As with other infectious diseases, therapy without the benefit of culture and sensitivity tests must be based on clinical and demographic variables that point the clinician toward the most likely pathogen(s). If *H. influenzae* is the organism in T.T.’s case for the reasons enumerated previously, then the choice of a β -lactamase–stable cephalosporin (e.g., cefpodoxime, cefdinir, cefuroxime) or a β -lactam/ β -lactamase inhibitor combination (e.g., amoxicillin-clavulanate) are effective choices. In contrast, the AAP/AAFP empirically recommends high-dose amoxicillin if the patient has no fever and mild pain, and high-dose amoxicillin-clavulanate if high temperature ($\geq 39^\circ\text{C}$) or severe pain is present. Cephalosporins or macrolides are recommended by AAP/AAFP if penicillin hypersensitivity is present (non–type I and type I, respectively). As discussed, fever and pain may not reliably indicate the pathogen, and high fever might be more reflective either of infection with *S. pneumoniae*²⁷ or from a coexisting viral infection. Therefore, more information on the patient’s history of recent antibiotic usage and vaccination, additional clinical/demographic variables, as well as regional and patient-specific expectations for bacterial resistance must be assessed. Although regular or high-dose amoxicillin should be among the first choices for a first-time infection, modifying factors might encourage a broader range of choices if organisms other than *S. pneumoniae* are potentially involved because amoxicillin probably would

Table 96-3 Modifying Factors for Consideration of Alternatives to Amoxicillin in Treating Acute Otitis Media

| | First Infection, No Modifying Factors | Modifying Factors Present (See Table 96-4) |
|--------------------------------|--|---|
| First-line therapy | Amoxicillin (40–45 mg/kg/day) or high-dose amoxicillin (80–90 mg/kg/day) (**dose selection depends on patient experience and regional resistance prevalence) | High-dose amoxicillin (80–90 mg/kg/day); high-dose amoxicillin/clavulanate (80–90/6.4 mg/kg/day), cefuroxime, cefpodoxime, cefdinir |
| Treatment failure at day 3 | High-dose amoxicillin-clavulanate, cefuroxime, cefpodoxime, cefdinir; ceftriaxone IM (if compliance problems or seriously ill) | Ceftriaxone IM, levofloxacin, clindamycin; (tympanocentesis for culture) |
| Treatment failure at day 10–28 | High-dose amoxicillin/clavulanate, cefuroxime, cefpodoxime, cefdinir IM ceftriaxone, levofloxacin | High-dose amoxicillin/clavulanate, cefuroxime, cefpodoxime, cefdinir, IM ceftriaxone, levofloxacin; tympanocentesis for culture |

not be effective against β -lactamase-producing pathogens.³⁷ The recommendations for alternatives to amoxicillin (Tables 96-3, 96-4, and 96-5) are consistent with the modified Centers for the Disease Control and Prevention guidelines for AOM treatment in 1999.³⁸ Ten days of antibiotic treatment is recommended for patients who are younger than 2, otitis prone, or in a daycare facility.

The specific antibiotic choice is affected by multiple variables (e.g., past history of antibiotic use by the patient; past patient history of success with antibiotics and consideration of microbial resistance; previous history of adherence to therapy; interactions of patient with multiple siblings or in a daycare facility). T.T. has previously been treated with antibiotics for two previous episodes of otitis, has been on prophylaxis, and has been successfully treated instead of selection of resistant strains. Although T.T. also had two more recent cases of URI (presuming that they were viral), they are spaced apart sufficiently in time for the label of recurrent or otitis prone not to apply. However, other factors (e.g., bilateral disease, conjunctivitis, conjugate pneumococcal vaccination) in the case suggest that T.T. may have β -lactamase producing pathogens

or penicillin-nonsusceptible *S. pneumoniae* for which alternatives to amoxicillin should be sought.

The dosing regimens for the antibiotic treatment of AOM are based on the doses that have been associated with the most positive outcomes in clinical studies. For example, ceftriaxone has been evaluated in single-dose regimens; however, the three-dose regimen showed greater efficacy in young children with recurrent disease.³⁹ High-dose regimens of amoxicillin and amoxicillin-clavulanate are recommended to enhance efficacy against nonsusceptible strains of *S. pneumoniae*. In another example, once-daily dosing of cefdinir 14 mg/kg/day was associated with 80% middle-ear fluid eradication of pneumococcus and statistically better clinical resolution in children younger than 2 years versus 55% for the twice-daily dosing regimen.⁴⁰ Similarly, twice daily dosing of cefdinir was less effective in a comparison with high-dose amoxicillin-clavulanate in a subgroup of patients younger than 2 years, but equivalent in older patients.⁴¹ A non-FDA-approved dose of cefdinir 25 mg/kg once daily in patients with recurrent AOM eradicated less susceptible middle ear pathogens in North and Central American children. The magnitude of the dose in the presence of bacterial infection might have assisted the penetration of the

Table 96-4 Modifying Factors and Useful Antibiotics

| Modifying Factors | Useful Antibiotics When Modifying Factors Present |
|---|--|
| • Daycare center attendance | Cefpodoxime 10 mg/kg/day PO BID |
| • Recent antibiotic use (within 30–60 days) | Cefdinir 14 mg/kg/day QD |
| • Resistance suspected/documented | Cefuroxime 30 mg/kg/day PO BID |
| • Bilateral disease | Amoxicillin/clavulanate 90/6.4 mg/kg/day PO BID |
| • Conjunctivitis-otitis syndrome | Ceftriaxone 50 mg/kg/dose IM \times 3 days |
| • Recurrent AOM/otitis prone | Levofloxacin 10 mg/kg/day PO BID (not FDA-approved for AOM) ¹⁸⁰ |
| • Past/current amoxicillin failure | Clindamycin 30 mg/kg/day PO TID (lacks activity against <i>H. influenzae</i> and <i>M. catarrhalis</i>) |
| • AOM in patient with chronic OME | |
| • TM perforation/tympanostomy tubes | |
| • Immunosuppression | |
| • Infant <6 months old | |

AOM, acute otitis media; BID, twice a day; IM, intramuscularly; OME, otitis media with effusion; PO, orally; QD, daily; TID, three times a day; TM, tympanic membrane. Adapted from reference 180.

Table 96-5 Drugs With Less Reliability in the Management of Acute Otitis Media

- Cefixime and Ceftibuten: Good for once daily dosing against β -lactamase-producing *H. influenzae* and *M. catarrhalis*, but low activity against nonsusceptible *S. pneumoniae*
- Loracarbef and Cefaclor: Achieves high concentrations in the middle ear, but MICs prohibitively high; substantial failure data, serum sickness-like syndrome.
- Cefprozil: High *H. influenzae* MICs compared to other second- and third-generation cephalosporins.¹⁷⁶
- Trimethoprim-Sulfamethoxazole: BID dosing and inexpensive, but high resistance rates for susceptibility *S. pneumoniae*, *H. influenzae*, GABHS; lacks clinical success in culture-positive AOM.¹⁷⁷
- Azithromycin: Intracellular drug disposition for mostly extracellular bugs, failures in younger children; unacceptably poor eradication of *H. influenzae* and nonsusceptible *S. pneumoniae*¹⁷⁸; may be useful when coexistent atypical pneumonia (clarithromycin likely better for AOM). However, good activity on biofilm-producing organisms in chronic/recurrent otitis.¹⁷⁹

AOM, acute otitis media; BID, twice a day; GABHS, group A β -hemolytic streptococcus; MIC, minimum inhibitory concentration.

β -lactams,⁴² and could have disproportionately increased middle ear fluid levels than lower doses.⁴³ Additionally, middle ear fluid half-lives for β -lactams are more prolonged than serum half-life in pharmacokinetic studies using the of chinchilla model of otitis.⁴⁴

The adverse effect profiles of antibiotics also must be considered in the choice of an antibiotic for treatment of AOM. High-dose amoxicillin-clavulanate has not caused more diarrhea than a more modest dose, but it is associated with more diarrhea than with most cephalosporins.⁴¹ Products containing probiotics (e.g., lactobacillus, saccharomyces) can lessen antibiotic-associated diarrhea.⁴⁵ The pain from ceftriaxone intramuscular injections can be lessened with lidocaine, but large doses might need to be divided and injected into more than one anatomical site in older or larger-sized patients. Clindamycin has not been formally evaluated in the management of AOM, is poor tasting, and has a greater potential for inducing antibiotic-associated diarrhea than other antibiotics. Poor taste also reduces the ease of use of cefuroxime and cefpodoxime in comparison with cefdinir.

Failed Treatment Sequelae

Failed or inadequately treated otitis can result in hearing impairment and subsequent learning difficulties,²² or possibly more serious sequelae (e.g., mastoiditis, labyrinthitis, ossicle sclerosis, sinus thrombosis, meningitis, brain abscess). Mastoiditis can present with postauricular swelling and protrusion of the pinna with redness over the mastoid prominence. Extension of disease results in opacification and coalescence of the mastoid air cells and subperiosteal abscess. *S. pneumoniae*, *S. aureus*, and *P. aeruginosa* are the common pathogens in cases of acute mastoiditis, whereas *P. aeruginosa* is the primary pathogen in cases of chronic mastoiditis (≥ 3 weeks of symptoms).³⁵ Pediatric mastoiditis in the pneumococcal conjugate vaccine era has not changed from the prevaccination period, but ceftriaxone nonsusceptibility significantly increased from 7% to 30% (all but one isolate being highly resistant).³⁵ Although methicillin-resistant *Staphylococcus aureus* (MRSA) was not frequently isolated, vancomycin, clindamycin, or linezolid might be needed to treat some cases of acute mastoiditis. Intravenous antibiotics should be sufficient for treatment of milder cases of acute mastoiditis; however, they might need to be supplemented with tympanostomy tube insertions, abscess drainage, and mastoidectomy for progressively severe mastoiditis.⁴⁶

OME can develop in 40% of the cases of AOM at 1 month after appropriate treatment, 20% by 2 months, and 10% by 3 months. Patients with continued otitis for longer than 3 months are deemed to have chronic OME. A 10-day trial of a β -lactamase-resistant antibiotic and prednisone 1 mg/kg/day can be helpful in the treatment of chronic OME, and might be sufficient to delay or avoid the need for tympanostomy tube insertion.

Preventive Treatment

When three distinct AOM episodes occur within 6 months (or four within 1 year), prophylactic treatment with sulfisoxazole (50 mg/kg/day) might be effective. Influenza vaccine can prevent the development of AOM cases subsequent to an episode of influenza, and oseltamivir treatment of influenza also can reduce secondary AOM.⁴⁷ Adherence to pediatric im-

munization schedules (see Chapter 95) is essential in minimizing the potential of chronic OME and minimizing other risk factors (see Question 4) also can be useful. Oral xylitol solution has had some benefit in trials. If the patient has tympanostomy tubes already inserted and if these tubes appear to have increased purulent drainage, antibiotic eardrops (e.g., ciprofloxacin/hydrocortisone 3 drops BID or ofloxacin 5 drops BID) can be initiated.

PHARYNGITIS AND GROUP A β -HEMOLYTIC STREPTOCOCCAL INFECTION

Standard of Practice

In an effort to limit the overuse of antibiotics within health care organizations, HEDIS measures were developed to assess children 2 to 18 years of age who received an antibiotic prescription for the management of pharyngitis and who also were tested for group A β -hemolytic streptococcus (GABHS). Although the probability of bacterial infection only is about 15% to 36% in children seen as outpatients for a sore throat, the antibacterial prescription rates in the United States varied from 47% to 54% from 1998 to 2003.⁴⁸ Testing to identify a bacterial cause for pharyngitis was performed in 57%, with a higher percentage of testing in private plans as compared to Medicaid plans. These numbers are similar to the 43% antibiotic prescription rate among more than 125,000 pharyngitis visits from five health plans, where 75% of children underwent testing.⁴⁹ The national HEDIS data for 2006 was 70.7% appropriate diagnostic testing and antibiotic prescribing for pharyngitis.

Practice perspective contributes to the misuse of antibiotics for pharyngitis. Of 948 family medicine and pediatric practitioners responding to a survey, 401 (42%) would initiate antibiotics before knowing the results of diagnostic tests and continue them despite negative results. About 27% of practitioners prescribed antibiotics in this manner often or almost always. Family practice physicians were significantly more likely than pediatricians to initiate antibiotics before learning the test results (76% vs. 57%; $p < .01$), less likely than pediatricians to perform in-office throat cultures (13% vs. 32%; $p < .01$), and more likely than pediatricians to admit that parent expectations might have an effect on their decision to provide antimicrobial treatment (90% vs. 58%; $p < .01$). Overall, the stated reasons for prescribing antibiotics were to prevent acute rheumatic fever (95%), prevent local suppurative complications (71%), shorten clinical course (70%), decrease contagiousness (70%), and prevent acute glomerulonephritis (57%).⁵⁰ The incidence of acute rheumatic fever, poststreptococcal glomerulonephritis and other nonsuppurative complications actually have been decreasing in children in the United States, whereas suppurative complications (e.g., retropharyngeal abscess) have increased.^{51,52}

Throat culture is the standard for determining the presence of GABHS pharyngitis, as many other viral and bacterial etiologies exist for pharyngitis. Nevertheless, the rapid-antigen-determination test (RADT) is commonly used within office, urgent care, and emergency room practice in determining the need for antibiotics. These RADT have acceptable although not high sensitivity (70%–90%).^{53,54} However, 6.8% (range, 3.5%–9.8%) of patients with negative RADT have a positive

throat culture for GABHS; therefore, culture confirmation has been advocated.⁵⁴

Testing and Initial Treatment

8. M.G., a 14-year-old female, comes to the urgent care center complaining of fatigue, a sore throat, and tender cervical adenopathy for the past 2 days. She reports that she had been studying with two classmates who had complained of similar symptoms. On physical examination, her temperature is 101°F and her other vital signs are normal. Her pharynx is beefy red, with petechiae on the palate and pus on the tonsils. She denies sexual activity or tampon use. She has been self-administering ibuprofen every 6 hours for pain relief for the past 2 days. What testing should be undertaken for this patient?

This sore throat case scenario describing M.G. is often met with an unnecessary antibiotic prescription. She could be treated with antibiotics justifiably in the following four situations: (a) Initiate an antibiotic if the RADT is positive. If the RADT is negative, obtain a throat culture and start antibiotics, but discontinue the antibiotic if the culture is negative. (b) As in the first situation, initiate an antibiotic if the RADT is positive. If the RADT is negative, obtain a throat culture and, unlike the first situation, start antibiotics only if culture is positive. (c) Initiate an antibiotic without undertaking a RADT, but obtain a throat culture and discontinue the antibiotic if the culture result is negative. (d) Initiate an antibiotic only if a throat culture is positive. Although these guidelines are well-supported in the literature, only two-thirds of physician respondents agreed with these management options; 36% of family practitioners would start and continue antibiotics either without testing or regardless of the test results.⁵⁰ Appropriate clinical and diagnostic assessment is crucial to appropriate antibiotic use in pharyngitis.

Adolescents, who had recent close physical contact with individuals with pharyngitis, also should be tested with a monospot for infectious mononucleosis (an Epstein-Barr virus infection) because the latter can present with similar symptoms (fever, exudative pharyngitis, lymphadenopathy). A culture for *N. gonorrhoeae* also might be considered for M.G.; however, it would be unnecessary because other hallmarks of gonococcal disease (e.g., tenosynovitis, vulvovaginitis, sexual history) are absent.

9. On the assumption that M.G. had been tested appropriately and an antibiotic should be initiated, what would be a reasonable treatment initiative?

Because GABHS resistance to penicillin is minimal, a 10-day course of penicillin or ampicillin is the option of choice. A 5-day course of therapy with a β -lactamase stable cephalosporin is equally effective, possibly superior, and supported by studies and meta-analyses.⁵⁵ M.G. does not have a history of a penicillin allergy; however, patients with a non-type 1 penicillin allergy can be treated with a cephalosporin (e.g., cephalexin). A macrolide should be prescribed if a type 1 allergy exists. The dosing regimen for azithromycin in children with streptococcal pharyngitis is different than for other indications. The azithromycin should be dosed at 12 mg/kg PO once daily for 5 days for a total course of 60 mg/kg, based on

a meta-analysis that supports the superiority of this regimen over a 3-day course of 10 mg/kg/day.⁵⁶

Recurrent and Systemic Group A β -Hemolytic Streptococcus Infection

10. M.G. completes a 10-day course of ampicillin after testing positive for GABHS, and returns to her usual state of good health for several weeks. About 4 days ago, she again developed a sore throat, fever, nonproductive cough, and rhinorrhea. Two days ago, she felt dizzy when she walked, and her symptoms worsened the next day. She developed left upper quadrant, sharp abdominal and epigastric pain, especially prominent at the lower left costal margin, which she rated as an 8 (on a 10-point scale) and worse with inspiration and movement. Her temperature is 103.8°F, and she is unable to swallow liquids. She has no neck stiffness, headache, or dysuria, but feels dizzy. On presentation to the pediatric ED, she had a heart rate of 124 beats/minute; blood pressure of 90/50 mm Hg, and respiratory rate of 38 breaths/minute. Her O₂ saturation was 93%. Her breath excursions are asymmetric and she splints her inspirations on the left. On auscultation, she has egophony at the left lower base, and occasional crackles on the right. She has a sandpaperlike rash on her anterior neck, chest, and arms, but no areas of cellulitis or abscess. Her white blood cell (WBC) count is 4,700/mm³ with 88% polymorphonuclear neutrophilic leukocytes, and >50% band forms. Her CRP is 32.5 mg/dL, blood urea nitrogen is 14 mg/dL, creatinine 0.8 mg/dL. Her antistreptolysin-O titer is mildly elevated. Coagulation parameters were within normal limits, except for a slightly elevated fibrinogen level. Her weight is 49.5 kg. She had a lactate level of 4.5 mmol/L. She received normal saline boluses of 20 mL/kg \times 3, and her blood pressure increased to 110/66 mm Hg, and her heart rate decreased to 96 beats/minute. Treatment with pressor drugs were not begun. Her urine is nitrite and leukocyte negative, blood culture is pending. Her chest x-ray (anteroposterior and lateral view) shows a left lower lobe consolidation and a large pleural effusion. Her brother had strep throat after M.G. finished her initial treatment. The throat culture is positive for a pathogen. Why could this be a recurrence of GABHS infection?

M.G. presents now with a clinical picture consistent with toxic shock syndrome. Although many organisms can cause systemic inflammatory response syndrome, which then can progress to septic shock, the slow onset of M.G.'s symptoms is more suggestive of infection with a gram-positive organism. The nonpetechial rash and presence of a pleural effusion make meningococcus less likely. The elevated antistreptolysin O titer is suggestive of recent infection and will peak in another 2 to 3 weeks.⁵¹ The high CRP level supports the presence of an encapsulated organism and potential for producing a superantigen response. The superantigens activate large populations of T cells without the typical antigen presentation through histocompatibility complex molecules. This leads to a massive overproduction of proinflammatory cytokines (e.g., tumor necrosis factor, IL-6) producing the systemic inflammatory response syndrome (vasodilatation, capillary leak, and hypoperfusion).⁵⁷ The hemodynamic abnormalities and lactate level in M.G. also is compatible with systemic inflammatory response syndrome. Although no history is provided regarding a recent varicella infection in M.G., varicella is a recognized risk for invasive GABHS infection. A relationship between nonsteroidal

anti-inflammatory use and invasive GABHS infection has some weak epidemiologic support⁵⁷; however, support is somewhat stronger for non-necrotizing invasive disease in patients taking ibuprofen combined with acetaminophen.^{57–59}

Pneumococcus is certainly a consideration for M.G., particularly given the greater number of cases of empyema in children despite the routine use of 7-valent conjugate-pneumococcal vaccine, which does not protect against serotypes 1, 3, and 19A. The likelihood of bacteremia and dissemination with this organism shortly after a full course of ampicillin is unlikely, but infection with a penicillin-resistant strain of *S. pneumoniae* is a possibility.⁶⁰ Staphylococcal toxic shock is possible, but absence of tampon use, influenza, recent surgery, and premorbid cutaneous lesions or burns reduce the likelihood of infection with this pathogen. More common in children is streptococcal toxic shock syndrome (STSS) and invasive GABHS infection, which can be associated with necrotizing fasciitis, myositis, and septic arthritis, but mostly with infections of sterile sites, including the lung and pleural space. The described rash is very consistent with STSS and production of pyrogenic exotoxins from M1 and M3 strains of GABHS,⁶¹ as is the presence of a large pleural effusion. These strains are also common in asymptomatic carriers of *Streptococcus pyogenes*. Genetically low levels of protective antibodies to the M proteins and family of superantigens places the patient at risk for STSS, and a variety of other invasive disease manifestation (including the more benign scarlet fever).⁶¹ M.G.'s low WBC and profound left shift indicate peripheral consumption of neutrophils, most likely from chemotaxis, sequestration, and destruction within the pleural empyema.

11. What additional empiric treatment should be initiated in M.G.?

Ampicillin can eradicate *S. pyogenes* pharyngitis, but failures do occur on a number of pharmacologic grounds. The carrier state and spread from close contacts may cause for repeated cases. Importantly, other pathogens and commensals in the nasopharynx have a protective/enhancing effect on local GABHS, and ampicillin/penicillin may select for these. Among 548 cases of GABHS tonsillopharyngitis, β -lactamase producing organisms (e.g., *H. influenzae*, *M. catarrhalis*, *S. aureus*) were cocultured in 39%, 22%, and 17% cases, respectively. These pathogens, therefore, can inactivate the penicillins in situ and cause clinical failures. This is reflected in the widening efficacy differences observed between cephalosporins and penicillin over a 30-year period,⁶² and in the greater number of symptomatic relapses seen in patients treated for GABHS pharyngitis with penicillin and amoxicillin compared with treatment with β -lactamase stable cephalosporins and amoxicillin-clavulanate.⁶³ Additionally, under the concept of bacterial interference, penicillins eradicate commensal α -hemolytic streptococci, which are natural competitors of GABHS occupancy in the mucosa; cephalosporins spare this organism. This contributes to increased GABHS carriage in patients treated with penicillin. Differences in cultures of protective α -hemolytic streptococcus, β -lactamase producing penicillin-inactivating copathogens and GABHS from tissue obtained at the time of tonsillectomy in patients pretreated with cefdinir or penicillin have been demonstrated.⁶⁴ Cephalosporins have also been more effective in prophylaxis

of intrafamilial transmission of GABHS.⁶⁵ Therefore, oral cefuroxime or cefdinir should be considered if relapse or past failure to eradicate occurs (particularly if copathogens are isolated), or if a higher rate of microbiologic failures and clinical relapses are recognized within a family or local community.⁶⁶

Beside the fluid boluses for hemodynamic support for M.G., with the necessary monitoring for response for further intervention, antibiotic management must be promptly begun. With concerns for pneumococcus, staphylococcus, and GABHS infection, cell wall active agents and protein synthesis agents are needed. Although penicillins, cephalosporins, and vancomycin can be used depending on the risk assessed for penicillin-resistant *S. pneumoniae* and MRSA, use of protein-synthesis inhibitors is critical for the treatment of invasive GABHS infection. Clindamycin, a ribosome-bound agent, can decrease exotoxin, superantigen, and cytokine production, and, thereby, the clinical effects of toxic shock syndrome, while eliminating this pathogen. Clindamycin added to a β -lactam enhances the clinical outcome of invasive *S. pyogenes*.⁶⁷ Therefore, IV clindamycin (40 mg/kg/day divided into three to four doses) should be added to empiric coverage with a cephalosporin effective against GABHS, nonsusceptible *S. pneumoniae*, and β -lactamase-producing pathogens (e.g., cefotaxime at 200 mg/kg/day divided into four doses). Clindamycin will additionally cover community-acquired MRSA if this pathogen is considered as an etiology for the pleural effusion, and cover cephalosporin-resistant *S. pneumoniae*. Vancomycin (40–60 mg/kg/day divided into three to four doses) alternatively can be used to cover MRSA, resistant pneumococcus, and GABHS. Vancomycin, however, is a cell wall active agent and will not confer protection against GABHS toxin production, and may act like a β -lactam in disseminating preformed toxin. Intravenous immunoglobulin is often added to bind circulating exotoxin and superantigens, and has improved clinical outcomes,⁵⁷ although different brands have varying efficacy in these neutralizing properties.⁶⁸

Pleural Empyema

12. Three days after admission to the pediatric intensive care unit, M.G.'s throat culture grew *S. pyogenes*. Vancomycin, clindamycin, and cefotaxime were started upon her admission to the pediatric intensive care unit. The rash is fading, but pleuritic chest pain remains, and the patient is placed on patient-controlled analgesia with morphine. The lactate level is now normal, but the CRP is still 30.5 mg/dL. Thoracentesis of the pleural effusion yields 300 mL of exudate, which shows gram-positive cocci, but the culture is negative. The fluid reaccumulated after 24 hours, but the patient is breathing more comfortably, and she is weaned to room air with O₂ saturation remaining above 95%. Her CRP is still 27 the next day, and her temperature remains at 101.8°F. What further interventions in M.G.'s care should be implemented?

The throat culture, the pleural fluid Gram stain, and clinical course denote the most likely pathologic entity is STSS, with recurrence of GABHS from an earlier pharyngitis or familial reacquisition. The vancomycin can be discontinued, but treatment should continue with both the clindamycin and the cefotaxime. The sustained CRP elevation is concerning, and the reaccumulated pleural fluid remains a pyrogenic source, although the pleural fluid culture being negative in the face of

a positive Gram's stain may represent dead organisms. Pleural fluid often reaccumulates after thoracentesis.⁶⁹ Ultrasound or computed tomography can help to determine whether the loculated areas of pus exist that must be drained. Thick pleural fluid and loculation in the presence of unremitting fever, pain, and respiratory difficulty may require surgical decortication of the pleura.⁶⁹ More conservative management can be attempted with placement of a chest tube, with injection into the pleural space of tissue plasminogen activator (2 mg in 20 mL normal saline) if drainage is inadequate. Antibacterials should be continued for 2 to 4 weeks depending on M.G.'s clinical progress and whether surgical intervention is employed. Management with early decortication for pediatric empyema has been advocated for more rapid and definitive resolution, and shortening of length of stay (LOS) and overall cost of care.⁷⁰ Monitoring lung function recovery for M.G. to rule out restrictive disease should be long-term.

CROUP

Clinical Presentation

13. Y.M., a 3-year-old male who attends daycare, developed a cold at the end of the school week. According to his mother, his cold was accompanied by coughing and post-tussive emesis of whitish, thick phlegm. Overnight on Saturday, his cough, which had become harsher through the day, now sounded like a seal, and he continued to have emesis in an attempt to clear his airway. He did not turn blue, but his mother became concerned when he became inconsolable and seemed not to be able to catch his breath. When brought to the emergency department at his local hospital, he was not toxic appearing, but had audible inspiratory stridor and a barking cough. His temperature was 104°F, his respiratory rate was 38 breaths/minute and shallow, his heart rate was 142 beats/minute. He exhibited perioral cyanosis, retractions, and seemed tired and somewhat listless. His oxygen saturation was 97%. He was placed on 30% oxygen by mask with nebulized medication, and was able to take sips of fluid after his respirations became deeper and slower, although he still had stridor and harsh coughing. Direct fluorescence antibody test for influenza was negative. Why is this clinical picture consistent with croup?

Croup, or acute laryngotracheitis, is a viral upper airway infection that can affect the structures that the anatomical name suggests. It has an annual prevalence of about 3% and occurs predominantly between 6 months and 3 years of age, primarily during the cold weather months.⁷¹ Males have 1.5 times the prevalence over females. Symptoms include hoarseness, barking cough and a high-pitched audible inspiratory stridor, that are caused by subglottic inflammation, edema, and narrowing. In-drawing of the chest wall and respiratory muscle retractions can be seen. Greater work of breathing from increased inspiratory airway resistance coupled with lower lung volumes generated for the effort made creates perceived air hunger.⁷² The rapid respiratory rate and increased intrathoracic pressure attempt to maintain the necessary minute inspiratory volume, but with steadily increasing fatigue of the child and potentially altered sensorium. Parainfluenza virus and respiratory syncytial virus (RSV) are the usual viral etiologic agents, but rhinovirus, adenovirus, and mycoplasma can also cause croup; influenza can cause the most severity.⁷¹ High fever, toxic ap-

pearance, and concurrent bronchitis are more indicative of secondary bacterial tracheitis (e.g., *S. aureus*, streptococci), and often requires intensive care admission.⁷³ Spasmodic croup is distinguished from acute laryngotracheitis by the suddenness of onset, but with noninflammatory subglottic edema and the lack of fever and coryza; this can occur more in atopic children. Recurrent croup also can have some of the components of allergy or gastroesophageal reflux.⁷⁴

About 85% of croup cases in the emergency department are mild.⁷⁵ A validated croup scoring system based on the degree of stridor, intercostal respiratory muscle retractions, air entry, level of consciousness, and cyanosis in room air, has been used in clinical studies of severity and response to therapy, but seldom is utilized in routine clinical practice.⁷¹ Anteroposterior view on x-ray of the neck shows a steeple sign with the column of air narrowing proximally.

Initial Treatment

Bronchodilators

The great majority of cases of croup are managed at home (<5% need hospitalization). Caregivers generally are instructed to provide warm ambient humidification, despite the absence of sound evidence as to its efficacy, with the hope of a possible marginal benefit from a rather risk-free intervention.⁷⁶ Enhanced humidification might serve to relax the child and, thereby, lessen the risk of respiratory muscle fatigue. Mucolytics have essentially no role and the ability to administer aerosolized bronchodilators in a home situation to a child with upper airway inflammation and stridor is difficult and might delay more beneficial therapy. In moderate to severe disease, the patient should be administered nebulized racemic epinephrine 2.25% (0.25–0.5 mL diluted with normal saline to a 3 mL volume), which decreases capillary hydrostatic pressure via precapillary arteriolar vasoconstriction leading to diminished laryngeal edema.^{71,75} The β -agonist effect can relax bronchial smooth muscle, but this is secondary to the larger airway effects. Doses of racemic epinephrine can be repeated every 2 to 3 hours if needed. L-Epinephrine (1:1,000 diluted in 5 mL of saline) can alternatively be used, and repeated doses can diminish the potential need for intubation.⁷⁷

Corticosteroids

Because edema and inflammation are the main pathophysiological factors in the development of symptoms of croup, corticosteroids have long been utilized in the management of moderate-to-severe disease. In addition, meta-analysis of clinical trials has supported the benefit of steroids in croup.⁷⁸ Corticosteroids also have been used increasingly for the treatment of mild croup. Even a single oral dose of dexamethasone 0.6 mg/kg can significantly hasten symptom resolution, and reduce sleep disturbance, parental stress, and revisits for medical care.⁷⁹ Smaller oral doses have also been very successful, and intramuscular administration has been especially useful for use in children with emesis.^{80,81} Prednisone 1 mg/kg can be used with similar effect,⁸² but the longer half-life and greater potency of dexamethasone may be advantageous. Although budesonide in 2 to 4 mg doses can be administered via nebulizer, it is doubtful whether it provides additive effects to the systemic dexamethasone.⁸³ Budesonide also can be nebulized

together with epinephrine for severe cases. Repeated doses of steroids are not advocated because of the risk of bacterial and fungal complications.⁷¹ Influenza vaccination should help to prevent the most severe cases of croup. If testing for influenza is positive in the presence of severe croup, neuraminidase inhibitors should be considered along with the above specified treatments. The patient should be observed and monitored for 2 to 4 hours, and hospitalization should be considered if the stridor and repeated epinephrine doses are not resolving stridor at rest or chest wall in-drawing. Secondary bacterial infection and empiric antibiotic therapy with vancomycin and cefotaxime should be considered at that point.

14. What pharmacologic treatment should be initiated for Y.M.?

This child should be treated with a single oral dose of dexamethasone of 0.6 mg/kg (presuming oral tolerance continues after being able to take small volumes of liquid), and supported with oxygen by mask. The treating clinician can administer an additional dose of racemic epinephrine for the continued stridor, but consideration should be given to not administering additional doses if the normal oxygen saturation is maintained because the already rapid heart rate is likely to increase more with continued catecholamine use. The dose of racemic epinephrine should be repeated if the stridor or oxygen saturation worsens (or cannot be maintained once off oxygen), or if the response to the dose of dexamethasone is lacking after four hours of monitoring. Acetaminophen (15 mg/kg) should be given for fever and any intercostal or upper airway pain due to the vigorous cough.

BRONCHIOLITIS

Etiology

Bronchiolitis is a common illness of the small airways (bronchioles) caused by an infection, usually from a virus, resulting in inflammation of the bronchioles and subsequent mucus production. It is the most common lower respiratory tract infection in infants, and is the top primary diagnosis among hospitalized infants younger than 1 year.⁸⁴ It most commonly occurs in the winter months and usually is caused by RSV, which can be isolated in 75% of children younger than 2 years who are hospitalized with this airway disease.⁸⁵ Rhinoviruses have also been implicated.⁸⁶ It is estimated that 22.8 per 1,000 emergency department visits by children during RSV season can be attributable to bronchiolitis. Reinfections within or during subsequent seasons are not unusual given the lack of lasting immunity and the high communicability of this infection. As with other respiratory viruses, dissemination of this infection is through aerosolization and touch. Hand washing is mandatory for caregivers to minimize the spread of this disease. Specific genetic susceptibility may also play because four single-nucleotide polymorphisms in innate immune genes are strongly associated with RSV bronchiolitis susceptibility.⁸⁷

The infection causes edema, inflammation, mucus production, necrosis, and cell sloughing within small airway epithelium, resulting in bronchospasm. Infants younger than 6 months are at highest risk of hospitalization, which occurs in 0.5% to 2.0% of all RSV infections. Premature neonates, infants with chronic lung disease, and children with congenital

heart disease and heart failure are at added risk for morbidity and mortality from bronchiolitis.⁸⁸ Hypoxia can develop from ventilation/perfusion mismatching. Gas exchange is further compromised by the mucus plugging, airway obstruction, and subsequent air trapping distal to the narrow airways.

Clinical Presentation

15. M.V., a 3-month-old male born at 31 weeks of gestation, is admitted for poor feeding and respiratory distress. M.V.'s mother relates that the infant had been fussy for the past 2 days, had a runny nose, and was stopping feeds prematurely and tiring. His respirations had gone from panting to grunting over the last 12 hours, and he was turning blue around the mouth. His temperature was 101°F, with a respiratory rate of 82 breaths/minute and a heart rate of 180 beats/minute. On physical examination, nasal congestion was seen in one nare and he had crackles and occasional wheezing bilaterally on chest auscultation. His tympanic membranes are clear. His oxygen saturation was 88% on the pulse oximeter and his venous blood gas showed a pH of 7.35, PCO₂ of 56 mm Hg, and a PO₂ of 50 mm Hg. He received a dose of nebulized albuterol and more wheezing was heard bilaterally. Continuous albuterol was applied, but the oxygen saturation went only to 90%. M.V. has a WBC of 8,700/mm³, with 42% neutrophils (<10% band forms), 50% lymphocytes, 6% monocytes, and 2% eosinophils; few atypical lymphocytes were seen on the smear. His CRP was 1.3 mg/dL. A chest x-ray was obtained and a diagnosis of bronchiolitis was made. The patient was transferred to the pediatric intensive care unit for close monitoring.

M.V.'s coryza and rhinorrhea are common clinical findings, and can occur with or without fever. Normal respiratory rates are age dependent; M.V.'s high respiratory rate is within the expected range for young infants with bronchiolitis (can exceed 70–90 breaths/minute), and his respirations that sound like panting is common with this illness. His difficulties with feeding and sleeping result from the rapid respiratory rate that is required for adequate minute ventilation. At this point, sedating medications must be avoided because these can slow the respiratory rate and potentially compromise his minute ventilation. As his condition worsens, his respirations progressed from panting to grunting because he closes his glottis against exhaling pressure as a means of keeping his alveoli open for gas exchange, a process known as “auto-peak end-expiratory pressure.” Nasal congestion is important to identify and treat because young infants tend to be obligate nose breathers, and nasal obstruction can cause respiratory impairment. Wheezing, nasal flaring, increased intercostal muscle retractions, and cyanosis can result if treatment is not promptly instituted or if treatment fails. When apnea is present, immediate attention is paramount, and increases the need for mechanical ventilation, especially in infants younger than 8 weeks old and in premature infants. Pulse oximetry should be used to assess the degree of oxygen saturation. Blood gases also should be obtained to monitor oxygen content for deteriorating or mechanically ventilated patients. Both the low oxygen saturation and elevated PCO₂ reflect M.V.'s significant respiratory distress. Peribroncholar infiltration of lymphocytes can be appreciated on the chest x-ray as peribronchial cuffing. Lobar atelectasis can occur due to the cell sloughing, and hyperinflation on the chest x-ray results from air trapping. WBC count and CRP are most

often normal,⁸⁹ as they are in M.V., and bacterial cultures generally can be avoided because the development of concurrent bacterial infection is very low in bronchiolitis.⁹⁰ Nevertheless, bacterial colonization of endotracheal tube aspirates is common in ventilated patients.⁹¹

Laboratory Testing

16. What testing should be done on M.V. to identify the causative agent?

Rapid RSV-antigen testing using direct immunofluorescent antibody staining or enzyme-linked immunosorbent assay of a nasal aspirate or wash, or a deep nasopharyngeal swab sample, reliably detect active viral shedding with sensitivity and specificity of nearly 90%. A simple nasal mucus swab does not obtain sufficient epithelial cells, and leads to increased false-negative results. During the season when influenza is endemic, the obtained specimen should be tested for both viruses. The availability of effective testing for RSV and influenza with rapid turnaround times has enhanced the ability to distinguish serious bacterial infections from viral infections in young infants; thereby, decreasing extensive laboratory testing, time in the emergency department, and needless antibiotic exposure.⁹²

Treatment

17. What available treatments should be used to M.V.?

As with croup, the treatment of bronchiolitis is controversial when evidence-based benefit is balanced against risk, and recommendations for treatment often fly against practice traditions. More than 50% of bronchiolitis episodes are treated with bronchodilators, corticosteroids, or antivirals despite only limited supportive evidence for such treatments.⁹³

Bronchodilators

The use of bronchodilators has been declining because the literature does not support their routine use, and they do not seem to decrease LOS in hospitals or prevent the need for hospitalization. Some individual infants, however, seem to experience early benefit based on scores of clinical improvement.⁹⁴ Aerosolized administration of bronchodilators by mask or hood to infants with bronchiolitis also results in similar outcomes. The hood generally is the preferred aerosolized method of administration because the mask or nasal prongs often become displaced with the head movements of young infants.⁹⁵ Additionally, nebulized epinephrine, in contrast with placebo or albuterol, has been beneficial in some outpatients; however, epinephrine can promote adverse increases in heart rate.⁹⁶ Several international studies have demonstrated decreased hospital LOS for infants with moderate viral bronchiolitis when treated with nebulized 3% saline. Nevertheless, formal recommendations for the use of nebulized saline are lacking.⁹⁷ Therefore, an aerosolized bronchodilator should not be used in treating M.V. because he already has an increased heart rate and it would unnecessarily expose him to potential adverse effects from a treatment with unproven efficacy.

Corticosteroids

A variety of corticosteroid have been studied in the treatment of RSV bronchiolitis; however, the routine use of these drugs has not been endorsed by the AAP.⁸⁵ Corticosteroids might prove to have a role in early or later disease course. In a randomized, placebo-controlled trial of 174 children (<2 years old), a single dexamethasone 0.6 mg/kg dose decreased duration of symptoms, decreased the need for oxygen, and decreased hospital LOS.⁹⁸ In a larger, multicenter trial, 600 infants (2–12 months old) randomly received 1 mg/kg of oral dexamethasone or placebo in the emergency department to treat moderate to severe bronchiolitis; outcome measures of hospitalization and clinical score were evaluated over a 4-hour observation period. The mean improvement of symptom scores and in the LOS for those hospitalized were not different, and the hospital admission rates also did not differ for the steroid (39.7%) and placebo (41%) groups.⁹⁹ These results do not exclude the possibility that corticosteroids, used later in the course of the disease, might decrease residual inflammation, wheezing, and bronchial remodeling. The prevention of the development of pulmonary dysfunction with corticosteroids has been studied with mixed results.¹⁰⁰ Therefore, unlike for croup where the benefit of corticosteroids is seen within 4 hours, the use of a corticosteroid in M.V. must be predicated on his clinical course. M.V.'s worsening wheezing provides justification for early use of methylprednisolone (2 mg/kg loading dose, and 0.5 mg/kg Q 6 hr for maintenance).

Supportive Care

The mucolytic recombinant human deoxyribonuclease (e.g., Dornase) had no effect on LOS, supplemental oxygen needs, or symptom scores.¹⁰¹ Intravenous fluids should be given as needed because infants may not be feeding adequately and insensible losses may be increased with the higher respiratory rates. Nasal suctioning and 0.0625% to 0.125% phenylephrine every 4 to 6 hours should be applied to keep M.V.'s nasal passage patent. Higher concentrations or more frequent administration of phenylephrine should be avoided because catecholamine-induced hypertension has been observed owing to the nasal vascular (mainly arterial) uptake. Supplemental oxygen should be continued for M.V. if an oxygen saturation of <90% is sustained.

Antivirals

The antiviral, ribavirin, generally is delivered by mist tent as 6 g over 12 hours for 3 consecutive days when used for treatment of bronchiolitis. The airborne spread of ribavirin is of concern during administration of ribavirin, and safety policies need to be established to minimize healthcare worker exposure because of potential adverse effects. Although initial studies of ribavirin efficacy were positive, other larger cooperative clinical trial results have been mixed and its use has decreased, even among patients at significant clinical risk.¹⁰² Out of 11 heterogeneously designed trials, 7 were associated with patient benefits, and 4 noted no benefit. Ribavirin might be of value in immunocompromised or cardiovascular-impaired patients with severe disease,⁸⁵ but should be deferred in M.V.

Antibacterials

The empiric use of antibacterials is not at all common because concurrent bacterial pneumonia is not an expectation, despite

the occasional appearance of pulmonary infiltrates and atelectasis on chest x-ray. Acute otitis media can certainly be caused by RSV, but it can be difficult to differentiate viral from bacterial etiologies. Although some evidence suggests that more than 50% of hospitalized children with bronchiolitis develop AOM, antibacterials should not be administered to M.V. empirically in the absence of a specific diagnosis.⁸⁵ Macrolide antibiotics might have benefit in RSV-associated bronchiolitis that some speculate might be attributable to their immunomodulatory effects; however, the needed 3-week course of therapy cannot be supported based on present data.¹⁰³

18. Is M.V. a candidate to receive RSV prophylaxis?

Palivizumab

A polyclonal RSV immunoglobulin was utilized for the prevention of RSV infection, but interest waned because increased mortality was noted in patients with congenital heart disease. A humanized monoclonal anti-RSV antibody, palivizumab (Synagis) is available for clinical use. When monthly palivizumab intramuscular injections of 15 mg/kg were administered during the RSV seasonal months to high-risk infants and children with hemodynamically significant congenital heart disease, RSV hospitalizations were decreased.¹⁰⁴ Table 96-6 identifies patients who could benefit from palivizumab administration. M.V. is eligible for palivizumab, despite his current infection, because there is a lack of durable immunity against RSV. M.V. should have received his first dose of palivizumab before discharge from the hospital after birth. This medication is costly and cost-effectiveness strategies should be considered. Opportunities for greater use of palivizumab are notable; only half of the children presenting to an ED with bronchiolitis who met AAP criteria for palivizumab prophylaxis received it.¹⁰⁵ In 2-year follow-up studies, the incidence of recurrent wheezing decreased in infants who received this drug compared to those who did not.¹⁰⁶ A more potent second-generation

monoclonal antibody, motavizumab, is currently undergoing phase III clinical trials.¹⁰⁷ Although palivizumab is FDA approved for prophylaxis against RSV, it also has been used intravenously for the treatment of severe upper and lower respiratory RSV infection in high-risk patients, including those with malignancy.^{108,109} Efforts to develop an appropriately attenuated and immunogenic live RSV vaccine are ongoing.¹¹⁰

KAWASAKI DISEASE

Kawasaki disease (KD), also known as mucocutaneous lymph node syndrome, is an inflammatory vasculitis with multiple clinical features. Although it is one cause of fever of unknown origin in children, Kawasaki syndrome or KD is unique. It occurs in children younger than 5 years, has a slight male predominance, and occurs more frequently in children of Asian descent.¹¹¹

Diagnosis

The diagnosis of KD is based on a constellation of symptoms, including a fever of at least 5 days' duration in the absence of an alternative diagnosis and with at least four of the following five features:¹¹¹

- bilateral bulbar conjunctival injection;
- oral mucous membrane changes (e.g., injected or fissured lips, injected pharynx, strawberry tongue, periungual desquamation during the subacute and convalescent phases);
- peripheral extremity changes (e.g., painful erythema of palms or soles, edema of hands or feet) especially during the acute phase;
- polymorphous rash; and
- cervical lymphadenopathy (at least one lymph node >1.5 cm in diameter).

Atypical or incomplete KD refers to cases in which fever is accompanied by three or fewer of these features. These cases occur more in infants and in chemically induced KD (e.g., carbamazepine, griseofulvin, mesalamine, carpet shampoo exposure). Additional clinical findings of KD may include hepatic dysfunction, gallbladder hydrops, pseudo-obstruction, urethritis, aseptic meningitis, arthralgia, and arthritis.

Etiology

The etiology of KD is not well defined, but it has been linked to viral (coronavirus), bacterial, and rickettsial exposures. KD mimics a number of infectious diseases, including toxic shock syndrome, Rocky Mountain spotted fever, scarlet fever, bacterial cervical adenitis, and staphylococcal scalded skin syndrome. It also has been linked to a superantigen hypothesis, in which proinflammatory cytokines advance vascular inflammation in the acute phase (first 10 days). In this hypothesis, vascular endothelial factors are released and stimulate myointimal proliferation and medial thinning, leading to local dilatation, ectasia, and aneurysm formation. This occurrence in the coronary arteries of the affected child represents the most concerning, and potentially life-threatening, complication of this disease. Myocarditis and pericarditis can also present during this period as early complications.

Table 96-6 Indications for Palivizumab

- Infants and children <24 months old with chronic lung disease of prematurity who have required medical therapy within 6 months of RSV season (including diuretics or corticosteroids or supplemental oxygen)
- Infants born at ≤32 weeks gestation, with or without chronic lung disease:
 - ≤28 weeks gestation during the first 12 months of life
 - 29–32 weeks gestation during the first 6 months of life (if overlapping with the start of RSV season)
- Infants 32–35 weeks of gestation with ≥2 of the following risk factors:
 - child care attendance, school-aged siblings
 - exposure to environmental air pollutants
 - congenital abnormalities of the airways
 - severe neuromuscular disease
- Children ≤24 months old with hemodynamically significant cyanotic and acyanotic congenital heart disease
 - Infants who are receiving medication to control congestive heart failure
 - Infants with moderate to severe pulmonary hypertension
 - Infants with cyanotic heart disease

RSV, respiratory syncytial virus.

19. J.H., a 4-year-old Korean male, is in a kindergarten class where several children have come down with the flu. J.H. has been febrile with respiratory symptoms, but his fever has lasted for 9 days and had been as high as 104.6°F. On physical examination, J.H.'s hands and feet are swollen and red, his tongue is red and pimply, and his lips show small fissures. His conjunctiva are red bilaterally without discharge, and there is a maculopapular rash with irregular borders on the chest. He has a 2-cm mobile cervical node on the left side of his neck and a few shoddy inguinal nodes. He has an I/VI systolic ejection murmur, and the point of maximal impulse is normally located. His abdominal examination is benign. He complains of burning on urination. He has quadriceps muscle and knee pain, and his parents suspected that this was the influenza that had spread among his classmates. His parents have not given him antibiotics and deny any other drug use except for ibuprofen for the fever. The laboratory results show a WBC count of 27,500 cell/mm³ with 12% band forms, and 50% lymphocytes with atypical lymphocytes and toxic granulation seen on smear. His platelet count is 325,000 cells/mm³, and his hemoglobin is 10.7 gm/dL, with a mean corpuscular volume of 89 μm³. He has a CRP of 12.7 mg/dL, an erythrocyte sedimentation rate (ESR) of 88 mm/hr, an albumin of 2.9 g/dL, and an alanine aminotransferase of 102 IU/mL with normal ammonia. Urinalysis shows 5 to 10 WBC per high-power field (hpf), but nitrite negative. Blood and urine cultures are negative. Antibiotics are not started. What diagnostic findings and considerations in J.H. are consistent with KD?

J.H. has a fever of unknown origin for more than a week, and his age (<5 years) and nationality (Korean) fit the typical profile of a patient with KD. More important, J.H. has some signs and symptoms referable to influenza, but the presence of the prominent swelling of the hands and feet (criterion C); a maculopapular versus an urticarial rash (criterion D); and the unilateral cervical adenopathy (criterion E) and the high fever for 9 days differentiates this illness from the usual flu symptom pattern. In addition, J.H.'s conjunctiva are red bilaterally (criterion A); his tongue is red and pimply in appearance (criterion B).

The laboratory test results of J.H. also are consistent with those commonly noted in patients with KD. Leukocytosis (J.H.'s is 27,500 cells/mm³), anemia (J.H.'s hemoglobin is 10.7 and normocytic), elevations in CRP (J.H.'s CRP is 12.7 mg/dL) and ESR (88 mm/hour in J.H.), transaminasesemia (alanine aminotransferase in J.H. is 102 IU/mL), and sterile pyuria (5–10 WBC/hpf in J.H.) are present. J.H.'s platelet count is normal, but the platelet count can rise to more than 1 million/mm³ during the subacute phase (days 11–21) of KD, when fever often dissipates and toes and fingers desquamate. During the convalescent phase (days 21–60), the development and presence of coronary artery aneurysms are prominent concerns. J.H.'s ESR and CRP are increased and in the ranges (>50 and 10, respectively) where coronary aneurysms are observed more frequently.¹¹²

Treatment

20. What treatment should be offered to J.H. during the acute phase?

Medications to provide a measure of comfort for the patient (e.g., analgesics and antipyretics) are essential, but the need for

treatment to minimize the potential for coronary aneurysms, as detected by echocardiography, is paramount. The risk of coronary artery ectasia and aneurysm is higher if treatment is delayed beyond 10 days from initial symptoms. In one study, 7% of patients with complete KD had an aneurysm on the initial echocardiogram versus 30% of those with incomplete KD.¹¹³ KD patients treated by day 7 of illness had 6% occurrence of aneurysm versus 27% among those treated at days 8 to 10. A delay in diagnosis of KD, whether due to the lack of access to health care or to the lack of health insurance, or more than one visit to a health care provider before establishment of the diagnosis, increases the risk of the development of coronary aneurysms. Patients younger than 6 months, and those with atypical KD, who have diagnosis and treatment delay of 10 days or more after fever onset, also are at higher risk of developing aneurysms.^{114,115}

Intravenous immunoglobulin has become the mainstay of treatment to minimize the risk of aneurysm in patients with KD. The recommended doses of IV immunoglobulin has been modified over time from 400 mg/kg/day for 5 days to 1 g/kg for 2 days to the current regimen of a single dose of 2 g/kg, delivered as a 12-hour infusion.¹¹¹ An additional dose of IV immunoglobulin at the same dose is warranted if defervescence of fever and clinical indications of improvement have not occurred by 36 to 48 hours after the first dose of IV immunoglobulin. A third dose can be given if necessary with the addition of 1 to 3 days of pulse methylprednisolone at 30 mg/kg/dose.¹¹⁶

Corticosteroids are appropriate if refractory fever continues after two doses of IV immunoglobulin, but the effect on coronary artery dilatation and aneurysm is uncertain.¹¹⁷ The use of methylprednisolone combined with first-dose IV immunoglobulin does not add to the cardiac efficacy of prompt IV immunoglobulin treatment given alone, although greater reductions were observed with ESR, CRP, and febrile days with the combination.¹¹⁸ In contrast, a meta-analysis of eight KD studies showed improved coronary protective efficacy in regimens that included corticosteroids, which were the mainstays of therapy with aspirin before the emergence of IV immunoglobulin.

An antiplatelet drug such as aspirin is still used during the febrile phase at doses of 80 to 100 mg/kg/day divided every 4 or 6 hours. Once the patient's fever diminishes, the dose of aspirin is reduced to 3 to 5 mg/kg/day (especially important if the platelet count is very high in the subacute phase) and continued for 6 to 8 weeks until evidence of no development of coronary aneurysms; treatment length is indefinite if coronary aneurysms form, because these can rupture during adulthood. J.H., still with the potential for influenza to have been a trigger for KD, should have an enzyme immunoassay for influenza to assess the risk of Reye syndrome because of the intent to prescribe aspirin. Clopidogrel can be used as an alternative to aspirin, or for persistent platelet counts higher than 1 million/mm³, with doses of 0.2 mg/kg/day for children younger than 2 years and 1 mg/kg/day for older children being well-tolerated and effective.¹¹⁹ The rare occurrence of coronary thrombosis in patients with KD could be treated with medications (e.g., thrombolytics, heparin, warfarin), similar to treatment algorithms in adults. Revascularization and coronary bypass surgery have been performed in severe cases.

PEDIATRIC URINARY TRACT INFECTION

Urinary tract infections (UTIs) in children are common causes of febrile illness in infants, children and adolescents.¹²⁰ Up to 7% of girls and 2% of boys will have a symptomatic, culture-confirmed UTI by 6 years of age; and more so with younger age (7% of febrile newborns). The yearly prevalence of UTIs in children is estimated to be 2.4% to 2.8%. In a large cohort of febrile children younger than 2 years, 2.1% were diagnosed with UTI; and in 13% of Caucasian girls younger than 6 months of age.¹²¹ The prevalence in that age group presenting to the pediatric emergency room was 3.3%.¹²² Among 1,025 febrile infants evaluated during seasons where bronchiolitis is prevalent, 9% were diagnosed with a UTI.¹²³

The importance of UTIs in children is not limited to the need for prompt diagnosis and treatment, but also concern for the potential ramifications of prolonged untreated, poorly treated, and repeated infection. The relationship of UTI to loss of nephron mass with consequent decrease in glomerular function, childhood hypertension, reflux nephropathy, and renal scarring is well-established; the needs for treatment and prophylaxis are important pediatric issues.

Clinical Features and Risk Factors

21. K.P., a 2-month-old male, presents to the emergency department with fever and a small amount of blood in his diaper. The mother claims to be changing the infant's diaper with the usual frequency, but noticed over the last 2 days the urine was malodorous. Although somewhat irritable, the infant has been behaving otherwise normally. Birth history was unremarkable, although the mother had a case of acute pyelonephritis during the second trimester, and had two more such cases in the past. On examination, the child is flushed in appearance, but otherwise normal appearing and responsive. His temperature is 103.8°F and his heart rate is 180 beats/minute; other vital signs are normal for age. He is uncircumcised, but no outward anomalies (e.g., abnormal urethral opening, spina bifida) are noted. Crying is elicited on abdominal palpation, but no organomegaly is appreciated, nor is pain elicited on palpation of the flank area. A urinalysis and urine culture was obtained via a collection bag (the infant is noted to cry while urinating). A blood culture is obtained, but a lumbar puncture is deferred due to the lack of significant mental status change. Stool was also obtained for microscopy and culture. What demographic and clinical features of childhood UTI are relevant to this patient's UTI?

This patient demonstrates some salient demographic and clinical features of pediatric UTIs, which differ from the UTIs experienced by adolescents and adults. Serious bacterial infection can be identified in 7% to 12% of febrile infants younger than 3 months old, and 67% to 85% of these can be attributed to UTIs.^{121,124,125} The incidence of UTIs in males is much higher during early infancy than in later childhood and adolescence. The incidence of UTI during the first year of life is 2.7% in males versus 0.7% in females. This gender difference for UTI reverses to 0.1 to 0.2% in males and 0.9 to 1.4% in females 1 to 5 years old, and 0.04 to 0.2% in males and 0.7 to 2.3% in females 6 to 16 years old.¹²⁰ UTIs in adults most commonly result from ascending infection from the lower urinary tract, whereas in young infants the UTI often results from a

hematogenous spread to the urinary tract. As a result, concern for the possibility of sepsis in young infants is important, and a blood culture is essential in the face of K.P.'s clinical findings.

Family history also might be of relevance because the children of mother's with a history of pyelonephritis have a higher incidence of acute pyelonephritis, although pyelonephritis during pregnancy has no inheritability impact. Of interest, K.P.'s mother had experienced a bout of pyelonephritis during her second trimester. Lower human IL-8 CXCR1 receptor expression has been noted in both of these family patient groups compared with children without UTIs.¹²⁶ Adolescents who self-catheterize because of spina bifida or severe bladder dysfunction are at higher risk for recurrent UTIs, particularly if poor catheterization routines are employed.¹²⁷

An anatomical urologic anomaly, or the presence of renal stones, is commonly associated with UTIs in male infants; therefore, a thorough clinical and radiologic search for these etiologies is prudent. The gross hematuria in the case of K.P. more predominantly occurs in males with UTI, and is often observed in concert with vesicoureteral reflux (VUR), or with other urinary tract anomalies found more often in boys (e.g., posterior urethral valves, ureteropelvic junction obstruction, hypospadias, ureterocele).¹²⁸ The hematuria in K.P. also can be indicative of hypercalciuria, which can increase the potential for nephrocalcinosis and urolithiasis (seen more typically in low-birth-weight premature infants). Medical trauma, particularly if this patient had multiple prior urethral catheterization attempts, could also cause hematuria, and heighten the risk of subsequent UTI. The lack of organomegaly in K.P. tends to exclude polycystic kidney disease as causative or associated with UTI.

The clinical risk factors associated with UTIs in young children are summarized in Table 96-7. Uncircumcised boys harbor significantly higher concentration of uropathogens that may ascend into the urinary tract than in circumcised infants; bacteriuria is 10- to 12-fold more common during the first 6 months of life among uncircumcised males than in those circumcised. Lack of circumcision was the highest multivariate predictor of UTI in 1,025 febrile infants who were more than 60 days old.¹²³ In this same study, a temperature exceeding 39°C (102.2°F) also provides high predictive value. K.P.'s heart rate is appropriately elevated in the presence of a high fever and potential serious bacterial infection. His crying on abdominal palpation is common but nonspecific, and eliciting true flank pain in infants with pyelonephritis is more elusive than in adults. K.P.'s dysuria needs to be observed at the time of his urination because discomfort in the infant during

Table 96-7 Urinary Tract Infection Risk Factors for Young Children

- Known urinary tract abnormalities
- Uncircumcised boys
- History of urinary tract infection
- Temperature >39°C
- Fever >24 hr
- No apparent source for fever
- Ill appearance
- Suprapubic tenderness
- Nonblack race

urination might be attributable to other causes. K.P.'s decreased feeding, along his vomiting, diarrhea, and signs of dehydration often are noted in infants with pyelonephritis. Systemic signs and symptoms of hesitancy, dysuria, frequency, anorexia, and abdominal or flank pain are most easily noted in older verbal children. Because K.P. is uncircumcised, a baseline probability of UTI would be about 6%, but the addition of one or more of the factors in Table 96-7 increases the probability to 10 to 25% before any urine testing.¹²⁹

Urinalysis

22. The dipstick of K.P.'s urine is positive for nitrites and leukocyte esterases. Microscopy of his urine shows 10 WBCs/hpf, and the initial urine culture has grown 10⁴ gram-negative rods/mL. The patient's CRP is 5.5 mg/dL, and the WBC count is 15,500/mm³ with a differential showing 82% neutrophils (20% band forms). What is the diagnostic value of these tests for UTI? Can cystitis and pyelonephritis be clinically discriminated in a similar fashion as in adults?

Individually, these urine tests contribute varying amounts of information to the diagnosis of UTI in children. Overall for children, a positive urinalysis for leukocyte esterases, nitrites, or pyuria has a sensitivity of 82%, and a specificity of 92%.¹³⁰ The positive LR of a nitrites and leukocyte esterases present on urinalysis in a young child suspected of a UTI is 28, and the probability of UTI in K.P. with his test results is about 75 to 90%.¹²⁹

K.P. does have pyuria (i.e., ≥ 5 WBCs/hpf). In one study, infants 3 months old or younger seen in the emergency room with fever and pyuria had a positive yield on urine culture of 81%.¹³¹ The combination of pyuria and bacteriuria has a positive predictive value as high as 85%,¹³² yet 10% of infants can have a negative urinalysis in presence of a culture- and nuclear scan-proven UTI.

As with adults, the validity of any of these tests depends on the method of urine collection. Urine can be collected for study in infants or children by clean-void catch, suprapubic aspiration, bag specimen, and urethral catheterization. Suprapubic aspiration is utilized more commonly in septic neonates and occasionally in infants when contamination using other collection methods is suspect; however, suprapubic aspiration is invasive and is more painful than catheterization.¹³³ The threshold of organisms needed for a positive urine culture (≥ 100 CFU/mL) is much lower when urine is obtained by suprapubic aspiration than other methods of urine collection because sterility of the bladder urine is assumed. The more common methods of bag collection, catheterization, and clean-void catch have been compared. In over 1,500 young infants (0–3 months old), leukocyte esterases tested from bag specimens showed somewhat lower sensitivity (76% vs. 86%) and statistically lower specificity (higher false-positive rate) than urine from catheterization (84% vs. 94%), although these were not from matched specimens.¹³⁴ Specificity using nitrites testing was nearly 100% by either collection method, but the sensitivity was unacceptably low for both collection methods (25% and 43%, respectively). Diagnostic yield was also lower for bag specimens at various cutoff points for white cell counts in urine microscopy relative to the presence of infection. No

statistical differences were detected in infection rates by urine culture (8.5% vs. 10.8%, respectively),¹³⁴ although it is usually accepted that bag specimens will have a higher false-positive rate and more multiorganism and contaminated urine cultures than catheterization specimens.

These differences in technique probably are smaller in males than females. In a study using matched specimens in 303 children at risk for UTI, dipstick testing from bag specimens had higher sensitivity in girls but lower specificity than catheter-obtained specimens.¹³⁵ Only in the subset of boys 90 days old or younger were both sensitivity and specificity statistically similar between urine sampling methods. Therefore, bag urine testing for leukocyte esterases and white cells can be used as a screening method toward more selective catheterization strategy in young infant boys, but this would not be applicable for girls or older children, in whom urinary catheterization is the preferred collection method for urine testing. Urine for urinalysis and culture of a catheterized urine specimen should generally be collected from non-toilet trained children with symptoms of UTI.¹²⁹ In toilet-trained children, the collection of a midstream urine sample after thorough cleaning of the perineum with soap reduces the culture contamination rate by two-thirds.¹³⁶

As with other serious bacterial infections, K.P. demonstrates an elevated peripheral WBC count, with a left shift; the CRP is also elevated. Although these tests have significantly higher values in infants with pyelonephritis than cystitis, their diagnostic accuracy (around 50%) in localizing the infection suffers from poor specificity.¹³⁷ Procalcitonin, although not routinely measured, has been shown to have the highest accuracy among blood measurements in differentiating upper from lower UTI. The most accurate method in children to distinguish pyelonephritis from cystitis is using technetium-labeled dimercaptosuccinic acid renal scan, which shows irregularly patterned and incomplete uptake into the kidney cortex in the presence of pyelonephritis, and detects pyelonephritis in 60% to 70% of infants with UTI.^{138,139}

Urinary Pathogens and Susceptibility

23. What could be anticipated from K.P.'s urine culture and sensitivity tests? Are there pathogen susceptibility differences between children and adults?

As always, the urine collection technique is important in the proper interpretation of the urine cultures. The magnitude of bacteriuria in K.P.'s case is significant, particularly in boys, if the urine was obtained via a clean catch method or obtained from a urine bag or pad; however, a urine collection bag that has been attached for a prolonged period can cause false-positive results from colonizing skin organisms in the introitus. A single organism, excluding typical skin commensals, can be noted to be potentially pathogenic. *Escherichia coli* is the expected pathogen in 60% to 90% of cases of childhood UTI, although strain differences exist in toxins, uroepithelial receptor binding and adhesions, fimbriation, and antibiotic resistance.¹²⁰ Specific urovirulence gene expression in *E. coli* is associated with lobar nephronia (focal abscess) in children.¹⁴⁰

Antimicrobial susceptibility data for urinary isolates from children differ somewhat from adults, and can be age, acuity,

and gender dependent. When compared to adults, tested outpatient isolates were overall less susceptible to ampicillin, trimethoprim-sulfamethoxazole, and nitrofurantoin in children younger than 14 with UTI; antimicrobial resistance increased through the years of study.^{141,142} Comparative data specific for *E. coli* showed similar child–adult differences.¹⁴³ Susceptibility was comparatively higher for ciprofloxacin and levofloxacin in children.¹⁴¹ Regional differences in gram-negative rod susceptibility among children are also observed.¹⁴¹

The susceptibility of *E. coli* to ampicillin and amoxicillin continues to decrease throughout the world, and the resistance of this organism to these aminopenicillins is estimated to be about 50% to 70%. These penicillins should not be selected for the initial management of pediatric UTI.^{141,143,144} In one study, the susceptibility of 11,341 urinary *E. coli* isolates collected in children with UTI demonstrated pansusceptibility to tested antibiotics in only 41.8% to 59.4% within four different age groupings, with the lowest susceptibility noted in children 1 to 24 months of age.¹⁴⁵ Similar data on resistance to at least one tested antibiotic (48%) have been observed by others.¹⁴⁴ Resistance to two or more antibiotics ranged from 15.9% to 27.3% among the groups, with the most common co-resistance being observed with ampicillin and trimethoprim-sulfamethoxazole (10.5%–18.3%).¹⁴⁵ Resistance to three or more antibiotics was low in all age groups (3.1%–5.2%). The range of intermediate and full resistance combined for cefazolin and amoxicillin-clavulanate was 5.7% to 11.8% and 13.3% to 22.5%, respectively. Although improved activity over ampicillin is observed with the inclusion of a β -lactamase inhibitor (e.g., clavulanate), the inhibitor does not fully prevent resistance. In a study of 77 gram-negative rods from children with UTI (72 of which were *E. coli*), resistance to ampicillin was 46% and to ampicillin-sulbactam was 28%.¹⁴⁴ The first-generation cephalosporin, cephalexin, was associated with more bacterial resistance than second or third-generation oral cephalosporins.¹⁴²

Non-*E. coli* gram-negative rods (e.g., *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*, *Enterobacter* spp., and enterococci), are encountered more often in males, neonates, children with reflux and underlying renal or urinary abnormalities, and children who have received antibiotics in the month before the UTI.^{146–148} Additionally, a greater proportion of these organisms are found in UTIs with lower colony counts ($\leq 50,000$ CFU/mL).¹⁴⁹ These gram-negative organisms also tend to be more resistant to the antibiotics typically recommended for initial treatment (e.g., aminoglycosides, cephalosporins). This led to inappropriate initial therapy for these non-*E. coli* infections (19% vs. 2% for *E. coli*; $p = .0001$), resulting in longer hospitalizations.^{146,150} Higher rates of resistance to multiple antibiotics have been noted by other investigators, with children younger than 4 years having a greater incidence of antibiotic resistance. *P. aeruginosa* often is the pathogenic organism in children with chronic pyelonephritis.

Among 361 pediatric patients hospitalized for UTI over a 5-year period, statistically lower susceptibility was observed for parenteral penicillins, cephalosporins, and trimethoprim-sulfamethoxazole in patients with a history of UTIs, and lower still in patients receiving antibiotic prophylaxis.¹⁵⁰ This pattern was consistent with the finding of more non-*E. coli* UTI in these patients, and the greater likelihood of those organisms being more resistant. The sensitivity to the aminoglycosides

and aztreonam, however, did not vary among these groups and was at least 95% (carbapenems were not tested). *Pseudomonas* resistance patterns resemble those of adults, except that less resistance is seen for the fluoroquinolones.^{143,151} This is understood as being a function of much lower volume of usage of this class of antibiotics in children, and therefore, less selective pressure toward enzyme target and efflux expression of resistance. Pediatric urinary bacterial isolates have lower susceptibility to trimethoprim-sulfamethoxazole, with *E. coli* susceptibility of 70% to 75%.^{152,153} High susceptibility is still maintained for *E. coli* for nitrofurantoin (<3% resistance), but its use is limited in infants to prophylaxis, given the high percentage of cases of pyelonephritis among UTIs in infants, the lack of localizing signs and symptoms distinguishing upper tract infection in this age group, and the absence of effective serum and tissue concentrations of this drug.

Treatment Selection

24. K.P. has been febrile for 48 hours and the culture and sensitivity are pending. What should be the therapeutic approach, anticipated response and follow-up monitoring?

K.P.'s treatment should begin promptly because delays in initiation of the antibiotic management enhance the risk of renal scarring or abscess formation. The use of a cephalosporin as initial therapy in an outpatient setting is reasonable, provided follow-up of the culture and sensitivity report is ensured. Ampicillin/amoxicillin or trimethoprim-sulfamethoxazole cannot be relied upon empirically, given the baseline resistance rates that now exist. A variety of treatment regimens and approaches have been evaluated in managing pediatric UTIs. A 10-day course of an appropriate oral antibiotic can be as effective as parenteral antibiotics, even in the management of pyelonephritis.¹⁵⁴ However, use of parenteral antibiotics is recommended if patients are toxic in appearance, dehydrated, or have decreased oral intake. Cefixime, cefpodoxime, and cefdinir are potent single daily-dose oral agents for *E. coli* and non-*E. coli* UTIs, although cefdinir does not have an FDA indication for UTI.¹⁵⁵ Multiple daily doses of amoxicillin-clavulanate, cephalexin, cefprozil, and cefuroxime are alternative choices pending culture and sensitivity reporting. Experience with fluoroquinolones has been limited; however, these can be used to treat complicated UTIs in children with multi-resistant urinary isolates, despite the relative contraindications to the use of fluoroquinolones in children (see Question 21).¹⁵⁶

K.P. would likely require hospitalization and therapy should be initiated with either a parenteral cephalosporin (e.g., cefotaxime 100–200 mg/kg/day or ceftriaxone 50–100 mg/kg/day) or an aminoglycoside, with dosage adjustments to achieve targeted serum levels, depending on severity of infection and/or simultaneous infection at other sites. Alternatively, the less ill infant could be treated in an outpatient health care facility with daily intravenous injections of an aminoglycoside.¹⁵⁷ Intravenous therapy should be continued for at least 3 to 7 days, and should be followed by a course of therapy with an appropriate oral antibiotic (assuming an uncomplicated clinical course). The AAP has recommended a 7- to 14-day course of antibiotic therapy for all children 2 months to 2 years of

age with UTI based on comparative data, which showed better efficacy with this 1- to 2-week course of treatment than with shorter treatment courses. This treatment regimen can utilize a combination of parenteral and oral therapy. Meta-analysis supports this recommendation for longer treatment lengths for pediatric UTIs, with lower failure rates observed even in the absence of evidence of pyelonephritis.¹⁵⁸ A good treatment response for K.P. would be anticipated with the correct antibiotic selection. Generally, fever resolves within 48 hours in approximately 90% of infants. Few failures are reported, and the need for follow-up cultures for proof of effect may be dubious.¹⁵⁹ For lobar nephronia, 3 weeks of therapy (IV and oral) has proven better than shorter courses.¹⁶⁰

Recommended follow-up testing and treatment traditionally includes a renal ultrasound or renal scan of the UTI diagnosis to detect anomalies, structural lesions, calculi or obstruction, and a voiding cystourethrogram or renal scan within 3 months to evaluate for VUR, with antibiotic prophylaxis until the voiding cystourethrogram is performed.¹⁶¹

Complications of Urinary Tract Infections in Children and Prophylaxis

25. K.P. is discharged from the hospital after responding well to 6 days of intravenous cefotaxime for *K. pneumoniae* (10⁵ CFU/mL). He also has completed 14 days of therapy with oral cefixime (8 mg/kg once daily), which was continued until the voiding cystourethrogram performed a month later revealed grade III reflux of the left collecting system. What therapeutic initiatives should be considered?

VUR is the most common urologic abnormality in children, with a 1% to 2% incidence, and is discovered in 30% to 50% of children with one or more episodes of UTI.^{139,162} Higher prevalence exists in offspring of those previously affected (via autosomal-dominant inheritance). VUR occurs when the high pressure in the bladder produces a breakdown of normal ureterovesicular junction barriers to retrograde urinary flow. This creates an increased risk of ascending travel of contaminated urine and repeated upper tract infections, delaying resolution of VUR and furthering the risk of renal scarring and damage.

VUR (grades I–V) is classified by the extent of dilatation and tortuosity of the ureters, ascending toward deformity of the kidney calyces and papillary structures.¹⁶² VUR should be treated either medically or surgically to prevent further damage to the kidney parenchyma (primarily scarring) and avoid progression to hypertension and renal insufficiency. Spontaneous resolution of VUR is affected by age, severity grade, and whether it is unilateral or bilateral. Children receiving long-term antimicrobial prophylaxis who are younger than 2 years, who have a lower severity grade, and who have only unilateral reflux have higher rates of spontaneous resolution.^{162,163}

Although some investigations suggest that antibiotic prophylaxis may not be necessary for the prevention of reinfection and scarring when managing patients with lower grades of reflux,¹⁶⁴ long-term antimicrobial prophylaxis has been the standard approach endorsed by several medical societies.¹⁶⁵ Longitudinal studies with 10-year follow-up suggest that antimicrobial prophylaxis is as effective as surgical approaches

in patients with grades III and IV VUR in preventing new scarring, although more febrile UTIs can occur in the prophylaxis group.^{163,164} Boys with grade III VUR given prophylaxis with trimethoprim-sulfamethoxazole showed reduction in further UTIs.¹⁶⁶

Antibiotic doses for prophylaxis usually are to the usual daily treatment doses. Nitrofurantoin, trimethoprim, trimethoprim-sulfamethoxazole, cephalexin, cefixime, and amoxicillin are the most commonly utilized antibiotics for this indication. Although prophylaxis with antibiotics is considered to be safer in children than in adults, long-term prophylaxis can result in adverse effects. Even with these lower doses, antibiotic use was modified in nearly 10% of children. Severe or life-threatening complications from low-dose antibiotic prophylaxis have been rare.^{167,168} When antibiotics for prophylaxis in children were compared, fewer adverse reactions were associated with nitrofurantoin than for cefixime. Although nitrofurantoin was associated with more adverse effects than trimethoprim, it was more effective than trimethoprim.¹⁶⁹

All of these antibiotics can facilitate the growth of resistant bacteria over time, especially for non-*E. coli* isolates, which pose a greater risk for children with urologic abnormalities.^{165,170} In K.P., reinfection with *Klebsiella* may occur with the development of an expressed extended-spectrum β -lactamase if a low-dose cephalosporin is utilized chronically. An organized strategy for continuing with the same antibiotic, changing to a different one, or otherwise modifying prophylactic regimens based on other parameters, requires study.

Table 96-8 Selected Uses of Fluoroquinolones in Children

- Urinary tract infections caused by *P. aeruginosa* or other multidrug-resistant, gram-negative bacteria (FDA licensed for complicated *E. coli* urinary tract infections and pyelonephritis attributable to *E. coli* in patients 1–17 years of age)
- Complicated acute otitis media failing to respond to initial antibiotic treatment¹⁸⁰
- Chronic suppurative otitis media or malignant otitis externa caused by *P. aeruginosa*
- Exacerbation of pulmonary disease in patients with cystic fibrosis who have colonization with *P. aeruginosa* and can be treated in an ambulatory setting
- Gastrointestinal tract infection caused by multidrug resistant *Shigella* species, *Salmonella* species, *Vibrio cholerae*, or *Campylobacter jejuni*
- Gram-negative bacterial infections in immunocompromised hosts in whom oral therapy is desired or resistance to alternative agents is present
- Serious infections attributable to fluoroquinolone-susceptible pathogen(s) in children with life-threatening allergy to alternative agents
- Documented bacterial septicemia or meningitis attributable to organisms with in vitro resistance to approved agents or in immunocompromised infants and children in whom parenteral therapy with other appropriate antimicrobial agents has failed
- Chronic or acute osteomyelitis or osteochondritis caused by *P. aeruginosa* (not for prophylaxis of nail puncture wounds to the foot)
- Mycobacterial infections caused by isolates known to be susceptible to fluoroquinolones
- Treatment exposure to aerosolized *Bacillus anthracis* to decrease the incidence or progression of disease (FDA licensed)

Adapted from reference 156.

Fluoroquinolone Usage in Pediatrics

26. K.P., now 14 months old, is continued on prophylactic doses of nitrofurantoin, but has his third infection over the past 6 months. The last urine culture showed 10^5 CFU/mL *P. aeruginosa*, which is resistant to cephalosporins and penicillins. K.P. has had a number of courses of aminoglycosides to treat acute infection, and the MICs of the organism have risen. Because there is concern for aminoglycoside-induced nephrotoxicity, ciprofloxacin 15 mg/kg/day divided into two doses a day is prescribed because the organism on sensitivity testing is sensitive to the fluoroquinolones. Why do the benefits of fluoroquinolone therapy to K.P. outweigh the well-publicized contraindication to use this class of agents in children?

The contraindications for the use of fluoroquinolones in pediatric patients have been based largely on juvenile animal cartilage toxicity studies (species- and dose-dependent toxicity). When benefits of therapy outweigh concerns for the musculoskeletal adverse effect of fluoroquinolones, these drugs should be prescribed. In one study, myalgias and arthralgias of large joints occurred in 3.8% of patients treated with a fluoroquinolone versus 0.4% of controls who received other antibiotics (odds ratio = 3.7). The musculoskeletal adverse effect

was evident during the first week of therapy, but was transient. The risk of this adverse effect was greatest with pefloxacin, a quinolone not available in the United States.¹⁷¹ In a review of database-assessed claims, <1% of 6,000 fluoroquinolone-treated children experienced tendon or joint disorders.¹⁷² The fluoroquinolone-induced arthropathy was judged not a permanent adverse effect based on the absence of MRI changes in children who received fluoroquinolones for a prolonged period for the treatment of cystic fibrosis.^{173,174} K.P. has a complicated UTI with a multiresistant organism. The use of ciprofloxacin for K.P. in this situation is reasonable, despite the potential for toxicity to cartilage. Table 96-8 lists clinical situations when fluoroquinolones can be considered on the basis of clinical and literature support. Nevertheless, the use of fluoroquinolones in children should not be encouraged for common childhood infections because of this adverse effect and because of the need to discourage the development of bacterial resistance to these drugs, particularly when first- and second-line alternatives are available. Although nalidixic acid was not associated with arthropathy in one study when used for the treatment of recurrent UTIs, this drug has not been as effective as others for the treatment of UTIs (Chapter 64: Urinary Tract Infections).¹⁷⁵

Adequate nutrition is an essential component of the health maintenance of children, and, in part, has been responsible for the dramatic reduction of infant mortality seen in the United States during the 20th century. Clinical experience has confirmed the value of optimal nutrition in resisting the effects of disease and trauma and in improving the response to medical and surgical therapy. The metabolic demands of rapid growth and maturation, in addition to the low nutritional reserves present during infancy, make the potential benefit of good nutrition to critically ill pediatric patients even greater.

Breast-feeding is the ideal method of feeding an infant up to 1 year of age. When this is not feasible, a wide variety of infant formulas are available that provide appropriate nutrients for infants using the oral route. A pediatric patient who has a functioning intestinal tract, but is unable to achieve adequate oral intake, can be fed enterally using a tube inserted into the stomach or small intestine. Indications for providing specialized enteral nutrition include malnutrition, malabsorption, hypermetabolism, failure to thrive, prematurity, and disorders of absorption, digestion, excretion, or utilization of nutrients.

Despite the many formulas and feeding techniques available, several medical and gastrointestinal (GI) dilemmas arise in infants and children that limit the use of the GI tract for nutritional support. Premature infants with severe respiratory

disease, congenital abnormalities of the GI tract, or necrotizing enterocolitis are typical candidates for support with parenteral nutrition (PN). Older children with short bowel syndrome, severe malnutrition, intractable diarrhea, or inflammatory bowel disease have been treated successfully with PN therapy. Pediatric patients receiving chemotherapy for the treatment of malignancies or bone marrow transplant, and children with severe cardiac failure, also have been successfully rehabilitated with PN.

Many disorders that adversely affect nutrient intake or absorption also have an adverse impact on fluid and electrolyte status. Consequently, fluid, electrolyte, and nutrient management should be approached in an integrated manner. This chapter reviews selected aspects of fluid and electrolyte management and nutrition therapy for the pediatric population.

FLUID AND ELECTROLYTE MAINTENANCE

Management of fluid and electrolyte disturbances involves providing normal daily maintenance requirements, and replacing deficits and ongoing losses. To design rational fluid therapy, it is necessary to know the normal composition of body water, and to understand the routes through which water and solutes are lost from the body and the effects of disease and medications

on water and electrolytes. Sodium-containing fluids are often referred to as fractions of normal saline (NS) (0.9% NaCl). Normal saline contains 154 mEq/L of sodium chloride.

Requirements

The general recommendations for calculating maintenance fluid, electrolyte, and nutrient requirements on the basis of weight are provided in Table 97-1. These requirements can be altered when fluid and electrolyte losses are increased or when excretion is impaired.

When abnormal fluid losses are present from any of the sources listed in Table 97-2, they must be added to the patient's daily fluid and electrolyte formula. Replacement fluid is generally 1 mL for every 1 mL lost, but can be replaced as 0.5 mL for every 1 mL lost. In general, a solution of one-half NS with 20 mEq of KCl/L is used to replace upper GI tract losses; however, the electrolyte content of GI secretions varies widely. The composition of a replacement fluid can be estimated based on knowledge of the usual electrolyte distribution of the fluid type being lost. Estimates are listed in Table 97-3. If serum electrolyte concentrations are abnormal, indicating that the replacement fluid is not appropriate, a sample of the fluid lost from the patient can be analyzed for electrolyte content, and electrolyte replacement fluid can be individualized.

The requirements for fluid and calories normalized to body weight are much greater in very small children than in older children and adults as can be seen in Table 97-1. This is because infants have a much larger body surface area relative to weight, lose more fluid through evaporation, and dissipate more heat per kilogram than their older counterparts. Furthermore, very low-birth-weight (VLBW) infants cannot concentrate urine and are at increased risk for dehydration if inadequate fluids are provided.

Calculation of Maintenance Fluid and Electrolyte Requirements

1. P.J., a 2-day-old, 3.5-kg term female infant has developed abdominal distention, and her oral feedings have been stopped. Calculate a maintenance fluid and electrolyte prescription for her. Her admission serum electrolytes include the following: sodium (Na), 137 mEq/L (normal, 135–145 mEq/L); potassium (K), 4.2 mEq/L (normal, 3.5–5 mEq/L); chloride (Cl), 105 mEq/L (normal, 102–109 mEq/L); and bicarbonate (HCO_3^-), 23 mEq/L (normal, 22–29 mEq/L). While P.J. receives nothing by mouth (NPO), her fluid and electrolyte needs must be met intravenously. Estimate her requirements.

[SI units: Na, 137 mmol/L (normal, 135–145); K, 4.2 mmol/L (normal, 3.5–5.0); Cl, 105 mmol/L (normal, 102–109); HCO_3^- , 23 mmol/L (normal, 22–29)]

Although a commercially available intravenous (IV) solution will be used, each component of the solution can be calculated separately. Using the guidelines in Table 97-1, P.J.'s maintenance requirements can be estimated as follows:

| | | |
|-----------|--|--------|
| Fluid | $100 \text{ mL/kg} \times 3.5 \text{ kg} = 350 \text{ mL/day}$ or 15 mL/hour | |
| Sodium | $2\text{--}4 \text{ mEq/kg/day} \times 3.5 \text{ kg}$ $= 7\text{--}14 \text{ mEq/day}$ | (97-A) |
| Potassium | $2\text{--}3 \text{ mEq/kg/day} \times 3.5 \text{ kg}$ $= 7\text{--}10.5 \text{ mEq/day}$ | |

Fluid and electrolyte requirements can be met by infusing a solution of 5% dextrose with one-quarter NS (38 mEq/L) and 20 mEq/L of KCl at 15 mL/hour. This provides 12 mEq (3.4 mEq/kg/day) of NaCl and 7 mEq (2 mEq/kg/day) of KCl in 360 mL (103 mL/kg/day) of fluid per day.

Adjustment for Ultraviolet Light Therapy

2. On the third day of life, P.J.'s indirect bilirubin is 15.2 mg/dL (normal, 0.6–1.05 mg/dL). It is decided to use phototherapy lights to treat her hyperbilirubinemia. How will this modify her maintenance fluid needs?

[SI unit: bilirubin, 259.92 $\mu\text{mol/L}$ (normal, 10.3–179.5)]

Table 97-2 details situations that alter maintenance fluid needs. Phototherapy lights will increase P.J.'s insensible losses and will increase her maintenance fluid needs by 10% to 20%. This can be met by increasing her IV fluid rate to 17 mL/hour (116 mL/kg/day). Although her increased fluid loss will be free from solutes and the solution she is receiving contains sodium and potassium, the electrolytes she receives still will be within the range of normal, and her kidneys should be able to compensate for the small increase.

Dehydration

Clinical Presentation: Vomiting

ACUTE MANAGEMENT

3. H.S., a 2-year-old lethargic girl, is seen in her pediatrician's office with a 2-day history of vomiting and minimal oral intake. Yesterday, she required only three diaper changes instead of her usual eight and has needed only one change today. Her vital signs are as follows: temperature, 39°C; pulse, 140 beats/minute (normal, 80–130 beats/minute); respiratory rate, 30 breaths/minute (normal, 30–35 breaths/minute); and blood pressure (BP), 80/45 mmHg (normal, 80–115 mmHg systolic and 50–80 mmHg diastolic). On physical examination, her eyes appear sunken, her mucous membranes are dry, and her skin is dry and cool to touch. Although she is crying, there are no tears and the skin over her sternum tents when pinched. Her weight today is 11.4 kg; 3 weeks ago, it was 12.9 kg. What do these findings represent? What immediate treatment should be provided?

H.S.'s lethargy, decreased urine output, tearless crying, dry mucous membranes, dry skin with fever, sunken eyes, mild tachycardia with low normal blood pressure, and poor skin turgor are all signs of dehydration. This is consistent with her 2-day history of vomiting and poor intake. Her weight loss of 1.5 kg gives a further clue to the extent of dehydration. Dehydration or fluid loss is determined most accurately by weight loss. Because 1 g of body weight is approximately equal to 1 mL, her fluid deficit is estimated to be 1,500 mL. The percentage dehydration is estimated using the following formula:

$$\% \text{ Dehydration} = \frac{\text{Normal body weight} - \text{Actual body weight}}{\text{Normal body weight}} \times 100 \quad (97-1)$$

If recent weights are unavailable, the extent of dehydration can be approximated from physical findings as described in Table 97-4. Tachycardia and marginal blood pressure dictate

Table 97-1 Daily Parenteral Nutrient Requirements in Children

| <i>Nutrient</i> | <i>Weight/Age</i> | <i>Requirement</i> | |
|--|--|---|--|
| Macronutrients | | | |
| Fluid | <1.5 kg | 150 mL/kg | |
| | 1.5–2.5 kg | 120 mL/kg | |
| | 2.5–10 kg | 100 mL/kg | |
| | 10–20 kg | 1,000 mL + 50 mL/kg for each kg > 10 kg | |
| | >20 kg | 1,500 mL + 20 mL/kg for each kg > 20 kg | |
| Calories | Up to 10 kg | 100 kcal/kg | |
| | 20 kg | 1,000 kcal + 50 kcal/kg for each kg > 10 kg | |
| | >20 kg | 1,500 kcal + 20 kcal/kg for each kg > 20 kg | |
| Protein ^a | Infants | 2–3 g/kg | |
| | Older children | 1.5–2.0 g/kg | |
| | Adolescents and older | 1.0–1.5 g/kg | |
| Fat ^b | Infants and children | Initially: 0.5–1 g/kg then increase by 0.5–1 g/kg (maximum of 3 g/kg in preterm neonates, 4 g/kg older infants and children) ($\geq 4\%$ of calories as linoleic acid) | |
| | >50 kg | One 500 mL bottle (100 g fat) | |
| Electrolytes and Minerals^c | | | |
| Sodium | Infants and children | 2–4 mEq/kg | |
| Potassium | Infants and children | 2–3 mEq/kg | |
| Chloride | Infants and children | 2–4 mEq/kg | |
| Magnesium | Preterm and term infants | 0.25–0.5 mEq/kg | |
| | Children > 1 yr (or > 12 kg) | 4–12 mEq | |
| Calcium | Preterm and term infants | 2–3 mEq/kg | |
| | Children > 1 yr (or > 12 kg) | 10–20 mEq | |
| Phosphorus | Preterm and term infants | 1.0–1.5 mmol/kg | |
| | Children > 1 yr (or > 12 kg) | 10–20 mmol | |
| Trace Elements | | | |
| Zinc | Preterm Infants | 400 mcg/kg | |
| | Term Infants | | |
| | <3 mos | 250 mcg/kg | |
| | >3 mos | 100 mcg/kg | |
| | Children | 50 mcg/kg (up to 5 mg) | |
| Copper | Infants and children | 20 mcg/kg (up to 300 mcg) | |
| Manganese | Infants and children | 1 mcg/kg (up to 50 mcg) | |
| Chromium | Infants and children | 0.2 mcg/kg (up to 5 mcg) | |
| Selenium | Infants and children | 2 mcg/kg (up to 80 mcg) | |
| Vitamins | Preterm Infants < 2.5 kg (2 mL/kg MVI^e Pediatric) | Term Infants/Children < 11 yrs (5 mL MVI Pediatric) | Children > 11 yrs (10 mL MVI-12) |
| | | | |
| Vitamin A | 280 mcg/kg | 700 mcg | 1 mg |
| Vitamin D | 160 IU/kg | 400 IU | 200 IU |
| Vitamin E | 2.8 mg/kg | 7 mg | 10 mg |
| Vitamin K ^d | 80 mcg/kg | 200 mcg | None |
| Thiamine | 0.48 mg/kg | 1.2 mg | 3 mg |
| Niacin | 6.8 mg/kg | 17 mg | 40 mg |
| Riboflavin | 0.56 mg/kg | 1.4 mg | 3.6 mg |
| Pyridoxine | 0.4 mg/kg | 1 mg | 4 mg |
| Vitamin B ₁₂ | 0.4 mcg/kg | 1 mcg | 5 mcg |
| Biotin | 8 mcg/kg | 20 mcg | 60 mcg |
| Vitamin C | 32 mg/kg | 80 mg | 100 mg |
| Folic acid | 56 mcg/kg | 140 mcg | 400 mcg |

^a“Infant” amino acids contain histidine, taurine, tyrosine, and cysteine, which are essential in infants but not older patients.

^bBecause linoleic acid represents 54% of the fatty acid in soy bean oil and 77% in safflower oil, 7% to 10% of calories must be provided as fat emulsion. This can be given daily over 24 hours (preferred in patients predisposed to sepsis and preterm infants) or two to three times weekly.

^cThese doses are guidelines and all patients should be evaluated individually for appropriateness of dosing. For example, patients with short bowel syndrome may require large doses of magnesium and patients with renal insufficiency may require none to low amounts of potassium, calcium, phosphorous, and magnesium.

^dFor patients receiving MVI-12, it may be desirable to add vitamin K.

^eMVI, multivitamin.

Table 97-2 Situations That Alter Maintenance Fluid Requirements

| Situation | Mechanism | Extent of Change (%) |
|-------------------------------------|-----------------------------|----------------------|
| Extreme prematurity | ↑Skin losses | Varies |
| Radiant warmer use | ↑Insensible water loss | 20–40 |
| Croup tent | ↓Evaporative water loss | 20–50 |
| Diarrhea or vomiting | ↑GI loss | Varies |
| Fever | ↑Insensible water loss | 10–15°C |
| Renal dysfunction | ↑Or ↓renal loss | Varies |
| Hyperventilation | ↑Pulmonary evaporative loss | Varies |
| Phototherapy for hyperbilirubinemia | ↑Insensible water loss | 10–20 |
| GI tract suction or ostomy | ↑GI loss | Varies |
| Mechanical ventilation | ↓Insensible water loss | 20–30 |

GI, gastrointestinal.

the need for immediate IV rehydration. Normal serum sodium concentration ranges from 135 to 145 mEq/L of sodium; thus, normal saline approximates the sodium concentration of plasma and is often used as a volume expander. In this patient, 10–20 mL/kg of normal saline (12.9 kg × 10–20 mL/kg = 129–258 mL) should be infused as rapidly as possible to establish normal blood pressure. For symptomatic patients, including those with seizures, the serum sodium concentration should be increased acutely only to the degree necessary to abate symptoms.

CALCULATION OF REQUIREMENTS

4. Calculate H.S.'s fluid and electrolyte needs. Her serum electrolyte results were as follows: Na, 128 mEq/L (normal, 135–145 mEq/L); K, 3.1 mEq/L (normal, 3.5–5 mEq/L); Cl, 88 mEq/L (normal, 102–109 mEq/L); and HCO₃⁻, 30 mEq/L (normal, 22–29 mEq/L).

[SI units: Na, 128 mmol/L (normal, 135–145); K, 3.1 mmol/L (normal, 3.5–5); Cl, 88 mmol/L (normal, 102–109); HCO₃⁻, 30 mmol/L (normal, 22–29)]

In addition to normal maintenance fluids, H.S. must be provided with fluids and electrolytes to replace her deficit secondary to dehydration and compensate for increased insensible water loss because of fever. Each component of the fluid can be calculated separately, using Equations 97-2 to 97-4.

$$\text{Fluid deficit} = \text{Weight loss (kg)} \times 1,000 \text{ mL/kg} \quad (97-2)$$

$$\text{Fever adjustment} = 10\% \times \text{Maintenance for each } ^\circ\text{C} > 30^\circ\text{C} \quad (97-3)$$

$$(\text{CD} - \text{CO}) \times F_d \times \text{Weight} = \text{mEq required} \quad (97-4)$$

where *CD* is the concentration of sodium desired (mEq/L), *CO* is the concentration observed (mEq/L), *F_d* is the apparent distribution factor as a fraction of body weight (Table 97-5), and weight is the baseline weight before illness (kg). In consideration of both maintenance needs and current deficits, fluid and electrolyte requirements for H.S. would be estimated as follows.

Fluid

$$\begin{aligned} \text{Maintenance} & 1,000 \text{ mL} + (50 \times 2.9) = 1,145 \text{ mL} \\ \text{Fever} & 2^\circ\text{C} \times 0.1 (1,145) = 229 \text{ mL} \\ \text{Deficit} & 1.5 \text{ kg} \times 1,000 \text{ mL/kg} = 1,500 \text{ mL} \\ \text{Total fluid} & = \underline{2,874 \text{ mL}} \end{aligned} \quad (97-B)$$

Sodium

$$\begin{aligned} \text{Maintenance} & 3 \text{ mEq/kg} \times 12.9 \text{ kg} = 38.7 \\ \text{Deficit} & (135 - 128 \text{ mEq/L}) \times \\ & 0.6 \text{ L/kg} \times 12.9 \text{ kg} = 54.2 \\ \text{Total sodium} & \sim 93 \text{ mEq} \end{aligned} \quad (97-C)$$

Chloride

H.S. has a mild metabolic alkalosis as evidenced by her serum chloride of 88 mEq/L and her serum bicarbonate of 30 mEq/L. This is most likely because of the loss of hydrogen and chloride in her vomitus. Thus, both the sodium and potassium replacements should be administered as chloride salts.

Potassium

Potassium is primarily an intracellular ion. It moves in and out of cells in exchange for hydrogen ions to maintain a normal blood pH. Therefore, in metabolic alkalosis, the intracellular shift of potassium will decrease the serum potassium concentration. When the pH normalizes, as will occur with rehydration, the hydrogen ions will move intracellularly and the potassium will move extracellularly, thus causing the serum potassium concentration to increase. Additionally, potassium is also excreted by the kidney in exchange for hydrogen ion conservation. These factors make the serum potassium concentration difficult to interpret. Intravascular volume depletion causes hypoperfusion of the kidney and can result in acute renal failure; therefore, the prudent approach is to give no potassium until urine output is clearly established. Then, only maintenance doses of potassium should be administered until a normal acid

Table 97-3 Body Fluid Volumes and Electrolyte Content

| Source | Volume (L/day) | Na ⁺ (mEq/L) | K ⁺ (mEq/L) | Cl ⁻ (mEq/L) | HCO ₃ ⁻ (mEq/L) |
|-----------------|----------------|-------------------------|------------------------|-------------------------|---------------------------------------|

Table 97-4 Clinical Signs of Dehydration

| Severity | Dehydration (%) | Psyche | Thirst | Mucous Membranes | Tears | Anterior Fontanel | Skin | Urine-Specific Gravity |
|----------|-----------------|-----------------------------|----------|------------------|---------|-------------------|---------|------------------------|
| Mild | <5 | Normal | Slight | Normal to dry | Present | Flat | Normal | Slight change |
| Moderate | 6–10 | Irritable | Moderate | Dry | ± | ± | ± | Increased |
| Severe | 10–15 | Hyperirritable to lethargic | Intense | Parched | Absent | Sunken | Tenting | Greatly increased |

base and fluid status are established and the serum potassium can be assessed more accurately. Hence, H.S. should receive approximately 26 to 39 mEq of potassium (2–3 mEq/kg 12.9 kg) once urine flow is established.

ADMINISTRATION OF FLUID REQUIREMENTS

5. How should these calculated needs be given?

Requirements for the first 24 hours of parenteral fluid therapy should provide approximately 2,875 mL of fluid (maintenance fluid, fever replacement, and deficit replacement). In addition to fluid, at least 93 mEq of sodium (maintenance needs and deficit replacement) should be provided in the first 24 hours. It is important to provide sufficient amounts of sodium and water.

Rehydration fluids are usually dispensed in volumes less than the 24-hour requirement. This is to prevent wasting IV fluids caused by changes in electrolyte needs during replacement therapy. Because this patient requires approximately 3 L of fluid, only 1 L would be prepared initially, and this would likely consist of dextrose 5% and 0.2% NS (or greater). Approximately 15 mEq/L of potassium would be added to the next liter of IV solution if the patient had a reasonable urine output.

The infusion rate should be calculated to provide one-third of the daily maintenance fluid plus one-half of the deficit replacement during the first 8 hours. The remainder of the maintenance fluid (adjusted for fever) and deficit replacement should be administered over the next 16 hours. Usually, serum electrolytes are monitored every 6 to 8 hours during rehydration therapy to ensure that appropriate electrolytes are being provided. Usually, the concentration of serum electrolytes is monitored frequently during fluid replacement therapy of deficits. In general, the serum sodium concentration should not be increased > 10 to 12 mEq/L/day. After the initial fluid deficits are replaced, the infusion rate of the IV fluid would be decreased to 48 mL/hour (1,152 mL or approximately maintenance fluid rate).

Clinical Presentation: Diarrhea

6. S.B., a 4-month-old, 5.9-kg boy, is seen in his pediatrician’s office because of a 4-day history of diarrhea (five to eight large, liq-

uid stools each day). On a well-child visit 4 weeks ago, his weight was 6 kg. Since the onset of diarrhea, he has only been receiving oral rehydration fluids. Physical examination reveals the following: temperature, 39.8°C; pulse, 110 beats/minute (normal, 80–160 beats/minute); respirations, 45 breaths/minute (normal, 20–40 breaths/minute); and BP, 100/58 mmHg (normal, 75–105 mmHg systolic and 40–65 mmHg diastolic). His skin is pale, warm, and dry. He is very irritable, and his mucous membranes are dry. S.B.’s serum electrolytes are as follows: Na, 159 mEq/L (normal, 135 to 145 mEq/L); K, 3.3 mEq/L (normal, 3.5–5.0 mEq/L); Cl, 114 mEq/L (normal, 102–109 mEq/L); and HCO₃⁻, 12 mEq/L (normal, 22–29 mEq/L). Correlate S.B.’s history and physical findings with the reported laboratory values.

[SI units: Na, 159 mmol/L (normal, 135–145); K, 3.3 mmol/L (normal, 3.5–5.0); Cl, 114 mmol/L (normal, 102–109); HCO₃⁻, 12 mmol/L (normal, 22–29)]

Diarrheal fluid losses commonly contain high concentrations of bicarbonate, accounting for S.B.’s metabolic acidosis. This, in turn, has resulted in a rapid respiratory rate as the body attempts to compensate for the acidosis by eliminating carbon dioxide. The increased insensible water losses of fever and tachypnea have resulted in the loss of water in excess of sodium, producing hyponatremia.

ACUTE MANAGEMENT

7. How will S.B.’s management differ from that of H.S. (see Questions 3–5)?

Unlike H.S., S.B. has relatively normal vital signs and will not require rapid fluid replacement to correct hypotension. Hyponatremia in S.B. indicates fluid losses in excess of sodium and this should be corrected. With hyponatremia, the central nervous system (CNS) increases intracellular osmolarity load to prevent intracellular dehydration of cells in the CNS. Rapid correction of hyponatremia can cause excessive movement of water into the cells of the CNS and has been associated with seizures. Therefore, S.B.’s fluid and electrolyte deficits should be corrected over 2 to 3 days at a consistent rate, rather than rapidly. In general, serum sodium should not be decreased >2 mEq/hour (maximum, 15 mEq/L/day).

CALCULATION OF REQUIREMENTS

8. Estimate S.B.’s fluid and electrolyte requirements to correct his deficits.

S.B.’s requirements are estimated using the same methods described in Question 4. First, the approximate extent of dehydration must be estimated. S.B.’s weight of 6 kg at the time of his well-child visit at 3 months of age was at the 50th percentile. If his growth has continued at this rate, his current pre-illness

Table 97-5 Electrolytes and Apparent Distribution

| Electrolyte | F _d (L/kg) |
|-------------|-----------------------|
| Sodium | 0.6–0.7 |
| Bicarbonate | 0.4–0.5 |
| Chloride | 0.2–0.3 |

F_d, apparent distribution factor as a fraction of body weight.

weight should be approximately 6.5 kg. This weight should be used to calculate his maintenance requirements. Thus, his water deficit is approximately 0.6 L, or 9%. Using this approximation, his fluid and electrolyte requirements can be estimated as follows.

Fluid

Maintenance $6.5 \times 100 \text{ mL/kg} = 650 \text{ mL/24 hour}$
 Fever $2.8^\circ\text{C} \times 0.1 (650 \text{ mL}) = 182 \text{ mL/24 hour}$ (97-D)
 Deficit $600 \text{ mL/3 days} = 200 \text{ mL/24 hour}$
 Total daily needs = 1,032 mL or 43 mL/hour

Sodium

Maintenance $3 \text{ mEq/kg} \times 6.5 \text{ kg} = 19.5 \text{ mEq/24 hr}$
 Deficit This is calculated at total body deficit (normal – actual)
 Normal $145 \text{ mEq/L} \times 0.6 \text{ L/kg} \times 6.5 \text{ kg} = 566 \text{ mEq}$ (97-E)
 Actual $159 \text{ mEq/L} \times 0.6 \text{ L/kg} \times 5.9 = 563 \text{ mEq}$
 Deficit = 3 mEq
 or 1 mEq/day

Potassium

As noted in Question 4, the serum potassium value of 3.3 mEq/L may not be indicative of S.B.'s total body potassium status. A metabolic acidosis in S.B. should have facilitated the movement of hydrogen ions into the cells and the movement of potassium from the intracellular to the extracellular space. Thus, the serum potassium of 3.3 mEq/L probably indicates a total body deficit. Therefore, a maintenance potassium dosage of 13 to 20 mEq/day (~2 to 3 mEq/kg) of potassium should be given. Serum electrolytes should be measured every 8 to 12 hours and the intake of all electrolytes should be readjusted based on the results.

Bicarbonate

With metabolic acidosis, bicarbonate should be administered as well. No maintenance amount is customarily given, but deficit replacement is calculated in a manner similar to that used for sodium (Table 97-5). The volume of distribution of bicarbonate is 0.5 L/kg. For S.B. the bicarbonate deficit is as follows:

$$\begin{aligned} \text{Calculated Deficit Requirement} &= (\text{Normal} - \text{Actual}) \times \text{Vd} \times \text{Wt} \\ &= (23 - 12) \text{ mEq/L} \times 0.5 \text{ L/kg} \times 65 \text{ kg} \\ &= 36 \text{ mEq} \end{aligned} \quad (97-F)$$

Initially, about half this amount should be replaced over the first 8 to 12 hours. His serum electrolytes then should be reassessed, and the dosages adjusted accordingly. The entire bicarbonate deficit need not be replaced at once because other compensatory mechanisms will contribute to endogenous bicarbonate sparing.

REPLACEMENT FLUID COMPOSITION

9. Recommend an appropriate replacement fluid for S.B.'s therapy.

S.B.'s fluid and electrolyte maintenance requirements and deficits should be corrected with dextrose 5% and approximately 0.2% NS with half as the chloride salt and half as NaHCO_3 . An infusion of this solution at 43 mL/hour should correct approximately half the calculated fluid and bicarbonate

deficits within 24 hours in addition to his normal daily doses. After he urinates, 15 mEq/L KCl can be added to the next liter of solution to provide approximately 2.6 mEq/kg/day to this patient. The concentration of serum electrolytes should be measured often and the concentration of electrolytes in the replacement fluid should be adjusted every 8 to 12 hours based on laboratory results. The amount of fluid replacement should be modified based on whether this patient's diarrhea has resolved and fever has subsided.

ADMINISTRATION OF REQUIREMENTS

10. By what route should the fluid calculated above be administered?

Rehydration of the dehydrated patient may be achieved by either the oral or intravenous route. In some patients, vomiting may preclude effective oral rehydration. If the losses are diarrheal and no problem with vomiting exists, the oral route may be a cost-effective alternative to the parenteral route. Various solutions have been used to rehydrate children orally. In an asymptomatic dehydrated child, the sodium concentration of an oral rehydration fluid should contain at least 70 mEq/L of sodium.²⁻⁴

The composition of several products is shown in Table 97-6. A glucose concentration of 2% optimizes water and electrolyte absorption from the GI tract⁵; more concentrated glucose solutions can worsen rather than ameliorate diarrhea. Use of the oral route and the more concentrated sodium solutions may allow safe rehydration of hypernatremic dehydration in a shorter time frame than the 2 to 3 days previously noted.^{5,6}

S.B.'s output must be measured to account for ongoing fluid loss. This often is accomplished by weighing the baby's diapers when they are dry and again when they are full. Composition of additional replacement fluids can be determined by using the average composition of the patient's losses (Table 97-3). As an alternative, the composition of the losses can be determined by actual laboratory measurement. If prolonged therapy is necessary, specific analyses are recommended because of the wide range of normal values for diarrheal stool and other GI tract fluids. Because frequent adjustments may be necessary, replacement fluid should be administered separately if PN is being used as a maintenance solution.

INFANT NUTRITION

Growth assessment is an important focus of pediatric health care during the first year of life. With the exception of the intrauterine period, the most rapid growth occurs during the

Table 97-6 Composition of Oral Rehydration Products

| Product | Na^+ (mEq/L) | K^+ (mEq/L) | Cl^- (mEq/L) | Bicarbonate Source (mEq/L) | Carbohydrate (%) |

WHO, World Health Organization.

first year. On average, a normally growing infant gains approximately 30 g/day. Typically, healthy infants weigh approximately three times their birth weight by their first birthday. Caloric requirements can be estimated using the formula provided in Table 97-1.

The American Academy of Pediatrics (AAP) has suggested that infant feeding be divided into three stages.⁷ In the nursing period, only liquids are provided. During the transitional period, solid foods are introduced, but human milk, or commercially prepared infant formula, still provides the major source of the infant's caloric and nutrient supply. In the modified adult period, most nutrition is derived from the solid foods consumed by other household members.

At birth, the human GI tract is adapted for the consumption of a human milk-based diet. Intestinal lactase is present from 36 weeks' gestation and exhibits its maximal activity during infancy. Pancreatic amylase secretion is low, and the bile salt pool is decreased relative to older persons, resulting in decreased fat absorption.⁸ Human milk provides nutrients in their most usable form for the developing GI tract.

Human Milk Feeding

11. M.E.'s mother will breast-feed her infant. What are the nutritional implications of this decision for M.E.?

Human milk is the ideal food for a human infant. There are three phases to human milk production. During the first 5 days of lactation, a viscous, yellow liquid known as *colostrum* is produced. Colostrum is rich in protein, minerals, and other substances (e.g., immunoglobulins). During the next 5 days, transitional milk is produced; in the last phase, mature human milk is produced. The exact nutritional content of human milk varies from mother to mother; however, mature human milk provides sufficient protein, minerals, and calories regardless of the mother's nutritional status.⁹ Mature human milk generally provides 70 kcal/100 mL and fat accounts for >50% of the caloric content.¹⁰ The fat in human milk is highly digestible and absorbable.¹¹ An additional 40% of calories is provided as carbohydrates, primarily in the form of lactose, and the remaining 10% is provided as protein. Whey and casein are the two primary proteins in mature human milk, with whey being the major protein component (whey-to-casein ratio of 55:45).⁸ Human milk is of such biologic quality and bioavailability that adequate growth can be attained with a lower overall intake of protein than is provided by commercially prepared infant formulas, which contain lower whey-to-casein ratios.^{9,11}

The iron content of human milk is inadequate for term infants; however, supplementation generally is unnecessary in the breast-fed infant.¹² Regardless of maternal status, the vitamin D and fluoride contents of human milk are inadequate. Thus, M.E. will require 400 IU of vitamin D and 0.25 mg/day of fluoride while she is exclusively breast-fed.^{9,13}

12. Aside from nutrients, what other benefits are associated with human milk and breast-feeding?

Human milk provides the infant with protection against a wide variety of infectious diseases, including otitis media, diarrhea, pneumonia, and bronchiolitis. Evidence further suggests that human milk provides protection against noninfec-

tious disorders, such as allergies, inflammatory bowel disease, insulin-dependent diabetes mellitus, and sudden infant death syndrome.¹⁴ Human milk contains immunologically active cellular components and antibodies. These include secretory IgA, both T- and B-lymphocytes, macrophages, and neutrophils.^{9,11} The lipases and amylase present in human milk may facilitate digestion of fat and carbohydrates in the still developing GI tract. Proteins present in human milk serve as carriers for trace minerals and facilitate their absorption.⁹ Oligosaccharides and glycopeptides may promote the colonization of the GI tract by *Lactobacilli* and decrease colonization by *Bacteroides*, *Clostridia*, enterococci, and gram-negative rods, all of which may be pathogenic.¹¹

13. What potential complications are associated with breast-feeding? What instructions should be given to M.E.'s mother?

Complications associated with breast-feeding are few; however, there are some potential problems. "Breast milk jaundice" associated with an indirect (unconjugated) hyperbilirubinemia can occur in the breast-fed infant during the first week of life, and generally resolves by the fourth week of life. Although the infant's skin, sclera, and palate become yellow, this is generally not a dangerous condition. Nevertheless, if the bilirubin level becomes too high, the infant could develop an encephalopathy known as kernicterus. Therefore, the mother should temporarily stop breast-feeding and feed the infant formula until the jaundice starts to resolve.

Some maternal infections have the potential to be transmitted to the infant during breast-feeding. Human immunodeficiency virus (HIV) and human T-lymphotropic virus 1 (HTLV-1) can be transmitted via breast milk and, therefore, maternal infections with these viruses are contraindications to breast-feeding.¹⁵ Other viruses, such as herpes simplex virus, can be transmitted if contact with active lesions occurs during breast-feeding. Similarly, some medications taken by the mother are detectable in her breast milk. Only a few agents (e.g., antineoplastics, radiopharmaceuticals, ergot alkaloids, iodides, atropine, lithium, cyclosporine, chloramphenicol, bromocriptine), however, are absolute contraindications to breast-feeding.¹⁵ (See Chapter 46, Obstetric Drug Therapy for additional information concerning the transfer of medications and chemicals into breast milk.)

14. E.R.'s mother decides not to breast-feed her infant. She received a sample package of infant formula at the time of her discharge from the hospital. How are these products prepared and how do they differ from human milk?

Examples of infant formulas and their individual components are provided in Table 97-7. According to AAP guidelines for commercially prepared infant formula composition, formula should provide 20 kcal/oz; osmolality should be between 300 and 400 mOsm/L; protein quantity should be a minimum of 1.8 g/100 kcal and should not exceed 4.5 g/100 kcal; and fat quantity should be between 3.3 and 6 g/100 kcal, supplying between 30% and 54% of calories. Infant formulas generally begin with a cow's milk base; however, intolerance to pure cow's milk has resulted in several modifications. The predominant protein in cow's milk is casein, which is more difficult for infants to digest than the human milk protein, whey. Consequently, infant formulas generally have less casein than cow's

MCT, medium-chain triglyceride.

milk, although not to the level of human milk. Casein-to-whey ratios of infant formulas and human milk are compared in Table 97-7. The casein present in cow's milk formulas also may be heat denatured to improve its digestibility. In addition, the fat source in cow's milk is replaced by one of several vegetable oils allowing for easier digestion. Last, the carbohydrate source in cow's milk-based formula is supplemented with lactose or sucrose because the lactose content of cow's milk is only 50% to 70% of that in human milk. Soy-based and protein hydrolysate formulas are available for infants who are intolerant of cow's milk-based formulas.

Soy-based formulas use soybean as the protein source. The soy is heat treated to enhance protein digestibility and improve the bioavailability of some nutrients. Although nutrients, such as methionine, zinc, and carnitine, are still present, their concentrations are relatively low. Therefore, methionine is routinely added to all soy-based formulas by the manufacturer. Zinc and carnitine may not be added and exogenous supplementation may be necessary. Soy-based formulas substitute sucrose, corn syrup, or a combination of the two for lactose as the carbohydrate source. Additionally, soy protein formulas are more expensive than cow's milk-based formulas. The AAP recommends that the use of soy-based formula be limited to patients with primary lactase deficiency (galactosemia); patients with secondary lactose intolerance from enteric infections or other causes; vegetarian families in which animal protein formulas are not desired; and infants who are potentially cow milk protein allergic, but who have not demonstrated clinical manifestations of allergy. Long-term use of soy-based formulas in premature and low birth weight infants should not be recommended. Soy-based formulas have aluminum contamination, and have been associated with the development of rickets. Soy-based formulas are also not recommended for infants with documented allergic reactions to cow's milk protein because of the potential for cross-antigenicity between the two proteins. Soy protein formulas are not recommended for the routine management of colic.¹⁶

Elemental formulas, made with hydrolysate formulas, are another option for infants who are intolerant of cow's milk-based formulas. The milk proteins (i.e., casein and whey) are heat treated and enzymatically hydrolyzed to enhance digestibility of protein hydrolysate formulas, which are fortified with additional amino acids that are lost during processing. As with soy protein formulas, protein hydrolysates substitute sucrose, tapioca, or corn syrup for lactose as the carbohydrate source. Protein hydrolysate formulas often include significant amounts of medium-chain triglycerides (MCT) because they are easily absorbed. Because the proteins are extensively hydrolyzed, these formulas probably are the least allergenic of the infant formulas and, therefore, may be appropriate for infants with true allergy to cow's milk protein. Nevertheless, prospective studies on the safety of such a substitution in human infants have not been undertaken because it would be unethical to intentionally expose infants with documented allergies to a potential allergen. Protein hydrolysate formulas are the least palatable of the available pediatric formulas, and are more costly than other formulas.¹⁷

Infant formula is available from the manufacturer in three forms: ready-to-feed form, reconstitutable powder, and concentrated liquid. The ready-to-feed form is the most convenient but also the most expensive. The powder and the concentrated liquid are less expensive; however, both require that predetermined amounts of boiled water be added before use. To save money, some parents will dilute infant formula to a greater extent than is recommended to make the formula last longer. This practice should be discouraged because excessive free water intake by infants <1 year of age may result in hyponatremia and, ultimately, seizures. Similarly, supplementing an infant's diet with free water, for whatever reason, may also result in hyponatremia and seizures and should be discouraged. Recently, use of dry powder formula in the neonatal intensive care unit has been associated with severe bacterial infection. Because of this, dry powder formula in neonatal intensive care patients should be used cautiously.¹⁸

Introduction of Pure Cow's Milk

15. At her 2-month-old, well-child checkup, E.R. is found to have a hematocrit (Hct) of 33% (normal, 35%–45%). After questioning her mother, the pediatrician learns that E.R. was taken off infant formula 1 month ago and changed to whole cow's milk to decrease food costs. How are these two findings related? What should be added to E.R.'s diet?

[SI unit: hematocrit, 0.35 (normal, 0.35–0.45)]

Pure cow's milk, straight from the dairy counter in the grocery store, is not recommended for infants <1 year of age. Unlike human milk, the iron in cow's milk is present in inadequate concentrations and absorbed poorly from the human GI tract. For this reason, most infant formulas are fortified with iron. Cow's milk has been associated with GI blood loss in infants <140 days of age.¹⁹ When the milk is heated to a higher temperature than the usual pasteurization temperature, as it is in formula preparation, the association of cow's milk with GI bleeding is no longer present; therefore, the component responsible for the blood loss appears to be a heat-labile protein. Furthermore, cow's milk contains excessive amounts of solute that cannot be eliminated by the immature kidney. Also, cow's milk does not contain taurine, an amino acid that is important in retinal development.

To treat E.R.'s anemia, iron should be added to her diet. This can be done by changing back to an iron-fortified infant formula, feeding her an iron-fortified cereal, or giving a therapeutic ferrous sulfate liquid medication. The appropriate iron replacement dose for severe anemia is 4–6 mg/kg/day of elemental iron in divided doses with follow-up of the infant's hemoglobin and hematocrit.

Introduction of Solid Foods

16. At her 4-month-old, well-child checkup, M.E.'s mother asks her pediatrician about the introduction of "baby foods" into M.E.'s diet. When and how should solids be introduced?

Human milk or commercially prepared infant formula provides adequate nutrition for an infant for the first 12 months of life. Introduction of solid foods before the age of 4 months, although common in the past, is discouraged because the younger infant is unprepared to swallow foods other than liquids. Solids (first cereals, then fruits and vegetables) should be introduced when the child has good control of the head and neck movements (i.e., usually at the age of 4–6 months).⁷ Preferably, one new food should be introduced at a time, at 1-week intervals, to allow assessment of food allergy.

Therapeutic Formulas

Phenylketonuria

17. L.B. is a 2-week-old infant whose newborn screen is positive for phenylketonuria (PKU). Discuss the concepts behind the production of therapeutic formulas and the dietary management of patients with inborn errors of metabolism. How must L.B.'s diet be modified?

Inborn errors of metabolism are disorders in which an enzyme or its cofactor is absent or insufficient to meet metabolic

demands. As a result, one or more precursor compounds in a metabolic pathway can accumulate before the defective step. Correspondingly, one or more metabolic products that normally would have been generated after the defective step in the metabolic pathway are not sufficiently available.

The dietary management of metabolic errors is based on the following strategies:

- Reduce the intake of a precursor compound that cannot be metabolized.
- Supplement the deficient compounds that would have been produced if the normal metabolic pathway had not been blocked.
- Add a substrate that provides an alternative pathway for elimination of an accumulated toxin.

Therapeutic formulas are designed to reduce the intake of precursor compounds or to provide the deficient metabolic end product.

When hydroxylation of phenylalanine to tyrosine does not take place, phenylalanine accumulates in the blood and results in mental retardation. Because PKU has been diagnosed in L.B., his diet should be modified using a formula containing little or no phenylalanine (e.g., Lofenalac, Phenex-1, Phenyl-Free). The tyrosine deficiency of PKU also can be managed by the addition of tyrosine to the phenylalanine-free therapeutic formulas that are available for patients with PKU. When L.B. progresses to solid foods, protein must be provided from predominately phenylalanine-free sources; therefore, patients with PKU should take in only minimal protein from table foods.²⁰

Other Metabolic Errors

18. What other metabolic errors present in infancy require a specialized diet?

Other metabolic errors present in infancy include galactosemia (galactose cannot be metabolized to glucose), homocystinuria (methionine is not converted to cysteine), urea cycle disorders (ammonia detoxification is impaired), and maple syrup urine disease (metabolism of the branched chain amino acids, leucine, isoleucine, and valine is blocked).

These metabolic errors are managed by manipulating the diet.²¹ In galactosemia, the carbohydrate source should not contain galactose or lactose. In homocystinuria, methionine should be present only in quantities sufficient to meet basic requirements, and cysteine should be supplemented. In the urea cycle disorders, protein often is provided only as essential amino acids, and a high-energy diet is provided to maximize the formation of nonessential amino acids from nitrogen and to minimize ammonia production. In maple syrup urine disease, natural protein is fed in small quantities to provide the minimal requirement of branched chain amino acids, and a branched chain-free supplement is added to provide adequate protein intake.

Route of Administration

Nutritional support using the GI tract is the preferred approach when possible. Enteral nutrition provides several advantages. First, interposition of the GI mucosa between the nutrient supply and the circulation allows absorptive function to provide

a homeostatic control. Second, the flow of nutrients from the GI tract to the liver via the portal circulation before reaching the systemic circulation also assists homeostatic control. Third, the lack of enteral nutrition allows normal GI tract flora to overgrow and translocate into the blood, ultimately resulting in bacteremia. Finally, the intestinal mucosa depends on intraluminal absorption for much of its energy supply. Hence, provision of at least a small amount of enteral feeding, referred to as trophic feeds, helps to ensure a healthy GI tract and may facilitate advancement to full enteral feedings at the appropriate time.^{22,23}

Normal oral feeding is the most basic method for patients who are willing and able to eat or drink. Patients whose GI motility, structure, and function are normal but whose oral feeding is prevented by an altered state of consciousness, incoordination of sucking and swallowing, or other conditions that prevent adequate oral ingestion can be fed by a GI tube in intermittent boluses or by continuous infusion.

Bolus tube feedings more closely mimic the normal state. They periodically distend the stomach, which aids in gastric secretion and emptying. When bolus tube feeding is undertaken, the volume of formula required to provide sufficient calories for a 24-hour period is administered through the tube in equal aliquots every 2, 3, 4, or 6 hours. The frequency of administration depends on the patient's age, gastric capacity, and the infant's ability to maintain a normal serum glucose concentration between feedings. In general, younger and more premature infants require more frequent feedings. Intolerance to bolus tube feedings can be manifested as diarrhea, gastroesophageal reflux with emesis, or poor motility. Poor motility usually is apparent when large volumes of feeding, referred to as residuals, remain in the stomach when the next feeding is due.

Continuous tube feedings can be given at a constant rate of infusion by pump into the stomach or duodenum when bolus feedings have failed. This approach may be better tolerated by premature infants and children with diarrhea.²⁴

Patients with intrinsic GI disease (Table 97-8) or malabsorption may require total or supplemental PN. Concurrent administration of low-volume, trophic enteral feedings may provide important nutrients to the gut mucosa even when the parenteral route supplies all of the necessary systemic nutrients.^{22,23} Administration of PN into a peripheral vein is limited to those patients expected to require parenteral feeding only for a short time (i.e., 2 weeks) because the amount of nutrients that can be safely infused peripherally is limited. In patients who require long-term PN, the IV solution is more concentrated and must be administered into a central vein.

Nutritional Assessment

The patient's nutritional status should be assessed before beginning a nutritional support regimen and reassessed at regular intervals during the course of treatment. If the patient previously was well nourished, the goal is to maintain that status until a normal diet can be resumed. In a child who was previously malnourished, an effort should be made to promote "catch-up" growth and to normalize the biochemical nutritional measures. About one-third of children admitted to the hospital are malnourished at the time of their admission.²⁵ Malnutrition in chil-

GI, gastrointestinal.

dren is a risk factor for decreased social skills and impaired intellectual development.²⁶⁻²⁸

Factors used to determine nutritional status in children include dietary history, weight, height, and visceral protein measurements (e.g., albumin, prealbumin, retinol binding protein, transferrin). Other measurements used in adults, such as 24-hour creatinine excretion, 24-hour nitrogen excretion, and nitrogen balance, are reserved for older children because complete collections of urine are difficult to obtain and because the percentage of nonurea nitrogen present in urine is variable in infants.

Anthropometric Measurements

Height, weight, and head circumference are used to determine nutritional status in infants and children. Standards for these measurements have been derived from pediatric patients in the United States and compiled into graphs referred to as growth curves (<http://www.cdc.gov/growthcharts>).²⁹ An individual patient's measurements are compared with the graph of normal values for that specific age group. As prematurely born infants age, a standard growth curve adjusted for prematurity can be used. Using these measurements, comparisons with standards are possible: weight for age, height for age, and weight for height.²⁹ A weight that is below the fifth percentile for the patient's height is considered an indication of acute

malnutrition. Similarly, a height and weight that are below the fifth percentile for the patient's age indicates chronic malnutrition. It is important to consider the height and weight of the child's parents because genetics are important determinants of the height and weight that a child may ultimately achieve. Additionally, the revised growth charts include the body mass index (BMI) for age for children >2 years. The BMI helps identify children at risk for obesity and type 2 diabetes, two problems that have recently become a concern in children.²⁹

Biochemical Measurements

Numerous biochemical indices are used in the assessment of nutritional status. Several, such as the quantitative excretion of compounds such as 3-methyl-histidine and creatinine, are difficult to use in children because they require cumbersome 24-hour urine collections. Also, reliable standards for very young children are unavailable.

Of the biochemical markers of nutritional status, the most readily available and widely used is the serum albumin concentration. Although a low serum albumin can be a specific indicator of protein-calorie malnutrition, albumin's long half-life (20 days)³⁰ makes it an insensitive indicator for developing and resolving malnutrition.

Prealbumin, fibronectin, transferrin, and retinol-binding protein are plasma transport proteins that also can function as biochemical markers of nutritional status.^{30–33} They have the advantage of being more sensitive than albumin to acute nutritional changes because their half-lives are shorter, and they are useful when exogenous albumin infusions are given.³⁴ Nevertheless, transferrin, fibronectin, and retinol-binding protein are influenced by factors other than nutrition (e.g., stress), and are less specific indicators of nutritional status.^{35,36}

Laboratory and Clinical Assessments

The nutritional status of a patient receiving PN should be evaluated at regular intervals (e.g., weekly). The adverse effects of enteral and PN should include evaluations of the patient for signs and symptoms of fluid overload, GI losses (e.g., stool, emesis, ostomy output), and metabolic imbalances. The patient should be weighed and the fluid intake, urine output, and GI losses assessed daily.

Blood and urine glucose concentrations initially should be monitored daily until the patient is stable on a formulation; subsequently, the frequency of monitoring can be reduced. Several laboratory tests also should be monitored routinely in those receiving PN (Table 97-9). The frequency of monitoring the subjective and objective data of a patient should be modified based on the clinical condition of the patient.

Clinical Presentation: Nutritional Assessment

19. T.C., a 4-month-old, lethargic boy, is seen in his pediatrician's office for routine well-baby care. At examination, he has a moderately distended abdomen and dry mucous membranes. No other remarkable abnormalities are noted. His weight is 6.5 kg (50th–75th percentile for age). At a previous well-baby visit when he was 2 months old, T.C. weighed 5.6 kg (75th percentile for age), and his length was 57 cm (50th percentile for age). His mother reports that for the past 5 to 7 days, he has had five to eight large, liquid stools per day. His diet has not been changed and consists

Table 97-9 Routine Laboratory Monitoring of Pediatric and Neonatal Parenteral Nutrition^a

| Test | Frequency |
|--|---|
| Electrolytes, glucose, BUN, SrCr | Daily until stable, then 2–3 times/wk |
| Calcium | 1–2 times/wk |
| Phosphorus | 1–2 times/wk |
| Magnesium | 1–2 times/wk |
| Triglycerides | QOD until stable on maximal fat dose, then weekly |
| PA or RBP | Weekly |
| Total protein, albumin | Weekly if PA, RBP not available |

| Bilirubin (total, direct) ^a | Weekly |
| Hgb, WBC count | Weekly |
| AST, ALT, GGT | Monthly |

^aBilirubin (indirect) daily in the newborn, until normal.

ALT, alanine aminotransferase; AST, aspartate aminotransferase; BUN, blood urea nitrogen; GGT, γ -glutamyl transpeptidase; Hgb, hemoglobin; PA, prealbumin; RBP, retinol binding protein; SrCr, serum creatinine; WBC, white blood cell.

of 5 to 6 oz of a commercial, infant formula every 4 hours around the clock. He is to be hospitalized for evaluation of his diarrhea and weight loss and for fluid and nutritional management.

After correction of his initial fluid and electrolyte deficits, an assessment of his nutritional status shows the following: weight, 6.5 kg (50th–75th percentile); length, 62 cm (50th percentile); albumin, 3.8 g/dL (normal, 4–5.3 g/dL); and prealbumin, 7 mg/dL (normal, 20–50 mg/dL). What do these data suggest about the nature of T.C.'s malnutrition?

[SI units: albumin, 38 g/L (normal, 40–53); prealbumin, 70 mg/L (normal, 200–500 mg/L)]

If T.C. had continued to gain weight at his previous rate, his weight, extrapolated from the appropriate growth chart, should be approximately 7.2 kg. His growth in length has continued to progress at the same rate. Thus, the decrease in weight for age with a normal progression in length for age indicates malnutrition of a relatively short duration. This is further validated by a near-normal serum concentration of albumin with a decrease in prealbumin.

Role of Enteral Nutrition in Chronic Diarrhea

20. After initial IV rehydration and receiving nothing by mouth (NPO) for 48 hours, T.C.'s stool output has decreased dramatically. Is this characteristic of infants with chronic diarrhea? Should enteral intake be initiated?

A prompt decrease in stool output when enteral intake is stopped is typical of infants with chronic diarrhea. Nonetheless, evaluation of bowel function and adaptation has shown that enteral nutrition is superior to PN with regard to histologic recovery, improvement of D-xylose absorption,³⁷ protein absorption, and disaccharidase activity.^{38–40} In fact, improvement in histology or absorptive function might not occur until enteral nutrients are given.^{38,39} Thus, for T.C., every effort should be made to provide some nutrition enterally, whether this route is used exclusively³⁸ or in combination with supplemental PN.⁴⁰

Choice of Formula

21. What type of enteral formula should be chosen for T.C.?

The enteral regimen should be initiated with a lactose-free formula, such as an elemental formula or a soy-based formula. Although any soy-based formula would be appropriate, Isomil DF is a soy-based formula with added fiber that is indicated for infants with diarrhea. Infants with chronic diarrhea can have small bowel mucosal damage and decreased disaccharidase activity.^{39,40} Carbohydrate absorption depends on digestion of disaccharides and polysaccharides to monosaccharides through disaccharidase activity in the intestinal lumen. Substitution of free glucose orally may overcome the problem of carbohydrate digestion and absorption. Administration of large amounts of oral glucose should be limited, however, because of its osmotic effect and potential to worsen diarrhea. Furthermore, incompletely absorbed carbohydrate is available to colonic bacteria for fermentation, the end products of which can produce diarrhea through colonic irritation.

Unlike carbohydrate, protein rarely causes diarrhea, but the mucosal damage present in patients with chronic diarrhea, such as T.C., can reduce the absorptive surface area so that protein malabsorption may occur. This can be minimized through the administration of a formula containing protein in the form of dipeptides and tripeptides, which are absorbed more efficiently than free amino acids.⁴¹

Dilution of hypertonic formulas to half strength may improve formula tolerance.³⁸ The concentration is increased in a step-wise fashion to full strength if there is no carbohydrate malabsorption and if stool output is not excessive (defined by Orenstein as $\geq 40\%$ of enteral intake).³⁸ Tolerance may be improved by continuous infusion of the enteral product.²⁴ If enteral refeeding results in the return of diarrhea, fluid and electrolytes must be replaced with an equal volume of an IV solution of similar electrolyte composition to the stool loss.³⁸

Monitoring

22. How can T.C.'s tolerance to the formula and his recovery of intestinal function be assessed?

Malabsorption or formula intolerance can be assessed by stool studies, which would include assessing for the presence of reducing substances and stool pH. Lactose is a reducing sugar and its presence in stool is an assessment of carbohydrate absorption. The bacterial fermentation products of malabsorbed carbohydrates can result in a decreased stool pH, which suggests malabsorption. To further evaluate carbohydrate absorption D-xylose may be given orally; a blood sample is drawn 4 to 5 hours later to determine the amount absorbed. This test may be of initial prognostic value in predicting which patients will require prolonged courses of treatment.³⁷ More than 5% of ingested fat in a stool collection (usually 3 days) is indicative of fat malabsorption. All these tests can be followed serially during treatment to help guide the refeeding process.

Reinstitution of Standard Formula

23. Once the diarrhea has resolved and the enteral diet is well tolerated, how should standard infant formula be reinstated for T.C.?

Standard formula feedings are restarted somewhat arbitrarily in patients such as T.C., although the D-xylose absorp-

tion test may be a useful guide.^{37,38} The diarrhea should have resolved completely, and full maintenance fluid and caloric intake should be established using an enteral elemental or soy-based formula. Regardless of the time chosen, a gradual step-wise conversion is suggested. A small volume of standard formula is substituted for an equal volume of elemental or soy-based formula and the substitution volume is increased daily until the elemental or soy-based formula is eliminated completely from the regimen.

If a specific nutrient intolerance has been identified, a standard formula that does not contain that nutrient must be selected. For example, a patient with cow's milk protein intolerance may require a soy protein formula or an elemental formula.

Pediatric Parenteral Nutrition

Nutrient Requirements

The basic requirements for a parenteral nutrient regimen are listed in Table 97-1. These guidelines for the initiation of a nutrient regimen should be individualized to specific patient needs because requirements can vary from patient to patient. The correct regimen for any specific patient is that which supplies sufficient nutrients to promote a normal rate of growth without toxicity. In particular, patients with ongoing, abnormal nutrient losses may require much larger doses of certain nutrients. Individualization of the nutrient prescription cannot be overemphasized.

Many of the requirements listed in Table 97-1 apply to nutrients administered by the enteral route as well. In some instances, the absorption of a particular nutrient from the GI mucosa is incomplete and enteral requirements are substantially higher. This is particularly true of the major minerals (calcium, magnesium, and iron) and trace elements.⁴² In some cases, parenteral doses may be greater than enteral doses to achieve the same blood concentration.⁴¹

Indications

Parenteral nutrition is indicated for any patient unable to take in sufficient nourishment to maintain normal growth. Some specific indications are listed in Table 97-8.

Very Low-Birth-Weight Infants

Extremely premature infants require specialized nutritional support for two distinct reasons. First, the third trimester in utero is a time of rapid growth and accumulation of protein, glycogen, fat, and minerals.⁴³ The infant born in the very early stages of the third trimester does not accumulate these stores and, therefore, must receive nutrients earlier than a more mature infant. Second, extreme prematurity is associated with poor coordination of the suck and swallow reflex, poor GI motility, and incomplete absorption.⁴⁴ Therefore, enteral nutrients may need to be administered via an orogastric or nasogastric tube, and PN supplementation probably will be needed. PN, especially amino acids, should be initiated soon after birth to duplicate intrauterine growth and prevent a catabolic state in the first few days of life. The fetus in utero has a continuous supply of amino acids that is immediately stopped after preterm birth.^{45,46} On the first day of life, a type of PN called "vanilla" PN may be started. "Vanilla" PN does not actually contain vanilla, but the

name relates to the colorless solution. Most PN formulations have multivitamins added that give the solution a yellow coloring, whereas “vanilla” PN does not contain multivitamins. It is prepared as a standardized solution containing amino acids and dextrose and is used for infants weighing <1 kg in the first 24 hours of life. There has been some reluctance to administer amino acids this soon after birth because of increased risk of hyperammonemia, uremia, and metabolic acidosis. Several studies, however, have shown early introduction of amino acids is safe, provides a positive nitrogen balance, and promotes better health outcomes.^{47,48}

Respiratory Distress

Respiratory distress may preclude the ability to consume sufficient nutrients enterally because high respiratory rates prevent coordinated breathing and swallowing. In infants who are hypoxic, or at high risk for hypoxia, aggressive enteral feedings during the acute phase of their illness can increase the likelihood of bowel ischemia. Often, these situations are resolved in 3 to 5 days, but this can rarely be predicted at the outset. Trophic feedings (1–5 mL/hour) are often implemented to maintain GI tract integrity. Nutritional support in such cases is initiated by giving parenteral fluids, which provide dextrose as a caloric source. This allows the infant to conserve endogenous energy substrates, an important consideration for the VLBW infant whose entire body composition may contain a 3- to 4-day energy supply.⁴³ PN should be initiated as soon as it becomes clear the enteral feeding will be impossible for 3 to 5 days or when several days have elapsed and no clear time frame can be determined for the establishment of enteral feeding. Although a short course (5 days) of PN may be used, the quantity of nutrients supplied during the process of initiation and gradual increase to full requirements is so low that extremely short courses may be difficult to justify. Peripheral PN using fat emulsion as a significant source of calories, however, can provide up to 70 kcal/kg and, with appropriate types and amounts of protein, can result in modest weight gain and nitrogen equilibrium.

Gastrointestinal Anomalies

Infants with GI anomalies often require PN because the implementation of enteral feedings may be delayed. For example, GI tract atresias or stenosis can obstruct, or partially obstruct, the lumen of the GI tract. This prevents or slows the passage of fluids and nutrients and can result in vomiting, depending on the location of the obstruction. Similarly, infants with necrotizing enterocolitis have zones of ischemic bowel and are at risk for bowel perforation if fed enterally.⁴⁹ Infants with these disorders need PN until the viability of the entire GI tract can be assured.

Chronic Renal Failure and Hepatic Disease

Chronic renal or hepatic disease requires modification of a normal diet to account for the impaired elimination of nitrogenous waste or impaired protein metabolism. Careful caloric supplementation with a reduced amount of protein may permit normal growth while minimizing excess urea production in an infant with renal failure.

24. Approximately 48 hours after discharge from the hospital, T.C. returns to the emergency department (ED) with abdominal distention and bloody diarrhea. He is diagnosed with postgas-

troenteritis syndrome. T.C. cannot receive nutrients enterally, and PN is to be initiated because he is nutritionally depleted. Describe how a regimen of PN should be instituted in T.C. What aspects of his disease may alter specific nutrient needs?

When initiating PN, the protein (amino acids), glucose (dextrose), fat (lipids or fat emulsion), fluid and electrolyte, mineral, and vitamin components of the regimen are managed as separate entities. In addition, the route of PN delivery is important to consider because the amount of glucose, potassium, and calcium must be limited if the infusion is given peripherally. In general, 12.5% dextrose, 40 mEq/L potassium, and 10 mEq/L calcium are the maximal amounts that should be provided by infusion into a peripheral vein. These nutrients can be increased if a central venous line is placed. The fluids, electrolytes, minerals, and vitamins are initiated at full daily maintenance doses after correction of any pre-existing abnormalities. Protein should be initiated at full daily doses in term infants and children with normal renal and hepatic function. Glucose and fat are started at lower doses and increased daily until requirements are reached. Forgetting to increase doses in T.C. will lead to underfeeding.

Protein should be started in T.C. at full daily requirements of 2 to 3 g/kg/day. Azotemia and acidosis have occurred in infants receiving >4 g/kg/day of protein; however, these complications are rare at the recommended dosage.

Parenteral glucose administration is initiated at 5 to 8 mg/kg/minute (7.2–11.5 g/kg/day). This closely approximates normal endogenous glucose production⁵⁰ and should be tolerated. At normal maintenance fluid rates, 10% glucose represents a generally well-tolerated starting solution for patients of virtually any age or size, except the VLBW infant. In T.C.’s case, the glucose concentration will begin and continue at 10% because of the peripheral line limitations. This concentration of glucose will provide 7.3 mg/kg/minute. If a central line later becomes necessary, the concentration of glucose can be increased by 5% each day until the caloric requirement is met. This glucose increment should be accompanied by blood and urine glucose monitoring. If the blood glucose is ≥ 150 mg/dL or if the urine glucose exceeds “trace” amounts, the PN infusion rate should be decreased by at least 25% and a second IV solution should be added to provide needed fluids and electrolytes. Alternatively, the dextrose concentration can be decreased or insulin can be infused concomitantly and titrated to a desired serum glucose concentration of 120 to 140 mg/dL.

Fat should be initiated at 1 g/kg/day and increased daily by 0.5 to 1 g/kg/day until the maximal dosage of 3 g/kg/day is reached. The daily fat dose should be infused at a constant rate because fats are better tolerated when infused over 24 hours.⁵¹ Serum triglycerides should be monitored every other day while the dose of fat is being increased. Patients with a fasting triglyceride concentration of 150 mg/dL or less may have their fat dose increased. In patients who are receiving inadequate calories, triglycerides may be elevated because endogenous fats are being mobilized. If the triglyceride concentration is >150 mg/dL, the serum sample must be examined visually. A clear sample with a mildly elevated triglyceride concentration probably indicates the use of endogenous fat stores for energy. Conversely, a turbid or lipemic sample indicates the patient’s inability to use the amount of intravenous fat administered. In this case, further increases in the fat dose should be delayed until triglyceride concentrations decrease.⁵²

25. T.C. has a single peripheral IV line. Can the glucose–amino acid solution and the IV fat emulsion be infused through the same IV line?

Not only can they be infused through the same peripheral IV line, but doing so may prolong the patency of the IV site and reduce the likelihood of local complications, such as phlebitis.^{53,54} Lipids dilute the hypertonic glucose–amino acid solution. The fat, however, has two more important effects. It acts as a mechanical barrier to the vascular endothelium and has a local modulating effect on prostaglandin and leukotriene mediators of inflammation.⁵⁴

Special Considerations and Complications

26. J.H., a 4-day-old boy, was born at 31 weeks' gestation. His birth weight was 1,950 g, and he now weighs 2,000 g. On the first day of life, he was given a commercial preterm infant formula by orogastric tube in gradually increasing quantity with supplemental IV fluids. Now, on the fourth day of life, he has developed a distended abdomen and his stools contain bright red blood. An abdominal radiograph shows pneumatosis intestinalis (gas within the intestinal wall). All enteral feedings are stopped (NPO). What do these findings represent? What are the implications for J.H.'s nutritional management?

Abdominal distention, bloody stools, and pneumatosis intestinalis are characteristic of necrotizing enterocolitis.⁴⁹ The causes of this disorder are unclear, but it occurs more often in premature than in term infants; it can occur in clusters of cases, rarely is seen before enteral feeding is instituted, and can be associated with rapid increases in enteral intake.⁵⁵ Because J.H. will receive antibiotics for 10 to 14 days and remain NPO, he requires PN. The planned duration of the regimen makes central venous access a necessity.

Parenteral Nutrition

Goals of Long-Term Support

27. The following day, intestinal perforation requires the resection of two-thirds of J.H.'s distal jejunum and one-third of his ileum, with creation of a jejunostomy. The ileocecal valve and the entire colon are left intact. During the operation, a central venous catheter is placed. What is the goal of PN for J.H.?

J.H. will be NPO for a prolonged time. Therefore, the goals of his PN must be to promote normal growth as well as healing of his diseased gut and surgical wounds.

Because J.H. is a premature infant, it will be difficult to predict how well he will tolerate PN. VLBW infants tolerate normal doses of pediatric amino acids without difficulty; however, some clinicians initiate protein at a lower daily dose (e.g., 1.0 g/kg/day) and advance by 0.5 g/kg/day each day until a goal of 2 to 3 g/kg/day is achieved. The problem with this approach is that it is easy to forget to advance the protein, which leads to underfeeding. Fat should be started at 0.5 to 1 g/kg/day and increased by 0.5 g/kg/day up to 3 g/kg/day. Glucose should be initiated at 5 to 10 g/kg/day and increased by 2 to 3 g/kg until the desired caloric intake is achieved. Appropriate doses of electrolytes and minerals may be started immediately using the guidelines listed in Table 97-1.

Fat Emulsions: Complications

28. What must be considered in making decisions regarding fat administration in J.H.?

Although J.H. can receive adequate calories using only glucose and crystalline amino acids, he will require fat to provide a more physiologic diet and to prevent essential fatty acid deficiency (EFAD), which develops quickly in low birth weight infants who have little fat reserve.⁵⁶ J.H. should receive a minimum of 5% of his total caloric requirement as fat emulsion to minimize the risk of EFAD.⁵² Ideally, his nutrition regimen will provide approximately 40% of calories from fat, which is similar to what is provided by human milk.

Infusions of fat emulsions have been associated with impaired oxygen transport and pulmonary ventilation-perfusion mismatch. This adverse effect generally occurred when the dose of fat was ≥ 4 g/kg and infused over a relatively short (4 hours) period. Current practice is to increase gradually the doses of fat from 0.5 to 1 g/kg/day up to a maximum of 4 g/kg/day and to infuse the fat emulsion over 24 hours to minimize the likelihood of pulmonary problems and to promote clearance.

It is unclear if IV fat administration is detrimental to patients with sepsis. Rapid IV infusion of fat and in vitro incubation of leukocytes with fat emulsion has resulted in impaired leukocyte chemotaxis and phagocytosis.⁵⁷ On the other hand, the linoleic acid in IV fat is the precursor to arachidonic acid, prostaglandins, thromboxane, interleukins, and immunemediating cells. Theoretically, this may minimize bacteremia. Necrotizing enterocolitis, intestinal perforation, and surgery predispose J.H. to sepsis. Therefore, he should have his IV fat infused at an appropriate dose over 24 hours. Because fat clearance can be impaired during infection, it is also prudent to monitor his triglyceride concentrations.

Free fatty acids can displace bilirubin from its albumin binding sites, thereby placing the infant at risk for kernicterus.⁵⁸ Therefore, before advancing the fat dose, the total bilirubin and direct bilirubin should be measured. Patients with an indirect bilirubin (total bilirubin–direct bilirubin) ≤ 10 mg/dL whose albumin levels are normal are at low risk for kernicterus. Indirect bilirubin usually peaks before 1 week of age. After the risk for indirect hyperbilirubinemia has passed, the fat dose can be increased as recommended in Table 97-1. The infusion of 1 g/kg over 24 hours is associated with minimal risk for decreased bilirubin binding;⁵⁸ however, rapid infusion of this same dose can displace bilirubin from albumin binding sites. Given the low level of indirect bilirubin found on routine monitoring (see Question 36) and the planned fat infusion rate, J.H. should not be at risk for kernicterus.

Egg phospholipids are used to emulsify fats; therefore, patients with a known allergy to eggs (e.g., fever, chills, urticaria, dyspnea, bronchospasm, chest pain) should not receive fat emulsion.⁵²

Glucose Intolerance

29. Because J.H. is a premature infant, PN should be initiated using 5% glucose, 2.5 g/kg/day of amino acids, and 0.5 g/kg/day of fat emulsion. The volume of PN should be 240 mL based on a maintenance fluid requirement of 120 mL/kg (Table 97-1). On the second day, he receives 10% glucose and 2.5 g/kg/day of amino acids and 1 g/kg/day of fat. On the third day, glucose is increased

to 15%, amino acids remain at 2.5 g/kg, and fat emulsion is increased to 1.5 g/kg/day. On the fourth day, glucose is increased to 20%, amino acids remain at 2.5 g/kg, and fats are increased to 2 g/kg/day. After this solution has infused for 8 hours, his urine tests 1% for glucose (normal, no glucose) and his blood glucose level is 210 mg/dL (normal, 120 mg/dL). Explain this new finding and the problems it may cause. How should hyperglycemia be managed?

[SI unit: blood glucose, 11.7 mmol/L (normal, 6.66)]

Maximal glucose oxidation rates in milligrams per kilograms per minute are inversely related to age, and decrease from 15 to 18 mg/kg/minute in neonates and young infants to 4 to 5 mg/kg/minute in adults. In full-term neonates and infants receiving maintenance fluids (100 mL/kg), glucose concentrations can be started at 10 g/kg/day (equivalent to dextrose 10%) and advanced by 5 g/kg (equivalent to dextrose 5%) every 24 hours up to approximately 25 g/kg/day (equivalent to dextrose 25%).

In preterm neonates, such as J.H., dextrose is started at a lower dose and advanced at smaller increments, usually 2 to 3 g/kg/day. Glucose tolerance varies significantly, so each patient should be considered individually.

At J.H.'s prescribed fluid rate of 10 mL/hour, 20% glucose represents 16.7 mg/kg/minute of glucose. The hyperglycemia and glycosuria probably have occurred because the increases in the infusion rate have exceeded J.H.'s ability to adapt to the glucose dose. Patients who have been euglycemic on their glucose dose and then become glucose intolerant should be evaluated, however, for other causes, such as infection.⁵⁹

Hyperglycemia and glycosuria can result in serum hyperosmolarity, osmotic diuresis, and dehydration. Regardless of the cause, the hyperglycemia should be treated by reducing the glucose administration rate. The rate of the PN infusion can be decreased further if hyperglycemia continues or increased if the hyperglycemia resolves.

When the PN order is written for the subsequent days, the glucose increases should be made in smaller amounts up to the maintenance calorie requirements per day. Frequent blood and urine glucose monitoring must be continued. Severe glucose intolerance in patients who require PN can be managed with insulin to normalize serum glucose. Although insulin is compatible with PN solutions, it does adsorb to glass, polyvinyl chloride, and filters, resulting in decreased delivery of insulin.⁶⁰ The addition of albumin can decrease the binding of insulin to solution containers.⁶¹ Frequently, pediatric patients have changing insulin requirements that prevent the addition of insulin to PN solutions. A separate continuous infusion of regular insulin (initial dose: 0.05 to 0.1 units/kg/hour) titrated to control serum glucose concentrations offers a practical solution to minimize waste of the PN solution.⁶² It is essential to discontinue the insulin infusion if the PN solution is discontinued to avoid hypoglycemia.

Effects of Bronchopulmonary Dysplasia and Mechanical Ventilation

30. J.H. remains dependent on a ventilator because of his immature lungs. How could J.H.'s respiratory disease influence his nutritional regimen?

At older than 28 days of age, J.H.'s ventilator dependence defines him as having bronchopulmonary dysplasia (BPD),

a chronic lung disease of infancy. BPD is characterized by an increase in resting energy expenditure, increased work of breathing, and growth failure.^{63,64} Therefore, J.H.'s caloric requirement may be higher than expected. Additionally, J.H.'s ventilator may also alter the approach to his caloric supply. Very high carbohydrate loads have been associated with an increase in carbon dioxide production.⁶⁵ This, in turn, may make it difficult to wean J.H. from the mechanical ventilator. As discussed, rapid infusions of fat emulsion can also have a detrimental effect on pulmonary function. Fat emulsion should not be omitted from J.H.'s PN regimen; rather, a slower infusion rate, with gradual dose increases, while monitoring pulmonary function is appropriate.

Pediatric Amino Acid Formulations

31. Why would a specialized pediatric amino acid solution be preferable to a standard adult formulation for J.H.?

Patients 1 year of age or older tolerate standard adult amino acid preparations (e.g., Aminosyn [Abbott Laboratories] and Travasol [Baxter Healthcare]) well. For infants <1 year of age, two specifically designed pediatric amino acid formulations (PAAF)—TrophAmine (B. Braun) and Aminosyn PF (Abbott Laboratories)—are available. PAAF were developed in response to the abnormal plasma amino acid patterns noted in infants receiving adult amino acid formulations. The products were designed with the goal of producing plasma amino acid patterns closely matching those of 2-hour postprandial, human-milk-fed infants. Theoretically, normal plasma amino acid patterns will promote normal protein synthesis in growing infants.

Pediatric amino acid formulation differ from conventional amino acid formulations in several ways. First, they contain a higher content of branch chain amino acids (leucine, isoleucine, and valine), and a lower content of glycine, methionine, and phenylalanine (Table 97-10). In addition, PAAF have a higher percentage of essential amino acids with a wider distribution of the nonessential amino acids. Finally, PAAF are unique in that they contain three essential amino acids for neonates: taurine, tyrosine (as *N*-acetyl-L-tyrosine), and cysteine (added as L-cysteine HCl). Adult solutions contain little if any of these amino acids. Neonates have immature liver functions. This results in decreased levels of both hepatic cystathionase and phenylalanine hydroxylase enzymes. Without these enzymes, neonates cannot adequately convert methionine to cysteine or phenylalanine to tyrosine or synthesize taurine from cysteine. Deficiencies in these amino acids can have a significant impact on the health of the neonate. For example, taurine has a role in retinal development, protection and stabilization of cell membranes, neurotransmission, regulation of cell volume, and bile acid conjugation. Taurine also may be important in decreasing or preventing cholestasis associated with long-term PN.

Several investigators have studied the clinical, nutritional, and biochemical effects of TrophAmine in term and preterm infants.^{66,67} The use of TrophAmine was found to result in nearly normal amino acid patterns. In addition, patients receiving TrophAmine had greater weight gain and significantly better nitrogen utilization than similar groups using the adult formulations. TrophAmine and Aminosyn-PF, given over a 7-day period, produced comparable weight gain and nitrogen retention.⁶⁸ In one study, some of the VLBW infants

Table 97-10 Pediatric Amino Acid Solutions

| | TrophAmine 6% | Aminosyn-PF 7% |
|---|---------------|----------------|
| Essential Amino Acids (EEA) (mg/1 g Total Amino Acids) | | |
| Isoleucine | 81.7 | 76.3 |
| Leucine | 140.0 | 118.7 |
| Lysine | 81.7 | 67.9 |
| Methionine | 33.3 | 17.9 |
| Phenylalanine | 48.3 | 42.9 |
| Threonine | 41.7 | 51.4 |
| Tryptophan | 20.0 | 17.9 |
| Valine | 78.3 | 64.6 |
| Cysteine HCl ^a | 3.3 | 0 |
| Histidine | 48.3 | 31.4 |
| Tyrosine | 23.3 | 6.3 |
| Taurine | 2.5 | 7.1 |
| Nonessential Amino Acids (mg/1 g Total Amino Acids) | | |
| Alanine | 53.3 | 70.0 |
| Arginine | 121.7 | 123.0 |
| Proline | 68.3 | 81.4 |
| Serine | 38.3 | 49.6 |
| Glycine | 36.7 | 38.6 |
| L-aspartic acid | 31.7 | 52.9 |
| L-glutamic acid | 50.0 | 82.3 |
| Sodium (mEq/L) | 5.0 | 0 |
| Acetate (mEq/L) | 56.0 | 32.5 |
| Chloride (mEq/L) | <3 | 0 |
| % essential amino acid | 60.1 | 50.2 |
| % branched chain amino acid (g amino acid/1 g nitrogen) | 30.0 | 26.0 |

^a40 g of cysteine syringe available.

experienced metabolic acidosis.⁶⁶ L-cysteine, an HCl salt, provides an additional 5.7 mEq Cl/100 mg and may have contributed to the acidosis. Whereas the manufacturer's recommended dose of 40 mg L-cysteine per gram of amino acid may be too much for the VLBW infant; the most appropriate dose of L-cysteine for the VLBW infant has not been determined.

To date, PAAF have been effective in producing a positive weight gain, positive nitrogen balance, and normalizing amino acid patterns in preterm neonates. They also allow for the provision of larger doses of calcium and phosphorus because PAAF lower the pH of the final PN solution. Providing greater amounts of calcium and phosphorus, in appropriate ratios, should minimize metabolic bone disease. Further evaluation of these products is needed to determine the magnitude of the proposed benefits (i.e., improved nitrogen retention, better weight gain, enhanced bone growth, and decreased cholestasis) and the most appropriate L-cysteine dose to use in VLBW infants. In any event, these potential benefits, and clinical experience with these products, have resulted in the use of PAAF as the standard of care in infants requiring PN.

Carnitine

32. Why would carnitine supplementation be warranted in J.H.?

Carnitine has many functions within the body, but it primarily serves to transport long-chain fatty acids (LCFA) across the

mitochondrial membrane where they undergo β -oxidation to produce energy. Deficiency in carnitine lessens LCFA availability for oxidation, resulting in the accumulation of LCFA and a decrease in ketone and adenosine triphosphate (ATP) production. This can adversely affect the CNS and skeletal and cardiac muscles. Carnitine deficiency in premature infants also has been linked to disorders such as GI reflux, apnea, and bradycardia.⁶⁹

Whereas carnitine is a nonessential nutrient in adults and is readily available from a diet that includes meat and dairy products, it appears to be an essential nutrient in neonates and infants. This population has low body stores of carnitine and a decreased ability to synthesize it on their own. The premature infant has even lower stores of carnitine because carnitine accumulation occurs during the third trimester. Human milk and most cow's milk-based infant formulas contain carnitine. Some soy-based formulas have additional carnitine added during manufacturing. PN, however, is not routinely supplemented with carnitine. Therefore, infants who are exclusively fed by PN are at risk for developing complications associated with carnitine deficiency.⁶⁹

Because J.H. has two risk factors for the development of carnitine deficiency (prematurity and exclusive use of PN), and because carnitine has little or no adverse effects associated with its use, it is appropriate to provide J.H. with a carnitine supplement. Carnitine is available as both an oral and IV formulation. The recommended dose in J.H. is 10 to 20 mg/kg/day. The addition of carnitine directly to PN improves carnitine plasma concentrations and nutritional status.

Septicemia

33. J.H. was diagnosed with necrotizing enterocolitis and received 14 days of antibiotics. On his sixth day off antibiotics, he begins having 15 to 20 episodes of bradycardia per day. His physical examination is remarkable for cold extremities and slow capillary refill, but his chest radiographs show no acute change. Laboratory evaluation at this time includes electrolytes, blood glucose, complete blood count, and blood cultures, which are reported as follows: Na, 139 mEq/L (normal, 135–145 mEq/L); K, 4.7 mEq/L (normal, 3.5–5.0 mEq/L); Cl, 112 mEq/L (normal, 102–109 mEq/L); HCO₃⁻, 17 mEq/L (normal, 22–29 mEq/L); glucose, 164 mg/dL (normal, 70–105 mg/dL); platelet count, 36,000/mm³ (normal, 150,000–450,000/mm³); and white blood cell (WBC) count, 24,300/mm³ (normal, 5,500–18,000/mm³). WBC differential includes 52% segmented neutrophils (normal, 20%–50%) and 27% immature neutrophils (normal, 3%–5%). Blood cultures are drawn; results will be unavailable for at least 24 hours. What is the likely cause of these findings? How might J.H.'s nutrition regimen affect the diagnostic evaluation and treatment selected?

[SI units: Na, 139 mmol/L (normal, 135–145); K, 4.7 mmol/L (normal, 3.5–5.0); Cl, 112 mmol/L (normal, 102–109); HCO₃⁻, 17 mmol/L (normal, 22–29); glucose, 9.1 mmol/L (normal, 3.9–5.8); platelet count, 36 × 10⁵/L (normal, 150–450); WBC count, 24.3 × 10² cells/L (normal, 5.5–18.0)]

This constellation of findings (metabolic acidosis, hyperglycemia, thrombocytopenia, leukocytosis, bradycardia, and poor perfusion) is nonspecific but could represent septicemia.

The presence of a central venous catheter predisposes J.H. to infection with gram-negative bacteria and bacteria normally found on the skin (e.g., coagulase-negative staphylococci).⁷⁰

Cultures growing coagulase-negative staphylococci must not be presumed to be the result of contamination in symptomatic patients. The typical antimicrobial sensitivities of this organism dictate that vancomycin be among the empiric antibiotics. A third-generation cephalosporin to cover gram-negative organisms should be added empirically as well.

The central venous catheter and the use of broad-spectrum antibiotics also predisposes J.H. to fungal infection.⁷¹ Candidal infection can occur and, when fat emulsions are used, as in J.H., systemic infection with *Malassezia furfur* must be considered. *M. furfur* is a normal skin fungus that requires an exogenous source of fatty acids. The empiric use of antifungal drugs is not indicated in patients with *M. furfur*; however, the clinician should screen specifically for this fungus by culture.

Metabolic Bone Disease (Rickets)

34. On the chest radiograph taken to evaluate the septic episode just described, the radiologist notes that J.H. has two rib fractures and that the bones appear undermineralized. The most recent laboratory values show a serum calcium (Ca) of 9.3 mg/dL (normal, 8.5–10.5 mg/dL), a serum phosphorus of 3.6 mg/dL (normal, 4.0–8.5 mg/dL), and an alkaline phosphatase of 674 U/L (normal, 350 U/L). What diagnosis is suggested by these findings? How and why has J.H.'s nutrition regimen placed him at risk for this disease?

[SI units: Ca, 2.3 mmol/L (normal, 2.1–2.6); phosphorus, 1.16 mmol/L (normal, 1.3–2.7); phosphatase, 674 U/L (normal, 350)]

During the last trimester of pregnancy, bone accretion is accelerated reaching its peak at about 36 weeks. Premature infants, therefore, require larger calcium and phosphorous doses. Limitations to venous access, however, may preclude the infusion of concentrated calcium solutions peripherally, and the patient's end-organs may be resistant to vitamin D. Thus, metabolic bone disease is not unexpected in a premature infant such as J.H.

Aluminum, a contaminant in some parenteral salt products (particularly calcium), also may play a role in impaired bone mineralization.⁷² Low serum phosphorus with high alkaline phosphatase, undermineralized bones, and fractures resulting from routine handling are consistent with a diagnosis of rickets.

Parenteral nutrition solutions provide calcium and phosphorus in much smaller amounts than the infant would accumulate in utero.⁷³ Solution pH, temperature, calcium salt, and final calcium and phosphorus concentrations influence their solubility in PN solutions. An acidic PN solution favors the solubility of these salts. The pH of commercially available amino acid preparations ranges from 5.4 (in the PAAF) to 7 (in adult amino acid formulations). The addition of L-cysteine, with a pH of 1.5, also makes the solution more acidic. Because dextrose also is acidic, solutions with higher dextrose concentrations are more acidic. Of note, colder storage temperatures promote calcium and phosphorus solubility. Therefore, refrigerated PN solutions may appear to be free of precipitate on visual inspection. Calcium and phosphate can precipitate, however, when warmed to room temperature, or when infused into patients with fever or in incubators. Calcium salt selection is another important consideration because the chloride salt dissociates rapidly and favors precipitation, whereas the gluconate and gluceptate salts dissociate less quickly.

Serum phosphorus concentrations should be monitored several times per week and phosphorus intake adjusted to prevent symptomatic hypophosphatemia. Serum calcium is not useful as an indicator of disease activity because it will remain normal at the expense of bone mineralization. This is demonstrated by J.H.'s serum calcium at the time of diagnosis (see Question 33).

Liver Disease Associated With Parenteral Nutrition

35. On the 56th day of life, J.H. is noted to be mildly jaundiced. A review of his laboratory tests reveals the following:

| Test | Age (days) | | | | |
|--|------------|-----|-----|-----|-----|
| | 22 | 29 | 36 | 43 | 50 |
| Aspartate aminotransferase (AST) (U/L) (normal, <40) | 14 | 17 | 15 | 20 | 25 |
| Alanine aminotransferase (ALT) (U/L) (normal, <28) | 6 | 7 | 10 | 10 | 11 |
| Alkaline phosphatase (IU/L) (normal, <350) | 103 | 158 | 345 | 506 | 695 |
| Bilirubin | – | – | – | – | – |
| Indirect (normal, <1 mg/dL) | 0.9 | 0.9 | 0.8 | 0.8 | 0.9 |
| Direct (normal, <0.2) | 0.1 | 0.1 | 0.8 | 1.6 | 3 |

Could this be related to his PN?

In past decades, hepatic damage has been reported in up to one-third of infants receiving PN,⁷⁴ with a higher prevalence (up to 50%) in VLBW infants such as J.H.⁷⁵ Although it is still a concern today, hepatic damage is less prevalent because of current better understanding of how to treat infants requiring long-term PN. The laboratory abnormalities reported in J.H. are typical of this complication. The first change observed is usually an elevated direct (conjugated) bilirubin, which can occur as early as 2 weeks after beginning PN.⁷⁶ Increases in the serum concentrations of the hepatic enzymes, AST and ALT, lag 2 weeks or more behind the rise in direct bilirubin.⁷⁶ Alkaline phosphatase also can rise, but it is a nonspecific indicator of liver disease. Alkaline phosphatase is produced by the liver, GI tract, and bones.⁷⁶ Although the laboratory results observed in J.H. are consistent with the pattern associated with liver disease induced by PN, PN-associated cholestasis is a diagnosis of exclusion; therefore, other causes, such as viral hepatitis, must be ruled out.

RISK FACTORS

36. What clinical factors placed J.H. at high risk for developing cholestatic liver disease secondary to PN?

Although components of PN solutions are commonly blamed for the development of cholestasis, many potential causes exist.⁷⁷ J.H. has several other risk factors for developing cholestasis, and prolonged enteral fasting may be the most significant.⁷⁸ Stimulation of bile flow and gallbladder contraction depend on GI hormones, which depend on enteral feeding for their release.⁷⁹ Absence of these secretagogues, therefore, can promote cholestasis.^{80–82} Immature hepatic function secondary to prematurity also places J.H. at risk, as does the duration of PN therapy. As the duration of PN use increases, so does the prevalence of hepatic disease in premature infants;

25% of infants nourished in this manner for ≥ 30 days show evidence of cholestasis.⁷⁵ Surgical patients have a greater likelihood of developing hyperbilirubinemia than medical patients, especially those requiring GI surgery.^{83,84} Many surgical procedures are associated with a higher risk of jaundice.⁷⁸ Finally, J.H.'s infection increases his risk for cholestasis.⁸⁵

The use of adult amino acid preparations in infants increases the risk of cholestasis. In one study, the incidence of cholestasis in VLBW infants receiving TrophAmine was reduced to 23% relative to historical controls of 30% to 50%.⁸⁶ In another study comparing the two PAAF mentioned above, no difference in the incidence of cholestasis was found in infants 1 year of age, and the overall incidence of cholestasis was 27%.⁸⁷ These investigators did not assess whether or not the patients were provided with L-cysteine, which may be important because L-cysteine is a precursor for taurine and taurine forms the water-soluble nontoxic bile acid, taurocholate.

An additional risk factor for cholestasis not present in J.H. is the administration of large amounts of protein or dextrose. Because amino acids are actively transported in hepatocytes, it is important to provide appropriate types and amounts of amino acids to minimize the development of cholestasis. In one study, a high-protein regimen (3.6 g/kg/day) was associated with an earlier onset and greater degree of cholestasis than a low-protein regimen (2.3 g/kg/day).⁸⁸ Similarly, dextrose overload is a known cause of hepatic steatosis and has been shown to decrease bile flow.⁸⁹ Therefore, overly aggressive feeding of J.H. with PN should be avoided.

In addition to the hepatic damage, gallstones have been reported in infants and children receiving PN.^{90,91} The ileal resection performed during the acute phase of his necrotizing enterocolitis may put J.H. at increased risk for this hepatobiliary complication as well.⁹⁰

37. What modifications can be made in J.H.'s regimen in the presence of cholestasis?

First, the institution of enteral feeding must be considered. Even low-volume trophic feeding may help alleviate the condition and should be attempted in cholestatic patients. Next, the protein and glucose dose provided by the PN should be evaluated. During cholestasis, calories should be provided using an appropriate mix of protein, carbohydrate, and fat.

Although the effect of cycling a patient off PN has not been evaluated in clinical trials, this should be considered. Cycling PN, when the infusion rate is gradually decreased to off for a period and then restarted and gradually increased to the desired rate, will decrease the length of time the liver is exposed to PN. VLBW infants, however, may become hypoglycemic even with very gradual decreases in infusion rate, so this option should be used with care. In any event, a short time off PN (e.g., 2 hours) should be attempted.

The trace elements provided by the formulation should be examined. Both copper and manganese are enterohepatically

recycled and may accumulate in liver disease. Manganese can also contribute to hepatotoxicity and should be removed from J.H.'s PN solutions. Studies have not established when removal of copper and manganese is warranted. The inappropriate removal of copper could lead to anemia, osteopenia, and neutropenia.⁹² Therefore, decreasing the copper dose and monitoring serum concentrations of both copper and manganese should guide therapy.

Pharmacologic interventions have had limited success in the management of PN-associated cholestasis. Neither phenobarbital nor bile acid binding agents, such as cholestyramine, are effective in reducing or reversing PN-associated cholestasis.^{93,94} Ursodiol 10 to 20 mg/kg/day has been used successfully in the treatment of other cholestatic liver diseases, and preliminary reports indicate that it may also improve PN-associated cholestasis in children.⁹⁵ Ursodiol, a naturally occurring nontoxic bile acid, presumably works by displacing and replacing the endogenously produced, potentially toxic bile salts that accumulate with cholestasis.

Sincalide, is part of the endogenous hormone cholecystokinin (CCK), and may improve signs of PN-associated cholestasis. CCK is secreted in the small intestine in response to meals and stimulates gallbladder contraction and increases intestinal motility. In PN-dependent patients, such as J.H., endogenous CCK secretion is diminished. For J.H., the dose of sincalide would be 0.12 mcg/kg/day.⁹⁶

The antibiotic, metronidazole, also appears promising in the prevention of PN-associated cholestasis in adults. Metronidazole inhibits the bacterial overgrowth in the GI tract that occurs with intestinal stasis. The bacteria are responsible for increased formation of hepatotoxic bile acids such as lithocholate; 15 mg/kg/day of metronidazole has been shown to prevent lithocholate accumulation.⁹⁷

PROGNOSIS

38. Project the course of J.H.'s liver disease if PN is discontinued and enteral feedings are instituted within 2 weeks. What may occur if enteral feedings cannot be instituted?

If PN can be discontinued soon after the onset of cholestasis, the prospects for J.H. to recover normal hepatic function are good. Jaundice usually resolves within 2 weeks after PN is discontinued, and the biochemical abnormalities normalize soon thereafter.⁹⁸ The pathologic changes observed on biopsy resolve even more slowly. Biopsy evidence of cholestasis has been observed for up to 40 weeks after resolution of clinical and serologic evidence of hepatic disease.^{98,99}

If enteral feedings cannot be instituted successfully, the prognosis for J.H.'s liver function is not as good. Studies have demonstrated that infants receiving PN for ≥ 90 days had biopsy evidence of irreversible liver damage.⁸¹ Thus, it clearly is advantageous to convert J.H.'s nutrition to the enteral route as soon as he tolerates such a change.

Cystic fibrosis (CF) is a severe, complex, hereditary disease that affects 1 of every 3,200 live births, or approximately 30,000 children and adults in the United States. One in 31 Americans carry the autosomal recessive gene for CF, which arises from a mutation in coding for the cystic fibrosis transmembrane regulator protein (CFTR). This genetic mutational error results in the complex, multisystem disease of CF, which is characterized by malabsorption and a state of chronic lung inflammation and infection.

The course and severity of cystic fibrosis are variable and unpredictable. The median life expectancy (i.e., about 40 years) for a child born with CF in 1990 was about double what would have been expected for a child diagnosed with CF 20 years earlier because of advances in the management of this disorder.¹ Although therapy continues to rely on treatment of symptoms rather than the underlying pathologic causes, continuing improved understanding of CF is likely to result in better control and perhaps a cure. CF is still a lethal disease, but aggressive therapy can decrease the morbidity of this disease and increase the life expectancy of the patient.²

HISTORY

In early history (~3,000 BC), the forehead of a newborn was licked crosswise for cleaning, and if a salty taste was perceived,

the baby was considered “bewitched” and expected to soon die.³ This early observation is consistent with the later discovery that patients with CF lose excess chloride “salt” in their sweat and with the subsequent establishment of the “sweat chloride test” for the diagnosis of CF.⁴ The term “cystic fibrosis” was first used in 1938 to describe “cystic fibrosis of the pancreas” from postmortem pancreatic lesions.⁵ Cystic fibrosis, therefore, is a relatively newly described disease. As a result, most patients cannot relate a long family history of this disease.⁶

GENETIC BASIS

Cystic fibrosis is caused by mutations in the CFTR, which is a member of the ATP binding cassette (ABC) family. CFTR is dependent on cyclic adenosine monophosphate (cAMP) for chloride transport: defective coding for CFTR inhibits the normal regulation of ion transport in and out of the cell on the apical surface of secretory epithelial cells.⁷ CFTR also regulates the transport of bicarbonate and sodium ions, mucous rheology, pulmonary inflammation, and bacterial adherence.^{8–12}

Approximately 5% of Caucasians are asymptomatic carriers of the CF mutation. The high frequency of this mutation has been attributed to a heterozygote-selective advantage that presumably protected the carrier against dehydration from cholera, cancer, and other disease.^{13–21}

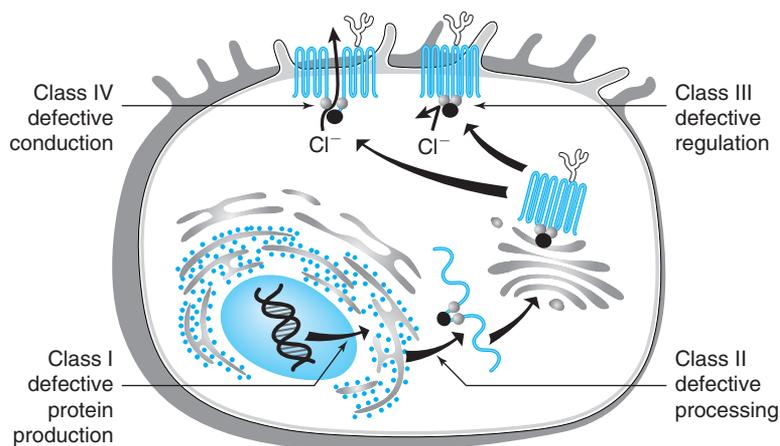

FIGURE 98-1 Classification of mutations: Class I mutations include those in which the production of the cystic fibrosis transmembrane regulator (CFTR) protein is blocked. These are called *stop mutations*. Defective protein processing is responsible for the class II mutations. In this class, the protein is made, but it is unable to make its way from the point of origin on the endoplasmic reticulum to the apical membrane, where it is needed for proper operation. This includes the most common, $\Delta F508$, mutation, which is caused by improper folding of the protein. Class III mutations cause the disruption of the channel to open properly. Class IV mutations are unable to achieve proper ion conduction. Class V is a milder form of class I mutations and includes mutations that cause reduced production of functional CFTR. (From ref. 25, with permission.)

Almost two decades have passed since the identification and cloning of the gene responsible for CF, and >1,000 new CFTR mutations have been discovered.^{22–24} These mutations have been grouped into five major classes according to the functional consequence of the defect (Fig. 98-1).^{25,26} The most common variant is $\Delta F508$, representing 66% of all mutations. Approximately 90% of all patients with CF have at least one copy of this mutation.²⁷ Interestingly, even among individuals with identical genotypes, a broad spectrum of disease severity is seen.^{28,29} The contribution of genetic factors other than the malfunctioning CFTR can have a great influence on disease severity.^{30–37} For example, an increased expression of transforming growth factor $\beta 1$ is associated with a poorer clinical outcome.³⁸ Another potentially important modifier may be an anti-inflammatory mediator, macrophage inhibitory factor.³⁹ As genetic modifiers are better understood, more effective therapies can be developed.^{40,41}

CLINICAL MANIFESTATIONS

Genotype, environmental factors, and modifier gene status all contribute to the highly variable clinical course of CF. The linking of the loss of CFTR function to clinical manifestations of the disease, however, has been central to gaining an understanding of the disease and in the discovery of new therapies. Normally, CFTR is highly expressed on the membranes of epithelial cells of the lungs, sweat glands, salivary glands, and male genital ducts as well as the pancreas, kidney tubules, and digestive tract. The CFTR performs different functions in specific tissues; therefore, a dysfunctional or absent CFTR has different effects on different organs resulting in the multiorgan clinical manifestations of CF (Table 98-1).

Sweat Glands

Fluid secreted by the sweat glands in patients with CF is normal, but a defect in the reabsorption of electrolytes leads to

sweat with a high salt content. CFTR, in the apical membrane of the resorptive area of the sweat gland, functions as an ion channel for chloride transport and also activates an associated epithelial sodium channel (ENaC).⁴² Normally, these channels efficiently reabsorb sodium chloride from sweat. In patients with CF, loss of these functioning channels blocks the ability of the sweat ducts to reabsorb salt, leading to sweat sodium chloride (NaCl) concentrations of >100 mM (Fig. 98-2). The loss of these sodium and chloride ion channels serves as the basis for the diagnostic sweat chloride test and as the scientific basis for the “infant who tastes of salt” in folklore.

Sinus Involvement

Nasal polyps, which are outgrowths of normal sinus epidermis, can be found in up to 20% of older patients with CF and may become sufficiently large to block nasal passages. The pathogenesis of these polyps is unknown, but the obstruction of nasal passages can lead to infection. The faulty ionic transport of chloride across the apical membrane of epithelial cells lining exocrine glands leads to dehydration of extracellular fluids and the development of thickened inspissated mucus in nasal and sinus passages. Most patients with CF develop sinus disease with pan-opacification of the sinuses in 90% to 100% of patients >8 months of age. On radiographic examination, >90% of adult-age patients have pansinusitis, which can contribute to pulmonary exacerbations.^{43,44} The impact of sinusitis on the CF population is significant.

Pancreatic Involvement

The exocrine and ultimately the endocrine function of the pancreas are affected in CF. Pancreatic enzymes normally are secreted into bicarbonate-rich fluid from the pancreatic duct, and CFTR is needed to secrete the bicarbonate into the lumen. The loss of CFTR function inhibits secretion of digestive enzymes and bicarbonate into the duodenum, and the enzymes are

trapped in the pancreas by ductal obstruction. Over time, these enzymes (lipase, protease, amylase) accumulate and eventually begin to digest the pancreatic tissue.^{12,45} The term *cystic fibrosis* arises from the fibrotic scar tissue that replaces the destroyed pancreas. Without these enzymes, there is poor digestion of fats and, to a lesser extent, proteins and carbohydrates are absorbed poorly. As a result, 90% of patients with CF experience pancreatic insufficiency characterized by steatorrhea (fatty stools), decreased absorption of the fat-soluble vitamins (A, D, E, and K), malnutrition, and failure to thrive. Early in life, serum concentrations of amylase and lipase are increased secondary to pancreatic autodigestion. This destructive process can result in either painful or asymptomatic chronic pancreatitis.

Eventually, the progressive destruction of the pancreas affects its endocrine function, leading to glucose intolerance in about 17% of children and 75% of adults.^{46,47} Diabetes mellitus occurs in approximately 40% of adult patients with CF.⁴⁸ The additional diagnosis of diabetes in CF is associated with significantly increased morbidity and mortality,^{49,50} and

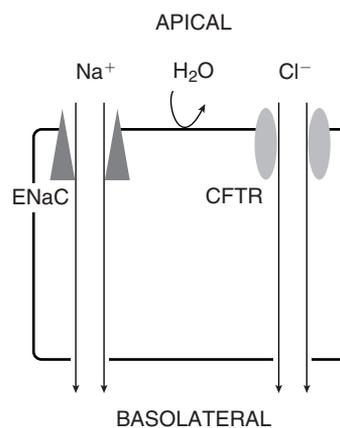

FIGURE 98-2 Normal salt (NaCl) absorption in the sweat duct with working epithelial sodium channel (ENaC) and cystic fibrosis transmembrane regulator (CFTR).

a decrease in insulin sensitivity is associated with pulmonary exacerbations.⁵¹ Early aggressive insulin therapy can result in improved clinical outcomes.⁵²

Intestinal Involvement

Meconium ileus, an intestinal obstruction at birth, occurring in 20% of newborns with CF, is an inheritable trait of this disease.⁵³ Outside the neonatal period, distal intestinal obstruction syndrome (DIOS, also called *meconium ileus equivalent*) can occur at any age and results from the complete or partial obstruction of the intestine. Intestinal obstruction occurs in 10% to 20% of patients and results from the inspissation of intestinal secretions and incompletely digested intestinal contents. A right lower quadrant mass, abdominal distention, failure to pass stools, and vomiting can accompany DIOS.

Gastrointestinal reflux disease (GERD) is common in both children and adults with CF.^{54–56} Children with CF should be screened for GERD and treated, if diagnosed. Other intestinal complications include rectal prolapse, intussusception, and appendiceal abscesses.

Hepatic Involvement

Located on the apical surfaces of the cells lining the intrahepatic and extrahepatic bile ducts and the gallbladder, CFTR functions to facilitate ion transport.⁵⁷ In patients with CF, the abnormal chloride efflux across the cells results in the reduction in water and sodium movement into the bile. The resulting decrease in the volume and flow of bile leads to stasis and obstruction of the biliary tree. With chronic obstruction, there is inflammation, giving rise to the characteristic lesion of focal biliary cirrhosis.⁵⁸

Liver disease develops in the first decade of life. Significant liver disease is seen in 13% to 25% of children with CF.^{59–61} Prevalence rates may be underestimated. Progressive cirrhosis is associated with portal hypertension, hypersplenism, esophageal varices, ascites, and, in a small number of patients, complete hepatic failure requiring transplantation. Approximately 30% of adult patients with CF have abnormal gallbladder function and size (absent or small gallbladder) with 5% to 10% of patients developing gallstones.⁶²

Genitourinary Involvement

Approximately 98% of males with CF are infertile secondary to *in utero* obstruction of the vas deferens or related structures. Hormonal secretion and secondary sexual characteristics are normal. In a small number of patients, infertility can be the only manifestation of disease, and CF may go undiagnosed until fertility testing is performed. The prevalence of infertility is higher in women with CF and hypothesized to be related to the production of thick and tenacious cervical mucus. Hundreds of pregnancies have been carried successfully to term, but these are not without risk, especially for patients with moderate to severe pulmonary disease.⁶³

Bone and Joint Involvement

Patients with CF have low bone mineral density, slower rate of bone formation, high rate of bone loss, accelerated rate of bone loss, and arthritis.^{64,65} Osteoclastic precursors are elevated during acute pulmonary exacerbation.⁶⁶ Although early, aggressive treatment of pulmonary exacerbations can improve bone health, sufficient intake and absorption of the fat-soluble vitamins, D and K, are important, and oral bisphosphonates may also be indicated.^{65,67–73}

Patients with CF often suffer from intermittent arthritis symptoms, but only about 2% of patients have persistent symptoms. The three types of intermittent CF arthritis are (a) hypertrophic osteoarthropathy, (b) immunoreactive, and (c) CF arthropathy. The first two types are associated with pulmonary disease flare-up. The third type, CF arthropathy, affects large joints and may be accompanied by fever and erythema nodosum.^{74–78}

Pulmonary Involvement

The relationship of ion-channel disruption (resulting from CFTR dysfunction) to lung tissue destruction has yet to be firmly established. Presently, the CF gene mutation is believed to cause CFTR dysfunction, which in turn causes ion transporter defects, and subsequent changes in the airway secretions. The changes in airway secretions promote the infection-inflammation-tissue damage cycle (Fig. 98-3). Chronic infection combined with inflammation has been the hallmark of lung disease in CF. The cycle of unchecked inflammation and infection has been the focus of much investigation and ongoing debate to “Which came first—infection or inflammation.”⁷⁹ Although the inflammatory response appears to set up bacterial colonization in the airways, infection also can stimulate an inflammatory response. In either case, the cycle of inflammation and infection eventually leads to lung tissue damage and bronchiectasis.⁸⁰

This pattern of inflammation and infection has not been observed in any other tissue where CFTR is expressed. Differences in the airway surface liquid, mucus, and other protective mechanisms in the lung of the patient with CF are being studied, and some of these differences may help explain the inflammation–infection cycle (Table 98-2).

Infection

Despite repeated courses of aggressive antibiotic therapy, patients with CF eventually develop endobronchial bacterial col-

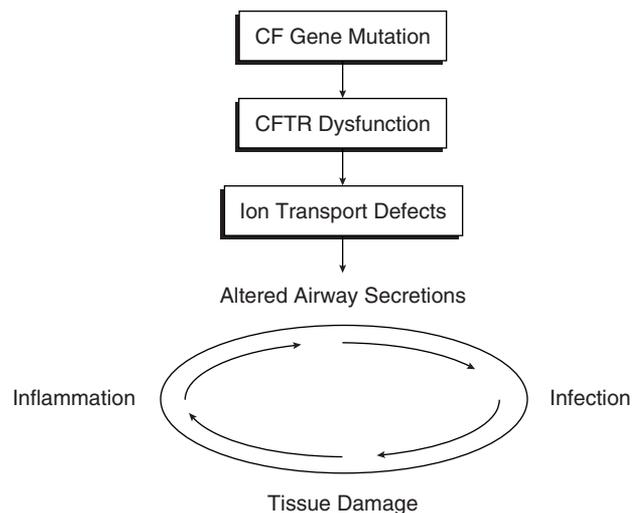

FIGURE 98-3 Pathologic cycle in lung disease. CFTR, cystic fibrosis transmembrane regulator. (From ref. 235, with permission.)

onization and infection. Understanding why bacteria seldom are eradicated is important to treating this disease.

The lower airways of a normal lung are always maintained free of pathogens through various lung defense mechanisms. For example, a thin film of liquid on the airway surfaces called the *airway surface layer* (ASL) contains antimicrobials, antioxidants, proteases, and other substances that work to eliminate pathogens. The ASL also signals molecules to turn on the cellular immune system by recruiting neutrophils and macrophages to the site of microbe invasion. In addition, the ASL can remove invading microbes from the lung by moving a mucous gel toward the mouth through ciliary motion. Mucociliary clearance of microbes and debris is aided by the cough reflex to keep the airways clean. Because coughing is an important defense mechanism necessary for patients with CF, cough suppressants should not be prescribed or taken by them.

Local antibacterial peptides in the ASL are inactivated by high concentrations of salt similar to the concentrations found in CF ASL.^{81,82} The ion channel dysfunction associated with CF can dehydrate and thicken mucus as well as deplete periciliary fluid and collapse cilia.^{83,84} Thick mucus, which is not easily cleared, serves as a nidus for bacterial growth and, when combined with impaired mucociliary clearance, promotes chronic bacterial infection.⁸⁵

Cystic fibrosis epithelial tracheal cells express high numbers of surface receptors for *Pseudomonas aeruginosa* and *Staphylococcus aureus*.⁸⁶ *S. aureus* is frequently responsible for the initial bacterial colonization, whereas *P. aeruginosa* is the most common pathogen isolated in chronically colonized patients.

The oxygen radicals produced by the inflammatory response in infected CF airways induce bacterial mutations of *P. aeruginosa* that lead to production of alginate, a biofilm that allows the organism to become more resistant to antibiotics. Mucoid *P. aeruginosa* bacteria also produce exotoxin A, protease, and elastase, which damage lung tissue and decrease the effectiveness of the neutrophils (polymorphonuclear leukocytes [PMN]) and macrophages.^{87,88} *Burkholderia cepacia*, another

Table 98-2 Host Abnormalities That Predispose to Chronic Lung Infection

| Abnormality | Proposed Impact | Proposed Intervention(s) |

Adapted from Saiman L, Siegel J. Infection control recommendations for patients with cystic fibrosis: microbiology, important pathogens and infection control practices to prevent patient-to-patient transmission. *Am J Infect Control* 2003;31(3 Suppl):S1, with permission.

opportunistic pathogen found in patients with CF, is highly resistant to virtually all antibiotics. Patients may be asymptomatic or may have a fulminant infection leading to death. Such patients infected with mucoid strains of *P. aeruginosa* and *B. cepacia* experience increased morbidity and mortality.⁸⁹⁻⁹¹

Viruses, fungi, and mycobacteria are also potential pathogens. Viruses can predispose patients to subsequent bacterial infection and may be responsible for activating the inflammation cycle. *Aspergillus fumigatus*, a fungus, has been associated with allergic bronchopulmonary aspergillosis (ABPA) in 5% to 25% of patients with CF. ABPA is an immunologic reaction to *Aspergillus*, which can lead to progressive pulmonary fibrosis if left undiagnosed and untreated. Nontuberculous mycobacteria have emerged as pathogens in the CF population.^{92,93} The clinical course associated with nontuberculous mycobacteria infection is variable and it complicates the diagnosis and treatment of the patient with CF.

Inflammation

Inflammation is the lung's response to chronic infection.^{86,94} Neutrophils (PMN) are "called" to the site of an infection by interleukin-1 (IL-1), interleukin-8 (IL-8), leukotriene (LTB₄), endotoxin, and tumor necrosis factor (TNF- α).⁹⁵ IL-8 is a major chemoattractant, and when bound to heparan sulfate-containing proteoglycans, its activity is prolonged.⁹⁵ When neutrophils arrive at the site, they release proteases, oxidants, elastases, and cytokines. Antiproteases and interleukin-10 (IL-10), an anti-inflammatory cytokine, subsequently are released in an effort to counterbalance the inflammatory system. Platelets also are dysfunctional and can contribute to inflammation through nitric oxide pathway.⁹⁶ Anti-inflammatory compounds are relatively low in patients with CF, and levels of neutrophils, proteases, elastases, oxidants, and cytokines all

are increased.⁹⁷⁻⁹⁹ These abnormalities lead to a sustained and destructive cycle of unchecked inflammation that begins at a very early age.⁹⁴

Arachidonic acid (AA), an agonist in the inflammation pathway, is increased, and docosahexaenoic acid (DHA), a down-regulator of AA, is decreased in the bronchial lavage fluid in patients with CF. This imbalance of fatty acids favors the inflammatory and mucus-producing AA, and, therefore, provides an explanation for the role of CFTR in causing inflammation and increased mucus production in the airways.¹⁰⁰

DIAGNOSIS

Diagnostic Criteria

Most children with CF are diagnosed in the first year of life (median age at diagnosis, 6 months), but 8% are not diagnosed until later (> 18 years of age).¹⁰¹ A positive diagnosis of CF is contingent on having one or more of the characteristics listed in Table 98-3, a history of CF in a sibling, or a positive newborn screening test result. These must then be accompanied by two positive sweat chloride tests, two positive nasal potential differences (NPD) tests, or identification of two CF mutations.^{102, 103} The classic triad of clinical signs and symptoms for the diagnosis of CF are a positive sweat chloride test, gastrointestinal (GI) malabsorption, and chronic pulmonary disease. With the discovery of the CF gene, DNA typing is now available for 95% of the CF mutations.

When the pilocarpine iontophoresis test (i.e., sweat chloride test) is conducted at a certified CF center and is positive (> 60 mEq/L) on two different days, the diagnosis of CF can be applied.¹⁰⁴ Sweat collection amounts may be inadequate in a preterm or neonate < 1 week of age. Currently, a sweat chloride

Table 98-3 Phenotypic Features Consistent With Diagnosis of Cystic Fibrosis (CF)

1. Chronic sinopulmonary disease manifested by:
 - Persistent colonization or infection with typical CF pathogens (e.g., *St. aureus*, nontypeable *H. influenzae*, mucoid and nonmucoid *P. aeruginosa*, and *B. cepacia*)
 - Chronic cough and sputum production
 - Persistent chest radiograph abnormalities (e.g., bronchiectasis, atelectasis, infiltrates, hyperinflation)
 - Airway obstruction manifested by wheezing and air trapping
 - Nasal polyps; radiographic or computed tomographic abnormalities of paranasal sinuses
 - Digital clubbing
2. Gastrointestinal and nutritional abnormalities including:
 - *Intestinal*: meconium ileus, distal intestinal obstruction syndrome, rectal prolapse
 - *Pancreatic*: pancreatic insufficiency, recurrent pancreatitis
 - *Hepatic*: chronic hepatic disease manifested by clinical or histologic evidence of focal biliary cirrhosis or multilobular cirrhosis
 - *Nutritional*: failure to thrive (protein-calorie malnutrition), hypoproteinemia and edema, complications secondary to fat-soluble vitamin deficiency
3. Salt loss syndromes: acute salt depletion, chronic metabolic alkalosis
4. Male urogenital abnormalities resulting in obstructive azoospermia (CBAVD)

CBAVD, congenital bilateral absence of the vas deferens.
From ref. 103, with permission.

value of >40 mmol/L is required for the diagnosis of CF in the newborn period; infants with values >30 mmol/L, require follow-up. In programs that perform mutation analysis, confirmatory sweat testing should be obtained even in infants who test positive for two mutations. A false-positive sweat chloride test finding for CF can result from glucose-6-phosphate dehydrogenase deficiency, hypothyroidism, glycogen storage disease, untreated adrenal insufficiency, and malnutrition.¹⁰⁵

A second diagnostic test for CF evaluates the pattern of increased NPD. Abnormalities of ion transport in respiratory epithelia results in patients with CF having a higher basal NPD, which reflects enhanced Na⁺ transport across a relatively Cl⁻ impermeable barrier. This test can be effective in diagnosing CF in infants in the first few hours of life. Older children may need mild sedation before initiating the test for NPD. Inflamed mucosa or nasal polyps can generate a false-negative NPD finding. The NPD test should be repeated on a separate day at a reputable CF center if the first test is positive for CF.¹⁰⁶

Genetic Testing

Prenatal Screening

If both parents are known to be carriers of CF, the American College of Medical Genetics (ACMG) and the American College of Obstetrics and Gynecology (ACOG) recommend prenatal screening.¹⁰⁷ Amniocentesis, chorionic villus sampling (CVS) and pancreatitis-associated protein (PAP) all have been used to diagnose CF *in utero*. Genetic testing for CF should

be conducted at a center that has knowledgeable genetic counselors who understand the validity and reliability of the tests as well as the sociomedical implications for a child diagnosed with CF.

Neonatal Screening

Growing consensus is that early aggressive therapy improves the quality of life and extends the life-span of patients with CF.^{108,109} CF is included on the 2006 newborn screening list released by the American Academy of Pediatrics and is advocated by many clinicians.^{105,110–115} Early diagnosis is associated with improved height and weight, likely owing to early introduction of nutritional interventions, and improved survival.^{116,117} Immunoreactive trypsinogen (IRT) concentration is high in the blood of infants with CF. If elevated in a blood-spot screen, the IRT may be repeated or a mutation analysis for genotype can be performed. Newborns who present with meconium ileus are always suspected of having CF; however, in this subset of patients, for reasons not understood, IRT has a high prevalence of false-negative results.¹¹⁸ If neonatal screening is to be effective, an infrastructure must be in place to provide education and counseling for families.^{119,120}

Clinical Presentation

1. L.T., a 9-month-old male, is brought to the pediatric primary care clinic. His mother states, “He can’t seem to eat enough food and cries constantly.” She says that he has 8 to 10 stools per day, but she thought this was because he ate so much. On further questioning, she says that the stools are large, greasy, and foul smelling. He has never been hospitalized, but has had three ear infections and three chest colds, which were treated with antibiotics. When plotted on a standard growth curve, L.T. is found to be in the fifth percentile for both weight and height (7.5 kg and 68 cm). The pregnancy and delivery were uncomplicated, and L.T.’s medical history is otherwise unremarkable. Physical examination shows a poorly nourished, small-for-age infant in no apparent distress. Family history is unremarkable. Review of systems reveals diffuse crackles in the lower lung fields; all other systems are within normal limits. A sweat chloride test is ordered and the results are a chloride concentration of 110 mEq/L (normal, <60 mEq/L). L.T.’s chest x-ray study shows mild peribronchial thickening of both upper lobes. What subjective and objective data for L.T. are suggestive of the diagnosis of CF?

L.T. fulfills the classic triad for the diagnosis of CF: elevated sweat chloride, chronic recurrent pulmonary infections, and apparent pancreatic insufficiency. Although not showing symptoms of pulmonary infection at present, the baby has had several chest colds, and chest x-ray study indicates chronic inflammation. As illustrated by L.T., the earliest chest x-ray study shows peribronchial thickening in the upper lung fields. As the lung disease progresses, hyperinflation, as evidenced by increased anteroposterior diameter of the chest (barrel chest) and flattening of the diaphragm, is evident. Eventually, areas of collapse, consolidation, and abscess formation and bronchiectasis develop, indicating severe pulmonary tissue destruction. L.T.’s pancreatic insufficiency is suggested by his multiple daily fatty stools and failure to thrive despite a voracious appetite. In summary, a positive sweat test, evidence of GI malabsorption, and

pulmonary involvement support the probable diagnosis of CF in L.T.

Laboratory Testing

2. What further testing can be done to confirm the diagnosis of CF in L.T.?

The sweat chloride test should be repeated on another day to affirm laboratory testing reliability and to rule out other conditions that can cause an elevated sweat chloride level (see Diagnostic Criteria above). Genetic testing can be done to identify CFTR mutations. Because genetic testing cannot identify all the possible mutations that can cause CF, it is not the diagnostic test of choice. A diagnosis of CF is likely if the second sweat chloride test is positive, especially in light of L.T.'s clinical presentation.

Pulmonary Testing

3. What testing and follow-up should be completed to define L.T.'s pulmonary involvement?

Baseline pulmonary function tests, chest x-ray studies, oxygen saturation, and sputum cultures are a part of the normal workup. Spirometry should be performed at least every 6 months, and complete pulmonary function tests should be performed once a year. The percent of the predicted forced expiratory volume in 1 second (FEV_1) stratifies the level of lung disease. Greater than 90% is considered normal; between 70% and 89% is mildly impaired, 40% to 69% is moderate impairment and <40% is severely impaired. Arterial blood gases or pulse oximetry need to be completed on patients with severe disease. Children such as L.T., who are younger than 5 years of age, are unable to perform the tasks associated with pulmonary function testing adequately. Chest x-ray studies should be obtained annually, whenever the patient has a pulmonary-related hospital admission, and before any surgery. Respiratory tract cultures and sensitivities should be completed annually and before initiation of antibiotic therapy. Because obtaining a voluntary sputum sample from an infant is difficult, an oropharyngeal swab can be used to initiate a gag reflex and cough, and then a sputum sample is collected. The sputum sample obtained actually may contain only normal upper airway flora rather than bacteria colonizing the lower airway; therefore, it is important to interpret persistently normal flora from a sputum culture of an infant with caution.¹⁰⁸ The need for a smoke-free environment for L.T. should be emphasized to the family.¹²¹

Gastrointestinal Testing

4. What testing and follow-up should be completed in L.T. to define GI and nutritional involvement?

L.T.'s head circumference, height, and weight should be plotted on standard growth charts every 3 months for the first year. An experienced, knowledgeable registered dietician should meet with the family to help them understand the importance of appropriate nutrition and help develop a plan for L.T. Nutritional assessments should be completed annually, or more often if L.T. shows evidence of weight loss or poor weight gain. Serum lipase and amylase, fasting blood glucose, liver function tests, albumin, prealbumin, serum electrolytes, iron, and vitamins A, D, and E levels should be determined at least annually. An abdominal examination should be done to determine liver

and spleen size and consistency at each office visit. Although quantification of fecal fat content may assist in the titration of pancreatic enzyme doses, an accurate dietary fat intake history is needed for accurate quantification. Many CF centers undertake this assessment only in patients who have demonstrated excessive pancreatic enzyme dose requirements.

THERAPY

The management of a case of CF is costly and complex. In addition, the emotional, physical, and social effects of caring for a chronically ill child can be overwhelming. Family socioeconomic status also seems to be a predictor of the health of a child with CF. The risk of death in the lowest income group (<\$20,000/year) increased by 44%, and patients in this group had consistently lower pulmonary functions and body weights than those with higher income.^{122,123}

In a review of more than 18,000 patients with CF, those who were monitored frequently and treated aggressively had better lung health as measured by FEV_1 .¹²⁴ Aggressive preventive therapies, therefore, apparently result in better outcomes than treating problems as they arise.^{108,125–127} Although a cure for CF is still the ultimate goal, new therapies to target malabsorption and the infection–inflammation cycle are being vigorously studied.

Control of Malabsorption

Patients with untreated CF have pancreatic insufficiency and are malnourished. Early diagnosis and treatment of malabsorption (i.e., meeting caloric needs, providing vitamin, mineral, and digestive enzymes) are beneficial to the patient.

Caloric Needs

Poor nutrition correlates with negative prognosis; therefore, maximizing the nutritional status of the patient with CF is important. CF patients are hypermetabolic and do not absorb fats and proteins normally. Therefore, the CF diet must be high in calories, fat, and protein. An infant at diagnosis may need a total daily caloric goal of 120 to 150 kcal/kg to make up for lost time. Weight gain, fat stores, and growth then drive the daily caloric goal. When a patient has a significant weight loss or falls below the tenth percentile for weight or height for age, it is indicative of nutritional failure, which requires therapeutic intervention.¹²⁸ Supplementation does not seem to be of benefit.¹²⁹ Some patients at nutritional risk benefit from night-time enteral feedings.^{130,131}

Vitamin and Mineral Supplementation

The malabsorption of fats in patients with CF with pancreatic insufficiency also results in decreased GI absorption of the fat-soluble vitamins (A, D, E, and K). Approximately 45% of the CF population is deficient in one of these vitamins, even when pancreatic enzymes are being used appropriately.¹³² The current recommendations for replacement therapy are listed in Table 98-4.¹²⁸ Concerns about inadequate supplementation of vitamins D and K resulting in poor bone health have arisen.^{67,68,133–135} Calcium, sodium, and iron supplements might also be needed. A new vitamin supplement AquADEK has been formulated for patients with CF as a soft gel, rather than a chewtab, with added antioxidants, selenium, and more

Table 98-4 Daily Recommended Doses of Fat-Soluble Vitamins for Patients with Cystic Fibrosis (CF) and Vitamin Content in ADEK and AquADEK Formulations

| Age | Vitamin A (IU) | Vitamin E (IU) | Vitamin D (IU) | Vitamin K (mg) |
|------------------------|----------------------------------|----------------|----------------|----------------|
| 0–12 mon | 1,500 | 40–50 | 400 | 0.3–0.5 |
| 1–3 yr | 5,000 | 80–150 | 400–800 | 0.3–0.5 |
| 4–8 yr | 5,000–10,000 | 100–200 | 400–800 | 0.3–0.5 |
| >8 yr | 10,000 | 200–400 | 400–800 | 0.3–0.5 |
| Vitamin Content | | | | |
| ADEK Chew Tab | 9,000 (60% as β carotene) | 150 | 400 | 0.15 |
| ADEK drops | 3,170 | 40 | 400 | 0.1 |
| AquADEK liquid 1 mL | 5751 (87% as β carotene) | 50 | 400 | 0.4 |
| AquADEK softgels | 18,167 (92% as β carotene) | 150 | 800 | 0.7 |

Adapted from ref. 128, with permission.

zinc, vitamin D and K.^{128,136,137} Some patients purportedly have experienced a “niacin flush”-like reaction to AquADEK.

Enzyme Supplementation

The mainstay of treatment for pancreatic insufficiency is exogenous replacement of pancreatic digestive enzymes. The goals of pancreatic enzyme supplementation are to (a) improve weight gain, (b) minimize steatorrhea, and (c) eliminate abdominal cramping and bloating. Supplementation with currently available therapies does not fully restore fat absorption and the absorption of sufficient fat-soluble vitamins continues to be problematic.¹³⁸ The digestive enzymes (lipase, protease, amylase) are available in a mixture of approximately one part amylase to three parts protease and three parts amylase in capsules that contain enteric-coated microspheres of these enzymes (Table 98-5). The enteric coating protects these enzymes from gastric acid. Because the breakdown of fat is the most important function of these enzymes, dosing is based on the lipase content, and the dose varies according to weight, age, dietary fat intake, and symptom severity. The initial dose for

infants is 2,000 to 2,500 units of lipase/kg per breast-feeding or per 120 mL of bottle-feeding: the dose is decreased to 1,000 units/kg/meal when infants begin to eat solid food. For children >4 years of age, 500 units of lipase/kg/meal is the empiric dose for enzyme supplementation.¹³⁹ A full dose is taken with meals, and half the prescribed dose is taken with snacks. Subsequent dosing adjustments are titrated to response.

Although enzyme dose is not correlated with growth or GI symptoms, lack of weight gain; smelly, greasy stools; and abdominal pain or bloating might be indicative of insufficient enzyme supplementation.^{140,141} Generic substitutions of pancreatic enzymes have resulted in therapeutic failure and are not recommended.¹⁴²

High-strength pancreatic enzymes have been associated with colonic strictures, which are accompanied by symptoms similar to that of DIOS and which must be differentiated from DIOS by ultrasound or x-ray study.¹⁴³ Although cause and effect have not been firmly established, doses >6,500 units lipase/kg/meal have been associated with stricture formation. As a result, most recommend that the daily dose of lipase not exceed 10,000 units of lipase/kg.¹⁴⁴

When patients require unusually high doses of enzyme supplements, it sometimes can be attributable to high gastric acidity. The enteric coating on the pancreatic enzyme microspheres dissolves at a pH of 5.8, and the enzymes are destroyed at a pH of 4.0. Patients with CF have longer postprandial periods of time when the pH is <4.0 in the bowel and also have significantly less time when the pH is >5.8. Because enzymes may be less effective when the bowel pH is very low,^{145,146} adding an H₂-antagonist or a proton-pump inhibitor to increase gastric pH might help lower the enzyme dosing requirement.^{147–149}

Table 98-5 Selected Pancreatic Enzymes

| Product ^a | Microencapsulated Enzymes | | |
|----------------------|---------------------------|----------|---------|
| | Lipase | Protease | Amylase |
| Creon 5 | 5,000 | 18,750 | 16,600 |
| Creon 10 | 10,000 | 37,500 | 33,200 |
| Creon 20 | 20,000 | 75,000 | 66,400 |
| Pancrease | 4,500 | 25,000 | 20,000 |
| Pancrease MT 4 | 4,000 | 12,000 | 12,000 |
| Pancrease MT 10 | 10,000 | 30,000 | 30,000 |
| Pancrease MT 16 | 16,000 | 48,000 | 48,000 |

^aDosing and comparison of products based on lipase content. Adapted from Drug Facts and Comparisons, Inc., 2007, with permission.

5. Significant laboratory findings for L.T. include the following: serum vitamin E, 2.5 mg/L (normal, 3–15.8 mg/L); vitamin A, 26 mcg/dL (normal, 30–90 mcg/dL); lipase, 47 U/L (normal, 0.1–208 U/L); amylase, <30 U/L (normal, 0–110); albumin, 2.7 g/dL (normal, 3.4–5.1 g/dL); all other laboratory values are within normal limits. Pancreatic enzymes are to be started in L.T. What would be a reasonable dosing and monitoring plan for his pancreatic enzyme therapy?

The dosing of pancreatic enzymes is empirically started at 1,000 U/kg based on the lipase component. The initial dose for

L.T., who weighs 7.5 kg, would be 7,500 U, with a full dose for meals and a half-dose for snacks. To simplify drug therapy, it is best to select a single capsule strength that can be used for both meals and snacks. Therefore, a product with close to the desired amount (e.g., Creon 10) should be selected and dosed as one capsule with meals, and half a capsule with light meals or snacks. For the best result, the supplements should be given at the beginning of the meal or snack.¹⁵⁰ This is challenging, especially for an infant. Capsules can be opened and the microspheres put on the nipple of a mother nursing her infant or on the nipple of a bottle. Alternatively, the capsules can be opened and added to a spoonful of cereal or applesauce and given just before nursing or giving a bottle. The microspheres should not be chewed or put on hot food or liquid because the coating can be destroyed. The dose of the pancreatic enzymes should be adjusted to minimize steatorrhea, and the dose increased as needed. L.T.'s family should also be taught the signs of constipation or stomach pain in an infant.

L.T.'s weight gain and growth should be assessed every 3 months for the first year. As L.T. grows, his enzyme requirements will change and eventually he will need to become responsible for taking them on his own before eating. Neighbors, friends, and teachers should store a few supplements for L.T. to accommodate spontaneous eating of snacks.

6. In addition to enzyme replacement, what fat-soluble vitamin supplementation is appropriate for L.T.?

L.T.'s laboratory evaluation reveals vitamin A and E deficiencies, which are relatively common in patients with malabsorption. The long-term effects of inadequate fat-soluble vitamin intake are unclear. Vitamins A, D, E, and K, however, should be prescribed for L.T. because of the theoretic benefits, low cost, and low risk. L.T. should be started on 1 mL of AquADEK or ADEK drops daily (Table 98-4). Vitamins A, D, and E should be monitored yearly; his vitamin K need not be monitored unless risk factors are present or clotting difficulties are suspected.¹²⁸

Control of Infection

Mucociliary Clearance

Sputum in patients with CF is difficult to mobilize because pulmonary secretions are thick as a result of both the CFTR defect and the large amounts of viscous DNA from the breakdown of white blood cells and the bacterial debris left over from chronic infections. Mechanical clearance methods and inhaled mucolytics can be helpful in mobilizing pulmonary secretions.

MECHANICAL METHODS

Methods used to mechanically break up and mobilize mucus in the pulmonary tree include traditional hand percussion and postural drainage (P&PD); oscillating positive-end pressure (OPEP) with the flutter valve; high-frequency chest-wall oscillation (HFCWO) with the ThAIRapy vest; intrapulmonary percussive ventilation (IPV); and autogenic drainage (a technique of deep breathing exercises). These mechanical approaches for mobilizing mucus are about equal in efficacy, and the selection of the most appropriate one for a patient depends on the ability, motivation, preference, and resources of the patient.¹⁵¹ When the traditional P&PD was compared with HFCWO and

OPEP, clinical efficacy and safety were comparable, but 50% of patients preferred the HFCWO, 37% preferred OPEP, and 13% preferred P&PD.¹⁵²

DORNASE ALFA

Dornase alfa (Pulmozyme) is an inhaled recombinant form of human deoxyribonuclease I, which breaks up the DNA formed by the PMN that block airways in the patient with CF. It has a beneficial effect on neutrophilic airway inflammation when compared with controls and reduces exacerbation frequency in patients.^{153–157} It is safe for use in infants, but does not seem to be of benefit in an acute exacerbation.¹⁵⁸ Dornase alfa is very expensive, with costs averaging about \$1,200/month; and the cost:benefit ratio for its use continues to be debated.^{159,160} Nevertheless, this medication improves lung function, reduces exacerbations of patients >6 years of age, and is recommended.¹⁶¹ More than 50% of patients with CF use dornase alfa.¹⁰¹

HYPERTONIC SALINE

Inhalation of hypertonic saline (IHS) also improves mucociliary clearance. When twice-daily inhaled normal saline was compared with 7% (hypertonic) sodium chloride, the IHS-treated patients experienced better overall lung function and fewer exacerbations.^{162,163} In another study, IHS also improved lung function and mucociliary clearance.¹⁶⁴ Although not compared in a head-to-head trial with IHS, dornase alfa seems to increase lung function more, but at a much higher financial cost than IHS. A short-acting β_2 -agonist should be given before IHS treatment because IHS has been associated with bronchospasm.¹⁶⁵ IHS is available commercially and is recommended to improve lung function and reduce exacerbations in all patients >6 year of age.¹⁶¹

BRONCHODILATION

The chronic use of inhaled β_2 -agonists improves lung function in patients with bronchial hyperresponsiveness or a positive bronchodilator response, and is recommended for use.¹⁶¹ No clear consensus exists for the use of other bronchodilators. Although leukotriene modifiers have improved lung function in small studies, the overall data are insufficient to support a recommendation.¹⁶⁶ Studies in support of inhaled anticholinergic medications for the treatment of CF also are limited, and the results have been mixed.¹⁶⁷ Cromolyn use also is not routinely recommended because of limited evidence of positive outcomes with this drug.¹⁶¹

7. What mucus clearance methods would be appropriate for L.T.'s therapy?

Methods of mechanical assistance to remove pulmonary secretions are all equally effective, but hand P&PD would be the method of choice for L.T. because he is only 9 months of age. His parents should be taught the method of using a cupped hand or a vibrator device to shake loose the secretions that have accumulated in L.T.'s lungs. The other methods of chest physiotherapy can be used when L.T. is older and better able to participate.

Dornase alfa improves sputum viscosity in patients with CF and they are able to benefit from this drug early in the course of their lung disease.¹⁵³ In the Pulmozyme Early Intervention Trial (PEIT), the risk of pulmonary exacerbations was

reduced by 34% in young patients with mild lung function abnormalities, and pulmonary function tests also were improved in patients with close to normal pulmonary function. The addition of dornase alfa is a viable consideration if the cost and scheduling of regular treatments are not issues for L.T.

Patient counseling is important if dornase alfa is prescribed for L.T. Dornase alfa should not be mixed with other drugs because it is an enzyme that can be denatured. Only approved nebulizers can be used because of the variability of delivery of aerosolized medications from different nebulizers. Baseline pulmonary function tests should be obtained, and L.T. should be re-evaluated in 6 weeks. Evidence of improvement should include the following: diminished dyspnea and cough, increase in sputum production, increased appetite, improved subjective measures (e.g., perception of energy, ability to sleep), and improvement in pulmonary function tests. Dornase alfa should be discontinued if the patient does not appear to be benefiting from therapy.¹⁶⁰

Immunizations

8. A Gram's stain of L.T.'s sputum reveals normal respiratory flora, and the throat culture is pending. What immunizations should be considered for L.T. at this time?

L.T. has no evidence of a pulmonary infection at this time. He should receive all childhood immunizations at the usual recommended times (see Chapter 95: Pediatric Immunizations) and an annual flu vaccine as well. Prevention of influenza may help avoid the onset of a bacterial infection. When an immunization for *P. aeruginosa* is available, it will be essential for patients with CF.¹⁶⁸

Antibiotic Therapy

Antibiotics are commonly used for the patient with CF to improve or delay the decline of pulmonary function. The indications for antimicrobial use include (a) treatment for an exacerbation, (b) prevention of colonization with *P. aeruginosa*, and (c) maintenance therapy for chronic *P. aeruginosa*. Bacterial resistance to antibiotics commonly develops in the patient with CF because pathogens often are not eradicated from the patient's airway. As a result, such patients probably need to receive broad-spectrum antibiotics more often than might be indicated in other populations.¹⁶⁹⁻¹⁷²

DIFFERENCES IN KINETICS

The physiologic changes in the patient with CF affects how the body absorbs, distributes, and clears drugs. Lack of bicarbonate secretion in the GI tract and prolonged GI transit times can affect the rate and extent of absorption of some drugs (e.g., oral ciprofloxacin). In addition, the apparent volume of distribution of drugs that are distributed in total body water can be increased because patients with CF have alterations in their body water:mass ratio.^{173,174} For example, the volume of distribution is typically increased for aminoglycosides and β -lactams.

Both hepatic and renal clearances are increased for many drugs in patients with CF. *N*-acetyltransferase activity is increased,¹⁷³ but the P450 system does not seem to be greatly affected and remains isoenzyme dependent (i.e., CYP1A2, CYP2A6, CYP2C9, and CYP3A4 enzyme activity is not changed in these patients).¹⁷⁴⁻¹⁷⁶ CYP2C8 activity and biliary

secretion, however, may be enhanced.¹⁷⁷ The malfunctioning CFTR is hypothesized to increase the renal tubular clearance of organic anion drugs in these patients (e.g., penicillins and trimethoprim).^{173,178-180}

These increases in clearance and volume of distributions make it necessary to adjust doses of some antibiotics for patients with CF. Increased clearance requires larger daily doses and possibly shorter dosing intervals. Table 98-6 contains an abbreviated list of suggested dosage regimens.

MONITORING AND ADVERSE EFFECTS

The prolonged, repeated use of aminoglycosides in patients with CF increases the risk for drug-related toxicity; however, the nephrotoxicity, ototoxicity, and vestibular damage associated with aminoglycosides seem to be less common in these patients than in the rest of the population.¹⁸¹ Nevertheless, diligence in monitoring for these adverse effects are essential. The Cystic Fibrosis Center recommends urinalysis and assessment of the blood urea nitrogen (BUN) and creatinine serum concentrations after each course of aminoglycosides. Some clinicians suggest audiometric assessments for patients who have had 10 or more courses of intravenous (IV) aminoglycosides.¹⁸¹ The adverse effects most often encountered with β -lactams are elevated liver enzymes, diarrhea, hypersensitivity reactions, and fungal overgrowth.

Broad-spectrum antibiotics can cause overgrowth of *Clostridium difficile* in the gut lumen or fungus in the oropharyngeal cavity. Patients should be instructed to report any episodes of diarrhea, difficulty in swallowing, or white plaques in their mouth.

INHALED ANTIBIOTICS

Patients with CF frequently receive large doses of systemic antibiotics to treat lung infections. The site of infection in CF is the airway lumen, not the lung parenchyma, however. Aerosolized administration of an antibiotic delivers the drug directly to the site of infection and, theoretically, should improve drug concentrations in the airway lumen and decrease the risk of systemic toxicity. Aerosolized tobramycin and colistin have been the most studied antibiotics for inhalation in patients with CF, but other antibiotics are also administered via this route.^{182,183} Chronic inhalation of tobramycin reduces exacerbations, improves lung function, and is recommended for use in patients with persistently positive *P. aeruginosa* cultures and mild or moderate-to-severe lung disease.¹⁶² Other inhaled antibiotics (e.g., colistin, gentamicin) do not have sufficient evidence to support a recommendation for use in patients with CF with positive cultures for pseudomonas.^{161,184} More than 40% of all such patients in the United States are prescribed inhaled tobramycin.¹⁰¹

ANTIBIOTIC PROPHYLAXIS

9. When is it appropriate to give L.T. antibiotics to prevent lung infection and colonization?

Some clinicians prescribe prophylactic antibiotics in an effort to prevent *S. aureus* infections in young children and subsequent pseudomonas infections. In one randomized study, cephalexin significantly decreased colonization with *S. aureus*, but it also increased *P. aeruginosa* infections.¹⁸⁶ Thus, routine

Table 98-6 Antibiotic Doses For Cystic Fibrosis

| Systemic Antibiotics | | | |
|-------------------------|----------------------|------------------------|------------------------------|
| Drug | Daily Dosage (mg/kg) | Frequency | Maximal Individual Dose (mg) |
| Amikacin | 30 | Divided Q 8, 12, 24 hr | TDM |
| Ceftazidime | 150–225 | Divided Q 8 hr | 2,000 |
| Cefuroxime | 150–225 | Divided Q 8 hr | 1,500 |
| Ciprofloxacin IV | 30 | Divided Q 8 hr | 400 |
| Ciprofloxacin PO | 40 | Divided Q 12 hr | 1,000 |
| Gentamicin | 10–15 | Divided Q 8, 12, 24 hr | TDM |
| Imipenem | 40–80 | Divided Q 6 hr | 1,000 |
| Oxacillin | 200 | Divided Q 6 hr | 2,000 |
| Piperacillin | 200–400 | Divided Q 6 hr | 4,000 |
| Ticarcillin/clavulanate | 200–400 | Divided Q 6 hr | 3,100 |
| Tobramycin | 10–15 | Divided Q 8, 12, 24 hr | TDM |
| Inhaled Antibiotics | | | |
| Drug | Dosage | Interval | |
| Amikacin | 7.5 mg/kg/dose | BID–TID | |
| Gentamicin | 2.5 mg/kg/dose | BID–TID | |
| TOBI | 300 mg | BID | 30 days on, 30 days off |
| Colistin | 37.5–75 mg | BID–QID | |

BID, twice daily; Q, every; TID, three times daily; TDM, therapeutic drug monitoring (gentamicin/tobramycin desired C_{max} 12–15 mg/L multiple daily dosing, C_{max} >20 mg/L once daily dosing); TOBI, tobramycin for inhalation.
Adapted from ref. 210, with permission.

antistaphylococcal prophylaxis is not recommended for young children with CF and would not be recommended for L.T.¹⁶¹

ACUTE PULMONARY EXACERBATION

Diagnosis

10. B.W., a 19-year-old woman, was diagnosed with CF at 3 years of age after a history of chronic pneumonias. She presents to the pulmonary clinic with increasing cough and sputum production over the past 2 weeks, with a change in sputum color from white to green. She currently weighs 45.2 kg and states she has lost 4 pounds. B.W. is a slightly thin adult woman whose breathing is labored. Pulmonary function tests reveal an FEV₁ of 65% of predicted normal and a forced vital capacity (FVC) of 60% (her usual baselines are FEV₁, 85%, and FVC, 80%). *P. aeruginosa* grew out of her sputum sample taken at the clinic 4 weeks ago for the first time. Other pertinent laboratory findings: white blood cell (WBC) count, 17,000/mm³ (normal, 4,500–11,000/mm³) with 4% bands (normal, 0%–11%), 35% segmented neutrophils (normal, 36%–66%), 50% lymphocytes (normal, 24%–44%), 11% eosinophils (normal, 1%–4%); BUN, 7 mg/dL (normal, 5–18 mg/dL); and creatinine, 0.5 mg/dL (normal, 0.6–1.3 mg/dL). All other blood work, liver function tests, and electrolytes are within normal limits. Heart rate and blood pressure are normal. Temperature is 99.2°F, respiratory rate is 25 breaths/minute (normal, 12–16) with an oxygen saturation of 95% (normal, 97%–100%). A number of new pulmonary infiltrates are seen on chest radiograph. Her current medications include the following: one multiple vitamin every day (QD), two microencapsulated pancreatic enzyme capsules (16,000 U lipase/capsule) with meals, and one or two capsules with snacks as needed.

What subjective and objective findings does B.W. exhibit that would lead to the diagnosis of a pulmonary exacerbation?

The onset of a pulmonary exacerbation of CF usually is marked by an increase in symptoms, such as an increase in sputum production (usually purulent), increased cough, dyspnea, weight loss, and a 15% to 20% decline in pulmonary function tests over baseline. All these findings are present in B.W. An increase in WBC count, fever, or appearance of a new infiltrate on chest radiograph may or may not be present. Traditional management for an acute CF exacerbation includes nutritional repletion, antibiotics, and chest physiotherapy.¹⁷¹

Early Treatment of *Pseudomonas aeruginosa*

11. B.W. is admitted to the hospital for a “cleanout,” consisting of aggressive chest physiotherapy, aggressive nutritional repletion, and antipseudomonal antibiotics. Because *P. aeruginosa* was found in her sputum 4 weeks ago, the following sensitivities to antibiotics were tested and noted: *P. aeruginosa* strain resistant to all antibiotics except tobramycin and ceftazidime. What is the value in giving antibiotics at this time?

If given in the early phase of colonization, antibiotics can prevent the switch to a chronic mucoid infection. A combination of inhaled tobramycin with oral ciprofloxacin (see Question 14 on restricted use of quinolones), or inhaled antibiotics alone, are used to treat early pseudomonas infection.^{186,187} In 14 of 15 patients treated with inhaled tobramycin for 1 year, colonization was not only prevented, but pseudomonas was eradicated.¹⁸⁸ Because pulmonary tissue damage probably is related to bacterial load because of the infection–inflammation cycle, decreasing bacterial burden might slow the progression of lung disease. Therefore, it would be beneficial to treat B.W. aggressively with antipseudomonal therapy.

Aminoglycoside Dosing

12. B.W. is admitted to the hospital for a course of antibiotic treated because of her clinical presentation. What would be a good antimicrobial treatment plan for B.W. based on her current laboratory data? Why might an extended-interval dosing regimen for aminoglycoside therapy be of potential advantage for B.W.?

In patients with CF, *P. aeruginosa* infection should be treated with a combination of two antibiotics (e.g., an aminoglycoside with a β -lactam) to lessen the risk of bacterial resistance to antimicrobials. Given the aforementioned sensitivities for B.W., ceftazidime plus tobramycin would be a good initial choice of antibiotics for this exacerbation. B.W.'s renal and liver functions are normal, therefore, standard CF dosing can be prescribed.

Ceftazidime 2 g IV every 8 hours could be administered to B.W. by continuous infusion because the β -lactams are time-dependent bactericidal antibiotics and the administration of ceftazidime, as a constant infusion, in a patient with CF is likely to be safe and effective.¹⁸⁹

Extended-interval dosing of aminoglycosides (i.e., Q 12 hr or Q 24 hr compared with Q 8 hr) is easier and less costly to administer, and potentially it limits toxicity. The efficacy of extended-interval dosing of aminoglycosides, however, needs to be studied further in the CF population because of the altered pharmacokinetics in patients with CF. Nevertheless, several studies with small sample sizes suggest that the use of extended-interval dosing of aminoglycosides is safe and effective for both children and adults with CF.^{190–196} A large, multicenter trial investigating this issue more fully is currently underway.

In B.W., the initial dosing regimen of IV tobramycin would be 225 mg (5 mg/kg) every 12 hours. Target peak concentrations of 12 to 15 mg/L should be verified on the third dose. Target trough concentrations should be <2 mg/L. A serum trough tobramycin level should be measured at least every 7 days while B.W. is on therapy, along with serum concentrations of BUN and creatinine.

The antibiotics should be administered for 2 weeks, and extended for an additional 7 days if B.W. fails to reach specified endpoints at day 14. After the initiation of antibiotics in this hospitalization, IV home-antibiotic therapy should be a consideration for B.W.¹⁹⁷ The duration of B.W.'s antibiotic therapy should be based on her clinical response. Ideally, her pulmonary function (e.g., FEV₁) should improve by 10% to 20% and should be evaluated weekly. The purulent nature and volume of the sputum should decrease and a gradual overall improvement in subjective feeling should be noted. Improved appetite and increased weight gain should be assessed daily with the goal of reaching baseline weight.

Inhaled Tobramycin

13. Why should (or should not) inhaled aminoglycosides be added to the parenteral regimen of B.W.?

Tobramycin for inhalation (TOBI) is a special formulation of tobramycin for inhalation. Aerosolized antibiotics have been used in combination with IV antibiotics for treatment of acute exacerbations. Although eradication of *P. aeruginosa* from the sputum might be enhanced with these combined routes of therapy, the response could be only temporary.¹⁹⁸ The evidence for the addition of inhaled antibiotics to par-

enteral therapy is not strong, but the evidence for using inhaled tobramycin prophylactically to reduce bacterial load and avoid future exacerbations is getting stronger. Improved pulmonary function, along with a decrease in exacerbations or hospitalizations, has been demonstrated with TOBI prophylactic regimens.^{170,198–201} TOBI can be prescribed as twice-daily inhalations (300 mg) administered as a 30-day on and 30-day off schedule. Although this is a time-consuming and expensive therapy, it has been deemed cost-effective.^{202,203} B.W. should be discharged on TOBI 300 mg twice daily (BID) prophylactic cycle schedule.

ORAL ANTIBIOTICS

14. B.W. reaches her clinical endpoints and is sent home on TOBI therapy. Six months later, she calls the clinic from her college dorm. She has signs of an exacerbation, but refuses IV antibiotics or hospitalization, because she is in the middle of final exams. What alternative to IV therapy is available to treat B.W.? She now weighs 53 kg.

The quinolone family of antibiotics is currently the only option for oral coverage of *P. aeruginosa*. Emergence of resistant strains of staphylococcal and pseudomonas species have led the CF medical community to restrict the use of quinolones to the treatment of acute CF exacerbations.^{204,205} Oral fluoroquinolones (e.g., ciprofloxacin) have become widely used in patients with CF, because they are less expensive, easy to administer, and as effective as IV therapy in an acute exacerbation.^{206,207}

Quinolones are not approved for use in patients <18 years of age because of the risk of arthropathy. One study of 634 children failed, however, to demonstrate any arthropathy in the patients, although reversible arthralgias were noted.²⁰⁸ This risk is further complicated by the underlying problems with bone metabolism seen in CF. Although this issue has not been fully resolved, quinolones are used with caution in certain pediatric populations. In addition, B.W. is of childbearing age and quinolones are relatively contraindicated because of possible effects on cartilage development in the fetus. If a quinolone is used, B.W. should be counseled to use appropriate birth-control techniques.

Because of the past sensitivities of B.W.'s organisms and her refusal to be admitted to the hospital, ciprofloxacin 1,000 mg orally twice daily for 1 week can be initiated in addition to the aerosolized tobramycin.²⁰⁹ After 1 week of the combined aerosol and oral therapies, B.W. should be re-evaluated for hospital admission if her condition worsens, or her therapy can be continued if her condition improves.

Control of Inflammation

The inflammatory response in CF airways can be treated with drugs that block PMN chemotaxis, proinflammatory cytokines, or any other step in the inflammatory cascade. Corticosteroids, nonsteroidal anti-inflammatory agents (NSAID), and macrolides all have been used to control the inflammation seen in CF lung disease.

Corticosteroids

15. J.J., an 18-year-old young man with CF, returns to the clinic for a routine 6-month visit. He now has severe pulmonary disease as reflected by his pulmonary function tests (FEV₁ is 39% of

predicted normal and FVC is 37%) and marked chest radiographic changes that include areas of bronchiectasis and hyperinflation. He is chronically colonized with a resistant strain of *P. aeruginosa* and has a chronic productive cough, which currently is at baseline. Because the lung damage in CF is from inflammation secondary to the bacterial infection, what anti-inflammatory therapies might be considered for use in J.J.?

Oral corticosteroids are not recommended in the treatment of CF. Although prednisone 1 to 2 mg/kg every other day can reduce the decline of lung function and decrease pulmonary exacerbations in patients with pseudomonas infections, it also can result in cataracts, glucose intolerance, and persistent growth retardation.^{210–212} Inhaled steroids do not show an improvement in pulmonary function in patients with CF when used alone.²¹³ Many such patients with concurrent reactive airway disease, asthma, or ABPA in addition to CF respond to corticosteroids.

Nonsteroidal Anti-Inflammatory Agents

Nonsteroidal anti-inflammatory drugs have been used to slow lung function decline. High-dose ibuprofen (20–30 mg/kg BID with doses titrated to a therapeutic range of 50–100 mg/L) can significantly slow the annual rate of FEV₁ decline in children between 6 and 13 years of age.²¹⁴ Ibuprofen serum concentrations must be measured and monitored closely to stay in the therapeutic window because lower concentrations can increase PMN infiltration. Because these doses are much higher than the recommended doses to treat pain or fever, concerns about long-term side effects, including GI bleeding and renal toxicity, together with the need for frequent blood draws have not made this method of treatment common. For patients ≥6 years of age with an FEV₁ >60% of predicted, chronic oral ibuprofen is recommended to reduce the loss of lung function.¹⁶¹ Less than 5% of the CF population is using ibuprofen.^{101,215}

16. Is J.J. a candidate for high-dose ibuprofen? He has refused routine blood draws in the past and worries about the side effects of medication.

For maximal benefit, ibuprofen therapy must be started early, before the disease is as advanced as J.J.'s. Because J.J. does not like having to come in for blood draws or the having possible side effects of GI distress or renal impairment, and his lung disease is too advanced, high-dose ibuprofen should not be recommended.

Macrolide Antibiotics

17. When and why would azithromycin be indicated for J.J.?

Macrolide antibiotics, which have both immunomodulatory properties and antimicrobial activity, have been shown to improve pulmonary function tests, reduce exacerbations, and improve quality of life in children and adults with end-stage disease.^{216,217–220} In a 3-month prospective, randomized, double-blind, placebo-controlled study of azithromycin (250 mg/day) in 60 adults with CF, FEV₁ improved, C-reactive protein decreased, and fewer IV antibiotics were needed in the azithromycin group.²¹⁹ In a 15-month, randomized, double-blind, placebo-controlled, crossover trial, 41 children with CF received azithromycin. FEV₁ improved by 5.4% in the treatment group, and most patients required fewer courses of antibiotics while on azithromycin. No changes in sputum bacterial density, inflammation markers, exercise tolerance, or

quality of life were detected.²¹⁸ Patients improve on long-term azithromycin therapy regardless of whether they had a positive pseudomonas culture.²²¹ The development of bacterial resistance with long-term use of azithromycin is of genuine concern, and patients should be followed up closely if azithromycin is initiated on this basis.^{223,224} Recommendation is that patients with persistent *P. aeruginosa* sputum cultures receive chronic azithromycin to improve lung function and reduce exacerbations.¹⁶¹

In recent long-term studies, azithromycin had a definite role for use in a patient with *P. aeruginosa* and possibly also a role in patients before pseudomonas is cultured. J.J. should be started on 500 mg azithromycin thrice weekly and monitored for improvement of his lung function and a decrease in exacerbations.

Other Strategies

18. What other approaches may be tried to modify the course of CF in B.W. and J.J.?

J.J. and B.W. are both colonized with pseudomonas in their lungs. J.J. should be started on a trial of azithromycin, TOBI, and both patients may be candidates for hypertonic saline and dornase alfa inhalation therapy. Re-evaluation of the type of mechanical clearance method, nutritional status, exercise regimen, and enzyme dose should be considered. J.J. and B.W. should also be tested for liver disease, bone disease, and insulin resistance. J.J. and B.W.'s disease course and weight history should be carefully evaluated along with a fasting blood glucose, HbA_{1c}, and oral glucose tolerance test.

FUTURE THERAPIES

19. What kind of treatments might be available to help patients with CF in the future?

Many drugs are being evaluated to intercede at various levels of the pathologic cascade (Fig. 98-3) seen in CF. Fixing the inactive or malfunctioning CFTR by repairing the mutant gene would be a cure for CF. Much research is focused on developing new therapies for CF, as can be seen in Figure 98-4.

Correcting the Gene

Gene therapy to correct the CFTR in the lungs is being actively pursued. CFTR is expressed in low levels in the lungs so that only 6% to 10% of the cells need active CFTR to correct the chloride channel deficiency. Several vectors are being developed to deliver the good gene and allow it to be incorporated into these cells, including several viruses, a new compacted DNA and lipid DNA complex.^{222–225} Viral vectors in general are problematic because they do not allow for repeated administration. Two nonviral vectors that have found some success are DNA nanoparticles and lipid DNA complexes. Nanotechnology has been used to “compact” or tightly bind strands of DNA, making it sufficiently tiny to pass through a cell membrane and into the nucleus. Four of the 12 patients receiving the nanoparticles via the nose exhibited some normal chloride response during the 2-week period studied.²²⁶ Although each of these vectors needs work, real hope exists for a gene transfer to the lung in the not too distant future.

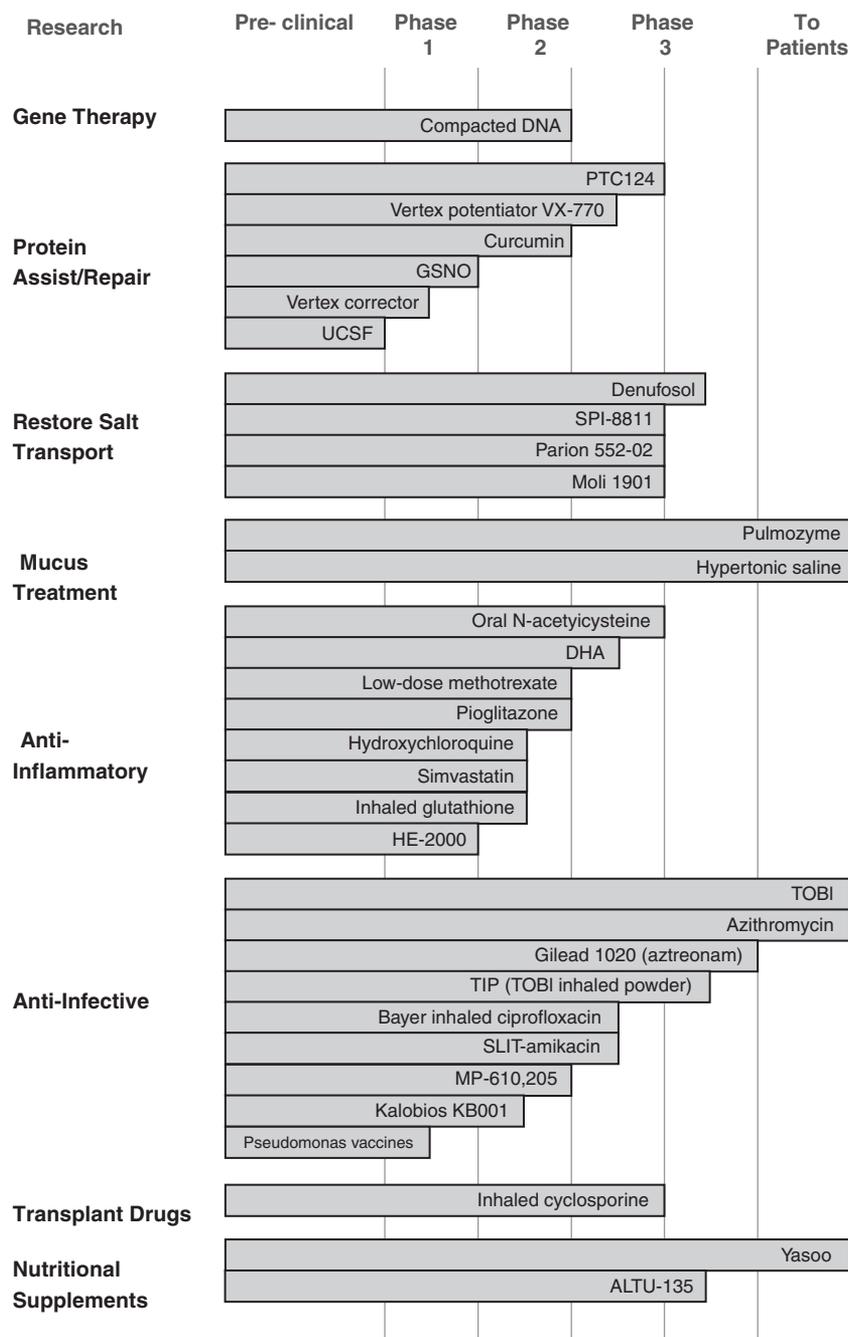

FIGURE 98-4 Drug pipeline for cystic fibrosis. (Reprinted with permission from the Cystic Fibrosis Foundation.)

Restoring Salt Transport

Several therapies are directed at restoring CFTR function from a mutation-specific standpoint. The most common mutation, $\Delta F508$, is caused by a misfolding of the responsible protein. Several “chemical chaperones,” such as cellular osmolytes and low-molecular-weight compounds, when added to cells, rescue the folding of mutated proteins such as $\Delta F508$ CFTR.^{227,228} Gentamicin has been shown to restore a class I mutation in vitro, and genistein has been shown to correct the G551D mutation.²²⁹ Restoring normal ion transport (Na channel blockers, Cl channel activators) would also be an effective

cure for CF. At this point, short-acting sodium channel blockers are of no benefit.^{228,230–232} Alternative molecules are in phase II clinical trials and research stages.

Other

Drugs to combat the inflammation–infection cycle of CF, drugs to improve the outcome from lung transplants, new therapies, and rapidly improving scientific understandings of CF provide much hope for more effective treatment of this disease, and even perhaps a cure.

Demographic and Economic Considerations

Demographic changes and U.S. medical progress in the last half of the 20th century have created imperatives to improve our knowledge about the health care and drug therapy of older adults. The Federal Interagency Forum on Aging-Related Statistics recently published an updated chart book, which provides the most current information on the health and well-being of older Americans in the United States (Table 99-1).¹

The oldest-old category (i.e., those older than 85 years of age) is going to have the greatest impact on the health care system because the number of people in this group has increased faster than any other age category, and many are physically and medically frail. This group will triple its size by 2040, which is more than double the growth rate of the next fastest-growing category.² By 2050, at least half of Americans will live to age 85; they will number almost 21 million and comprise 5% of the total U.S. population.³ Because the frail elderly are often dependent and in ill health, they require the highest level of health services. They have the highest health care expenditures, hospitalization rates, and home health visits.¹

Approximately 4% of the 35 million U.S. residents 65 years of age or older in 1999 resided in long-term care facilities

(LTCFs).⁴ Elderly LTCF residents are predominantly women, 75 years and older, white non-Hispanic, and widowed. Although the prevalence of functional disability in the elderly is expected to be reduced,⁵ the national expenditure for long-term care services for the elderly is expected to grow through the year 2040.⁴ Of older adults who live at home, about 10% in the 65- to 74-year-old age group and up to 50% in the over 85 age group require assistance with everyday activities.² Up to 64% of those who receive care rely on informal care from children and other relatives.¹ Thus, it is important to include the caregiver in the counseling and monitoring of activities when feasible.

Health care for the elderly is increasingly based on a prospective reimbursement system in institutional settings. Managed care practices aim to minimize high-cost hospitalizations by shifting care to lower-cost alternatives, such as home health care, assisted living, and hospice care. The escalating costs and affordability of medications is a national concern, especially in the Medicare population. As reforms are put in place to enhance access to drugs, it is especially important to keep in mind that this population is particularly vulnerable to drug-related morbidity and mortality, which costs the U.S. health care system at least \$30.1 billion annually.⁶

Table 99-1 Profile of Older Americans**Current Status of the Older Population**

- The older population, persons age 65 years and older, numbered 35 million in 2000, representing 13% of the U.S. population. This means that since 1900, the percentage of Americans age 65 years and older tripled (4.1% in 1900 to 13% in 2000), and their numbers have increased 10-fold (from 3.1 million to 35 million in 2000).
- There are more women than men in the older population. Among persons 65 years old in 2000, 58% were women. In the oldest old group, 70% of persons age 85 years and older were women.
- The older population is getting older. In 2000, the 85 and older age group (4 million) was 31 times larger than in 1900.
- The expected number of years of life increased by approximately 60% since 1900. In 2003, life expectancy was 79.8 years for women and 76.8 years for men.
- In 2003, the most common and costly health conditions among all persons age 65 and older were heart disease, diabetes, stroke, and cancer.
- Among all persons age 65 and older, the five leading causes of death are heart disease, cancer, stroke, chronic obstructive pulmonary diseases, and pneumonia and influenza.

Future Growth of the Older Population

- Although the rate of growth slowed during the 1990s because of the relatively small number of births during the Great Depression of the 1930s, the most rapid increase is expected between the years 2010 and 2030, when the baby boom generation reaches age 65.
- By 2030, there will be about 70 million older persons, 2.7 times their number in 1980. If current fertility and immigration levels remain stable, the only age groups to grow significantly will be those older than 55 years of age.
- By 2030, persons age 65 and older are expected to represent 20% of the population; the population age 85 years and older will more than double to approximately 9.6 million persons.

From reference 1.

Age-Related Physiological, Pharmacokinetic, and Pharmacodynamic Changes

An important determinant of drug-related problems in the elderly is an increased physiological vulnerability to medication adverse effects and an impaired ability to recover from drug-induced insults. The progressive decrease in the ability of each organ system to maintain homeostasis in the face of challenge is a definition of physiological aging.⁷ Disruption of homeostatic “balance” predisposes an older adult to disease or medication side effects. Homeostatic mechanisms in the cardiovascular and nervous systems are less efficient, drug metabolism and excretion decrease, body tissue composition and drug volume of distribution change, and drug receptor sensitivity may be altered. Age-associated changes are progressive, occurring gradually over a lifetime, rather than abruptly at any given age (e.g., 65 years of age). The physiological processes of aging often result in an increased susceptibility to many diseases. However, older people remain a heterogeneous group, with chronologic age not always reflecting “functional age” (Table 99-2). Distinct separation of these interrelated factors is difficult because all may contribute to variability in drug response. In particular, pharmacodynamic changes in the aging population is a research topic fraught with many methodological and logistic constraints, as evidenced by the scarcity of information on aging and pharmacologic effects. Resnick and Marcantoni-

Table 99-2 Factors That May Influence Functional Age

Poor vs. good or adequate nutrition
 Smoking vs. quit smoking vs. never a smoker
 Acute or chronic diseases vs. good health
 Acute or chronic drug therapy vs. no drug use
 “Couch potato” vs. lifelong habit of exercise
 Institutionalized vs. living independently at home

nio summarized six geriatric clinical care principles in Table 99-3.⁷

Absorption

Changes in the gastrointestinal (GI) tract with age may influence drug absorption. Gastric pH increases, intestinal blood flow diminishes, and some impairment of both active and passive transport mechanisms occurs.⁸ However, the significance of these changes is not clear. One study found nearly 90% of healthy, independently living elders were able to acidify gastric contents (pH 3.5), even in the basal unstimulated state (ages, 65–96 years).⁹ However, these volunteers were “functionally” young (Table 99-2), with an average of only 2.1 self-reported disease states and 1.6 over-the-counter (OTC) and prescription medications. Assessment of age-associated changes in absorption requires careful attention to methodology. For example, samples must be collected for four to six half-lives in older subjects to obtain a complete area under the time-concentration curve (AUC). Also, intravenous (IV) and oral (PO) data must be compared in the same subject to validate the assumption that clearance is constant:

$$AUC = \frac{(S)(F)(Dose)}{Cl} \quad (99-1)$$

where $(S)(F)$ is the fraction of dose administered that will reach systemic circulation and Cl is clearance.

Transdermal administration is becoming increasingly common and is used for several medications taken by older adults. Alterations in the stratum corneum, lipid composition of the skin, changes in sebaceous gland activity, and changes in the dermis and epidermis may affect drug absorption.¹⁰ Lipophilic drugs (e.g., estradiol) appear to be less affected by aging than do hydrophilic compounds (e.g., acetylsalicylic acid).¹¹

The following generalizations can be concluded: the extent of absorption via the oral route is similar in older patients and in young adults, the rate of absorption is reduced or unaltered in older patients, and drugs that undergo first-pass metabolism are absorbed more completely in the older patient. Changes in transdermal absorption of drugs have not been sufficiently studied; thus, close monitoring is warranted.

1. I.W., a 75-year-old woman, 5'4", 120 lb, serum creatinine (SrCr) of 1.9 mg/dL, has an acute exacerbation of heart failure (HF). She is given furosemide 40 mg orally, but this produces little increase in urine output or resolution of her symptoms. What might be an explanation for I.W.'s lack of response to furosemide? How might the desired response to furosemide be achieved?

The extent of furosemide (Lasix) absorption is not changed in older patients, but the rate of absorption is slowed. This results in a diminished efficacy of the drug because active secretion into the urine (rate of entry) must reach the steep portion

Table 99-3 Geriatric Clinical Care Principles

| <i>Care Principle</i> | <i>Outcome/Example</i> |
|--|--|
| Because of impaired physiological reserve in older patients, disease often presents at an earlier stage. | <ul style="list-style-type: none"> • Mild disease may tip the “balance.” • Drug side effects may occur with agents and doses unlikely to be toxic in younger people. • Stoic elderly may be less likely to seek help for dysfunction until symptoms are advanced. |
| Presentation of a new disease depends on the organ system made most vulnerable by previous changes, and this “weak link” often differs from the organ newly diseased. | <ul style="list-style-type: none"> • Presentation is often atypical, with the “weakest link” being the brain (confusion), lower urinary tract (incontinence), musculoskeletal system (falling), or cardiovascular system (fainting). |
| Clinical findings abnormal in younger patients are common in older people and may not be responsible for a particular symptom. | <ul style="list-style-type: none"> • An elderly patient with syncope due to medications and dehydration, but with ventricular ectopy on a cardiac monitor, may be harmed by misdirected antiarrhythmic therapy. |
| Because comorbid disease and drug use are common, symptoms are often due to multiple causes. | <ul style="list-style-type: none"> • Incontinence may involve a combination of fecal impaction, drugs inducing confusion, and impaired mobility due to arthritis. |
| Because many homeostatic mechanisms may be compromised concurrently, multiple abnormalities can be amenable to treatment, and small improvements in several areas may yield dramatic benefits to overall function. | <ul style="list-style-type: none"> • Falls associated with diabetic polyneuropathy are exacerbated by concomitant drug use, arthritis, and orthostatic hypotension, which are more easily treated than the underlying disease. |
| Because older patients are more likely to suffer adverse consequences of disease, treatment and prevention may be equally or more effective. | <ul style="list-style-type: none"> • Thrombolytics for AMI. • β-Blockers after MI. • Hypertension treatment. • Immunization (influenza, pneumococcal pneumonia). • Fall prevention (modify drugs that induce orthostasis or confusion, remove environmental hazards, address balance, peripheral edema, nocturia). |

AMI, acute myocardial infarction; MI, myocardial infarction.

of the sigmoid dose–response curve for maximal effect of the drug.¹² I.W. should be given a 40-mg dose of furosemide intravenously to bypass the problem of decreased rate of absorption. High sodium intake or concurrent use of nonsteroidal anti-inflammatory drugs (NSAIDs) can also decrease the effectiveness of furosemide. Further increases in the dose of furosemide may be necessary, with consideration of a continuous infusion in patients with severe chronic renal insufficiency (see Chapter 19).¹²

Distribution

A number of changes that can affect the distribution of drugs in the body may occur with aging. Cardiac output decreases about 1% per year from ages 19 to 86.¹³ In many older patients, this decline in cardiac output is accompanied by an increase in peripheral vascular resistance and a proportional decrease in hepatic and renal blood flow. However, noninstitutionalized older adults who are free of coronary artery disease or other debilitating health problems exhibit little age-related declines in cardiac output (functionally young).¹⁴ Body composition undergoes changes during normal aging. Total body water and lean body mass both decline with age, and total fat content increases between ages 18 and 85 years from 18% to 36% in men and from 33% to 48% in women.^{15,16} Thus, the volume of distribution (Vd) of drugs that are distributed primarily in body water or lean body mass (e.g., lithium, digoxin) is decreased in older adults; unadjusted dosing can result in higher blood levels. Conversely, the Vd of highly lipid-soluble drugs, such as long-acting benzodiazepines (e.g., diazepam), may be increased, thereby delaying maximal effects or leading to accumulation with continued use.¹⁷ Factors with special applicability in older patients that may affect binding include protein concentration, disease states, coadministration of other drugs,

and nutritional status. Serum albumin concentrations fall progressively for each decade beyond 40 years of age, reaching a mean of 3.58 g/dL (normal, 4 g/dL) in those older than 80 years of age.¹⁸ Decreased albumin concentrations are important because albumin is a major site of drug binding. Increases in α_1 -acid glycoprotein in older patients¹⁹ affect the binding of weak bases such as lidocaine and propranolol. Data are lacking concerning age-related changes in tissue protein binding of drugs. However, the Vd of digoxin decreases in subjects with impaired renal function, as does the myocardial-to-serum concentration ratio.²⁰ Finally, an important factor in determining the significance of changes in protein binding status is whether a drug is restrictively or nonrestrictively cleared.²¹

Altered Protein Binding

2. O.T., a 90-year-old woman, 5'8", 132 lb, is brought to the emergency department (ED) for evaluation of a “shaking spell.” In the ED, another “spell” is observed, starting with shaking of the left arm and progressing into a generalized tonic-clonic seizure. A loading dose of phenytoin (Dilantin) 1,000 mg is given IV over 30 minutes. O.T. is admitted to the neurology unit for further evaluation and given phenytoin 300 mg QHS. What is your assessment of O.T.’s phenytoin therapy given her age? What laboratory tests should be ordered, and how often should these be monitored?

O.T. received an average phenytoin loading dose of 17 mg/kg (normal, 15–20 mg/kg) and is receiving the average daily maintenance dose. A sodium serum concentration should be obtained to rule out a hyponatremia-induced seizure, and an albumin serum concentration should be obtained because of phenytoin’s high (90%) protein binding. A phenytoin serum concentration should be measured before O.T. is discharged from the hospital to document that the desired therapeutic

serum concentration has been achieved. The serum phenytoin concentration should be obtained whenever an adverse drug reaction or seizure occurs. A follow-up, steady-state phenytoin serum concentration should be obtained in 10 to 14 days to determine if the current dose is appropriate.

3. The serum albumin concentration is 2.2 g/dL (normal, 3.2–5.2 g/dL), Na is 140 mEq/L (normal, 138–145 mEq/L), and the phenytoin serum concentration is 15 mcg/mL (normal, 10–20 mcg/mL). O.T. complains of drowsiness and has a wide-based, unsteady gait. What is the likely cause of her symptoms?

[SI units: albumin, 22 g/L (normal, 32–52); phenytoin, 59.5 mmol/L (normal, 40–80)]

O.T. could have a phenytoin free-fraction percentage of up to 18%, compared with the normal value of 10%, because of her low albumin serum concentration.²¹ This would produce a free phenytoin concentration of 27 mcg/mL (normal, 10–20 mcg/mL), explaining O.T.'s symptoms (assuming O.T.'s serum phenytoin concentration is at steady state). In O.T.'s case, free phenytoin concentration monitoring would be appropriate, if available, and her dosage should be adjusted accordingly. A dietary consultation to examine the reason for her low albumin may contribute to her overall health.

Metabolism

O.T.'s phenytoin metabolism may be affected due to factors shown to influence hepatic drug metabolism, which include disease states, concurrent drug use, nutritional status, environmental compounds, genetic differences, gender, liver mass, and blood flow. Hepatic microsomal enzyme activity is reduced with increasing age in animals, but the clinical significance of this is controversial in humans. Large interindividual variation in liver metabolism exists for any given drug and, in most cases, may be more important than the changes associated with aging.^{8,22–25} Also, liver mass declines and hepatic blood flow decreases 45% between the ages of 25 and 65.²⁶ Unfortunately, clinical tools for the assessment of hepatic metabolism are not readily available. Age-related changes in the liver metabolism of warfarin and long-acting benzodiazepines have been reported in humans.^{27–29} Compounds undergoing phase I metabolism (reduction, oxidation, hydroxylation, demethylation) have a decreased or unchanged clearance, whereas compounds metabolized by phase II processes (conjugation, acetylation, sulfonation, glucuronidation) have no change in clearance with age. Drugs with high hepatic-extraction ratios, such as the nitrates, barbiturates, lidocaine, and propranolol, may have reduced hepatic metabolism in older adults.³⁰

Reduction in Hepatic Reserve

4. D.A., an independently living 65-year-old man, 5'10" tall and weighing 260 lb, has a chief complaint of severe shortness of breath (SOB; respirations, 26 breaths/minute), palpitations (heart rate [HR], 120 beats/minute), and nausea. He has a history of chronic obstructive pulmonary disease (COPD) and HF. D.A.'s current medications are theophylline-SR (Theo-Dur) 450 mg Q 8 h, captopril (Capoten) 12.5 mg TID, and furosemide (Lasix) 20 mg QD. At his last visit to his physician 2 months ago, his theophylline serum concentration was 15 mcg/mL (therapeutic

range, 8–12 mcg/mL). After a long history of heavy smoking, D.A. finally took his physician's advice and abruptly quit. The diagnosis of acute HF is made on the basis of the chest radiograph, 2% pitting edema, and "junky" sounding lungs. Based on the information given, what potential problems should be added to the list of differential diagnoses to be considered?

Theophylline toxicity should be suspected for two reasons: (a) lack of hepatic microsome/enzyme stimulation from his recent smoking cessation, and (b) the known reduction of theophylline hepatic metabolism secondary to acute HF.²¹ The theophylline dose should be held until the serum theophylline concentration is within the desired therapeutic range. In patients who are at high risk of developing theophylline toxicity, other treatment options such as an inhaled anticholinergic agent (e.g., tiotropium) with or without an inhaled β_2 -agonist should be considered in place of theophylline (see Chapter 24).

Although the potential for theophylline toxicity can be predicted reasonably in D.A., the sudden onset of clinical deterioration or an adverse effect often arises unexpectedly in many older patients. Patients often do well while medically stable only to abruptly experience a "cascade of disasters" when hospitalized or when they begin taking additional medications. As presented in the answer to question 3, the process of aging can be associated with declining liver mass, decreased hepatic blood flow, altered nutritional status, and a host of other physiological changes. These alterations result in a loss of "hepatic reserve," making the patient susceptible to adverse effects because new drugs compete for the same metabolic enzymes. The concept of a lost "reserve" in the elderly applies to other organ systems as well. Therefore, D.A.'s response to renally excreted drugs (e.g., captopril, furosemide) should also be considered during this episode of acute HF.

Excretion

Age-related changes in renal function result in more adverse drug events (ADEs) than any other age-related physiological alterations. Compounding these changes in the kidney are the arteriosclerotic changes and a declining cardiac output that decrease renal perfusion by 40% to 50% between the ages of 25 and 65. This is accompanied by a corresponding decrease in glomerular filtration and urea clearance.³¹ Urine concentrating ability declines with age, as does renal sodium conservation.^{32,33} Tubular secretory capacity and creatinine clearance (CICr) may also be reduced.^{34,35} The kidney loses functioning cells with age, and histologic studies reveal a decline in the absolute number of nephrons.³⁶ All these measures of kidney function decline uniformly, leading to the concept of the "intact nephron." Significant variability can occur in the rate of decline in renal function in a minority of elderly patients³⁷ (Table 99-2).

The plasma half-life is prolonged for a number of renally excreted drugs in "healthy" older adults. The highest-risk drugs are those that depend entirely on the kidney for elimination. Examples of these are listed in Table 99-4.

Age-related changes in renal function are evaluated using the CICr, an estimate of glomerular filtration rate. The Cockcroft-Gault equation is used most commonly to estimate CICr.³⁸ Many controversies exist with regard to the use of this equation. One relates to whether the actual or lean body weight (LBW) should be used.^{39,40} The use of LBW may reflect SCr

Table 99-4 Drugs Highly Dependent on Renal Function for Elimination^a

| | | |
|-----------------------|--------------------------------|------------------|
| Acetazolamide | Diffunisal | Metoclopramide |
| Acyclovir | Digoxin | Nadolol |
| Allopurinol | Enalapril | Nitrosourea |
| Amantadine | Ethambutol | Penicillamine |
| Amiloride | Fluconazole | Pentamidine |
| Aminoglycosides | Flucytosine | Phenazopyridine |
| Amphotericin B | Fluoroquinolones | Plicamycin |

| Captopril | H ₂ blockers (most) | Sulfamethoxazole |
| Cephalosporins (most) | Imipenem | Sulfapyrazone |
| Chlorpropamide | Lisinopril | Thiazides |
| Cisplatin | Lithium | Ticarcillin |
| Clonidine | Methenamine | Trimethoprim |
| Colistimethate | Methotrexate | Vancomycin |

This list is not comprehensive; see references 156 and 157 for additional details.

production more accurately because creatinine is produced in muscle mass, which is decreased in older patients. There is also a question of whether one should use the actual creatinine value when it is <1.0 mg/dL or whether it should be rounded to 1.0. Finally, for certain subpopulations of older patients (i.e., ambulatory and healthy vs. hospitalized, malnourished, and/or critically ill), other methods may produce more accurate estimates of renal function.

Table 99-5 provides a composite picture of the age-related physiological changes, disease states, and pharmacologic factors that affect pharmacokinetic processes in older adults.

Pharmacodynamic Changes

Homeostasis and Postural Hypotension

D.A. is susceptible not only to decreased clearance (i.e., hepatic metabolism, renal elimination), but also to pharmacodynamic changes. Pharmacodynamic changes are defined loosely in this chapter as alterations in concentration–response relationships or receptor sensitivity. Drug side effects that are mild or nonexistent in younger patients may be significant in older adults due to inefficient homeostatic adjustments. For example, the higher rate of orthostatic hypotension observed in older patients is often the result of impaired baroreceptor function and a failure of cerebral blood flow autoregulation. Orthostatic hypotension occurs in 20% of ambulatory patients older than 65 years of age and in 30% of those older than 75,⁴¹ and it is often aggravated by drugs with sympatholytic activity (e.g., α -adrenergic blocking agents, phenothiazines, tricyclic antidepressants [TCAs]), volume-depleting drugs (e.g., diuretics), and vasodilating agents (e.g., nitrates, alcohol).⁴² In one study of 100 geriatric psychiatric outpatients, almost 40% complained of dizziness and falling, which were attributed to psychiatric medications.⁴³ Patients with impaired cardiac output and patients taking concurrent diuretic therapy (e.g., patient D.A.) are especially vulnerable. Also, aging impairs balance and posture maintenance, and drug effects on posture control may contribute to drug-induced falls in older adults.⁴⁴ Table 99-6 reviews the therapeutic agents commonly associated with adverse drug reactions that may affect the mobility of older patients.

Receptor Sensitivity

An exaggerated response to some drugs (e.g., nitrazepam, heparin [in females], warfarin) may reflect an intrinsic, age-related change in receptor sensitivity.^{45,46} The aging central nervous system (CNS) is particularly vulnerable to qualitative

Table 99-5 Changes Affecting Pharmacokinetic Parameters

| Parameter | Physiological Changes | Disease States | Pharmacologic Factors |
|---|--|---|--|
| Absorption (bioavailability, first-pass metabolism) | Gastric pH Absorptive surface Splanchnic blood flow GI motility Gastric emptying rate | Achlorhydria, diarrhea, gastrectomy, malabsorptive syndromes, pancreatitis | Drug interactions, antacids, anticholinergics, cholestyramine, food |
| Distribution | Cardiac output TBW Lean body mass Serum albumin α_1 -Acid glycoprotein Body fat Altered relative tissue perfusion | CHF; dehydration; edema, ascites; hepatic failure; malnutrition; renal failure | Drug interactions, protein binding displacement |

| Antihypertensives | Orthostatic hypotension |
| β -Adrenergic blockers | Ability to respond to work load |

TCAs, tricyclic antidepressants.

and quantitative alterations in drug response. The aging brain, like the aging kidney, loses a significant number of active cells during later life, and some brain atrophy is a common, although not necessarily pathological, finding in older adults. Normal aging also involves a reduction in cerebral blood flow and oxygen consumption, and increased cerebrovascular resistance.⁴⁷ Older adults often have cerebral blood flow rates that are as much as 20% lower than those of younger persons.¹³ In addition, inhibitory and excitatory pathways in the CNS are delicately balanced to modulate cognitive functions and behavior. With aging, there is a selective decline in some pathways and the preservation of others. For example, cholinergic neurons in the neocortex and hippocampal areas of the brain normally decrease with age. Pathological cholinergic deficits are associated with memory loss, confusion, and other cognitive impairments.⁴⁸ Drugs with anticholinergic properties are particularly notorious for inducing mental fuzziness and confusion in older patients. Several examples of therapeutic classes with anticholinergic properties are listed in Table 99-7.

Table 99-7 Categories of Anticholinergic Drugs That Can Induce Confusion in Older Patients

| Therapeutic Class | Examples (Brand Name) |
|-------------------|--|
| Antispasmodic | Belladonna (Generic) Dicyclomine (Bentyl) Propantheline (Pro-Banthine) |
| Antiparkinson | Benzotropine (Cogentin) Trihexyphenidyl (Artane) |
| Antihistamine | Diphenhydramine (Benadryl) Chlorpheniramine (Chlor-Trimeton) |
| Antidepressant | Amitriptyline (Elavil) Imipramine (Tofranil) |
| Antiarrhythmic | Quinidine Disopyramide (Norpace) |
| Neuroleptic | Thioridazine (Mellaril) Chlorpromazine (Thorazine) |
| Hypnotic | Hydroxyzine (Vistaril) |
| OTC agents | Antidiarrheals Doxylamine Cold remedies |

OTC, over the counter.

Both central and peripheral responsiveness of adrenergic receptors decline with aging.⁴⁹ Monoamine-oxidase activity increases with normal aging, and this is reflected by a decline in norepinephrine and dopamine levels in aging brains.⁵⁰ The decline in CNS dopamine synthesis is associated with increased sensitivity to dopamine blocking agents (e.g., neuroleptics, metoclopramide). However, β -receptor sensitivity to both β -agonists and β -antagonists decreases, even if the number of β -receptors does not decrease in older patients.^{51,52} Because these neurologic and biochemical reserves are reduced as a normal consequence of aging, iatrogenic behavioral disorders are relatively common in older adults, and drugs are one of the most common causes of sudden, unexplained mental impairment in the older adult. For example, in one study, 11% of 300 patients older than 65 years of age experienced cognitive impairment as a result of an adverse drug reaction, and the risk increased ninefold when patients were taking four or more prescription drugs.⁵³

In conclusion, D.A. is susceptible to significant variations in response to his medications and needs to be monitored carefully because of both pharmacokinetic and pharmacodynamic alterations attributable to aging. His theophylline therapy, in particular, should be evaluated.

Problems Associated With Drug Use in Older Adults

Polymedicine

Multiple medication use is the primary cause of drug-related adverse events in the older population according to the Centers for Disease Control and Prevention.⁵⁴ Polydrug therapy thrives under conditions in which multiple chronic diseases exist in patients with communication problems, especially when the physician is under pressure to be time efficient. These factors can lead to misdiagnoses and unclear drug indications. For these reasons, monitoring drug therapy in these patients is not only challenging but imperative. Busy health care providers often assign a low priority to nursing home patients in terms of individual attention, and much of the prescribing of medications and follow-up is done by telephone. Duplicative prescribing within the same drug class often occurs, and unrecognized drug side effects are treated with more drugs. With minimal actual patient contact, prescribers may continue drugs in patients long after the original problem has resolved to avoid the inconvenience of meticulous dosage adjustments and follow-up monitoring. Careful drug regimen review is essential to identify potentially unnecessary or inappropriate medications and to systematically taper and discontinue these agents, with attentive monitoring of the older person.^{55–57}

Adverse Drug Events

An ADE includes preventable and nonpreventable events and accounts for errors related to prescribing and administration. The combining of several medications can also increase the risk of clinically significant drug interactions and subsequent ADEs in the elderly. Age per se is not an independent risk factor for ADEs, but rather, increased risk is derived from age-related factors (e.g., physiological changes), chronic disease states, use of different health care providers, and inappropriate prescribing.⁵⁸

Twenty-eight percent of hospitalizations of older persons are a result of ADEs and poor medication adherence.⁵⁹

Table 99-8 Predictors of Adverse Drug Events

- More than four prescription medications
- Length of stay in hospital longer than 14 days
- More than four active medical problems
- Admission to a general medical unit vs. a specialized geriatric ward
- History of alcohol use
- Lower mean Mini-Mental Status Examination score (confusion, dementia)
- Twenty-four new medications added to medication regimen during hospitalization

Adapted from references 61 and 63.

Adverse drug reactions in older patients cared for in the community may be as high as 35%.⁶⁰ An estimated 32,000 hip fractures, 163,000 cases of drug-induced cognitive impairment, and 61,000 cases of neuroleptic-induced Parkinsonism occur annually.⁵⁹

ADEs can be difficult to detect in older patients because they often present atypically and with nonspecific symptoms, such as lethargy, confusion, lightheadedness, or falls. Nevertheless, most adverse reactions represent extensions of a drug's pharmacologic effect, have identifiable predictors, and are preventable (Table 99-8).^{61–63} Adverse drug reactions remain a significant problem, with some experts placing the direct health care costs for adverse drug reactions at \$3.6 billion annually.⁶⁴

ADVERSE DRUG REACTIONS IN OLDER PATIENTS

5. S.E., an 85-year-old woman, 5'2" and 102 lb, with a SrCr of 1.6 mg/dL, is admitted for chest pain, SOB, and to rule out myocardial infarction (MI). Her physician is concerned about overeducation with narcotics and prescribes ketorolac (Toradol) 30 mg Q 6 h IV. She has a history of severe HF and angina for which she takes lisinopril 10 mg QD, furosemide 40 mg QD, aspirin 81 mg QD, and nitroglycerin SR 6 mg BID. The lisinopril dosage is increased to 20 mg QD, and the furosemide dosage is also increased to 40 mg BID. Her BP is 110/66 mm Hg, and her urine output has been 20 to 30 mL/hour for 4 hours since ketorolac was initiated. What risk factors are present in S.E. for drug-induced renal problems?

[SI unit: SrCr, 141.4 mol/L]

S.E. has a number of risk factors for the development of drug-induced acute renal failure (ARF). Angiotensin-converting enzyme (ACE) inhibitors are indicated for HF management and improve renal function by increasing cardiac output. However, they can diminish efferent arteriole glomerular capillary filtration pressure and precipitate ARF in predisposed patients. A 13% incidence of azotemia has been reported in LTCF residents started on a short course of NSAID treatment.⁶⁵ A low serum sodium concentration, high-dose diuretics, diabetes, severe HF (i.e., New York Heart Association [NYHA] class IV), use of a long-acting ACE inhibitor, and concurrent NSAID use are all risk factors for drug-induced ARF (see Chapter 31). Patients with these risk factors should be monitored closely when an ACE inhibitor is initiated and when the dosage of an ACE inhibitor is increased (see Chapter 19). Renal prostaglandins (PGE₂, PGI₂) increase or help maintain renal blood flow when renal function is compromised by intrinsic

renal disease, HF, liver disease with ascites, or hypertension; therefore, the use of a prostaglandin inhibitor such as ketorolac places S.E. at an increased risk for ARF. Furthermore, the ketorolac dose is excessive for S.E. based on the recommended maximum dose of 15 mg every 6 hours for elderly patients.⁶⁶

Disease-Specific Geriatric Drug Therapy

Cardiovascular Disease in the Ambulatory Older Patient

6. T.M. is a 78-year-old woman who presents to a “brown bag” session being sponsored by the local senior center and school of pharmacy. She reports that recently she has begun to feel “sluggish” and fainted a few times. She lives at home alone on a modest, fixed retirement income. She has a number of chronic medical problems, including coronary artery disease (CAD), congestive heart failure (CHF), hypertension, diabetes, and hyperlipidemia. She visits different specialists on a sporadic basis for management of her various disease states and takes “a lot of medications,” the names of which she does not know. She admits to skipping her medications periodically. T.M. usually maintains a fairly active social life, hosting and visiting her elderly friends regularly and attending the local seniors' lunch social three times a week. She is highly interested in matters relating to her health, and she often self-medicates with nonprescription medications and herbal remedies she hears about through her peers. Because of the recent weakness, however, she is now afraid to attend social gatherings. Review of her “brown bag” reveals the following items: glyburide 2.5 mg BID, HCTZ 25 mg QD, propranolol 20 mg QID, niacin 500 mg TID, ASA 325 mg PRN, digoxin 0.25 mg QD, isosorbide dinitrate (ISDN) 20 mg QID, NTG 0.4 mg SL PRN, captopril 25 mg TID, furosemide 40 mg BID, acetaminophen 500 mg PRN, verapamil 60 mg QID, multivitamins with minerals, calcium carbonate 500 mg TID, hawthorn tincture 20 drops BID, ibuprofen 200 mg PRN, rosiglitazone 2 mg BID, and dandelion 10 mL BID. She also drinks a glass of red wine with dinner and several cups of licorice tea with breakfast and lunch. What initial steps are necessary for safe and effective management of T.M.'s drug therapy?

Like many ambulatory older patients who are being treated for multiple chronic medical conditions, T.M. is at high risk for drug-induced problems secondary to nonadherence, medication errors, inappropriate prescribing, self-medicating, and polymedicine. She is representative of more than 9 million older adults who live at home alone. The isolated community-dwelling older patient is typically female, 75 years of age or older, has multiple medical issues, and takes multiple medications.⁶⁷ Many of these individuals lack close support and a daily routine, and may not be fully aware of the time of day or the day of the week. Limited time awareness makes adherence to complex medication regimens more difficult in this population. In addition to older people like T.M., a second high-risk group of older persons consists of those individuals who were recently discharged from the hospital. The postdischarge period can be a time of confusion for these patients, who often must cope with new drugs or replacement drugs added to an already complex prehospitalization regimen. A summary of the various factors contributing to nonadherence in the older patient is presented in Table 99-9.⁶⁸

T.M. needs a primary care provider to coordinate her medical care and to follow-up on her new-onset “sluggishness and fainting.” She should also be advised to establish a relationship at one pharmacy that can monitor all her medications.

Table 99-9 Factors Influencing the Inability to Comply With a Medication Regimen

| |
|---|
| Three chronic conditions |
| More than five prescription medications |
| Twelve medication dosages per day |
| Medication regimen changed four times during the past 12 months |
| Three prescribers involved |
| Significant cognitive or physical impairments (e.g., memory, hearing, vision, color discrimination, child-resistant containers) |
| Living alone in the community |
| Recently discharged from the hospital |
| Reliance on a caregiver |
| Low literacy |
| Medication cost |
| Demonstrated poor compliance history |

Adapted from references 68 and 68.

Furthermore, T.M. should be counseled to discontinue alcohol, which can interact with several of her current medications and worsen her conditions. Finally, assessment of the risk for medication-related problems (MRPs) is highly recommended by doing a drug regimen review such as with the brown bag event, medication therapy management,⁶⁹ and/or using validated tools such as a self-administered questionnaire to identify potential for MRPs.⁷⁰

7. T.M. presents to the multidisciplinary geriatric care team on the advice of pharmacists and students at the “brown bag” session. During the pharmacy intake interview, she admits to selective adherence with many medications based on how they make her feel and their cost. Her “glass” of wine with dinner is 32 oz, four times a week. She also reveals that she has not been taking her furosemide and potassium supplement because she feels that they were contributing to her “sluggishness” and fainting. She is using hawthorne and dandelion instead. The geriatrician’s summary of T.M.’s history and physical examination reads as follows: 78-year-old white female, 5’6”, 189 lb. Vital signs: BP, 168/82 mm Hg; HR, 54 beats/minute; temperature, 98.7°F; and respiratory rate, 18/minute. Pertinent laboratory values: SCr, 1.5 mg/dL (nl 0.6–1.2 mg/dL); BUN, 35 mg/dL (nl 8–18 mg/dL); Na, 153 mEq/L (nl 138–145 mEq/L); K, 3.1 mEq/L (nl 3.5–5 mEq/L); Mg, 1.5 mEq/L (nl 1.6–2.4 mEq/L); glucose, 250 mg/dL (nl 70–110 mg/dL); A1c, 9.5%, cholesterol, 259 mg/dL; low-density lipoprotein (LDL), 140 mg/dL; high-density lipoprotein (HDL), 40 mg/dL; triglycerides (TG), 200 mg/dL; proteinuria; and digoxin level, 1.5 ng/mL. Electrocardiogram showed sinus bradycardia with an old anterior MI. Echo: EF 25%. Problem list: new-onset sluggishness and fainting, chest pain/SOB on exertion, 3(+) pitting edema bilaterally, NYHA class II–III HF, hypertension, type 2 diabetes, obesity, excessive alcohol intake, CAD, and hyperlipidemia. What factors may be contributing to T.M.’s feeling of sluggishness and fainting?

T.M.’s sluggishness and fainting are most likely due to her low heart rate, somewhat dehydrated state, and multiple medications that have the potential for producing weakness. Specifically, digoxin 0.25 mg daily is considered a high dose for an elderly patient who has moderate kidney compromise. A level of 1.5 ng/mL is excessive for the CHF condition (ther-

apeutic range 0.5–1.2 ng/mL for HF); therefore, one or two doses should be held, and then the dose should be lowered to 0.125 mg daily. Her condition on the new dose should be re-evaluated after about 2 weeks.⁷¹ After stabilization of the current exacerbation, one can try discontinuing digoxin to evaluate whether T.M. is actually benefiting from this agent. Dizziness can result from T.M.’s use of supplements. Although hawthorn has been approved for use by the German Commission E in NYHA class II HF, it may increase digoxin’s toxicity and should be discontinued.^{72,73} Dandelion can also produce mild diuretic, hypokalemic, and hypoglycemic effects. Therefore, its use needs to be monitored closely.⁷⁴ In addition, the licorice tea T.M. drinks has mineral corticoid properties and may cause blood pressure elevation, salt and water retention, as well as low potassium levels, all of which are already present in T.M.⁷⁵ In general, elderly patients should be advised not to self-medicate with supplements without clear indication and cautioned against potential drug interactions with their prescription medications. Furthermore, T.M. is also taking propranolol and verapamil, which may lower the heart rate and contribute to the sluggishness. Switching propranolol to an extended-release β -blocker should help, and verapamil can be discontinued at this point because it may not have benefits toward T.M.’s other medical problems.

HEART FAILURE

8. What is appropriate management for T.M.’s stage of HF?

HF is a common cause of morbidity and mortality in older patients. The standard therapy for HF typically consists of three or more medications (diuretics, β -blockers, and ACE inhibitors, with or without digoxin and spironolactone). Standard use of multiple medications in the treatment of HF makes close monitoring of drug therapy essential. T.M. has stage II–III HF. Based on her history of an old MI and low EF, she is also in stage B of the American College of Cardiology/American Heart Association classification scheme. Although such a patient is symptomatically relieved with diuretics, the recommended therapy for stage B includes an ACE inhibitor or ARB, and a β -blocker. Concurrent behavioral modification with weight loss and salt restriction will also allow this medical therapy to be more effective.⁷⁶

9. What factors should be considered for the selection of a diuretic in HF?

Two diuretics were prescribed for T.M., although she is taking only the HCTZ. Loop diuretics are generally more effective than thiazides; furosemide is also preferred in her case because HCTZ is generally ineffective in moderate to severe renal compromise (CrCl <30 mL/minute).⁷⁷ It should be explained to T.M. that the HCTZ is duplicative in its action and needs to be replaced with furosemide, which is the more effective diuretic in her case. It will help resolve her current HF exacerbation and bilateral edema. Potassium supplementation will depend on current potassium level and the potential of hyperkalemia with a concurrent ACE inhibitor, which T.M. will be maintained on. Regular monitoring of SCr and potassium is essential, and K⁺ supplementation should be given if necessary. Elderly patients often dislike taking diuretics due to the frequent need to urinate. In the case of T.M., she may be

advised to take the furosemide later on during the day after her outings when she is home.

ACE INHIBITORS AND ANGIOTENSIN RECEPTOR BLOCKERS

10. T.M. has been taking captopril 25 mg TID. Why is this an inappropriate choice of ACE inhibitor for T.M.?

ACE inhibition is essential in the management of HF due to its benefits in ventricular remodeling.^{78,79} The current ACE inhibitor in T.M.'s regimen is captopril 25 mg TID, which is inconvenient and may contribute to poor adherence. A more suitable ACE inhibitor may be ramipril, initiated at 1.25 to 2.5 mg daily. Alternatively, fosinopril 5–10 mg QD may also be desirable based on its 50% hepatic and 50% renal elimination profile.⁸⁰ So far, T.M. has not complained of any cough, so she may tolerate a long-acting ACE inhibitor such as ramipril or fosinopril. However, if an intolerable cough develops or if she does not respond to an ACE inhibitor, then an ARB such as candesartan can be substituted and initiated at 4 mg daily and titrated up as needed. Recent studies have also supported the addition of an ARB to ACE inhibitor therapy based on a lower mortality and hospitalization rate compared to an ACE inhibitor alone.⁸¹

β -BLOCKERS

11. T.M. is being treated with propranolol 20 mg QID. Why is this an inappropriate choice of β -blocker for T.M.?

The β -blockers carvedilol, metoprolol, and bisoprolol have been proven to reduce morbidity and mortality in patients with HF.^{82–84} One of these agents should be considered in patients with HF, unless the patient is in stage IV CHF, where there is no evidence of benefits. In T.M.'s case, propranolol should be discontinued for several reasons. It is probably contributing to her feeling of sluggishness because it is a nonselective β -blocker; she may also be taking it inconsistently due to the four-times-daily regimen. Extended-release forms of metoprolol (Toprol XL 25 mg daily)⁸⁵ and carvedilol (Coreg CR 10 mg daily) that require only one daily dose are available.⁸⁶ An appropriate β -blocker should be substituted for propranolol and initiated when her current exacerbation of HF has resolved.

CORONARY HEART DISEASE/HYPERLIPIDEMIA

12. T.M. does not take her niacin because she experienced unbearable facial flushing. Despite her history of MI, she does not believe that cholesterol and "heart disease" are major health concerns for her because she is a woman. Is it important to manage cholesterol in an elderly woman with coronary heart disease (CHD)? Are women older than age 65 at greater, lower, or equal risk of death due to CHD compared with their male counterparts?

Elevated cholesterol levels have been shown to increase the risk for CHD in older adults.⁸⁷ This increased risk is statistically significant, even after adjusting for indicators of frailty and poor health.⁸⁰ Furthermore, CHD is the number one cause of death in women older than age 65.⁸⁸ Serum total cholesterol levels >240 mg/dL are present in 42% of women older than 65 years of age compared with just 25% of men older than 65 years of age.⁸⁹ After age 65, the mortality from CHD is equal in men and women.⁹⁰ T.M. has a history of MI with multiple CHD risks and risk equivalents; therefore, her LDL goal should be <100 mg/dL with a more aggressive option of

<70 mg/dL. The American Diabetes Association (ADA) has also recommended that the TG goal for a patient with diabetes be <150 mg/dL.⁹¹ Therefore, T.M. needs to be aggressively treated to lower her LDL and TG levels in light of her risk category, which confers a 10-year CHD risk of >20%.^{87,91}

13. What is an optimal therapeutic plan for management of T.M.'s hyperlipidemia?

T.M.'s treatment plan should begin with lifestyle and dietary modifications. However, her history of MI places her at extremely high risk, so she should be started with aggressive lipid-lowering therapy. Statins are the drugs of choice for lowering LDL and should also be considered in the elderly population as they are effective and well tolerated. An adequate dose of a statin is able to lower the LDL up to 60% and the TG up to 35%.⁸⁹ Monotherapy with statins, therefore, should be adequate to bring her LDL and TG to target levels. Clinicians will need to titrate up to effective dosages with effective education and monitoring of liver function. Elderly patients are likely to be nonadherent due to the fear of myopathy and rhabdomyolysis, and counseling needs to be done to validate the fear, as well as the relatively low risk, of these adverse effects.⁹⁰ If combination therapy is indicated, then addition of niacin is reasonable because it may also raise the HDL level. The strategy of taking an aspirin (indicated for her CAD and diabetes mellitus [DM]) half an hour before taking the niacin may prevent the flushing syndrome. Fibrates or the cholesterol absorption inhibitor ezetimibe can also be combined with statins to further reduce the levels of LDL and TG, if necessary. Discontinuation of alcohol would be beneficial because it can increase triglycerides by as much as 50%.⁹²

14. What other interventions should be implemented to optimize management of T.M.'s CAD?

Any strategy to optimize her CAD management should take into consideration her functional status, comorbidities, and risks versus benefits. T.M. is still experiencing anginal pain on her current regimen, possibly due to her inability to adhere to the four-times-daily regimen of ISDN. A once daily long-acting nitrate preparation (ISMN) may be better suited for her, with sublingual NTG available as needed. Calcium channel blockers such as verapamil, like nitrates, may relieve anginal symptoms but have not been shown to improve survival.⁹³ Therefore, verapamil may be discontinued. However, the other mainstays of angina therapy, aspirin and β -blockers, have proven to increase survival in patients with CHD and should be considered because aspirin is also indicated for MI prevention and β -blockers may be beneficial for CHF. To prevent further endothelial injury from the atherosclerosis that leads to plaque rupture, statins are indicated as described previously. Interestingly, ACE inhibitors (ramipril) have also been shown to reduce mortality and improve secondary prevention of CAD, particularly in the age group 65 years or older.⁹⁴

HYPERTENSION

15. T.M. has uncontrolled hypertension. How should this be managed in light of her advanced age?

T.M.'s blood pressure is well above the goal of <130/80 mm Hg for diabetic patients as set forth by the ADA and the Seventh Report of the Joint National Committee on

Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC VII).^{91,95} Hypertension is present in more than two-thirds of individuals older than 65 years of age. Despite having the highest prevalence of hypertension, this population is the least likely to have their blood pressures adequately treated and controlled.⁹⁶ Treatment of elderly patients, such as T.M., should be based on the same guidelines published for the general care of hypertension. Standard doses of antihypertensive drugs and multiple-drug therapy are needed in the majority of older patients. However, in many of these patients, lower initial doses are needed to minimize the risk of adverse effects such as postural hypotension. T.M. is taking furosemide, propranolol, isosorbide dinitrate, captopril, and verapamil, all of which have hypotensive effects. T.M. is also a patient with compelling indications as defined by JNC VII, such as DM, HF, and CAD. In such a patient, the use of a diuretic, ACE inhibitor or ARB, and/or β -blocker in appropriate combination may improve morbidity and mortality outcomes. Although adequate dosing and combination therapy are essential in achieving blood pressure control in the elderly population, close monitoring is also necessary. With moderate doses of diuretics, potential of hypokalemia and insulin resistance require frequent monitoring of potassium and glucose status. The use of ACE inhibitors or ARBs, however, raises the risk of hyperkalemia and renal failure. β -blockers, although indicated for earlier stages of CHF and high coronary risk associated with DM and HTN, are not generally desired due to multiple undesired effects, such as reduced insulin sensitivity, erectile dysfunction, depression, and lack of energy, all of which are more likely in an elderly patient. Therefore, it is recommended for T.M. that adequate doses of furosemide, benazepril, or candesartan with close monitoring be the main therapeutic approaches for her hypertension. Extended- or controlled-release formulations of metoprolol and carvedilol may be considered if deemed beneficial for CHF and if tolerated. Verapamil should be reserved as second-line treatment in this patient due to a lack of benefit in CHF.⁹⁵

Diabetes in the Elderly

16. T.M. reports that she frequently feels light headed and shaky after she takes the glyburide. She admits to not taking glyburide regularly because it also causes fast heartbeats. What is an optimal therapeutic plan for the management of T.M.'s diabetes?

Comprehensive diabetes education needs to be initiated, stressing the importance of weight loss, self-monitoring of blood glucose, alcohol abstinence, and medication adherence. A 5% to 10% weight loss will improve her glucose control and cardiovascular status.⁹¹ T.M.'s alcohol consumption and self-reported erratic meal schedule may be contributing to the hypoglycemia (in addition to the glyburide), as well as to the worsening of her HTN and CHF. The daily allowance of alcohol recommended is 1.5 oz of distilled alcohol for men and women, respectively. In T.M.'s case, this would be one small glass of wine (3–4 oz).⁹² Glyburide is also a long-acting sulfonylurea and is associated with severe hypoglycemia more commonly than other sulfonylureas due to its active metabolites. In general, the elderly are more susceptible, even at low doses, to hypoglycemia. The incidence of hypoglycemia in the elderly population is high, and symptoms may be unrecognized.⁹⁷ Among the second-generation sulfonylureas, glipizide or glimepiride

are better choices. Alternatively, T.M. could be treated with a meglitinide, such as repaglinide, which does not require dose adjustment in elderly patients. Use of a meglitinide also allows for a more flexible meal pattern because it is taken with each meal and can be skipped if a meal is skipped. Any new diabetes medication should be initiated in low doses and gradually titrated upward to avoid hypoglycemic episodes and to achieve glycemic goals in accordance with ADA guidelines.⁹¹ Current treatment algorithm states that metformin with lifestyle modification is the initial management approach. However, metformin is contraindicated in T.M. due to SCr >1.4 mg/dL. When metformin is contraindicated, glitazones, sulfonylureas, and/or basal insulin can be used to achieve a hemoglobin A1c goal of <7%. Because the glitazones are also contraindicated in T.M. due to CHF, a combination of repaglinide plus basal insulin is reasonable to bring her diabetes under control. Recent new incretin mimetics may work to prevent progressive β -cell exhaustion and insulin deficiency, and should be considered early on during the disease state. Both exenatide (glucagon like peptide analog) and sitagliptin (dipeptidyl peptidase inhibitor) do not promote hypoglycemia: exenatide has the advantage of inducing weight loss, and the dosage of sitagliptin may have to be adjusted when CrCl <50 mL/minute.^{98,99} In general, the priority of diabetes management in the elderly population should be on reduction of cardiovascular risks with strict control of blood pressure and lipids in addition to avoidance of hypoglycemia events. Therefore, an A1c goal of <8% may be acceptable in some elderly patients who are prone to have hypoglycemia.¹⁰⁰ Comprehensive screening of diabetic complications should be done routinely to decrease morbidity and mortality.⁹¹

Depression and the Older Patient

Significant depression is the most common mental illness among older adults, occurring in about 15%; it is a source of significant morbidity and mortality in this population.¹⁰¹ Unfortunately, depression remains underrecognized and undertreated, even though it is a major risk factor for suicide in the elderly, who have a suicide rate that is more than five times the national average.^{102,103} Older patients may be at increased risk of depression due to the high prevalence of comorbid medical conditions (i.e., stroke, cancer, MI, rheumatoid arthritis, dementia, Parkinson disease, DM).¹⁰⁴ Refer to Chapter 79 for further discussion of risk factors for depression and potential drug-induced causes. Most patients are treated in the primary care setting.¹⁰³

17. J.W. is a married, 5'8", 110-lb, 79-year-old woman who presents for a psychiatric evaluation. Her husband says she just has not been herself lately. The changes in J.W. began on a family vacation 6 months earlier when she got lost on the cruise ship. Since that incident, she has become increasingly anxious and has developed insomnia. Although she does not feel sad or "depressed," she generally does not feel well. J.W.'s normally positive attitude toward life has become pessimistic. Her husband confirms that she has become more forgetful and no longer enjoys eating. In fact, she has lost 18 lb over the past 2 months. J.W. no longer does her volunteer work at the local children's center. She says she wants to die because she is no longer the person she used to be, but she denies having any specific suicidal thoughts. Her medical history is significant for diabetes and hypertension,

which are both well controlled on glipizide 5 mg QAM and HCTZ 25 mg QD. Her medical evaluation and physical examination are unremarkable. Laboratory results and head CT scan are within normal limits. J.W. is diagnosed as having a major depressive episode. What symptoms of depression are present in J.W.?

J.W.'s presenting symptoms are quite typical of major depression in an older patient, which is commonly quite different than that of younger depressed patients. Criteria set forth in the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition*, for diagnosing depression were developed using younger subjects and may not be applicable to the older depressed patient.^{105,106} Older patients are less likely to report suicidal thoughts, but are more likely to experience weight loss as a symptom of depression. Anxiety, irritability, somatic complaints, or a change in functional ability may be more significant features in late-life depression than depressed mood. Memory problems, such as J.W.'s forgetfulness, may be due to a lack of concentration or effort stemming from her depression. This is distinct from dementia, which manifests itself prominently with impairment in short- and long-term memory (see Chapter 100). Therefore, depressed mood cannot be relied on for determining whether an older patient has a depressive disorder.¹⁰² Table 99-10 lists atypical depressive symptoms that may be found in older adults. The presence of any one of these symptoms should be considered a red flag and should prompt further evaluation for major depression.

18. J.W.'s physician decides to prescribe antidepressive medication. Which antidepressants are preferred for use in older adults?

Selection of an antidepressant drug for elderly patients must take into consideration age-related changes in pharmacokinetic, pharmacodynamic, and physiological parameters that make this population more vulnerable to adverse effects. Although the available antidepressants are about equally effective, selective serotonin reuptake inhibitors (SSRIs) are better tolerated than older agents, such as the tricyclic antidepressants. Therefore, low-dose SSRIs should be considered first-line therapy for most older patients. Of course, this does not preclude the use of sound clinical judgment that incorporates the patient's history of response, comorbidities, and the drug's side effect profile. J.W. should start taking a low-dose SSRI with gradual dose titration to achieve control of her depressive

Table 99-11 Antidepressant Dosing in Older Adults

| | Initial Dosage | Maximum Dosage |
|----------------------|----------------|----------------|
| Citalopram HBr | 10 mg QD | 40 mg QD |
| Escitalopram Oxalate | 5 mg QD | 20 mg QD |
| Fluoxetine HCL | 5 mg QD | 40 mg QD |
| Fluvoxamine | 25 mg QHS | 200 mg QHS |
| Paroxetine HCL | 10 mg QD | 40 mg QD |
| Sertraline HCL | 25 mg QD | 150 mg QD |
| Mirtazapine | 7.5 mg QD | 45 mg QD |
| Bupropion | 37.5 mg BID | 75 mg BID |
| Duloxetine | 20 mg QD | 40 mg QD |
| Venlafaxine | 25 mg BID | N/A |

symptoms. Table 99-11 lists recommended starting doses for antidepressants in older patients. Full antidepressant response may take twice as long in older patients compared with younger patients; it may take 8 to 12 weeks before assessment of J.W.'s full response can be made.¹⁰⁷

Asthma and Chronic Obstructive Pulmonary Disease in the Elderly

Epidemiologic studies estimate the prevalence of asthma in the elderly to be between 6.5% and 17% and even higher for COPD.^{108,109} Although many patients have a history of childhood asthma that persists into adulthood, a significant proportion (up to 48%) are diagnosed with asthma after age 65.¹¹⁰ Rates of hospitalization for asthma are highest in the older population, and asthma-related mortality for adults age 65 to 74 years is higher compared with younger adults, possibly due to underdiagnosis and undertreatment of the disease.¹¹¹ Symptoms of asthma, including wheezing, cough, chest tightness, and dyspnea are similar in both older and younger patients (see Chapter 23). However, because the elderly are more likely to have coexisting medical conditions (e.g., HF, angina, COPD, gastroesophageal reflux disease [GERD]) with symptoms that mimic asthma, accurate diagnosis and assessment of severity is often more difficult.¹¹³

COPD is a lung disease caused by chronic bronchitis and/or emphysema seen largely in those older than 65 years. This chronic condition is a major cause of morbidity and mortality in the older population,^{112,113} but it is often undiagnosed because patients tend to accept worsening pulmonary function as part of the "normal" aging process or may be less aware of the symptoms of airflow obstruction.^{114,115} Drug therapy for COPD in the elderly does not differ significantly from standard management regimens (see Chapter 24). However, older patients with pulmonary disease and coexisting medical problems may be more sensitive to the adverse effects of pharmacologic agents.

19. J.C., a 67-year-old woman, 5'6", 145 lb, presents to the ED with complaints of SOB for the past 2 days. She was in her usual state of health until 4 days ago when she developed flulike symptoms consisting of fever, cough, and mild wheezing. J.C. has a history of asthma, diabetes, hypertension, headache, and GERD. Her current medications include glipizide 5 mg QD, lisinopril 10 mg QD, metoprolol 50 mg BID, lansoprazole 30 mg QD, ibuprofen 200 mg Q 6 h PRN for headache, albuterol metered-dose inhaler (MDI) 2 puffs QID PRN for SOB, and fluticasone (44 g) MDI 2 puffs BID. Her drug regimen has been unchanged for the past

2 years, and she reports taking all medications as prescribed. The only recent change has been the need for albuterol every 3 to 4 hours for coughing and wheezing over the past few days. What factors (including medications) may have contributed to her acute asthma exacerbation?

Management of acute asthma exacerbations in previously stable elderly asthmatics should begin with a review of the medication history for asthma-inducing agents. Aspirin and other NSAIDs are known to induce acute bronchoconstriction in approximately 3% to 5% of adult asthmatics.¹¹⁶ J.C. should be queried about her previous (especially recent) use of ibuprofen in relation to her asthma symptoms. If she reports worsening of her asthma following ingestion of ibuprofen, further use of aspirin and NSAIDs should be avoided. Alternative agents for pain control include acetaminophen or selective cyclo-oxygenase (COX)-2 inhibitors (e.g., celecoxib). Non-selective β -blockers, including topical ophthalmic formulations, can precipitate acute bronchoconstriction and should be avoided in patients with reactive airway disease. Although cardioselective β -blockers are generally considered safe for use in patients with asthma, it is important to recognize that cardioselectivity may be lost with higher dosages. Because J.C. has been taking low-dose metoprolol (a cardioselective agent) for years without problem, this medication is unlikely to be contributing to her current asthma exacerbation. One of the most important triggers for asthma exacerbations is respiratory infection (particularly viral). J.C. reports the recent onset of symptoms consistent with influenza, and this is likely precipitating her current pulmonary symptoms. As a future prophylactic measure, J.C. should be counseled to receive the influenza vaccine annually. In addition, because she is older than 65 years, she should receive a one-time pneumococcal vaccine to reduce the risk of developing pneumococcal pneumonia.

20. Are the medication regimens used to treat asthma in elderly patients different from those used in children and younger adults? Should J.C.'s asthma regimen be changed?

Medications used in the management of persistent form of asthma in the elderly are similar to those used in younger patients and consist of bronchodilators in combination with anti-inflammatory agents (see Chapter 23). The primary difference relates to drug selection and monitoring, which may be more complicated in the elderly because of the greater likelihood of coexisting medical conditions and increased potential for drug-disease and drug-drug interactions.

Inhaled β_2 -agonists are an important class of drugs used to treat asthma in all age groups. The low incidence of drug interactions and reduced side effect profile make inhaled β_2 -agonists ideal for use in the older asthmatics. However, both inhaled and oral β_2 -agonists can cause dose-dependent systemic side effects, such as tremor, tachycardia, hypokalemia, and arrhythmias, which are of particular concern in patients with cardiac conditions.¹¹⁷ Inhaled corticosteroids are the preferred treatment for all forms of persistent asthma and, in general, are well tolerated by older patients. However, elderly patients receiving high dose therapy are at an increased risk for osteoporosis, cataracts, skin thinning, and bruising.¹¹⁸ In addition to the well-known complications associated with systemic corticosteroid use (see Chapter 44), these agents can acutely cause confusion, agitation, and hyperglycemia. Theophylline

should be used with caution in the elderly because of the potential for CNS stimulation, nausea, vomiting, and, in higher doses, arrhythmias and seizures.

J.C. is currently maintained on low doses of an inhaled corticosteroid (fluticasone) in combination with a short-acting β_2 -agonist (albuterol), and this is an appropriate regimen for a patient with mild-persistent asthma. J.C.'s asthma control should be re-evaluated within the next 3 months. If her asthma symptoms are not well controlled, she may benefit from an increase in her fluticasone dose or the addition of a long-acting inhaled β_2 -agonist (salmeterol or formoterol). Because J.C. is postmenopausal, she is at risk for osteoporosis; calcium and vitamin D supplementation should be initiated.

21. J.C. was admitted to the hospital and given intravenous methylprednisolone for 4 days. She is discharged home with glipizide 5 mg QD, lisinopril 20 mg QD, fluticasone HFA (44 g) 2 puffs BID, albuterol 2 to 4 puffs Q 4 hours PRN, and prednisone 40 mg QD 7 days. What are some of the important counseling points for J.C. regarding her discharge medications?

Appropriate use of MDIs is difficult for most patients, but may be particularly problematic in the elderly population because of decreased hand strength or arthritis, difficulty timing actuation to inhalation, or impaired mental function. The use of spacer/holding chamber devices can alleviate this problem by minimizing the coordination necessary for proper use of an MDI, resulting in improved pulmonary drug delivery. In addition, spacers may reduce the incidence of systemic and local (cough, hoarseness, thrush) side effects associated with inhaled corticosteroids. J.C. should be discharged with a spacer device to use with her albuterol and fluticasone MDIs. Even though J.C. previously used an MDI, she should be asked to demonstrate her MDI technique and reinstructed, if necessary, to ensure she is using the inhaler and spacer correctly. If J.C. is unable to correctly use her MDIs with a spacer, use of nebulized solutions, breath-activated inhalers, or dry-powdered delivery devices should be considered. Although J.C. is prescribed prednisone for a short course, counseling for J.C. should also include more frequent monitoring of blood glucose while she is taking systemic corticosteroid therapy because of her diabetes.

Infectious Diseases in the Elderly

Infections are among the most common problems in the elderly and are a significant cause of morbidity and mortality. Infections are also one of the most frequent reasons for hospitalization of older ambulatory persons.¹¹⁹ Antibiotic therapy for an infection in the elderly is often delayed because they present with atypical signs and symptoms. The older population is also more likely to have polymicrobial infections than younger people, and treatment duration is usually longer because of other comorbidities present in this population.¹²⁰

PNEUMONIA

22. Three days after J.C. is discharged from the hospital, she presents again to the ED. This time, she is accompanied by a neighbor who noted that J.C. suddenly became forgetful and confused and continued to have difficulty breathing. Her neighbor reports that J.C. has been staying in bed the past 2 days and has not eaten much. J.C. has a low-grade fever, and chest examination reveals faint breath sounds with light crackling rales over

her right lung base. A chest radiograph confirms the diagnosis of pneumonia. How is J.C.'s clinical presentation consistent with community-acquired pneumonia in the elderly? How should she be treated for her respiratory infection?

Pneumonia is the leading infectious cause of mortality in the elderly, who have a 5- to 10-fold increased risk of developing pneumonia compared with younger adults.¹²¹ Most patients admitted to hospital for the treatment of community-acquired pneumonia (CAP) are elderly.¹²² Risk factors for CAP in the elderly include alcoholism and asthma, but other medical conditions common in older population, such as dementia, CHF, cerebrovascular disease, and chronic obstructive lung disease, can also increase the risk of pneumonia in this population.¹²³ *Streptococcus pneumoniae*, the most common cause of CAP in the elderly, is responsible for up to 50% of cases.^{124–126} Viral pneumonia is the second most common cause of lower respiratory infection in older ambulatory patients. Respiratory symptoms and fever are often subtle or absent in older patients with pneumonia; instead, like J.C. they may present only with altered mental status (delirium, acute confusion, memory problems) or a decline in functional status. Delirium or acute confusion is a common presentation in elderly patients who may have new-onset lower respiratory infection. In many cases, management of pneumonia in the elderly requires hospitalization because they are at greater risk for mortality and complications. Early empiric antibacterial therapy is particularly important for older patients with pneumonia (see Chapter 60). J.C. should be hospitalized again and treated aggressively for pneumonia with broad-spectrum IV antibiotics.

PREVENTION

23. After 7 days of hospitalization, J.C. is discharged home with an oral antibiotic to finish the 14-day course of therapy. What preventive measures are available to J.C. after she is discharged?

Both influenza and pneumococcal vaccinations are beneficial in the prevention of pneumonia in the older population.^{127,128} Among the elderly residents of nursing homes, influenza vaccine was found to be up to 60% effective in preventing pneumonia and hospitalization, and it was up to 70% effective in preventing hospitalization of ambulatory older adults. Among the respiratory viruses, influenza virus causes the greatest morbidity and mortality.¹²⁹ Influenza virus damages respiratory epithelial cells, decreases cell-mediated immunity, and exacerbates or worsens many chronic underlying medical conditions common to the older population. A yearly influenza vaccine is therefore recommended for all persons age 65 years and older. Amantadine, rimantadine, or oseltamivir are effective for the early treatment of influenza and for prophylaxis against influenza. Unlike oseltamivir, which is active versus both influenza A and B, amantadine and rimantadine are only active versus influenza A. If amantadine or rimantadine are selected, they should be given at a reduced dose of 100 mg orally per day in older patients; the dose of amantadine should be further reduced in patients with renal impairment to avoid CNS adverse effects. Although the previous agents are effective in the prevention of influenza, vaccination should be the primary prophylactic intervention. The pneumococcal vaccine has been shown to be up to 80% effective in preventing pneumococcal bacteremia in those older than 65 years of age,¹³⁰ although the reduction in the risk of pneumonia with

pneumococcal vaccine is questionable.¹³¹ Pneumococcal vaccine is nonetheless recommended in all adults age 65 and older to prevent bacteremia. Pneumococcal vaccination is generally given one time; if the vaccination was administered before the age of 65, however, another pneumococcal vaccine should be given. J.C. should be offered both influenza and pneumococcal vaccines after she is discharged from the hospital.

URINARY TRACT INFECTION

24. A.H. is a 72-year-old Hispanic woman who is currently wheelchair-bound because of pain in her right hip. Her granddaughter brings A.H. to the geriatric clinic because she has recently developed urinary incontinence. Her granddaughter reports that A.H. has been feeling weak the past 2 days and fell while getting out of the wheelchair. A urinalysis indicates the presence of a urinary tract infection (UTI), and A.H. is prescribed a 7-day course of ciprofloxacin 500 mg PO BID. Is this therapy appropriate?

UTI is the most common bacterial infection in the elderly.¹³² The frequency of bacteriuria in ambulatory older adults is 10% to 30% in women and 5% to 10% in men. These figures are even higher in elderly people residing in LTCFs. Impaired voiding with residual urine in older women and obstructive uropathy from prostatic disease in older men predispose them to bacteriuria. The severity of UTI in the older population ranges from mild cystitis to life-threatening urosepsis; both are more difficult to treat because of resistant organisms and age-related decreases in host defenses. The majority of UTIs in the older population do not present typically, but there are often nonspecific manifestations such as decline in functional status, cognitive impairment, weakness, falls, and urinary incontinence.¹³³ A.H.'s presentation (weakness, urinary incontinence, and a recent fall) is consistent with this pattern. As with most UTIs, those in the elderly are caused primarily by *Escherichia coli*. However, other species of bacteria such as *Klebsiella* sp., *Proteus* sp., and *Enterococcus* sp. are also frequently involved (see Chapter 64).¹³⁴

Oral antibiotics are appropriate for most elderly patients with symptomatic UTI.¹³⁵ One study suggests that fluoroquinolones are significantly better tolerated than trimethoprim-sulfamethoxazole for the treatment of UTI in elderly women.¹³⁶ There was better clinical resolution at the end of the therapy, and the incidence of drug-related adverse events was significantly lower in women treated with a fluoroquinolone. This study suggests that a fluoroquinolone may be the preferred agent for a broad range of UTIs in the elderly and should be considered as initial therapy in the majority of the older population. Ciprofloxacin is a reasonable choice for A.H. because *E. coli* is the most likely causative agent and fluoroquinolones are well tolerated in the elderly.

The most important effect of age on antibiotic therapy for UTI is impaired renal function. Many older patients have limited renal function reserve due to prostatic disease or chronic UTIs.¹³⁷ Nitrofurantoin should not be used in those patients with significantly impaired renal function due to increased risk of peripheral neuropathy and acute pneumonitis, which may occur more frequently in geriatric patients. For those patients requiring IV therapy for UTI, aminoglycosides pose a distinct disadvantage in older patients due to their drug-related nephrotoxicity and the need for serum drug-level monitoring.¹³⁷

Osteoarthritis Pain

Arthritis is the most common cause of disability in people older than 75 years of age, with prevalence rates up to 30%.¹³⁸ It is also the most common cause of immobility in the older population, resulting in confinement in bed or to the house. Osteoarthritis, also called degenerative joint disease, is the most common type of joint disease in the older population. Its prevalence increases with age. Nonpharmacologic management of osteoarthritis, such as physical therapy and occupational therapy, have been shown to decrease pain and improve function in patients with osteoarthritis, both alone or in combination with appropriate analgesics.¹³⁹

25. C.W., a 71-year-old retired school teacher, has been suffering from osteoarthritis of his hands for 5 years. He is an active older adult who enjoys volunteer work at the local hospital. He presents to the geriatric clinic with increased arthritis pain, which is uncontrolled by his current pain medication. He also complains of increased heartburn and gastric reflux symptoms. He also takes several other medications for his diabetes, hypertension, hypercholesterolemia, and GERD. C.W.'s current medications include glipizide 10 mg QD, verapamil sustained-released 240 mg QD, atorvastatin 10 mg QD, famotidine 20 mg BID, docusate sodium 100 mg BID, and ibuprofen 200 mg QID PRN. What modifications can be made to his drug regimen to better control his arthritis pain and minimize side effects from his pain medication?

Acetaminophen is the drug of choice for mild to moderate arthritis pain (see Chapter 43). For elderly patients with reduced hepatic function or for those who drink more than two alcoholic beverages a day, the recommended maximum daily dose is 2.5 g/day.¹³⁹ Acetaminophen is preferred over NSAIDs in the elderly because of its low renal and GI toxicity. C.W.'s past medication history should be reviewed. If he has not tried acetaminophen in the past for his arthritis pain, acetaminophen 1 g TID should be initiated. Older patients suffering from osteoarthritis pain often find relief from NSAIDs, which should be used with caution because of their potential GI side effects and renal toxicity. In a group of UK population age 65 or older, for example, the risk of GI complications was found to be 4.03 per 1,000 patient-years, compared to 1.36 for all individuals 25 or older.¹⁴⁰ Up to 2% of older persons maintained on NSAID therapy are hospitalized due to serious GI complications, and up to 30% of all peptic ulcer-related hospital admissions and mortality in those older than 65 years are associated with chronic NSAID use. NSAID-associated renal toxicity is not as common as GI toxicity, but advanced age is one of the major risk factors.¹⁴⁰ Renal toxicities of NSAIDs in the elderly include sodium and water retention and increased risk for hypertension.¹⁴¹ Thus, ibuprofen may be contributing to C.W.'s increased GERD symptoms and to his hypertension. Nonacetylated salicylates, such as salsalate, can be used if acetaminophen does not provide adequate pain relief. Compared to NSAIDs, nonacetylated salicylates have fewer renal and GI side effects. Currently available selective COX-2 inhibitor celecoxib is preferred in older patients because it is less likely to cause GI side effects than nonselective agents; however, the risk of adverse renal events is equivalent.¹⁴¹ A COX-2 inhibitor or an addition of more potent gastroprotective agent such as a proton pump inhibitor to ibuprofen are options for C.W., who

may experience reduced GI symptoms with equally effective pain relief.

26. C.W. reveals that he has tried acetaminophen without much relief of his pain. He is prescribed celecoxib and tries it for several months, but his pain continues and he is still experiencing GI distress. What other pain medication options does C.W. have?

For moderate to severe chronic pain due to osteoarthritis, the topical analgesic, capsaicin, has been shown to provide temporary pain relief. However, capsaicin requires multiple daily applications for effective management of pain, and optimal efficacy takes 4 to 6 weeks of continued use. Glucosamine and chondroitin have also been shown to decrease osteoarthritis pain and delay progression of the disease.¹⁴² Glucosamine 1,500 mg combined with 1,200 mg chondroitin daily is recommended and is well tolerated by most elderly patients. However, glucosamine might increase the insulin resistance in diabetic patients, and C.W. should be counseled to monitor his blood glucose more closely when initiating this agent.

Another option for C.W. is a long-acting opioid medication combined with acetaminophen, which can provide relief from pain with minimal side effects (see Chapter 9). Codeine and tramadol are “weak” opioids that have ceiling effects and generally do not provide adequate analgesia. The use of propoxyphene should be avoided in the elderly because of its limited efficacy and the risk for neural and cardiac toxicity.¹⁴³ Meperidine should also be avoided in older adults because of its high potential for CNS side effects, especially in those with reduced renal function. C.W. is a candidate for opioid therapy. He should be started on the lowest dose of a short-acting formulation on a scheduled regimen and counseled on the side effects. Constipation may be a particular problem because he is also taking verapamil, which can also cause significant constipation. The elderly are also at increased risk for constipation due to age-related reduced bowel motility. To prevent opioid-associated constipation in C.W., prophylactic laxatives and stool softeners should be started at the initiation of opioid therapy. Bulk laxatives are ineffective and should be avoided. He should be counseled to drink adequate fluids as well.¹⁴³

Rehabilitative Geriatric Medicine

The geriatric population forms a major part of rehabilitative medicine. Relative to persons younger than 65 years of age, people 65 and older have more than twice as much disability, four times the activity limitation, and about twice as many hospital stays lasting about 50% longer.¹⁴⁴ The goal of all rehabilitation programs is to develop a person to the fullest physical, psychological, social, vocational, avocational, and educational potential consistent with his or her physiological, anatomical, and environmental limitations. Realistic goals based on functional activities that are essential to the independence and well-being of the individual should be established. The patient, family, and interdisciplinary rehabilitation team should work together to establish these goals. In the older person, rehabilitation often means working to obtain optimal function, despite residual disability caused by an irreversible medical condition. Rehabilitation can take place in the home, hospital, or nursing home setting.

Functional Assessment

Meticulous clinical evaluation of the patient's medical and functional status is the first step in a rehabilitation program.¹⁴⁵ The functional status evaluation should include an assessment of age, gender, and environment-appropriate activities of daily living (ADLs). According to the National Center for Health Statistics, more than 25% of noninstitutionalized persons at least 65 years of age are unable to perform one or more ADLs due to chronic health condition.¹⁴⁶ ADLs include dressing, eating, bathing, grooming, using the toilet, and moving around within the home. Instrumental activities of daily living (IADLs) are other activities that determine an individual's functional independence. IADLs include food preparation, laundry, house-keeping, shopping, the ability to use the telephone, use of transportation, medication use, financial management, and child care, if appropriate. Leisure and recreational activities important to a person's physical and psychological well-being can also be considered IADLs. A disability or dysfunction is defined as any deviation from the normal or characteristic ability of a person to perform tasks of living. Impairments are defined as abnormalities in organs or body systems that can lead to dysfunction. When the inability to perform tasks results in social disadvantage, the condition is viewed as a handicap.¹⁴⁷

Pharmacists' Role in Geriatric Rehabilitation

27. B.L., a 5'10", 180-lb, 78 year-old man, experienced an embolic stroke 7 days before transfer to the rehabilitation unit. His medical history is significant for atrial fibrillation and GERD. Medications at the time of transfer are digoxin 0.25 mg QD, warfarin 5 mg QD except 2.5 mg on Monday/Thursday, ranitidine 150 mg BID, metoclopramide 10 mg QID, metoprolol 50 mg BID, and milk of magnesia PRN for constipation. His laboratory values are as follows: Na, 135 mEq/L; K, 4.2 mEq/L; SCr, 1.5 mg/dL; BUN, 23 mg/dL; and digoxin level, 1.2 ng/mL. His vital signs are BP, 110/70 mm Hg; HR, 60 beats/minute; and temperature, 98.4°F. What is the pharmacist's role in the initial evaluation of B.L.?

[SI units: Na 135 mmol/L; K 4.2 mmol/L; SrCr 132.6 mmol/L; BUN 8.2 mmol/L]

An interdisciplinary "geriatric assessment" team is essential to accomplishing a comprehensive functional evaluation of the rehabilitation patient. These teams, including a pharmacist member as the pharmacotherapy specialist, significantly reduce length of stay, readmissions, drug costs, and patient mortality.^{148,149} A physician trained and certified in rehabilitation medicine (i.e., a physiatrist) usually leads the team. Other disciplines represented on the team are physical therapy, occupational therapy, speech therapy, recreational therapy, behavioral medicine (psychologist, social worker), and nursing. The pharmacist's role in the initial assessment is to obtain a complete medication history so that an accurate assessment of drug therapy can be made. Adverse reactions to medications can be detrimental to the functional capacity of the geriatric patient by worsening cognition, psychological state, vascular reflexes, balance, bowel and bladder control, muscle tone, and coordination, any of which may already be impaired by the present illness or injury. It is the responsibility of the team pharmacist to alert the rest of the team to drug-induced problems, facilitate medication adherence, provide medication education, advocate

Table 99-12 Indicators of the Inability to Self-Medicate

to discontinue unnecessary medications, screen for drug interactions, and recommend appropriate changes in therapy based on the physiological effects of aging. The team pharmacist should also make some assessment of the individual's ability to self-medicate. Table 99-12 lists conditions and skills that have been identified as possible indicators of an older person's ability to self-medicate.

Drug Effects on Functional Ability

28. During the initial team meeting to discuss B.L., the physical therapist mentions that the patient walks with a stooped posture and has a shuffling gait and poor balance. The speech therapist reports that B.L. has difficulty in swallowing, noting that the problem is out of proportion for the location of his stroke. A flat affect, crying episodes, fatigue, and drowsiness are reported by the occupational therapist. The psychologist notes confusion and possible dementia on neuropsychological testing. Can any of B.L.'s problems be attributed to his current medication regimen?

Functional impairments in older adults can be medication induced.¹⁵⁰ Table 99-13 lists several examples of drugs that can interfere with the functional, physical, social, and psychological assessment of the older patient. Dopamine-depleting drugs may produce extrapyramidal side effects and interfere with physical and occupational therapy goals. Neuroleptics, tricyclic antidepressants, and excessive doses of antihypertensives can increase the risk of falls by causing orthostatic hypotension. Problems with balance and/or tinnitus may be precipitated by drugs that affect the vestibular system and cause damage to the eighth cranial nerve (e.g., aminoglycosides, loop diuretics, high serum concentrations of aspirin). Long-term corticosteroid use may lead to proximal muscle wasting and slow the recovery of strength, even when patients are undergoing aggressive rehabilitative therapy.

CNS medications may lead to oversedation and decrease the capability to learn, ambulate, eat, or use the toilet, as well as increase the risk of falls. Drugs such as benzodiazepines, antihypertensives, neuroleptics, H₂ blockers, and analgesics have been reported to cause reversible cognitive impairment. Digoxin toxicity in the elderly may initially manifest as confusion, delirium, nightmares, or hallucinations. Medications that cause a relative dominance of dopamine over acetylcholine in the brain may produce psychosis, hallucinations, or delirium.

Depression is an important adverse reaction to look for in patients undergoing rehabilitation because it may mimic dementia on neuropsychological testing. Depression may be worsened or induced by some antihypertensives (e.g., central agonists, highly lipophilic β -blockers). Metoclopramide is an important yet often overlooked potential contributor to depression.

Table 99-13 Drug Effects on Other Assessments

| Assessments | Drug Effects | Drug Examples |
|---------------|---|---|
| Functional | Movement disorders (extrapyramidal, tardive dyskinesia) Balance (neuritis, neuropathies, tinnitus, dizziness, hypotension) | Neuroleptics, metoclopramide, amoxapine, methyl dopa Metronidazole, phenytoin, aspirin, aminoglycosides, furosemide, ethacrynic acid, β -blockers, calcium channel blockers, neuroleptics, antidepressants, diuretics, vasodilators, benzodiazepines, levodopa, metoclopramide |
| Physical | Supporting structures (arthralgias, myopathies, osteoporosis, osteomalacia) Incontinence (urinary retention, secondary oversedation) Sexual dysfunction | Corticosteroids, lithium, phenytoin, heparin Anticholinergic agents, TCAs, neuroleptics, antihistamines, smooth muscle relaxants, nifedipine, phenylpropanolamine, prazosin; benzodiazepines, sedatives, hypnotics Hypotensive agents, CNS depressants, SSRI antidepressants |
| Social | Malnutrition Poor dental health | Drugs affecting appetite Anticholinergic agents, glucose-containing oral liquid/chewable dosage forms |
| Psychological | Cognitive impairment (metabolic alterations; memory loss, dementia) Behavioral toxicity (insomnia, nightmares, sedation, agitation, delirium, psychosis, hallucinations) Depression | β -Blockers, corticosteroids, diuretics, sulfonyleureas, methyl dopa, propranolol, hydrochlorothiazide, reserpine, neuroleptics, opiates, cimetidine, amantadine, benzodiazepines, anticonvulsants Anticholinergics, cimetidine, ranitidine, famotidine, digoxin, bromocriptine, amantadine, baclofen, levodopa, opiates, sympathomimetics, corticosteroids Reserpine, methyl dopa, β -blockers, metoclopramide, corticosteroids, CNS depressants |

TCA, tricyclic antidepressant; CNS, central nervous system; SSRI, selective serotonin reuptake inhibitors.
Adapted from reference 150.

B.L. is receiving several medications that may be contributing to the functional impairments found during the initial assessment. Metoclopramide has dopamine-blocking activity and can produce pseudo-Parkinson symptoms like those reported by the physical therapist. Dopamine blockers can cause swallowing difficulties. Metoclopramide has also been known to produce mental depression in some patients that may or may not recur when the drug is reinstated at lower dosages. B.L. is at even greater risk for these adverse effects from metoclopramide because it is primarily renally excreted and B.L. has reduced renal function, with an estimated ClCr of 42 mL/minute. H_2 blockers, such as ranitidine, can cause confusion and agitation in older patients with decreased renal function. Metoclopramide and ranitidine should be discontinued at this time. B.L.'s GERD should be reassessed, and if chronic therapy is needed, a proton pump inhibitor (e.g., rabeprazole, others) is an appropriate choice because there is a low likelihood that it will cause functional impairment.

B.L.'s problem of depressive symptoms reported by the occupational therapist and potential dementia reported by his psychologist are compatible with CNS effects of metoprolol, a highly lipophilic β -blocker. Metoclopramide may also be a contributor to these findings. If B.L. must continue taking a β -blocker for additional rate control, he should be switched to an agent with low-lipid solubility, such as atenolol, which has a lower likelihood of producing CNS side effects. Otherwise, the dose of metoprolol should be reduced immediately and then tapered.

B.L.'s digoxin level is currently within normal limits, and he does not have any clinical signs of digoxin toxicity. However, the pharmacist team member should monitor B.L. for signs and symptoms of digoxin toxicity and make appro-

priate dose adjustments as necessary. Finally, B.L. should have an INR drawn to ensure that the dose of warfarin is correct.

The contribution of medication to functional deficits must not be overlooked when assessing patients undergoing rehabilitation. Defined criteria for determining medications that are potentially inappropriate in the elderly has been published by Beers and recently updated.¹⁵¹ When using these criteria, it is important to keep in mind that these are "potentially" inappropriate medications. The pharmacotherapy specialist trained in geriatric care is responsible for applying patient-specific criteria, such as history of use and response, when evaluating the appropriateness of a drug in a particular patient.

Long-Term Care Facility

The LTCF environment is governed in part by the Omnibus Budget Reconciliation Act (OBRA), as well as by numerous other laws and regulations. Table 99-14 summarizes the mandated responsibilities of the "supervising pharmacist" in a LTCF. The completion of these responsibilities must include monthly review of each resident's medication profile to determine the following:

1. Is each drug clearly indicated?
2. If indicated, is it being dosed and administered appropriately?
3. Are the laboratory results and vital signs being done appropriately, and are they available for adequate evaluation of therapy?
4. Are any real or potential problems with drug side effects or interactions present?

Table 99-14 Basic Requirements of OBRA 1990 Legislation

Prospective DUR
 Retrospective DUR
 Education and intervention programs
 Patient counseling and provision of information to patients/caregivers
 Documentation of DUR and educational activities

OBRA, Omnibus Budget Reconciliation Act; DUR, drug utilization review.
 From reference 160.

5. What specific recommendations can be made to optimize this resident's drug therapy?
6. If neuroleptic agents are being prescribed, has their use been justified and is the therapy being monitored?
7. Have therapeutic goals been established for chronic drug therapies?
8. Are any unnecessary drugs present?

OBRA regulations require inclusion of a pharmacist on the pharmaceutical and infection control committees. The pharmacist is also required to participate in drug use evaluations. All medication errors and adverse drug reactions must be reported to the patient's physician and documented by the pharmacist or the nurse. The American Society of Consultant Pharmacists publishes detailed information concerning standards of practice in the LTCF environment.¹⁵²

29. As a new consulting pharmacist to a 60-bed, skilled nursing facility, several multiple drug use problems become apparent during initial chart reviews. A typical case is D.M., an 82-year-old man who has resided there for the past month. D.M.'s past medical history is significant for hypertension, depression, constipation, long-standing mild cognitive impairment that is now worsening, and dizziness. In the nurses' notes, it is documented that D.M. had a fall when getting out of bed last week.

At admission, D.M.'s weight was 165 lb; BP, 100/60 mm Hg; pulse, 85 beats/minute; and temperature, 98.6°F. Subsequent vital signs are not recorded systematically into his medical record. Sporadic documentation in the nurses' notes indicate little change from admission values. No laboratory information is available at this time. D.M. has no known allergies.

Current medications include felodipine 10 mg QD, diltiazem CD 240 mg QD, HCTZ 25 mg QD, nortriptyline 150 mg QHS, thioridazine 25 mg TID, haloperidol 0.5 mg BID, benztropine 1 mg BID, docusate sodium 100 mg BID, milk of magnesia 30 mL QD, flurazepam 15 mg QHS, and acetaminophen one to two 325-mg tablets Q 4 to 6 h PRN pain. D.M. follows a 2-g sodium diet.

D.M. is ambulatory and takes his meals in the facility's cafeteria. He is not in any acute distress, but the nurses' notes indicate that D.M. is often confused and complains of dizziness when ambulating. His weight has decreased 4 lb since being admitted. What should be expected of this LTCF with respect to medication monitoring, and what OBRA deficiencies can be found in the review of D.M.'s case?

Under OBRA, the establishment of goals of antihypertensive therapy and monitoring for these goals are required. D.M.'s blood pressure should be measured and documented in his medical record with a signature and date on a regular basis. D.M.'s dizziness, a symptom of orthostatic hypotension, may

be due to overtreatment of his hypertension as evidenced by his low admission blood pressure. Orthostatic hypotension occurs in more than half of frail, elderly LTCF residents and is most common when patients first arise, indicating that this may have been the cause of D.M.'s recent fall. D.M. is currently being inappropriately treated with two calcium channel blockers. Discontinuation of one of them should reduce this patient's dizziness and help prevent future falls. Preferably, felodipine should be discontinued because dihydropyridine calcium channel blockers are known to cause orthostasis. The use of antipsychotic and anti-Parkinson agents have also been associated with orthostatic hypotension. Because D.M. is being treated with a diuretic, he should have a chemistry panel drawn to check for electrolyte abnormalities.

In the admission workup, D.M. was described as having a long-standing history of mild cognitive impairment, but subsequent nursing notes suggest that his symptoms of disorientation and confusion worsened quickly after admission. Chronic dementia is not normally characterized by rapid deterioration of mental acuity (see Chapter 100). This should raise the suspicion that a reversible factor could be responsible for D.M.'s mental decline. Overprescribing of psychotropic drugs in institutionalized elderly patients is well documented.^{153,154} The cognitive impairment of chronic degenerative dementia can be greatly exaggerated by D.M.'s treatment with flurazepam, nortriptyline, thioridazine, haloperidol, and benztropine.

Neuroleptics are some of the most commonly prescribed drugs in nursing home residents. It is only appropriate to use these drugs in elderly patients with documented psychotic behavioral disturbances or in those with impulsivity and agitation associated with functional or organic disorders, such as degenerative dementia. Unfortunately, neuroleptics are often unnecessarily prescribed for anxiety, insomnia, confusion, "senility," and failure to conform to the institution's standards for behavior. OBRA regulations require that these drugs be used for a specified condition, at the lowest possible dosage, and for the shortest possible time. The regulations also mandate tapering of the dose and careful documentation of all clinical assessments that justify the ongoing need for neuroleptics. Even when a neuroleptic agent is indicated, the use of two or more, as in D.M., is irrational. Unless extrapyramidal symptoms have been clearly documented, D.M.'s treatment with benztropine is not indicated.

Antidepressant treatment may not be indicated for D.M., but if it is, nortriptyline is a poor choice because it has significant anticholinergic and sedating side effects (see prior discussion of depression in this chapter). D.M. is being treated with several sedating medications (flurazepam, haloperidol, and thioridazine). These agents may induce pseudodepression, which should resolve by reducing the number of sedating drugs. Flurazepam, a long-acting benzodiazepine, may increase the risk of falls and bone fractures in the geriatric population. Continuous nightly use of long-acting benzodiazepines increases the relative risk of hip fractures by 50% compared with shorter-acting benzodiazepines.¹⁵⁵ Elderly patients naturally sleep for shorter periods with a shallower sleep that is subject to frequent awakenings. Thus, the need for scheduled bedtime sleep agents must always be evaluated critically (see Chapter 77).

In light of the atypical deterioration of D.M.'s cognitive function, the doses of all psychotropic medications should be gradually tapered down and then discontinued. A baseline

assessment of D.M.'s cognitive function and psychiatric status should be performed by a geriatrician, psychiatrist, or clinical psychologist to establish the presence or absence of psychotic behavioral disturbances or depression. If any of these disorders are present, then each should be managed with a single drug,

titrated to the appropriate therapeutic dose. In accordance with established immunization practices, D.M., other LTCF residents, and staff members should receive an annual influenza vaccine. A pneumococcal vaccination should also be administered to D.M. if he has not previously received one.

With the continuing growth in the elderly population, the incidence and prevalence of cognitive disorders continues to rise.^{1,2} Alzheimer disease (AD) is the most common cause of dementia, accounting for approximately half of all diagnosed cases.³ Vascular dementias (VaDs), dementia with Lewy bodies (DLB), and Parkinson disease with dementia (PDD) are the next most common dementias, with frontotemporal dementia, pseudodementia, and other forms occurring less often.^{3,4} Dementia is currently the fifth leading cause of death in the United States.⁵

Incidence and Prevalence

The exact incidence and prevalence of dementia are difficult to determine for several reasons, including a lack of universally accepted diagnostic criteria, demographic variables, and well-designed epidemiologic studies.^{6–9} Prevalence estimates have ranged from 2.5% in Great Britain to 24.6% in the former Soviet Union.⁷ Studies in the United States have estimated the prevalence of dementias to be from 3.5% to 16.1% for the population age 65 years and older.^{10,11} The worldwide prevalence of AD appears to be about 1% of the elderly population, with an exponential age-related increase.^{9,12} AD currently affects approximately 2.3 million Americans.² The prevalence in the United States may be more than 10% of those age 65 and older, increasing sharply with age, from 3% among those 65 to 74 years of age to as much as 47.2% of those older than 85 years.^{13,14} The incidence of dementia for people age 50 and older in the United States has been estimated at 527

new cases/100,000 population per year, with 437/100,000 diagnosed as AD.¹⁵ The incidence increases with age, and women may be at a slightly higher risk than men.^{1,16}

Life expectancy following a diagnosis of AD is reduced by as much as 69% for those diagnosed before age 70 years and by 39% for those diagnosed after age 90 years.¹⁷

The cost of dementia is staggering. The annual direct and total costs of treating a dementia patient are estimated to be almost \$48,000 and \$174,000, respectively.¹⁸ Managed care organizations spend 1.5 times more on patients with dementia than on nondemented enrollees.¹⁹ The cost to society in the United States of treating dementia is approximately \$148 billion annually.²⁰

Clinical Diagnosis

Dementia is a syndrome that exhibits impaired short- and long-term memory as its most prominent feature. Multiple cognitive deficits that compromise normal social or occupational function must be present before dementia can be diagnosed (Table 100-1).²¹ Commonly, forgetfulness is the primary complaint of patients or the first symptom noted by the family.²¹ Family members or others may note several symptoms that should prompt a medical evaluation (Table 100-2).²² Memory loss often accompanies several diseases or disorders in elderly individuals. Therefore, a medical history, physical examination, and medication history are essential in excluding systemic illness or medication toxicity as causes of the dementia (Table 100-3).²³ Laboratory and other tests to assist in differentiating

Table 100-1 Diagnostic Criteria for Alzheimer-Type Dementia

- The presence of multiple cognitive deficits manifested by both
 - Impaired memory (ability to learn new information or to retrieve information previously learned), and
 - At least one of the following:
 - Aphasia* (language difficulties)
 - Apraxia* (diminished ability to perform motor activities in the presence of intact motor function)
 - Agnosia* (inability to recognize or name objects despite intact sensory function)
 - Disruption of executive function* (diminished ability to plan, organize)
- The previous deficits significantly interfere with normal work or social activities and represent a decline from previous ability to function
- The previous deficits cannot be attributed to any of the following:
 - Central nervous system conditions that cause progressive cognitive or memory impairment (e.g., cerebrovascular disease)
 - Systemic conditions known to cause dementia (e.g., hypothyroidism, neurosyphilis, HIV infection)
 - Substance-induced conditions (e.g., drug toxicity)
- The deficits do not occur exclusively during the course of a delirium
- The disturbance is not better accounted for by another Axis I disorder (schizophrenia, major depressive disorder)

Adapted from reference 21, with permission.

dementia from other disorders are listed in Table 100-4. In patients with primary degenerative dementia, or AD, test results will generally be normal; evidence of cerebrovascular disease is present in patients with VaDs.

Brain imaging, such as a computed tomography (CT) scan or magnetic resonance imaging (MRI), can be useful in establishing the presence of a dementia, but neither is diagnostic. A CT scan is useful when a space-occupying lesion, such as a tumor, is suspected as a possible cause. An MRI scan is capable of identifying small infarcts, such as those found in some VaDs, and atrophy of subcortical structures such as the brainstem.²³

The initial test in mental status screening is generally the Folstein Mini-Mental Status Exam (MMSE).²⁴ This test rapidly assesses orientation, registration, attention and calculation, recall, and language. Patients with dementia exhibit

Table 100-2 Symptoms Suggesting Dementia

| Symptom | Evidence |
|--|--|
| Difficulty learning or retaining new information | Repeats questions; difficulty remembering recent conversations, events, etc.; loses items |
| Unable to handle complex tasks | Cannot complete tasks that require multiple steps (e.g., difficulty following a shopping list) |
| Impaired reasoning | Difficulty solving everyday problems; inappropriate social behavior |
| Impaired spatial orientation and abilities | Gets lost in familiar places; difficulty with driving |
| Language deficits | Problems finding appropriate words (e.g., difficulty with naming common objects) |
| Behavior changes | Changes in personality; suspiciousness |

Adapted from reference 22.

Table 100-3 Causes of Dementia Symptoms

| Central Nervous System Disorders | Systemic Illness | Medications |
|---|------------------------|---------------------------------------|
| Adjustment disorder (e.g., inability to adjust to retirement) | Cardiovascular disease | Anticholinergic agents |
| Amnesic syndrome (e.g., isolated memory impairment) | Arrhythmia | Anticonvulsants |
| Delirium | Heart failure | Antidepressants |
| Depression | Vascular occlusion | Antihistamines |
| Intracranial causes | Deficiency states | Anti-infectives |
| Brain abscess | Vitamin B12 | Antineoplastic agents |
| Normal pressure | Folate | Antipsychotic agents |
| Hydrocephalus | Iron | Cardiovascular agents |
| Stroke | Infections | Antiarrhythmics |
| Subdural hematoma | Metabolic disorders | Antihypertensives |
| Tumor | Adrenal | Corticosteroids |
| | Glucose | H ₂ -receptor antagonists |
| | Renal failure | Immunosuppressants |
| | Thyroid | Narcotic analgesics |
| | | Nonsteroidal anti-inflammatory agents |
| | | Sedative hypnotics and Anxiolytics |
| | | Skeletal muscle relaxants |

deficits in multiple areas. Those who score below the normal range on the MMSE or who exhibit symptoms characteristic of dementia receive further testing (Tables 100-1 and 100-2). The Blessed Dementia Scale evaluates daily functional capacity (e.g., shopping, performing household tasks), activities of daily living (e.g., eating, dressing, toileting), and personality. The Blessed Information-Memory-Concentration Test evaluates orientation, memory, and concentration.²⁵ All screening tests are subject to limitations. Therefore, additional psychometric testing is often ordered to further establish the presence and type of dementia.²²

Dementias may be classified as cortical or subcortical, according to the areas of the brain preferentially affected by the

Table 100-4 Dementia Screening Tests

| Test | Rationale for Testing |
|--|---|
| Complete blood count with sedimentation rate | Anemic anemia, infection, neoplasms |
| Metabolic screen | |
| Serum electrolytes | Hypernatremia, hyponatremia; renal function |
| Blood urea nitrogen, creatinine | Renal function |
| Bilirubin | Hepatic dysfunction (e.g., portal systemic encephalopathy, hepatocerebral degeneration) |
| Thyroid function | Hypothyroidism, hyperthyroidism |
| Iron, B12, folate | Deficiency states (B ₁₂ , folate neuropathies), anemias |
| Stool occult blood | Blood loss, anemia |
| Syphilis serology | Neurosyphilis |
| Urinalysis | Infection, proteinuria |
| Chest roentgenogram | Neoplasms, infection, airway disease (anoxia) |
| Electrocardiogram | Cardiac disease (stagnant anoxia) |
| Brain scan | Cerebral tumors, cerebrovascular disease |
| Mental status testing | General cognitive screen |
| Depression testing | Depression, pseudodementia |

disorder. AD, a typical cortical dementia, disrupts the cerebral cortex. Patients with cortical dementias display impaired language rather than impaired speech, a learning deficit (amnesia), reduced higher cortical functions (e.g., inability to perform calculations, poor judgment), and an unconcerned or disinhibited affect. Subcortical dementias such as PDD primarily affect the basal ganglia, thalamus, and brainstem. Deficits include abnormal motor function, disrupted speech patterns rather than language difficulties, forgetfulness (impaired recall), slowed cognitive function, and an apathetic or depressed affect.²⁶

ALZHEIMER DISEASE

Etiology

A definitive cause for AD has yet to be determined. Although elevated aluminum concentration has been noted in patients with Alzheimer-type dementia, this finding has not been consistent.^{27–29} For example, patients with aluminum toxicity, as seen in dialysis dementia, do not exhibit AD-type lesions.³⁰ Increased concentrations of cerebral aluminum may be a secondary process resulting from an underlying pathological condition.³¹ Other reported risk factors for AD include young (15–19 years) or old (older than 40 years) maternal age,^{32–34} head trauma,^{34,35} small head circumference and brain size,^{36,37} and low intelligence.³⁸

Genetics play a significant role in the development of Alzheimer-type dementia. The high familial occurrence of Alzheimer dementia has been linked to autosomal-dominant traits on chromosomes 21, 14, and 1.³⁹ The risk to first-degree relatives of patients with AD is 24% to 48% and may be as high as 64% for offspring.^{40–43} Familial dementia of the Alzheimer type is associated with an early onset, faster progression, family history of psychiatric problems, and more prominent language difficulties.^{40,44–46} However, there is some association between changes on chromosome 14 and late-onset AD.^{47,48}

In families with a history of Down syndrome or other defects on chromosome 21, the prevalence of Alzheimer-type dementia is increased significantly. AD affects virtually all Down syndrome patients who survive into old age.^{45,49,50} Mutations on chromosome 14 are responsible for most cases of familial early-onset AD, whereas chromosome 1-associated mutations account for cases in only a small cohort of families.^{51,52} However, differences in risk based on age at onset and discordance for the disease among monozygotic twins indicate some heterogeneity in the genetic etiology.^{43,45,53} Clinically, patients with familial dementia of the Alzheimer type are indistinguishable from those with nonfamilial, or sporadic, forms of the disease, suggesting a combination of genetic and environmental causes.^{52,46} Despite the familial patterns, these mutations account for only approximately 5% of all cases of AD.⁵⁴

Abnormalities in serum protein and alterations in immune function are often found among patients with AD. Amyloid precursor protein (APP), a normal protein found throughout the body (e.g., platelets and peripheral lymphocytes),⁵⁵ maps on chromosome 21 and is produced in excess in patients with Down syndrome.⁴⁹ Because of overproduction or transcription errors, an abnormal subunit (i.e., β -amyloid) is produced.^{49,56} This finding is consistent in families with a high incidence of Alzheimer-type dementia, especially those with early-onset (before age 65) forms.^{45,49,56}

Mutations on chromosome 14 occur in the presenilin-1 gene, and mutations on chromosome 1 occur in the presenilin-2 gene.^{51,52,57} These mutations also code for alterations in the processing of APP. The abnormal cleavage of APP produces a 42-amino acid form of β -amyloid that demonstrates a higher toxicity than other amyloid forms.³⁹

Apolipoprotein E (ApoE), a protein that is involved in cholesterol and phospholipid metabolism, plays a role in the development of sporadic, late-onset AD.⁵⁸ The ApoE gene resides on chromosome 19 and possesses three alleles: $\epsilon 2$, $\epsilon 3$, and $\epsilon 4$. The $\epsilon 3$ allele is most common, the $\epsilon 2$ allele appears to be protective against AD, and the $\epsilon 4$ allele increases the risk for AD.^{59,60} The presence of ApoE-4, the protein coded for by the $\epsilon 4$ allele, appears to increase the deposition of β -amyloid and promote its change to a more pathological configuration.³⁹ Measurable memory decline in people with either one or two copies of the $\epsilon 4$ allele occurs much earlier than in those with no copies and well in advance of the first clinical symptoms of AD.^{61,62} The risk for developing AD by age 80 years has been estimated at 47% for people with one copy of ApoE- $\epsilon 4$ and at 91% for those who carry two copies. In contrast, the risk is approximately 20% for those with no ApoE- $\epsilon 4$ copies.⁵⁹

Amyloid protein can commonly be found in the neuritic plaques, which occur in Alzheimer-type dementia; and cerebral amyloid angiopathy occurs in 50% to 90% of patients with progressive dementia and neurofibrillary degeneration.^{63,64} Amyloid protein is also noted in blood vessel walls of patients with AD.⁵⁵ β -Amyloid protein deposits occur early in the course of Alzheimer dementia and are distinct from the amyloid proteins found in other amyloid disorders, such as primary amyloidosis or multiple myeloma.^{31,55}

Neuropathology

Although brain atrophy is the most obvious finding among patients with Alzheimer-type dementia, it is not diagnostic for AD or other dementias because some degree of atrophy accompanies normal aging.⁶⁵ Atrophic changes induced by AD are found primarily in the temporal, parietal, and frontal areas of the brain; the occipital region, primary motor cortex, and somatosensory areas are generally unaffected (Fig. 100-1).

Neuronal changes in the cerebral cortex associated with AD include neurofibrillary tangles, neuritic plaques, amyloid angiopathy, and granulovacuolar degeneration. These changes lead to loss of neurons and synapses (Fig. 100-2).³⁹ Neurofibrillary tangles (NFTs) are found primarily in the pyramidal regions of the neocortex, hippocampus, and amygdala, but they are also noted in areas of the brainstem and locus ceruleus.^{39,66} Tangles are a prominent feature of Alzheimer-type dementia, but can be found in several other brain disorders (e.g., Down syndrome, postencephalitic Parkinson disease) and even in normally aging brains, although they are generally less numerous and histologically different.^{39,67} Conversely, Alzheimer-type dementia may also occur in the absence of NFTs.⁶⁷

NFTs are composed of paired helical filaments, combinations of fibrils with a characteristic width and contour, containing a tau protein with an abnormal pattern of phosphate deposition.^{39,68,69} They are highly immunoreactive and are most likely to form in large pyramidal neurons. NFTs typically begin in the transentorhinal cortex and spread to the limbic cortex and the neocortex.³⁹ Although the nerve structures (axons,

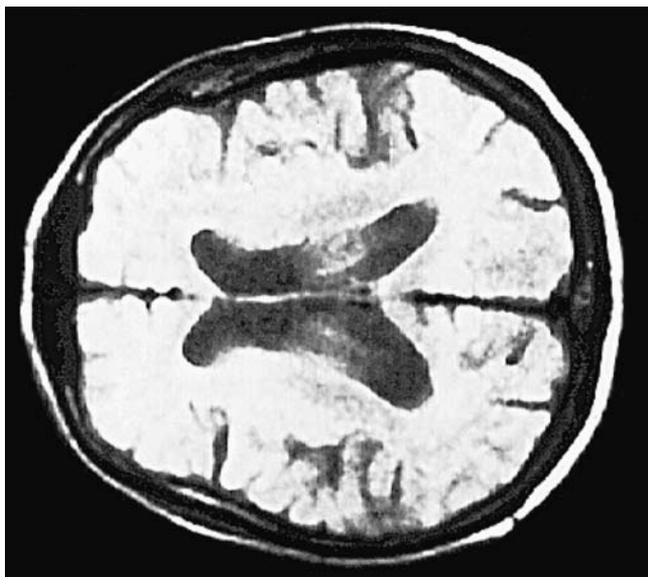

FIGURE 100-1 Alzheimer disease: MRI scan. Ventricles are enlarged, and there is generalized atrophy, with greater atrophy present near the temporal areas.

dendrites, and nerve terminals) found within NFTs contain amyloid deposits, abnormal axons may occur independently of amyloid deposition. Thus, the presence of amyloid protein is not required for the development of tangles.⁷⁰ The presence of NFTs in the neocortical areas is associated with the presence of Alzheimer-type dementia, and their number in the nucleus basalis is correlated with the severity and duration of the disease.^{71,72}

Neuritic plaques are spherical bodies of tissue composed of granular deposits and remnants of neuronal processes.³ Diffuse plaques, considered to represent the early stage of plaque formation, contain no amyloid core. They have been found in areas in the cerebellum and throughout cerebral hemispheres that are not related to AD symptoms.³⁹ The typical neuritic plaques of AD may develop from preamyloid deposits with subsequent deposition of amyloid protein and accumulation

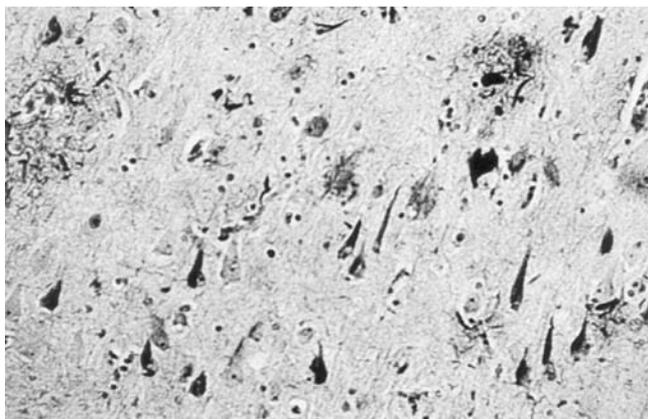

FIGURE 100-2 Numerous plaques (large, round bodies) and tangles (tear-shaped bodies) are found throughout the cortex in Alzheimer-type dementia.

of oligosaccharide, aggregation of amyloid subunits, and β -pleating of the protein.^{73,74} They are spherical structures between 50 and 200 μm wide and exhibit a three-tiered structure: a central amyloid core, a middle region of swollen axons and dendrites, and an outer zone containing degenerating neuritic processes.³⁹ The plaques are concentrated in the cerebral cortex and hippocampus, but they are also found in the corpus striatum, amygdala, and hypothalamus.⁷⁵ Rare plaques have also been found in nondemented elderly patients.⁷¹

Plaques contain APP, which can be cleaved by a defective metabolic process to form β -amyloid.^{76–78} In addition to β -amyloid, plaques also contain protein, apolipoprotein E, and acute phase inflammatory proteins such as α_1 -chymotrypsin and α_2 -macroglobulin.^{39,79} Although β -amyloid is found in both normal and AD subjects, NFTs occurring in the plaques of nondemented subjects do not contain the abnormal protein seen in individuals with dementia.⁷¹ The deposition of amyloid in neuritic plaques correlates with the severity of AD, and the density of cortical plaques is associated with decreased choline acetyltransferase and the severity of cognitive impairment.^{76,80} β -Amyloid has been identified in plaques associated with Down syndrome and in both familial and sporadic forms of dementia of the Alzheimer type.^{76,81} The process of development from the time of amyloid deposition to plaque formation may take as long as 30 years.^{76,82}

In addition to neuritic plaques, APP and β -amyloid produce an amyloid angiopathy outside brain tissue. APP has been located in the adenohypophysis, adrenal gland, cardiac muscle, and peripheral nervous system.⁷⁷ Amyloid deposits, identical to those found in neuritic plaques, have been found in cerebral blood vessels as well as in the vasculature of skin, subcutaneous tissue, and intestine.^{39,76,83}

Granulovacuolar degeneration is the other major histologic finding in AD. It consists of clusters of intracytoplasmic vacuoles that contain tiny granules. The vacuoles appear to be specifically located in the pyramidal neurons of the hippocampus. Granulovacuolar degeneration can also occur, albeit rarely, in individuals without dementia.³⁹

The loss of cortical neurons that originate in the nucleus basalis and project into the cerebral cortex is the most significant histopathological consequence of AD.^{39,80,84,85} Cell loss, granulovacuolar degeneration, and neurons with NFTs are concentrated in this area.³⁹

Accompanying these changes are decreased concentrations of several neurotransmitters and enzymes. Choline acetyltransferase levels are reduced 60% to 90% in the cortical and hippocampal regions.^{39,80} Acetylcholine and acetylcholinesterase (AChE) are also decreased, whereas muscarinic receptors in the cortex and hippocampus remain at normal levels or are moderately decreased.^{80,86} Nicotinic receptor proteins are also reduced in patients with Alzheimer-type dementia when compared with age-matched controls.^{87,88} Decreased choline acetyltransferase activity has been correlated with plaque density and disease severity.⁸⁰ Cortical synapse loss, especially in the midfrontal region, is associated with disease severity.⁸⁹

Changes affecting AChE have significant implications for the management of AD symptoms. Many isoforms of AChE have been identified; they possess identical amino acid sequences, but display different posttranslational modifications, predominate at diverse anatomical and microanatomical locations, and function in different ways.⁹⁰ The predominant form

of AChE in the cortical and hippocampal regions of humans is G4, a tetrameric form that is membrane bound. The monomeric form, G1, is found in a much lower concentration. There is a selective loss of the G4 form in patients with AD, allowing the G1 form to assume greater importance.

Although cholinergic activity is most significantly affected by Alzheimer-type dementia, other neurochemical systems are also altered. Norepinephrine, serotonin, and γ -aminobutyric acid levels may be normal or moderately decreased.³⁹ Somatostatin and corticotropin-releasing factor are also reduced in patients with Alzheimer-type dementia.^{80,91}

Clinical Presentation and Diagnosis

1. C.L., a 63-year-old woman, complains of increasing memory problems over the past 2 years. She states that she began writing reminder notes to herself, but she often forgot to look at them. Eventually, she began to lose items around her house, forget appointments, and fail to pay some important bills. During the past 2 to 3 months, she has had difficulty following a shopping list and has become disoriented in the store. One week ago, she became agitated when she heard the low-battery alarm in her smoke detector. C.L. admits to becoming increasingly depressed over her memory problems but denies appetite or sleep changes or suicidal ideation. She also denies hallucinations, delusional thoughts, or symptoms of anxiety. C.L.'s medical history is significant for type 2 diabetes mellitus, which is diet controlled, and bilateral open-angle glaucoma, treated with dipivefrin 0.1%, one drop twice daily. Her family history is negative for stroke and positive for diabetes mellitus and hypertension. She reports that two or three of her maternal relatives had "memory problems" and that one aunt was diagnosed with AD 5 years ago.

Physical examination reveals a moderately obese woman who is well dressed and groomed. Her blood pressure (BP) is 140/86 mmHg supine and 132/82 mmHg standing, with pulse rates of 74 beats/minute and 78 beats/minute, respectively. She is awake and oriented to place and person. During the interview, she is reserved but becomes easily irritated with the physician.

The Folstein MMSE score was 23/30, with errors in orientation, attention, and calculation (inability to spell "world" backward), recall, and language (difficulty with word finding). Her score on the Blessed Dementia Scale was 25/33, with deficits in personality, memory, concentration, and habits. Neurologic examination revealed no deficits. The rest of the physical examination was within normal limits.

Laboratory tests performed include renal and liver chemistries, thyroid function tests, glycosylated hemoglobin, vitamin B12 and folate levels, syphilis and HIV tests, complete blood count (CBC) with sedimentation rate, and urinalysis. All results were normal with the exception of a fasting glucose level of 150 mg/dL (normal, <126 mg/dL) and a glycosylated hemoglobin of 8.4% (normal, 4%–6%). Chest radiograph and electrocardiogram (ECG) were normal. Depression testing revealed a sad, mildly anxious individual who was not depressed. What is the most probable diagnosis for C.L.?

[SI units: fasting glucose, 8.3 mmol/L; glycosylated hemoglobin, 0.084%]

C.L. is in the early stages of AD. She displays several trigger symptoms associated with dementia, including problems learning new information, difficulty with complex tasks (shop-

ping), impaired reasoning (recognizing the smoke alarm battery warning), and increased irritability.²² Her score of 23/30 on the Folstein MMSE indicates a mild stage of the dementia as evidenced by errors in orientation, calculation, recall, and language.²⁴ Personality and habit changes and deficits in memory and concentration are revealed in C.L.'s score on the Blessed Dementia Scale.²⁵ Secondary medical causes of cognitive impairment can be eliminated by C.L.'s generally normal physical examination and laboratory test results. C.L.'s fasting glucose and glycosylated hemoglobin levels are mildly elevated, but cannot account for her significant cognitive decline. MRI or CT scanning may be useful in many cases to help eliminate brain pathology, such as stroke, but the lack of any abnormal neurologic findings renders imaging in C.L. unnecessary.

Secondary psychiatric causes for C.L.'s decline can also be discounted. Although she is sad and anxious, the absence of alterations in appetite or sleep patterns, absence of suicidal thoughts, and the results of psychological testing indicate C.L. is not depressed. She is fully conscious, alert, and oriented to place and person. She exhibits no psychotic behavior and no evidence of delirium.

C.L.'s slowly progressive decline, its impact on her social and occupational function (forgetting appointments, failing to pay bills), normal physical examination and laboratory findings, and family history meet the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition (DSM-IV) criteria for AD (Table 100-1). Because she is younger than 65 years, she also may be classified as early-onset type.²¹ Her history and course to date satisfy the criteria for Alzheimer-type dementia and do not indicate a likely alternative explanation for her condition. Thus, C.L. can be classified as probable AD according to the criteria established by the National Institute of Neurological and Communicative Disorders-Alzheimer's Disease and Related Disorders Association Task Force (Table 100-5).⁹²

2. C.L.'s children are very concerned about the family history for dementia. They ask if there are any tests they should receive at this time to determine their risk. What should they be told?

Although there is a strong genetic association with AD, such instances account for a small minority of cases.⁵⁴ There is no apparent family history of Down syndrome. Mutations in the presenilin-1 and presenilin-2 genes have been documented in only a few families worldwide.⁹³ The test that would most likely be performed is ApoE-4 genotyping, but this is not recommended because the sensitivity and specificity of the test is not yet known.^{93,94}

Prognosis

3. What is the likely prognosis for C.L.?

AD follows a predictable course that may progress over 10 years or more.^{17,95} Two common rating scales for dementia are the Global Deterioration Scale and the Clinical Dementia Rating Scale. According to the Global Deterioration Scale (Table 100-6), C.L.'s impaired social functioning, anxiety, and objective cognitive decline as well as her continued ability to concentrate and perform some complex skills, combined with her preserved affect and social interaction, are consistent with

Table 100-5 National Institute of Neurological and Communicative Disorders-Alzheimer's Disease and Related Disorders Association Criteria for Dementia of the Alzheimer Type (DAT)

Definite DAT

Clinical criteria for probable DAT
Histopathological evidence for DAT (autopsy or biopsy confirmed)

Probable DAT

Dementia established by clinical examination and documented by mental status testing (e.g., history and physical examination, Folstein Mini-Mental Status Exam)
Confirmation of dementia by neuropsychologic tests (e.g., Blessed Dementia Scale and other tests)
Deficits in at least two areas of cognitive function (e.g., language, memory)
Progressive deterioration of memory and other cognitive function
Undisturbed consciousness
Onset between the ages of 40 and 90 yrs
Absence of systemic or other brain disease capable of producing dementia

Possible DAT

Atypical onset, presentation, or progression of dementia with an unknown etiology
Presence of a systemic or other brain disease capable of producing dementia, but not believed to be the cause of the dementia
Gradually progressive decline in one intellectual function in the absence of another identifiable cause

Unlikely DAT

Sudden onset
Focal neurologic findings (e.g., deep tendon reflexes, hemiparesis)

Adapted from reference 92.

the features of stage three dementia of the Alzheimer type. This stage of AD is generally associated with a period of mild cognitive decline.⁹⁶ The more general Clinical Dementia Rating Scale also places C.L. in the category of mild dementia.⁹⁷ Clinical diagnoses of AD using clinical criteria for probable

Table 100-6 Stages of Dementia of the Alzheimer Type

| Stage of Cognitive Decline | Features |
|-------------------------------------|--|
| No cognitive decline | Normal cognitive state |
| Very mild cognitive decline | Forgetfulness, subjective complaints only; no objective decline |
| Mild cognitive decline | Objective decline through psychiatric testing; work and social impairment; mild anxiety and denial |
| Moderate cognitive decline | Concentration, complex skills decline; flat affect and withdrawal |
| Moderately severe cognitive decline | Early dementia; difficulty in interactions; unable to recall or recognize people or places |
| Severe cognitive decline | Requires assistance with bathing, toileting; behavioral symptoms present (agitation, delusions, aggressive behavior) |
| Very severe cognitive decline | Loss of psychomotor skills and verbal abilities; incontinence; total dependence |

Adapted from reference 96.

AD have a sensitivity of approximately 85% when compared with autopsy-confirmed cases.^{93,98}

Because of technologic advances, it is possible to diagnose dementia earlier and to keep patients alive into the final stages of the disease. The early diagnosis of AD in C.L. will allow her condition to be followed closely. Although it is less expensive to maintain a patient at home, caregiver burden can become a significant consideration.^{99,100} Eventually, C.L. should be moved into a sheltered environment (e.g., a relative's home, residential care facility, or nursing home) before suffering an injury caused by her poor judgment (e.g., failing to dress properly for the weather, falling). In the later stages, interventions ranging from tube feedings to life support may prolong life, yet prove to be controversial.¹⁰¹ Death in the late stage of AD is commonly associated with the development of infections such as pneumonia, urinary tract infections, or decubitus ulcers.

Treatment

4. What is an appropriate initial treatment strategy for C.L.?

Maintaining independence as long as possible is an important goal in treating a patient with dementia. Keeping patients in familiar surroundings allows them to function without the added burden of having to attempt to adapt to a strange environment. C.L. appears to be functioning reasonably well at home, although her forgetfulness is causing some problems for her. She is still eating well (her laboratory testing indicated no deficiencies in total protein or albumin, vitamin B12, or folic acid) and performing normal daily activities such as dressing, grooming, bathing, and toileting. Some regular supervision from family members, neighbors, or household help will ensure that C.L. remains safe in her own home.

C.L.'s diabetes mellitus and general medical condition should also be monitored closely. Because both hyperglycemia and hypoglycemia can impair cognitive processes, either complication can exacerbate her memory problems. Concurrent diseases and many medications can reduce function and increase cognitive impairment in demented patients, so any new findings in C.L. must be evaluated carefully to distinguish new problems from a worsening of her dementia.

C.L.'s family needs to be educated about what to expect as her dementia progresses. They should be referred to the Alzheimer's Association Website. Results of trials investigating precursor loading and agonists have been disappointing. Moderate success has been demonstrated with cholinesterase inhibitors¹⁰² (Fig. 100-3). However, the long-term value of this strategy is limited by the fact that the disease process is unaltered and neuronal degeneration continues.¹⁰³

TACRINE

Tacrine, the first agent approved for the symptomatic treatment of mild to moderate AD, is an aminoacridine derivative that reversibly inhibits both AChE and butyrylcholinesterase (BChE).¹⁰⁴ It has a relatively low bioavailability, which is further decreased when the drug is taken with meals. Multiple daily doses are required because tacrine's half-life is short (Table 100-7).¹⁰⁴ Significant cholinergic adverse effects, primarily nausea, vomiting, diarrhea, and abdominal pain, and a high risk of hepatotoxicity have rendered this agent obsolete.^{105,106}

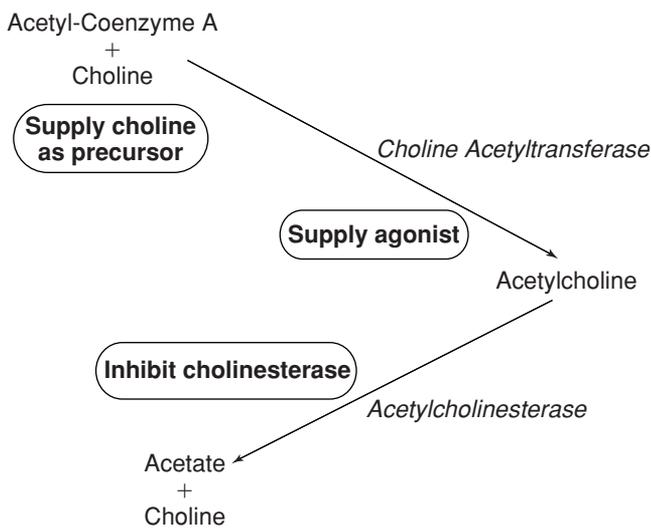

FIGURE 100-3 Potential strategies for cholinergic manipulation.

DONEPEZIL

Donepezil represents the first of what has been termed the “second-generation” cholinesterase inhibitors.¹⁰² It is a piperidine derivative that is more selective for AChE than BChE and, like tacrine, it reversibly inhibits cholinesterase activity. Donepezil is completely bioavailable and exhibits a long half-life, allowing it to be given as a single daily dose.¹⁰⁷ It is highly protein bound, primarily to albumin (Table 100-7).¹⁰⁸

Donepezil may improve cognition, global function, and behavioral symptoms across all stages (mild, moderate, and severe) of AD. In a multicenter, double-blind, placebo-controlled trial, subjects with mild to moderately severe AD improved over a 12-week treatment period.¹⁰⁹ Subjects taking 10 mg of donepezil at bedtime improved their cognitive function as measured by the Alzheimer’s Disease Assessment Scale-Cognitive Subscale (ADAS-Cog), and their overall function as measured by the Clinician’s Interview-Based Impression of Change with caregiver input (CIBIC-Plus).^{110,111} A 24-week multicenter, placebo-controlled trial using dosages of 5 mg/day and 10 mg/day demonstrated similar results. Both 5 and 10 mg doses were superior to placebo; adverse effects were less common with the 5 mg dose.¹¹² A long-term, open-label follow-up study to these trials demonstrated that donepezil effects may persist for almost 3 years.¹¹³ Interruption or discontinuation of donepezil treatment was followed by a return of cognition and function to baseline or below.

Donepezil is the only cholinesterase inhibitor currently indicated for the severe stage of AD. A 6-month, double-blind, parallel group, placebo-controlled study in patients with severe AD (MMSE 1–10) showed at 6 months an improvement in the severe impairment battery (SIB) and Modified Alzheimer’s Disease Cooperative Study activities of daily living inventory for severe AD (ADCS-ADL-severe).¹¹⁴ The domains that showed a significant improvement over placebo were language, praxis, visuospatial, bowel/bladder function, and ability to get dressed. There were no differences noted in the neuropsychiatric inventory for behavioral issues associated with dementia.

The most common adverse effects of donepezil are associated with cholinergic activity. They tend to be mild to moder-

ate in nature and resolve with stabilization of the dose.^{109,112} In a 144-week extension trial of donepezil, the most frequently encountered adverse effects were nausea, diarrhea, and headache.¹¹³

RIVASTIGMINE

Rivastigmine is a carbamate derivative that inhibits both AChE and BChE activity. BChE provides an alternate pathway for acetylcholine metabolism. Rivastigmine inhibits the activity of both cholinesterases, primarily in the central nervous system (CNS).¹¹⁵ Its AChE inhibition is greater for the G1 as compared to the G4 form.¹¹⁶ The drug binds to the esteratic site of the AChE and BChE molecule and slowly dissociates. Because of this, it is often referred to as a “pseudoirreversible” inhibitor.¹¹⁷ Rivastigmine’s biological half-life is approximately 1 hour, but because its slow dissociation extends its activity for at least 10 hours, it can be dosed twice daily. Rivastigmine is bound approximately 40% to serum proteins and is metabolized via hydrolysis to renally excreted inactive compounds.¹¹⁶ Rivastigmine absorption is nearly complete, but because it undergoes a significant first-pass effect, the resultant bioavailability is approximately 36% (Table 100-7).

In two large clinical trials conducted in patients with mild to moderately severe AD, rivastigmine improved cognition, the ability to perform daily activities, and global function over 24 weeks.^{118,119} In each multicenter, double-blind, placebo-controlled trial, subjects were randomized to receive placebo or low-dose (1–4 mg/day) or high-dose (6–12 mg/day) rivastigmine in two divided doses during a 26-week period. In one study, subjects in both dosage groups demonstrated statistically significant improvement after 26 weeks on the ADAS-Cog and CIBIC-Plus scales.¹¹⁸ In the other trial, only those subjects taking 6 to 12 mg/day improved on the same scales.¹¹⁹ An open-label extension study that included subjects from both previous studies found that subjects taking 6 to 12 mg/day of rivastigmine had significantly better cognitive function after 1 year than did subjects who had originally received placebo.¹²⁰

Adverse effects typically included nausea, vomiting, diarrhea, and other cholinergically mediated gastrointestinal (GI) effects.¹²¹ They are most common when rivastigmine is taken on an empty stomach or when the dose escalation is too rapid. Headache, dizziness, and fatigue are also common adverse effects. Increasing the dose by 1.5 mg twice daily at 4-week intervals increases drug tolerability and reduces the frequency and severity of GI side effects.

GALANTAMINE

Like other agents used to treat AD, galantamine enhances cholinergic activity by inhibiting AChE. However, it also stimulates nicotinic receptors at a site distinct from that stimulated by acetylcholine, an action that does not rely on the presence of acetylcholine.¹²² This action is referred to as allosteric modulation. Galantamine is rapidly and completely absorbed, reaches peak serum levels in <2 hours, and has a half-life of approximately 5 hours. It exhibits low protein binding and has a large volume of distribution. Galantamine is metabolized primarily by CYP2D6 and CYP3A4, and is eliminated in the urine (Table 100-7).^{123,124}

Clinical trials have shown galantamine to be effective for the symptomatic treatment of mild to moderate AD. Doses of 16 and 24 mg/day produced clinically meaningful improvement

Table 100-7 U.S. Food and Drug Administration–Approved Drugs for Alzheimer Disease (AD)

| <i>Generic Drug (Brand Name) and Mechanism</i> | <i>Dosage Form and Dosage</i> | <i>Indication and Effect</i> | <i>Adverse Effects</i> | <i>Other</i> |
|---|--|---|---|--|
| Donepezil HCl (Aricept) Reversibly inhibits acetylcholinesterase (AChE), primarily in central nervous system (CNS) | 5-, 10-mg tablets 5, 10 mg ODT 1 mg/mL oral solution 5 mg daily, usually at bedtime Dose may be increased to 10 mg after 4–6 weeks | Symptomatic treatment of mild to severe AD Small improvements in cognition and function occur within 12–24 weeks; benefits may last for at least 2 years | Cholinergic effects, particularly affecting the gastrointestinal (GI) tract (nausea, anorexia, diarrhea); headache; bradycardia may occur | Completely bioavailable and may be given as a single daily dose due to long half-life (70 hours) Metabolized by CYP3A4 isoenzymes |
| Galantamine HBr (Razadyne and Razadyne ER) Reversibly inhibits AChE, primarily in CNS; also stimulates nicotinic receptors at a site distinct from that of acetylcholine | 4-, 8-, 12-mg tablets 4 mg/mL oral solution 8, 16, 24 mg extended release capsule 4 mg BID, with food Dose may be increased every 4–6 weeks in 4 mg BID increments, to a maximum dose of 1 mg BID Extended-release (ER) formulation can be given once daily starting at 8 mg daily and increasing as noted previously | Symptomatic treatment of mild to moderate AD Small improvements in cognition and function occur within 12–24 weeks. Benefits may last for more than 1 year | Cholinergic effects, particularly affecting the GI tract (nausea, anorexia, diarrhea); headache; bradycardia may occur | Highly bioavailable Initial dose is not therapeutic; slow titration increases tolerability Metabolized by CYP2D6 and CYP3A4 isoenzymes |
| Rivastigmine tartrate (Exelon) Reversibly inhibits AChE and butyrylcholinesterase (BChE), primarily in CNS | 1.5-, 3-, 4.5-, 6-mg tablets 4.6, 9.5 mg/24 hr extended release patch 2 mg/mL solution 1.5 mg BID, with food Dose may be increased every 4–6 weeks in 1.5 mg BID increments, to a maximum dose of 6 mg BID | Symptomatic treatment of mild to moderate AD Small improvements in cognition and function occur within 12–24 weeks. Benefits may last for more than 1 year | Cholinergic effects, particularly affecting the GI tract (nausea, anorexia, vomiting, diarrhea); headache; bradycardia may occur | Highly bioavailable Therapeutic effect greatly exceeds biological half-life (1 hour), allowing for twice daily dosing Metabolized by hydrolysis Initial dose is not therapeutic; administration with food and slow titration are necessary to increase tolerability |
| Tacrine (Cognex) Reversibly inhibits AChE and BChE, in CNS and periphery | 10-, 20-, 30-, 40-mg tablets Initially 10 mg QID, with increases of 10 mg QID every 4 weeks; maximum dose is 40 mg QID | Symptomatic treatment of mild to moderate AD Small improvements in cognition and function occur within 12–24 weeks | Cholinergic effects, particularly affecting the GI tract (nausea, anorexia, vomiting, diarrhea); abdominal pain; headache; bradycardia may occur. Increases in ALT levels require frequent monitoring | Poor bioavailability, further reduced by giving with food Adverse effects limit patient tolerability Multiple daily doses require frequent dosing Metabolized by CYP1A2, CYP2D6 Initial dose is not therapeutic |
| Memantine (Namenda) Uncompetitive antagonist of the N-methyl-D-aspartate type of glutamate receptors | 5- and 10-mg tablets and solution, oral: 5 mg/day for 1 week; 5 mg BID for 1 week; 15 mg/day given in 5 mg and 10 mg separated doses for 1 week; then 10 mg BID Severe impairment: Creatinine clearance 5–29 mL/min): 5 mg BID | Symptomatic treatment of moderate to severe AD Small improvements in cognition and function as well as less burden on caregivers | Well tolerated, yet can cause headaches and dizziness | Can be used as monotherapy or in conjunction with cholinesterase inhibitors |

BID, twice daily; QID, four times daily; ODT, orally disintegrating tablets.

in ADAS-Cog and CIBIC-Plus scores during a 5-month, randomized, placebo-controlled trial.¹²⁵ A similar trial conducted in Europe and Canada that evaluated patients over 6 months used doses of 24 and 32 mg/day. Both doses were more effective than placebo, but patients in the 32 mg/day group exhibited more adverse effects.¹²⁶ A 6-month, open-label extension trial showed that patients treated with galantamine 24 mg/day maintained ADAS-Cog scores throughout the entire 12 months of the study.¹²⁷

As with the other cholinesterase inhibitors, cholinergic effects in the GI tract are the most commonly encountered adverse effects. Nausea, diarrhea, vomiting, and anorexia were the most frequent events encountered during clinical trials.¹²⁴ They were typically present during the dose escalation phases of the studies. A dose titration interval of 4 weeks reduces the severity of adverse effects and increases tolerability.

C.L. is in the mild stage of the disease, so a cholinesterase inhibitor would be the first choice. It is unlikely that a cholinesterase inhibitor will produce a dramatic or long-lasting improvement in C.L.'s cognitive abilities. Systematic reviews of cholinesterase inhibitor therapy have consistently concluded that these agents provide modest benefits, at best, in the majority of patients.^{128,129} Treatment, however, may slow her cognitive decline, help maintain her ability to care for herself for 1 year or more, and reduce the risk for nursing facility placement for as much as 2 years.¹³⁰ The choice of drug is based on the agent most likely to produce a positive response with the fewest adverse effects. Ease of adherence must also be considered. All agents exhibit similar adverse effect profiles. Rivastigmine may be less prone to drug interactions because of its metabolic pathway. It is also available as a patch that is applied daily. Donepezil and galantamine can be given as a single daily dose. They can be given at bedtime, which may make cholinergic side effects less troublesome. We decide to start C.L. on donepezil.

6. How should treatment with donepezil be instituted in C.L., and how should therapy be monitored?

C.L. should receive donepezil 5 mg at bedtime. She should be monitored for cholinergic side effects (particularly nausea and diarrhea), insomnia, headache, and dizziness, the adverse effects most commonly reported in clinical trials.^{109,112} Her family and physician should look for improvements in her memory, orientation, and ability to concentrate on complex tasks, such as shopping. She may also become less irritable. If she has not improved noticeably after 4 to 6 weeks, the dose of donepezil may be increased to 10 mg at bedtime.

If her condition does not respond to donepezil after a trial of 3 to 6 months or she is unable to tolerate the donepezil, it is reasonable to switch C.L. to another cholinesterase inhibitor. Both rivastigmine and galantamine have additional mechanisms of action that might prove beneficial. Rivastigmine is started at a dose of 1.5 mg twice daily with meals to slow absorption and improve tolerability. The dose may be increased at 4-week intervals by 1.5 mg twice daily, up to the maximum dose of 6 mg twice daily. Galantamine can be started at 4 mg twice daily or 8 mg daily and increased every 4 weeks by 8 mg, up to a maximum dose of 24 mg daily. Taking galantamine with meals may improve tolerability of GI effects. If a trial of a sec-

ond agent does not improve or stabilize a patient's condition, there is no value in attempting a third agent.

MEMANTINE

7. C.L. tolerated donepezil well, with the exception of some mild nausea and occasional loose stools. She was once again able to engage in normal activities with the help of reminder notes and became much less irritable, according to her family.

One year later, C.L. is exhibiting some decline in her cognition and is becoming more disoriented, particularly in the afternoon and evening. Her physician considers her to now be in the moderate stage of AD. What other drug therapy strategies may be appropriate for C.L.'s worsening AD?

Evidence that release of glutamate in the CNS can lead to excitotoxic reactions and cell death has led to research into the use of N-methyl-D-aspartate (NMDA) antagonists to treat AD and other neurodegenerative disorders.¹³¹ Memantine is an uncompetitive NMDA receptor antagonist with moderate affinity and voltage-dependent binding. It is completely absorbed after oral administration, reaches peak serum concentrations in 3 to 8 hours, and is moderately protein bound (Table 100-7).¹³⁰

Two large clinical trials have evaluated memantine in subjects with moderate to severe AD. A dose of 10 mg/day for 12 weeks increased functional ability (e.g., dressing, toileting, participating in group activities) and reduced care dependence compared with placebo.¹³² A 28-week trial using a dose of 20 mg/day improved CIBIC-Plus scores, activities of daily living, and global function compared with placebo.¹³³ Overall, the benefits of memantine are modest.¹³⁴ Common adverse effects include diarrhea, insomnia, dizziness, headache, and hallucinations.¹³¹ The combined use of memantine and a cholinesterase inhibitor has been shown to be superior to a cholinesterase inhibitor alone in individuals with moderate to severe dementia.^{135,136} C.L. should be started on memantine 5 mg daily, with the dosage increased in weekly intervals by 5 mg/day, up to a dose of 10 mg twice daily.¹³⁷

Investigational Agents

Several medications are being studied for the management of dementia at various stages. Some are medications already approved for other uses, and others are new and investigational agents. The Alzheimer's Association and clinicaltrials.gov are great resources to find and gather additional information on investigational treatments.

ESTROGEN

Estrogen has several beneficial effects on the brain, including improved cerebral blood flow, increased glucose transport and metabolism, and facilitated repair of damaged neurons.¹³⁸ Retrospective studies have demonstrated a link between postmenopausal estrogen replacement and improved performance on memory testing in older women.¹³⁹ A reduced risk for dementia has been found among postmenopausal estrogen users in some studies but not in others.¹⁴⁰ The Women's Health Initiative Study found that women taking combined estrogen and progestin were more likely to develop dementia than those who had not taken these hormones. The hazard ratio for developing dementia was 2.05.¹⁴⁰ One recent study found no link between estrogen and AD among nonsmokers, but an elevated risk among smokers.¹⁴¹

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

The recognition that acute phase inflammatory proteins are present in neuritic plaques has led to the investigation of nonsteroidal anti-inflammatory drugs (NSAIDs) for the treatment or prevention of AD.⁷⁹ In retrospective studies, people who took NSAIDs had a lower prevalence of AD when compared with nonusers.^{142–145} Acetaminophen did not appear to have any protective effects.¹⁴⁵ Prospective pilot studies using indomethacin and diclofenac/misoprostol in patients with mild to moderate AD produced promising but inconclusive results.^{146,147} Although an epidemiologic study demonstrated reduced risk for AD with NSAID use,¹⁴⁸ clinical trials of naproxen, rofecoxib, and celecoxib showed no effect on cognition when compared with placebo.^{149,150}

MONOAMINE OXIDASE INHIBITORS

Findings of decreased central norepinephrine and increased monoamine oxidase type B (MAO-B) among patients with Alzheimer-type dementia led to the investigation of the MAO-B inhibitor, selegiline (Eldepryl), as a potential treatment.^{66,151} Improvement in memory, attention, and social interaction, as well as reductions in anxiety, depression, and tension, were demonstrated in some clinical trials, although others found no significant benefit.^{151–154} An investigation that evaluated selegiline and vitamin E (2,000 IU/day), alone and in combination, found that each agent independently delayed the progression of AD longer than did the combination.¹⁵⁵ However, concerns with vitamin E in doses >400 IU/day in individuals with cardiovascular disease has been associated with increased mortality.¹⁵⁶

ALTERNATIVE MEDICINES

Extract of ginkgo biloba has been used for many years in Europe to improve memory performance. Although its mechanism is not well understood, it may function as an antioxidant and may increase cholinergic activity.^{157–159} Increasing interest in alternative medicines in the United States has led many people to use the crude extract. Three published trials have evaluated EGb 761, a specific combination of constituents, as a treatment for AD. Two trials found modest improvement in memory without significant adverse effects,^{158,159} whereas the third found no benefit after 24 weeks of treatment (see Chapter 3).¹⁶⁰

Two factors must be considered when referring C.L. for investigational treatments. The first is the appropriateness of individual therapies for her, and the second is the likelihood that she will be able to comply with a research protocol. The most recent evidence regarding hormone replacement therapy suggests that the benefits may not outweigh the potential risks. Likewise, NSAID therapy poses significant GI, renal, and cardiovascular risks; therefore, neither should be used solely for the treatment of AD (see Chapter 43). Any decision to pursue investigational therapy should be discussed fully by C.L., her family, and her physician.

LEWY BODY DEMENTIAS

Etiology

Lewy bodies are hyaline-containing inclusion bodies typically found in people with Parkinson disease. Recently, attention

has been given to distinguish DLB and PDD to help further research.¹⁶¹ It is known that up to 25% of patients with dementia have Lewy bodies in the brainstem and cortex.¹⁶² Many of these patients display extrapyramidal signs without the classic presentation of Parkinson disease.¹⁶³ The role of α -synuclein is a common biological theme in both DLB and PDD, with α -synuclein aggregates found in Lewy bodies and neurites.

Clinical Presentation

8. J.F. is a 72-year-old woman who was diagnosed with mild cognitive impairment 6 months ago. She had been increasingly forgetful and confused for about 1 year before the diagnosis. Approximately 3 months ago, J.F. and her family decided that J.F. should move in with them so she would not be left alone. Since moving in with the family, her son has noted that she seems “spaced out” at times. Some days, she appears to be very clear and not confused; other days she is very forgetful and requires assistance with daily tasks. Her daughter-in-law reported that J.F. has been unsteady on her feet at times and has fallen twice. She notes at times she moves very slowly and has difficulty initiating movement. Recently, J.F. reported seeing people coming out of the painting on the wall (a European street scene), stating that “they were walking all through the house trying to steal anything that can be hidden in a coat pocket.”

At the physician visit, J.F. was found to be medically stable. Vital signs, serum chemistries, and CBC were within normal limits. Her MMSE score was 21/30. During the review of systems, J.F.’s daughter-in-law had to answer some questions because J.F. appeared either not to hear them or to ignore them. On physical examination, she demonstrated mild cog-wheeling rigidity bilaterally, bradykinesia, and masked facies; she did not display a resting tremor. What is the most likely explanation for J.F.’s presentation?

Given her physical health, inability to live by herself because of impaired cognition, and MMSE score, J.F. meets the criteria for dementia. Her rigidity, bradykinesia, and masked facies may be consistent with early Parkinson disease (see Chapter 53). There have been revised criteria for the clinical diagnosis of DLB¹⁶⁴ (Table 100-8). J.F. exhibits all the central features, two core features, and the supportive feature of repeated falls. Her presentation is consistent with probable DLB versus PDD due to her temporal sequence and lack of well-established diagnosis of Parkinson disease.

Treatment

9. What is an appropriate treatment for J.F.?

To date, cholinesterase inhibitors are the only treatment strategy for the cognitive symptoms of both PDD and DLB. The largest randomized, placebo-controlled trials have used rivastigmine (up to 12 mg/day) in subjects with mild to moderate disease, and this medication has received U.S. Food and Drug Administration indication for PDD. Rivastigmine was reported to worsen tremor in 10% of the patients with PDD, yet overall there was not a statistically significant difference between groups.¹⁶¹

Levodopa/carbidopa therapy should be started to help the symptoms of Parkinsonism, yet it is important to monitor for

Table 100-8 Revised Diagnostic Criteria for Dementia with Lewy Bodies (DLB)

1. *Central features (essential for a diagnosis of possible or probable DLB):* Dementia is defined as a progressive cognitive decline that interferes with normal social or occupational function. There is prominent or persistent memory impairment usually evident with progression but not necessarily present in the early stages. Deficits on tests of attention, executive function, and visuospatial ability may be especially prominent.
2. *Core features (two core features are sufficient for diagnosis of probable DLB, one for possible DLB):* (a) Fluctuating cognition with pronounced variations in attention and alertness, (b) recurrent visual hallucinations that are typically well formed and detailed, and (c) spontaneous features of parkinsonism.
3. *Suggestive features (if one or more is present in the presence of one or more core features, a diagnosis of probable DLB can be made. In the absence of core features, one or more suggestive features are sufficient for possible DLB. Probable DLB should NOT be diagnosed on the basis of suggestive features alone):* (a) Rapid eye movement sleep behavior disorder, (b) severe neuroleptic sensitivity, and (c) low dopamine transporter uptake in basal ganglia demonstrated by single-photon emission computed tomography (SPECT) or positron emission tomography imaging (PET).
4. *Supportive features (commonly present but not proven to have diagnostic specificity):* (a) Repeated falls and syncope; (b) transient, unexplained loss of consciousness; (c) severe autonomic dysfunction; (d) hallucinations in other modalities; (e) systematized delusions; (f) depression; (g) relative preservation of medial temporal lobe structures with reduced occipital activity; (h) generalized low uptake on SPECT/PET perfusion scan with reduced occipital activity; and (i) abnormal (low uptake) MIBG myocardial scintigraphy.
5. A diagnosis of DLB is less likely in the presence of cerebrovascular disease, presence of any other physical illness or brain disorder, or if Parkinsonism only appears for the first time at stage of severe dementia.
6. Need to evaluate the temporal sequence of symptoms to differentiate between DLB and Parkinson disease dementia (PDD). DLB should be diagnosed when dementia occurs before or concurrently with Parkinsonism. PDD should be used to describe dementia that occurs in the context of well-established Parkinson disease (generally the 1 year rule between the onset of dementia and Parkinsonism should be followed in the diagnosis).

Adapted from reference 164.

follows multiple small or large cerebrovascular occlusions.¹⁶⁶ A number of diseases, including atherosclerosis, arteriosclerosis, and vasculitis, lead to the production of emboli and thrombi that potentially occlude brain vessels. Hemorrhagic phenomena and disorders such as hypertension or cardiac disease can produce episodes of cerebral ischemia or hypoxia and are responsible for some cases of VaD.^{23,165} Specific risk factors for VaDs include advancing age, diabetes mellitus, small vessel cerebrovascular disease, hypertension, heart disease, hyperlipidemia, cigarette smoking, and alcohol use.^{167–170}

Neuropathology

VaDs are typically subcortical. Most patients with MID have blockage of multiple blood vessels and infarction of the cerebral tissue supplied by those vessels. When the distribution of a large artery or medium-size arteriole is blocked, focal neurologic deficits can result (see Chapter 55). Depending on the area affected, there may be significant cognitive impairment. More often, however, a patient may have suffered transient ischemic attacks (TIAs) or multiple microinfarcts that have remained unrecognized.^{171,172} Patients with subcortical VaDs often exhibit small, deep ischemic infarcts in arterioles of the basal ganglia, thalamus, and internal capsule.^{6,173} A history of atherosclerosis, diabetes mellitus, or hypertension is often present without a history of stroke.^{171,174,175} MRI scans can be very useful in diagnosing VaDs because areas of cerebral infarction are easier to visualize than they are with CT scanning (Fig. 100-4). Lesions in white matter may occur in as many as 85% of patients with VaD.¹⁷⁶ Deep white matter lesions known as leukoaraiosis often include demyelination and may represent early changes in dementia.^{175,177,178} Although patients with Alzheimer-type dementia may also exhibit leukoaraiosis, it is much more prevalent in those with MIDs.^{6,179} Blood flow in patients with leukoaraiosis is reduced in all brain regions except parietal white matter, especially in the putamen and

adverse effects such as worsening psychosis and cognition. Typical antipsychotics, such as haloperidol, may worsen her extrapyramidal symptoms (EPS) and should be avoided. Novel atypicals, namely, quetiapine and clozapine, may be less likely to exacerbate the Parkinsonism but should be instituted after a trial of a cholinesterase inhibitor or if more acute symptom control of behaviors are required.^{161,164}

VASCULAR DEMENTIAS

Etiology

VaD is a broad classification of cognitive disorders caused by vascular disease. The most common cause of VaD is occlusion of cerebral blood vessels by a thrombus or embolus, leading to ischemic brain injury.¹⁶⁵ The term multi-infarct dementia (MID) refers specifically to the cognitive decline that

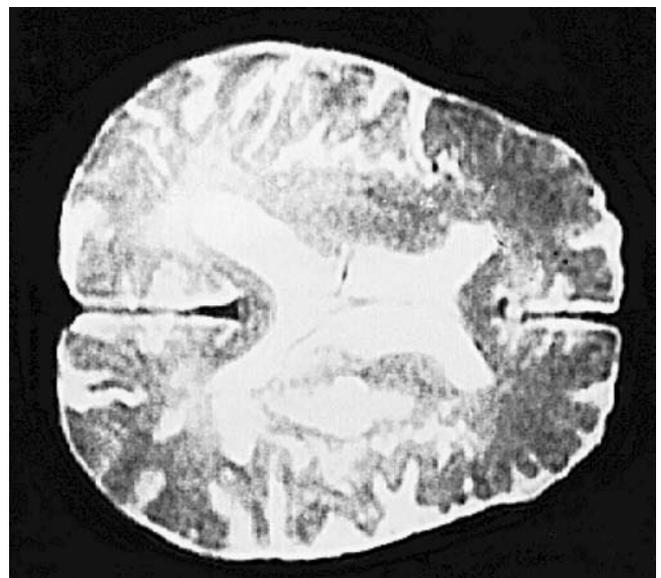

FIGURE 100-4 A large stroke is visible to the right of the ventricles. There is evidence of atrophy in the right temporal area.

thalamus.¹⁸⁰ Patients with long-standing uncontrolled hypertension often develop multiple leukoaraiosis lesions, leading to ischemic periventricular encephalopathy.¹⁷⁵ The lesions are too small to be visualized grossly but are evident on MRI scans.¹⁶⁵ Known as Binswanger disease, this disorder is characterized by focal neurologic deficits, emotional lability, gait disturbances, and urinary incontinence.^{175,181} Patients with Binswanger disease exhibit activation of the coagulation-fibrinolysis pathway, which may lead to microthrombi and microcirculatory disturbances.¹⁸²

VaDs typically have an earlier onset than dementia of the Alzheimer type.⁹⁵ Unlike AD, males are affected more often than females, and survival is shorter for VaD patients.^{95,183}

Clinical Presentation

10. D.V., a 73-year-old man, is accompanied by his daughter for evaluation of “fuzzy thinking.” Although his chief complaint is impaired memory, he denies significant impact on his daily routine. D.V. states his memory problem began 2 years ago after a dizzy spell and subsequent fall. However, his daughter states that the impairment began approximately 1 year before that episode. The memory loss has been slowly progressive. D.V. states that he feels useless because of his memory problems and his “boring” daily routine. Although D.V. is generally independent, he relies on his daughter for assistance with most financial matters. He has voluntarily quit driving because of a lack of confidence in his abilities. D.V.’s daughter reports that according to her mother, D.V. is sometimes disoriented at night when he awakens to urinate. He has no history of urinary incontinence. D.V. has a questionable history of TIAs, but no focal neurologic deficits. He has a long history of mild hypertension, which is treated with a diuretic. He drinks alcohol occasionally and smokes about half a pack of cigarettes per day. His medical history is unremarkable except for the possible TIAs, hypertension, and a mildly enlarged prostate. His family history is positive for diabetes and heart disease.

On physical examination, D.V. is found to be a mildly obese man who is well dressed and groomed, alert, and oriented to person. His BP is 160/92 mmHg sitting and 168/95 mmHg standing. Cardiac examination is normal. Neurologic findings include somewhat diminished extraocular movements laterally and slightly asymmetric reflexes, with right greater than left. Muscle tone is normal in the lower extremities. He has a mild shuffling gait. Vibratory sensation is diminished but within normal limits for his age. His score on the Folstein MMSE was 22/30, including errors in orientation and recall. His score on the Blessed Dementia Scale was 16/33, with errors in memory and orientation. Psychologic evaluation found him to be mildly depressed.

A full laboratory analysis was generally within normal limits. D.V.’s serum potassium (3.8 mEq/dL) and sodium (138 mEq/dL) were in the low normal range, and his blood urea nitrogen (BUN) (18 mg/dL) was in the upper normal range. Serum total cholesterol was 246 mg/dL, and fasting triglycerides were 230 mg/dL. A chest radiograph revealed a mildly enlarged heart; his ECG was normal. An MRI scan indicated generalized atrophy with enlarged ventricles, periventricular white matter ischemic changes, bilateral basal ganglion lacunar infarcts, and small cortical infarcts in the right parietal lobe. What subjective and objective evidence exists for a diagnosis of dementia in D.V.?

[SI units: BUN, 6.4 mmol/L of urea; total cholesterol, 6.36 mmol/L; triglycerides, 2.60 mmol/L]

D.V.’s major complaint is “fuzzy thinking” and impaired memory that he attributes to his dizzy spell and fall. However, his family began to note problems a full year before that episode, with progression over time. Although D.V. denies that his impairment significantly affects his daily routine, he has voluntarily stopped driving and relies on his daughter for assistance with financial matters. His memory difficulties appear to have affected his mood and made him feel useless. D.V. is disoriented at night when he awakens to urinate. These factors satisfy the DSM-IV criteria for interference with normal activities.²¹

Multiple deficits are present on both the Folstein MMSE²⁴ (orientation, recall) and on the Blessed Dementia Scale²⁵ (memory, orientation), indicating impaired short- and long-term memory. D.V.’s inability to drive reflects poor judgment behind the wheel of a car; a disturbance of higher cortical function is indicated by his need for assistance with financial matters. There is no evidence of a delirium being present. Evidence of an organic cause is provided by the MRI scan.

Diagnosis

11. What type of dementia does D.V. have?

There is sufficient evidence to indicate that D.V. suffers from a VaD. Although DSM-IV provides diagnostic criteria for VaD (Table 100-9), it is not clear that D.V. satisfies the requirements.²¹ VaDs commonly present suddenly after a cerebrovascular insult. This is followed by a period of stability and further declines after additional episodes, in a stepwise pattern. Cognitive impairments are variable and depend on the area of the brain affected by the insult.²¹

With the exception of the dizzy spell and fall, D.V.’s deterioration has had a pattern that resembles a downhill slide rather than stepwise decline. Although his cognitive deficits

Table 100-9 Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Criteria for Vascular Dementia

- The presence of multiple cognitive deficits manifested by both
 - Impaired memory (ability to learn new information or to retrieve information previously learned)
 - At least one of the following:
 - Aphasia* (language difficulties)
 - Apraxia* (diminished ability to perform motor activities in the presence of intact motor function)
 - Agnosia* (inability to recognize or name objects despite intact sensory function)
 - Disruption of executive function* (diminished ability to plan, organize)
- The previous deficits significantly interfere with normal work or social activities and represent a decline from previous ability to function
- Focal neurologic deficits (e.g., hyperactive deep tendon reflexes, gait disturbances, weak extremities) or laboratory evidence indicating cerebrovascular disease (e.g., multiple infarctions of the cortex or white matter) judged to be etiologically linked to the disorder
- The deficits do not occur exclusively during the course of a delirium

Adapted from reference 21.

are “patchy” (e.g., he appears to have no language difficulty), they are not particularly prominent. D.V. displays some neurologic signs and symptoms, including diminished extraocular movements, asymmetric reflexes, and a mild shuffling gait, but they are subtle and might be easily missed by an untrained observer as being related to a dementia. Reliance solely on the clear presence of diagnostic criteria may often lead to a missed diagnosis.¹⁸⁴ The Hachinski Ischemic Scale ranks signs and symptoms associated with cognitive impairment of cerebrovascular origin and is used to help differentiate between AD and MID.¹⁸⁵ According to this scale, D.V.’s nocturnal confusion, depression, hypertension history, and focal neurologic signs and symptoms are sufficient to indicate VaD.

D.V.’s history and clinical presentation do not suggest dementia caused by a single large stroke or several small strokes. Large strokes produce significant motor damage, typically on one side of the body (the side contralateral to the stroke). Multiple smaller strokes cause prominent motor deficits in discrete areas controlled by the affected areas. Neither of these patterns describes D.V.’s condition. However, he is clearly exhibiting signs of dementia and has significant cerebrovascular disease. He possesses several risk factors for a VaD, including hypertension, smoking, and hyperlipidemia. His MRI indicates a lacunar state, with multiple small infarcts in the deep penetrating arterioles at the base of the brain, particularly in the basal ganglia, internal capsule, thalamus, and pons (see Chapter 55). These MRI findings are consistent with D.V.’s long-standing hypertension and neurologic presentation. The absence of a significant gait disturbance and urinary incontinence argues against Binswanger disease.

Because diagnostic criteria for VaDs are vague, arriving at a specific diagnosis is difficult. Therefore, diagnostic criteria (Table 100-10) have been proposed for ischemic VaD, providing a structure for the most common type of these disorders.¹⁶⁵

Table 100-10 Proposed Diagnostic Criteria for Ischemic Vascular Dementia (IVD)

Definite IVD (Requires Histopathological Examination of the Brain)

Clinical evidence of dementia
Pathological confirmation of multiple infarcts, some extracerebellar

Probable IVD

Dementia
Evidence of at least two ischemic strokes by history, neurologic signs, or neuroimaging, or a single stroke with clearly documented temporal relationship to the dementia onset
Supporting evidence of multiple infarcts in regions affecting cognition, history of transient ischemic attacks or vascular risk factors, elevated Hachinski score

Possible IVD

Dementia, plus one or more of the following:

- History or evidence of a single stroke (but not multiple strokes) without clearly documented temporal relationship to dementia onset
- Binswanger disease (without multiple strokes), including all of the following:
 - Early-onset urinary incontinence unexplained by urologic disease, or gait disturbance not explained by peripheral cause
 - Vascular risk factors
 - Extensive white matter change on neuroimaging

Adapted from reference 165.

According to this diagnostic scheme, D.V. suffers from probable ischemic VaD.

Treatment

12. How should D.V. be managed?

Several treatment options that modify risk factors for VaDs are available.

Smoking Cessation

D.V. should be counseled to stop smoking because cigarette smoking reduces cerebral blood flow and increases the risk for stroke.¹⁸⁶ Among smokers with MID, cessation of cigarette use improves cognitive performance.¹⁸⁷

Antihypertensive Therapy

Hypertension and hyperlipidemia, both present in D.V., are additional risk factors for stroke and MID. Control of systolic hypertension reduces the risk of stroke by 36% in elderly patients,¹⁸⁸ and maintaining the systolic BP between 135 and 150 mmHg is associated with improved cognition among MID patients. A systolic BP that exceeds 150 mmHg indicates inadequate control, whereas a systolic BP below 135 mmHg may lead to inadequate cerebral perfusion.¹⁸⁷ As in nondemented individuals, nonpharmacologic treatment (e.g., diet, weight loss, exercise) is an essential component. The antihypertensive agent must be chosen carefully in this population to maximize compliance and minimize adverse reactions.¹⁸⁹ Both thiazide diuretics and β -adrenergic blockers may increase lipid levels, a potential complication in D.V. α -Adrenergic blockers and sympatholytic agents may cause depression or impair cognitive activity. Calcium channel blockers or angiotensin-converting enzyme (ACE) inhibitors are acceptable because they are well tolerated by elderly patients and may help preserve renal function in patients with diabetes mellitus (see Chapter 13). Dihydropyridine calcium channel blockers have been shown to improve cognition in patients with dementia¹⁹⁰ and reduce the risk of dementia in elderly patients with isolated systolic hypertension.¹⁹¹ Because D.V. has benign prostatic hyperplasia, he may benefit from the use of an α -adrenergic blocking agent, such as doxazosin (Cardura) 1 mg at bedtime or terazosin (Hytrin) 1 mg at bedtime (see Chapter 101). Evidence indicating an increased risk for negative cardiac outcomes, however, makes the α -adrenergic blocking agents less attractive choices.¹⁹² The use of a vasodilating calcium channel blocker, such as amlodipine 5 mg/day, is an appropriate first choice. An ACE inhibitor such as benazepril (Lotensin) 10 mg/day is an appropriate alternative. Both agents exhibit the advantage of once-daily dosing over some other agents within their respective classes. This feature is important for maximizing adherence in patients with declining memory.

Antiplatelet Therapy

Prophylaxis against future cerebrovascular events is indicated in MID, but few studies that have looked specifically at individuals with dementia are available. Cerebral perfusion and cognitive performance were improved in MID patients receiving aspirin 325 mg/day for 1 year when compared with a control population.¹⁹³ Aspirin dosages as low as 30 mg/day reduce the

incidence of TIAs and are associated with fewer adverse effects than higher dosages.¹⁹⁴

Other agents that affect the coagulation process include clopidogrel (Plavix), ticlopidine (Ticlid), aspirin/dipyridamole (Aggrenox), and warfarin (Coumadin). None of these agents has been evaluated specifically in people with VaDs. Guidelines from the American College of Chest Physicians recommend the use of antiplatelet therapy in patients with a history of TIA or atherothrombotic stroke that is not of cardiogenic origin. Warfarin is recommended after cardioembolic cerebral ischemic events. According to those guidelines, aspirin 25 mg/dipyridamole extended-release 200 mg twice daily is recommended as the first-line agent.¹⁹⁵

Cholinesterase Inhibitors

Deficits in cholinergic transmission and nicotinic receptor binding abnormalities have been noted in VaD.¹⁹⁶ Early clinical trials with donepezil,¹⁹⁷ galantamine,¹⁹⁸ and rivastigmine¹⁹⁹ have demonstrated improvement in cognition and daily function among patients with VaD. As of yet, however, the use of these agents remains investigational and controversial.

BEHAVIORAL DISTURBANCES IN DEMENTIA

Several types of behavioral disturbances may develop during the course of a dementia, particularly during the later stages (Table 100-11).⁹⁶ The disturbances can be classified into two broad categories: psychologic behavior and nonpsychologic behavior. Psychologic behavior includes agitation and anxiety, depression, withdrawal, psychotic behaviors, and aggression. Agitation and anxiety are often managed best with nonpharmacologic treatment. Pharmacologic interventions are appropriate when nondrug therapies are unsuccessful or the behavior is severe. Nonpsychologic behaviors such as wandering, inappropriate motor activity, shouting, and incontinence respond better to environmental modification than to drug therapy.^{200,201} The first step in evaluating altered behavior in patients with dementia is to ensure that the problem is not the result of an unrecognized medical problem or to an adverse effect of a medication (see Chapter 99).

Agitation

13. T.G., a 62-year-old man, has recently been diagnosed with AD, for which he takes donepezil 10 mg at bedtime. He also has hypertension that is treated with hydrochlorothiazide 12.5 mg daily and amlodipine 5 mg daily. He no longer takes his daily walks around the neighborhood because he is afraid he will get lost; instead, he follows his wife around the house as she does her daily chores. Other times, he paces throughout the house. He also expresses worry about the burden he will place on his family as his condition worsens. Recently, he has had episodes of incontinence and awakens four to five times during the night to urinate. His concerns contribute to his nighttime awakenings, making him quite tired during the day. How should T.G.'s agitation and anxiety be managed?

Agitation and anxiety are common problems in the early stages of dementia. Patients are aware of their progressive cognitive decline and have sufficient insight to understand the consequences. T.G.'s shadowing of his wife and pacing through the house are examples of agitated behavior. T.G. is exhibiting anxiety, as evidenced by his worry about placing a burden on his family. His poor sleep is due both to nocturia and anxiety.

His behaviors should first be addressed with nonpharmacologic treatments. Although T.G. has been taking hydrochlorothiazide without difficulty, he may no longer be recognizing the cues to urinate. The drug should be discontinued; if his blood pressure rises, the amlodipine dose can be increased. Shadowing and pacing are demonstrations of unfocused energy. T.G.'s wife can give him simple tasks to perform, such as drying dishes, folding laundry, or simple gardening, to help channel his energy. She also could accompany him on walks to alleviate his fear of getting lost. Appropriate strategies to manage agitated behaviors without medication are listed in Table 100-12.

When nonpharmacologic interventions are not successful in reducing problem behaviors, medications can be considered. Benzodiazepines are the most commonly used anxiolytics and will address T.G.'s insomnia and anxiety. However, they are associated with several negative outcomes in the elderly, including confusion, amnesic syndromes, ataxia, and falls.²⁰² Long-acting benzodiazepines are generally considered

Table 100-11 Behavior Disturbances in Dementia

| Behavior | Typical Presentation | Treatment |
|----------------------|--|---|
| Anxiety | Excessive worrying, sleep disturbances, rumination | Trazodone Buspirone (if no insomnia) Short-acting benzodiazepine Selective serotonin reuptake inhibitor (SSRI) antidepressant |
| Depression | Withdrawal, loss of appetite, irritability, restlessness, sleep disturbances | Trazodone SSRI antidepressant |
| General agitation | Repeated questions, wandering, pacing | Often unresponsive to medications; redirecting activity may be effective; safety-proofing the residence reduces wandering |
| Psychotic behaviors | Delusions (often of theft), hallucinations, misperceptions | Atypical antipsychotic, if associated with paranoid features SSRI antidepressant, if associated with withdrawal, tearfulness, themes of loss |
| Aggressive behaviors | Physical or verbal aggressiveness toward others, excessive yelling and screaming, manic features | Anticonvulsant, such as divalproex or carbamazepine, possibly in combination with an atypical antipsychotic |

Adapted from references 200, 201, 202, 249, and 212.

Table 100-12 Nonpharmacologic Behavior Management Strategies

| | |
|--------------------|--|
| General strategies | Safety-proof living areas. Issue one-step commands for directions. Maintain a daily routine of activities. Avoid arguing incorrect statements. Avoid startling the patient. |
| Anxiety | Limit unusual or overly stimulating environments. Listen to and acknowledge frustrations. Provide reassurance. Engage the patient in enjoyable activities. Limit noise and distractions. |
| Aggression | Identify the precipitating cause or situation. Focus on the patient's feelings and concerns. Avoid getting angry or upset. Maintain a simple, pleasant, and familiar environment. Employ music, exercise, etc., as a calming activity. Shift the focus to another activity. |

Adapted from references 200, 201, and 250–252.

in up to half of dementia patients.^{206–208} Delusions typically involve suspicion of theft by family members, which may be secondary to the patient's inability to remember where valuable items were placed and incorrectly concluding that they were stolen.²⁰⁷ Another common delusion is the misidentification of people or objects. Capgras syndrome, the belief that a person has been “replaced” by an identical-looking impostor or the belief that photographs or television pictures are real individuals, may occur in almost half of demented individuals.^{207,209,210}

Psychotic symptoms respond best to antipsychotic agents, although these are not highly effective, and no single antipsychotic is more effective than any other. Delusions, hallucinations, aggression, and uncooperativeness symptoms respond best, but overall improvement occurs in only about 18% of patients.^{210,211}

The choice of an antipsychotic agent is determined by the symptoms displayed by the patient as well as the potential for adverse effects. First, it is important to evaluate the target symptoms to determine whether they will respond to pharmacotherapy. Then, an appropriate agent that has a relatively low risk for adverse effects can be chosen.²¹² The atypical antipsychotic agents are better tolerated by older adults than are the conventional neuroleptics (see Chapter 78).^{202,212,213}

T.G. is experiencing a delusion of theft, suspiciousness, and aggressive behavior. It is possible that the verbal abuse and threats are consequences of fear brought on by the false belief that his family is stealing from him and plans to abandon him. The delusions and suspiciousness may respond to the use of an antipsychotic agent, which may then diminish his aggression as well.

T.G. has no major contraindications to the use of any antipsychotic agent, and his target symptoms will probably respond to any of the available agents. Therefore, the choice can be made according to which antipsychotic agent is least likely to cause intolerable adverse effects. Risperidone has been evaluated in a case series and in a large double-blind, placebo-controlled trial.^{214,215} In the case study series, symptoms improved in half of the patients taking dosages ranging from 0.5 mg every other day to 3 mg twice daily. However, 50% also experienced EPS, even at the lowest dosage used.²¹⁴ Subjects in the double-blind trial received either placebo or risperidone at dosages of 0.5 mg/day, 1 mg/day, or 2 mg/day for 12 weeks. Daily doses of 1 or 2 mg reduced psychosis and improved behavior, but extrapyramidal symptoms (EPS) and somnolence were common adverse effects.²¹⁵ Low doses of olanzapine, 5 to 15 mg/day, were superior to placebo for reducing agitation, aggression, and psychosis during a 6-week study among nursing facility residents.²¹⁶ Somnolence and gait disturbances were the most common adverse effects. Quetiapine has been shown to reduce agitated and psychotic behaviors at doses of 100 to 200 mg/day.²¹⁷ Clozapine poses significant toxicity risks and requires careful monitoring.²¹² Significant concerns exist regarding marginal benefit with an increased risk for serious adverse effects, including stroke and mortality among patients with dementia who take either conventional or atypical antipsychotics.^{218–220} Because T.G. does not have cardiovascular or cerebrovascular risk factors and does not have gait or balance problems, either risperidone 0.25 mg HS or quetiapine 25 mg HS can be initiated. Doses of risperidone may be increased by 0.25 mg/day in weekly intervals, up to 2 mg/day; quetiapine doses can be increased by 25 mg/day, up to 200 mg/day

inappropriate for geriatric patients because age-associated accumulation increases the risk of acute toxicity.²⁰³ Benzodiazepines with short half-lives, such as lorazepam (Ativan) or oxazepam (Serax), may be used, if necessary, but only for a short term and with caution.

Trazodone is a sedative antidepressant that is effective for insomnia and agitated behaviors in patients with AD.^{202,204} Treatment is started at 25 mg at bedtime (HS) and may be increased to a dose of 250 mg/day in divided doses. Another alternative treatment is buspirone, which does not cause the cognitive impairments associated with the benzodiazepines. Dosage begins at 5 mg three times daily and may be increased up to 15 mg three times daily. However, buspirone requires 3 to 4 weeks to become fully effective and will not concurrently manage T.G.'s insomnia because it has no sedative effect.²⁰⁵ Citalopram has been shown to reduce agitated behaviors in people with dementia and could be used.²⁰⁵

If the nondrug strategies are ineffective in reducing T.G.'s insomnia and agitation, trazodone should be initiated at a dose of 25 mg HS. It may be increased by 25 mg/day at 5- to 7-day intervals, up to 100 mg. Doses above 100 mg/day should be split into two daily doses.

Psychosis

14. T.G.'s mental status continues to decline to the point that he requires help with bathing and dressing. During a physician visit, he accuses his wife and children of stealing from him. He also cannot locate his coin collection, which he placed in a “safe” location when his memory began to decline; during the night, he rummages through the house looking for it. He believes his family has been plotting to steal his assets and then turn him out onto the street. T.G.'s son reports that T.G. has been verbally abusive and has threatened several members of the family recently. How should T.G.'s psychotic behavior be managed?

Delusions and hallucinations are common among demented individuals. Paranoid ideation or delusions have been reported

in divided doses. Once his behavior has stabilized, the medication should be continued for about 3 months. At that time, the dose should be decreased in weekly intervals to determine whether the medication is still required. T.G. should be monitored closely for adverse effects, including EPS, which can occur with the atypical antipsychotics.^{212,221}

Aggressive Behaviors

15. After 3 months, T.G.'s delusions have subsided, but he continues to be verbally abusive and often displays angry, emotional outbursts, especially when he requires help with bathing or toileting. At other times, he is withdrawn and apathetic. He has also been found wandering in the neighborhood on three occasions. These behaviors persist despite treatment with quetiapine 100 mg twice daily. What alternative treatments can be attempted?

Although psychotic symptoms respond to antipsychotic agents, many other behaviors do not. More than 80% of patients with dementia exhibit at least one disruptive behavior such as angry outbursts, screaming, and abusive language, and more than 50% display multiple aggressive behaviors.^{206,222,223} About 21% display assaultive or violent behavior.²⁰⁶ Such behaviors are typically directed at caregivers, precipitated by receipt of assistance with activities of daily living such as bathing and toileting, and increase in frequency with dementia severity.^{206,222,224} Several of these behaviors may be merely defensive responses to perceived threats in cognitively impaired individuals.²²⁴ Behavioral disturbances must be addressed because they can have a negative effect on the patient's ability to perform activities of daily living.²²⁵

Some behaviors exhibited by T.G. are not likely to respond to medications. Wandering is typically unaltered by the use of medications unless the patient is oversedated. Nonpharmacologic treatments, such as periods of physical exercise and rest, or environmental modification are much more effective.^{201,226} T.G.'s reactions to assistance with bathing and toileting may be caused by confusion and fear. Breaking the tasks down to step-by-step procedures, accomplished individually, often helps modify aggressive behaviors.²²⁶

Verbal abuse and aggressiveness place both the patient and the caregiver at risk for injury. Anticonvulsant agents have been shown to reduce rage and aggressive behaviors in patients resistant to treatment with antipsychotics.²²⁷ Carbamazepine and valproic acid (including divalproex) are the most well-studied agents.^{228,229} Carbamazepine (Tegretol) 200 to 1,000 mg/day, titrated to a serum level of 5 to 8 mcg/mL, reduces severe agitation in dementia patients.^{228–230} Significant adverse effects include dizziness, drowsiness, ataxia, and agranulocytosis. Patients should be monitored for CNS effects (e.g., increased confusion, daytime drowsiness) and require baseline and periodic CBCs with differentials. Carbamazepine also induces hepatic microsomal enzymes, causing more rapid metabolism of several drugs.

Valproic acid and divalproex, alone and in combination with an antipsychotic, are also effective in managing acute aggressive behaviors.^{231–233} Common adverse effects are nausea, vomiting, and dizziness. They do not produce blood dyscrasias and are subject to fewer drug interactions than carbamazepine.²⁰¹ This makes these agents a better choice for the treatment of T.G.'s symptoms, and they may be added to his

quetiapine treatment unless his symptoms are determined to be caused by depression (see the following). The initial dosage of divalproex should be 125 mg/day; it may be increased by 125 mg/day every 3 to 6 days until the behavior improves or until a maximum therapeutic serum level is reached.²²⁷ When his behavior has stabilized, the quetiapine dose should be reduced, and if T.G.'s psychotic symptoms do not recur, the drug may be discontinued. Likewise, divalproex treatment should be re-evaluated after 2 to 3 months.

Depression

16. How should T.G.'s social withdrawal and apathy be treated?

Depression often accompanies dementia and may significantly impair a patient's functional capacity, cognitive abilities, and communication.^{234,235} T.G. is withdrawn and apathetic, symptoms suggestive of depression. Screaming and irritability are also believed to be a symptom of depression in individuals with dementia, perhaps reflecting feelings of loneliness, boredom, or the need for attention.^{222,236} Because a definite diagnosis of depression relies heavily on a patient interview and response to questions, a formal diagnosis in patients with dementia is difficult, if not impossible. Therefore, one must rely on patient observation to make a clinical evaluation.

The selective serotonin reuptake inhibitors have not been well studied in patients with dementia, but are effective antidepressants with adverse effects that are better tolerated than those of the tricyclic antidepressants. Sertraline, in doses of 50 to 150 mg/day, was superior to placebo in reducing depression in AD patients during a 12-week trial.²³⁷ Citalopram has also demonstrated effectiveness in small trials; in contrast, fluoxetine and fluvoxamine have not demonstrated benefit.²⁰²

Trazodone (Desyrel) reduces disruptive and aggressive behaviors in cognitively impaired patients and thus is a reasonable choice for treatment of depression in T.G.^{201,238,239} This drug is sedating, may help with sleep disorders, and is free of anticholinergic effects. It does, however, possess α -adrenergic blocking activity, which may cause orthostasis. If it is determined that T.G. is depressed, trazodone may be initiated at 50 mg HS and increased to 100 mg HS after several days. If necessary, dosages for T.G. can be increased by 50 mg/day every 5 to 7 days. If further dosage increases are needed, the total daily dose should be divided into two or three doses up to a maximum daily dose of 300 mg.²⁰¹ The trazodone should induce a restful sleep at night, increase T.G.'s sociability, and decrease his abusive behaviors. If he does not respond to trazodone, either sertraline 50 mg/day or citalopram 10 mg/day may be tried. Dosages may be increased weekly up to a maximum of 150 mg/day or 40 mg/day, respectively.

Social Support

17. T.G.'s family indicates that caring for him at home has become so burdensome that they are considering placing him in an institution. What social support services are available to families facing this decision?

Institutionalization is a typical outcome for patients in the late stages of dementia. The total care required to manage a dementia patient usually becomes unmanageable for most

families as the disease progresses. Caregiver stress is often exacerbated by the patient's declining memory, inability to communicate, physical decline, and incontinence, as well as the caregiver's loss of freedom and depression.²⁴⁰ Caregivers commonly experience anger, helplessness, guilt, and worry, and suffer from physical stressors such as fatigue and illness.²²⁶

Outside assistance is essential to families caring for a patient with dementia. Families should be referred to the Alzheimer's Association as soon as a diagnosis of dementia is received. The association has local affiliates in most major cities. The book *The 36-Hour Day* is a valuable resource for families as well.²²⁶ It describes the symptoms, behaviors, and problems that can be encountered when caring for a patient with dementia.

Support groups, individual and family counseling, and other sources of support are useful and may help families cope for a longer period.²⁴¹ However, the key intervention to reduce caregiver stress is respite care, which allows a family time away from the responsibilities of taking care of a frail individual.²⁴² Respite care brings a person into the home or allows the patient to go to a day care center or similar environment on a regular schedule. Such programs may delay the need to institutionalize a patient.

PSEUDODEMENTIA

Clinical Presentation and Diagnosis

18. G.Y., an 86-year-old woman, lives alone in a low-income housing unit. Over the past 6 weeks, she has become disoriented and confused. A neighbor brought her to the hospital after finding her wandering through the neighborhood in her nightclothes. She eats only one meal a day—a frozen pot pie—because she generally forgets to eat her other meals. Several bills remain unpaid. She has difficulty sleeping and expresses little desire to live because “all my friends are gone.” Her score on the Folstein MMSE is 18/30 with multiple deficits. Most errors are attributable to answers of “I don't know” or “I can't.” She currently takes propranolol 40 mg three times daily for high BP, cimetidine 400 mg twice daily for gastroesophageal reflux disease, and temazepam 15 mg HS PRN for insomnia. What subjective and objective data support a diagnosis of pseudodementia in G.Y.?

Depression

G.Y. clearly exhibits cognitive impairment as evidenced by her symptoms of confusion and disorientation, forgetting to eat, wandering, and a low score on the Folstein MMSE.²⁴ However, the rapid course of her decline, her lack of effort on mental status testing, and the medications she is taking suggest that her impairment might be secondary to causes other than true dementia.²⁴³

Depression is the most common cause of pseudodementia, accounting for at least 50% of cases. Depressive symptoms in G.Y. include self-neglect, insomnia, loss of desire to live, and lack of effort on mental status testing. When given a mental status screening test, depressed patients tend to give “I don't know” answers, which reflect dysphoria or an inability to cooperate, whereas demented patients typically provide incorrect answers.²⁴³

Medications

Medications are often responsible for cognitive impairment in older adults, accounting for dementia symptoms in approximately 12% of patients with cognitive impairment. Psychotropic medications, analgesics, antihypertensives, corticosteroids, and cimetidine are often implicated (see Chapter 79).^{23,203,244}

Treatment

19. What is the proper treatment for G.Y.'s pseudodementia?

Initial therapy should consist of the discontinuation of her medications, all of which may be contributing to her cognitive decline. Because the medications are relatively short acting, her mental status should improve significantly within 48 hours. At that time, her hypertension and gastroesophageal reflux disease can be re-evaluated and more appropriate therapy instituted, if warranted.

G.Y. should be evaluated for depression, and psychotherapy should be initiated if she is in fact depressed. She should also be referred to a social services agency or senior center to provide her with assistance and to offer her opportunities for social interaction.

SEXUAL DYSFUNCTION

Sexual dysfunction has been described as a public health concern by a National Institutes of Health Consensus Panel.^{1,2} Sexual dysfunctions are highly prevalent in both sexes, ranging from 10% to 52% in men and from 25% to 63% in women.^{3,4} In addition, advancing age is accompanied by a decrease in sexual function. Intercourse decreases from an average of once a week at the age of 65 to once every 10 weeks at the age of 80.⁵ The frequency of sexual intercourse among the elderly actually has increased over the past 40 years, but still is substantially less than in younger individuals.^{5–8} Although individual variations in frequency are large, most studies show that sexual activity among the elderly depends on the life pattern and past experiences of good or poor sexual function in each patient. Elderly patients may experience physiologic changes and encounter additional interference with sexual activity because of

disability, disease, and medications. Furthermore, interest in sexual activity declines with aging.⁹

Poor health often is cited by elderly women as a reason for not participating in sexual activity, and among men, erectile dysfunction is the leading cause of decline in activity.^{5,10} The major factors that correlate with reduced sexual activity include an older spouse, poor mental or physical health, marital difficulties, previous negative sexual experiences, and negative attitudes toward sexuality in the aged.¹¹ During the postmenopausal years, women undergo substantial physiologic change. The major physiologic event of natural menopause is a decrease in estrogen production. Little doubt exists that a decline in estrogen production is associated with many of the physiologic changes causing elderly women to report a low interest in sexual activity. The medical literature is replete with research and data on elderly male sexual dysfunction, but little, if any, data exist on female sexual dysfunction.

Male Sexual Dysfunction

Aging men may experience andropause, a syndrome consisting of weakness, fatigue, reduced muscle and bone mass, impaired hematopoiesis, oligospermia, sexual dysfunction, and psychiatric symptoms.¹² The relationship between declining testosterone and andropause is not firmly established. Free testosterone levels begin to decline at the rate of 1% per year after age 40 years. By the age of 60 years, 20% of men have levels below the lower limit of normal.¹³ The physiologic and psychological effects of declining hormone levels in men are less dramatic than those experienced by women.

Sexual function is considered an interaction among motivation, drive, desires, thoughts, fantasies, pleasures, experiences (referred to as the *libido*), penile vasocongestion, erection, orgasmic contractions, and ejaculations (referred to as *potency*).^{14,15} Testosterone plays an important role in male libido and sexual behavior, and may play some role in penile erection. Elderly men show a strong correlation between advancing age and diminishing bioavailable serum testosterone levels.^{16,17} Testosterone progressively declines after the seventh decade, partly because of testicular and hypothalamic-pituitary dysfunction.¹⁸

Male sexual dysfunction, denoting the inability to achieve a satisfactory sexual relationship, may involve inadequacy of erection or problems with emission, ejaculation, or orgasm. *Erectile dysfunction* is the inability to achieve and maintain a firm erection sufficient for satisfactory sexual performance.¹⁹ *Premature ejaculation* refers to uncontrolled ejaculation before or shortly after entering the vagina. *Retarded ejaculation* usually is synonymous with delayed ejaculation. *Retrograde ejaculation* denotes backflow of semen into the bladder during ejaculation caused by an incompetent bladder neck mechanism.

The neurologic structures in the brain most closely associated with sexual function and arousal are the limbic system and the hypothalamus. The psychogenic sexual arousal mechanism involving sensory organs (e.g., vision, auditory, olfactory, tactile) and imaginative stimuli participate in sexual function through the hypothalamus and limbic systems. Subsequent nerve transmission down the spinal cord to the autonomic nervous system and sacral and thoracolumbar centers mediates the penile erection. Furthermore, the reflexogenic mechanism of penile erection (stimulation of the genital area) also involves nerve transmission by the pudendal nerve to the sacral erection center. Neurotransmission in the peripheral nervous system is mediated by adrenergic and cholinergic stimulation and may be diminished in advanced age.²⁰ Neurochemical mediators also are involved with sexual function. For example, dopamine is associated with sexual arousal (stimulation), whereas serotonin has an inhibitory effect.^{21,22} In the elderly, reduced onset of sexual arousal may be attributed to global cerebrovascular disease and diminished sensory input to the central nervous system (CNS). Peripheral mechanisms of sexual arousal also may be affected by aging.

Erectile dysfunction (ED), once regarded as a psychosocial disorder, today is regarded as caused by a variety of medical, psychological, and lifestyle factors. According to data from the Massachusetts Male Aging Study (MMAS), the combined prevalence of minimal, moderate, and complete erectile dysfunction among all elderly men is 52%.^{23,24} According to the

Baltimore Longitudinal Study of Aging, ED was a problem in 8% of all healthy men by age 55, and its prevalence increased to 25%, 55%, and 75% for men 65, 75, and 80 years of age, respectively.²⁵ Erectile dysfunction is estimated to affect as many as 30 million men in the United States. Of males aged 45 years or older in the United States, 5% seek prescription drug therapy for ED, on an annual basis.²⁶

Approximately 80% of all cases of ED now are thought to be related to organic disease and subject to numerous influences.^{14,27–29} In one study,¹⁷ neurologic and vascular disorders were the primary causes of ED among elderly men, and psychogenic factors were the cause in <10%. The single most common etiology for erectile failure in the elderly is severe atherosclerosis (e.g., vascular disease and diabetes mellitus).¹⁷ Cardiovascular disease, hypertension, diabetes mellitus, elevated low-density lipoprotein cholesterol, and cigarette smoking are associated with a greater probability of complete erectile dysfunction in men.²³ Therefore, prevention of cardiovascular disorders by interventions such as low-fat and low-cholesterol diets and abstinence from tobacco should minimize the development of geriatric sexual erectile dysfunction.

Different physiologic mechanisms are involved in erection, emission, ejaculation, and orgasm. Except for nocturnal emissions, ejaculation requires stimulation of the external genitalia. Ejaculation occurs in three phases. The first phase is termed *emission*. Efferent signals traveling in the hypogastric nerve activate secretions and transport sperm from the distal epididymis, vas deferens, seminal vesicles, and prostate to the prostatic urethra (Fig. 101-1). The second phase is the coordinated closing of the internal urethral sphincter and the relaxation of the external sphincter to direct the semen into the bulbous urethra. The coordinated closing of the internal sphincter and relaxation of the external sphincter is mediated by α - and β -adrenergic stimulation. The third phase, *external ejaculation*,

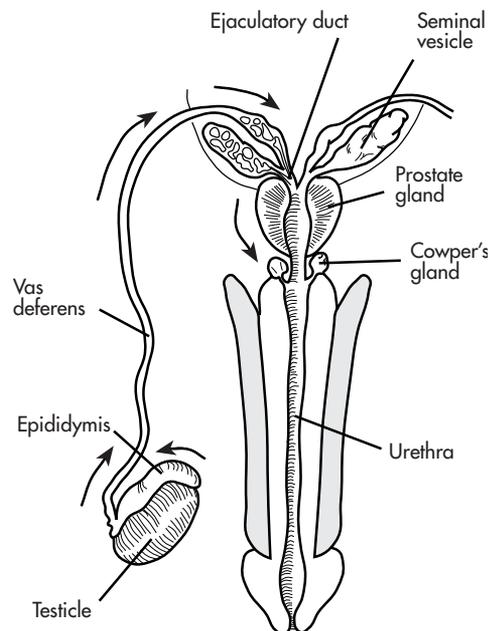

FIGURE 101-1 A diagram showing the sources and direction of seminal flow. (From reference 321, with permission.)

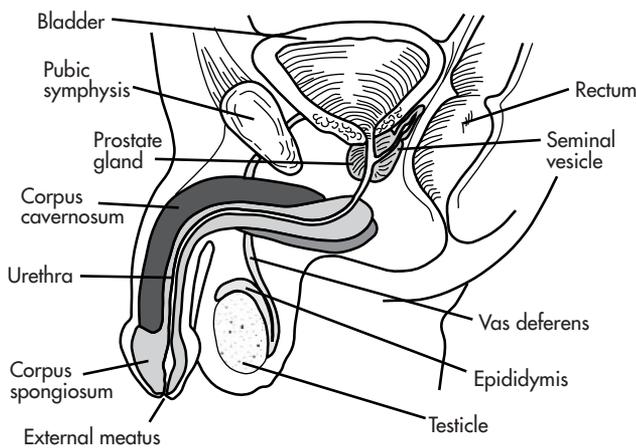

FIGURE 101-2 A diagram showing the relations of the bladder, prostate, seminal vesicles, penis, urethra, and scrotal contents. (From reference 321, with permission.)

involves the somatomotor efferent segment of the pudendal nerve to contract the bulbocavernosus muscle, which forces the semen through a pressurized conduit, the much-narrowed urethral lumen compressed by the engorged corpora cavernosa and corpus spongiosum (Fig. 101-2), to produce 2 to 5 mL of ejaculate.²⁸ In the elderly male, ejaculation is less vigorous and the total ejaculate is likely to be reduced.³⁰

The hemodynamics of penile erection involve the pudendal artery (the major blood supply to the penis), of which the terminal portion divides into three branches: (a) the bulbourethral artery, (b) the dorsal artery, and (c) the cavernous artery. The cavernous artery supplies the corpora cavernosa; the dorsal artery, the glans penis; and the bulbourethral artery, the corpus spongiosum. The corpora cavernosa and the corpus spongiosum (also referred to as *corporal smooth muscle*) are the erectile muscle tissues, which appear to be under β -adrenergic control.^{14,28} Thoracolumbar or sacral erection-center stimulation shunts the blood to these structures and an erection ensues. The sympathetic nervous system also is involved in the constriction of veins in the erectile tissue that diminishes venous outflow. The resultant high intracavernous (IC) pressure converts a soft, flaccid organ to a blood-distended erect penis. Distention of the erectile tissue further results in compression of the venules, reducing the venous capacity to minimum, which allows full erection of the penis. These actions maintain erection in the corpora cavernosa without diverting too much cardiac output for penile erection.³¹

The biochemical basis of erection is simply an extension of the neuronal physiologic mechanisms. The erectile system involves neural initiation, cellular translation, and vascular transduction. Central initiation of an erection involves erectogenic stimuli (tactile), erotic imagery at the cerebral cortex, or both. The nuclei that integrate erectile signaling are highly specific.³² The medial preoptic area (MPOA) of the hypothalamus may be the integration for the central control of erection. It receives sensory impulses from the amygdala that have inputs from cortical association areas.³³ The signals generated follow the spinal pathways and create an erection through receptor interaction and cellular mechanisms in the vasculature in the periphery. As a result of erectogenic or erotic activity, dopamine,

acting via the D_2 -receptor, is the initiating neurotransmitter. Inhibitory stimuli such as anxiety can dampen the response of the dopaminergic system.

The cellular mechanisms that control the vascular response necessary for penile erection are similar to equivalent mechanisms elsewhere in the vasculature. Cellular mechanisms are designed to induce vascular relaxation and thus cause an erection. Essentially, two cellular factors are believed to induce vascular relaxation. The first factor, prostaglandin E_1 , is released at the local level as a result of the spinal pathway message; it causes adenylyl cyclase to accelerate the production of cyclic adenosine monophosphate (cAMP) and results in intracellular release of potassium, a known vasodilator. A second factor involves the release of nitric oxide from local neuronal tissue. Nitric oxide is the main neurotransmitter mediating erection. Once called endothelium-derived relaxing factor, nitric oxide has been shown to induce relaxation of vascular smooth muscle.⁶ Nitric oxide induces the formation of cyclic guanosine monophosphate (cGMP) in the vascular system; cGMP is postulated to activate protein G, leading to the phosphorylation of proteins regulating corporal smooth muscle through ion channel changes.³⁴ This results in the opening of potassium channels and hyperpolarization of the muscle cell membrane, sequestration of intracellular calcium by the endoplasmic reticulum, and blocking of calcium influx by calcium channel inhibition.³⁵ Nitric oxide is released by endothelial cells and efferent neuronal cells in response to erectogenic stimuli.

The major arteries needed for an erection are the feeder pelvic vessels and the penile vessels themselves. In all of these components, multiple competing systems exist in a state of balance. The final vascular consequence of these actions depends on the intracellular response and the interaction of the vascular wall complex (smooth muscle, endothelium, nerves plus the effects of stromal and luminal blood pressure). The vascular wall complex is the interplay of vasodilators (prostaglandin E_1 , nitric oxide, potassium), the inhibition of the vasoconstrictor mechanisms, and the resultant relaxation of the vascular wall.³⁶

The process of orgasm is the least understood sexual process. Simultaneous with emission and ejaculation are involuntary rhythmic contractions of the anal sphincter, hyperventilation, tachycardia, and blood pressure elevation. Because erectile dysfunction is more likely in male patients with coronary artery disease, the understanding of the cardiovascular stresses involved with sexual intercourse can aid in patient management. Cardiac and metabolic expenditures during sexual intercourse vary depending on the type of sexual activity. Healthy males with their usual female partners generally achieve a peak heart rate of 110 beats/minute with woman-on-top coitus and an average peak heart rate of 127 beats/minute with man-on-top coitus.³⁷ There is significant individual variation in cardiovascular response, when measured as oxygen uptake and metabolic expenditures, for male-on-top coitus.

In a study of medication-free patients with coronary artery disease who were in the New York Heart Association functional class I or II, sexual activity was compared with near-maximal exercise treadmill test.³⁸ Electrocardiographic changes representing ischemia during intercourse were found in one-third of the patients; however, two-thirds of these patients remained asymptomatic. All patients with ischemia during coitus also demonstrated ischemia during exercise treadmill testing. The

average heart rate during coitus was 118 beats/minute, with some patients attaining a heart rate of 185 beats/minute at orgasm. Intercourse in patients with coronary artery disease may provoke increased ventricular ectopic activity that is not necessarily elicited by other stimuli.³⁹ These electrocardiographic changes and associated symptoms can be abolished with the use of β -blockers.⁴⁰ Sexual activity is a likely contributor to the onset of myocardial infarction only 0.9% of the time.⁴¹ Coital death is rare, accounting for 0.6% of sudden death cases.⁴² The hemodynamic changes associated with sexual activity may be far greater with an unfamiliar partner, in unfamiliar settings, and after excessive eating and alcohol consumption.

Erectile Dysfunction

Pathogenesis

Erection involves the neurologic, psychological, hormonal, arterial, and venous systems. In a study of 1,500 elderly men over a period of 10 years, organic erectile dysfunction was diagnosed in >1,050 subjects.⁴³ As a result of research in vascular physiology, neurophysiology, and neuropharmacology of the penis, most urologists today believe that up to 80% of elderly erectile dysfunction cases are organic in origin and that the remainder are owing to psychological factors⁴⁴ (Table 101-1). In most elderly male sexual dysfunction studies, 50% involve vascular problems, and 30% relate to diabetes mellitus.⁴⁵

NEUROGENIC DISORDERS

Erectile dysfunction can be caused by damage to the brain, spinal cord, cavernous or pudendal nerves, terminal nerve endings, and the receptors. Neurogenic erectile dysfunction can be caused by diabetes, spinal cord injury, cauda equina lesions, polyneuropathy, myelopathy, multiple sclerosis, dorsal nerve dysfunction from alcohol abuse or parkinsonism, and radical pelvic surgery.⁴⁴ Erectile dysfunction was the presenting symptom in 12% of males with unrecognized diabetes mellitus.⁴⁶ Similarly, erectile dysfunction can be the presenting symptom of temporal lobe epilepsy.⁴⁷

Approximately 95% of patients with upper motor neuron lesions resulting from spinal injury are capable of erection

through the reflexogenic mechanism,⁴⁸ whereas only 25% of patients with complete lower motor neuron lesions can have erections through the psychogenic mechanism.⁴⁸ With incomplete lesions, up to 90% of patients in both groups retain erectile ability. Patients who have a cerebrovascular accident, dementia, epilepsy, Parkinson disease, or a brain tumor most likely experience erectile failure through loss of sexual interest or overinhibition of the spinal erection centers.⁴⁴

HORMONAL DISORDERS

The incidence of erectile dysfunction with a hormonal cause has been estimated to be 5% to 35%, depending on which medical specialty is reporting the finding.⁴⁹ The most common hormonal disorder associated with ED in the elderly is diabetes mellitus. Approximately 75% of elderly male diabetics experience ED owing to a combination of vascular, neurologic, and psychological factors.⁵⁰ Insulin dosage, duration, and glycemic control are unrelated to sexual dysfunction.

Other hormonal disorders, such as hypothyroidism, hyperthyroidism, Addison's disease, and Cushing's syndrome, are associated with erectile dysfunction. Patients with hypogonadism due to pituitary or hypothalamic tumors, antiandrogen therapy, or orchiectomy experience ED. These patients can have a normal erection from visual stimulation, however, indicating that the erectile mechanism is intact.⁵¹

VASCULAR DISORDERS

Atherosclerosis is the leading vascular disease associated with male erectile dysfunction. The age of onset of coronary artery disease parallels the onset of ED, indicating a generalized atherosclerotic etiology for the erectile dysfunction.⁵² The degree of arteriolar narrowing and clinical presentation, however differ from patient to patient. Some patients can have severe coronary artery disease but retain the capability of a full erection. As long as the arterial flow into the penis exceeds the venous outflow, the patient can be potent. Narrowing of the arterial lumen lowers pressure in the cavernous arteries, and poor arterial flow can only partially fill the sinusoidal system. Overall, the partial filling of the sinusoidal system causes inadequate expansion of the sinusoidal wall, resulting in partial compression of the venules. The net effect is a partial erection, difficulty in maintaining an erection, or the most common complaint, early detumescence. Intrapenile arterial disease resulting from diabetes mellitus, atherosclerosis, or aging does not respond to present surgical techniques.

Signs and Symptoms

1. F.M., a 66-year-old man, was referred to a urologist because he was experiencing a loss of interest in sexual activity. He describes the inability to maintain a firm erection for the past 6 months in >75% of sexual attempts with his sexual partner. Physical examination was unremarkable except for an enlarged prostate gland and evidence of pubic and axillary hair loss. Vital signs were as follows: blood pressure (BP), 160/95 mmHg; pulse, 88 beats/minute; respirations, 14 breaths/minute; and temperature, 98.7°F. Current medications include ramipril 5 mg/day and glyburide 5 mg/day. F.M.'s medical history is positive for cigarette smoking, hypertension, and diabetes mellitus. Significant laboratory results include the following: random blood sugar, 200 mg/dL (normal, 70–110); serum creatinine (SrCr), 1.5 mg/dL (normal, 0.6–1.2); blood urea nitrogen (BUN), 22 mg/dL (normal, 8–18);

Table 101-1 Causes of Erectile Dysfunction

| Vascular | Iatrogenic |
|-----------------------------|-----------------------|
| Atherosclerosis | Pelvic radiation |
| Penile Raynaud's phenomenon | Lumbar sympathectomy |

free testosterone level, 30 pg/mL (normal, 52–280); luteinizing hormone (LH), 4 mU/mL (normal, 1–8); follicle-stimulating hormone (FSH) level, 40 mIU/mL (normal, 4–25); and serum prolactin level, 28 ng/mL (normal, <20). What signs and symptoms does F.M. have that would suggest the need for a complete medical workup for erectile dysfunction?

[SI units: glucose, 11.1 mmol/L (normal, 3.9–6.1); SrCr, 132.6 μ mol/L (normal, 50–110); BUN, 7.9 mmol/L urea (normal, 3.0–6.5); LH, 4 IU/L (normal, 1–8); FSH, 40 IU/L (normal, 4–25); serum prolactin, 28 mg/L (normal, <20)]

F.M. presents with the complaint of loss of interest in sexual activity and the inability to maintain a full erection during >75% of sexual encounters with his partner. On physical examination, F.M. is found to have a noticeable loss of pubic and axillary body hair. With longstanding androgen deficiency, there may be loss of hair in the androgen-dependent areas of the body, fine wrinkling of the skin around the mouth and eyes, noticeable loss of muscle mass and strength, altered body-fat distribution, and osteoporosis. In contrast, overt hypogonadism results in a change in the pattern of pubic hair from the male diamond shape to the female inverted triangle appearance. At this point, it appears that F.M.'s loss of pubic and axillary hair is the result of androgen deficiency, with the cause yet to be determined. The laboratory results for gonadal function coincide with what is expected in an elderly male with erectile dysfunction (see Question 4).

Urologic Workup

2. What clinical evaluations and laboratory tests should be included in the medical workup of F.M. to determine the cause of his erectile dysfunction?

A detailed medical and sexual history and thorough physical examination are essential in the evaluation of sexual dysfunction. General medical history and physical examination should consider drug-induced erectile dysfunction (Table 101-2); cigarette smoking (cigar and pipe tobacco have not been associated with sexual dysfunction); prior surgery (e.g., transurethral resection of prostate [TURP], aortoiliac bypass, prostatectomy); prior physical trauma (e.g., herniated disc, testicular trauma); voiding dysfunction; visual field defects (visual field changes may be one of the first presenting symptoms of diabetes mellitus, the most common endocrine abnormality associated with male sexual dysfunction and may be associated with pituitary tumor pressure on the optic nerve); femoral artery bruits; testicular atrophy; Peyronie's plaques (a fibrous palpable plaque along the shaft of the penis, causing penile curvature and poor erection distal to the plaque, thought to be caused by atherosclerosis or severe vasculitis); pedal pulses; and neurologic examination. Hormonal and metabolic screening should be included with the history and physical examination.

Although laboratory-based diagnostic procedures are available, it is proposed that sexual function is best assessed in a naturalistic setting with patient self-report techniques. One such self-reporting tool, the International Index of Erectile Function (IIEF), has been demonstrated to address the relevant domains of male sexual function (erectile function, orgasmic function, sexual desire, intercourse satisfaction, and overall satisfaction),

is psychometrically sound, and has been linguistically validated in 10 languages.⁵³

F.M.'s endocrine status should include assessment of his diabetes, thyroid function tests, and a serum lipid profile. Neuropathy and atherosclerosis are common findings among male patients with diabetes mellitus, and both are potential causes of ED. Patients experiencing hypothyroidism may have decreased libido, and hypothyroidism is associated with hyperprolactinemia, which can result in an inhibition in the release of testosterone. Elevated serum lipids (e.g., total cholesterol, triglycerides) may be associated with significant vascular damage that could contribute to erectile dysfunction. Diabetes mellitus is best evaluated with a hemoglobin-A_{1c} and a fasting blood glucose tests.⁵⁴

The serum concentrations of free testosterone, prolactin, and LH should be evaluated. Testosterone, as with all other hormones secreted into the plasma, is available to tissues only in the free form (i.e., unbound to serum proteins, particularly the sex hormone-binding globulin). Only 1% to 2% of testosterone is free and physiologically active; therefore, measurement of the unbound serum testosterone provides the best estimate of biologically available testosterone. Low testosterone serum concentrations are associated with primary and secondary hypogonadism. Primary hypogonadism is associated with testicular disease (e.g., Leydig cell tumors), whereas secondary hypogonadism is the result of pituitary or hypothalamic disease.

The serum prolactin concentration should be determined, because a high serum concentration of prolactin inhibits release of testosterone from the testes. Therefore, a low serum testosterone concentration may be caused by hyperprolactinemia. Hyperprolactinemia may be caused by prolactin adenomas, diabetes mellitus, or drug therapy (e.g., neuroleptics, metoclopramide).

LH stimulates testicular steroidogenesis and secretion of testosterone. LH increases the conversion of cholesterol to pregnenolone, a precursor of testosterone. FSH is required for spermatogenesis in early puberty, but is not a required gonadotropin for the maintenance of spermatogenesis in adult men. Normal testicular function depends on stimulation by the gonadotropin LH, which is secreted by the anterior pituitary gland. Consequently, a low normal serum concentration of LH is associated with secondary hypogonadism.

In patients with symptoms of prostatic disease, expressed prostatic secretions (EPS) should be examined because prostate inflammation has been associated with ejaculatory dysfunction. During prostatic inflammation, the EPS contains leukocytes and macrophages, and microscopic examination of the EPS can determine the degree of prostate inflammation. The presence of >20 white blood cells (WBC) per high-powered field (HPF) in the EPS is abnormal, and indicative of prostatitis. Only about 5% of prostatitis can be attributed to a bacterial infection; the remaining 95% is owing to unknown etiologies.

Ideally, assessment of erectile dysfunction should include urologic, endocrinologic, psychiatric, and neurologic evaluations as close together as possible. The chief complaint of ED must be identified carefully and described, because medical intervention is indicated if it occurs over a 6-month period and in >50% of attempts.²⁸ A detailed history should determine whether ED varies with partners, sexual settings, position, and

Table 101-2 Common Drug-Induced Alterations in Sexual Response

| <i>Drug Categories</i> | <i>Clinical Considerations</i> |
|---|--|
| Antihypertensives | |
| Diuretic Thiazides | Temporal association with sexual dysfunction. Reported incidence varies between 0 and 32% ^{307–311} ; however, impotence generally is not considered common. Mechanism believed to be a “steal syndrome” whereby blood is routed from erectile tissues to skeletal muscle. ⁸⁹ |
| Spironolactone | Associated with ↓ libido, impotence, and gynecomastia. Mechanism may be hormone related. Incidence is dose related and reported to be 5%–67% ^{89,312,313} and much more commonly encountered than with the thiazides. May be owing to antiandrogen effects of drug. |
| Sympatholytics | |
| Methyldopa Clonidine | Central action mediated causing vasodilation resulting in erectile dysfunction. Reported incidence: 10%. ^{89,92} Also ↓ libido. Induces erectile dysfunction. Mechanism similar to methyldopa and other central α_2 -agonists. Incidence reported to be 4%–70% and dose related. ^{314–316} Also ↓ libido. |
| Guanabenz, guanfacine | Incidence and mechanism believed to be similar to other central α_2 -agonists. |
| Nonselective β-Blockers | |
| Propranolol | Associated with erectile dysfunction and ↓ libido. Mechanism believed to be caused by ↓ vascular resistance and central effects. Erectile dysfunction reported to begin at doses of 120 mg/day. Incidence may be as high as 100% at higher dosages. ^{86,92,317} |
| Selective β-Blockers | |
| Atenolol, metoprolol, pindolol, timolol (drops) | Incidence of erectile dysfunction is significantly less than nonselective β -blockers. ³¹⁸ |
| α-Blockers | |
| Doxazosin, prazosin, terazosin | Associated with erectile dysfunction and priapism. ^{92,315} Reported incidence: 0.6%–4%. ³²⁰ Mechanism is local α_1 -blockade resulting in vasodilation. Erectile dysfunction and priapism appears to be unique to the nonspecific α_1 -antagonists. |
| Phenoxybenzamine | Associated with priapism, retrograde ejaculation, and inhibited emissions during erection. Effects are dose related. ^{321,322} |
| Direct Vasodilators | |
| Hydralazine | Associated with erectile dysfunction. Mechanism is vascular smooth muscle relaxation. Incidence not reported. ³²¹ |
| Calcium Channel Blockers | |
| Nifedipine | Associated with erectile dysfunction. Mechanism believed to be vasodilation and possibly muscle relaxation. Reported incidence: <2%. ⁷⁹ |
| Diltiazem, verapamil | Similar to nifedipine. Reported incidence: <1%. |
| Antiarrhythmics | |
| Class 1A Disopyramide | Associated with erectile dysfunction in patients treated for ventricular arrhythmias. Incidence not reported. Mechanism believed to be caused by strong anticholinergic effect. ^{89,321} |
| Anticonvulsants | |
| Carbamazepine, phenytoin | May be associated with sexual dysfunction through decreasing DHEA, which is a precursor to testosterone, estrogen, and pheromones. ²⁶⁷ |
| Antidepressants | |
| Selective serotonin reuptake inhibitors | Drugs with prominent serotonin agonist effects commonly cause delayed ejaculation and anorgasmia. The reported incidence for delayed ejaculation among men is 2% to 12%; for anorgasmia among women users, the incidence appears to be <3%. This adverse effect is directly dose related. ²⁶⁷ |
| Tricyclic antidepressants (TCA), monoamine oxidase inhibitors | Associated with impairment of sexual performance in both male and female: ↓ libido, anorgasmia, retrograde ejaculation, erectile dysfunction. Mechanism believed to be caused by anticholinergic and serotonergic effects. Incidence not reported; several case studies in the literature. ²⁰ |
| Trazodone | Associated with priapism in men and ↑ libido in women. Mechanism similar to TCA. Incidence not reported but believed to be dose related. ²⁰ (Note: The literature reports that overall there is less sexual dysfunction with desipramine than with other antidepressants.) |
| Antipsychotics | |
| Phenothiazines | Frequently associated with sexual dysfunction. Commonly, ↓ libido is reported. Mechanism is due to hyperprolactinemia secondary to central dopamine antagonism. Thioridazine is the most often reported offender. Erectile and ejaculatory pain are very common with this drug class; the α -antagonism and anticholinergic effects are responsible. Priapism is common with this drug group, owing to the peripheral α -blockade property. Incidence for all sexual dysfunction with this drug class: approximately 50% of users. ²⁰ |

Table 101-2 Common Drug-Induced Alterations in Sexual Response (Continued)

| <i>Drug Categories</i> | <i>Clinical Considerations</i> |
|----------------------------|---|
| Anxiolytics | |
| Short-acting barbiturates | Biphasic effect. At low doses, libido ↑, similar to ethanol, and at higher doses, CNS depression causes ↓ libido and performance. ²⁰ |
| Benzodiazepines | Biphasic effect. At low doses, ↑ libido, whereas at higher dosages, CNS depression causes performance failure. Some reports of anorgasmia (men and women) and ejaculatory failure. ²⁰ |
| Substances of Abuse | |
| Alcohol | Alcohol is thought to impair sexual function through its chronic effects on the nervous system. Short-term use of alcohol can induce erectile dysfunction through its sedative effects. More than 600 mL/wk of alcohol increases the probability of erectile dysfunction. ²²² |
| Cocaine | Biphasic effect. At low doses, there is enhanced sexual desire (similar to amphetamines) and possibly performance. At higher dosages, there may be arousal dysfunction, ejaculatory dysfunction, anorgasmia. Freebasing has been associated with spontaneous orgasm. Continued use (“on a run”) causes significant loss of sexual interest and performance ability. Chronic use associated with hyperprolactinemia resulting in ↓ libido. ²⁰ |
| Ethanol | At low doses actually may enhance libido. Sexual dysfunction is dose related and caused by CNS depressant effects. ^{89,92,319} |
| Hallucinogens | Biphasic effect for most drugs in this category. At low doses, libido is enhanced; at higher doses, libido is severely ↓. No reports on chronic use. ²⁰ |
| Marijuana | Biphasic effect similar to ethanol. With chronic use there is a ↓ in libido. Mechanism may be due to ↓ testosterone. Incidence not reported. ²⁰ |
| Opioids | Associated with sexual dysfunction: erection lubrication, orgasm, and ejaculation. Chronic use associated with ↓ libido. Mechanism may be owing to α-antagonism, alterations in testosterone, and the intoxicating effects. Incidence not reported. ^{88,92,319,323} |
| Miscellaneous | |
| Amyl nitrate | Associated with intense and prolonged orgasms in both male and female. Impotence has been reported in some cases owing to vasodilation. ²⁰ |
| Cimetidine, ranitidine | Associated with ↓ libido and erectile dysfunction. Mechanism due to antiandrogen qualities and drug-induced elevation of prolactin. May be dose related. ^{92,324} |
| Metoclopramide | Associated with ↓ libido and erectile dysfunction. Mechanism is through CNS dopamine antagonism, resulting in hyperprolactinemia. Incidence not reported. ⁹² |

CNS, central nervous system; DHEA, dehydroepiandrosterone; SSRI, selective serotonin reuptake inhibitors; TCA, tricyclic antidepressants.

masturbation, and if morning and nocturnal erections are impaired.

Clinicians should ask the patient to estimate the degree of penile rigidity, especially with regard to the ability for vaginal penetration, and ask about nocturnal penile tumescence to differentiate psychogenic from organic causes of ED. The examiner should ascertain the presence of associated problems (e.g., atherosclerosis, diabetes mellitus) and attempt to correlate these problems to identified concerns with libido, orgasm, and ejaculation. Ideally, the sexual partner should be present during history taking. A pattern of progressive erectile dysfunction often indicates organic cause, whereas a pattern of intermittent episodes of ED with an abrupt onset suggests a psychogenic cause.

Relationship of Medical History and Erectile Dysfunction

3. What is the relationship among hypertension, cigarette smoking, diabetes mellitus, and F.M.'s erectile dysfunction?

HYPERTENSION

Among elderly men, erectile dysfunction most often is caused by neurovascular diseases.¹⁷ The high degree of arteriosclerosis among elderly American men is the leading cause of ED.^{17,55,56} In the MMAS, heart disease with hypertension and low serum high-density lipoprotein correlated with erec-

tile dysfunction.¹⁴ The hemodynamics of erection can be impaired in patients with myocardial infarction, coronary bypass surgery, cerebrovascular accidents, and peripheral vascular disease.^{57–60} In several studies of impotent men, the number of abnormal penile vascular findings significantly increased when the history included hypertension and cigarette smoking.^{61–63} In one report, 8% to 10% of all untreated hypertensive elderly males were impotent at the time of diagnosis of hypertension.⁶⁴ Control of blood pressure among hypertensive male patients does not necessarily improve erectile function, and antihypertensive medications can have a significant effect on erectile dysfunction and sexual performances (Table 101-2).^{65–67}

CIGARETTE SMOKING

The prevalence of cigarette smoking among men with erectile dysfunction is higher than in the general population.^{62,68,69} When the relation between cigarette smoking and erectile physiology was studied in 314 men with ED,⁷⁰ smoking was noted to further compromise penile physiology in men experiencing difficulty maintaining erections long enough for satisfactory intercourse. Several investigators report lower penile blood pressure indices, penile arterial insufficiency, and abnormal blood perfusion associated with cigarette smoking.^{62,71} Clearly, cigarette smoking is counterproductive in men with existing ED.

DIABETES MELLITUS

Diabetes mellitus has been associated with erectile dysfunction. In the MMAS, male patients with diabetes mellitus were three times more likely to have ED than patients without diabetes.¹⁴ Other investigators using exclusively diabetic populations have found a prevalence of ED as high as 75% among subjects.^{72,73} The onset of ED in the diabetic patient occurs at an earlier age when compared with the general population. In a few cases, it may be the presenting symptom of diabetes mellitus and, in most cases, ED follows within 10 years of the diagnosis, regardless of insulin-dependence status.^{74,75} Researchers disagree as to the exact contribution of diabetes mellitus to erectile dysfunction, but most of the literature supports an atherosclerotic etiology.^{76,77} Other possible causes also include autonomic neuropathy and gonadal dysfunction.⁷⁴

Gonadal Function in Erectile Dysfunction

4. What is the significance of the gonadal function results for F.M.?

GONADOTROPINS

Abnormalities of primary or secondary hypogonadism must be ruled out, particularly in patients with a decreased libido with or without erectile dysfunction. The results of F.M.'s gonadal function tests are relatively normal for an aged male. Testosterone serum levels decline with aging as a result of hypothalamic-pituitary changes or Leydig cell dysfunction. The understanding of changes that take place in the hypothalamic-pituitary level with advancing age is in a state of flux. For some time, most investigators focused on the increased serum concentration of male gonadotropins (LH, FSH), believing that all elderly males had some degree of primary hypogonadism.⁷⁸ Other studies have shown, however, that LH levels in elderly males are lower than the median of that in younger patients.⁷⁹ These findings show that LH levels do not increase in response to the decrease in testosterone serum concentrations in the aged male, indicating a defect in the hypothalamic-pituitary axis, leading to secondary hypogonadism.⁸⁰ Secondary hypogonadism results when there is a dysregulation of pituitary LH release, resulting in low serum testosterone levels.⁴⁴

TESTICULAR SIZE AND AGING

Testicular size decreases with age; however, the testicular degeneration is sporadic, thereby allowing most elderly men to maintain a normal or slightly decreased sperm output.⁷⁸ Overall, spermatogenesis decreases and is accompanied by an increase in serum concentration of FSH. FSH elevation correlates well with a decline in the number of Sertoli cells that secrete inhibin. Inhibin normally decreases FSH.⁸¹

TESTOSTERONE

As a result of primary or secondary hypogonadism in the elderly male, available testosterone declines. Approximately 60% to 75% of circulating serum testosterone is bound to a β -globulin known as sex hormone-binding globulin or testosterone-binding globulin. Approximately 20% to 40% of testosterone is bound to serum albumin, and 1% to 2% is unbound, or free. The unbound portion of testosterone is the

only active portion of the total serum testosterone concentration. Testosterone serum concentrations are 20% higher in the morning than in the evening, and this should be taken into consideration when evaluating laboratory results. In virtually all cases of male erectile dysfunction, the serum concentration of testosterone should be measured in the morning.

Testosterone production is regulated by feedback with the hypothalamus and pituitary. The hypothalamus produces gonadotropin-releasing hormone (Gn-RH) in response to low testosterone levels. Gn-RH induces the pituitary to secrete LH and FSH, which in turn stimulate the Leydig cells of the testes to secrete testosterone. Less than 10% of cases of erectile dysfunction studied are caused strictly by hypogonadism.^{17,82} The role of testosterone in ED is complex. After testosterone production decreases, libido eventually declines and precedes the decrease in frequency of erections.⁸³ Men given antiandrogens maintain their erectile capacity but have a decreased libido.⁸⁴ On the other hand, high dosages of androgens given to hypogonadal men increase both the frequency of erections and libido.⁸⁵ It would seem reasonable to postulate that at physiologic levels, testosterone modulates the cognitive processes associated with sexual arousal more than it contributes to erectile capability.

ENDOCRINE DISORDERS

Many endocrine disorders can result in erectile dysfunction. Patients with prolactinomas commonly have ED, but prolactinomas account for <1% of erectile dysfunction cases.⁸⁶ Prolactin inhibits the release of testosterone, resulting in secondary hypogonadism. Hyperprolactinemia may be more prevalent in diabetic patients.⁸⁷ In the elderly, however, hyperprolactinemia often is secondary to the use of medications. F.M.'s serum prolactin level is elevated, most likely because of his diabetes mellitus.

In summary, aged males have a decrease in testosterone because of defects in testicular and hypothalamic-pituitary function. Secondary hypogonadism in elderly males is common, and the point at which this becomes pathologic has not yet been established. Correspondingly, the use of hormonal therapy to treat physiologic secondary hypogonadism is extremely controversial. Therefore, the gonadal function tests for F.M. are normal for his age and do not provide an explanation for his ED.

Medications That Cause Erectile Dysfunction

5. What medications are known to contribute to male erectile dysfunction? Is it likely that a medication is causing F.M.'s erectile dysfunction?

Several general statements can be made regarding sexual function and medications. Drugs that affect libido generally have a central mode of action. For example, medications that block central dopamine transmission can decrease libido, and opiates have an antiandrogen effect.⁸⁸ Drugs that alter hemodynamics may interfere with erection. Excessive sympathetic tone is thought to cause the "steal syndrome," which increases blood flow to muscles, drawing blood away from the erectile tissue.⁸⁹ Drugs that block the peripheral sympathetic system can cause retrograde ejaculation, or no ejaculation at all.

Numerous drugs have been associated with altered sexual function⁹⁰ (Table 101-2).

Few studies exist in the literature solely devoted to drug-induced erectile dysfunction or sexual dysfunction.^{66,67} A few studies and review articles, however, list medications as one of many potential causes for ED.^{14,21,25,44,91}

Most studies documenting drug-induced erectile dysfunction have been subjective and based on case reports, uncontrolled studies, and clinical impressions. In a study (MMAS) from the New England Research Institute at Boston University Medical Center, complete erectile dysfunction was most significant for smokers being treated with cardiac drugs.¹⁴ In this study, erectile dysfunction was statistically correlated with antihypertensive, vasodilator, cardiac, and hypoglycemic drugs. The probability of moderate as well as complete ED was particularly high for vasodilator drugs.¹⁴ Although the MMAS is one of the most well-designed studies to date, the medications reported are not considered to be the universe of all medications associated with ED. Diagnosis of drug-induced sexual dysfunction should be restricted to a reproducible dose-related effect that disappears on discontinuation of the drug.⁹² A much larger survey of a controlled study in a clinical population would be required to establish any suspect medication as causative, rather than temporal.

F.M.'s sexual dysfunction (e.g., loss of interest in sexual activity and erectile dysfunction) is not caused by his current drug regimen, ramipril and glyburide. Although the MMAS¹⁴ reported a correlation between the use of antihypertensives and hypoglycemic drugs with erectile dysfunction, clinicians must look at the individual drugs themselves and the conditions for which they are prescribed. Sexual dysfunction has not been reported for ramipril, or any of the other angiotensin-converting enzyme (ACE) inhibitors, or for the hypoglycemic agent, glyburide. Although ramipril is an antihypertensive, its pharmacologic effects do not contribute to a decline in libido or cause ED (an advantage that ACE inhibitors have over other antihypertensive medications). Similarly, the pharmacologic action of glyburide does not contribute to F.M.'s decreased libido or ED. In most sexual dysfunction cases, it is less likely that the medication is the direct cause of the problem; rather, it is the medical condition for which the drugs were prescribed. The ability of a drug to induce sexual dysfunction simply is an extension of its pharmacologic actions. As a general rule, drugs that manipulate the sympathetic or the parasympathetic system, both centrally and peripherally, are associated with sexual dysfunction.

F.M. is a patient with hypertension and diabetes who smokes cigarettes. Those three factors are more likely to be the cause of F.M.'s sexual dysfunction than are his medications. Again, in the MMAS¹⁴ study, cigarette smoking combined with hypertension was determined to be the most significant cause of ED. Diabetes mellitus is the most common hormonal disorder associated with ED in the elderly population.⁵⁰ The continued loss of interest in sexual activity experienced by F.M. most likely is the result of having experienced ED during past and present sexual events.

F.M.'s subjective and objective findings are common among elderly men. His sexual dysfunction is caused by atherosclerosis and possible neuropathy secondary to diabetes mellitus. Because cigarette smoking is no doubt contributing to F.M.'s

ED, cessation should be encouraged; some improvement can be expected.²⁰ There is no need to alter F.M.'s drug regimen.

Management

Essentially, there are three levels to the management of erectile dysfunction. Level I mandates lifestyle and drug therapy modifications. Specifically, the patient should be instructed to modify smoking and alcohol use. The patient's drug regimen should be checked periodically to ensure that drugs associated with ED are not being prescribed. If necessary, psychosocial counseling should be provided. After careful consideration, oral medications for management of ED should be instituted. If level I therapies have failed or are not acceptable to the patient, then level II therapy is instituted. These interventions include a vacuum construction device to elicit an erection, intracavernosal injections, or transurethral inserts. Level III management involves placement of a penile prosthesis.

Pharmacotherapy

Any therapy directed at male sexual dysfunction must include the elimination of drugs causing adverse sexual effects. Drug therapy is directed primarily toward treatment of erectile dysfunction and includes hormonal therapy, bromocriptine, yohimbine, prostaglandin E₁, sildenafil, tadalafil, vardenafil, and apomorphine.

TESTOSTERONE

6. Should F.M. be treated with testosterone?

Primary hypogonadism with severely deficient serum levels of bioavailable testosterone is the only appropriate indication for the use of androgen hormone therapy.⁹³ The goal of androgen replacement therapy is to restore potency and libido by maintaining normal serum levels of testosterone.⁹⁴ Testosterone has no benefit in the treatment of eugonadal or mildly hypogonadal elderly men and actually may enhance the growth of undiagnosed adenocarcinoma of the prostate or cause further erectile dysfunction.²⁷ In eugonadal men, testosterone enhances the rigidity of the erection, but does not change the penile circumference.⁹⁵ F.M. would not be a candidate for testosterone therapy.

7. Which type of patient would benefit from testosterone therapy?

Unless testosterone deficiency is severe, for example, if free testosterone serum levels are <7 to 8 pg/mL, testosterone replacement therapy will not improve the success rate of intercourse.⁹⁶ Testosterone replacement in patients with primary hypogonadism generally restores libido and potency. In some patients with secondary hypogonadism caused by disorders of the hypothalamus or pituitary, Gn-RH analogs can be administered to differentiate between hypothalamic and pituitary abnormalities and to correct testosterone deficiency.⁹⁴ Libido and potency then are restored.

8. How should testosterone be used as a treatment for erectile dysfunction?

Testosterone replacement therapy is available in several formulations, including gels, topical body or scrotal patches, and intramuscular injection. In a study by Monga et al.,⁹⁷

transdermal testosterone system (Testoderm-TTS) nonscrotal application was determined to provide improved erections and intercourse when compared with Testoderm scrotal patches. In this study, intramuscular testosterone or transdermal testosterone was favorably accepted by the study patients.

Because of poor drug bioavailability, oral testosterone replacement therapy is less effective than parenteral testosterone in achieving normal serum testosterone levels. Oral administration also is associated with a higher incidence of hepatotoxicity and adverse serum lipid effects.^{27,98} A long-acting testosterone intramuscular formulation, such as the enanthate or the cypionate ester, is still considered the regimen of choice for the treatment of primary hypogonadism. A dose of 50 to 400 mg should be administered intramuscularly every 2 to 4 weeks. Side effects of testosterone therapy include early gynecomastia, increases in hematocrit (sometimes to the point of polycythemia), and fluid retention that may worsen hypertension or congestive heart failure (CHF).

Results of several studies have demonstrated that serum testosterone levels are normalized while using transdermal testosterone applications.^{99–102} The system normalizes dihydrotestosterone:testosterone ratios and reduces LH levels toward the normal range. The testosterone transdermal system (TTS) is well tolerated, with application site reactions such as pruritus, burnlike blisters, and erythema being the most commonly reported events. Nightly applications of the TTS patch in men with hypogonadism results in a 24-hour serum testosterone concentration profile that mimics the circadian pattern observed in healthy young men.⁸³ The adhesive side of the TTS patch should be applied to a clean, dry area of the skin on the back, abdomen, upper arms, or thighs. The patient should be instructed to avoid application over bony prominences or on a part of the body that may be subject to prolonged pressure during sleep or sitting (e.g., the deltoid region of the upper arm, the greater trochanter of the femur, and the ischial tuberosity); do not apply to the scrotum. The sites of application should be rotated, with an interval of 7 days between applications to the same site. The area selected should not be oily, damaged, or irritated.

Topical testosterone gel should be applied once daily in the morning to clean, dry skin on the upper arms, shoulders, or abdomen. Topical testosterone gel is available as a 1% gel in unit-dose packets containing a 25- or 50-mg dose. The dose can be as high as 100 mg/24 hours. After the gel has dried on the site of application, it should be protected with clothing to prevent transfer to a nonuser. The patient's hands should be washed.

Commonly reported adverse effects in chronic users include acne, edema, gynecomastia, and dermatologic reactions to injections or transdermal applications of testosterone. The most serious risk of prolonged testosterone use is prostate carcinoma, although the association between high concentrations of testosterone and the risk of prostate carcinoma is controversial.^{103,104} Three studies suggest that testosterone replacement therapy is relatively safe in hypogonadism.^{105–107} Baseline assessment of the prostate should be done before starting testosterone replacement therapy. This should consist of a transrectal ultrasound, digital palpation of the prostate gland, and analysis of the total and free prostate-specific antigen (PSA) levels. Fine-needle biopsy of the prostate gland may

be necessary in some hypogonadal men, because the PSA analysis may not be completely reliable.¹⁰⁸

BROMOCRIPTINE

9. Because F.M.'s prolactin serum concentration is 28 ng/mL, should bromocriptine (Parlodel) be prescribed to decrease his hyperprolactinemia and treat his erectile dysfunction?

[SI unit: prolactin, 28 mcg/L]

Hyperprolactinemia may be treated with the ergot alkaloid, bromocriptine. Normalization of the serum prolactin level is mandatory if potency is to be restored. Even with normalization of prolactin levels, approximately 50% of elderly male patients are unable to achieve erectile function and desire.^{94,98} Bromocriptine therapy may be initiated with twice-daily 1.25-mg doses taken with meals to minimize gastrointestinal upset. Thereafter, doses may be increased weekly, at a rate of no more than 2.5 mg/day. Because bromocriptine is associated with dizziness, drowsiness, hypotension, and cerebrovascular accidents, the patient should be forewarned.^{27,94}

F.M. is not a candidate for treatment with bromocriptine because he does not have secondary hypogonadism, and his ED probably is secondary to atherosclerosis associated with his hypertension, diabetes, and cigarette smoking. Normalizing the prolactin serum level in F.M. would not correct his problem. Furthermore, the elevation of F.M.'s serum prolactin concentration is not significant to warrant drug therapy. With only a 50% (or less) response rate to bromocriptine in elderly men, the risk of adverse reactions (e.g., dyskinesia, dizziness, hallucinations, dystonia, confusion, cerebrovascular accidents) outweighs the benefit of this drug therapy.

SILDENAFIL

10. Would sildenafil citrate (Viagra) be appropriate for F.M.? What are its side effects and contraindications? Does it interact with other drugs?

F.M. has diabetes mellitus and atherosclerosis and therefore is a candidate for sildenafil. In a multicenter, randomized, double-blind, placebo-controlled, flexible dose-escalation study, sildenafil was shown to be effective and well tolerated for erectile dysfunction in men with diabetes.¹⁰⁹ Sildenafil citrate is an orally active and selective inhibitor of cGMP-specific phosphodiesterase type 5, the predominant phosphodiesterase isoenzyme metabolizing cGMP in the corpus cavernosum. Sildenafil facilitates an erection in response to sexual stimulation by enhancing the nitric oxide-induced relaxation of corpus cavernosal smooth muscle. The results of double-blind, placebo-controlled clinical trials in men with ED of various causes have demonstrated that sildenafil significantly improves erectile function and the rate of successful sexual intercourse, with therapeutic outcomes approaching those of normal men of the same age.¹¹⁰

The typical dose of sildenafil is 50 mg orally, taken 1 hour before sexual activity. Sildenafil citrate may be taken anywhere from 4 hours to 0.5 hour before sexual activity, however. The maximal recommended dosing frequency is once per day. The following factors are associated with increased plasma levels of sildenafil: age >65 years (40% increase in area under the curve [AUC]), hepatic impairment (e.g., cirrhosis, 80% increase), severe renal impairment (creatinine clearance <30 mL/minute,

100% increase), and concomitant use of potent cytochrome P450 (CYP) 3A4 inhibitors (erythromycin, ketoconazole, itraconazole, 200% increase). Because higher plasma levels may increase both the efficacy and the incidence of adverse events, a starting dose of 25 mg should be considered in these patients. The dose may be increased to 100 mg or reduced to 25 mg. Because F.M. is >65 years of age, he should be started on 25-mg tablets of sildenafil. The dose may be increased under strict supervision.

F.M. should be counseled on the adverse effects of sildenafil. The vasodilating action of sildenafil affects both the arteries and the veins, so the most common side effects are headache and facial flushing.¹¹¹ Sildenafil causes small decreases in both systolic and diastolic blood pressures, but clinically significant hypotension is rare. Studies of sildenafil and nitrates taken together show much greater drops in blood pressure. For that reason, sildenafil is contraindicated in patients taking long-acting nitrates or short-acting, nitrate-containing medications.²⁷ In phase II/III studies before U.S. Food and Drug Administration (FDA) approval, >3,700 patients received sildenafil and almost 2,000 received placebo in double-blind and open-label studies. Approximately 25% of patients had hypertension and were taking antihypertensive medications, and 17% were diabetic. In these studies, the incidence of serious cardiovascular adverse effects was similar to the double-blind sildenafil group, the double-blind placebo group, and the open-label group. Twenty-eight patients had experienced a myocardial infarction. When adjusted for patient-years of exposure, no significant differences were seen in the myocardial infarction rates between the sildenafil and the placebo group, and no deaths were attributed to sildenafil.^{112,113} Nevertheless, several deaths caused by myocardial infarction or arrhythmia have been associated with the use of sildenafil.¹¹⁴ Deaths associated with sildenafil (and presumably other PDE5 inhibitors) are most likely caused by increased cardiac workload in patients with unstable angina.¹¹⁵

Transient visual anomalies (mostly blue-green color-tinged objects, increased perception of light, and blurred vision) have been reported in patients taking sildenafil, especially at higher dosages (>100 mg). These visual effects appear to be related to the weaker inhibiting action of sildenafil on the enzyme, phosphodiesterase-6 (PDE-6), which regulates signal transduction pathways in the retinal photoreceptors. Sildenafil is 10-fold selective for PDE-5 over PDE-6. In patients with inherited disorders of retinal PDE-6, such as retinitis pigmentosa, sildenafil should be administered with extreme caution.

The vasodilator actions of nitrates are profoundly amplified with concomitant use of sildenafil. This interaction likely applies to all nitrates and nitric oxide donors, regardless of their predominant hemodynamic site of action. Sildenafil also may potentiate the inhaled form of nitrate, such as amyl nitrite, and therefore is contraindicated in patients using this product. Dietary sources of nitrates, nitrites, and L-arginine (the substrate from which nitric oxide is synthesized) do not contribute to the circulating levels of nitric oxide in humans and therefore are unlikely to interact with sildenafil. The anesthetic agent, nitrous oxide, is eliminated unchanged from the body, mostly via the lungs, within minutes of inhalation. It does not form nitric oxide in the human body and does not itself activate guanylate cyclase. As such, no contraindication exists to its use after administration of sildenafil.

It is unknown how much time must elapse from the time a patient takes sildenafil before a nitrate-containing medication might be given without the marked hypotensive effect being produced. On the basis of the pharmacokinetic profile of sildenafil, it can be assumed that the coadministration of a nitrate within 24 hours is likely to produce an exaggerated hypotensive response and therefore is contraindicated. After 24 hours, the administration of nitrates can once again be considered. In patients in whom sildenafil may have a prolonged half-life, the nitrate-free period must be extended. All patients taking nitrates must be warned of the contraindications and the potential consequences of taking sildenafil in the 24-hour interval after taking a nitrate preparation, including sublingual nitroglycerin. Although sublingual nitroglycerin is short-acting, its use within a 24-hour time period before sexual relations does suggest that it may be needed again after sildenafil-enhanced sexual activity.

Sildenafil is metabolized by both the CYP 2C9 pathway and the CYP 3A4 pathway. Thus, inhibitors of the CYP 3A4 isoenzyme, such as erythromycin or cimetidine, may lead to competitive inhibition of its metabolism; however, CYP 3A4 is a high-capacity pathway. The effects of erythromycin or cimetidine on the half-life and physiologic effects of sildenafil are not known, but clinicians should be warned about the potential interaction.

Inadequate physical sexual stimulation while using any of the PDE-5 inhibitors can lead to treatment failure. Adequate sexual stimulation is needed to trigger the events leading to erection.¹¹⁶ PDE-5-inhibitors cannot initiate an erection, they can only assist in the process. Some patients may need several attempts at sexual stimulation before they are successful with intercourse.

11. Is F.M. a candidate for tadalafil or vardenafil?

TADALAFIL

Similar to sildenafil, tadalafil (Cialis) is a selective inhibitor of phosphodiesterase-5 (PDE-5). Tadalafil has several times more affinity for PDE-5 than sildenafil.¹¹⁷ The clinical significance of this increased affinity for PDE-5 is unknown because comparative clinical trials between the PDE-5-inhibitors (sildenafil, tadalafil, and vardenafil) have not been conducted. Tadalafil and vardenafil, however, have minimal or no effect on visual disturbance (impairment of blue-green color discrimination), which is a well recognized side effect of sildenafil.¹¹⁸ Tadalafil's extended half-life of 17.5 hours relative to sildenafil most likely precludes its use in patients with angina or hypertension. Tadalafil is metabolized by the hepatic CYP 3A4 isozyme. Food has no effect on the oral absorption of tadalafil in contrast to sildenafil (bioavailability decreased by 29%). Tadalafil may be advantageous in a subset of patients, based on its shorter onset of action (16 minutes) and 24-hour duration of action.¹¹⁹ Specifically, patients with psychogenic or neurogenic ED and those with stable cardiovascular systems may prefer tadalafil because it offers the potential for multiple sessions of intercourse encounters with a single daily dose. F.M. has hypertension that most likely would be affected by tadalafil; therefore, extreme caution is advised. Perhaps the shorter-acting sildenafil would be the PDE-5-inhibitor drug of choice for F.M. The warnings regarding the use of nitrates while taking tadalafil are similar to the warnings for sildenafil.

VARDENAFIL

Vardenafil (Levitra) is the third FDA-approved oral PDE-5 inhibitor for treatment of erectile dysfunction. Vardenafil, as with the other PDE-5-inhibitors, has an affinity for PDE-6 and will therefore cause ocular adverse effects. The warnings regarding the use of nitrates while taking vardenafil are similar to the warnings for sildenafil. Patients using vardenafil may experience headache, flushing, or rhinitis; the incidence of these side effects are dose related.¹²⁰ Vardenafil is metabolized by the hepatic CYP 3A4 isozyme and has a reported half-life of 5 hours.¹²¹ Thus, drugs known to inhibit the CYP 3A4 isozyme have the potential to prolong its half-life. Vardenafil 10 mg does not impair the ability of patients with stable coronary artery disease to exercise at levels equivalent to or greater than that attained during sexual intercourse.¹²²

12. What other drug therapy is available for F.M.?**YOHIMBINE**

Yohimbine, an indole alkaloid derived from the bark of the West African yohimbine tree, has been classified as an aphrodisiac in many pharmacopoeias. Yohimbine hydrochloride is an α_2 -adrenergic antagonist that decreases the outward blood flow from the penile corporal tissue. The effectiveness of yohimbine relies on an adequate penile blood supply. It has been used in treating ED among diabetics with some degree of success.¹²³ In a trial of men with psychogenic ED, yohimbine produced a 47% response rate versus 28% among placebo users.¹²⁴ This finding was affirmed in a subsequent study.¹²⁵ Men with psychogenic or neurogenic ED have some response.^{123–125} Despite its modest efficacy, yohimbine is used in patients who do not accept more invasive methods because it is safe, available, and easy to use. Because F.M. is experiencing vasculogenic, neurogenic, and psychogenic ED, his response to yohimbine may be none to slight, at best, owing to his atherosclerosis and resultant low penile blood supply. Again, the risk of side effects compared with the slight benefit that F.M. may experience suggests that other therapies be considered.

In some patients, yohimbine has been associated with nausea, tachycardia, a slight elevation in blood pressure, anxiety, and panic attacks.⁹⁸ The drug regimen used in clinical trials is 6 mg orally three times a day, and beneficial effects usually become apparent within 2 to 3 weeks.^{21,123,124} In some of the trials, the point was made that the dose of 18 mg/day may be too low; however, dose-response trials would be necessary before higher doses could be recommended.

INTRACAVERNOSUS INJECTIONS

In 1982, inadvertent injection of papaverine into the penis was found to produce an erection.¹²⁶ This landmark observation ushered in a new methodology for the diagnosis and therapy of erectile dysfunction. By 1986, papaverine injection into the penis had gained worldwide popularity for the treatment of ED.¹²⁷ In 1983, the α -blocker, phenoxybenzamine, also was noted to be effective.¹²⁸ Shortly thereafter, the combination of papaverine with another vasodilator, phentolamine, reportedly enhanced and prolonged erection duration.¹²⁹ These vasoactive drugs, when injected into the cavernosa, cause prolonged penile arterial vasodilation and venous compression, thus allowing the patient to achieve and maintain an erection. Erectile dysfunction responds favorably to the self-injection of vasoac-

Table 101-3 Agents Used to Treat Vasculogenic Erectile Dysfunction

| Drugs | Route | Mechanism |
|------------------------------|-------|--|
| Papaverine | ICI | Phosphodiesterase inhibitor; penile arteriolar vasodilator |
| Phentolamine | ICI | α -Adrenergic blockade; direct vasodilator |
| Prostaglandin E ₁ | ICI | α -Blockade; vasodilator |
| Atropine | ICI | Antimuscarinic; smooth muscle relaxant |

ICI, intracavernous injection.

tive drugs into the penis.^{127,130,131} Originally, the IC regimen of papaverine with phentolamine was prescribed as a short-term measure taken while patients were awaiting the results of counseling or a penile implant. Currently, self-injection of vasoactive drugs has become accepted as a nonsurgical method of treating ED (Table 101-3).

Papaverine–Phentolamine Combination

Papaverine, a nonspecific phosphodiesterase inhibitor, increases the serum concentration of cAMP, resulting in penile arteriolar and corporal sinusoidal smooth muscle relaxation. In laboratory studies, papaverine blocks voltage-operated calcium channels, inhibits the release and storage of intracellular calcium, increases calcium efflux, and inhibits calcium-activated chloride and potassium currents in vascular smooth muscle.^{132–134} Papaverine also may relax an elastic venous valve mechanism that is kept open by an α -adrenergically mediated smooth muscle contraction.^{135–137}

Phentolamine exerts its relaxant effects by α -adrenergic receptor blockade of both α_1 - and α_2 -adrenoceptors. In addition, phentolamine also may have a direct, nonspecific relaxant effect on vessels.¹³⁸ The combined use of papaverine with phentolamine exerts a greater effect than would be experienced with either drug alone.¹³⁹ The use of alprostadil (prostaglandin E₁) by IC injection is addressed in Question 19.

Candidates for Intracavernous Injection Therapy**13. What objective data must be obtained to ensure that F.M. can receive IC injections safely?**

Patients who have failed to obtain a satisfactory erection while on oral drug therapy, such as sildenafil, tadalafil, yohimbine, or sublingual apomorphine (available in Europe), are candidates for the IC injections of vasoactive drugs. The patient must have a complete medical workup to include assessment of the penile arterial system. Doppler sonography of the penis identifies penile architecture, defines the thickness of any plaques, measures the diameter of cavernous arteries (before and after vasodilation), and allows visualization of the penile arteries. This noninvasive assessment of the individual penile arteries is much more accurate than the penile brachial pressure index (PBI). The PBI is the ratio of the penile systolic blood pressure (measured by continuous-wave Doppler analysis) to the brachial artery systolic pressure. This method of assessment measures all the penile arteries rather than signals from a single penile artery. PBI ratios that are normal (i.e., >0.6) do not always indicate normal penile blood flow, because the PBI is obtained while the penis is flaccid. F.M. should have

sonography combined with Doppler analysis to assess the adequacy of his penile arterial blood flow.

In some urologic practices, the functional evaluation of penile arteries is obtained by IC injection of vasoactive drugs at the office. If the patient develops a fully rigid erection within 12 minutes of injection of papaverine hydrochloride 30 to 60 mg or prostaglandin E₁ 10 to 20 mg and maintains a rigid erection for 30 minutes, adequate arterial flow and an intact venous mechanism can be assumed.²⁸ The patient then is a candidate for at-home IC injection of vasoactive drugs.

14. The Doppler sonography analysis of F.M.'s penile arteries showed severe atherosclerosis, indicating a vasculogenic etiology for his erectile dysfunction. Is F.M. still a candidate for IC injection therapy?

Patients with psychogenic or neurogenic erectile dysfunction who respond to test doses of IC injections of a vasoactive drug are optimal candidates for IC injection therapy.¹⁴⁰ Patients with vasculogenic ED are less responsive to the IC injections of vasoactive drugs, and corporeal veno-occlusive dysfunction is the primary potential obstacle to this treatment.^{141,142}

An abnormal veno-occlusive mechanism can result in penile venous incompetence, causing rapid detumescence or partial erection (referred to as venogenic erectile dysfunction). The veno-occlusive mechanism of the corpora cavernosa can be assessed through an elaborate and quite painful invasive process, using angiocatheters and iodinated contrast media. In a study to determine the effectiveness and safety of IC therapy in vasculogenic impotent men, 40% of the participants had arteriovenogenic ED, and 32% had venogenic ED (i.e., they had a dysfunctional veno-occlusive mechanism), with only 28% of participants having pure arteriogenic ED.¹⁴³ Only 4% of the participants failed to achieve a sustained rigid erection, however; massive veno-occlusive mechanism dysfunction was cited as the reason. At a mean follow-up of 20 months, the remaining 96% of patients (including those with some degree of veno-occlusive mechanism dysfunction) still were using the IC injection therapy. Given these findings, F.M. has a good chance of responding to IC injection therapy, even if it is determined that he has some veno-occlusive disease. Absolute contraindications to IC injection therapy are anticoagulant therapy, Peyronie's disease, and idiopathic priapism.

Dosing

15. What is the protocol for starting a patient on an IC injection therapy program for home use?

The initial dose of the papaverine–phentolamine combination should take into consideration the underlying etiology for the erectile dysfunction, the findings of the Doppler sonography, and the patient's response to a test dose of the IC injection. Generally, patients with neurogenic ED are started on the lowest doses (usually 0.5 mL), whereas patients with severely compromised penile arterial blood flow would receive larger doses (e.g., 1.0 mL). It should be kept in mind that there may be excessive sympathetic stimulation in an anxious patient while at the physician's office, and more drug may be required to overcome the vasoconstriction.¹⁴⁴ This implies that at-home use may require a lower dose. The standard mixture for the most common vasoactive IC injection solution is 30 mg/mL of papaverine and 1 mg/mL of phentolamine, for a total vol-

ume of 10 mL. The initial test dose administered in the physician's office generally is 0.5 mL (but may be as low as 0.25 mL) of the 30:1 mixture, using a tuberculin syringe with a 26-gauge needle. The patient is observed for both therapeutic and adverse effects, such as bradycardia, hypertension, dizziness, or flushing. If any of these adverse effects are observed, atropine should be injected IC.¹⁴⁵ In the event that the patient's erection becomes prolonged beyond 30 to 60 minutes, the subsequent dose of papaverine–phentolamine should be reduced. Prolonged erection, which may progress to a pulsatile priapism, is the most significant complication of IC injections of vasoactive drugs. Treatment should be instituted immediately with epinephrine 1 mg/mL, 10 to 20 mL injected IC as an irrigant, and then aspirated.¹⁴⁰ Prolonged erections can lead to intracorporeal hypoxia, resulting in corporeal fibrosis.¹⁴⁵ In some cases, the physician may choose single-drug IC injection with papaverine 25 to 60 mg, or prostaglandin E₁ 10 or 20 mg/dose.

Extemporaneous Compounding

16. What procedures should be taken when extemporaneously compounding a papaverine–phentolamine injectable solution, and what expiration date is acceptable?

The method used to extemporaneously compound the papaverine–phentolamine mixture was developed in the early 1980s without consideration of pharmaceutical product stability. Nevertheless, the compounding of the papaverine–phentolamine solution has not changed much from those early days. The final product usually consists of a 10-mL vial of papaverine and phentolamine in a ratio of 30:1 mg/mL. Papaverine hydrochloride is available in a 30-mg/mL, 10-mL multidose vial that also contains 0.5% chlorbutanol as a preservative. Phentolamine mesylate (Regitine) is available in vials containing 5 mg of active drug and 25 mg of mannitol, in a sterile lyophilized form. Extemporaneous compounding of this product requires sterile technique. One vial of papaverine and two vials of phentolamine are needed to make the final product. Using a small-gauge needle and 3-mL syringe, remove 2 mL (i.e., 60 mg) from the papaverine vial and use 1 mL to reconstitute the first vial of phentolamine. With the remaining 1 mL of papaverine solution in the syringe, reconstitute the second vial of phentolamine. Using the empty syringe, remove the solution from both phentolamine vials and instill this volume into the 10-mL papaverine multidose vial. Each milliliter of the final concentration in the papaverine vial should contain 30 mg of papaverine hydrochloride with 1 mg of phentolamine mesylate (plus 0.5% chlorbutanol and 5 mg of mannitol).

Currently, the FDA has not approved either papaverine or phentolamine alone or in combination as a treatment modality for erectile dysfunction. The addition of phentolamine mesylate to a multidose vial of papaverine hydrochloride for at-home patient use is not mentioned in the respective manufacturers' package inserts.^{146,147} In a product-stability study, the combination of papaverine and phentolamine was stable for at least 40 days when stored at room temperature.¹⁴⁸ In this study, the concentration of papaverine hydrochloride was 25 mg/mL and phentolamine mesylate was 0.83 mg/mL. Thus, the common practice of using a 30-day expiration date on extemporaneously prepared papaverine–phentolamine multidose preparations is justified.

Patient Instructions

17. What instructions should be provided to the patient for IC injection therapy?

Once the dose of IC injection vasoactive drug is determined for the patient at the physician's office, the patient then is taught self-injection using a 26-gauge needle, 1-mL syringe.

Patients should be instructed to inject into the right side of the penis (lateral aspect), approximately 4 cm from the glans after the area has been cleaned with an alcohol swab. The tip of the needle should be placed into the center of the right corpus cavernosum with a quick jab. The injection is administered within a 1- to 2-minute period. If pain is felt in the glans penis, the rate of injection should be slowed (next time) to perhaps 3 or 4 minutes. On withdrawal of the needle, the puncture site is compressed and the penis should be massaged gently by squeezing intermittently for approximately 3 minutes to distribute the drug throughout the shaft. A tourniquet at the base of the penis is not necessary. Sterile technique should be stressed when discussing this procedure with patients.

The number of injections per month is limited by a 10-mL supply to prevent long-term complications. The 10-mL volume allows patients to have intercourse 10 to 20 times per month if doses of 0.5 to 1 mL are used.

Adverse Effects

18. F.M. has been using papaverine–phenolamine 30:1 mixture at a dose of 1.0 mL per sexual episode over the past 6 months. He has injected himself 32 times. For the past month, he has noticed a lateral deviation of his penis when rigid, and now he feels a “hard spot” (induration) below the surface of the skin on the shaft. What are the adverse effects associated with repeated use of papaverine–phenolamine IC injections?

Penile induration and corporeal fibrosis are complications of IC injections, particularly when papaverine hydrochloride is used. The appearance of induration or fibrosis significantly correlates to the number of injections administered.¹⁴⁹ Men with penile induration or fibrosis injected the papaverine–phenolamine mixture two and one-half times more often than those who did not experience this side effect. Similarly, men who administered higher doses also were more likely to develop penile induration or fibrosis ($p < 0.01$). Hence, a 10-mL solution of the papaverine–phenolamine combination should be dispensed on a monthly basis to manage both the frequency of use and the total dose. The patient should be educated about the complications and side effects of penile injection with vasoactive drugs (Table 101-4).

Corporeal fibrosis, which can result in Peyronie disease, is the limiting factor with any combination of papaverine, because the relative acidity of the drug (pH, 3–4) is associated

with sclerosis.^{150–153} The frequency of IC papaverine injections should be limited. At least 94% of patients using IC self-injection experience at least one complication, with 70% of users reporting at least two to three complications.¹⁵⁴ Injection site pain is related more to the injection of the drugs than to the insertion of the needle.¹⁵⁵ The pain is described as a burning sensation in the glans penis occurring 30 seconds after the injection begins and lasting for 1 to 2 minutes after the injection is stopped. The most devastating complication, priapism, is experienced by approximately 4% of patients and requires treatment. Of interest, none of the patients who experienced priapism had vasculogenic impotence. Self-administration side effects, such as pain, bruising, and swelling, usually do not occur when physicians inject the vasoactive drugs into the penis.¹⁴⁹

Systemic effects of papaverine–phenolamine initially were believed to be insignificant. The use of this mixture has been associated, however, with abnormal liver function tests (LFT) in 40% of recipients, mostly involving mild to moderate elevations of serum alkaline phosphatase and serum lactic dehydrogenase.¹⁴⁹ Hepatotoxicity, which may have an immune mechanism, has been associated with papaverine injection infrequently. A patient may be advised to discontinue the use of this medication if the LFT are indicative of hepatocellular injury.

The adverse effects from the use of papaverine–phenolamine generally do not prevent continued use of this therapy. After an episode of priapism, patients are instructed not to use the injection for at least 1 month.¹⁵⁴ Most patients who have experienced one or more adverse effects (e.g., bruising, pain, fibrosis, priapism) from the papaverine–phenolamine injections generally still resist penile implantation for as long as possible and continue the injection therapy.¹⁵⁴

Several studies have reported various degrees of satisfaction among users of IC self-injection.^{130,131,154} Eventually, most users discontinue the use of IC injection and consider a penile implant. Complications resulting from IC injection of vasoactive drugs do not prevent successful prosthetic implantation.¹⁵⁴

Alprostadil

19. What other drugs can be used by IC injection in patients who are unresponsive to the papaverine–phenolamine mixture? How is alprostadil used to treat erectile dysfunction?

Patients with vasculogenic erectile dysfunction are less likely to respond to papaverine–phenolamine by IC injection. These patients generally require larger doses of papaverine–phenolamine and thus are more likely to develop penile induration. However, 96% of patients with vasculogenic ED responded to a four-drug vasoactive mixture of papaverine hydrochloride 12.1 mg/mL, prostaglandin E₁ 10.1 mg/mL, phenolamine mesylate 1.01 mg/mL, and atropine sulfate 0.15 mg/mL. The solution was obtained by mixing 250 mg papaverine hydrochloride (14.4 mL), 200 mg of prostaglandin E₁ (0.4 mL), 20 mg of phenolamine mesylate (2 mL), and 3 mg of atropine sulfate (3 mL), for a total of 19.8 mL.¹⁴³ Doses administered were from 0.1 to 1.0 mL via a 27-gauge self-injection device.

Prostaglandin E₁ (alprostadil) is available for IC injection, as a urethral insert (referred to as *medicated urethral system for erection* [MUSE]) and as a topical cream. All of these

Table 101-4 Side Effects of Papaverine-Phenolamine ICI for Vasculogenic Impotence

| | |
|-------------------------|--|
| Prolonged erection | Penile induration |
| Priapism | Pain at injection site |
| Painless penile nodules | Bruising or bleeding at injection site |
| Peyronie's disease | Abnormal LFT |

ICI, intracavernous injection; LFT, liver function tests.

pharmaceutical preparations have been shown to be efficacious for men with ED,^{19,156,157} with users reporting successful intercourse 65% of the time. The efficacy of alprostadil was similar, regardless of the patient's age or the cause of ED, which included vascular disease, diabetes, surgery, and trauma. Prostaglandin E₁ has α -blocking properties mediated through a membrane receptor. It relaxes the cavernous and arteriolar smooth muscle while restricting venous outflow.¹⁴⁰ The addition of an oral α -blocker may have a beneficial effect in patients with ED for whom IC injection therapy alone fails. The synergistic effects of vascular dilation and blockade of sympathetic inhibition may explain this response.¹⁵⁸ Prostaglandin E₁ is an acceptable alternative to papaverine and patients experience few side effects.^{159,160} The use of IC papaverine with prostaglandin E₁ has proved, however, to be superior to prostaglandin E₁ alone.¹⁶¹ Prostaglandin is metabolized in the local tissue and is unlikely to cause any systemic effects.¹⁶² The most common side effects of urethral alprostadil inserts are penile pain, which occurs in 29% to 49%¹⁶³ of users, and hypotension within 1 hour of use, which occurs in 3.3% of users. Urethral bleeding has been reported in 5% of users. Patients should be advised about hypotension, particularly if they also are using nitrates or antihypertensive medications. Less than 2% of users have reported swelling of leg veins, leg pain, perineal pain, and rapid pulse. Penile induration has not yet been reported with use of prostaglandin E₁.

BENIGN PROSTATIC HYPERPLASIA

Benign prostatic hyperplasia (BPH), a common cause of urinary dysfunction symptoms in elderly men, results from proliferation of the stromal and epithelial cells of the prostate gland.^{164,165} There is both a static and a dynamic component to prostate enlargement. The static component increases the prostate size by smooth muscle cell proliferation in the prostate stroma, whereas the dynamic component contributes to an enlarged prostate through an increase in smooth muscle tone in the prostate and bladder neck. The term *benign prostatic hypertrophy* often is used inappropriately because the prostate gland pathology results from hyperplasia rather than hypertrophy. BPH rarely is detected in men <40 years of age. After age 40, the prevalence of BPH is age dependent.¹⁶⁶ Approximately 75% of men who live to the age of 70 develop clinical symptoms of BPH that are sufficiently severe to necessitate medical attention, and approximately 90% of octogenarians have evidence of BPH. Essentially, all men will develop BPH if they live long enough. The microscopic incidence of BPH is fairly constant among several Western and developing countries,¹⁶⁷ suggesting that the initiation of BPH may not be environmentally or genetically influenced. Although BPH and prostatic cancer often coexist, no compelling evidence indicates that BPH predisposes patients to the development of prostate cancer.¹⁶⁸ The appearance of atypical prostatic hyperplasia correlates, however, with the presence of latent prostatic carcinoma.¹⁶⁹

The cause of BPH is unclear; however, most hypotheses are based on hormonal and aging processes. This is because intact, normally functioning testes are essential for BPH to develop,¹⁷⁰ and castration before puberty prevents the development of BPH. The prostate is dependent on androgens both for embryologic development and maintenance of size and function in the mature male.¹⁷¹ Testosterone, the major circulating

androgen, is metabolized to dihydrotestosterone (DHT) by 5 α -reductase. The two isoenzymes of 5 α -reductase are designated type I and type II. Type II is found predominantly in the prostate and other genital tissues, whereas type I is found throughout the body, as well as in the prostate.¹⁷² For testosterone to be active in the prostate, it must be converted to DHT; therefore, DHT is the obligate androgen responsible for normal and hyperplastic prostate growth. Within the prostate, DHT initiates RNA synthesis, protein synthesis, and cell replication. The exact role of testosterone may be only to initiate fibroadenomatous hyperplasia, eventually resulting in glandular enlargement.

Stromal hyperplasia in the prostate periurethral glands is one of the earliest microscopic findings in men with BPH.¹⁶⁷ As men increase in age, testosterone serum concentrations decrease and the peripheral conversion of testosterone to estrogen increases. At one time, estrogens were thought to initiate stromal hyperplasia, which in turn induces epithelial hyperplasia. It is now known, however, that estrogens do not have a direct effect on the development of BPH and prostatic carcinoma, but progesterone does play a role in their pathogenesis. Progesterone receptors have been shown to exist in prostate stromal cells, whereas estrogen receptors were essentially nonexistent.¹⁷³

Pathophysiology and Clinical Presentation

20. G.M., a 72-year-old man, presents to the emergency department with severe lower abdominal discomfort of 4 days' duration. His history consists of having increasing difficulty initiating urination, a significant decrease in the force of his urinary stream, occasional midstream stoppage, and postvoid dribbling. Physical examination is unremarkable except for the abdominal and rectal examination. Abdominal examination reveals distention, tenderness, and increased dullness in the hypogastrium with a large mass, believed to be the bladder. On rectal examination, the prostate is found to be severely enlarged, firm, and rubbery without nodules or undue hardness. G.M. gives a history of nocturia (approximately four to five times a night) and daytime urinary frequency (eight to ten times a day). G.M. indicates that when he is able to urinate he does not feel relieved. Laboratory findings are as follows: BUN, 45 mg/dL (normal, 8–18); SrCr, 3.2 mg/dL (normal, 0.6–1.2); serum prostatic acid phosphatase, 3 U/L; and serum PSA, 7.1 ng/mL (normal, 0.1–4.0). A urethral catheter was inserted, and 900 mL of urine was obtained. G.M. subsequently was scheduled for a urologic workup. What is the pathophysiologic basis for G.M.'s symptoms?

[SI units: BUN, 16.1 mmol/L urea; SrCr, 282.9 μ mol/L; serum prostatic acid phosphatase, 3 U/L (normal, 2.5–11)]

Symptoms of BPH can be both obstructive and irritative, and descriptions of the symptoms need a frame of reference for standardization. The Boyarsky index, a questionnaire consisting of nine questions to quantify the severity of BPH,¹⁷⁴ has been developed. Five questions are designed to assess obstructive symptoms and four to assess irritative symptoms. Although some limitations to the use of this questionnaire (Table 101-5) may exist, it is one of the most common measures used to quantify symptoms in BPH studies¹⁶⁷ and it correlates well with the pathophysiology of BPH. The format of the Boyarsky

Table 101-5 BPH Symptom Scoring System (Boyersky Index)^a

| | |
|---|---|
| Nocturia | |
| 0 | Absence of symptoms |
| 1 | Urinate 1 time/night |
| 2 | Urinate 2–3 times/night |
| 3 | Urinate ≥ 4 times/night |
| Daytime Frequency | |
| 0 | Urinate 1–4 times/day |
| 1 | Urinate 5–7 times/day |
| 2 | Urinate 8–12 times/day |
| 3 | Urinate ≥ 13 times/day |
| Hesitance (lasts ≥ 1 min) | |
| 0 | Occasional ($\leq 20\%$ of the time) |
| 1 | Moderate (20%–50% of the time) |
| 2 | Frequent ($\geq 50\%$ of the time) |
| 3 | Always present |
| Intermittency (lasts \geq min) | |
| 0 | Occasional ($\leq 20\%$ of the time) |
| 1 | Moderate (20%–50% of the time) |
| 2 | Frequent ($\geq 50\%$ of the time) |
| 3 | Always present |
| Terminal Dribbling (at end of voiding) | |
| 0 | Occasional ($\leq 20\%$ of the time) |
| 1 | Moderate (20%–50% of the time) |
| 2 | Frequent ($\geq 50\%$ of the time) |
| 3 | Always present (may wet clothes) |
| Urgency | |
| 0 | Absence |
| 1 | Occasionally difficult to postpone urination |
| 2 | Frequently difficult to postpone urination |
| 3 | Always difficult to postpone urination |
| Impairment of Size and Force of Urinary Stream | |
| 0 | Absence |
| 1 | Impaired trajectory |
| 2 | Most of the time size and force are restricted |
| 3 | Urinate with great effort and stream is interrupted |
| Dysuria | |
| 0 | Absence |
| 1 | Occasional burning sensation during urination |
| 2 | Frequent ($> 50\%$ of the time) burning sensation |
| 3 | Frequent and painful burning sensation during urination |
| Sensation of Incomplete Voiding | |
| 0 | Absence |
| 1 | Occasional sensation |
| 2 | Frequent ($> 50\%$ of the time) sensation |
| 3 | Constant and urgent sensation, no relief on voiding |

^aSymptom scoring provides the clinician with a tool to measure the relative need for, and efficacy of, different interventions. No specific score is associated with the need for a specific intervention. A low symptom score in the absence of significant urine retention generally indicates that medical management can be attempted before considering surgical intervention.¹⁷⁴ BPH, benign prostatic hyperplasia.

index is designed to help the clinician educate the patient about the obstructive and irritative symptoms of BPH. The Boyersky index was the first of three patient questionnaires developed to quantitatively assess BPH and the effectiveness of individual treatment.¹⁷¹ As such, this questionnaire has been used in numerous clinical trials to measure the outcome of interventions. The Boyersky index is not useful in comparing different treatment therapies among BPH patients, because it has not been sufficiently validated for this purpose; rather, it is useful in evaluating an individual's response to therapy.

The Multidisciplinary Measurements Committee of the American Urologic Association (AUA) also has published a Urinary Symptom Index for Prostatism¹⁷⁵ (Table 101-6). The AUA recognized the importance of a validated symptom index for assessing the baseline severity of prostatism, disease progression, and the effectiveness of different therapies. The AUA symptom index allows comparison between therapies and is the preferred questionnaire for BPH research. It has been validated through internal consistency reliability, constructive reliability, test-retest reliability, and criterion reliability.¹⁷¹ The AUA index, however, may not be BPH specific.¹⁷⁶ When 101 men and 96 women between the ages of 55 and 79 used the AUA index, urinary symptoms and severity of urinary symptoms were similar in both groups. Therefore, symptoms associated with prostatism can be associated with aging as well as BPH. The National Institutes of Health (NIH) convened a chronic prostatitis workshop to come to consensus on a new classification system for the diagnosis and management of prostatitis.¹⁷⁷ This group developed a symptom index that provides a valid outcome measure for men with prostatitis. This index attempts to quantify the pain and discomfort associated with prostatism, and should help differentiate prostatism from prostatic hyperplasia. The symptom index is self-administered.

G.M. presents with obstructive symptoms consistent with BPH as follows: (a) a history of difficulty in initiating urination (hesitancy), (b) a decrease in urinary force, (c) occasional midstream stoppage, (d) postvoiding dribbling, and (e) a feeling of incomplete bladder emptying. The common obstructive symptom of decreased force and size of urine stream is caused by urethral compression from prostate gland hyperplasia. Hesitancy, another obstructive symptom, is the result of the bladder detrusor muscle taking a longer time to generate the initial increased pressure to overcome urethral resistance. Urinary stream intermittency is caused by the inability of the bladder detrusor muscle to sustain the increased pressure until the end of voiding. Terminal dribbling and incomplete emptying occur for the same reason, but also may be caused by obstructive prostatic tissue at the bladder neck, causing a "ball valve" effect.

G.M. also has a history of classic irritative symptoms that are consistent with BPH as follows: (a) nocturia approximately four to five times a night and (b) daytime urinary frequency of 8 to 10 times a day. Incomplete emptying of the bladder results in shorter intervals between voiding, explaining the complaint of frequency. Also, a large prostate gland provokes the bladder to trigger a voiding response more frequently. This response is more pronounced if the prostate is growing intravesically and compromising the bladder volume. Bladder detrusor muscle becomes hypertrophied as a result of the greater bladder residual urine volume, which can result in increased detrusor muscle excitability. Clinically, this excitability may result in bladder instability. The symptoms of urinary frequency are

Table 101-6 American Urological Association (AUA) Urinary Symptom Index for Prostatism

| Symptom | Score | | | | | |
|--|------------|---------------|---------------|-----------|---------------|---------------|
| | Not at All | <1 in 5 Times | <1/2 the Time | =1/2 Time | >1/2 the Time | Almost Always |
| 1. Over the past month or so, how often have you had a sensation of not emptying your bladder completely after you finished urinating? | 0 | 1 | 2 | 3 | 4 | 5 |
| 2. Over the past month or so, how often have you had to urinate again <2 hr after you finished urinating? | 0 | 1 | 2 | 3 | 4 | 5 |
| 3. Over the past month or so, how often have you found you stopped and started several times when you urinated? | 0 | 1 | 2 | 3 | 4 | 5 |
| 4. Over the past month or so, how often have you found it difficult to postpone urination? | 0 | 1 | 2 | 3 | 4 | 5 |
| 5. Over the past month or so, how often have you had a weak urinary stream? | 0 | 1 | 2 | 3 | 4 | 5 |
| 6. Over the past month or so, how often have you had to push or strain to begin urination? | 0 | 1 | 2 | 3 | 4 | 5 |
| 7. Over the past month or so, how many times did you most times typically get up to urinate from the time you went to bed at night until the time you got up in the morning? | 0 times | 1 time | 2 times | 3 times | 4 times | 5 times |

Interpretation of AUA Symptom Index

AUA Symptom Score = Sum of questions 1–7 = _____

Mild prostatism ≤ 7

Moderate prostatism 8–18

Severe prostatism > 18

Highest possible score 35

Reprinted from reference 325, with permission.

more pronounced at night because cortical inhibitions are lessened and bladder sphincter tone is more relaxed during sleep. Obstructive symptoms are associated more with an enlarged prostate, and the predominance of irritative symptoms could suggest voiding dysfunctions in addition to those of BPH.

Urinary incontinence is not a common symptom of BPH. With advanced BPH, a large residual volume of urine in the bladder weakens the bladder sphincter and allows the escape of small amounts of urine when the bladder is full. As the residual bladder volume increases, the ureters will dilate, resulting in stasis of urine in the ureters. The end result may be ascending hydronephrosis caused by the transmission of high pressure to nephrons, which produces renal damage (Fig. 101-3). This can account for abdominal discomfort and flank pain during voiding and ascending urinary tract infections.

Acute urinary retention in BPH can occur as a result of increasing size of the prostate gland. Independent of gland size, drugs may precipitate acute urinary retention. Drugs, such as alcohol, anticholinergic agents, α -adrenergic agents, and neuroleptics, all have been associated with acute urinary retention in men with BPH. Commonly, when advanced BPH is present, acute urinary retention is exacerbated if the patient does not void at the first sign of urgency. G.M. is not taking any drugs commonly associated with urinary retention.

Clinical Findings

21. What objective findings in G.M. are associated with BPH?

G.M. presents with classic symptoms of BPH. The increasingly severe symptoms culminated in an episode of acute uri-

nary retention as evidenced by inability to void and lower abdominal discomfort. Objective symptoms associated with G.M.'s BPH include: (a) abdominal tenderness with increased dullness in the hypogastrium; (b) the finding of an enlarged bladder; (c) an enlarged, firm, and rubbery prostate gland; and (d) a return of 900 mL of urine via urinary catheter. The normal serum acid phosphatase, slightly elevated PSA, and digital rectal examination of the prostate suggest that G.M. does not have prostatic carcinoma at this time (see following section). The elevated BUN and serum creatinine may suggest hydronephrosis as a result of his BPH.

Urinalysis

Because patients with BPH also may have a urinary tract infection, a urinalysis with microscopic examination is essential. It is mandatory that G.M. give a urine specimen for urinalysis before the digital rectal examination of the prostate gland, because examination of the prostate causes prostatic secretions to be expelled into the urethra, which may contaminate the urine specimen and make it difficult to determine the source of an infection. The presence of WBC and bacteria in the urine necessitates a workup for infection. Similarly, hematuria requires a workup for urinary tract pathology other than BPH. Because BPH also can cause hydronephrosis, renal function and serum electrolytes should be evaluated.

Digital Rectal Examination

A serum PSA followed by a digital rectal examination of the prostate remains a fundamental part of evaluating a man with prostatism. The prostate examination should determine the size, shape, consistency, and nodularity of this gland. Prostatic

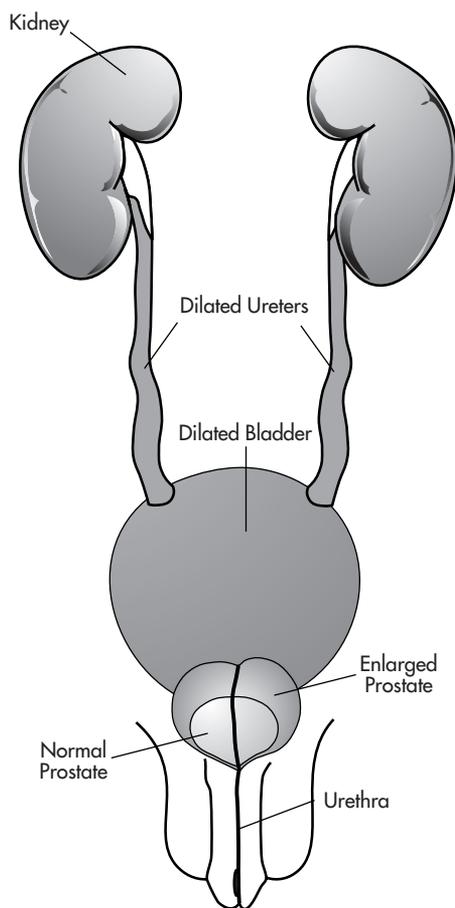

FIGURE 101-3 Flow of urine is interrupted by compression from a prostate that has enlarged from normal size. In this diagram, the ureters and bladder are dilated by backed-up urine.

hyperplasia results in a large, palpable prostate with a smooth mucosal surface rectally. The discernment of the right and left prostate lobes is lost in BPH. The digital rectal examination of a patient with BPH commonly finds asymmetry of the prostate, with one side being larger than the other. Prostatic enlargement can be in both an anteroposterior and a superoinferior direction. As a result, on digital rectal examination, the upper extent of prostate hyperplasia is not palpable. Occasionally, the degree of enlargement felt by digital rectal examination may be misleading, because a substantial portion of enlargement may be intravesical. The consistency of the gland may be soft or firm, depending on the predominance of glandular or fibromuscular elements.¹⁷⁸ The presence of firm-to-hard nodules; irregularities; induration; or a stony, hard prostate suggests possible prostate cancer. In those cases in which the prostate gland size or shape may be questioned, the patient should have a transrectal ultrasound (TRUS) to determine the gland volume.

Prostate-Specific Antigen

Prostate-specific antigen is a glycoprotein enzyme (molecular weight, 33,000) that is secreted in the cytoplasm of the prostatic cells; it aids in the liquefaction of semen. Some claim that this enzyme is specific for prostate origin, although a few isolated instances of elevation in nonprostate tumors have been reported. PSA correlates reasonably well, on average, with prostate weight owing to benign prostate glandular

Table 101-7 Age-Adjusted PSA Values

| Age Range (yr) | PSA Upper Limit (ng/mL) | PSA Density |
|----------------|-------------------------|-------------|
| 40–49 | 2.5 | 0.08 |
| 50–59 | 3.5 | 0.10 |
| 60–69 | 4.5 | 0.11 |
| 70–79 | 6.5 | 0.13 |

PSA, prostate-specific antigen.

hyperplasia.¹⁷⁹ Prostate cancer, however, produces approximately 10 times the amount of PSA on a tissue volume basis than does BPH.¹⁸⁰ For the past decade, men 50 years of age or older have been encouraged to have an annual measurement of serum PSA and a digital rectal examination, as a basic screen for prostate cancer and to monitor the growth of the prostate gland. Several investigators have proposed age-adjusted PSA reference ranges, which reflect the size of the prostate gland^{181–183} (Table 101-7). Studies have resulted in several formulas that try to adjust the PSA for the effect of BPH. The best-known formula for predicting the PSA level (PSA serum density) is as follows¹⁸⁴:

$$\text{PSA (in ng/mL or mcg/mL)} = 0.12 \times \text{gland volume (in cubic centimeters [cc] by transrectal ultrasound [TRUS])}$$

$$\text{TRUS gland volume} = \text{prostate height} \times \text{width} \times \text{length} \times 0.523$$

The PSA result for G.M. is slightly above the upper limit for his age. As such, he should have a TRUS to determine the prostate gland volume and hence, the PSA density. Once the prostate gland volume is determined, the significance of his PSA level of 7.1 can be determined.

Radiologic and Imaging Studies

22. Why should G.M. have his urinary tract evaluated with radiologic and imaging studies?

Visualization of the kidneys, ureters, and bladder (KUB) with intravenous pyelography (IVP) is commonly used to evaluate BPH in some institutions. The routine use of IVP is being questioned, however, because this procedure does not visualize the bladder outlet during voiding and therefore cannot be used to detect obstruction directly. As noted, G.M. is suspected of having hydronephrosis because his BUN and serum creatinine are elevated. Thus, the nephrotoxic risk of IVP may outweigh its potential benefit.^{185–187} Furthermore, when hydronephrosis is a concern, ultrasound is the preferred diagnostic maneuver, because it spares the patient exposure to radiation and possible adverse reactions to the contrast agent.¹⁸⁸ Presently, the consensus is that IVP is warranted only if hematuria is present.¹⁷⁸ Computed tomographic (CT) scanning and magnetic resonance imaging (MRI) have little value in BPH assessment.

Urodynamic Evaluation and Cystoscopy

23. Why should G.M. have urodynamic evaluation and cystoscopy for his BPH?

Because G.M. may be scheduled for a surgical procedure, it is important to determine the extent of urinary flow

obstruction and the urinary flow rate. An accurate determination of the urinary peak flow rate and the voided volume correlated with G.M.'s history will be useful in determining the degree of his urinary obstruction. Urodynamic evaluation involves assessing the urinary flow rate, bladder volume, detrusor pressure, and visualization of voiding. Peak *urinary flow rate* to assess prostatism is a useful method because it is non-invasive and requires only simple and inexpensive equipment.

The urinary flow rate depends on bladder volume,¹⁸⁹ and a nomogram that corrects for age has been developed.^{190,191} Flow rate represents the contributions of bladder contraction and outlet opening during voiding. A low flow rate may reflect diminished bladder contractility (e.g., owing to aging, disease, medications) or outlet obstruction. Thus, a low flow rate is not specific and cannot differentiate bladder outlet obstruction from an underactive detrusor muscle, nor does it discriminate well between those who will and those who will not benefit from surgery.¹⁹⁰⁻¹⁹² The use of urinary flow rates as predictors of surgery outcomes is controversial. Kadow et al.¹⁹³ found no significant difference in symptomatic outcomes from surgery when comparing pre-surgery urinary flow rates. In addition, although flow rates tend to improve after surgery, wide individual variation is seen, and an increased postoperative peak flow does not always correlate with symptom relief.¹⁹⁴

Voiding cystourethrography involves retrograde filling of the bladder with a contrast agent, followed by visualization of the bladder and urethra during the resting, voiding, and postvoiding phases. Although this procedure has the same problems as the IVP, it does have the advantage of providing a dynamic evaluation of the urethral outlet during micturition.¹⁷⁸ Voiding cystourethrography often is performed by technicians and read by radiologists who might not be well trained in lower urinary tract physiology and who therefore do not provide sensitive analyses.

Despite its utility, pressure–flow analysis is not widely used in the evaluation of prostatism because the patient must be able to forestall voiding during bladder filling, and then void on command. As a result, interpretable data are obtained in only 60% to 86% of cases analyzed in optimal laboratory settings.¹⁹⁵

Cystoscopy is used in prostatism to rule out intravesical pathology such as tumors or stones that also cause voiding symptoms and to evaluate bladder trabeculation, prostatic length and size, the presence of an enlarged median lobe, and the degree of obstruction. As with an IVP, cystoscopy is required if hematuria is present and also should be considered whenever there is pelvic pain with voiding.

In making treatment decisions, the roles of intravenous urography, the visual appearance of the prostate via cystoscopy, urodynamic studies, urine flow measurements, and the degree of obstructive and irritative voiding symptoms, collectively, remain controversial and do not provide data sufficient to dictate the best treatment for the patient.^{196,197} Therefore, these tests are not necessary for G.M.

Nonpharmacologic Treatment

Transurethral Resection of the Prostate

24. What nonpharmacologic treatment is best for G.M.? When should prostate surgery be undertaken in general?

G.M.'s subjective and objective findings, particularly the acute urinary retention and hydronephrosis, collectively indicate the need for a transurethral resection of the prostate gland. G.M. has been advised by his urologist that a TURP is the treatment of choice given the severity of his presentation (e.g., large prostate gland with acute urinary retention) and that the procedure will relieve his symptoms, allow him to lead a relatively normal life, and avoid sequelae of prolonged obstruction.

Transurethral resection of prostate provides significant relief of BPH symptoms in 86%, 83%, 75%, and 75% of patients at 3 months, 1 year, 3 years, and 7 years, respectively.¹⁹⁷ Of patients with severe BPH, 93% report reduced symptoms 1 year after a TURP.¹⁹⁶ The TURP is considered the “gold standard” for the treatment of BPH and is used in 90% of patients with symptoms of residual urine or acute urinary retention.¹⁶⁷ As a result, surgical alternatives are always compared with the outcome studies of TURP.

The need for a TURP in G.M.'s situation is fairly clear. In most cases, however, the need for a TURP is less clear because the symptoms do not inevitably worsen and men often are willing to live with their symptoms. Therefore, clinicians need to be able to talk with patients and help them answer the question of whether the discomfort, risk, and problems during the postsurgical recovery period are outweighed by the high probability that surgery will relieve symptoms. After conditions that clearly require surgery have been ruled out, the severity of a patient's symptoms and the degree to which they interfere with living a normal life are the dominant factors in any decision to proceed with prostate surgery. Because surgery for prostate enlargement most often is performed to improve the patient's quality of life, clinicians must counsel patients and help them make the decision. For a comparison of common surgical treatments please refer to Table 101-8.

Drug Therapy

α₁-Adrenergic Receptor Antagonists

25. What drug therapy should be prescribed to treat G.M.'s prostatic hyperplasia?

G.M. most likely will be scheduled for a TURP, because he presents with acute urinary retention and hydronephrosis owing to a moderately enlarged prostate gland (i.e., >40 g and <80 g). He should be started and maintained on an α₁-adrenergic receptor antagonist to reduce the tension of the bladder neck, the prostate adenoma, and the prostatic capsule. Similarly, he should receive finasteride to induce atrophy of the prostate gland and halt progression of the disease.

The prostatic capsule and BPH adenoma have plentiful α_{1A}-adrenergic receptors. The three known subtypes of the α₁-adrenergic receptor are α_{1A}, α_{1B}, and α_{1D}. Inhibiting the α_{1A}-adrenergic receptors can reduce the smooth muscle tone of the prostatic urethra, thereby reducing the functional component of urethral constriction and obstruction.

Phenoxybenzamine (Dibenzylamine), a nonselective α-antagonist, has been 80% effective in increasing urinary flow rates, but its use is hampered by a 30% incidence of side effects (fatigue, dizziness, hypotension), which are exacerbated by its long half-life.^{198,199} The dose of phenoxybenzamine is 5 to 20 mg/day orally. Prazosin (Minipress) 2 to 4 mg/day is more α_{1A}-selective and is less likely to cause side effects compared

Table 101-8 Common Procedures

| Therapy | Brief Description | Comments |
|--|--|--|
| Transurethral resection of the prostate (TURP) | A resectoscope is inserted into the urethra and obstructing tissue is removed a piece at a time. | Post-TURP syndrome: potentially life threatening, caused by the absorption of irrigating fluid. Cerebral edema and seizures may result from hypervolemia and hyponatremia. Late complications: erectile dysfunction (up to 30%), urinary incontinence, and bladder neck contractures, retrograde ejaculation. |
| Transurethral incision of the prostate (TUIP) | Shallow incisions in the prostatic urethra area relieve bladder outflow obstruction. | Advantageous in high-risk patients such as the elderly because it can be performed under local anesthesia. |
| Transurethral dilation of the prostate (TUDP) | Balloon catheter is positioned in the prostatic urethra and inflated. | Appropriate for men with smaller prostates who wish to avoid potential side effects of other procedures. |
| Visual laser ablation of the prostate gland (VLAP) | Laser is used to partially remove obstructing prostate. | Used in men with smaller prostates. |
| Transurethral microwave hyperthermia | Local microwave hyperthermia, delivered transurethrally or transrectally. | Not as effective as surgical therapy but can be completed as an outpatient in 1 hour. |

with phenoxybenzamine. The clinical efficacy of prazosin in improving urinary flow rates is somewhat less impressive.¹⁹⁹ Prazosin should be avoided in elderly patients because of its side effect profile, including high risk for first-dose syncope, and need for multiple daily doses.

TERAZOSIN

Terazosin (Hytrin), a long-acting α_{1A} -adrenergic receptor antagonist, has significantly reduced obstructive symptoms and improved urinary flow rates at doses of 1 to 5 mg/day (Table 101-9).^{171,200} The α_{1A} -blockade alone does not account for the long-term clinical responses exerted by this drug in the treatment of benign prostatic hyperplasia. Terazosin has been shown to induce prostate smooth muscle cell apoptosis resulting in reducing urinary symptoms. Terazosin (and doxazosin) has a quinazoline nucleus, which may account for this effect. Tamsulosin, which is not a quinazoline, does not induce prostate smooth muscle cell apoptosis.²⁰³

In most patients, the dose of terazosin will need to be increased to 5 to 10 mg/day to obtain desired results. Orthostatic hypotension, however, may occur in the beginning days of ther-

apy or during dosage adjustment periods. In patients who, for whatever reason, stop their terazosin therapy for 2 or more days, therapy should be reinstated cautiously to avoid the “first-dose” adverse effect of syncope.

Terazosin maintained the level of improvement in BPH symptom scores over a 30-month period. Only 10% of the patients experienced treatment failure.¹⁷¹ In this long-term study, the systolic blood pressure in normotensive and hypertensive patients was decreased by 4 and 18 mmHg, respectively. Apparently, terazosin typically only lowered the blood pressure significantly in the hypertensive patients.

Terazosin commonly is prescribed with finasteride to control the progression and symptoms of BPH despite the lack of adequate clinical studies.²⁰⁴ The mechanisms of action for both of these drugs are different, and the combined use of both produces a synergistic effect. When combined with finasteride, a smaller terazosin maintenance dose (1–5 mg/day) can be used, resulting in fewer dose-related side effects (e.g., orthostatic hypotension and dizziness).

DOXAZOSIN

Doxazosin (Cardura), another quinazoline derivative, is a long-acting selective α_{1A} -adrenergic receptor antagonist structurally related to prazosin and terazosin (Table 101-9). Doxazosin originally was prescribed primarily for hypertension and currently is not considered a first-line antihypertensive agent. (For a discussion of the current use of α -blocker in hypertension, see Chapter 13 Essential Hypertension.) Hypertension and BPH are linked by the sympathetic nervous system. As with terazosin, doxazosin improves urinary flow rates and symptoms in patients with BPH. These effects have been demonstrated in controlled clinical studies, within weeks, and over the long term. Doxazosin should be started at 1 mg/day. After 1 to 2 weeks, the dose can be increased over several weeks to 8 mg/day. As with other long-acting α_1 -adrenergic receptor antagonists, the first dose should be taken at bedtime to minimize lightheadedness and syncope (the first-dose effect), and the blood pressure of the patient should be monitored periodically during therapy. Most patients require between 4 and 8 mg/day for effective control of the urinary symptoms of BPH. Dosages >4 mg/day are associated with a greater frequency of dizziness, orthostatic hypotension, and syncope.^{200,201}

Table 101-9 Drug Therapy of Persistent Urinary Incontinence

| Type | Treatment With Initial Doses |
|------------|--|
| Urge | Oxybutynin 2.5 mg QD–TID; 5–30 mg XL Tolterodine 1–2 mg QD; 2–4 LA QD Trospium 20 mg BID Darifenacin 7.5 mg QD Solifenacin 5 mg QD |
| Stress | Pseudoephedrine 15–30 mg BID–TID Imipramine 25 mg QD Vaginal estrogen cream 0.5–1.0 g two times/wk |
| Overflow | Terazosin 1–5 mg QD (usually at HS) Doxazosin 1–8 mg QD Tamsulosin 0.4–0.8 mg QD Alfuzosin 10 mg QD Bethanechol 10 mg TID |
| Functional | None |

BID, twice daily; HS, at bedtime; LA, long acting; QD, every day; TID, three times daily; XL, extended release.

TAMSULOSIN

Tamsulosin, a nonquinazoline, is a long-acting α_{1A} -adrenergic receptor antagonist similar to doxazosin, terazosin, and prazosin. Tamsulosin and its metabolites are more specific for the prostatic α_{1A} -adrenergic receptors than any of the other α_{1A} -adrenergic receptor antagonists.²⁰⁵ Apparently, tamsulosin and its metabolites are less specific for the vascular α_{1A} -adrenergic receptors, and therefore cause less orthostatic hypotension than the other agents in the class. Consequently, no need exists to titrate tamsulosin to the recommended daily dose range of 0.4 to 0.8 mg. Coadministration of tamsulosin with antihypertensives does not require dosage adjustment of the antihypertensives. Tamsulosin is very effective in treating bladder outlet obstruction associated with BPH.^{206,207}

More than 90% of tamsulosin is absorbed following oral administration of a 0.4-mg dose under fasting conditions. Administration with food decreases the bioavailability by 30% and increases time to peak plasma concentration. Tamsulosin is hepatically metabolized by CYP isozymes, CYP 3A4 and CYP 2D6.²⁰⁸ Impaired renal function increases total tamsulosin plasma concentration by approximately 100% during steady-state administration. Because active, unbound drug levels are not affected, no dose modification is required in renally impaired patients with symptomatic BPH.²⁰⁹ As with all α_{1A} -adrenergic receptor antagonists, tamsulosin does not affect the PSA and must be taken indefinitely to maintain its therapeutic effect.²¹⁰

ALFUZOSIN

Alfuzosin is a quinazoline α_1 -adrenergic receptor antagonist that is selective for the α_{1A} receptor in the lower urinary tract. Because of alfuzosin's uroselectivity, it has a lower rate of hypotensive effects than doxazosin and terazosin. A lack of penetration of alfuzosin into the brain has been hypothesized to contribute to the decreased CNS effects such as somnolence. Unlike tamsulosin, alfuzosin will not cause ejaculatory dysfunction; the incidence is comparable to placebo.²¹⁰

Androgen Suppression

Considerable information has accrued concerning the endocrine basis for control of BPH (Fig. 101-4), the effect of age on hormone dynamics in men, and the hormonal changes in the hyperplastic human prostate. Maintenance of morphology and functional activity of the adult human prostate is controlled by, and dependent on, androgens. Prostatic regression after androgen deprivation is an active process that requires the synthesis of macromolecules.²¹¹ As a result of androgen deprivation,²¹² the loss of stromal and epithelial prostate cells is disproportionate, with four times greater loss of epithelial cells. Testosterone serves as the pro-hormone for the two active metabolites, DHT and 17- β -estradiol. Testosterone is metabolized to DHT by the enzyme 5 α -reductase (type I and type II). Thus, conversion of testosterone to DHT precludes its conversion to estrogen by the enzyme, aromatase, and the relative activity of these two enzymes is of paramount importance in prostate homeostasis.²¹³

Although the mean plasma testosterone level in men falls after the age of 60, the level of testosterone in subjects with BPH and age-matched controls is not different.²¹⁴ Moreover, the onset of BPH starts some 10 to 20 years before the plasma testosterone levels decrease. The serum concentration of DHT is increased, however, in men with BPH.^{211,215,216} The mech-

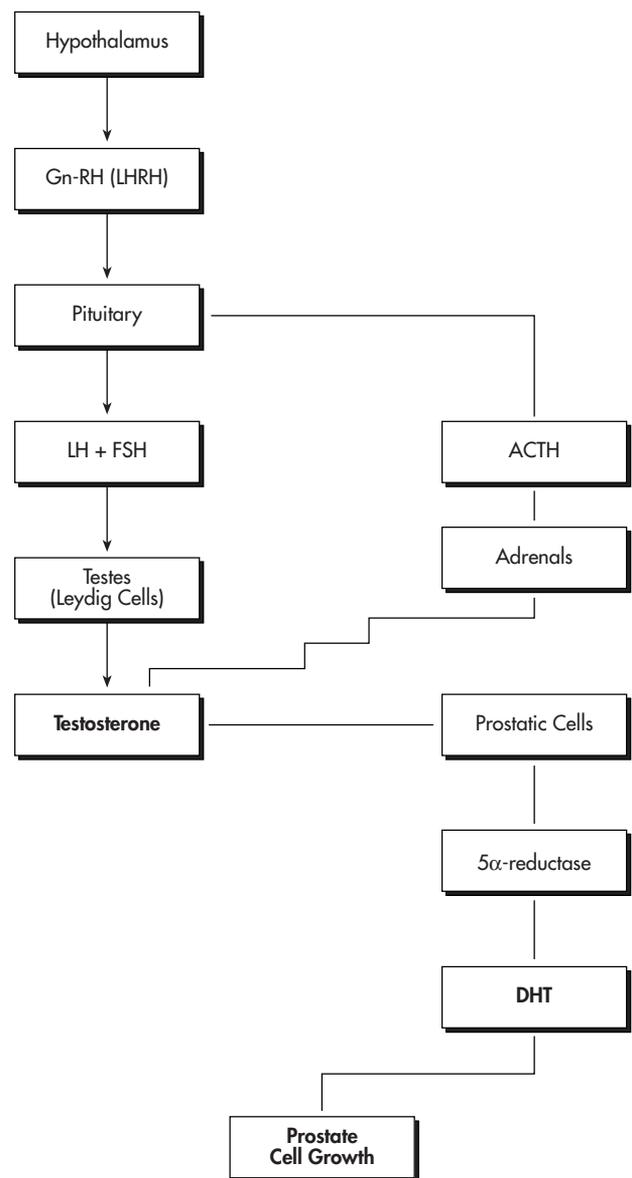

FIGURE 101-4 Pituitary-gonadal axis: endocrine basis for control of benign prostatic hyperplasia (BPH). The pituitary-gonadal axis plays an important role in prostatic growth. Neurons in the preoptic area of the hypothalamus secrete gonadotropin-releasing hormone (Gn-RH), also known as luteinizing hormone-releasing hormone (LHRH). LHRH is a small peptide that interacts with surface receptor sites on the plasma membrane of the pituitary cells. LHRH stimulates the pituitary to release both luteinizing hormone (LH) and follicle-stimulating hormone (FSH). LH secretion causes the Leydig cells of the testicle to produce testosterone. Testosterone appears to inhibit LHRH at the hypothalamic level and LH at the pituitary level. The adrenals only contribute approximately 1% of circulating testosterone. Testosterone diffuses into the prostatic cells, where it is converted to dihydrotestosterone (DHT) by 5 α -reductase. DHT binds to steroid receptor complexes in the nucleus of the prostate, which causes cell growth. ACTH, corticotropin; DHT, dihydrotestosterone; FSH, follicle-stimulating hormone; Gn-RH, gonadotropin-releasing hormone; LH, luteinizing hormone. (From reference 166, with permission.)

anism responsible for accumulation of DHT has not been established, but a significant increase in 5 α -reductase activity occurs, which is known to produce DHT.^{217,218}

One other major hormonal change associated with aging is the increased formation of estrogen from circulating

androgens in both the testes and the peripheral adipose tissue. Androgen conversion to estrogen via aromatase begins in men at approximately the third decade of life and increases with age,²¹⁹ but the plasma estrogen concentration is the same in men with BPH and age-matched controls without BPH.²¹⁵ Estrogen receptors are abundant in stroma cells,^{220,221} more so in patients with prostatic carcinoma than in patients with BPH.²²² Estrogen stimulation of stromal tissue was once believed to explain the prostatic growth that continued with age despite the decline in testosterone secretion by the testes. Progesterone receptors, however, appear to be more abundant than estrogen receptors in the stromal and epithelial cells of prostate tissue of patients with BPH. Thus, progesterone may play a more important role in the pathogenesis of BPH than estrogen. The known effect of DHT in initiating the BPH process is believed to be augmented by estrogen.²²³ The number of prostate androgen receptors can be increased by estrogens and can be reversed by the administration of antiestrogens.²¹⁴ The increase in androgen receptors induced by estrogens may allow for continued androgen-mediated growth despite the declining amount of testosterone produced with old age.

5 α -Reductase Inhibitors

FINASTERIDE

Finasteride (Proscar), a competitive inhibitor of 5 α -reductase (type II), decreases the conversion of testosterone to DHT, the principal androgen responsible for stimulation of prostatic growth. After 7 days of treatment with all doses of finasteride, prostatic tissue DHT declined to $\leq 15\%$ of control levels, and the testosterone concentration increased in a reciprocal manner.²²⁴ When finasteride was administered in 1- and 5-mg doses to men with BPH for a total of 12 months, the symptom score and urinary flow improved significantly. Finasteride 5 mg daily decreased the median prostate volume by 24% and improved the maximal urinary flow rate by 2.9 mL/s.²²⁵ Adverse effects in the finasteride groups occurred in $< 5\%$, and side effects, such as decreased libido and ejaculatory dysfunction, were dose related.²²⁶ The effectiveness of daily finasteride 5 mg was evaluated in 298 men over 24 months.²²⁷ A slight improvement over the results reported at the end of the 12-month period was noted. The median DHT levels had declined by 74.5% compared with 69.3% at 12 months, and prostate volume declined by 25.2% compared with 21.2% at 12 months. Patient symptom scores indicated slightly more improvement at 24 months, compared with 12 months. Obstructive symptom scores were responsible for most of the improved symptoms reported. The prevalence of sexual adverse experiences at 24 months was similar to that at 12 months. In those men who experienced finasteride-induced sexual dysfunction, 50% will experience resolution after discontinuing the medication.²²⁸ Inhibition of DHT by 5 α -reductase inhibitors does not affect testosterone-mediated functions on muscle mass, libido, or spermatogenesis. Thus, finasteride has an acceptable safety profile, halts disease progression, and improves the quality of life in patients with moderate BPH disease (i.e., enlarged prostate with symptoms of urinary obstruction, but not acute urinary retention). Finasteride improves objective pressure flow parameters after 1 year of therapy, and efficacy appears to be greatest in patients with large prostates (> 40 g).²²⁹ For those who do respond, the drug must be continued indefinitely because DHT serum concentrations return to pretreatment levels within 14 days of discontinuing

finasteride, and prostate size returns to pretreatment levels within 4 months.^{230,231}

Unlike leuprolide, finasteride does not affect the histologic features of BPH and prostate cancer.²³² Morphologic evaluation of patients treated with finasteride with symptomatic BPH having adenectomy showed a reduction in the size of the prostate and an increase in the stroma:epithelial and stroma:lumen ratios.²³³

DUTASTERIDE

Dutasteride (Avodart) is a competitive and specific inhibitor of both type I and type II 5 α -reductase isoenzymes. An advantage of dutasteride over finasteride is the additional inhibition of 5 α -reductase (type I) in the peripheral tissues, which produces a further decline in serum DHT. In a prospective study of 2,951 men with moderate to severe BPH, dutasteride 0.5 mg/day decreased DHT serum levels by 90% at 1 month in 58% of patients. At 24 months, 85% of those treated with dutasteride were noted to have a 90% reduction of serum DHT.²³⁴ Correspondingly, the patients noted reduction in urinary symptoms as early as 3 months after treatment and a significant ($p < 0.001$) reduction in symptoms by the sixth month when compared with those treated with placebo. Common side effects of dutasteride are similar to those of finasteride: impotence (4.7%), decreased libido (3.0%), ejaculation disorder (1.4%) and gynecomastia (1.0%).

Antiandrogens: Flutamide

Flutamide (Eulexin) is an orally administered nonsteroidal antiandrogen that inhibits the binding of androgen to its receptor. The safety and efficacy of flutamide were evaluated in a double-blind, placebo-controlled study of 31 male patients with symptomatic BPH.²³⁵ Patients received a daily dose of 375 mg of flutamide for 12 weeks. No significant differences were noted in the treatment and placebo groups with regard to any symptoms of prostatism (force of stream, frequency, nocturia). Based on the digital rectal examination, patients receiving flutamide had a significant reduction of prostate size. Of 15 patients treated with flutamide, 7 developed nipple tenderness and decreased libido. In another study, no significant difference was seen between flutamide and placebo.²³⁶ In this same study, which used flutamide 250 mg three times daily, 53% of the patients experienced breast tenderness and 11% experienced diarrhea. Because flutamide is a potent hepatotoxin in certain patients, serial blood aminotransferase levels should be monitored during the first few months of therapy.²³⁷ Flutamide also is associated with a 50% reduction in the serum concentration of PSA.^{204,236} In summary, flutamide results in toxicity with limited effectiveness; however, its use may be justified in patients who are unable to tolerate a 5 α -reductase inhibitor with or without an α_1 -adrenergic blocker.

Gonadotropin-Releasing Hormone: Leuprolide

Analogs of Gn-RH can cause regression of BPH. Leuprolide acetate (Lupron) is a synthetic nonpeptide analog of natural-occurring Gn-RH. It desensitizes LH-releasing hormone receptors (when given continuously and in therapeutic doses), thereby preventing the release of gonadotropin. Chronic leuprolide acetate therapy will suppress testicular testosterone production, causing a "chemical-like" castration. Because it reversibly binds to Gn-RH receptors, testosterone production resumes when it is discontinued. In a double-blind,

placebo-controlled study, patients with BPH received leuprolide 3.75 mg intramuscularly monthly for 24 weeks.²³⁸ No statistically or clinically significant differences were noted in the percentage change in total, obstructive, or irritative symptoms at 24 weeks between the placebo and leuprolide groups. Detrusor muscle pressure at maximal urine flow was improved at 24 weeks, and prostate volume was reduced. Of those patients receiving leuprolide acetate, 92% developed hot flashes, and of the sexually active patients, 95% experienced a loss of potency.

Leuprolide should be reserved for patients with prostate cancer. Its high cost, questionable effectiveness, and castrationlike adverse effects make it an undesirable choice for treatment of BPH.

Effect of Androgen Suppression on Prostate-Specific Antigen

26. What effect does androgen suppression have on PSA?

The possibility that antiandrogen treatment of BPH could adversely affect the interpretation of the PSA screening test for prostate cancer is of concern. For example, androgen suppression with leuprolide acetate reduces prostate volume primarily by inducing involution of the epithelial elements of the prostate.²³⁹ Because PSA primarily is produced by the epithelial cells of the prostate, these drugs can alter serum and prostate concentrations of PSA.²⁴⁰ Finasteride 5 mg/day also can reduce the serum PSA level by 50%.²⁴¹ Dutasteride reduces total serum PSA by ~40% after 3 months of treatment and by ~50% after 24 months.²³⁴ The serum PSA level reduction is predictable, however, and serum PSA levels can be recalculated during hormonal treatment for BPH. Nevertheless, patients receiving a 5 α -reductase inhibitor should have (a) a digital rectal examination of their prostate periodically, (b) a PSA level measured, and (c) any suspicious findings investigated immediately.²²⁷ Androgen suppression therapy is not contraindicated in BPH solely on the basis of its effect on serum PSA levels.²⁴²

27. What over-the-counter medications are available for prostate disorders?

Two agents, saw palmetto and pygeum, have been promoted for the treatment of BPH. Saw palmetto is an herbal product obtained from the fruit of the *Serenoa repens* tree. The active ingredients are phytosterols; β -sitosterol and β -sitosterol-3-O-glucosides are the most abundant. Saw palmetto has antiandrogen activity. Several trials have shown that it significantly improves benign prostatic hyperplasia symptoms,^{243–246} to a degree similar to finasteride.²⁴⁷ Pygeum (*P. africanum* bark extract) has been observed to moderately reduce urinary symptoms associated with enlargement of the prostate gland.²⁴⁸ Pygeum has been well tolerated in most studies; however, the safety has not been extensively or systematically studied.

URINARY INCONTINENCE

Urinary incontinence, both acute and chronic, is a common disorder among elderly individuals, affecting ~50% of the institutionalized elderly and 20% of the community-dwelling elderly.^{249,250} Neurologic impairment, immobility, female gender, and history of hysterectomy are independent risk factors

Table 101-10 Causes of Incontinence

for incontinence, but neither advanced age nor chronic bacteriuria seem to be. Incontinence has economic costs, and medical (e.g., cystitis, urosepsis, pressure sores, perineal rashes, falls) and psychosocial (e.g., embarrassment, isolation, depression, predisposition to institutionalization) consequences. Nevertheless, incontinence often is a neglected condition. Only a few patients whose lives are seriously disrupted seek medical attention; when they do, their incontinence often is attributed to aging and not evaluated further.^{249,251} Incontinence is not an inevitable consequence of aging. It is a pathologic condition that, when rationally approached, usually can be ameliorated or cured, often without invasive tests or surgery and almost invariably without an indwelling catheter (Table 101-10).^{252,253}

Neurophysiologic Considerations

The bladder can be thought of as a “balloon” with a narrow outlet, wrapped with a muscular layer, the detrusor muscle. The detrusor and the bladder outlet functions are coordinated neurologically to allow for storage and expulsion of urine.²⁵⁴ The detrusor muscle is innervated by the parasympathetic nervous system, and the bladder neck is innervated by the sympathetic nervous system (α -adrenergic) (Fig. 101-5). The proximal smooth muscle (internal) sphincter in the bladder neck also is innervated through the sympathetic nervous system (α -adrenergic). The distal striated muscle (external) sphincter of the urethra is supplied by the somatic nervous system.

Urine storage is the result of detrusor muscle relaxation and closure of both the internal and external sphincters. Detrusor relaxation is accomplished by CNS inhibition of the parasympathetic tone; sphincter closure is mediated by a reflex increase in α -adrenergic and somatic activity. Voiding occurs when detrusor contraction is coordinated with sphincter relaxation. Detrusor contraction is mediated by the parasympathetic nervous system, and relaxation requires inhibition of somatic and sympathetic nerve impulses to the outlet. The bladder capacity is ~300 mL in the elderly and ~400 mL in young adults. The relationship between the detrusor and the outlet is coordinated by a micturition center located in the CNS, perhaps the pons.²⁵⁵ The cortex and diencephalon also permit inhibition of what would otherwise be a reflex contraction of the detrusor muscle in response to bladder distention.

Age-Related Changes

Aging affects the lower urinary tract in several ways (Table 101-11). Structural and functional changes have been observed. Bladder capacity, the ability to postpone voiding, urethral and

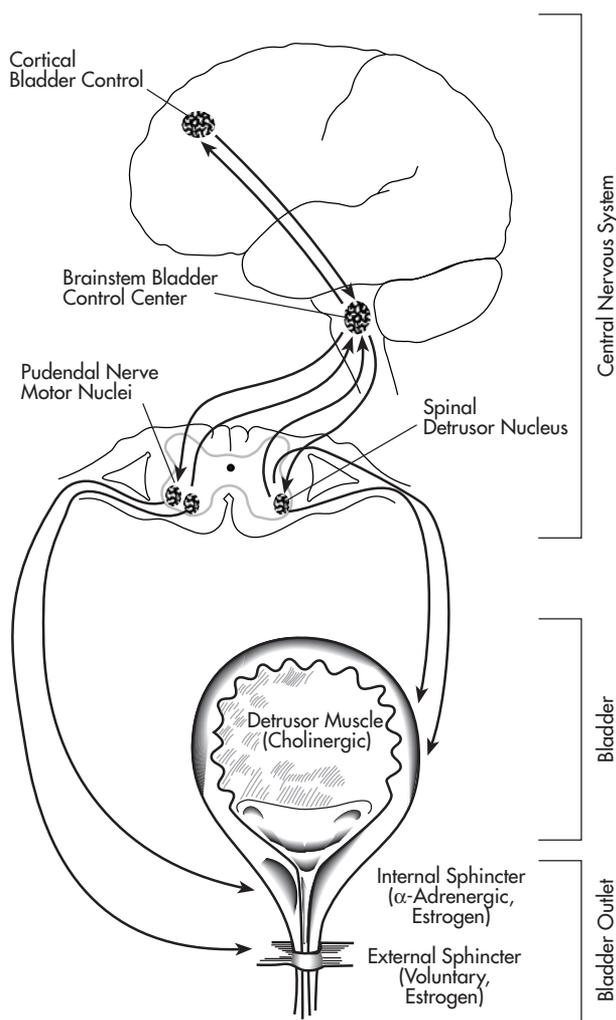

FIGURE 101-5 Neurologic bladder control. Three major components are involved in urine storage and release. (1) Central nervous system: Inhibition from the frontal lobe (cortical) micturition center permits bladder relaxation and filling, and sphincter closure to prevent leakage of urine. When cortical inhibition ceases (i.e., the patient wants to urinate), the brainstem (pontine) micturition center sends impulses down the spinal cord to the detrusor muscle, resulting in muscle contraction. (2) Bladder: Increase in bladder volume stimulates proprioception receptors in the bladder wall and sensory impulses are transmitted through the sacral nerves (S₂–S₄ roots) to trigger bladder contraction. This stimulus for bladder contraction is under inhibitory control by the central nervous system frontal lobe as described previously. Cholinergic stimulation results in bladder contraction. (3) Bladder outlet: The two major factors in maintaining urethral pressure are the internal and external sphincters. Internal sphincter: α-Adrenergic stimulation causes muscle contraction, preventing flow of urine. External sphincter: It consists of striated muscle under voluntary control. Contraction prevents flow of urine. Estrogen deficiency in women can result in decreased competence of the internal and external sphincters. (From reference 326, with permission.)

bladder compliance, maximal urethral closure pressure, and urinary flow rate all are reduced with normal aging.^{255,256} For women, these changes are correlated with the postmenopausal decline of estrogen production. Estrogen has trophic effects on the epithelium and on tissues lining and surrounding the urethra, bladder outlet, and vagina. Atrophy of these tissues can result in friability, inflammation, susceptibility to infec-

Table 101-11 Age-Related Changes in Urologic Function

| Weakness of pelvic floor muscles in women |

tion, diminished periurethral blood flow, and prolapse of pelvic structures. All of these effects can precipitate symptoms of urinary incontinence. For men, the age-related changes in the prostate gland are responsible for many of the changes in urination. The most common age-related change, in both women and men, is involuntary bladder contractions (detrusor motor instability). These involuntary bladder contractions occur in up to 20% of asymptomatic, neurologically normal, continent elderly patients.^{257–260}

In many elderly persons, nocturia is a common complaint and may stem from age-related increases in nocturnal urine production.²⁶¹ Each of these changes predisposes people to incontinence, but none alone precipitates it. This predisposition to incontinence, together with the increased likelihood that an older person will be subjected to additional pathologic, physiologic, or pharmacologic insults, underlies the higher incidence of incontinence in the elderly. The onset or exacerbation of incontinence in an older person is likely to be caused by a precipitating factor outside the lower urinary tract.²⁶² Correspondingly, reversal of the precipitating factor may be sufficient to restore continence without correction of the underlying urologic abnormality.

Drug-Induced Urinary Incontinence

Occasionally, reports of female stress incontinence from α₁-adrenergic receptor antagonists, which have a relaxant effect on urethral smooth muscle, have appeared in the medical literature.^{263–265} In one study, the incidence of genuine stress incontinence was significantly higher in women taking prazosin (86.2%) than in the nonprazosin group (65.7%) ($p < 0.01$). In 55% of the women contacted in the prazosin group, urinary incontinence was reduced or cured by prazosin withdrawal.²⁶⁶ There was a significant increase in functional urethral length, maximal urethral closure pressure, and abdominal pressure transmission to the urethra after prazosin withdrawal. In one case report, switching from doxazosin to enalapril briefly reduced the female patient's stress incontinence; however, she developed a persistent dry cough (from the enalapril) that continued to cause episodic stress incontinence. Her cough and stress incontinence resolved when she was switched to amlodipine.²⁶⁷

Classification

Urinary incontinence can be classified several different ways. The two most basic types of urinary incontinence are *acute (or transient) and reversible* or *chronic and persistent*. Persistent urinary incontinence (PUI), which refers to incontinence that is not acute and occurs over a long period of time, can be

classified further into four subgroups: (a) urge, (b) stress, (c) overflow, and (d) functional.

Acute Incontinence

Urinary incontinence that is of relatively recent onset or associated with an acute medical problem should prompt a review for reversible factors. These include the following: (a) cystitis, atrophic vaginitis, and urethritis; (b) CHF; (c) polyuria from diabetes; (d) delirium and acute confusional states; (e) immobility; and (f) medication side effects. The following medications are associated with acute onset urinary incontinence: diuretics; α -adrenergic agonists (e.g., pseudoephedrine); α -adrenergic antagonists (e.g., terazosin); anticholinergics; and neuroleptics. The management of acute forms of urinary incontinence depends on the identification and elimination of the reversible factor.

For women with urethritis and atrophic vaginitis with irritative voiding symptoms, estrogen replacement can be very helpful. An intravaginal estrogen cream is administered nightly for 7 days, followed by at least once-a-week application.²⁶⁸ For women with an intact uterus, the conjugated estrogen should be given in a cyclic manner with a progestational agent. In keeping with the Women's Health Initiative Trial, serious risks, including breast cancer and cardiovascular disease, appear, however, to outweigh long-term benefits of this combination of hormone therapy.²⁶⁹

Persistent Urinary Incontinence

URGE INCONTINENCE

Urge incontinence, the most common form of incontinence affecting the elderly, occurs when involuntary voiding is preceded by a warning of a few seconds to a few minutes. Urge PUI is characterized by precipitous urine leakage, most often after the urge to void is perceived. Urge PUI can be caused by a variety of genitourinary and neurologic disorders. It most often, but not always, is associated with detrusor motor instability (involuntary contraction of the bladder) or detrusor hyperreflexia (detrusor motor instability caused by a neurologic disorder). The most common causes are local genitourinary conditions, such as cystitis, urethritis, tumors, stones, bladder diverticula, and outflow obstruction. Neurologic disorders, such as stroke, dementia, parkinsonism, and spinal cord injury, can be associated with urge PUI.²⁷⁰

STRESS INCONTINENCE

Stress incontinence, the involuntary leakage that occurs only during stress, is common in elderly women but uncommon in men (unless the sphincter has been damaged during a TURP or prostatectomy). Stress incontinence occurs when an abrupt increase in intra-abdominal pressure (e.g., coughing, sneezing, laughing, lifting) overcomes urethral resistance. Typical stress PUI is characterized by daytime loss of small to moderate amounts of urine, infrequent nocturnal incontinence, and a low postvoiding residual volume in the absence of a large cystocele. The usual cause of stress PUI is urethral hypermobility owing to weakness and laxity of pelvic floor musculature, but other conditions, such as sphincter incompetence, urethral instability, or stress-induced detrusor instability, occasionally are responsible.²⁵⁵ Obesity or TURP in men also can predispose individuals to stress incontinence. Many factors have been suggested to contribute to the development of urinary stress

incontinence in women, including estrogen deficiency and a genetic defect in the connective tissue in such patients. The prevalence of urinary stress incontinence among first-degree relatives of patients with urinary incontinence is three times ($p < 0.005$) that of matched control groups of women without micturition disorders.²⁷¹

OVERFLOW INCONTINENCE

Overflow incontinence occurs when the weight of urine in a distended bladder overcomes outlet resistance. Leakage of small amounts of urine is common throughout the day and night. The patient may complain of hesitancy, diminished and interrupted flow, a need to strain to void, and a sense of incomplete emptying. The bladder usually is palpable, and the residual urine volume is large. If the cause is neurologically mediated, control of the perianal sphincter may be impaired.²⁷²

Overflow incontinence results from an anatomic outlet obstruction or an acontractile bladder.²⁷⁰ Common causes are BPH, urethral stricture, bladder-sphincter dyssynergia, diabetic neuropathy, fecal impaction, and anticholinergic medication use.

FUNCTIONAL INCONTINENCE

Functional incontinence occurs when a continent individual is unable or unwilling to reach the toilet to urinate. Common causes are musculoskeletal disorders, muscle weakness, impaired mental status, use of physical restraints, psychological impairment, environmental barriers, and medications (e.g., sedatives, neuroleptics).

Clinical Presentation and Evaluation

28. H.K., an 83-year-old female resident of a nursing facility, developed urinary incontinence 3 years before admission. She has been managed with adult diapers and bladder training. What objective and subjective data are needed to determine the pathophysiology (and hence the classification) of H.K.'s urinary incontinence?

The rationale for the clinical evaluation of H.K. is to classify the imbalance between bladder pressure and bladder sphincter resistance and, as a result, institute appropriate medical or surgical management of her urinary incontinence.

Documentation of H.K.'s urinary incontinence is accomplished most easily by having her or one of her nurses keep an incontinence record. Observations should be recorded every 2 hours regarding whether the patient is wet or dry, as well as associated symptoms or circumstances. A record maintained over 3 to 4 days will facilitate assessment of the voiding pattern. Knowledge of the voiding pattern can be used to design bladder training programs and to detect iatrogenic causes (e.g., diuretic ingestion, use of restraints). Successful bladder training relies on estimating when the bladder is full.

Physical examination of H.K. is paramount in determining the cause and classification of her urinary incontinence. A complete neurologic examination is mandatory. Clinical findings may identify specific pathophysiologic abnormalities. H.K. should have a thorough pelvic examination to determine the contribution of atrophic vaginitis, uterine prolapse, and bladder anatomy. Funneling of the bladder neck suggests stress incontinence, and palpation of the bladder suggests overflow

incontinence. The presence of physical restraints or musculoskeletal disability would suggest functional incontinence.

H.K.'s bladder should be catheterized immediately after urination to determine residual urine volume. Volumes >50 mL are abnormal and may indicate obstruction or an adynamic detrusor muscle. Although urodynamic studies are widely recommended and used, little evidence suggests that these produce clinically useful data for institutionalized geriatric patients. A urinalysis, blood chemistries, renal function, and glucose tolerance test should be performed. An abnormal urinalysis may suggest pathology (e.g., infection) that can be managed medically. Urinary tract infection is common in the incontinent patient.

Treatment options exist for each type of urinary incontinence (Table 101-9). Proper evaluation should guide the clinician in choosing the optimal course of drug therapy. Drug therapy should be based on sound principles of neurophysiology, urology, and pharmacology. Basically, drug therapy is directed at decreasing bladder contractility (detrusor instability) and increasing outlet obstruction (bladder neck and proximal urethra).

29. The incontinence record maintained by the nursing staff indicates that H.K. has urinary urges quite frequently, resulting in urine leakage. Throughout the day and night, H.K. urinates four to five times. Physical examination reveals atrophic vaginitis, no funneling of the bladder neck, and no bladder distention. H.K. does have a history of stroke. The urinalysis is normal, as are the blood chemistries. Postvoiding bladder catheterization produced a residual urine volume of 30 mL. What is the pathophysiology and classification of H.K.'s incontinence?

Most neuropathic disease processes can change bladder function. As illustrated by H.K., a cerebrovascular accident is commonly associated with bladder dysfunction and incontinence in the elderly. Neurologic injury above the level of the micturition center in the spinal cord, in most cases, results in bladder spasticity. Sacral reflexes are intact, but loss of inhibition from higher CNS centers results in spastic bladder and inappropriate sphincter behavior. The degree of spasticity varies between the bladder and sphincter, as well as from patient to patient with the same CNS lesions. H.K. has a spastic detrusor muscle resulting from an unchecked sacral reflex. H.K.'s bladder dysfunction is classified as urge urinary incontinence of the persistent type.

Drug Therapy

Anticholinergic Agents

30. What drug therapy should be prescribed for H.K.?

H.K. has detrusor instability and requires anticholinergic drug therapy. Detrusor muscle stabilization through pharmacologic intervention and behavioral modification is the treatment of choice for urge PUI. The major neurohormonal stimulus for physiologic bladder muscle contraction is acetylcholine-induced stimulation of postganglionic parasympathetic cholinergic receptor sites on bladder smooth muscle.²⁷³ Atropine and atropinelike substances depress true involuntary bladder contractions of any etiology.²⁷⁴ Other drugs with anticholinergic

properties also have local anesthetic and smooth muscle relaxant effects. These include tolterodine, flavoxate, oxybutynin, and dicyclomine. These drugs act directly on smooth muscle at a site that is metabolically distal to the cholinergic receptor. Because their effectiveness in treating urge incontinence is owing to their muscle relaxant property, rather than their anticholinergic effects, they are classified as antispasmodics.²⁷⁴ All agents in this group should be prescribed for a 2-week trial period. If no improvement has been observed with one drug, trial with another may be appropriate.

OXYBUTYNIN CHLORIDE

Oxybutynin (Ditropan, Generic) is available as an oral immediate-release tablet, an extended-release tablet, or a transdermal system. Oxybutynin is commonly used to produce an anticholinergic effect in the lower urinary tract. The transdermal system contains 36 mg of active drug and delivers 3.9 mg of oxybutynin per day when dosed twice a week.²⁷⁵ The transdermal system should be protected from moisture and humidity. Common side effects from the transdermal system at the application site are pruritus (14%) and site redness (8.3%). A comparison study of immediate-release oxybutynin and the transdermal system indicated that patients using the transdermal system experienced fewer side effects. Dry mouth was reported in 38% of the oxybutynin transdermal system users in contrast to 94% of those who used immediate-release tablets.²⁷⁶

Oxybutynin has been described as a strong independent smooth muscle relaxant with local anesthetic activity that has minor anticholinergic effects.^{274,277} This agent has been used successfully to depress uninhibited detrusor contractions in patients with and without neurogenic bladder dysfunction. Oxybutynin improves total bladder capacity, neuropathic voiding dysfunction, and bladder filling pressure.^{278,279} The dosage of oxybutynin chloride suggested for the elderly is 2.5 mg up to three times a day; in some cases, the dosage may need to be increased to 5 mg three times a day. Because oxybutynin is a tertiary-amine anticholinergic compound, the potential for CNS toxicity increases as the dose is increased. Compared with oral propantheline bromide 15 mg three times a day, a full dose of oral oxybutynin (5 mg three times a day) in one study produced a good response more frequently.²⁸⁰ Once-daily, controlled-release oxybutynin at doses of 5 to 30 mg reduced the number of incontinence episodes.^{16,281} Maximal benefit was demonstrated by maintenance week 4 and was sustained as long as the patient continued therapy.²⁸²

TOLTERODINE TARTRATE

Tolterodine (Detrol, generic Detrol LA) is a competitive muscarinic receptor antagonist (anticholinergic) indicated for the treatment of overactive bladder symptoms of urinary frequency or urge incontinence. At doses of 1 to 2 mg twice a day, compared with a placebo, the number of urinary voids per 24 hours decreased ($p = 0.0045$), the volume of urine per void increased ($p < 0.001$), and the mean number of incontinence episodes decreased by 50% ($p < 0.19$).²⁸³ No clinical or electrocardiographic evidence was seen of significant cardiac adverse events in the group studied. Tolterodine has greater selectivity for the bladder than the salivary glands *in vivo*, which is not attributable to muscarinic receptor subtype selectivity.²⁸⁴

Thus, tolterodine is much less potent in inhibiting salivation, suggesting that it may have less propensity to cause dry mouth in clinical use. The onset of pharmacologic action of tolterodine is <1 hour, and therapeutic efficacy is maintained during long-term treatment. In comparative trials, tolterodine and oxybutynin are equivalent in terms of efficacy, but tolterodine is better tolerated.

Despite short terminal half-lives of 2 to 3 and 3 to 4 hours for tolterodine and its active 5-hydroxy metabolite, respectively, twice-daily dosing is effective because of the drug's long pharmacodynamic effects.²⁸⁵ Dosage adjustment is recommended in the presence of hepatic impairment and during concurrent therapy with drugs that inhibit CYP 2D6 and CYP 3A4 isozymes.

TROSPIUM CHLORIDE

Trospium (Sanctura) is a quaternary ammonium antimuscarinic agent used for the management of overactive bladder and urge incontinence. The hydrophilic properties of trospium minimize the passage of the drug through the blood–brain barrier, thereby causing fewer CNS and cognitive adverse events.²⁸⁶ The long-term efficacy of trospium has been compared with oxybutynin in a 52-week study.²⁸⁷ No significant differences were found in urodynamic outcomes. In addition, the reduction in 24-hour micturition frequency and urgency episodes at 26 and 52 weeks of treatment was not significant. The incidence of dry mouth and gastrointestinal adverse events was significantly lower in the trospium group. The medication should be administered at a dose of 20 mg twice daily and for those patients with severe renal insufficiency (creatinine clearance <30 mL/minute), the dose should be reduced to 20 mg daily.

DARIFENACIN

Darifenacin (Enblex) is a selective M₃ muscarinic receptor antagonist indicated for the treatment of overactive bladder with symptoms of urinary incontinence, urgency, and frequency. A pooled analysis of three 12-week, double-blind, placebo-controlled trials (*N* = 1,059) demonstrated that darifenacin reduced the median number of incontinence episodes per week (*p* <0.01) versus placebo.²⁸⁹ Dry mouth and constipation were the most common reasons for discontinuation. The recommended starting dose is 7.5 mg once daily. Based on the individual response, the dose may be increased to 15 mg daily after 2 weeks.

SOLIFENACIN

Solifenacin (Vesicare) is a competitive muscarinic receptor antagonist used for the treatment of overactive bladder with symptoms of urinary incontinence. In clinical trials solifenacin showed significant reduction in the symptoms of urinary frequency, urgency, and urge incontinence compared with placebo.^{290,291} Safety concerns with solifenacin include an increased risk of QT interval prolongation in patients with a known history of QT interval prolongation or patients who are taking medications known to prolong the QT interval. The recommended dose of solifenacin is 5 mg once daily. If the 5-mg dose is well tolerated, it may be increased to 10 mg once daily.

PROPANTHELINE BROMIDE

Propantheline bromide (Pro-Banthine, generics) is an oral agent prescribed to produce an anticholinergic effect in the lower urinary tract. The adult dose is 15 to 30 mg every 4 to 6 hours. Higher doses sometimes are necessary and are well tolerated. Propantheline bromide is a quaternary ammonium anticholinergic compound that does not cross the blood–brain barrier.²⁷⁴ As such, CNS side effects are insignificant. Oral administration of propantheline in the fasting state is preferred to improve bioavailability. The anticholinergic effects of propantheline on the detrusor muscle when compared with other anticholinergic agents are similar.²⁷⁷ These anticholinergic agents differ primarily in their frequency of dosing and their side effect profiles. No other oral drug, however, is available whose direct anticholinergic binding potential approximates that of atropine.²⁹²

DICYCLOMINE HYDROCHLORIDE

Dicyclomine hydrochloride (Bentyl) is a tertiary-amine and has dose-related CNS effects.²⁷⁴ An oral dose of 20 mg three times a day will increase bladder capacity in patients with detrusor hyperreflexia. The dose for elderly patients is listed as 10 to 20 mg three times a day, but it may need to be increased to 30 mg three times a day.^{277,288} As the dose is increased, anticholinergic side effects become prominent.

FLAVOXATE HYDROCHLORIDE

Evidence for the efficacy of flavoxate hydrochloride (Urispas) is weak. The recommended adult dose is 100 to 200 mg three to four times a day.

β-Adrenergic Agents: Terbutaline

Terbutaline (Brethine) 5 mg orally three times a day reportedly benefits select patients with urge PUI and does not have significant effects on the bladders of healthy persons.²⁹³ The human bladder muscle has *β*-adrenergic receptors that, when stimulated, will increase the capacity of the bladder. The effect of *β*-adrenergic stimulation in patients with detrusor hyperactivity is inadequately studied, however.

Although any of the aforementioned drugs would be useful for H.K., oxybutynin is considered the drug of choice for the elderly. Oxybutynin has fewer anticholinergic effects and a more prominent detrusor relaxation effect than any of the other drugs except tolterodine. Tolterodine is a much more expensive agent when compared with oxybutynin and is best reserved for patients who are intolerant of, or fail, oxybutynin. Oxybutynin can be dosed once a day in some cases and, in most cases, twice a day. Flavoxate, dicyclomine, and propantheline require at least three doses a day. The systemic anticholinergic side effects from oxybutynin, tolterodine, flavoxate, and dicyclomine are relatively mild compared with propantheline. A beginning dose of oxybutynin for H.K. would be 2.5 mg/day; the dose can be increased by increments of 2.5 mg/day, not to exceed 5 mg three times a day.

Monitoring H.K. necessitates evaluating her urinary frequency through patient (and where possible, nurse or caregiver) interviews. Specifically, a reduction in the urinary urgency sensation is the desired outcome. Too much anticholinergic therapy can result in urinary hesitancy and possibly urinary retention. If the patient has to concentrate on the act of micturition,

the anticholinergic drug dose should be reduced. CNS and systemic side effects should be assessed as often as possible. As with all patients with urge incontinent, urinary tract infection is common. If symptoms of dysuria appear, or if urinary urgency reappears, a urinalysis should be obtained.

Increasing Bladder Outlet Resistance

31. M.K., a 68-year-old woman, has been diagnosed with urinary stress incontinence. What drug therapy would be appropriate for this classification of PUI?

IMIPRAMINE HYDROCHLORIDE

Imipramine hydrochloride (Tofranil, generics) is useful for increasing bladder capacity and increasing bladder outlet resistance.²⁹⁴ The pharmacologic mechanism of tricyclic antidepressants (TCA) in treating PUI has been studied extensively.²⁹⁵ The results and conclusions of the data reported demonstrate that, at best, the mechanism of action on the lower urinary tract is speculative. All the TCA have some degree of anticholinergic effect, both centrally and peripherally, but not at all sites. These drugs block the active transport system in the presynaptic nerve ending and prevent the uptake of norepinephrine and serotonin; they produce varying degrees of CNS sedation. All the TCA antagonize histamine receptors, both H₁ and H₂, to some degree, and they desensitize some α_2 -adrenergic receptors.^{295,296} Imipramine has significant systemic anticholinergic effects, but it has weak anticholinergic effects at the detrusor muscle.²⁹⁷ Imipramine has a significant inhibitory effect on the detrusor muscle, however, which is neither anticholinergically nor adrenergically mediated. Its detrusor inhibitory effect may be the result of peripheral blockade of norepinephrine reuptake. The ability of imipramine to increase bladder outlet resistance is believed to be owing to enhanced α -adrenergic effects in the smooth muscle of the bladder base and proximal urethra, where α -receptors outnumber β -receptors. Imipramine 75 mg/day produced continence in 68% of women with stress PUI within 4 weeks.²⁹⁸

The initial dose for imipramine is 25 mg orally at bedtime. The dose can be increased every third day by 25 mg until the patient is continent, side effects occur, or a dose of 150 mg/day is reached.²⁹⁴ Most patients become continent within 7 to 10 days, and some patients may become continent in as few as 3 to 5 days. The usual adult dose for voiding dysfunction is 25 mg four times a day, and for geriatric patients the dose is 25 mg twice a day, because the serum half-life is prolonged in the elderly.²⁹⁹ Weakness, fatigue, and postural hypotension are significant problems associated with imipramine. A threefold

increase in hip fractures was reported among elderly patients taking imipramine.³⁰⁰

α -Adrenergic receptor stimulation at the detrusor muscle and proximal urethra will increase the maximal urethral pressure (MUP) and the maximal urethral closure pressure (MUCP).³⁰¹ Oral α -adrenergic agonist agents should be used cautiously in the elderly because of side effects, which include anxiety, insomnia, blood pressure elevation, headache, tremor, weakness, palpitations, cardiac arrhythmias, and respiratory difficulties.³⁰²

ESTROGENS

Estrogens affect many aspects of uterine smooth muscle, including excitability, receptor density, and transmitter metabolism, especially adrenergic nerves.³⁰³ The detrusor and urethra are embryologically related to the uterus, and significant work has been done on estrogenic hormone effects on the lower urinary tract. α -Adrenergic stimulation of the urethra is estrogen dependent,³⁰⁴ and several studies have demonstrated the relationship of estrogen to α -adrenergic receptor density in the lower urinary tract.³⁰⁵ Estrogen therapy, in the form of vaginal suppositories (1 mg/day), facilitates urinary storage in some postmenopausal patients by increasing urethral outlet resistance and it has an additive effect with α -adrenergic therapy (pseudoephedrine 20 mg three times daily).²⁶³ The use of estrogen in the treatment of stress PUI requires further study. The use of long-term estrogen treatment must be considered carefully in light of the controversy over whether estrogen therapy predisposes to the development of endometrial carcinoma. If estrogen is combined with α -adrenergic agonist therapy, the lowest effective maintenance dose should be prescribed.

Decreasing Bladder Outlet Resistance

Overflow incontinence in female patients resulting from outlet obstruction or weak detrusor muscle is now being treated with α_{1A} -blockers by many urologists. Traditional treatments include cholinergic agents (e.g., bethanechol), Foley catheter, surgical procedures, or urethral caps. α_{1A} -Blockers, such as prazosin, terazosin, or doxazosin, are certainly not the drugs of choice, but they can decrease outflow resistance by decreasing sphincter tone.³⁰⁵ Most α_{1A} -receptors are found in prostate tissue; however, these same receptors are also located in the spinal cord, bladder neck, urethra, and periurethral tissue in women.³⁰⁶ The urinary symptoms suggestive of prostatism are not gender specific. Well-controlled, randomized, cross-over studies are needed to determine the efficacy of α_{1A} -blockers in overflow incontinence.

OSTEOPOROSIS

The term osteoporosis is derived from the Greek words *osteon* (bone) and *poros* (pore).¹ Although osteoporosis has many definitions, the World Health Organization (WHO) defines it as a disease “characterized by low bone mass and microarchitectural deterioration of bone tissue, leading to enhanced bone fragility and a consequent increase in fracture risk.”² Other definitions have been developed to help clinicians diagnose osteoporosis. For example, a WHO working group defined osteoporosis as “the presence of bone mineral density (BMD) or a T score that is 2.5 standard deviations (SD) or more below the mean peak value in young, healthy adults.”^{3,4} Osteopenia, a lesser degree of bone loss, is defined as a T score that is between 1 and 2.5 SD below the mean peak value in young, healthy adults. A Z score (mean value for BMD in normal subjects of the same age and sex) can aid in the diagnosis of osteoporosis. For example, a Z score <-1 at the lumbar spine or proximal femur indicates “a value in the lowest 25% of the reference range, a value at which the risk of fracture is approximately double. A Z score <-2 indicates a value in the lowest 2.5% of the reference range, a level associated with a considerably greater increase in the risk of fracture.”⁴

Incidence and Fracture Sites

Osteoporosis is a major health problem that affects approximately 10 million people in the United States, with 80% of the affected population being women 50 years of age and older. Another estimated 34 million Americans, 50 years and older, are at increased risk for osteoporosis, according to the National Osteoporosis Foundation.⁵ Estimates suggest that by 2010, 52 million Americans will have low bone mass and by 2020 the number may exceed 60 million.⁶ The incidence for osteoporosis increases with age; 30% of women 80 years of age or older develop osteoporosis without medical intervention.⁷

Annually, more than 1.5 million osteoporosis-related fractures occur in elderly Americans.^{5,8} Osteoporosis-related fracture sites predominantly include the vertebrae, distal radius (Colles' fracture), and hips. Approximately 50% of women age 50 years and older will sustain an osteoporosis-related fracture (i.e., fractures of spine, distal forearm, or hip) in their lifetime.⁵ Worldwide disability from hip fracture is projected to exceed 2.5 million people by the year 2025, with a projected 700,000 deaths. Patients who suffer hip fractures have a 12% to 20% higher mortality rate relative to persons of the same sex and similar age without fractures.⁹ In addition, hip fractures

result in a multitude of complications for the elderly, including prolonged hospitalization, decreased independent living, depression, fear of future falls, and lifelong disability. Vertebral fractures may be painless or result in pain that usually lasts <3 months. The initiating injury may be as minor as a cough or turning over in bed. Vertebral collapse or deformity can result in loss of height, kyphosis (dowager's hump), abdominal protrusion, decreased pulmonary function, and chronic back pain.

The annual direct cost for treating osteoporosis and osteoporosis-related fractures in the United States is estimated at \$14 billion per year, compared with \$7.5 billion for heart failure and \$6.2 billion for asthma. This figure will continue to rise in the next 20 years if prevention and early intervention measures do not reduce the incidence of osteoporosis.^{6,10,11} Thus, the impact of osteoporosis on the health care system as the baby-boom generation ages and lifespan increases is potentially staggering.

Physiology

Structurally, bone is either cortical or cancellous (trabecular), with the adult skeleton containing 80% cortical and 20% cancellous bone. Dense cortical bone forms the outer shell of the skeleton, whereas porous cancellous bone forms the interior structures in a honeycombed fashion. The proportions of cortical and cancellous bone vary at different sites in the skeleton, with cortical bone predominating in long bones (~90%) except at their ends, which are predominantly cancellous. This type of bone is also found in the vertebrae and distal forearms. A balance between osteoblast and osteoclast activity results in a continuous remodeling process; osteoclasts resorb bone, whereas osteoblasts help reform bony surfaces and fill bony cavities.

Bone remodeling normally is a continuous process that occurs in discrete skeletal foci called *bone-remodeling units*. This process begins with bone resorption that is initiated by osteoclasts excavating lacuna found on the surface of cancellous bone, or it occurs when cavities are formed in cortical bone (Fig. 102-1). Enzymes produced in this process dissolve bone mineral and proteins. Thereafter, bone formation occurs as os-

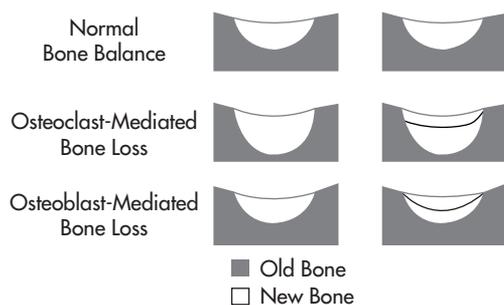

FIGURE 102-1 The bone remodeling cycle at the cellular level. In normal young adults (*top panels*), the bone removed by the osteoclasts (*left*) is replaced completely by the osteoblasts (*right*). In high-turnover bone loss (*middle panels*), such as that which occurs in women soon after menopause, the osteoclasts create a deeper resorption cavity that is not refilled completely. In low-turnover bone loss (*bottom panels*), such as that which occurs with aging, the osteoclasts create a resorption cavity of normal or decreased depth, but the osteoblasts fail to refill it. (From the *New England Journal of Medicine* 1992;372:621, with permission.)

teoblasts gradually refill spaces created during the resorption process. This occurs as collagen fills in bone cavities, which then are calcified.

Calcium and vitamin D are important nutrients required for bone growth. Parathyroid hormone, glucocorticoid hormones, calcitonin, estrogen, and testosterone are all factors involved in bone remodeling.¹² Parathyroid hormone (PTH) and glucocorticoid hormones have been associated with bone resorption, whereas calcitonin, estrogen, and testosterone have been associated with bone formation.¹³ The small intestine is the site for the absorption of dietary calcium; the kidneys reabsorb calcium in the tubular system; and the skeletal system serves as a reservoir for calcium. Calcium is primarily regulated by the actions of PTH, vitamin D, and calcitonin. The parathyroid gland releases PTH in response to low serum calcium levels, which in turn facilitates the mobilization of calcium and phosphate from bone and stimulates reabsorption of calcium through the tubular system in the kidneys.¹⁴ Vitamin D aids in intestinal absorption of calcium as well as phosphorous and magnesium. Increases in vitamin D levels decreases PTH levels. Vitamin D also increases bone resorption to prevent symptomatic hypocalcemia.¹⁵ Calcitonin is released in response to high serum calcium levels. Calcitonin decreases intestinal absorption of calcium and phosphorous, inhibits calcium excretion in the kidneys, and prevents bone resorption (Fig. 102-2).¹⁶

Changes in Bone Mass

Bone mass peaks during the third decade of life. At about 35 years of age, cortical bone gradually begins to decrease 0.3% to 0.5% yearly in both women and men.¹⁷ With menopause, the decline in 17β -estradiol concentrations further accelerates cortical bone loss by 2% to 3% per year that is superimposed on age-related bone loss. This loss gradually decreases over the next 8 to 10 years.¹⁷ This hormone-related, accelerated bone loss can also occur after surgical oophorectomy. Longitudinal data suggest that estrogen may play an important role in the development of osteoporosis in men as well.¹⁸ Serum testosterone concentration has been evaluated in many studies that have failed to connect a strong association between testosterone levels and bone density.^{19,20}

Cancellous bone loss begins between the ages of 30 and 35 with yearly decreases in women of 0.6% to 0.8% (linear decrease) or 2.4% (curvilinear decrease).^{17,21} Age-related cancellous losses in women appear to begin up to a decade earlier than cortical bone loss. The effect of menopause on cancellous bone loss is controversial; some studies indicate an increased rate of loss, whereas others do not.²¹ Thus, early cancellous bone loss in conjunction with postmenopausal decreases in cortical and possibly cancellous bone may lead to increased vertebral and distal forearm fractures, which predominate early after menopause.¹⁷ Men begin to lose bone mass after 30 years of age. Cortical bone in the proximal radius, as well as cortical and trabecular bone in the distal radius, lose content at a rate of approximately 1% annually.²² Spine and hip density also decline with increasing age.^{23,24} Women may lose as much as 50% of cancellous and 30% of cortical bone over their lifetimes, whereas men may lose only 30% and 20%, respectively.^{8,25} In addition, women may have an increased risk for osteoporosis because throughout life they have 30% less bone mass than men of a similar age.²⁶

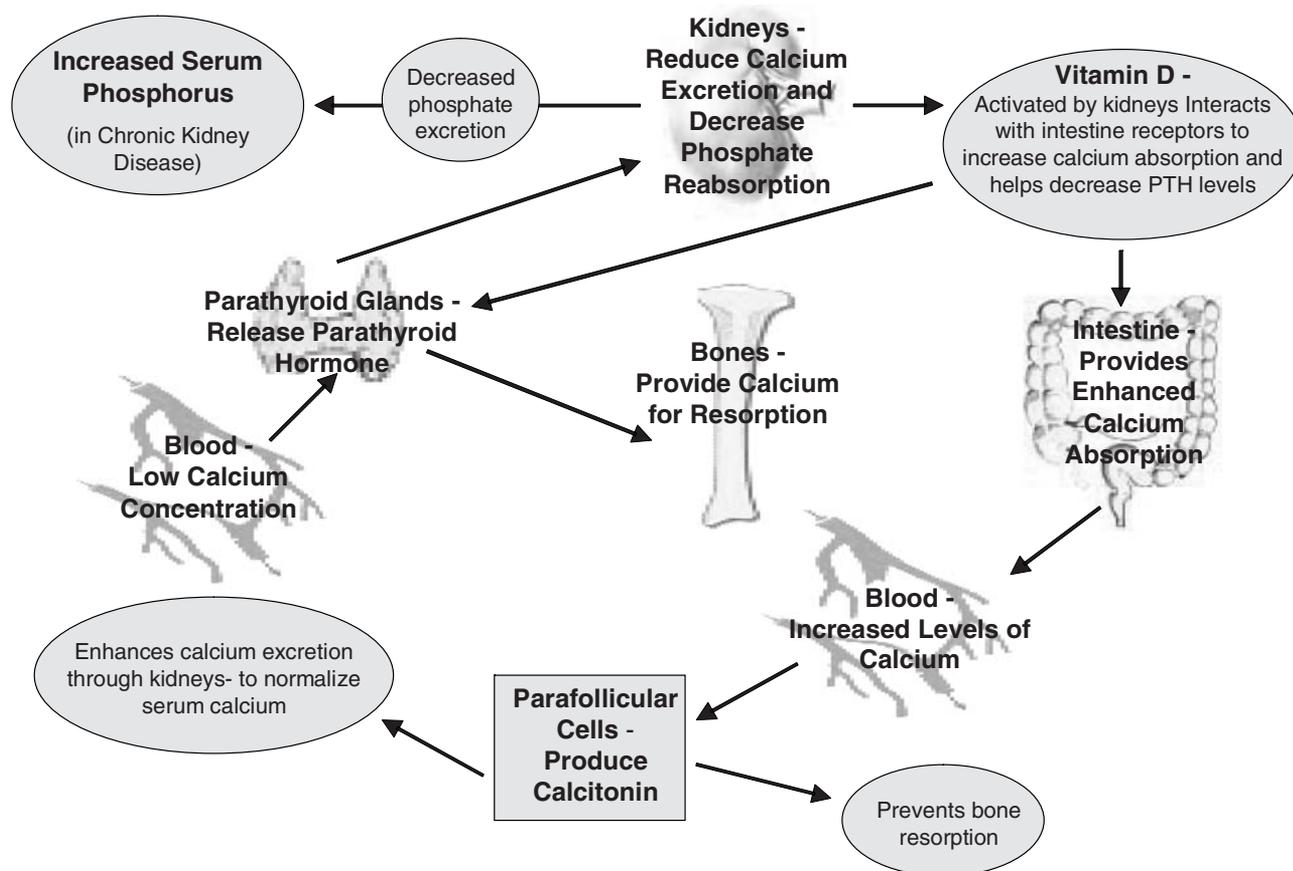

FIGURE 102-2 Pathway for calcium homeostasis with involvement from parathyroid hormone, vitamin D, and calcitonin.

Classification

Osteoporosis can be defined as primary or secondary. Sometimes primary osteoporosis is further classified as type I or II. Type I, *postmenopausal osteoporosis*, is associated with increased cortical and cancellous bone loss resulting from increased bone resorption. It typically occurs in women during the first 3 to 6 years after menopause. Postmenopausal osteoporosis is manifested by vertebral fractures, distal radius fractures, hip fractures, and even an increased tooth loss secondary to osteoporosis of the mandible. Postmenopausal osteoporosis can occur earlier in women who have had an oophorectomy. Type II, *senile osteoporosis*, occurs in both women and men 75 years of age and older with a female:male ratio of 2:1.²¹ Cortical and cancellous bone losses are proportional. These persons are at greatest risk for hip, pelvic, and vertebral fractures.

Secondary osteoporosis results from the use of various medications or the presence of particular disease states (Table 102-1). This type of osteoporosis can occur at any age and is equally common in men and women.

Risk Factors

1. T.J., a 28-year-old, thin white woman, is worried about developing osteoporosis. Her 75-year-old maternal grandmother has osteoporosis and recently her postmenopausal mother (age 53) was told that she was at increased risk for osteoporosis. T.J. is

5 ft 2 in, weighs 108 lbs, and is in good health. She jogs and occasionally does aerobic exercise. Her diet typically consists of cereal for breakfast, a sandwich for lunch, and meat with vegetables for dinner. Her only milk consumption consists of 1 cup of skim milk on her cereal. She occasionally has a dairy product for lunch or

Table 102-1 Risk Factors Associated with the Development of Osteoporosis

| | |
|--|--|
| <ul style="list-style-type: none"> ↑Age Female gender Caucasian or Asian Family history Small stature Low weight | Predisposing medical problems (e.g., chronic liver disease, chronic renal failure, hyperthyroidism, primary hyperparathyroidism, Cushing's syndrome, insulin dependent diabetes, gastrointestinal resection, malabsorption, irritable bowel disease, chronic obstructive pulmonary disease, and acquired immune deficiency syndrome or human immunodeficiency virus) |
| <ul style="list-style-type: none"> Early menopause or oophorectomy Sedentary lifestyle ↓Mobility Low calcium intake Excessive alcohol problems Cigarette smoking | Drugs (e.g., corticosteroids, long-term anticonvulsant therapy [e.g., phenytoin or phenobarbital], excessive use of aluminum-containing antacids, long-term high-dose heparin, furosemide, excessive levothyroxine therapy) |

dinner. T.J. takes no medications, vitamins, or calcium supplement routinely. She occasionally takes a medication for headache or menstrual cramps. She does not smoke cigarettes and occasionally drinks alcohol socially. Does T.J. have an increased risk for developing osteoporosis?

Table 102-1 lists risk factors associated with the development of osteoporosis. T.J. has several risk factors that could increase her risk for osteoporosis. She is a white woman of small stature and low weight, has a positive family history, and has a low calcium intake.

Gender, Race, Heredity, and Body Build

Recent studies suggest that the prevalence of osteoporosis in the United States varies with ethnicity. White and Hispanic Americans (after adjusting for weight, BMD, and other covariates) are at greater risk for osteoporosis than other ethnic or racial groups, especially those who are of small stature, such as T.J., and those who are proportionally underweight for their height.²⁷ The significance of heredity as a risk factor for osteoporosis is being studied. It has been proposed that approximately 75% of the genetic effect on a person's chance to develop osteoporosis is owing to a particular allelic variant in the gene that is responsible for encoding the 1,25-dihydroxyvitamin D receptor.²⁶ Data from a meta-analysis of 16 studies revealed conflicting results on the association of polymorphisms and fracture risk.²⁸ Women with a first-degree relative with osteoporosis typically have low bone mass.²⁹ In addition, black women of African ancestry typically have higher BMD than do white women.²⁷

Mobility and Physical Activity

Immobility owing to prolonged bedrest (especially in the elderly) has been associated with decreased bone mass. Conversely, weight-bearing exercise (e.g., walking, running, step aerobics, lifting weights) helps prevent bone loss. Exercise throughout life helps maintain skeletal mass and may help reduce bone loss in postmenopausal women. Exercise appears to stimulate osteoblastic activity to help maintain bone mass.³⁰ Thirty minutes of weight-bearing exercise three times weekly has been associated with improvements in bone density and a reduced hip fracture risk in older women.³¹

Cigarette Smoking and Alcohol Ingestion

Although T.J. does not smoke and only occasionally ingests alcohol, it is important to include questions concerning cigarette and alcohol use when obtaining a medication history from a person at risk for osteoporosis. Women who smoke, especially those who are thin, have an increased risk for fractures compared with nonsmokers.³² Cigarette smokers may have impaired calcium absorption and lower 17 β -estradiol levels, however, the mechanisms are unknown for affects on bone mass.²⁷

Excessive alcohol use by both women and men may predispose them to low BMD, but it is unclear whether moderate alcohol consumption has an effect on bone mass. Consuming as few as two alcoholic drinks daily significantly increases the fracture risk.³³ The proposed mechanism may be a direct effect of alcohol on osteoblasts, or it may be secondary to nutritional compromise that could result in impaired calcium and vitamin D intakes with subsequent decreased in bone formation.³⁴ Alcoholics also may be at risk for increased falls.

Table 102-2 Calcium Content of Selected Foods

| Food | Serving Size | Calcium (mg) |
|------------------------------|--------------|--------------|
| Dairy Products | | |
| Milk, dry nonfat | 1 cup | 350–450 |
| Yogurt, low fat | 1 cup | 345 |
| Milk, skim | 1 cup | 300 |
| Milk, whole | 1 cup | 250–350 |
| Cheese, cheddar | 1 oz | 211 |
| Cheese, cottage | 1 cup | 211 |
| Cheese, American | 1 oz | 195 |
| Cheese, Swiss | 1 oz | 270 |
| Ice cream or ice milk | 1/2 cup | 50–150 |
| Fish | | |
| Sardines, in oil | 8 med | 354 |
| Salmon, canned (pink) | 3 oz | 167 |
| Fruits and Vegetables | | |
| Calcium fortified juices | 1 cup | 100–350 |
| Spinach, fresh cooked | 1/2 cup | 245 |
| Broccoli, cooked | 1 cup | 100 |
| Collards, turnip greens | 1/2 cup | 175 |
| Soy beans, cooked | 1 cup | 131 |
| Tofu | 1 oz | 75 |
| Kale | 1/2 cup | 50–150 |

Dietary Intake

Calcium, in conjunction with vitamin D, is needed to strengthen bones, increase bone mass, and decrease fracture rates. Girls and women such as T.J. need an adequate calcium intake to achieve and help maintain optimal bone mass, but the typical American diet is low in calcium. The National Academy of Sciences published recommendations for calcium intakes based on age. For example, they recommended 1,000 mg/day of elemental calcium for women <51 years of age.³⁵ The National Institutes of Health (NIH) recommend the same amount of calcium for women in this age group.³⁶ Calcium is best ingested from the diet (Table 102-2 lists the calcium content of various foods), but if the diet is low in calcium, supplements can be used (Table 102-3; see Questions 2 and 3). A diet high in caffeine, protein, phosphorous and sodium has been associated with an increased risk of fractures by adversely effecting calcium balance.³⁷ Many studies have, however, found conflicting results. Patients with adequate calcium intake may negate the effects of these dietary risks.^{37–42}

Table 102-3 Percentage of Calcium in Various Salts

| Salt | % Calcium |
|--|-----------|
| Calcium carbonate | 40 |
| Tricalcium phosphate (calcium phosphate, tribasic) | 39 |
| Calcium chloride | 27 |
| Dibasic calcium phosphate dihydrate | 23 |
| Calcium citrate | 21 |
| Calcium lactate | 13 |
| Calcium gluconate | 9 |

Other Potential Risks

DRUGS

Various medications that may be associated with the development of secondary osteoporosis are listed in Table 102-1.

DISEASES

Patients with various diseases may be at higher risk than the general population for secondary osteoporosis (see Table 102-1 for specific diseases). In addition, women who have undergone oophorectomy before menopause have a high risk for developing osteoporosis at a younger age.

Prevention

Premenopausal Women

2. Although T.J. is premenopausal, what recommendations could be made to decrease her future risk of developing osteoporosis?

T.J.'s course of action should be to maximize her peak bone mass and prevent or decrease bone loss. This may be accomplished by ingesting a nutritious diet with adequate calcium and vitamin D intake and developing a lifelong exercise program.

EXERCISE

T.J. should be encouraged to participate regularly in weight-bearing exercises such as jogging, walking, running, biking, tennis, or weight lifting and to continue exercise appropriate for her age throughout life. Weight-bearing exercise is important for the maximization and maintenance of bone. Aerobic training is important in controlling weight, increasing cardiorespiratory endurance, and decreasing the risk for cardiovascular disease (CVD).

Young women such as T.J. should be informed that excessive exercise can cause amenorrhea. Women with exercise-induced amenorrhea have been reported to have decreased bone mineralization and an increased risk for fractures.⁴³

VITAMIN D INTAKE

Vitamin D helps regulate calcium by a complex interaction that involves PTH (also see Chapter 32 Chronic Kidney Disease) and by having a direct effect on bone. Studies have shown noted improvement in muscle strength and balance as well as reduced risk of falls with vitamin D supplementation.²⁷ Adult requirements for vitamin D range from 200 to 600 IU daily (200 IU daily for nonpregnant women ages 19–50 years). The North American Menopause Society (NAMS) recommends vitamin D doses of 700 to 800 IU daily in women at high risk of deficiency.²⁷ T.J. should be able to obtain adequate vitamin D intake from her diet and exposure to sunlight. Other sources of vitamin D include liver and fatty fish. She could also take a multivitamin daily that contains at least vitamin D 200 IU. Studies have found that when vitamin D is used in conjunction with calcium supplementation, bone loss can be reduced; however, the effectiveness of vitamin D alone for fracture prevention is unclear.^{27,44} Higher-than-recommended doses could lead to increased risks, including hypercalciuria and hypercalcemia.²⁷

CALCIUM INTAKE

T.J.'s diet should be calcium-enriched to ensure that she receives 1,000 mg/day of elemental calcium. Optimally, calcium should be from dietary sources. Because dairy products are the major source of dietary calcium in the United States, T.J. should select low- or non-fat dairy products to decrease her caloric intake and minimize her fat intake when possible. If T.J. were lactose intolerant, she could select dairy products containing lactase. Although nondairy sources may contain lower amounts of calcium, they may be included in a diet plan to increase calcium content, especially when a woman cannot or will not use dairy products (see Table 102-2 for the calcium content of selected foods). The ingestion of foods rich in phytates (i.e., cereal grains, legumes, and nuts) may decrease calcium absorption.

If T.J. cannot meet her daily calcium requirement from dietary sources, she can use a calcium supplement. Table 102-3 lists the percentage of elemental calcium available from selected calcium salts. (See Question 50 for further information on calcium supplements.)

MAGNESIUM

Currently, no evidence exists that magnesium supplementation is needed to prevent osteoporosis. People who might need extra magnesium beyond that found in their diets most likely are elderly women or individuals with gastrointestinal (GI) disease.²⁷

ISOFLAVONES

Isoflavones are a class of phytoestrogens found in soybeans, soy products, and red clover. Although some promote their use for the prevention or treatment of osteoporosis, the current data, mostly from small studies of short duration, are insufficient to support the use of isoflavones for this purpose.²⁷

SMOKING CESSATION

A woman who smokes should be encouraged to stop because cigarette smoking is associated with lowered BMD and increased fracture risk as well as other health problems.²⁷

3. If T.J. needs a calcium supplement, which calcium salt should be recommended?

Calcium carbonate is usually the calcium salt recommended for women such as T.J. because it is reasonably priced and contains the highest percentage of elemental calcium (40%); this allows fewer tablets per day to meet daily calcium requirements. If T.J. needs a calcium supplement, she should be advised to take it in divided doses (e.g., 500–600 mg/dose) to maximize absorption. In addition, calcium should be taken with fluids during or after meals that are low in fiber to increase absorption. Because their absorption may be decreased, medications such as tetracyclines, iron, quinolones, and atenolol should not be taken concomitantly with calcium. T.J. should be informed that the most common adverse effects associated with calcium are constipation, GI irritation, and flatulence. Doses exceeding 2,500 mg/day of elemental calcium can result in hypercalcemia, hypercalciuria, and, possibly, urinary stones. If T.J. or any family member has a history of urinary stones, she should be under medical supervision while taking calcium.

Table 102-4 Techniques for Measuring Bone Mineral Density

| Technique | Abbreviation | Measurement Sites |
|---|--------------|---|
| Dual-energy x-ray absorptiometry | DXA | Hip, spine, total body bone mineral density |
| Peripheral dual-energy x-ray absorptiometry | PDXA | Forearm, fingers, heel |
| Peripheral quantitative computed tomography | PQTC | Forearm |
| Quantitative ultrasound | QUS | Heel, shin |
| Quantitative computed tomography | QCT | Spine |
| Single-energy x-ray absorptiometry | SXA | Heel |

Postmenopausal Women

4. T.J.'s mother, M.J., age 53, also is a woman of small stature and low weight. She occasionally walks in the evenings, but otherwise exercises little. She currently is taking a calcium supplement to maintain her total calcium intake (dietary plus supplementation) of about 1 g/day. She takes no medications except omeprazole (OTC) for her gastroesophageal reflux disease (GERD) and occasional acetaminophen for headaches. M.J. was a cigarette smoker but stopped in her late twenties; she rarely drinks alcohol. She is in good health and has had no gynecologic surgery or major diseases. M.J. does admit to having a strong family history of breast cancer. Her last menstrual period was approximately 6 months ago, but she began experiencing menstrual irregularity 2 years ago. M.J. has been experiencing some menopausal symptoms, such as hot flashes, but states that these are mild and occur only at night. M.J., worried about developing osteoporosis, decided to make an appointment with her gynecologist to discuss preventive measures. A dual-energy x-ray absorptiometry (DXA), formerly DEXA, measurement of her spine was administered, which noted her T score to be a -2 and a Z score of -1 . In addition to the DXA, what other information should be obtained to determine whether she is at risk for developing osteoporosis or already has osteoporosis?

A medical history (including a medication history) and physical examination are needed in addition to a risk factor analysis. Other diagnostic tests should be obtained if needed.

From her history and risk factor analysis, it is determined that M.J. shares similar risk factors for osteoporosis with her daughter. In addition, she is early in the postmenopausal phase, has GERD and was a previous smoker. M.J. has no loss of height, does not complain of back pain, and does not have signs of kyphosis (abnormal curvature of the spine in the thoracic region), all of which may be signs of osteoporosis. (Women can lose 1 to 1.5 inches in height as part of the normal aging process, secondary to shrinking of intervertebral disks.²⁷) Biochemical markers of bone turnover are not needed for M.J. at this time (i.e., alkaline phosphatase, calcium and phosphorous levels).

The NAMS recommends a BMD measurement in women such as M.J., who are <65 years of age if risk factors for osteoporosis are present (e.g., body weight <127 lbs, fracture [other than skull, facial bone, ankle, finger or toe] after menopause, first-degree relative with a history of a vertebral or hip fracture), and smoking.²⁷ The National Osteoporosis Foundation (NOF) recommends BMD testing for women <65 years of age when risk factors for osteoporosis are present and for women >65 years of age, in the absence of risk factors for osteoporosis, and postmenopausal women who present with fractures to confirm diagnosis and severity of disease.⁵ Medicare has

specific guidelines for covering BMD testing and physicians should refer to the most recent guidelines.

Differential absorption of x-rays from two different energies determines the amount of mineral in a given region with a DXA. One x-ray energy source is blocked by the patient with the other x-ray energy source passing completely through the patient, with higher density bone blocking both x-rays. Lower density bone or soft tissue allows x-rays to be transmitted. X-ray energies completely transmitted are sent to a computer which then translates compiled data into an image with density measurements in grams per centimeter squared (g/cm^2), with pencil beam and fan beam DXA machines being the most commonly used.⁴⁵ Central DXA of hip or spine remain the preferred measurement for definitive diagnosis.⁵

Although DXA is the gold standard for determining BMD, other methods can be used for screening but should not be used for diagnosis or to follow a patient's response to therapy²⁷ (Table 102-4). For postmenopausal women who are not receiving medications for osteoporosis prevention, a DXA may be useful no more frequently than every 3 years because it takes approximately 3 to 5 years for a 0.5 change in SD from the mean in either T or Z scores to occur.²⁷ T-score values are supported by both the NOF and NAMS for diagnosis. The Z score can be useful when looking for secondary causes of osteoporosis, with a Z score of <-1.5 suggesting secondary causes for osteoporosis.^{5,27,45} In addition, it has been estimated that for every one point decrease in SD from the mean T score, a 10% to 12% change can occur in BMD. The magnitude of this change can be translated into a 1.5-fold change in risk for fractures.²⁷ As a result, a BMD determination should be obtained no more frequently than every 2 years to assess the effectiveness of pharmacologic interventions for the prevention or treatment of osteoporosis in a postmenopausal woman.²⁷

5. What preventive measures would help decrease M.J.'s likelihood of developing osteoporosis?

EXERCISE

Although M.J. goes for walks occasionally, she should begin an aerobic and weight-bearing exercise program appropriate for her age and physical condition because exercise (particularly weight-bearing exercise) in conjunction with appropriate calcium and vitamin D intake is important for maintaining healthy bones. Weight-bearing exercise improves muscular function and agility, whereas aerobic exercise helps improve cardiovascular health (also see Question 2).

VITAMIN D INTAKE

As with T.J., it is important for M.J. to have an adequate vitamin D intake for her diet and from exposure to sunlight.

The recommended daily allowance (RDA) for vitamin D for women between 51 and 70 years of age is 400 IU/day, and those >70 years of age an intake of 700 to 800 IU/day may be needed.²⁷ This may be achieved from ingesting foods that contain vitamin D (e.g., vitamin D fortified milk, fatty fish) or from ingesting a daily multiple vitamin containing vitamin D. For elderly persons who have limited exposure to sunlight because of minimal outdoor activities or because they live in areas where winters are long, vitamin D supplementation may be needed. Patients with renal or hepatic disease may need supplementation with active vitamin D metabolites, which are available by prescription only. (For further information about vitamin D, see Question 2.)

CALCIUM INTAKE

Because of her postmenopausal status and other risk factors, M.J. should increase her current intake of elemental calcium to at least 1,200 mg/day to prevent bone loss.³⁵ The NIH Consensus Development Panel on Optimal Calcium Intake recommended that postmenopausal women who do not receive EPT (estrogen-progestin therapy—formerly called hormone replacement therapy or HRT) or ET (estrogen therapy) should have a daily elemental calcium intake of 1,500 mg. Although calcium has antiresorptive activity, its use alone by postmenopausal women is not an alternative to ET, EPT, bisphosphonates, or a selective estrogen receptor modulator (SERM) for osteoporosis prevention. Calcium supplementation, however, helps delay BMD loss in postmenopausal women, and its use reduces the risk of hip fractures by 25% to 70%.⁴⁶ (Also see Questions 2 and 3.)

Estrogen-Progestin Therapy

Previously, EPT would have been considered first-line prevention for osteoporosis in a postmenopausal woman such as M.J., who has an intact uterus and is at risk for osteoporosis (Table 102-1) based on her risk factors and T score. Approved indications for use of these products include prevention of postmenopausal osteoporosis; however, not for the treatment of postmenopausal osteoporosis, with the recommendation that the agents are used for the shortest possible time (i.e., duration of menopausal symptoms).⁴⁷ Studies have not been conducted to evaluate fracture rate reduction in lower than standard doses of ET or EPT²⁷ (also see Chapter 48 Gynecologic and Other Disorders of Women). Since the publication of the Heart and Estrogen/Progestin Replacement Study (HERS) I⁴⁸ and HERS II⁴⁹ and the NIH Women's Health Initiative (WHI),⁵⁰ health care providers are less likely to prescribe ET or EPT for the sole purpose of osteoporosis prevention or to continue its use after a woman no longer needs ET or EPT for postmenopausal symptoms such as hot flashes. Table 102-5 lists oral and transdermal estrogens approved for the prevention of osteoporosis.

ESTROGEN EFFECTS ON BMD AND FRACTURE RATE

6. M.J. is considering hormone therapy. What effect does estrogen have on BMD in a postmenopausal woman such as M.J.? Can EPT or ET decrease fracture rates?

The primary effect of estrogen on BMD is related to its antiresorptive activity, which decreases bone loss and lowers fracture rates. Estrogen receptors (ER) are proteins that bind estrogens with high affinity and specificity.⁵¹ Researchers have

identified different ER, including α , β , and γ .⁵² ER act on the reproductive organs, however, α and β also have a role on cardiovascular organs and bone.⁵³ Although not fully understood, the interplay between estrogens and their receptors may stimulate osteoblast activity and the secretion of insulinlike growth factor 1 and transforming growth factor- β . In addition, estrogens possibly inhibit interleukin-1 (IL-1), IL-6, and the release of tumor necrosis factor. Both ER- α and ER- β have been isolated from primary osteoblastic cells of neonatal rats, which if it can be translated to humans, shows that both ER may have beneficial effects on BMD.⁵⁴ Estrogen may also affect calcium absorption and vitamin D receptors in osteoblasts.

An estimated 10% to 15% of a woman's bone mass is estrogen dependent⁵⁵; therefore, estrogen (oral or transdermal) appears to effectively delay or prevent osteoporosis in postmenopausal women.²⁷ The addition of a progestin to ET for women with a uterus does not appear to decrease estrogen efficacy as an osteoporosis preventative. More than 50 randomized, placebo-controlled clinical trials have shown that ET or EPT can increase BMD by 4% to 6% in the spine and 2% to 3% in hips.²⁷ These levels of BMD also have been noted to be maintained after 3 years of therapy.²⁷

In the Postmenopausal Estrogen/Progestin Interventions (PEPI) trial, a randomized, placebo-controlled, multicenter 3-year study of 875 postmenopausal women averaging 56 years of age, BMD increased in the spine 3.5% to 5% and in the hips at an average of 1.7% in all groups who received oral conjugated equine estrogens (CEE) 0.625 mg with or without a progestin (MPA or micronized progesterone [MP]).⁵⁶

In observational studies, ET or EPT appears to reduce fracture rates in postmenopausal women. In one meta-analysis, hip fracture risk was reduced by 25% for postmenopausal women who had used ET or EPT.⁵⁷ A second meta-analysis found that the use of ET or EPT for at least 1 year significantly reduced nonvertebral fracture risk (relative risk [RR] 0.73, 95% confidence interval [CI] 0.56 to 0.94). This effect on fracture rate was somewhat reduced in women who began ET or EPT after age 60 years.⁵⁸

The Study of Osteoporotic Fractures, a large prospective cohort study, showed decreased risks for wrist and nonspinal fractures in estrogen users who were >65 years of age and decreased risks in the incidence of hip fractures in those >75.⁵⁹ The relative risk for nonspinal fractures in postmenopausal women who were current estrogen users versus those not receiving ET or EPT was 0.66 and 95% CI was 0.24 to 0.64. Vertebral bone mass increases in women with known osteoporosis who receive ET or EPT, which can then decrease fracture rates.⁶⁰

In a randomized, placebo-controlled trial that enrolled 2,763 postmenopausal women (HERS), a different outcome was noted. No reduction in fracture risk was observed, even after 4 years of EPT (CEE 0.625 mg/day and MPA 2.5 mg/day). Women enrolled in HERS had histories of cardiac disease, but many were at low risk for fractures because they did not have osteoporosis. Women were enrolled in HERS to determine whether EPT use would decrease the incidence of CVD whereas fracture risk was a secondary observation.⁴⁸

The National Osteoporosis Risk Assessment Study and the Million Women Study, both large observational studies by design, found that ET or EPT provided significant relative risk reductions in fracture.^{61,62} These results were confirmed by the

WHI with both the ET and EPT arms, showing significant risk reductions in hip, vertebral, and total fractures compared with placebo.^{50,63}

CONTRAINDICATIONS TO ESTROGEN USE

7. What are contraindications to the use of ET or EPT in a postmenopausal woman?

Contraindications to ET or EPT include pregnancy; active deep vein thrombosis, pulmonary embolism, or a history thereof; active or recent (e.g., within the past year) arterial thromboembolic disease (e.g., stroke, myocardial infarction); undiagnosed abnormal genital bleeding; known, suspected, or a history of breast cancer; known or suspected estrogen-dependent neoplasia; liver dysfunction or disease; or known hypersensitivity to the product or any of its ingredients.⁶⁴ In addition, women with a history of asthma, diabetes mellitus, migraine, epilepsy, systemic lupus erythematosus, porphyria, and hepatic hemangiomas may have their disease exacerbated by the use of ET or EPT. Thus, women with any of the previously mentioned diseases who receive ET or EPT should be monitored closely by their physicians for potential problems.⁶⁴ ET or EPT therapy is associated with risks. Patients on ET or EPT are at increased risk for cancer, including endometrial (if not on EPT), breast (for EPT), and ovarian cancer as well as increased cardiovascular events, thromboembolic disease, stroke, gallbladder disease, and dementia (also see Chapter 48 Gynecologic and Other Disorders of Women). M.J. has a strong family history of breast cancer and starting her on EPT therapy may not be the treatment of choice for her to prevent osteoporosis.

ADVERSE EFFECTS

8. What are the potential adverse effects of estrogens and progestins administered to a postmenopausal woman such as M.J.?

Such a postmenopausal woman should be made aware of estrogen-related adverse effects, such as nausea, vomiting, dizziness, weight gain, breast tenderness, and breast enlargement. She must also be educated about the possible return of uterine bleeding if she begins using ET or EPT. Used alone, estrogens produce dose-dependent uterine bleeding; women who received 0.625 mg/day of CEE had a 1% to 4% incidence.⁶⁴ The addition of a progestin cyclically increases the incidence of uterine bleeding, normalizes the bleeding pattern, and reduces breakthrough bleeding. The continuous administration of both hormones decreases the incidence of bleeding, but breakthrough bleeding may continue for 6 months to 1 year until the endometrium becomes atrophic.

Adverse effects associated with progestin use may depend on the type of progestin prescribed, but typically these effects include edema, increased breast size, mastalgia, rash, acne, hirsutism, alopecia, headaches, and psychological effects (e.g., irritability, fatigue, mood swings, depression).⁶⁴ Edema and mastalgia may be more commonly noted with MPA or gestodene use. Alopecia, acne, and hirsutism may be more commonly noted with the use of the more androgenic agents, norethindrone and levonorgestrel.

Other Prevention Modalities

Selective Estrogen Receptor Modulators

9. Should a selective estrogen receptor modulator (SERM), such as raloxifene, be considered for the prevention of osteoporosis in M.J.?

RALOXIFENE

Raloxifene (Evista), a SERM, may be an alternate therapeutic choice for M.J. SERM are pharmaceutical agents that are “hormone-related” or “designer estrogens” that have estrogen agonist, antagonist, or both activity in various tissues where estrogen receptors are present. These compounds are also structurally diverse. For example, benzothiophene analogs, such as raloxifene, have agonistic (estrogenic) effects on bone and serum lipid profiles and antagonistic (antiestrogenic) effects on endometrial and breast tissues. Triphenylethylene analogs, such as tamoxifen (Nolvadex), have agonistic effects on bone, serum lipid profiles, and endometrial tissue, and antagonistic effects on breast tissue.

Raloxifene at a dose of 60 mg/day is the only SERM currently approved by the U.S. Food and Drug Administration (FDA) for the prevention and treatment of postmenopausal osteoporosis.⁶⁵ SERM are used for various health problems and disease states. For example, tamoxifen is used as an adjuvant for axillary node-negative or node-positive breast cancer in women, for metastatic breast cancer in women and men, and for the prevention of breast cancer in high-risk women. Clomiphene (Clomid) is used for ovulatory dysfunction and toremifene (Fareston) is used to treat metastatic breast cancer in postmenopausal women.

Raloxifene’s agonist activity on bone tissue is believed to occur through a reduction in bone resorption and a decreased rate of bone turnover, which then results in increased BMD. The effects appear to be mediated through action as an estrogen agonist at ER in bone. Raloxifene activity may be mediated through transforming growth factor- β 3 (TGF- β 3) and suppression of cytokinase IL-6.⁶⁶

Data supporting raloxifene’s effect on BMD were collected in three clinical osteoporosis prevention trials that were conducted in North America (544 women), Europe (601 women), and internationally (619 women, all of whom had undergone hysterectomy).^{65,66} The trials were all randomized, double-blind, placebo-controlled studies that lasted 2 years. Participants were postmenopausal women 45 to 60 years of age. All received calcium supplementation, and women in the treatment groups received raloxifene 60 mg/day; in the international study also had a CEE arm (0.625 mg/daily). The results of these studies showed loss of approximately 1% BMD in the women in the placebo groups. In contrast, those in the raloxifene groups had an increase in BMD of 1.3% to 2.4% in the hips, 1.6% to 2.5% in femoral neck, 1.3% to 2.7% in the trochanter, 1.3% to 2.4% in the intertrochanter, and 1.8% to 2.4% in the lumbar spine. The increase in BMD in the hips of women in the CEE arm of the international study was two times that noted for raloxifene.

The Multiple Outcomes of Raloxifene Evaluation (MORE) trial enrolled 7,705 postmenopausal women 31 to 80 years of age. Of these women, 5,129 were randomized to either a

60 mg/day or 120 mg/day raloxifene group and the remainder were in the placebo group.⁶⁷ MORE trial outcomes after 3 years were as follows for BMD: increases in femoral neck BMD were 2.1% (60 mg/day group) and 2.4% (120 mg/day group) compared with placebo, with spinal BMD increases of 2.6% and 2.7% in the raloxifene groups, respectively, compared with placebo. The RR for vertebral fractures was 0.7, 95% CI 0.5 to 0.8 for those in the 60 mg/day group, whereas those in the 120 mg/day group had an RR of 0.5, 95% CI 0.4 to 0.7. This translates into a 38% and 41% reduction in vertebral fracture rate for the 60 mg/day and 120 mg/day groups, respectively.⁶⁸ No significant difference in nonvertebral fractures was noted among groups.

Differences in BMD, bone architecture, and bone turnover were determined in a 6-month study in which raloxifene 60 mg/day was compared with CEE 0.625 mg/day in 51 white women ages 55 to 85 years.⁶⁹ During this short, randomized, double-blind study, most of the markers of bone resorption or formation were decreased in both groups, but to a greater extent in those receiving CEE. Total body and lumbar spine BMD increased in both groups with a greater increase in women receiving CEE. Hip BMD was similar for both groups. Overall, CEE had a greater effect on BMD, but effects were positive for raloxifene users. It should be remembered that study results were determined after only 6 months and that the number of women enrolled was small.

Sambrook, et al.⁷⁰ conducted the EFFECT (Efficacy of FOSAMAX versus EVITSA Comparison Trial), a randomized, double-blind, double dummy multicenter international study including 487 postmenopausal women with low bone density of the spine or hip (T score ≤ 2) to determine efficacy and tolerability of alendronate and raloxifene. Patients were randomized to either alendronate or raloxifene. After 1 year, BMD increased in both the alendronate and raloxifene groups in the lumbar spine (4.8% vs. 2.2%, respectively) and total hip (2.3% vs. 0.8%, respectively). Tolerability and GI effects were similar in both groups; however, significantly higher reports of vasomotor symptoms came from the raloxifene group.⁷⁰

The CORE Study assessed the effects of raloxifene on breast cancer for an additional 4 years beyond the 4-year MORE trial. A substudy assessed lumbar spine and femoral neck BMD at 7 years, including 386 women (127 placebo, 259 raloxifene) who did not take other bone-active agents from the fourth year of MORE and who were $\geq 80\%$ compliant with the study medication in CORE. When comparing MORE baseline BMD, after 7 years, raloxifene significantly increased lumbar spine (4.3% from baseline, $>2.2\%$ than placebo) and femoral neck (1.9% from baseline, $>3\%$ than placebo) BMD, with BMD significantly above MORE baseline at all time-frames observed at both sites with raloxifene.⁷¹

A paradox exists about how raloxifene can decrease vertebral fractures by up to 41% while increasing BMD by only 2% to 3%, rates that are lower than those noted for ET, EPT, or alendronate. In addition, raloxifene has not been observed to have a positive effect on hip fractures. It has been postulated that the antifracture effect of raloxifene on vertebral fractures occurs secondary to its normalization of the high turnover rate of cancellous bone, which then prevents further disruption of bone microarchitecture.^{72,73} This probably occurs through

raloxifene binding at estrogen β -receptor sites that are predominant in cancellous bone.^{72,73} In addition, a less potent antiresorptive agent, such as raloxifene, may help prevent vertebral fractures but not hip fractures because the threshold for preventing osteoclastic activity in cancellous bone, which is predominant in vertebrae, may be lower than in cortical bone, which predominates in hips. It should also be noted that ER in cortical bone are predominantly α , whereas those in cancellous bone are typically β . Thus, bone type and estrogen receptors are different in the hips compared with vertebrae. For these reasons, it may require a more potent antiresorptive agent to increase BMD in the hips.

Raloxifene might be considered for osteoporosis prevention in a woman such as M.J., even with her strong family history of breast cancer. This latter recommendation is based on results from the MORE trial. A 76% decrease was noted in risk for invasive breast cancer in postmenopausal women with osteoporosis (mean age, 66.5 years) who received raloxifene for 3 years.⁷⁴ A total of 7,705 women were assigned to raloxifene groups (60 mg twice daily or 60 mg daily) or a placebo group. Of those enrolled in either raloxifene group ($n = 5,129$), only 13 cases of breast cancer were reported versus 27 that occurred in the 2,576 women in the placebo group.

M.J. would be a candidate for raloxifene for prevention of osteoporosis, because her T score of <2 indicates that she is currently osteopenic.^{5,22} M.J. should speak with her physician before stopping raloxifene if her vasomotor symptoms worsen. Studies have shown that discontinuing raloxifene therapy resumes bone loss.^{71,75}

Dosing and Pharmacokinetics

If M.J. is to use raloxifene, she should take 60 mg once daily without regard for food.⁶⁵ Raloxifene is approximately 60% absorbed after oral ingestion and then undergoes extensive glucuronide conjugation, resulting in a 2% absolute bioavailability. Some circulating raloxifene glucuronide conjugates are converted back to the parent compound.⁶⁵ Raloxifene and its monoglucuronide conjugates are highly protein bound. Raloxifene is primarily excreted in feces, with $<0.2\%$ excreted unchanged and $<6\%$ eliminated in urine as glucuronide conjugates.⁶⁵ There appear to be no differences in pharmacokinetics based on age or gender. Raloxifene has a mean half-life of 27.7 hours after a single dose and 32.5 hours after multiple doses.⁶⁵

Contraindications and Potential Drug Interactions

Raloxifene is contraindicated for administration to women who are pregnant or who may become pregnant. It is also contraindicated for women with an active or previous history of venous thromboembolic events.⁶⁵ Hypersensitivity to raloxifene or any constituent in Evista tablets is also a contraindication to its use. Patients with hepatic dysfunction may need dosage adjustments, although more information is needed to clarify doses needed.⁶⁵ Cholestyramine, when coadministered with raloxifene, may decrease raloxifene absorption by 60% because of its effects on enterohepatic cycling.⁶⁵ Women who may be receiving warfarin as well as raloxifene should be monitored closely.⁶⁵ This may also be true for some other highly protein-bound medications. It does not appear that M.J. has any contraindication to the use of raloxifene.

Adverse Effects

M.J. should be counseled about adverse effects of raloxifene that might pertain to her if she begins the medication. Adverse effects include an increased risk for venous thromboembolic disease and an increase in hot flashes (25% in postmenopausal raloxifene users versus 18% in those receiving placebo).⁶⁵ The greatest risk for thromboembolic events is during the first 4 months of therapy.⁶⁵ To decrease the risk of thrombosis associated with immobilization, raloxifene should be discontinued for at least 72 hours before immobilization such as that associated with surgery. M.J. is still experiencing hot flashes which could be exacerbated by raloxifene, so she should be counseled extensively on this potential side effect.

Other Potential Effects of Raloxifene

10. What are other effects of raloxifene?

In addition to antagonist effects on breast tissue, raloxifene is an antagonist in the uterus. Therefore, vaginal bleeding is not likely to occur nor is endometrial hyperplasia and the risk for endometrial cancer.^{65,66} A decreased incidence of breast pain, flatulence, and abdominal pain have also been reported in women with an intact uterus who were administered raloxifene versus those receiving continuous EPT.⁶⁵

Raloxifene was thought to have benefits in the prevention of CVD. Most studies that have evaluated the effects of raloxifene on CVD have reported surrogate markers such as lipid serum concentrations rather than cardiovascular outcomes. For example, in the MORE study, postmenopausal women who received raloxifene had significantly fewer reports of hypercholesterolemia.⁷⁴ Total cholesterol and low-density lipoprotein cholesterol (LDL-C) concentrations in women who were using raloxifene were reduced significantly compared with those receiving placebo.⁷⁴ When compared with EPT, raloxifene showed similar reductions in LDL-C. Only EPT significantly increased high-density lipoprotein cholesterol (HDL-C), but it also elevated triglyceride concentrations.⁷⁶ It is currently unknown whether or not these effects translate into a reduction in mortality from CVD.

The RUTH trial was conducted to determine the effects of raloxifene on coronary heart disease (CHD) and breast cancer. The study included 10,101 postmenopausal women with CHD or multiple risk factors for CHD and had a mean follow up of 5.6 years. Raloxifene was found to have no significant effect on the risk of primary coronary events when compared with placebo. Invasive breast cancer risk was reduced with raloxifene versus placebo (absolute risk reduction of 1.2 cases per 1,000 women treated for 1 year). No significant death from any cause or total stroke was found; however, raloxifene was associated with an increased risk of fatal stroke (HR 1.49) and thromboembolism (HR 1.44).⁷⁷

Vogel, et al.⁷⁸ conducted the STAR trial to evaluate the relative effects and safety of raloxifene and tamoxifen on the risk of developing invasive breast cancer and other disease outcomes. They conducted a prospective, double-blind, randomized trial in 19,747 postmenopausal women of mean age 58.5 years with an increased 5-year breast cancer risk. No statistically significant difference was noted between tamoxifen and raloxifene (163 vs. 168 cases respectively, RR 1.02) and fewer cases of noninvasive breast cancer in the tamoxifen group (57) versus the raloxifene group (80) with a RR of 1.4. No differences

were found in other cancer sites, with the exception of uterine cancer, which was found to be more prevalent in the tamoxifen group (36 cases) versus the raloxifene group (23 cases) with a RR 0.62. No differences were found for ischemic heart disease, stroke, or death, with fewer cases of thromboembolic events and cataracts occurring in the raloxifene group.⁷⁸

Bisphosphonates

ALENDRONATE, RISEDRONATE, AND IBANDRONATE

11. Why should bisphosphonates be considered for the prevention of osteoporosis in a woman such as M.J.?

Another alternative treatment option for M.J. would be a bisphosphonate, such as alendronate sodium (Fosamax), risedronate sodium (Actonel), or the newest agent on the market, ibandronate (Boniva). Alendronate, risedronate, and ibandronate are approved for both the prevention and treatment of osteoporosis in postmenopausal women. Alendronate and risedronate are also approved for osteoporosis in men, glucocorticoid-induced osteoporosis prevention and treatment, and in Paget's disease.^{79–81} Alendronate, an aminobisphosphonate, decreases bone resorption, resulting in decreased fracture rates in postmenopausal women who are at risk for osteoporosis. The amino group on alendronate appears to increase selectivity for the antiresorptive surfaces of bone. Alendronate and risedronate have high affinities for bone hydroxyapatite and can be incorporated into bone; in doing this, they can then interfere with osteoclast-mediated bone resorption. Because of their incorporation into bone, bisphosphonates have long half-lives, estimated to be 1 to 10 years. Unlike etidronate (another bisphosphonate), alendronate, risedronate, and ibandronate do not inhibit bone mineralization, which could lead to osteomalacia.^{79–81}

Effects on Bone Mineral Density

A study of the efficacy and safety of oral alendronate (5 mg/day) for osteoporosis prevention in early postmenopausal women⁸² showed BMD increases in the spine of 2.9% (range 2.3%–3.5%) at 5 years for women receiving alendronate, whereas total body density was increased only 0.3%. In a 2-year prevention study in postmenopausal women <60 years,⁸³ placebo, 2.5 mg/day alendronate, 5 mg/day alendronate, and EPT were compared. An increased BMD in the spine, total hip, and total body were observed in the alendronate groups versus the placebo group. Results from the 5-mg group were as follows: lumbar spine, 3.5% (range 3.3%–3.7%); hip, 1.9% (range 1.8%–2.0%); and total body, 0.7% (range 0.6%–0.8%). These results were better than for those in the 2.5-mg group but lower than those who received estrogen; BMD for the HRT group was 1% to 2% greater than for the alendronate 5-mg group.

Another study found that women (ages 55–81 years) diagnosed with postmenopausal osteoporosis who were in an alendronate study group (alendronate 5 mg/day for 2 years followed by 10 mg/day for 1 year) had reduced risk for fractures at various anatomic sites compared with those in the placebo group.⁸⁴ For new vertebral fractures, the RR was 0.53 (95% CI 0.41–0.68); hip, 0.49 (95% CI 0.23–0.99); and wrist, 0.52 (95% CI 0.31–0.87). The Fracture Intervention Trial (FIT) was a multicenter, placebo-controlled trial that enrolled 2,027 women between the ages of 55 and 81 years who had vertebral

fractures and reduced BMD.⁸⁵ These women received placebo or alendronate 5 mg/day for 2 years and 10 mg/day during the third year. Relative to the placebo group, BMD increased by 6.2% in the spine and 4.7% in the total hip region after 3 years. Over 3 years, 18.2% of the placebo group and 13.6% of the alendronate group had fractures.

In 2000, Black, et al.⁸⁶ combined the data from the previous two studies to give overall information from the FIT. These investigators believed this was appropriate because fracture reduction rates in both studies with the use of alendronate were similar. The pooled information from 3 to 4 years of alendronate versus placebo use resulted in the following fracture risk data: hip RR 0.47 (95% CI 0.26–0.79); radiographic vertebral RR 0.52 (95% CI 0.42–0.66); clinical vertebral RR 0.55 (95% CI 0.36–0.82); and all clinical fractures RR 0.70 (95% CI 0.59–0.82). The investigators concluded from these data that women with osteoporosis (T score <−2.5), with or without previous vertebral fractures who took alendronate, had reduced risk for fractures.

A meta-analysis was used to determine the nonvertebral fracture rate in postmenopausal women with osteoporosis who had been treated for at least 3 years with placebo or alendronate (doses used in the five trials ranged from 1–20 mg/day).⁸⁷ The overall results showed a 12.6% incidence of nonvertebral fracture in the placebo groups and a 9.0% incidence in the alendronate groups. This resulted in a RR of 0.71 (95% CI 0.502–0.997) for those receiving alendronate.

Several studies have addressed the effects of risedronate on BMD. In a study of women 40 to 60 years of age (early postmenopausal) who had normal BMD for age, those receiving risedronate 5 mg/day for 2 years had BMD increases of 5.7% in lumbar spine and 5.4% in the hip compared with women taking placebo.⁸⁸ In another study, postmenopausal women (mean age 69 years) who were older than those mentioned in the previous study had increases in BMD of 4.3% in the spine and 2.8% in the femoral neck when risedronate use was compared with placebo over 3 years.⁸⁹

Ibandronate has been shown to have beneficial effects on BMD. McClung, et al.⁹⁰ evaluated the effects of ibandronate in early postmenopausal women resulting in a significantly increased BMD in the lumbar spine (1.9%) versus placebo (−1.9%) and total hip (1.2%) versus placebo (−0.6%) after 2 years. Follow-up from the Mobile Study revealed that the monthly ibandronate dose of 150 mg significantly improved BMD over the 2.5-mg daily dose in the lumbar spine (6.6% vs. 5%) after 2 years of treatment.⁹¹ Ibandronate is also available as an IV formulation of 3 mg administered every 3 months. One-year results from the Dosing Intravenous Administration (DIVA) study improved BMD in the lumbar spine (4.5% vs. 3.5%) and the total hip (2.1% vs. 1.5%) to a similar if not greater degree than daily oral tablets.⁹²

Many studies show the benefits of bisphosphonates in not only the prevention of osteoporosis-related fractures by increasing BMD, but also for the treatment of osteoporosis. Many of these studies have been conducted for 3 years with at least one of 7 years,⁹³ with a 3-year extension.⁹⁴ This latter study extension noted that during years 8 through 10, a total of 247 women receiving either alendronate 5 mg/day or 10 mg/day had similar safety and tolerance profiles as women in placebo groups. They noted that spinal BMD increased by 2.3% for those in the 10 mg/day group and 1.20% for the 5 mg/day

group; hip and total body BMD was maintained, if not slightly improved, at levels that were noted at 7 years; and forearm BMD was maintained in the 10 mg/day group but decreased slightly in the 5 mg/day group. Women who took alendronate for 5 years, but thereafter were in a placebo group, maintained their spinal and total body BMD over 5 years. Ten-year cumulative spinal BMD was 13.7% for the 10 mg/day group and 9.8% for the 5 mg/day group. Rates for nonvertebral fractures between years 8 and 10 were 8.1% for the 10 mg/day group, 11.5% for the 5 mg/day group, and 12.0% for the group who had been on alendronate for 5 years and off alendronate for 5 years. In addition, most bisphosphonate studies have been randomized, double-blind, and placebo-controlled with large sample sizes.

No consensus is currently available on how long to continue with bisphosphonate therapy. In the Fracture Intervention Trial Long-term Extension (FLEX) trial, 1,099 of the original FIT trial participants, did not have extremely low T scores (<−3.5) or BMD lower than their FIT baseline levels. Statistically significant bone loss occurred (2%–3% more than those who took alendronate for 10 years) when women were switched to placebo after 5 years of alendronate therapy; however, BMD remained well above FIT baseline. A gradual rise was seen in biochemical markers of bone turnover as well as a slightly higher risk of clinically detected vertebral fractures, suggesting that women at high risk for vertebral fracture or have T scores <−3.5 may benefit from continued bisphosphonate therapy. The FLEX study results suggest that women with good response to bisphosphonate therapy who are not at high risk for fracture may be able to take a “drug holiday” after 5 years of treatment.^{95,96}

Contraindications and Precautions

Although no dosage change is recommended for a patient with mild to moderate renal failure, alendronate, risedronate, and ibandronate use are not recommended for patients with significant renal insufficiency (e.g., creatinine clearance <35 mL/minute for alendronate and <30 mL/minute for risedronate and ibandronate). Hypocalcemia, if it exists, should be corrected before beginning therapy. Caution is warranted in patients who have any upper GI problem, such as esophageal disease, dysphasia, duodenitis, or ulcers. Sitting upright after ingesting alendronate is necessary to decrease the possibility of reflux into the esophagus and to decrease esophageal irritation as well as to ensure the absorption of oral bisphosphonates, which have low bioavailability. A patient who cannot sit upright for at least 30 minutes (60 minutes for ibandronate) after ingesting the drug should not use oral bisphosphonates.^{79–81} M.J.’s diagnosis of GERD (on omeprazole) may preclude her use of bisphosphonate therapy for prevention of osteoporosis.

Adverse Effects

Common adverse effects associated with the use of bisphosphonates include GI symptoms, such as acid regurgitation, dysphagia, abdominal distention, gastritis, nausea, dyspepsia, flatulence, diarrhea, and constipation. Although rare, esophageal adverse effects, such as esophagitis, esophageal ulcers, and erosions, have occurred and have been followed by esophageal stricture.^{79–81} The latter adverse effect is one of the reasons a patient should sit upright for 30 to 60 minutes after ingestion. In addition, musculoskeletal pain, headaches, and rash have been

noted. Increasing concern over osteonecrosis of the jaw (ONJ) or “death of tissue” or “dead jaw” can occur if blood loss in bone tissue is temporarily or permanently impaired, resulting in the eventual collapse of the bone. Patients taking oral bisphosphonates are at risk for the development of ONJ; however, most patients with ONJ are cancer patients receiving chemotherapy and concurrent IV bisphosphonate therapy. A fewer number of cases have been reported in patients on oral bisphosphonate therapy with active dental disease and recent dental procedures.

Dosing

For prevention of osteoporosis, alendronate and risedronate can be prescribed 5 mg daily or 35 mg once weekly or ibandronate 2.5 mg daily or 150 mg once monthly. It might be more convenient to take the medication once weekly or once monthly, and this might also increase adherence to therapy. Patients should be instructed to take their medication with 6 to 8 ounces of water early in the morning on arising and at least 30 minutes (60 minutes for ibandronate) before ingesting food, beverage, or other medications. Patients should not lie down, but should stay fully upright for at least 30 minutes (60 minutes for ibandronate) after ingesting an oral bisphosphonate to prevent esophageal irritation or ulceration and to ensure appropriate bioavailability. Patients should ingest adequate calcium and vitamin D, but should not take the calcium or vitamin D at the same time as the alendronate. Alendronate is available in a formulation with vitamin D (Fosamax Plus D) and risedronate is available in a formulation with calcium (Actonel with Calcium).^{79–81}

Treatment

12. T.J.’s 75-year-old grandmother, M.B., was diagnosed with osteoporosis 5 years ago when she broke her distal forearm. In addition, she has lost 2 inches in height (current height 5 ft and weight 100 lb) and has mild kyphosis. M.B. denies severe back pain but occasionally uses acetaminophen or ibuprofen for mild back pain. A recent bone scan revealed significantly decreased vertebral and forearm bone mass. M.B. had her last menstrual period before her hysterectomy approximately 25 years ago. Her only major medical problem is mild congestive heart failure (CHF) for which she receives hydrochlorothiazide 25 mg daily and enalapril 10 mg daily. In addition, M.B. takes CEE 0.625 mg daily and calcium carbonate 1,200 mg/day in divided doses with meals. Does M.B. have any clinical signs of osteoporosis? What changes, if any, should be made in her treatment plan? What other medications might be considered for the treatment of osteoporosis?

Clinical signs of osteoporosis exhibited by M.B. include a loss of 2 inches in height and the presence of mild kyphosis. She also has mild back pain that may be associated with osteoporosis. (See Question 4 for further information about osteoporosis clinical signs and symptoms.)

A treatment plan for M.B. should be aimed at preventing further bone loss and minimizing falls, which could lead to fractures.

Calcium and Vitamin D Intake

Calcium supplementation can slow or prevent further bone loss. M.B.’s calcium intake, which should be at least 1,200 mg/day of elemental calcium, is adequate according to Na-

tional Academy of Sciences,³⁵ but information from the NIH recommends 1,500 mg/day of elemental calcium for women such as M.B. who are age 65 and older.³⁶ Calcium absorption may be decreased in older people because of lower gastric acid secretion, decreased 1,25-dihydroxyvitamin D₃ serum concentration, and decreased endogenous estrogen serum concentration. To overcome this problem, M.B. should continue taking her calcium in divided doses with meals or use a more soluble calcium product such as calcium citrate. (Questions 2, 3, and 5 further discuss calcium requirements, supplementation, and product selection and the use of vitamin D for postmenopausal women.)

Estrogens

In light of the results from the WHI for both the ET and EPT arms and the previously published HERS, estrogen use is in question, especially if used long term.^{48,50} As discussed in Question 6, ET or EPT has positive effects on BMD and fracture rates but does not appear to prevent CHD⁵⁰ nor prevent further cardiovascular events in individuals with a history of heart disease.⁴⁸ Thus, M.B. and her physician should discuss whether she should continue ET or be switched to another drug for treatment of her osteoporosis.

Exercise and Prevention of Falls

M.B. should continue an exercise routine (particularly a weight-bearing exercise) that is appropriate for her age and physical condition. Exercise helps maintain bone mass, function, and agility. The prevention of falls, which often result in fractures, also should be considered part of M.B.’s therapy.

Fall prevention measures should be adopted in the elderly because nearly 90% of fractures are precipitated by falling.⁹⁷ These measures should include intrinsic (e.g., balance and gait problems, visual impairments, impaired cognition), extrinsic (inappropriate footwear, polypharmacy, sedatives, and so forth), and environmental factors (e.g., bad lighting in home, loose rugs, uneven pavement, lack of safety equipment). Fall risks should be evaluated at least annually and should be conducted to determine if underlying factors or medical conditions are associated with the falls.⁹⁸ Removal of contributing factors and treating underlying medical conditions with the fewest medications possible can reduce the risk of falling. The Assessing Care of Vulnerable Elders (ACOVE) project to improve patient outcomes suggests documentation and evaluation for falls and osteoporosis and the need for proper workup to improve quality of life and survival.⁹⁹

Thiazides

M.B. currently is receiving hydrochlorothiazide for mild heart failure, but thiazides may also increase calcium retention. Whether this effect has a long-term benefit on calcium balance is debatable. Data from a meta-analysis of 11 studies (none were prospective) established an RR of 0.82 (95% CI 0.73–0.91) for hip fractures and 0.88 (0.77–1.02) for all fractures related to osteoporosis in people taking thiazides.¹⁰⁰ In most of these studies, patients were age 65 years or older. It also appears that longer use of thiazides had a greater effect on the prevention of fractures. Thus, M.B.’s thiazide therapy may have a positive effect on her BMD; however, no randomized clinical trials are available that have evaluated thiazides’ effects on BMD. NAMS does not believe that thiazides prevent

bone loss or fracture risk, although in the elderly there may be some benefit.²⁷

Because M.B. has a history of fractures, she should continue calcium supplementation (possibly increasing it to 1,500 mg/day), hydrochlorothiazide (as long as it is needed for another health problem), and an adequate vitamin D intake. A decision needs to be made about her ET. If it is decided that she should not continue ET, then a decision should be made whether a bisphosphonate or raloxifene might be an alternative. If ET is discontinued, it would most likely be best to taper her off estrogen and not stop it abruptly. No guidelines show to how to taper estrogen, but NAMS recommends one of the following two ways: either skip progressively more days between doses or lower the dose of estrogen every 4 to 6 weeks until the hormone has been successfully tapered.¹⁰¹

Selective Estrogen Receptor Modulators

Raloxifene might be considered for M.B. because of her need for osteoporosis treatment and her history of CVD (see Question 10). Raloxifene is FDA approved for the prevention and treatment of postmenopausal osteoporosis. Ettinger, et al.⁶⁷ noted that at 3 years, women (ages 31–80) with postmenopausal osteoporosis who received raloxifene (60 mg or 120 mg daily) had increased BMD in the femoral neck (2.1% and 2.4%, respectively) compared with placebo. Subjects also had increased BMD in their spines of 2.6% and 2.7%, respectively, compared with placebo, but they also had an RR of 3.1 (95% CI 1.5–6.2) for venous thromboembolism versus those in the placebo group. In another study that compared raloxifene 60 and 120 mg/day with placebo,¹⁰² increases in BMD were noted in the total hip and ultradistal radius in the 60 mg/day group. Nonsignificant trends over placebo were noted for the lumbar spine, total body, and total hip in the 120 mg/day group. In addition, results showed a lower increase in BMD when compared with estrogen studies. (See Questions 9 and 10 for additional information about raloxifene.)

Another study was undertaken to ascertain whether raloxifene prescribed with alendronate would have an additive effect on biochemical markers for bone remodeling and BMD in postmenopausal women with osteoporosis.¹⁰³ Postmenopausal women (N = 331) who were 75 years of age or younger were divided into four groups: placebo; raloxifene 60 mg/day only; alendronate 10 mg/day only; or raloxifene plus alendronate (combination group) at 30 study sites worldwide. Markers of bone turnover (serum osteocalcin, bone-specific alkaline phosphatase, and urinary N- and C-telopeptide) were measured, as was BMD at baseline, at 6 months, and then 12 months later. In the final time period, markers of bone turnover were decreased in all groups except the placebo group. These markers were reduced 1.6-fold in the alendronate-only group compared with the raloxifene-only group. No differences were noted in marker reduction at 12 months between the alendronate-only and the combination groups, but lumbar spine BMD increased by 2.1%, 4.3%, and 5.3% from baseline for raloxifene-only, alendronate-only, and combination therapy, respectively. The increase in femoral neck BMD in the combination group was 3.7% above baseline compared with the alendronate-only (2.7%) and raloxifene-only (1.7%) groups. Total hip BMD and total body BMD were not determined. Overall, combination therapy was better at increasing BMD at some sites than either raloxifene or alendronate alone. Thus, combination therapy could be considered for individuals who do not respond to

either therapy alone. In addition, markers of bone turnover and BMD appear to respond better to alendronate alone than to raloxifene alone. The study did not address fracture rates.

Bisphosphonates

ALENDRONATE, RISEDRONATE, AND IBANDRONATE

A bisphosphonate, such as alendronate, risedronate, or ibandronate, can be an alternative to ET if another benefit of HRT (e.g., genitourinary) is not needed or can be provided by another medication.

In addition to the alendronate, risedronate, and ibandronate clinical studies described in Question 11, the following studies address the use of alendronate, risedronate, and ibandronate in the treatment of postmenopausal osteoporosis. In 1995, Liberman, et al.¹⁰⁴ performed a multicenter, double-blind, placebo-controlled study in which 994 postmenopausal women, ages 45 to 80 years with osteoporosis were enrolled. Alendronate 5 or 10 mg or placebo was administered daily for 3 years followed by 20 mg daily for 2 years, and then 5 mg/day for 1 year. All study participants received calcium 500 mg/day. Increases in BMD of $8.8 \pm 0.4\%$ were noted in lumbar spine, $5.9 \pm 0.5\%$ in the femoral neck, and $7.8 \pm 0.6\%$ at the trochanter in the alendronate 10 mg daily group. Vertebral fractures occurred in 6.2% of those receiving placebo and in 3.2% of those receiving alendronate (48% reduction in fracture rate). In another study, increases in lumbar spine BMD of 0.65%, 3.5%, and 5.7% were noted in elderly women who received 1, 2.5, or 5 mg of alendronate daily over 2 years with calcium supplements versus those receiving placebo.¹⁰⁵ A meta-analysis that compared the results of five studies performed in postmenopausal women between the ages of 42 and 85 years documented that alendronate, when given in doses of 10 mg/day for 3 years, increased BMD over placebo administration as follows: spine 8.8%, femoral neck 5.9%, and trochanter 7.8%.⁷⁹

In two clinical trials,^{89,106} the use of risedronate 5 mg daily for 3 years reduced vertebral fractures in postmenopausal women with osteoporosis by 41% and 49%, respectively. The incidence of nonvertebral fractures was reduced by 39% over the same time period.⁸⁹ McClung, et al.¹⁰⁷ studied two groups of women (5,445 women ages 70–79 with confirmed osteoporosis and 3,886 women age 80 years or older who had risk factors for osteoporosis or low BMD at the femoral neck) to determine whether risedronate could decrease the risk for hip fractures. All women were randomly assigned to receive risedronate 2.5 mg/day, 5 mg/day, or placebo for 3 years. In the osteoporosis group (i.e., women 70–79 years of age), the overall incidence of hip fracture in the risedronate groups was 1.9% with a rate of 3.2% among those in the placebo group (RR 0.6, 9% CI 0.4–0.9). Among the women age 80 years and older, the incidence of hip fractures was 4.2% among risedronate users and 5.1% in those in the placebo group. Thus, risedronate significantly reduced the risk of hip fracture in women diagnosed with osteoporosis but not in the women over age 80 who had risk factors for osteoporosis and low BMD but not osteoporosis.

A study to investigate the use of alendronate 70 mg once weekly for the treatment of osteoporosis showed that its effects on BMD in the lumbar spine and total hip were similar to that produced by alendronate 10 mg daily after 1 year.¹⁰⁸ The study addressed convenience of therapy while making

sure that efficacy was not diminished. Alendronate is approved for the treatment of postmenopausal osteoporosis in doses of 10 mg daily or 70 mg once weekly. Risedronate is approved for the treatment of osteoporosis in doses of 5 mg daily or 35 mg once weekly. Alendronate and risedronate are discussed in detail in Question 11. Risedronate has been shown to be effective and well tolerated in postmenopausal women with osteoporosis after 7 years of treatment.¹⁰⁹

In a study looking at older women, mean age 69 years, oral ibandronate significantly increased BMD in the spine and femoral neck when compared with placebo after 3 years of treatment.¹¹⁰ Daily oral ibandronate therapy has been associated with a decrease in morphometric vertebral fracture by over 52% over 3 years; however, no significant effect on decreasing nonvertebral fractures has been shown.¹¹⁰ Current studies do not show that ibandronate decreases nonvertebral fractures and, with significant data supporting use of alendronate and risedronate, careful consideration should be taken for ibandronate use in patients at high risk.

Combination therapy of ET and bisphosphonates has not been evaluated specifically for the treatment of osteoporosis. M.B. has been diagnosed with osteoporosis despite receiving ET. Further disease progression in M.B. may be prevented by switching to a bisphosphonate, because bisphosphonates have shown to have a greater effect on BMD than does raloxifene.

ZOLEDRONIC ACID

Zoledronic acid (Reclast) is the first IV bisphosphonate FDA approved for the treatment of postmenopausal osteoporosis. Zoledronic acid is approved as a single 5-mg infusion given once yearly over no <15 minutes through a separate vented infusion line.¹¹¹

In a randomized, double-blind, placebo-controlled trial, zoledronic acid was administered for 1 year to 351 postmenopausal women who had low BMD.¹¹² The study population was divided into five treatment groups and a placebo group. Doses of zoledronic acid 0.25 mg, 0.5 mg, 1 mg, or placebo were administered at 3-month intervals, whereas 4 mg of the drug was administered as a single dose or as two doses of 2 mg at 6-month intervals. Increases in BMD were as follows: spine BMD for treatment patients ranged from 4.3% to 5.1% above placebo; femoral neck BMD was 3.1% to 3.5% greater than placebo. When looking at nonvertebral BMD, results were not as good as those noted for vertebral BMD. In the distal radius, BMD was only slightly greater for the treatment groups than for the placebo group at 1 year (range 0.8%–1.6% compared with placebo, which decreased about 0.8%). Differences between treatment groups and the placebo group in terms of total body BMD were 0.9% to 1.3% higher for the treatment groups (significant for all except the 0.5 mg every-3-month group). No vertebral fractures were noted during the study period. Two nonvertebral fractures were noted in the group receiving four doses of 1 mg and one fracture was noted in each of the other groups, except the group receiving four doses of 0.25 mg of zoledronic acid. Dropout rates were similar for treatment and placebo groups. Because the duration of the study did not extend beyond 1 year, data from longer term studies are needed.

Black, et al.,¹¹³ in their report on the Health Outcomes and Reduced Incidence with Zoledronic Acid Once Yearly (HORIZON) Pivotal Fracture Trial, conducted as double-blind, placebo-controlled trial including 7,765 women, of which

3,889 patients were randomized to receive a single 15-minute infusion of 5 mg zoledronic acid and 3,876 patients were randomized to placebo. Patients received doses at baseline, and at 12 and 24 months and were followed until 36 months. Zoledronic acid decreased the risk of vertebral fractures by 70% (RR 0.3; 95% CI 0.24–0.38). Hip fractures were reduced by 41% (RR 0.59; 95% CI 0.42–0.83). BMD significantly increased in the lumbar spine by 6.71% (95% CI 5.69–7.74), total hip 6.02% (95% CI 5.77–6.28) and femoral neck 5.06% (95% CI 4.76–5.36).¹¹³

Adverse event reported have been similar to that of oral bisphosphonates, with decreased incidence of GI adverse events. Acute phase reactions including fevers, flulike symptoms, headache, and arthralgias primarily occur within the first 3 days following the infusion and the incidence decreases with subsequent doses. Increased incidence of atrial fibrillation was noted to be greater than placebo in clinical trials. ONJ has been reported once during clinical trials. Patients with creatinine clearance <30 mL/minute should not receive zoledronic acid.¹¹¹

ETIDRONATE

Etidronate (Didronel), another bisphosphonate available in the United States, inhibits bone resorption mediated by osteoclasts. It is not FDA approved for the treatment (nor for the prevention) of postmenopausal osteoporosis, but it is approved for the treatment of Paget's disease in the United States and for the treatment of osteoporosis in Canada. Studies have shown that, although etidronate has positive effects on fracture prevention, concern exists about the development of osteomalacia. To overcome this potential problem, alternating regimens of etidronate 400 mg/day for 2 weeks followed by a 13-week (3 months) course of calcium and vitamin D have been used.¹¹⁴ The cyclical regimen was chosen owing to daily high dose use possibly interacting with bone mineralization.¹¹⁵

A meta-analysis was used to evaluate 13 clinical trials of etidronate administration in an intermittent, cyclical fashion as therapy for postmenopausal osteoporosis (administered daily for 2 weeks, every 3 months).¹¹⁶ Results showed that, relative to controls, with 1 to 2 years of etidronate therapy at 400 mg/day, BMD was increased by 4.1% in the lumbar spine and 2.3% in the femoral neck. It was suggested that use of etidronate could reduce vertebral fractures by 37%, but not the risk for nonvertebral fractures.

Calcitonin

Calcitonin acts directly on osteoclasts to inhibit bone resorption primarily from vertebral and femoral sites. Both the injection and the intranasal spray are approved for the treatment, but not the prevention, of postmenopausal osteoporosis for those who have been diagnosed for at least 5 years.¹¹⁷ It also is effective in reducing corticosteroid-induced osteoporosis.

Calcitonin may increase BMD in the lumbar spine (cancellous bone) by 1% to 3%, but its use has little effect on cortical bone. In one study, new fractures were reduced. This resulted in an RR of 0.23 (CI 0.7–0.77).¹¹⁸ Various intermittent regimens of calcitonin are being used investigationaly to see whether they can help prevent a decrease in effectiveness that occurs after 1 to 2 years. Calcitonin is used in some patients because of its analgesic effects on bone pain, especially for those who suffer from vertebral compression fractures.²⁷ Although the mechanism of pain relief is unclear, a small study of 56 osteoporotic women who sustained atraumatic vertebral

fractures reported decreased pain scores and analgesic use in the calcitonin group versus placebo.¹¹⁹

A large, randomized, double-blind, placebo-controlled study (Prevent Recurrence of Osteoporotic Fracture [PROOF]) explored the effectiveness of intranasal calcitonin at a dose of 200 IU/day for 5 years versus other doses.¹²⁰ Calcitonin decreased the risk of developing new vertebral fractures in women with osteoporosis by 33%. Doses of 100 and 400 IU/day administered in this same trial did not result in positive results. No significant effect on hip BMD occurred at any dose.¹⁰¹ When compared with alendronate therapy, intranasal calcitonin 200 IU daily was inferior to alendronate 10 mg daily, only increasing BMD in the lumbar spine (1.18% vs. 5.16%), trochanter (0.47% vs. 4.73%), and the femoral neck (0.58% vs. 2.78%) after 12 months of therapy. Fracture data were not evaluated in this study.¹²¹

When used intranasally, calcitonin (Miacalcin) is dosed at 200 IU daily in alternating nares; given subcutaneously or intramuscularly (Calcimar) the dose is 100 IU/day.¹¹⁷ A patient using calcitonin should have adequate intake of calcium and vitamin D.

Adverse effects associated with intranasal calcitonin include nasal symptoms, such as rhinitis and epistaxis. Other adverse effects include arthralgia, headache, and back pain. When calcitonin therapy is administered by injection, adverse effects, such as flushing, nausea, and vomiting, as well as local irritation at the injection site (10%) can occur.^{117,122} Flushing typically occurs on the hands and face and is noted in approximately 2% to 5% of patients. Nausea and vomiting occur in about 10%. These latter reactions most commonly occur when therapy is initiated and usually subside with time. Injectable calcitonin should be refrigerated when not in use. The intranasal preparation should be refrigerated until it is opened for use; thereafter, it is stable for 30 days at room temperature.¹²²

Other Therapies

13. What other agents (both FDA approved and investigational) are possible alternative or additive therapies for the treatment of postmenopausal osteoporosis?

PARATHYROID HORMONE

Parathyroid hormone works differently from other medications discussed thus far because it stimulates new bone formation and activates remodeling, which then results in increased BMD and connectivity in trabecular bone more than cortical bone. This can be accomplished by administration of recombinant human PTH in women with postmenopausal osteoporosis.^{27,123,124} Despite an incomplete understanding of the mechanisms for PTH, it is known that PTH stimulates the interaction of preosteoblasts to osteoblasts within the first month of treatment, peaking 6 to 9 months after daily administration.¹²⁵ For example, in one study of 1,637 postmenopausal women who had previously sustained vertebral fractures, therapy (19 months of PTH 20 or 40 mcg daily subcutaneously) resulted in a reduction of new vertebral fractures by 65% and 69%, respectively, and a reduction of new nonvertebral fractures by 53% and 54%, respectively.¹²⁶

The FDA has approved the PTH derivative teriparatide (Forteo) for use by women and men with osteoporosis who do not adequately respond to other therapies. In addition, those diag-

nosed as having severe osteoporosis and who are at an increased risk for fracture may be considered for therapy. Teriparatide 20 mcg should be given once daily subcutaneously in the thigh or abdomen. Initial administration should be given when the patient can sit or lie down. Teriparatide pens are stable for up to 28 days, including the first injection from the pen. The remaining medication after 28 days should be discarded and teriparatide should never be shared. Teriparatide should be stored under refrigeration 2°C to 8°C (36°F–46°F) and injected immediately on removal from refrigeration. After use, the pen should be recapped and protected from light. Safety and efficacy with teriparatide have not been studied beyond 2 years and therapy is not recommended after 2 years.¹²⁷

Because osteosarcomas were noted in study animals that received teriparatide, the FDA has required a black box warning for this medication even though no osteosarcomas have been observed in patients.¹²⁷ This information may also be found in a medication guide that should be given to all patients receiving teriparatide. Children, adolescents, and individuals with Paget's disease are not candidates for teriparatide because those with growing bones are at increased risk for developing osteosarcomas. Studies have confirmed that BMD gains noted in the hip and spine decline after discontinuation with an approximate 2% loss in spinal BMD and 17% loss in trabecular BMD.^{125,128} Women who were randomized to the alendronate group of the Black, et al. study,¹²⁸ had a further increase of approximately 6% during the first year of therapy with alendronate. Similar effects were noted when estrogen therapy was started after discontinuing PTH,¹²⁹ suggesting that antiresorptive therapy should be started after discontinuation of PTH to preserve BMD.

Adverse effects that have been noted to be associated with teriparatide use include hypercalcemia, leg cramps, nausea, and dizziness. Orthostatic hypotension may occur within 4 hours of administration and spontaneously resolves after a few minutes to hours for the first several doses. Patients should immediately sit or lie down if symptoms occur.¹²⁷

Glucocorticoid-Induced Osteoporosis

14. T.J.'s father, D.J., age 56, was diagnosed with rheumatoid arthritis (RA) 10 years ago. The RA has progressed over the past 2 years, with increased swelling and tenderness in his hands and feet. D.J. made an appointment with his physician who noted that D.J.'s laboratory finding and imaging were suggestive of further progression of his RA. D.J. has been maintained on methotrexate, sulfasalazine, and hydroxychloroquine for the past 5 years. D.J. is not interested in starting injectable therapy at this time and would like to try an alternative treatment that will help alleviate his pain quickly. D.J.'s physician would like to have BMD testing performed on D.J. before initiating prednisone 10 mg daily. D.J. is curious about why he will need a DXA test. What should D.J.'s physician tell him?

Prednisone is classified as a glucocorticoid steroid. Glucocorticoids have several possible mechanisms that contribute to bone loss resulting in osteoporosis. Glucocorticoids have been linked to decreases in serum estrogen and testosterone and increases in bone urine calcium excretion and decreased calcium absorption, which are proposed to increase bone resorption. Glucocorticoids have direct action on bone cells, decrease serum testosterone, and decrease muscle, which results in

decreased bone formation. Both the increase in bone resorption and decrease in bone formation lead to decreased bone volume, resulting in a more rapid bone loss than other medications that have been associated with bone loss.^{130,131} Glucocorticoids are not thought to affect bone-resorbing activity of mature osteoclasts, because they do not have functioning glucocorticoid receptors.¹³² Decreases in BMD can be seen as soon as 3 to 6 months after glucocorticoid initiation; however, fracture risk appears to be contributed to by glucocorticoid duration and dose, but is independent of BMD.^{133,134} After discontinuation of glucocorticoid therapy, BMD begins to increase.¹³⁵

15. Are any medications available to prevent osteoporosis in D.J.?

Bisphosphonates

Alendronate and risedronate are FDA approved for the prevention and treatment of glucocorticoid-induced osteoporosis. They are thought to prevent glucocorticoid-induced osteoclast apoptosis, however, this theory has been challenged suggesting that glucocorticoids may overcome the proapoptotic effects of bisphosphonates. Another thought is that bisphosphonates may prolong the life of osteoblasts.^{136,137}

Saag, et al.¹³⁸ looked at alendronate 5- and 10-mg doses versus placebo and found that BMD in the lumbar spine increased in both alendronate groups and BMD declined in the placebo group 2.1%, 2.9% and -0.4%, respectively, over 48 weeks. Total body, trochanter, and femoral neck bone mass also increased in the alendronate groups. Vertebral fractures were lower in the alendronate groups versus placebo (2.3 vs. 3.7%),¹³⁸ with benefits of alendronate seen after 2 years.¹³⁹ Risedronate is also effective in the prevention and treatment of glucocorticoid-induced osteoporosis. Reid, et al.¹⁴⁰ conducted a 1-year study with risedronate versus placebo in patients taking >7.5 mg of prednisone daily for 6 or more months. They found increases in both lumbar spine and femoral neck (2.7% and 1.8%, respectively), with no change in BMD in patients taking placebo.¹⁴⁰ A study with IV pamidronate 30 mg every 3 months with oral calcium versus calcium alone also had promising results in patients taking glucocorticoids long-term. Spine and hip BMD increased in the pamidronate-calcium group (2.3% and 2.6%, respectively) and decreased in the calcium alone group (-4.6% and -2.2%, respectively).¹⁴¹

Calcitonin

Calcitonin has been studied for the prevention of glucocorticoid-induced osteoporosis as well. Luengo, et al.¹⁴² conducted a 2-year study in patients with asthma who had become glucocorticoid dependent. Patients were randomized to calcitonin nasal spray plus calcium or calcium alone. BMD increase was seen in the calcitonin-calcium group (2.7%) in year 1 versus a decrease in BMD seen in the calcium alone group (-2.8%). BMD preservation was also noted after the second year of the study.¹⁴²

Other Therapies

Researchers have conducted small studies to evaluate the prevention of glucocorticoid-induced osteoporosis. Thiazide diuretics with salt restrictions, estrogen and testosterone replacement, as well as PTH are agents undergoing investigation.

16. What recommendations should D.J.'s physician inform him of to prevent osteoporosis?

The American College of Rheumatology (ACR) recommends preventative therapy in patients taking prednisone 5 mg daily or higher (including therapeutic equivalents) for more than 3 months. The ACR recommends the following:

- Calcium 1,500 mg daily
- Vitamin D 800 IU daily
- Bisphosphonate therapy
- Replacement of gonadal steroids in men (if deficient)
- Exercise program (appropriate for individual patient)
- BMD screen if >3 months of glucocorticoid therapy will be needed
- Smoking cessation

Calcitonin can be considered for patients who have contraindications to bisphosphonates. ACR recommends 24-hour urine collections for all patients because glucocorticoids can cause hypercalciuria. The recommendation of a thiazide diuretic plus salt restriction may be implemented if significant hypercalciuria is present.¹⁴³

D.J. does not currently have any contraindications to bisphosphonate therapy. Alendronate 70 mg weekly or risedronate 35 mg weekly plus adequate calcium (1,500 mg daily) and vitamin D (800 IU daily) in divided doses could be used to prevent glucocorticoid-induced osteoporosis if he is to take prednisone 10 mg daily for an extended period. D.J. should be counseled on the proper administration and adverse effects of bisphosphonates (see Questions 11 and 12). D.J. should be encouraged to incorporate 30 minutes of weight-bearing exercise into his daily routine.

Osteoporosis in Men

17. D.J. presents to his physician 1 year later and finds himself in good health. D.J. is concerned about the development of osteoporosis in his wife's father. J.B., age 77, has become more frail and is falling occasionally. His wife, M.J., is osteopenic and his wife's mother, M.B., has osteoporosis. D.J. knows that osteoporosis occurs often in women, but was not aware that osteoporosis (excluding drug-induced) can occur in men. Should D.J. be concerned about osteoporosis in J.B.?

Osteoporosis is less common in men than in women; however, about 1.5 million men in the United States have osteoporosis with another 3.5 million at risk.¹⁴⁴ Projections suggest that 17% of men who reach 90 years of age will develop osteoporosis.¹⁴⁵ Although reasons are still unknown, mortality rates after hip fracture are higher in men than in women, with patient having a previous distal radius fracture correlating with a high absolute risk for hip fractures in men.¹⁴⁶

18. D.J. knows that BMD loss in both his wife and her mother has been attributed to a decrease in hormones. Is hormone loss the same cause of osteoporosis in men?

Bone loss for men may begin in their 30s with an estimated 1% loss of BMD occurring at the distal radius, with spinal content decreasing more quickly.^{22,23} Many risk factors contribute to osteoporosis in men (Table 102-1), however, androgen and

estrogen production are the primary hormonal contributors to the development of osteoporosis in this population.

Androgens and Estrogens

Androgen production, more specifically serum testosterone concentrations, is known to decrease with age. These decreased concentrations are thought to decrease bone formation and increase resorption. Testosterone has been linked to decreases in BMD versus dihydrotestosterone.¹⁴⁷ Despite testosterone's importance for skeletal health in men, research is now suggesting that estrogen may play a more important role in skeletal biology.¹⁴⁸ Khosla, et al.¹⁴⁹ found two genes required for estrogen effects; estrogen receptor α and aromatase. ER- α are found on osteoblasts, osteoclasts, and stem cells in bone. Aromatase is present in osteoblasts and stem cells in bone.¹⁵⁰ The absence of these genes results in an inability to convert androgen into estrogen.^{151,152} Replacement of estrogen in aromatase deficiency showed significant increases in bone mass and markers of bone turnover normalized.¹⁵² Further research is still needed to delineate the role of estrogen in hypogonadal osteoporosis.

19. Should J.B. be given supplementation for hypogonadism if his testosterone levels are low?

Hypogonadism may be a major contributor of bone loss in men with low serum estradiol being the main contributor.¹⁸ It would be appropriate for J.B.'s physician to order serum testosterone levels. Snyder et al.¹⁵³ found that replacing testosterone (then converted to estrogen), increased bone density by 5.9% when pretreatment serum testosterone levels were below 200 ng/dL (normal 300–1,000 ng/dL).

20. How is osteoporosis diagnosed in men?

The WHO criteria were established for diagnosing postmenopausal women with osteoporosis.² To date, no specific diagnostic criteria have been established for men. Currently, diagnosis of osteoporosis in men can be made when a T score is < -2.5 until further definitions of osteoporosis are established by the National Osteoporosis Foundation and the International Osteoporosis Foundation.

Investigational Agents

In the next few years, new agents should be approved for the prevention and treatment of diseases such as osteoporosis that affect postmenopausal women; an example of these new agents is the SERM bazedoxifene (Viviant).

In a randomized, double-blind, placebo-controlled trial, zoledronic acid was administered for 1 year to 351 postmenopausal women who had low BMD.¹¹² The study population was divided into five treatment groups and a placebo group. Doses of zoledronic acid 0.25 mg, 0.5 mg, 1 mg, or placebo were administered at 3-month intervals, whereas 4 mg

of the drug was administered as a single dose or as two doses of 2 mg at 6-month intervals. Increases in BMD were as follows: spine BMD for treatment patients ranged from 4.3% to 5.1% above placebo; femoral neck BMD was 3.1% to 3.5% greater than placebo. When looking at nonvertebral BMD, results were not as good as those noted for vertebral BMD. In the distal radius, BMD was only slightly greater for the treatment groups than for the placebo group at 1 year (range 0.8%–1.6% compared with placebo, which decreased about 0.8%). Differences between treatment groups and the placebo group in terms of total body BMD were 0.9% to 1.3% higher for the treatment groups (significant for all except the 0.5 mg every-3-month group). No vertebral fractures were noted during the study period. Two nonvertebral fractures were noted in the group who received four doses of 1 mg and one fracture was noted in each of the other groups except the group who received four doses of 0.25 mg of zoledronic acid. Dropout rates were similar for treatment and placebo groups. Because the duration of the study did not extend beyond 1 year, data from longer term studies are needed.

STRONTIUM RANELATE

Strontium ranelate has antiresorptive and mild anabolic effects. The exact mechanism of action remains unknown. Strontium has been shown to decrease the risk of spine and non-spine fractures (35%–49%), as well as increase BMD in the spine and femoral neck (14% and 8%, respectively). Studies have been conducted for up to 3 years. Nausea and vomiting have been associated with oral dissolved strontium, which abated after 3 months of therapy.^{154,155}

DENOSUMAB

Denosumab is a human monoclonal antibody that targets the receptor activator of nuclear factor κ B ligand (RANKL), which has been shown to be a necessary part of bone-resorbing osteoclasts. Initial studies show statistically significant increases in BMD when compared with both placebo and alendronate. Denosumab, being a monoclonal antibody, does function with the immune system, increasing the potential infectious complication.¹⁵⁶

STATINS

When it was discovered that bisphosphonates might suppress osteoclastic activity by inhibiting a step in the cholesterol synthesis pathway, speculation followed to whether agents, such as hydroxymethylglutaryl-coenzyme A (HMG CoA)-reductase inhibitors (i.e., statins) might display similar effects. In laboratory studies, statins inhibit osteoclastic-related bone resorption. It is unknown whether lipid-reducing doses of statins, which are used clinically, can have an effect on bone. Study results thus far have not presented consistent results and prospective clinical trials are needed.^{157,158}

 nausea and, 84-7

Aldactone. (see Spironolactone)**Aldapalene. (see Transretinoic acid)****Aldesleukin, 7-4^t**

pulmonary toxicity from, 89-30^t

Aldomet. (see Methyldopa)**Aldosterone antagonists, 18-9, 18-12**

adverse effects of, 13-22^t
 for hypertension, 13-10, 13-37
 for MI, 17-4, 17-8^t, 17-23–17-24

Aldosterone blockers, for diabetic nephropathy, 31-12**Alefacept, for psoriasis, 40-3^t, 40-7****Alemtuzumab (Campath), 34-6^t, 88-12^t**

for CLL, 90-12
 for HSCT, 92-2^t
 hypersensitivity from, 89-18^t
 for kidney transplantation, 34-2, 34-12

Alendronate sodium (Fosamax), 102-10–102-12, 102-13–102-14

adverse effects of, 51-17^t
 for end-of-life care, 6-4
 glucocorticoids and, 102-16

Allesse. (see Aviane)**Alfentanil, neonates and, 94-6^t****Alfuzosin**

for BPH, 101-21
 saw palmetto and, 3-19

ALG. (see Antilymphocyte globulin)**Alginate acid, 26-3–26-4****Alimta. (see Pemetrexed)****Aliskiren, 13-38, 31-8**

for hypertension, 13-10

Alka-Seltzer, for RA, 43-15**Alkylating agents**

pulmonary disorders from, 25-8^t
 for RA, 43-8

Allantoin, for burns, 41-20**Allegra. (see Fexofenadine)****Allopurinol (Zoloprim), 19-5**

adverse effects of, 51-18^t
 for ALL, 90-26–90-27
 allergic reactions to, 4-2
 azathioprine and, 42-10
 cataracts from, 42-10
 drug interactions with, 42-11^t
 EM from, 38-16
 hypersensitivity from, 42-10
 for hyperuricemia, 42-9
 for lymphoblastic lymphoma, 90-37
 maculopapular eruptions from, 38-17
 pulmonary disorders from, 25-2^t, 25-8^t
 renal failure and, 33-6^t
 SJS from, 38-16
 for TLS, 90-6

Allylamines, 71-4**Almotriptan (Axert), 54-8^t**

for migraine, 53-4

Alacril. (see Nedocromil)**Alomide. (see Lodoxamide)****Alosetron, for DP-IBS, 27-20****Aloxi. (see Palonosetron)****Alphagan P. (see Brimonidine)****Aprazolam (Xanax, Niravam), 12-29, 76-8^t, 76-12–76-13, 76-12^t**

abuse of, 83-11
 benzodiazepines and, 76-16^t
 for ET, 53-27^t
 mania from, 80-5^t
 nasal symptoms from, 24-23^t
 for panic disorder, 76-23
 for PMS, 47-24

Apriostatil. (see Prostaglandin E₁)**Alex. (see Loteprednol)****Altace. (see Ramipril)****Alteplase (tPA, Activase), 17-5^t**

bleeding with, 17-17
 for ischemic stroke, 55-4
 for MI, 17-4
 dosage of, 17-13
 for second infarction, 17-17
 stroke and, 17-17, 55-15–55-16, 55-15^t
 trial of, 17-14

Altretamine, 7-4^t

neurotoxicity of, 89-20^t, 89-21

Aluminum hydroxide, 31-23^t

for GERD, 93-10^t
 pregnancy and, 46-32^t

Alvimopan, 27-21**Amantadine (Symmetrel)**

adverse effects of, 51-16^t, 53-19–53-20, 72-6^t
 dosing of, 53-19
 for influenza, 60-14, 72-5^t, 72-12
 mania from, 80-5^t
 for PD, 53-3^t, 53-19–53-20
 pharmacokinetics of, 72-4^t
 properties of, 72-3^t
 for SSRI-induced sexual dysfunction, 79-17^t
 torsades de pointes and, 19-26^t

Amaryl. (see Glimepiride)**Ambien. (see Zolpidem)****Amcinonide, 38-8^t****Amerge. (see Naratriptan)****Amideate. (see Etomidate)****Amides, 9-16^t**

properties of, 9-18^t

Amifostine, 7-4^t, 89-27

for xerostomia, 89-8

Amikacin (Amikin), 56-8^t

adverse effects of, 56-15^t
 for aspiration pneumonia, 60-21^t
 for CF, 98-11^t
 for CNS infections, 58-9^t
 for HAP, 60-24^t
 for MAC, 70-34^t
 for MDRTB, 70-27
 for neutropenia, 68-9, 68-11
 penetration characteristics of, 58-7^t
 for peritonitis, 32-14
 renal failure and, 33-6^t
 for TB, 61-11^t, 61-13
 for UTIs, 64-10^t

Amiklon. (see Amikacin)**Amiloride (Midamor), 13-13, 18-12, 18-23, 31-13**

for ascites, 28-6
 dofetilide and, 19-11
 hyperchloremic metabolic acidosis from, 11-14
 hyperkalemia from, 11-18
 for hypomagnesemia, 11-29
 nasal symptoms from, 24-23^t

Amino acid substrates, 9-21^t, 9-22**Aminobenzoic acid, 41-8^t****Aminocaproic acid, 89-7^t**

for DIC, 15-34

Aminoglutethimide, for hormone-sensitive tumors, 88-25^t**Aminoglycosides, 33-5, 33-13–33-15, 56-8^t, 62-4**

adverse effects of, 56-15^t, 98-10
 aging and, 99-13
 ARF from, 30-3^t
 for aspiration pneumonia, 60-21^t
 ATN from, 30-14–30-15
 for CAP, 60-11^t, 60-12^t
 ceftriaxone with, 59-4–59-5
 for CF, 98-10, 98-12
 for CNS infections, 58-9^t
 desensitization to, 4-21
 dosing of, 56-22–56-23
 for gram-negative bacillary endocarditis, 59-23
 for HAP, 60-24^t, 60-25–60-26
 for Lyme disease, 75-5–75-6
 for MDRTB, 70-27
 for meningitis, 58-17
 for MRSE, 59-11
 for MSSA, 59-13
 for neonates, 94-3
 for neutropenia, 68-11
 with penicillin, 59-4–59-5
 for peritonitis, 32-14
 pregnancy and, 64-17
 for UTIs, 64-5^t, 64-10^t

Aminopenicillins, for diarrhea, 62-5**Aminophylline**

for anaphylaxis, 4-9^t
 anxiety from, 76-6^t
 for apnea, in neonates, 94-37–94-39

Aminopterin, teratogenic effects of, 46-31^t**Aminosaliclates, for IBD, 27-3–27-5****Amiodarone (Cordarone), 19-6^t**

adverse effects of, 19-22, 51-13, 51-15^t
 for atrial fibrillation, 19-12
 after bypass surgery, 19-13–19-14
 for cardiac arrest, 19-27^t
 before cardioversion, 19-10
 digitalis and, 18-48–18-49
 DILI from, 29-6^t
 dofetilide and, 19-11
 hyperthyroidism from, 19-22
 hypothyroidism from, 19-22
 vs. implantable defibrillators, 19-23
 intravenous, 19-29
 for MI, 17-7, 17-21–17-22, 19-20
 psoriasis from, 40-9^t
 pulmonary disorders from, 25-2^t, 25-6^t, 25-7^t, 25-10–25-11
 for sustained ventricular tachycardia, 19-22–19-23
 thyroid and, 49-33–49-34
 warfarin and, 15-29–15-30
 for Wolff-Parkinson-White syndrome, 19-16

Amitriptyline (Elavil), 31-29, 79-13^t, 99-6^t

for DPN, 50-79
 for migraine, 52-15^t, 52-16–52-17
 nasal symptoms from, 24-23^t
 for sleep disorders, 77-14
 for tension-type headaches, 52-23–52-24

Amlodipine (Norvasc), 16-15, 18-16, 18-63, 20-3

for angina, 16-16^t
 for hypertension, with heart transplantation, 35-6

Ammonium, 10-10**Amoxicillin (Amoxil, Polymox), 56-8^t, 95-9–95-10**

for AOM, 96-5–96-6, 96-6
 for CAP, 60-12^t
 for COPD, 23-12, 23-15
 drug-induced skin reactions from, 4-14
 for endocarditis prophylaxis, 59-24^t
 for *Helicobacter pylori*, 26-14^t, 26-16
 for Lyme disease, 75-4^t, 75-5–75-6
 maculopapular eruptions from, 38-17
 for neutropenia, 68-9
 for osteomyelitis, 66-4, 66-5^t
 for pneumonia, 60-10^f
 pregnancy and, 64-17
 psoriasis from, 40-9^t
 for *Streptococcus pneumoniae*, 56-11
 for UTIs, 64-5, 64-6^t, 96-18

Amoxicillin/clavulanate (Augmentin), 56-8^t

adverse effects of, 96-7
 for AECB, 60-4^t
 for AOM, 96-5, 96-6^t
 for CAP, 60-12^t
 DILI from, 29-2, 29-6^t, 29-14
 for gram-negative aerobes, 56-10^t
 for pneumonia, 60-10^f
 for UTIs, 64-5, 96-17

Amoxil. (see Amoxicillin)**Amphetamine**

abuse of, 83-14–83-15

- anxiety from, 76-6t
 ET from, 53-26
 during lactation, 46-39t
 mania from, 80-5t
 for obesity, 82-19
 overdose from, benzodiazepine for, 5-5
 psychosis from, 78-4, 78-4t
 pulmonary disorders from, 25-2t, 25-5t
 schizophrenia and, 78-3
- Amphotec.** (see **Amphotericin B colloidal dispersion**)
- Amphotericin**
 ATN and, 33-20
 drug fever from, 4-11
 hemodialysis and, 33-20
 hypokalemia from, 11-16t
- Amphotericin B, 71-3, 74-4t**
 adverse effects of, 56-16t
 ARF from, 30-3t
 for aspergillosis, 71-24
 for blastomycosis, 71-19
 for *Candida*, 71-10
 for CAP, 60-12t
 for coccidioidomycosis, 71-22
 for cryptococcosis, 70-24-70-25, 71-25
 dosing of, 56-19t, 71-12
 dyspnea from, 25-3t
 formulations of, 71-17t
 for fungal endocarditis, 59-22
 for gram-negative bacillary endocarditis, 59-23
 for histoplasmosis, 71-10
 for IA, 92-25
 for neonates, 94-31t
 for neutropenia, 68-5-68-6, 68-17
 in pregnancy, 71-19
 protocol for, 71-13t
 pulmonary disorders from, 25-2t, 25-7t
 renal failure and, 33-6t
 toxicity with, 92-26
- Amphotericin B colloidal dispersion (ABCD, Amphotec), 92-25**
- Ampicillin (Omnipen), 56-8t**
 for aspiration pneumonia, 60-21t
 for CDAD, 62-19t
 cefotaxime with, for NEC, 94-27
 for CNS infections, 58-9t
 for CRRT and HD, 56-21t
 dosing of, 56-19t
 drug-induced skin reactions from, 4-14
 EBV and, 4-2
 for endocarditis, 59-18, 59-24t
 for *Enterococcus faecalis*, 56-11
 for GBS, 46-29
 for gram-negative aerobes, 56-10t
 for gram-positive cocci, 56-9t
 for *Haemophilus influenzae*, 58-11t
 for *Listeria monocytogenes*, 56-11
 maculopapular rash from, 4-2, 4-4-4-5, 38-17
 for meningitis, 58-17
 for *Neisseria meningitidis*, 58-11t
 for neonates, 94-3, 94-31t
 OC and, 45-12t
 penetration characteristics of, 58-7t
 pregnancy and, 46-29, 64-17
 protein binding with, 94-4
 psoriasis from, 40-9t
 renal failure and, 33-6t
 for *Salmonella* spp., 62-11
 for sepsis, in neonates, 94-29
 for *Shigella* spp., 62-9
 with sulbactam, 62-4
 for typhoid fever, 62-12-62-13
 for UTIs, 64-5, 64-5t, 64-6t, 64-10t
- Ampicillin/amoxicillin, for UTIs, 96-17**
- Ampicillin/sulbactam (Unasyn), 34-30, 56-8t**
 for CAP, 60-11t
 for CRRT and HD, 56-21t
 for gram-negative aerobes, 56-10t
 for gram-positive cocci, 56-9t
 for HAP, 60-24t
 for PID, 65-9t
- Aprenavir (Agenerase), 61-21, 69-4**
 for HIV, 69-10t
 OC and, 45-12t
- Aminonite (Inacor), 18-57-18-58**
- Amyl nitrate, sexual dysfunction from, 101-7t**
- Amylinomimetics, 50-47, 50-51t, 50-59-50-60**
 adverse effects of, 50-59
 contraindications for, 50-60
 dosing of, 50-60
 drug interactions with, 50-60
 efficacy of, 50-60
 pharmacokinetics of, 50-59
 precautions with, 50-60
- Anabolic steroids, 38-15**
- Anakinra (Kineret)**
 dosing of, 43-10t
 for RA, 43-30
- Analgesics. (see also Patient controlled analgesia)**
 adverse drug reactions with, 99-6t
 adverse effects of, 51-15t
 alcohol interaction with, 84-21t
 CKD and, 31-3
 cognitive impairment from, 99-15
 combinations of, 8-13
 for DPN, 50-79
 in drug poisoning, 5-2t
 for epidural infusion, 9-31t
 epidurals, 9-29-9-30
 erythema nodosum from, 38-17
 failures with, 8-7t
 goals of, 8-12-8-13
 headache from, 52-18
 for MI, 17-7
 nephrotoxicity with, 8-15
 overuse of, 52-18-52-19
 renal failure and, 33-22
 selection of, 8-9
 sleep disorders from, 77-10t
- Anaprox. (see Naproxen sodium)**
- Anastrozole**
 for breast cancer, 91-7
 for hormone-sensitive tumors, 88-25t
- Ancef. (see Cefazolin)**
- Ancred, 55-14-55-15**
- Andidulafungin, adverse effects of, 56-16t**
- Androcur. (see Cyproterone)**
- Androgen, 48-6, 87-16**
 for BPH, 101-21
 estrogen with, 48-4t
 for hormone-sensitive tumors, 88-25t
 mania from, 80-5t
- Androgen hormone therapy, for sexual dysfunction, 101-9-101-10**
- Androgen receptor antagonists, 39-7**
- Anectine. (see Succinylcholine)**
- Anesthetics, 9-6-9-9, 9-6t, 9-7t**
 adverse effects of, 9-7, 9-7t, 51-15t
 drug fever from, 4-11
 fast-track, 9-33-9-34
 local, 9-16-9-18
 for mucositis, 89-9
 as preoperative agent, 9-3t
 psoriasis from, 40-9t
 for SE, 54-33
- Angiomax. (see Bivalirudin)**
- Angiotensin II-receptor antagonists**
 ARF from, 30-3t
 hyperkalemia from, 11-18
- Angiotensin receptor blockers (ARBs), 13-17t, 18-7, 18-12-18-13, 18-33, 31-7-31-8, 31-21, 99-9**
 adverse effects of, 13-22t
 angioedema from, 4-17
 ARF from, 30-9
 for atrial fibrillation, 19-12
 with β -blockers, 13-25
 CAD and, 13-30
 with CCB, 13-19
 CKD and, 13-30
 diabetes and, 13-30
 with hypertension, 50-76
 drug-induced hyperlipidemia from, 12-17t
 HF and, 18-34t
 for hyperkalemia, 31-13
 for hypertension, 13-8, 13-9, 13-18, 13-29-13-30, 31-12
 with heart transplantation, 35-6
 left ventricular dysfunction and, 13-30
 for MI, 17-4
 pregnancy and, 46-16t
 Raynaud's disease and, 14-12
 for stroke, 13-30, 55-5
 teratogenic effects of, 46-31t
 thiazides with, 13-25
- Angiotensin-converting enzyme inhibitors (ACEI), 13-17t, 16-20-16-21, 18-7, 18-9, 18-12-18-13, 18-26, 18-29-18-40, 31-4, 31-7, 99-9**
 adverse effects of, 13-22t, 18-36-18-39
 for angina, 16-9
 angioneurotic edema from, 4-1, 4-16-4-17, 38-17
 ARF from, 30-3t, 30-8-30-9
 for atrial fibrillation, 19-12
 with β -blockers, 13-25
 CAD and, 13-28
 with CCB, 13-19
 CKD and, 13-28
 CNi with, 34-29
 cough from, 18-32-18-33, 25-3t
 for dementia, 100-13
 for diabetes, 13-28
 with hypertension, 50-76
 dialysis and, 32-9
 diltiazem with, 31-12
 for dyslipidemia, 31-21
 ED and, 101-9
 for HF, 99-7
 for hyperkalemia, 31-13
 for hypertension, 12-27t, 13-8, 13-9, 13-18, 13-26-13-29, 20-7, 31-12, 31-21
 with heart transplantation, 35-6
 hypokinesia and, 17-20
- left ventricular dysfunction and, 13-28, 18-61
 lithium and, 80-11t
 for LVH, 31-21
 for MI, 17-4, 17-8t, 17-23
 after discharge, 17-25
 nasal symptoms from, 24-23t
 for nephrotic syndrome, 93-20
 for PAD, 14-7
 pregnancy and, 46-16t
 psoriasis from, 40-9t
 pulmonary disorders from, 25-2t
 race and, 18-60-18-61
 Raynaud's disease and, 14-12
 sleep disorders from, 77-10t
 stroke and, 13-28, 55-5, 55-7
 for systemic sclerosis, 44-4
 systolic dysfunction and, 18-30t
 teratogenic effects of, 46-31t
 thiazides with, 13-25
 verapamil with, 31-12
 weight loss from, 82-6
- Andidulafungin, 71-4, 92-26**
 for neutropenia, 68-17
- Anistreplase (Eminase), 17-5t**
 for MI, 17-4
 dosage of, 17-13
- Antacids, 26-3-26-4, 49-16**
 for aspiration pneumonia, 9-5
 benzodiazepines and, 76-16t
 diarrhea from, 62-2
 drug interactions with, 26-3-26-4
 for GERD, 26-28, 93-10, 93-10t
 iron and, 31-17
 for mucositis, 89-9
 pregnancy and, 46-32t
 as preoperative agent, 9-3t
 quinolones and, 70-32t
 for SRMB, 26-34, 26-35t
- Antazoline + naphazoline (Vasocon-A), 24-15t**
- Anthracycline, 91-3-91-4, 91-6**
 adverse effects of, 90-32-90-33
 CHF from, 89-24-89-25
 hypersensitivity from, 89-18t
- Anthrinal, for psoriasis, 40-3t, 40-4, 40-10**
- Anthranilates, 41-8t, 41-11, 41-12**
- Antidrogens**
 for acne, 47-7
 for hirsutism, 47-7
 for hormone-sensitive tumors, 88-25t
 for PCOS, 47-6t
 for prostate cancer, 91-19
- Antiarrhythmics, 8-27, 17-21-17-22**
 adverse effects of, 51-15t
 arrhythmias from, 19-18
 classes of, 19-5, 19-6t
 digitalis and, 18-52
 for DPN, 50-79
 HF from, 18-19t
 for MI, 17-7
 for pain, 8-5
 sexual dysfunction from, 101-2t
- Antibiotics**
 for AB, 60-2
 for acne, 39-5-39-7, 39-8-39-9, 39-9-39-10
 for acute osteomyelitis, 66-4t
 administration routes of, 56-14-56-18
 adverse effects of, 56-14, 56-15-56-16t, 98-10

Antibiotics (continued)

for AECB, 60-4t
 aerosolized, 60-26-60-29
 AIN from, 30-15
 amylinomimetics and, 50-60
 for animal bites, 67-8-67-9
 for AOM, 96-4, 96-5-96-7
 for aspiration pneumonia, 60-20-60-21
 bone and, 66-4, 66-8
 for brain abscess, 58-33-58-34
 bronchial penetration of, 60-26
 for *Campylobacter jejuni*, 62-16
 for CAP, 60-9-60-13
 for CAPD-associated peritonitis, 63-7
 for CF, 98-10-98-12, 98-11t
 for cholangitis, 63-4
 for cholecystitis, 63-4
 for cholera, 62-7
 classification of, 56-8t
 COC and, 45-11-45-12
 for COPD, 23-12
 with corticosteroids, 38-9
 for CRRT, 56-21-56-22t
 for diabetic soft tissue infections, 67-5-67-6
 for diarrhea, 62-5
 diarrhea from, 62-2
 dosing of, 56-18-56-23, 56-19-56-22t
 for endocarditis, 59-25-59-26
 for erysipelas, 67-7
 exenatide and, 50-58
 failure with, 56-23-56-24
 fixed drug eruptions from, 38-17
 for GBS, 46-29
 gonorrhea resistance to, 65-6
 for gram-negative aerobes, 56-10t
 for gram-positive cocci, 56-9t
 for HAP, 60-24t
 for HD, 56-21-56-22t
 in heart valves, 59-11
 for *Helicobacter pylori*, 26-16
 hemolytic anemia from, 87-4-87-5
 for HSCT, 92-23
 for HUS, 62-15
 for IBD, 27-6
 for Lyme disease, 75-5-75-6
 mania from, 80-5t
 for NEC, 94-27
 for neutropenia, 68-9
 for penetrating trauma, 63-11
 for peritonitis, 32-14
 photosensitive eruptions from, 38-15
 pramlintide and, 50-60
 for preterm labor, 46-28-46-30
 psoriasis from, 40-9t
 pulmonary disorders from, 25-8t
 for PVE, 59-10
 for Raynaud's disease, 14-11
 for RDS, 94-10-94-11
 resistance to, 39-6-39-7
 for respiratory acidosis, 10-11
 for *Salmonella* spp., 62-11
 for SARS, 72-17-72-18
 for secondary peritonitis, 63-8-63-10
 for sepsis, in neonates, 94-29-94-32
 for septic shock, 21-28
 synergy with, 68-11
 therapy costs of, 56-14

for travelers' diarrhea, 62-17-62-18
 for UTIs, 96-17-96-18, 99-13
 for variceal hemorrhage, 28-14
 for ventriculitis, 55-19
Anti-CD52 antibody. (see Alemtuzumab)
Anticholinergics
 adverse effects of, 51-15t, 78-19
 for allergic rhinitis, 24-9t
 for asthma, 22-29-22-30
 for BPD, 94-17
 for CF, 98-9
 for COPD, 23-13
 elderly and, 9-2
 for end-of-life care, 6-7
 GERD and, 26-23t
 levodopa and, 53-14t
 for motion sickness, 7-3
 for PD, 53-19
 for POAG, 51-7
 as preoperative agent, 9-3t
 psychosis from, 78-4t
 for rhinitis, 24-8-24-9
 toxicity from, 5-3, 5-14
Anticoagulants. (see also Heparin; Warfarin)
 for AF, 15-8t, 55-6
 alcohol interaction with, 84-21t
 for dental procedures, 15-28
 with dialysis, 32-5-32-7
 for DVT, 15-8t
 with epidural infusion, 9-32
 for LV dysfunction, 15-8t
 for MI, 15-8t
 OC and, 45-12t
 for PE, 15-8t
 pulmonary disorders from, 25-2t, 25-8t
 for stroke, 15-8t, 55-6, 55-11, 55-15
 for thrombosis, 17-6
 for valve replacement, 15-8t-9t
 for valvular disease, 15-8t
Anticonvulsants, 8-27, 31-29
 adverse effects of, 51-15t
 for alcohol withdrawal, 84-10-84-11
 for bipolar disorder, 80-16-80-17
 for brain abscess, 58-34
 for DPN, 50-79
 drug hypersensitivity syndrome from, 38-17
 in drug poisoning, 5-2t
 for ET, 53-27t
 hypersensitivity to, 4-2
 L-thyroxine and, 49-16
 for mania, 80-12-80-14
 mania from, 80-5t
 for pain, 8-5
 for panic disorder, 76-23
 pulmonary disorders from, 25-8t
 rifampin and, 70-30
 for RLS, 53-24-53-25, 77-19
 for schizophrenia, 78-9
 sexual dysfunction from, 101-2t
 SLE from, 4-12, 44-3
 sleep disorders from, 77-10t
Anti-D. (see Anti-D immune globulin)
Anti-D immune globulin (anti-D), 93-18
Antidepressants. (see also Tricyclic antidepressants)
 adverse effects of, 51-16t, 79-14t

aging and, 99-11t
 alcohol interaction with, 84-21t
 augmentation with, 79-24-79-25, 79-24t
 for bipolar disorder, 80-4
 depression with, 80-15-80-16
 for bulimia nervosa, 82-17
 cardiac disease and, 79-27
 for cluster headaches, 52-22
 discontinuation of, 79-18
 dosage for, 79-15t
 drug interactions with, 79-20-79-22, 79-21t
 in drug poisoning, 5-2t
 for GAD, 76-8-76-10
 for hot flushes, 48-6
 during lactation, 79-18-79-20
 mania from, 80-5t
 for migraine, 53-4
 for narcolepsy, 77-5
 for obesity, 82-20
 for pain, 8-5
 for PD, 53-22
 photosensitive eruptions from, 38-15
 for PMS, 47-24
 pregnancy and, 46-44, 79-18-79-20
 for PTSD, 76-30
 sexual dysfunction from, 101-2t
 for sleep disorders, 77-14
 for tension-type headaches, 52-23-52-24
 thyroid and, 49-32-49-33
 toxicity from, 5-3, 5-17
 treatment duration with, 79-18
 weight gain from, 79-12, 82-6
 weight loss from, 82-6
Antidiabetics, 50-45-50-60
 cardiovascular effects of, 50-71
 combination therapy with, 50-68-50-69
 for elderly, 50-74-50-75
 hepatic dysfunction from, 50-73
 hypoglycemia from, 50-72
 with insulin, 50-69-50-70
 lactic acidosis from, 50-71-50-72
 monotherapy with, failure of, 50-67-50-68
 renal dysfunction from, 50-72-50-73
 weight gain from, 82-6
 weight loss from, 82-6
Antidiarrheals, for DP-IBS, 27-20
Antidotes, 5-5
Antiemetics, 93-7
 for gastroparesis, 50-77
 for migraine, 52-11-52-12
 for NVP, 46-8
Antiepileptic drugs (AED), 54-1, 54-3t
 adverse effects of, 54-25-54-28
 bone density and, 54-18
 breastfeeding and, 54-30
 DILI from, 29-1, 29-14
 for elderly, 54-18-54-19
 interactions with, 54-25-54-28
 for neonates, 94-42-94-44
 OC and, 54-29-54-30
 pharmacokinetic properties of, 54-6t
 pregnancy and, 46-41-46-43
 for seizures, 54-5t
 skin rash from, 54-27-54-28
 weight gain from, 82-6
 weight loss from, 82-6

Antiestrogens

for hormone-sensitive tumors, 88-25t
 for PCOS, 47-6t
Antifibrinolytic agents
 for DIC, 15-34
 pregnancy and, 46-32t
Antifungals, 71-3t
 adverse effects of, 56-16t
 for diaper rash, 93-4
 drug interactions with, 71-14t
 for HSCT, 92-23
 for IA, 92-25-92-26
 for lung transplantation, 35-10
 for neutropenia, 68-5-68-6, 68-15-68-17
 in pregnancy, 71-19
 properties of, 71-9t
 rifampin and, 61-17, 70-32t
 toxicity with, 92-26-92-27
Antihistamines, 24-12t, 31-29
 adverse effects of, 51-16t
 allergen skin tests and, 24-21t
 for allergic conjunctivitis, 24-9, 24-14, 24-15t
 for allergic rhinitis, 24-9t, 24-10-24-11
 for anaphylaxis, 4-9t
 in drug poisoning, 5-2t
 hangover effect of, 77-5
 for insomnia, 77-5
 for motion sickness, 7-3
 for NVP, 46-8
 for otitis media, 90-2
 for panic disorder, 76-23
 proarrhythmic effects of, 19-25
 for pruritus, 38-10
 for rhinitis, 24-6-24-7
 for sleep disorders, 77-4
 sleep disorders from, 77-10t
 weight gain from, 82-6, 82-8
Antihyperlipidemic agents, 31-9
Antihypertensives, 31-4, 31-7-31-8, 99-10
 adverse drug reactions with, 99-6t
 adverse effects of, 13-22t, 51-16t
 coenzyme Q and, 3-37-3-38
 cognitive impairment from, 99-15
 combinations of, 13-25t
 for dementia, 100-13
 dementia from, 100-17
 for diabetes, 31-11-31-12
 with dialysis, 31-20-31-21
 ED from, 101-7, 101-9
 HF from, 18-19t
 for hot flushes, 48-6
 photosensitive eruptions from, 38-15
 pregnancy and, 46-15
 SLE from, 44-3
 sleep disorders from, 77-10t
 for stroke, 55-7
 weight loss from, 82-6
Anti-inflammatory agents, SLE from, 44-3
Antilymphocyte globulin (ALG), 87-16
 for heart transplantation, 35-4
 for kidney transplantation, 34-2
Antimalarials
 drug hypersensitivity syndrome from, 38-17
 for RA, 43-20-43-21

- Antimicrobials**
for neonates, 94-31*t*
SLE from, 44-3
- Antiminth. (see Pyrantel pamoate)**
- Antimotility drugs, for HUS, 62-15**
- Antimuscarinics, for PONV, 9-24*t*, 9-25-9-26**
- Antineoplastics**
adverse effects of, 51-17*t*
breast-feeding and, 97-7
chronic steatosis from, 29-16
during lactation, 46-39*t*
- Antilytics, sexual dysfunction from, 101-7*t***
- Antioxidants**
with dialysis, 32-4
for hyperlipidemia, 12-39
for PD, 53-21
as sunscreens, 41-12
- Antiplatelet drugs, 16-21-16-22**
for angina, 16-9
for dementia, 100-13-100-14
for ischemic stroke, 55-4
for KD, 96-14
for MI, 17-15
for stroke, 55-11-55-12
for thrombosis, 17-6
- Antipsychotics (Neuroleptics), 78-10-78-12, 100-15**
for acute agitation, 80-14
adverse drug reactions with, 99-6*t*
akathisia from, 78-19
for alcohol withdrawal, 84-9*t*, 84-11
for anorexia nervosa, 82-14
anxiety from, 76-6*t*
cardiovascular effects of, 78-21-78-22
cimetidine and, 78-16
classification of, 78-10
cognitive impairment from, 99-15
dementia from, 100-17
dosing of, 78-13
drug interactions with, 78-15-78-16
drug mechanism of, 78-10-78-12
in drug poisoning, 5-2*t*
efficacy of, 78-13
erythromycin and, 78-15
fluoxetine and, 78-16
flvoxamine and, 78-15
hepatic dysfunction from, 78-24
hyperprolactinemia from, 78-22
ketoconazole and, 78-15
levodopa and, 53-14*t*
lithium and, 80-11*t*
for OCD, 76-34-76-35
for panic disorder, 76-23
paroxetine and, 78-16
pharmacokinetics of, 78-15-78-16
photosensitive eruptions from, 38-15
proarrhythmic effects of, 19-25
quinidine and, 78-16
risperidone and, 78-16
ritonavir and, 78-15
seizures from, 78-25
sexual dysfunction from, 78-25, 101-2*t*
sleep disorders from, 77-10*t*
tardive dyskinesia from, 78-19-78-21
temperature dysregulation from, 78-24-78-25
- weight gain from, 78-22-78-23, 82-6, 82-8
- Antipyretics, hemolytic anemia from, 87-4-87-5**
- Antiretrovirals, hyperuricemia from, 42-8*t***
- Antisense phosphodiester oligodeoxynucleotides, 73-28**
- Antithrombotic agents, for MI, 17-24-17-25**
- Antithymocyte globulin (ATG, Atgam, Thymoglobulin), 34-6*t*, 87-16**
adverse effects of, 34-13
basiliximab and, 34-13
CMV from, 34-16
daclizumab and, 34-13
dosing of, 34-13
for GVHD, 92-20
for HSCT, 92-9
for kidney transplantation, 34-12
for lung transplantation, 35-8
phlebitis from, 34-13
for transplantation, 34-9
- Antithyroid drugs**
SLE from, 44-3
teratogenic effects of, 46-31*t*
- Anti-tumor necrosis factor medications, for RA, 43-2**
- Antivert. (see Meclizine)**
- Antivirals. (see also Highly active antiretroviral therapy)**
adverse effects of, 56-17*t*
for bronchiolitis, 96-12
complications with, 69-27-69-29
for HIV, 69-11-69-22
for HSCT, 92-23
for neutropenia, 68-6, 68-17-68-18
- Antizol. (see Fomepizole)**
- Anturane. (see Sulfipyrazone)**
- Anxiolytics**
for acute anxiety, 76-6
mania from, 80-5*t*
for PMS, 47-24
- Anzemet. (see Dolasetron)**
- Apidra. (see Insulin glulisine)**
- Apligraf, 41-19**
- Apokyn. (see Apomorphine)**
- Apomorphine (Apokyn)**
for PD, 53-3*t*, 53-7, 53-15
for sexual dysfunction, 101-9
- Appetite suppressants, sleep disorders from, 77-10*t***
- Apraclonidine (Lopidine), for POAG, 51-5, 51-10*t***
- Apreritant (Emend), 7-5, 7-6*t***
for PONV, 7-10*t*, 9-24*t*
- Aprisoline. (see Hydralazine)**
- Apri (Ortho-Cept), 45-5*t***
- AquADEK, 98-8-98-9, 98-8*t***
- Aquaretic agents, 11-12**
- Aranesp. (see Darbepoetin- α)**
- Arava. (see Leflunomide)**
- ARBs. (see Angiotensin receptor blockers)**
- ARDS, 24-13**
- Arfonad. (see Trimefaphan)**
- Argatroban, 15-5**
with dialysis, 32-6
for heparin-induced thrombocytopenia, 33-24
renal failure and, 33-6*t*
- Arginine, hyperkalemia from, 11-18**
- Arginine hydrochloride, 10-10**
- Aricept. (see Donepezil)**
- Aripiprazole (Abilify), 78-10**
for acute agitation, 78-14*t*, 80-14
adverse effects of, 78-12*t*
for alcoholism, 84-14*t*
for autism, 78-30
for bipolar disorder, 80-12*t*
dosing of, 78-17*t*
for mania, 80-12
for mania from, 80-5*t*
NMS from, 78-24
pharmacokinetics of, 78-16*t*
receptor-binding affinities of, 78-12*t*
weight gain from, 78-22
- Aristocort. (see Triamcinolone)**
- Aristolochia fangchi, 3-5**
- Aristolochic acid, hazards of, 3-6*t***
- Arixtra. (see Fondaparinux)**
- Aromatase inhibitors**
for endometriosis, 47-16-47-17
for hormone-sensitive tumors, 88-25*t*
for PCOS, 47-8
- Aromatic L-amino acid decarboxylase (AAD) inhibitors, 53-2**
- Arsenic trioxide (ATO), 7-4*t***
for APL, 90-5
- Artane. (see Trihexyphenidyl)**
- Asacol. (see Mesalamine)**
- Ascorbic acid, 42-10**
alcohol interaction with, 84-21*t*
- Ascrutin, for RA, 43-15**
- Asmanex. (see Mometasone)**
- Asparaginase (Elspar)**
for ALL, 90-27
anaphylaxis from, 90-33-90-34
hepatotoxicity from, 89-32*t*
neurotoxicity of, 89-20*t*
pancreatitis from, 90-33
pulmonary disorders from, 25-2*t*, 25-3*t*
for T-cell lymphoblastic lymphoma, 90-36*t*
- Aspirin, 15-7, 43-17*t*, 55-14**
for acute coronary syndromes, 17-22
allergic reaction to, 4-15-4-16
for AMI, 21-24
analgesic syndrome from, 31-3
anaphylaxis from, 4-16
for angina, 16-21-16-22
for atrial fibrillation, 19-12-19-13
bleeding from, 9-2, 43-16
for CAD, 16-21-16-22
for cancer prevention, 88-5*t*
clopidogrel and, 16-22
for colon cancer prevention, 88-4
for CVD, 50-80
for dementia, 100-13-100-14
DILI from, 29-3*t*, 29-6*t*
with dipyridamole, for ischemic stroke, 55-4
dosing of, 55-10
for dysmenorrhea, 47-11*t*
for end-of-life care, 6-5
fenoprofen and, 43-15
GERD and, 26-23*t*
ginkgo and, 3-11-3-12
for heart transplantation, 35-5
hepatitis and, 73-7
for hyperlipidemia, 99-9
hypersensitivity to, 43-15
for hypertension, 13-15
hyperuricemia from, 42-8*t*
- ibuprofen and, 16-23, 43-15
indomethacin and, 43-15
for ischemic stroke, 55-4
for KD, 96-14
for MI, 14-7, 16-31, 17-8*t*
as adjunct therapy, 17-13
after discharge, 17-24-17-25, 17-25
naproxen and, 43-15
nasal symptoms from, 24-23*t*
NSAIDs and, 16-23
for PAD, 14-7
with PCI, 16-27
for postinfarction arrhythmias, 17-21
for prevention, 16-23
PUD from, 26-10-26-11
pulmonary disorders from, 25-2*t*, 25-4*t*, 25-8*t*
for RA, 43-3, 43-6, 43-14-43-15
Reye's syndrome and, 43-35, 93-3
for silent myocardial ischemia, 16-26
for stroke, 14-7, 55-5*t*, 55-6, 55-8-55-10
for stroke prevention, 19-12-19-13
for sunburn, 41-15
for thrombosis, 17-6
toxicity with, 5-6-5-9
trial of, 17-14*t*
urticaria from, 38-17, 43-16
warfarin and, 15-19
- Aspirin/dipyridamole (Aggrenox), for dementia, 100-14**
- Astel. (see Azelastine)**
- Astemizole, drug interactions with, 19-25**
- Atabrine. (see Quinacrine)**
- Atarax. (see Hydroxyzine)**
- Atazanavir (ATV), 69-4**
for HIV, 69-10*t*, 69-14*t*
NNRTIs and, 69-21*t*
resistance to, 69-24*t*
with ritonavir, 69-16
for HIV, 69-14*t*
- Atenolol (Tenormin), 15-7, 16-14**
albuterol and, 4-8
for alcohol withdrawal, 84-9*t*, 84-11
anaphylaxis from, 4-8
diabetes and, 17-19
dosing of, 16-15
for ET, 53-27*t*
for hypertension, 31-21
melatonin and, 3-33*t*
for MI, 17-18, 17-19*t*
psoriasis from, 40-9*t*
pulmonary disorders from, 25-2*t*
renal failure and, 33-6*t*
sexual dysfunction from, 101-2*t*
for social anxiety disorder, 76-28
weight gain from, 82-6
- ATG. (see Antithymocyte globulin)**
- Atgam. (see Antithymocyte globulin)**
- Ativan. (see Lorazepam)**
- ATO. (see Arsenic trioxide)**
- Atomoxetine**
for ADHD, 81-3, 81-5-81-6
weight loss from, 82-6
- Atorvastatin (Lipitor), 12-12, 12-12*t*, 12-24*t*, 12-25*t*, 12-28, 50-77**
for atherogenic dyslipidemia, 12-37
for metabolic syndrome, 12-26
OC and, 45-12*t*
for stroke, 55-5, 55-7

- Atovaquone (Mepron), 74-5t, 77-16**
for lung transplantation, 35-10
for PCP, 70-9t, 70-10, 70-11t
rifampin and, 70-32t
for toxoplasmosis, 70-15
- ATRA. (see Transretinoic acid)**
- Atracurium (Tracrium), 9-13t**
action parameters for, 9-14t
adverse effects of, 9-13t
elimination of, 9-15t
- Atropine**
adverse effects of, 51-15t, 51-21
breast-feeding and, 97-7
for cardiac arrest, 19-27t
for conduction blocks, 19-17
drug fever from, 4-11
for ED, 101-12t
for nerve gas exposure, 54-25
as preoperative agent, 9-3t
via endotracheal administration, 19-28-19-29
- ATV. (see Atazanavir)**
- Atypical antagonists, 78-10**
for bipolar disorder maintenance, 80-17-80-18
- Atypical antipsychotics (AAP), 80-3**
for bipolar disorder depression, 80-15
for mania, 80-12
mania from, 80-5t
- Augmentin. (see Amoxicillin/clavulanate)**
- AUR. (see Gold)**
- Auranofin. (see Gold)**
- Aurothioglucose (Solganal), 43-22**
- Avandaryl. (see Rosiglitazone/glimepiride)**
- Avandamet. (see Rosiglitazone/metformin)**
- Avandia. (see Rosiglitazone)**
- Avastin. (see Bevacizumab)**
- Avelox. (see Moxifloxacin)**
- Aviane (Allese), 45-5t**
- Avobenzene. (see Butyl methoxydibenzoylmethane)**
- Avodart. (see Dutasteride)**
- Avonex. (see Interferon β -1 α)**
- Axert. (see Almotriptan)**
- Axid. (see Nizatidine)**
- AZA. (see Azathioprine)**
- Azactam. (see Aztreonam)**
- Azacytidine, 89-27**
- Azathioprine (AZA, Imuran)**
acneiform eruptions from, 38-15
adverse effects of, 34-7
allopurinol and, 42-10
bone marrow toxicity from, 35-11
for CD, 27-13, 27-15
DILI from, 29-3t, 29-6t
drug interactions with, 34-30t
for focal segmental glomerulosclerosis, 31-34
for GCA, 44-5
for HDV, 73-32
for heart transplantation, 35-3-35-4
for IBD, 27-4t, 27-5
for ITP, 93-19
for kidney transplantation, 34-2, 34-12
for lupus nephritis, 31-31-31-32
neonates and, 94-7t
pancreatitis from, 34-7
for RA, 43-5, 43-26
for transplantation, 34-7
VOD from, 29-16
for Wegener's granulomatosis, 31-32-31-33
- Azelaic acid (Azelex), 39-4-39-5**
- Azelastine (Optivar, Astelin), 24-11, 24-15t, 24-16t**
- Azelex. (see Azelaic acid)**
- Azilect. (see Rasagiline)**
- Azithromycin (Zithromax), 56-8t**
adverse effects of, 56-15t
for AOM, 96-6t
for BOS, 35-9
for *Campylobacter* spp., 62-3t
for *Campylobacter jejuni*, 62-16
for CAP, 60-11t, 60-12t
for CDAD, 62-19t
for CF, 98-13
for chancroid, 65-18
for *Chlamydia trachomatis*, 65-11
for cholera, 62-7
for diarrhea, 62-5
for endocarditis prophylaxis, 59-24t
for gonorrhea, 65-7
for HIV, 70-5t
for LGV, 65-12
for Lyme disease, 75-5-75-6
for MAC, 70-34t
penetration characteristics of, 58-7t
for pneumonia, 60-10f
for *Salmonella* spp., 62-12
for septic arthritis, 66-12
for *Shigella* spp., 62-9
for toxoplasmosis, 70-15
for travelers' diarrhea, 62-17
for typhoid fever, 62-12-62-13
- Azoles, 71-4**
adverse effects of, 65-22, 71-21
dofetilide and, 19-11
drug interactions with, 71-14-71-15t, 71-21-71-22
rifampin and, 61-17
for VVC, 65-22
- Azopt. (see Brinzolamide)**
- AZT. (see Zidovudine)**
- Aztreonam (Azactam), 56-8t, 59-23**
for aspiration pneumonia, 60-21t
for CAP, 60-11t
for CAPD-associated peritonitis, 63-7
for gram-negative aerobes, 56-10t
for gram-positive cocci, 56-9t
for neutropenia, 68-10
penetration characteristics of, 58-7t
renal failure and, 33-6t
for UTIs, 64-10t
- Azulfidine. (see Sulfasalazine)**
- BAC. (see Benzalkonium chloride)**
- Bacampicillin (Spectrobid), 56-8t**
- Bacillus Calmette-Guerin (BDG), for bladder cancer, 91-16**
- Bacitracin, 38-9t, 67-3**
for CDAD, 62-20-62-21
- Baclofen**
anxiety from, 76-6t
for GERD, 93-11
- Bactrim. (see Trimethoprim-sulfamethoxazole)**
- Balsalazide, for IBD, 27-4t**
- Balsalazide (Colazal), 27-9t**
- Baraclude. (see Entecavir)**
- Barbiturate**
adverse effects of, 51-17t
alcohol interaction with, 84-21t
anxiety from, 76-6t
benzodiazepines and, 76-16t
for DC cardioversion, 19-10
EM from, 38-16
fixed drug eruptions from, 38-17
GERD and, 26-23t
hepatic encephalopathy from, 28-18
NAS from, 94-44
respiratory acidosis from, 10-11
sexual dysfunction from, 101-7t
withdrawal from, 83-10
- Barley malt extract, 93-6t**
- Basiliximab (Simulect), 34-6t**
ATG and, 34-13
for kidney transplantation, 34-2, 34-10, 34-12
for lung transplantation, 35-8
- BCG. (see Bacillus Calmette-Guerin)**
- BEAC. (see Carmustine/etoposide/cytarabine/cyclophosphamide)**
- BEACOPP. (see Bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisone)**
- Beclomethasone (Beconase AQ), 24-16t**
for asthma, long-term, 22-27t
for BPD, 94-18
dosing of, 22-23t
for end-of-life care, 6-5
- Beconase AQ. (see Beclomethasone)**
- Belatacept, for transplantation, 34-10**
- Belladonna, 99-6t**
for opiate withdrawal, 83-10t
- Benadryl. (see Diphenhydramine)**
- Benazamides, 7-8**
for PONV, 9-24t, 9-25
- Benazepril (Lotensin), 3-7-3-8, 18-12**
for dementia, 100-13
- Benemid. (see Probenecid)**
- Bentyl. (see Dicyclomine)**
- Benzalkonium chloride (BAC), pulmonary disorders from, 25-2t, 25-4t**

- Benzoate-4-methylbenzylidene camphor, 41-8t**
- Benzoic acid, 71-5**
- Benzoic acid, 71-5**
- Benzenethiol, 41-11, 41-12**
- Benzocaine**
allergic contact dermatitis from, 38-16
for mucositis, 89-9
for sunburn, 41-15
- Benzodiazepines, 12-29, 93-17**
abuse of, 76-14-76-15
for acute agitation, 80-14
adverse effects of, 76-13-76-14, 99-6t
alcohol and, 76-14, 84-21t
intoxication from, 84-6
withdrawal from, 84-8-84-10, 84-8t
for amphetamine overdose, 5-5
for anorexia nervosa, 82-14
anxiety from, 76-6t
for CINV, 7-8
for cocaine overdose, 5-5, 20-16-20-17
cognitive impairment from, 99-15
comparison of, 76-8t, 76-12t
for DC cardioversion, 19-10
dependence on, 76-14-76-15, 77-11-77-12
depression from, 76-14
distribution of, 99-3
drug interactions with, 76-16-76-17, 76-16t
elderly and, 9-2
for epilepsy, 54-3t
for ET, 53-27t
falls and, 76-14
for GAD, 76-7-76-8, 76-11
GERD and, 26-23t
hepatic encephalopathy from, 28-18
for insomnia, 77-5
during lactation, 76-17
levodopa and, 53-14t
metabolic pathways of, 76-13f
NAS from, 94-44
OC and, 45-12t
for OCD, 76-35
opioids and, 9-4
overdose of, 76-17-76-18
for panic disorder, 76-23
physiological factors with, 76-18-76-19, 76-19t
pregnancy and, 76-17
as preoperative agent, 9-3t
respiratory acidosis from, 10-11
for RLS, 53-24-53-25, 77-19
for schizophrenia, 78-9
for sedation, 93-13
sexual dysfunction from, 101-7t
for sleep disorders, 77-2, 77-4
sleep disorders from, 77-10t
smoking and, 85-5t
for social anxiety disorder, 76-27-76-28
with SSRIs, 76-11-76-12, 76-24-76-25
toxicity with, flumazenil for, 5-5, 5-14
treatment duration with, 76-15
volatile inhalation agents and, 9-11
withdrawal from, 76-15-76-16, 76-15t, 83-10
- Benzoin acid, 71-5**
- Benzophenone-3 (Oxybenzone), 41-8t, 41-11, 41-12**
- Benzoyl peroxide**
for acne, 39-4, 39-6, 39-8
during pregnancy, 46-32t
sunscreen and, 39-8
- Benzotropine (Cogentin), 78-18, 99-6t**
for PD, 53-3t
- Bepidril, torsades de pointes and, 19-26t**
- Beractant (Survanta), 94-12t, 94-13**
- Betagan. (see Levobunolol)**
- Betamethasone, 38-8t, 44-7t**
administration routes of, 44-9t
for preterm labor, 46-28
- Betapace. (see Sotalol)**
- Betaxolol (Betoptic), for POAG, 51-4-51-5, 51-10t**
- Bethanechol**
for GERD, 26-29, 93-10t, 93-11
for urinary incontinence, 101-20t
- Bevacizumab (Avastin), 88-12t, 88-26**
for breast cancer, 91-6
for colon cancer, 91-9
for colorectal cancer, 88-22t
hypertension from, 89-26
for neovascular ocular disorders, 51-23
thrombosis from, 89-6
- Bexarotene, L-thyroxine and, 49-16**
- Bextra. (see Valdecoxib)**

- Bexxar. (see Tositumomab)**
- Bezafibrate, 12-14, 12-14t, 12-15**
- Biaxin. (see Clarithromycin)**
- Bicalutamide, for hormone-sensitive tumors, 88-25t**
- Bicarbonate (Sodium bicarbonate), 10-2, 11-1**
- acid-base and, 2-6
 - for acidosis, 5-8
 - for aspirin toxicity, 5-8
 - carbonic acid and, 10-3-10-4
 - with cardioplegia solution, 9-21t
 - children and, 97-5t, 97-6
 - diarrhea and, 97-5
 - DKA and, 50-44t, 50-45
 - for hyperkalemia, 11-19
 - for metabolic acidosis, 10-8, 31-14, 97-6
 - metabolic acidosis and, 97-6
 - renal control and, 10-3
 - for RTA, 10-6
 - for TCA toxicity, 5-5, 5-17-5-18
- Bicitra. (see Sodium citrate/citric acid)**
- Biguanides, 50-46-50-52, 50-48t, 50-49t**
- adverse effects of, 50-46

for CAP, 60-11†
for CNS infections, 58-9†
for CRRT and HD, 56-21†
dosing of, 56-19†
for gram-negative aerobes, 56-10†, 66-6†
for gram-positive cocci, 56-9†
for HAP, 60-24†
for meningitis, 58-17†
for neonates, 94-31†
for neutropenia, 68-9†
penetration characteristics of, 58-7†
penicillin resistance and, 60-13†
renal failure and, 33-7†
for UTIs, 64-10†
- Cefixime (Suprax), 56-8†**
for DGI, 65-10†
for diarrhea, 62-5†
for gonorrhea, 65-3†, 65-4, 65-5, 65-7†
for *Neisseria gonorrhoeae*, 56-13†
for neutropenia, 68-9†
renal failure and, 33-7†
for septic arthritis, 66-12†
for *Shigella* spp., 62-10†
for typhoid fever, 62-12–62-13†
for UTIs, 96-17, 96-18†
- Ceftizoxime (see Ceftizoxime)**
- Cefonicid (Monocid), 56-8†**
- Ceforanide (Precef), 56-8†**
- Cefotan.** (see Cefotetan)
- Cefotaxime (Claforan), 56-8†, 63-4, 75-4†**
for acute osteomyelitis, 66-4†
with ampicillin, for NEC, 94-27†
for aspiration pneumonia, 60-21†
for CAP, 60-11†, 60-12†
for cellulitis, 67-3†
for CNS infections, 58-9†
for croup, 96-11†
for gram-negative coverage, 66-6†
for *Haemophilus influenzae*, 58-11†
for neonates, 94-31†
penetration characteristics of, 58-7†
penicillin resistance and, 60-13†
renal failure and, 33-7†
for *Salmonella* spp., 62-12†
for sepsis, in neonates, 94-29†
for UTIs, 64-10†
with vancomycin, for NEC, 94-27†
- Cefotetan (Cefotan), 56-8†**
for aspiration pneumonia, 60-21†
for CRRT and HD, 56-21†
hemolytic anemia from, 87-6, 87-7†
for PID, 65-9†
renal failure and, 33-7†
for UTIs, 64-10†
- Cefoxitin (Mefoxin), 56-8†**
for aspiration pneumonia, 60-21†
for cellulitis, 67-3†
for gram-positive cocci, 56-9†
for penetrating trauma, 63-11†
for PID, 65-8†
renal failure and, 33-7†
for surgery, 57-2†
for UTIs, 64-10†
- Cefpodoxime (Claforan), 56-8†**
adverse effects of, 96-7†
for AOM, 96-5, 96-6†
for CAP, 60-12†
penicillin resistance and, 60-13†
for septic arthritis, 66-12†
for UTIs, 96-17†
- Cefpodoxime proxetil (Vantin), 56-8†**
- Cefprozil (Cefzil), 56-8†**
for AOM, 96-6†
for CAP, 60-12†
for UTIs, 96-17†
- Ceftazidime (Fortaz), 56-8†, 75-10**
for aspiration pneumonia, 60-21†
for CAP, 60-12†
for CF, 98-11†, 98-12†
for CNS infections, 58-9†
for CRRT and HD, 56-21†
for culture-negative endocarditis, 59-24†
dosing of, 56-19†
for gram-negative aerobes, 56-10†, 66-6†
for gram-negative bacillary endocarditis, 59-23†
for HAP, 60-24†
hemodialysis and, 33-16†
for HSCT, 92-23†
for neonates, 94-31†
for neutropenia, 68-9, 68-11†
for osteomyelitis, 66-7†
penetration characteristics of, 58-7†
for *Pseudomonas* spp., 33-5, 66-6, 66-10†
renal failure and, 33-5, 33-7†
for UTIs, 64-10†
- Cefibuten (Cedax), 56-8†**
- Ceftin.** (see Cefuroxime axetil)
- Ceftizoxime (Ceftizox), 56-8†**
for aspiration pneumonia, 60-21†
for CNS infections, 58-9†
for DGI, 65-10†
penetration characteristics of, 58-7†
renal failure and, 33-7†
for UTIs, 64-10†
- Ceftriaxone (Rocephin), 56-8†, 63-4, 67-2, 75-4†, 75-10**
with aminoglycosides, 59-4–59-5†
for AOM, 96-6†
for aspiration pneumonia, 60-21†
biliary pseudolithiasis from, 58-7†
for brain abscess, 58-33–58-34†
for CAP, 60-11†, 60-12†
for cellulitis, 67-3†
for CNS infections, 58-9†
for culture-negative endocarditis, 59-24†
for DGI, 65-10†
for diarrhea, 62-5†
dosing of, 56-19†
for endocarditis, 59-7–59-8, 59-8†, 59-25–59-26†
for gonococcal endocarditis, 65-9–65-10†
for gonococcal meningitis, 65-9–65-10†
for gonorrhea, 65-3†, 65-4, 65-5, 65-7†
for gram-negative coverage, 66-6†
for *Haemophilus influenzae*, 58-11†
for HAP, 60-24†
hemolytic anemia from, 87-6, 87-7†
for *Neisseria gonorrhoeae*, in neonates, 94-34†
for osteomyelitis, 66-4, 66-7†
penetration characteristics of, 58-7†
for PID, 65-8, 65-9†
for RMSF, 75-13†
for *Salmonella* spp., 62-12†
for sepsis, in neonates, 94-29†
for *Shigella* spp., 62-9†
for typhoid fever, 62-12–62-13†
for UTIs, 64-10†
for variceal hemorrhage, 28-14†
- Cefuroxime (Zinacef), 56-8†, 58-7**
adverse effects of, 96-7†
for AOM, 96-5, 96-6†
for aspiration pneumonia, 60-21†
for CAP, 60-12†
for cellulitis, 67-3†
for CF, 98-11†
dosing of, 56-19†
for gram-negative aerobes, 56-10†
for gram-positive cocci, 56-9†
for heart transplantation, 34-30†
penetration characteristics of, 58-7†
for UTIs, 64-10†, 96-17†
- Cefuroxime axetil (Ceftin), 56-8†, 75-4†**
for Lyme disease, 75-5–75-6†
penicillin resistance and, 60-13†
- Cefzil.** (see Cefprozil)
- Celecoxib (Celebrex), 4-16, 42-5, 43-17†**
for cancer prevention, 88-5†
cardiovascular toxicity from, 26-19–26-21†
for colon cancer, 91-9†
for dysmenorrhea, 47-11†
for GI tract disorders, 44-13†
for preterm labor, 46-27†
PUD from, 26-10–26-11†
for RA, 43-6†
SLE from, 44-4†
- Celexa.** (see Citalopram)
- CellCept.** (see Mycophenolate mofetil)
- Cenestin.** (see Synthetic conjugated estrogens (Cenestin, Enjuvia))
- Central α_2 -agonists, 13-38–13-39**
- Cephalexin (Keflex), 56-8†, 67-2, 67-5**
for endocarditis prophylaxis, 59-24†
for osteomyelitis, 66-5†
for UTIs, 64-6†, 96-17, 96-18†
- Cephalosporins, 56-8†, 62-9, 75-10**
adverse effects of, 56-15†, 96-7†
for AEBC, 60-4†
AIN from, 30-15†
alcohol interaction with, 84-21†
allergy to, 66-11†
for AOM, 96-5–96-7†
for aspiration pneumonia, 60-21†
for brain abscess, 58-33†
for CAP, 60-12†
for CDAD, 62-19†
for cellulitis, 67-3†

for diarrhea, 62-5†
for *Escherichia coli*, 56-13†
for gonorrhea, 65-3†, 65-5†
for *Haemophilus influenzae*, 56-13†
for heart transplantation, 34-30†
hemolytic anemia from, 87-6†
imipenem and, 4-6†
for *Klebsiella pneumoniae*, 56-13†
for Lyme disease, 75-5–75-6†
for neutropenia, 68-9†
neutropenia from, 87-12†
OC and, 45-12†
for osteomyelitis, 66-7†
penetration characteristics of, 58-7†
penicillin resistance and, 60-13†
for peritonitis, 32-14†
for pneumonia, 60-10†
pregnancy and, 46-32†, 64-17†
for *Pseudomonas* spp., 33-5†
pulmonary disorders from, 25-2†, 25-3†, 25-7†
for PVE, 59-10†
renal failure and, 33-5†
for *Salmonella* spp., 62-3†, 62-12†
for sepsis, in neonates, 94-30†
skin testing for, 4-6†
for UTIs, 64-5†, 64-10†, 96-17†
- Cephalothin**
hemolytic anemia from, 87-6†
for peritonitis, 32-14†
- Cephradine**
renal failure and, 33-7†
for UTIs, 64-6†
- Cerebryx.** (see Fosphenytoin)
- Cerubidine.** (see Daunorubicin)
- Cervidil.** (see Prostaglandin E₂)
- Cesamet.** (see Nabilone)
- Cetirizine (Zyrtec), 24-12†**
allergen skin tests and, 24-21†
for allergic rhinitis, 24-10†
- Cetuximab (Erbix), 88-12†**
hypersensitivity from, 89-18†
pulmonary disorders from, 25-5†
- Chantix.** (see Varenicline)
- Chasteberry, for PMS, 47-22**
- Chastetree, for PMS, 47-22**
- Chemokine receptor antagonists (CCR5), 69-11†**

Chemotherapy

acneiform and, 89-12–89-13
for acute lymphocytic leukemia, 88-20
adjuvant, 88-21
adverse effects of, 89-1–89-35
for ALL, 90-27
alopecia and, 89-11
for AML, 89-33–89-34, 90-5–90-8
anaphylactoid reactions and, 89-16
anemia and, 87-16–87-17, 89-5
bone marrow and, 89-2
for breast cancer, 91-3–91-4, 91-5–91-7, 91-6*t*
burns and, 41-18
for cancer, 88-14–88-25
cardiomyopathy and, 89-22–89-23
CHF and, 89-22
coagulation and, 89-5
combination, 88-20–88-21
conception and, 89-35
constipation and, 89-22
cranial nerves and, 89-22
cytopenias and, 89-2–89-3
cytotoxic, 88-14–88-20
diarrhea and, 89-10
dose intensity of, 88-19
dry skin and, 89-13
echinacea and, 3-17
encephalopathy and, 89-19
esophagitis and, 89-10
fertility and, 89-34–89-35
GI tract and, 89-6–89-7, 92-14
HBV and, 73-13
for HD, 88-20
hemolytic anemia and, 89-16
hypersensitivity and, 89-15–89-19
for indolent lymphoma, 90-17
induction, 88-21
infectious diarrhea and, 62-4
kidneys and, 89-26–89-29
leukoencephalopathy and, 89-19
liver and, 89-32–89-33, 89-32*t*
lungs and, 89-29–89-32, 89-30–89-31*t*
during malignancy, 88-23*f*
mucositis and, 89-6–89-7, 89-7*t*, 89-8–89-9
nails and, 89-11–89-12
nausea and, 89-6
neoadjuvant, 88-21
neutropenia and, 68-2*t*, 89-3
neutrophils and, 89-2
for NHL, 88-20
oogenesis and, 89-34
for ovarian cancer, 91-14–91-15
ovaries and, 89-34
paresthesia and, 89-21–89-22
photosensitivity and, 89-14
platelets and, 89-2
primary, 88-21
for prostate cancer, 91-20
radiation therapy and, 89-13–89-14, 89-14*t*
RBC and, 89-2
schedule dependency of, 88-19
skin and, 89-10–89-15
spermatogenesis and, 89-34–89-35
ST segment and, 89-25
stomatitis and, 89-8–89-9
sunscreen and, 89-15
thrombocytopenia and, 89-2
thrombosis and, 89-5

toxicity with, CNS and, 89-19
tumors and, site of, 88-20
VOD from, 29-16
vomiting and, 89-6
xerostomia and, 89-6–89-8, 89-7*t*

Chemotherapy-induced nausea and vomiting (CINV), 7-3–7-9**Chirocaine. (see Levobupivacaine)****Chloral hydrate, 5-11, 77-21, 93-11–93-13, 94-49**

alcohol interaction with, 84-21*t*
hepatic encephalopathy from, 28-18
for opiate withdrawal, 83-10*t*
for pediatric insomnia, 77-20
for sedation, 93-12*t*
sleep disorders from, 77-10*t*

Chlorambucil

for CLL, 90-11
for focal segmental glomerulosclerosis, 31-34
pulmonary disorders from, 25-2*t*
pulmonary toxicity from, 89-30*t*
for RA, 43-8

Chloramphenicol (Chloromycetin), 56-8*t*

adverse effects of, 51-16*t*, 56-16*t*
aplastic anemia from, 87-14–87-15
for aspiration pneumonia, 60-21*t*
breast-feeding and, 97-7
for CNS infections, 58-9*t*
hepatitis and, 73-7
for Lyme disease, 75-5–75-6
neonates and, 94-7*t*, 94-31*t*
OC and, 45-12*t*
penetration characteristics of, 58-7*t*
penicillin resistance and, 60-13
for RMSF, 75-11, 75-13
for *Salmonella* spp., 62-11
for typhoid fever, 62-12–62-13, 62-14

Chlordiazepoxide (Librium, Limbitrol, Librax), 76-8*t*, 76-12*t*, 76-13

for alcohol withdrawal, 84-8–84-10, 84-8*t*, 84-9*t*
hepatitis and, 73-7
nasal symptoms from, 24-23*t*
smoking and, 85-5*t*

Chlorhexidine gluconate, 89-7*t*

for mucositis, 89-9

Chloride (Cl), 2-6–2-7, 11-1

absorption of, 11-3, 11-3*f*
acid-base and, 2-6
blood chemistry reference values for, 2-3*t*
with cardioplegia solution, 9-21*t*
children and, 97-4, 97-5*t*

Chloroform, alcohol interaction with, 84-21*t***Chloromycetin. (see Chloramphenicol)****Chloroprocaine (Nesacaine), 9-16*t***

properties of, 9-18*t*

Chloroquine, 74-4*t*, 75-6–75-7

adverse effects of, 51-16*t*
malaria and, 74-2
psoriasis from, 40-9*t*

Chlorothiazide

for BPD, 94-16*t*
nasal symptoms from, 24-23*t*

Chlorpheniramine (Chlor-Trimeton), 24-12*t*, 99-6*t*

adverse effects of, 51-14, 51-16*t*
allergen skin tests and, 24-21*t*
for allergic rhinitis, 24-10
for panic disorder, 76-23

Chlorpromazine (Thorazine), 78-3, 99-6*t*

adverse effects of, 51-19*t*, 78-12*t*
for anorexia nervosa, 82-14
chronic intrahepatic cholestasis from, 29-16
DILI from, 29-7*t*, 29-14
dosing of, 78-17*t*
hepatic dysfunction from, 78-24
for migraine, 52-12, 52-13*t*
for NAS, 94-46–94-47
neutropenia from, 87-12–87-13
ocular effects from, 78-24
for PD, 53-22
pharmacokinetics of, 78-16*t*
pregnancy and, 46-32*t*
receptor-binding affinities of, 78-12*t*
for sedation, 93-12*t*
SLE from, 4-12, 44-3
smoking and, 85-5*t*
temperature dysregulation from, 78-25

Chlorpropamide (Diabinese), 3-16, 50-49*t*, 50-53, 50-67

DILI from, 29-7*t*
glaucoma and, 51-8
SIADH from, 50-54

Chlorthalidone, 13-13**Chlor-Trimeton. (see Chlorpheniramine)****Cholesterol absorption inhibitors, 12-25**

for hyperlipidemia, with heart transplantation, 35-7

Cholestyramine (Questran), 12-25*t*, 31-29, 49-16

adverse effects of, 13-25
for CDAD, 62-21
for DP-IBS, 27-20
with LEF, 43-26
raloxifene and, 102-9

Cholinergic agonists, for gastroparesis, 50-77**Cholinesterase inhibitors, 100-6**

for DLB, 100-10–100-11
for POAG, 51-6–51-7

Chondroitin, 3-24–3-28

adverse effects of, 2-27–2-28
dosing of, 2-27
for OA, 3-24, 43-39–43-40

CHOP. (see Cyclophosphamide, doxorubicin, vincristine, and prednisone)**Cialis. (see Tadalafil)****Gidofvir (Vistide)**

adverse effects of, 72-6*t*
for BK polyomavirus, 34-23
for CMV retinitis, 70-16–70-18*t*, 70-19, 72-5*t*
dosing of, 70-20*t*
for neutropenia, 68-18

Gilanesetron, 27-20–27-21**Gilastatin**

imipenem with, 62-9, 63-4
for neutropenia, 68-10, 68-11

Gilomast, for COPD, 23-10**Glostazol, 14-8**

verapamil and, 14-9

imetidine (Tagamet), 26-4–26-5

antipsychotics and, 78-16
for aspiration pneumonia, 9-5
benzodiazepines and, 76-16*t*
dementia from, 100-17
dofetilide and, 19-11
for GERD, 93-10*t*
interstitial nephritis from, 4-14

mania from, 80-5*t*
metformin and, 50-52
methadone and, 8-31–8-32
as preoperative agent, 9-3*t*
psoriasis from, 40-9*t*
for reflux esophagitis, 46-9
renal failure and, 33-7*t*
sexual dysfunction from, 101-7*t*
sildenafil and, 101-11
for SRMB, 26-35*t*
theophylline and, 22-26
for upper GI disorders, 26-4*t*

Cinacalcet, 31-27**Cinnamates, 41-8*t*, 41-11–41-12****Cinoxate. (see Diethanolamine p-methoxycinnamate)****CINV. (see Chemotherapy-induced nausea and vomiting)****Cipro. (see Ciprofloxacin)****Ciprofloxacin (Cipro), 56-8*t*, 62-9, 63-4, 75-10**

anaphylactoid reactions from, 4-14
for aspiration pneumonia, 60-20, 60-21*t*
for CAP, 60-11*t*, 60-12*t*
for CF, 98-11*t*
for chancroid, 65-18
for *Chlamydia trachomatis*, 65-11
for cholera, 62-7
for COPD, 23-15–23-16
for CRRT and HD, 56-21*t*
digoxin and, 70-32*t*
dosing of, 56-19*t*
for endocarditis, 59-14
for gonorrhea, 65-4, 65-5
for gram-negative coverage, 59-23, 66-6
for gram-positive cocci, 56-9*t*
for HAP, 60-24*t*
for MAC, 70-34*t*
for MDRTB, 70-27
for neutropenia, 68-4–68-5, 68-9, 68-10
for osteomyelitis, 66-7, 66-8
penetration characteristics of, 58-7*t*
for prosthesis infection, 66-9
for *Pseudomonas* spp., 66-6, 98-11
renal failure and, 33-8*t*
resistance to, 65-5*f*
for *Salmonella* spp., 62-12
for SBP, 63-5
for septic arthritis, 66-11, 66-12
for *Shigella* spp., 62-9
for surgery, 57-2*t*
theophylline and, 64-9, 70-32*t*
for travelers' diarrhea, 62-17, 62-18
for UTIs, 64-5, 64-6*t*, 64-8–64-9, 64-10*t*, 99-13
for variceal hemorrhage, 28-14
warfarin and, 70-32*t*

Cisapride, 12-29

drug interactions with, 19-25
for gastroparesis, 50-77
for GERD, 93-10*t*, 93-11
neonates and, 94-6*t*

Cisatracurium (Nimbex), 9-13*t*

action parameters for, 9-14*t*
adverse effects of, 9-13*t*
elimination of, 9-15*t*

Cisplatin (Platinol), 7-4*t*, 88-12*t*, 91-24–91-25

for bladder cancer, 88-22*t*
cranial nerve toxicity with, 89-22

- dosing of, 89-27t
 for gastric cancer, 88-22t
 for head and neck cancer, 88-22t
 hypersensitivity from, 89-18t
 nephrotoxicity from, 89-26
 neurotoxicity of, 89-20t, 89-21
 for non-small-cell lung cancer, 88-22t
 for ovarian cancer, 88-22t, 91-14
 paresthesia from, 89-21
 for small-cell lung cancer, 88-22t
 for testicular cancer, 88-22t
- Citalopram (Celexa), 79-13t**
 aging and, 99-11t
 for bulimia nervosa, 82-17
 for depression, 100-16
 for GAD, 76-10
 for hot flushes, 48-6t
 for panic disorder, 76-22–76-23
 for PMS, 47-24
 for PTSD, 76-30
 for social anxiety disorder, 76-27
- Citrate salts, for RTA, 10-6**
- Cladribine, 90-11–90-12**
- Claforan. (see Cefotaxime; Cefpodoxime)**
- Clarinet. (see Desloratadine)**
- Clarithromycin (Biaxin), 12-29, 56-8t**
 adverse effects of, 56-15t
 benzodiazepines and, 76-16t
 for *Campylobacter jejuni*, 62-16
 for CDAD, 62-19t
 for endocarditis prophylaxis, 59-24t
 for *Helicobacter pylori*, 26-14t, 26-16
 indinavir and, 70-32t
 for Lyme disease, 75-5–75-6
 for MAC, 70-34t
 mania from, 80-5t
 nevirapine and, 70-32t
 penetration characteristics of, 58-7t
 penicillin resistance and, 60-13t
 for pneumonia, 60-10f
 rifabutin and, 70-32t
 rifampin and, 70-32t
 ritonavir and, 70-32t
 theophylline and, 22-26
 for toxoplasmosis, 70-15
- Claritin. (see Loratadine)**
- Clavulanate, 95-9–95-10**
 for neutropenia, 68-9
 penetration characteristics of, 58-7t
- Clemastine (Tavist), 24-12t**
 allergen skin tests and, 24-21t
 for allergic rhinitis, 24-10
 proarrhythmic effects of, 19-25
- Cleocin. (see Clindamycin)**
- Clevudine, 73-28**
- Climara Pro, 48-4t**
- Clindamycin (Cleocin), 56-8t, 67-2**
 for acne, 39-5, 39-6
 during pregnancy, 46-32t
 for acute osteomyelitis, 66-4t
 adverse effects of, 56-15t, 96-7
 for AOM, 96-6t
 for aspiration pneumonia, 60-20, 60-21t
 for babesiosis, 75-15
 for brain abscess, 58-33
 for CAP, 60-12t
 for CDAD, 62-19t
 DILI from, 29-7t
 dosing of, 56-19t
 for endocarditis prophylaxis, 59-24t
 for GABHS, 96-7
 with gentamicin, 62-9
 for gram-positive cocci, 56-9t
 leucovorin with, for toxoplasmosis, 70-14
 for NEC, 94-27
 for neonates, 94-31t
 for osteomyelitis, 66-4, 66-5t
 penetration characteristics of, 58-7t
 penicillin resistance and, 60-13, 60-13t
 for PID, 65-8, 65-9t
 for pneumonia, 60-10f
 pregnancy and, 46-32t
 preterm delivery from, 65-19
 renal failure and, 33-8t
 resistance to, 39-6–39-7
 for septic shock, 21-28
 for surgery, 57-2t
 for toxoplasmosis, 70-15
- Clindamycin/primaquine, for PCP, 70-9t, 70-10**
- Clinoril. (see Sulindac)**
- Clobetasol propionate, 38-8t**
- Clofibrate, hepatotoxicity from, 89-32t**
- Clofibrate, hepatitis and, 73-7**
- Clomid. (see Clomiphene)**
- Clomiphene (Clomid), 12-8**
 adverse effects of, 51-18t
 for PCOS, 47-6t, 47-8
- Clomipramine**
 for cataplexy, 77-17
 fluoxetine and, 76-39
 fluvoxamine and, 76-39
 for OCD, 76-34, 76-35, 76-37–76-39
 for panic disorder, 76-23
 paroxetine and, 76-39
- Clonazepam (Klonopin), 76-8t, 76-12, 76-12t**
 for absence seizures, 54-19
 for ET, 53-27t
 for GAD, 76-8
 neonates and, 94-7t
 for OCD, 76-35
 for panic disorder, 76-23
 pregnancy and, 46-42
 for RLS, 77-19
 for seizures, 54-5t
 for sleep disorders, 77-5
 for social anxiety disorder, 76-27
 for tardive dyskinesia, 78-20
- Clonidine (Catapres), 8-26, 13-38–13-39**
 for ADHD, 81-3
 adverse effects of, 20-7, 51-16t
 for alcohol withdrawal, 84-9t, 84-11
 for anxiety nervosa, 82-14
 for DPN, 50-79
 for dyslipidemia, 31-21
 for hot flushes, 48-6t
 for hypertension, 13-10, 20-3, 20-5, 20-6, 20-7, 31-21
 melatonin and, 3-33t
 for migraine, 52-18t
 for NAS, 94-46–94-47
 nasal symptoms from, 24-23t
 for opioid withdrawal, 8-19, 83-6, 83-9–83-10
 for panic disorder, 76-23
 for pediatric insomnia, 77-20
 as preoperative agent, 9-3t
 psoriasis from, 40-9t
 for PTSD, 76-30
 Raynaud's disease and, 14-11
 for refractory ascites, 28-9
 sexual dysfunction from, 101-2t
 sleep disorders from, 77-10t
 for smoking treatment, 85-7t, 85-13, 85-22–85-23
 for tardive dyskinesia, 78-20
 weight loss from, 82-6
- Clopidogrel (Plavix), 16-22–16-23**
 for acute coronary syndromes, 17-22
 aspirin and, 16-22
 bleeding from, 9-2
 for dementia, 100-14
 DILI from, 29-7t
 for ischemic stroke, 55-4
 for MI, 16-31, 17-8t, 17-13–17-15, 17-24–17-25
 after discharge, 17-24–17-25
 trial of, 17-15
 for PAD, 14-8
 with PCI, 16-27
 for stroke, 55-8, 55-11
 thrombotic thrombocytopenic purpura from, 87-11
- Clorazepate (Tranxene), 76-8t, 76-12, 76-12t**
- Clotrimazole (Gyne-Lotrimin, Mycelex), 89-7t**
 for diaper rash, 93-3–93-4
 for neutropenia, 68-5–68-6
 for VVC, 65-21t, 65-22
- Cloxacillin (Tegopen, Cloxapen), 56-8t, 67-2**
 bioavailability of, 33-2
 dosing of, 67-2–67-3
- Cloxapen. (see Cloxacillin)**
- Clozapine (Clozaril), 78-10, 78-27–78-29**
 adverse effects of, 78-12t
 benzodiazepines and, 76-16t
 dosing of, 78-17t
 neutropenia from, 87-13–87-14
 NMS from, 78-24
 for PD, 53-22
 pharmacokinetics of, 78-16t
 for psychosis, 100-15
 for PTSD, 76-30
 receptor-binding affinities of, 78-12t
 seizures from, 78-25
 WBC abnormalities with, 78-28t
 weight gain from, 78-22, 82-6
- Clozaril. (see Clozapine)**
- CMF. (see Cyclophosphamide, methotrexate, fluorouracil)**
- CMV hyperimmune globulin, for CMV, 34-34**
- CNI. (see Calcineurin inhibitors)**
- Coal tar, 71-5**
 for psoriasis, 40-3t, 40-4, 40-10
- COC. (see Combined oral contraceptive)**
- Cocaine, 9-16t, 83-12–83-14**
 anxiety from, 76-6t
 for cluster headaches, 52-21
 during lactation, 46-39t
 mania from, 80-5t
 properties of, 9-18t
 psychosis from, 78-4, 78-4t
 pulmonary disorders from, 25-2t, 25-5t, 25-7t, 25-8t
 sexual dysfunction from, 101-7t
 teratogenic effects of, 46-31t
- Codeine, 8-9, 8-32, 93-15t**
 analgesic syndrome from, 31-3
 hepatic encephalopathy from, 28-18
 histamine and, 4-17–4-18
 for migraine, during pregnancy, 46-32t
 neonates and, 94-6t
 for pain, 93-14
 renal failure and, 33-22
- Coenzyme Q, 3-3t, 3-36–3-38, 18-66–18-67**
 for AD, 3-36
 adverse effects of, 3-37
 antihypertensives and, 3-37–3-38
 as antioxidant, 3-38
 for breast cancer, 3-36
 dosing of, 3-37
 drug interactions with, 3-37–3-38
 for HF, 3-37
 for hypertension, 3-36–3-37
 for Parkinson disease, 3-36
 for PD, 53-21
 warfarin and, 3-37
- Coffee, for asthma, 22-38**
- Cogentin. (see Benztropine)**
- Cognex. (see Tacrine)**
- Colazal. (see Balsalazide)**
- Colchicine, for gout, 42-6**
- Colesevelam (Welchol), 12-25, 12-25t, 50-77**
- Colestipol. (see Bile acid resins)**
- Colistin**
 adverse effects of, 98-10
 for CAP, 60-12t
 for CF, 98-11t
- Colyte, 5-5**
- Combination insulins, 50-17t, 50-19**
- Combined oral contraceptive (COC), 45-5–45-18**
 antibiotics and, 45-11–45-12
 biphasic, 45-5
 carbamazepine and, 45-12
 monophasic, 45-5
 multiphasic, 45-9
 for PCOS, 47-6–47-7, 47-6t
 phenobarbital and, 45-12
 phenytoin and, 45-12
 for PMDD, 47-24
 primidone and, 45-12
 triphasic, 45-5
- CombiPatch, 48-4t**
- Comfeel, 41-19**
- Comfrey**
 hazards with, 3-6t
 toxicity of, 29-17, 29-19t
- Compazine. (see Prochlorperazine)**
- COMT. (see Catechol-O-methyltransferase)**
- Comtan. (see Entacapone)**
- Convax, 95-5**
- Conceptrol, 45-25t**
- Concerta. (see Methylphenidate)**
- Conivaptan, for SIADH, 11-7t**
- Conjugate pneumococcal vaccine (Prevnar), 95-10, 96-5**
- Conjugated equine estrogens (CEE, Premarin), 48-4t, 48-5, 102-7**
- Contraceptive patch (Ortho Evra), 45-18–45-19**
- Contraceptive ring (NuvaRing), 45-19**

with ritonavir, 69-16
- Dasatinib, HF from, 89-25-89-26**
- Daunomycin, 18-19**
- Daunorubicin (Cerubidine, Daunoxome), 7-4t, 88-12t, 88-13t, 89-23-89-24**
adverse effects of, 90-37
for ALL, 90-27
alopecia from, 89-11t
nail changes from, 89-11t
skin pigment changes from, 89-11t
for T-cell lymphoblastic lymphoma, 90-36t
- Daunoxome. (see Daunorubicin)**
- Daypro. (see Oxaproxin)**
- DDP-4. (see Dipeptidyl peptidase-4 inhibitors)**
- Decadron. (see Dexamethasone)**
- Decomethasone, dosing of, 22-24t**
- Decoctions, 3-4**
- Decongestants**
for allergic conjunctivitis, 24-9, 24-15t
for allergic rhinitis, 24-9t, 24-11-24-13
during pregnancy, 46-32t
death from, in children, 93-5
for otitis media, 90-2
for rhinitis, 24-8-24-9, 24-13t
sleep disorders from, 77-10t
- Deferoxamine, 32-10**
histamine and, 4-15
for iron toxicity, 5-12-5-13
- Defibrotide, 92-16**
- Dehydroemetine, 74-3t**
- Dehydroepiandrosterone sulfate, neonates and, 94-6t**
- Delavirdine (Rescriptor), 61-21**
for HIV, 69-9t
resistance to, 69-23t
- Delfen, 45-25t**
- Deltasone. (see Prednisone)**
- Demeclocycline, for SIADH, 11-7t, 11-11**
- Demerol. (see Meperidine)**
- Demulen. (see Zovia 1/35)**
- Denavir. (see Penciclovir)**
- Denileukin diftitox, for GVHD, 92-20**
- Denosumab, 102-17**
- Deoxyspergualin, for transplantation, 34-10**
- Depakene. (see Valproate)**
- Depakote. (see Valproate)**
- Depo-Provera, 45-20-45-21**
- Depot medroxyprogesterone acetate (DMPA), 47-18**
- Deprivan. (see Propofol)**
- Dermagraft, 41-19**
- Desflurane**
chemical stability of, 9-10t
for general anesthesia, 9-12
properties of, 9-10t
pulmonary disorders from, 25-4t
- Desiccated thyroid, 49-11**
- Desipramine (Norpramin), 79-13t, 81-8**
for cataplexy, 77-17
melatonin and, 3-33t
- Desloratadine (Clarinet), 24-12t**
allergen skin tests and, 24-21t
for allergic rhinitis, 24-10, 24-11
- Desonide, 38-8t**
- Desoximetasone, 38-8t**
- Desyrel. (see Trazodone)**
- Dexadrine. (see Dextroamphetamine)**
- Dexamethasone (Decadron), 7-5, 7-6t, 8-24, 38-8t, 44-7t**
administration routes of, 44-9t
adverse effects of, 51-20-51-21
for ALL, 90-27
with clomiphen, 47-8
for croup, 96-11
for eyes, 51-20t
for Hodgkin disease, 88-23t
for meningitis, 58-9-58-10
for MM, 90-19-90-20, 90-20-90-21, 90-21t
for pain, 8-5
for PONV, 7-10t, 9-25, 9-25t
for preterm labor, 46-28
for stroke, 55-16-55-17
for T-cell lymphoblastic lymphoma, 90-36t
for typhoid fever, 62-14
- Dexamethasone, cytarabine, cisplatin (DHAP), 90-16, 90-18**
- Dexamethasone, thalidomide, cisplatin, doxorubicin, cyclophosphamide, etoposide (DT-PACE), 90-20-90-21, 90-21t**
- Dexedrine. (see Dextroamphetamine)**
- Dexfenfluramine, 18-3**
- DexFerrum. (see Iron-dextran)**
- Dexmedetomidine, for sedation, 93-12t, 93-13**
- Dexrazoxane (Zinecard), 89-24, 90-33**
- Dextran, 28-8**
pulmonary disorders from, 25-2t, 25-8t
- Dextroamphetamine (Dexedrine), 7-3t, 8-31**
for ADHD, 81-3
for depression, 55-17
for narcolepsy, 77-17
- Dextromethorphan, 8-5**
abuse of, 83-15-83-16
for cough, during pregnancy, 46-32t
- Dezocine, 8-20**
- DHAP. (see Dexamethasone, cytarabine, cisplatin)**
- DHE. (see Dihydroergotamine)**
- DiaBeta. (see Glyburide)**
- Diabinese. (see Chlorpropamide)**
- Dialysate**
with CAPD, 32-11-32-12
composition of, 32-4-32-5
flow of, 32-4
- Diazepam (Valium), 54-31, 76-8t, 76-12t, 76-13**
for alcohol withdrawal, 84-8-84-10, 84-8t, 84-9t, 84-11
for cluster seizures, 54-23-54-24
distribution of, 99-3
for eclampsia, 46-19
hepatitis and, 73-7
herbs and, 3-5
INH and, 61-16
for NAS, 94-46-94-47
neonates and, 94-6t, 94-43, 94-43t
pharmacokinetics of, 94-3t
as preoperative agent, 9-3t
protein binding with, 94-4, 94-5
rifampin and, 61-17
for sedation, 93-12t
smoking and, 85-5t
for tardive dyskinesia, 78-20
withdrawal from, 76-15
- Diazoxide (Hyperstat), 20-11-20-12**
adverse effects of, 20-13, 51-16t
for hypertension, 20-3, 20-4t-5t
- Dibenzoylmethanes, 41-8t, 41-11, 41-12**
- Dibenzylidene. (see Phenoxybenzamine)**
- Dichlorphenamide, for glaucoma, 51-13t**
- Diclofenac (Voltaren), 8-9-8-10, 43-17t**
ARF from, 30-7-30-8
CH from, 29-15
DILI from, 29-3t
for dysmenorrhea, 47-11t
for eyes, 51-21, 51-22t
hemolytic anemia from, 87-5
for migraine, 52-12
nateglinide and, 50-52
- Diclofenac potassium (Cataplam), 8-9-8-10**
- Dicloxacillin (Dynapen), 56-8t, 67-2**
dosing of, 67-2-67-3
- for osteomyelitis, 66-5t
for prosthesis infection, 66-9
- Dicyclomine (Bentyl), 99-6t**
adverse effects of, 51-15t
for opiate withdrawal, 83-10t
for urinary incontinence, 101-27
- Didanosine, 69-4, 69-15**
anemia from, 86-18
with emtricitabine, for HIV, 69-14t
for HIV, 69-8t
with lamivudine, for HIV, 69-14t
resistance to, 69-23t
- Didronel. (see Etidronate)**
- Dietary supplements. (see Nutritional supplements)**
- Diethanolamine p-methoxycinnamate (Cinoxate), 41-8t, 41-11**
- Diethylcarbamazine, 74-4t**
- Diethylpropion**
anxiety from, 76-6t
for obesity, 82-19
- Diethylstilbestrol, teratogenic effects of, 46-31t**
- Differin. (see Transretinoic acid)**
- Diflorasone diacetate, 38-8t**
- Diflucan. (see Fluconazole)**
- Diflunisal (Dolobid), 8-9-8-10, 43-17t**
- Digitalis (Digoxin, Lanoxin), 18-4, 18-9, 18-13-18-15, 18-26, 18-44-18-54, 19-14**
adverse effects of, 51-18t
amiodarone and, 18-48-18-49
antiarrhythmics and, 18-52
anxiety from, 76-6t
arrhythmias from, 19-18
ciprofloxacin and, 70-32t
dialysis and, 32-3
diltiazem and, 18-63
distribution of, 99-3
drug interactions with, 18-49t
feeding tubes and, 36-16
for heart rate control, 19-9
herbs and, 3-5
hyperkalemia from, 11-18
hyperthyroidism and, 49-20-49-21
mortality and, 18-28
nateglinide and, 50-52
nifedipine and, 18-63
pediatric dosing of, 18-53-18-54
pharmacokinetics of, 94-3t
propafenone and, 18-48-18-49
protein binding with, 33-2
psoriasis from, 40-9t
quinidine and, 18-47-18-48
renal failure and, 33-8t
rifampin and, 70-30, 70-32t
sitaglitin and, 50-59
for supraventricular tachycardias, controlling ventricular rate in, 19-8t
toxicity with, 18-49-18-53
vs. vasodilators, 18-28-18-29
weight loss from, 82-6
withdrawal from, 18-27-18-28
- Digoxin. (see Digitalis)**
- Dihydrocodeine, bioavailability of, 33-2**
- Dihydroergotamine (DHE), for migraine, 52-11, 52-12, 53-4**
- Dihydropyridines, 13-17t, 13-31, 16-15**
for angina, 16-16t
for hypertension, 13-18
psoriasis from, 40-9t
- Dilantin. (see Phenytoin)**
- Dilapan, for labor induction, 46-20**

- Diloxanide furoate, 74-3f**
Diltiazem (Cardizem), 12-29, 13-31, 16-15
 with ACEI, 31-12
 for angina, 16-10, 16-16f
 for asthmatics, 19-9
 for atrial fibrillation, 13-33
 benzodiazepines and, 76-16f
 buspirone and, 76-20f
 for controlling ventricular rate, 19-9
 digitalis and, 18-63
 for heart transplantation, 35-5
 HF and, 16-16
 for hypertension, with heart transplantation, 35-6
 for hyperthyroidism, 49-23f
 intravenous, 20-14-20-15
 lithium and, 80-11f
 for MI, 17-7
 after discharge, 17-25
 for migraine, 52-17–52-18
 for nocturnal leg cramps, 14-14
 for paroxysmal supraventricular tachycardia, 19-15–19-16
 for proteinuria, 31-8
 psoriasis from, 40-9f
 risks with, 19-9
 sexual dysfunction from, 101-2f
 for supraventricular tachycardias, controlling ventricular rate in, 19-8f
 sustained release, 16-18
- Diltiazem CD (Cardizem CD), 15-7**
Dimenhydrinate (Dramamine), 7-3f
 for migraine, during pregnancy, 46-32f
 safety of, 93-7
- Dimetane. (see Brompheniramine)**
Dimethylsulfoxide (DMSO), 89-15
Dinoprostone. (see Prostaglandin E₂)
Dioxybenzone, 41-8f, 41-11
Dipentum. (see Olsalazine)
Dipeptidyl peptidase-4 inhibitors (DPP-4), 50-58–50-59
Diphenhydramine (Benadryl), 24-12f, 89-7f, 93-5, 99-6f
 allergen skin tests and, 24-21f
 for allergic rhinitis, 24-10
 for cough, during pregnancy, 46-32f
 for GAD, 76-10
 hangover effect of, 77-5
 for nocturnal leg cramps, 14-14
 for NVP, 46-8f
 for pediatric insomnia, 77-20
 for PONV, 9-24f
 proarrhythmic effects of, 19-25
 urinary complications with, 24-18–24-19
 weight gain from, 82-6
- Diphenoxylate/atropine, 62-5**
 for DP-IBS, 27-20
- Diphtheria and tetanus vaccine (DTP), 95-5–95-6, 95-9**
Diphtheria, tetanus, acellular pertussis (DTaP), 95-3, 95-6
Dipivefrin (Propine), for POAG, 51-12f
Dipyridamole
 adenosine with, 19-15
 aspirin with, for ischemic stroke, 55-4
 for stroke, 55-8, 55-10
- Dipyrrone, agranulocytosis from, 87-14**
- Direct renin inhibitors, 13-38**
Direct thrombin inhibitors
 with dialysis, 32-6
 for heparin-induced thrombocytopenia, 33-24
- Dirithromycin (Dynabac), 56-8f**
Disalcid. (see Salsalate)
Disease-modifying antirheumatic drugs (DMARDs)
 combinations of, 43-27–43-28
 for JIA, 43-35
 for RA, 43-5, 43-6–43-7, 43-9–43-10
- Disease-modifying antirheumatic drugs (DMARDs), for CTDs, 44-2**
Disopyramide (Norpace), 19-6f, 99-6f
 anxiety from, 76-6f
 HF from, 18-19
 sexual dysfunction from, 101-2f
- Dissociative drugs, 83-15–83-16**
Disulfiram, 84-13–84-16
Ditropan. (see Oxybutynin)
Diuretics, 11-13–11-14, 13-17f, 18-7, 18-9, 18-11–18-12, 18-20, 18-63. (see also Loop diuretics; Thiazide diuretics)
 absorption of, 12-25
 adverse effects of, 51-18f
 anorexia nervosa and, 82-2
 for ascites, 28-5–28-6
 for ATN, 30-11–30-12
 for BPD, 94-15–94-16, 94-16f
 for calcium stones, 30-17
 complications with, 28-6–28-7
 diabetes and, 13-23
 for diabetic nephropathy, 31-12
 dyslipidemia from, 13-23–13-24
 hyperkalemia from, 13-23, 28-6–28-7
 hyperlipidemia from, 12-17f
 for hypertension, 12-25, 13-8, 13-10, 13-18, 13-20–13-26, 13-20f, 20-9, 31-20
 with heart transplantation, 35-6
 hyperuricemia from, 42-7–42-9, 42-8f
 hypokalemia from, 28-6–28-7
 hyponatremia from, 11-9, 28-6–28-7
 lithium and, 80-11f
 metabolic alkalosis from, 11-14, 28-6–28-7
 osmotic, 11-14
 for PMS, 47-22–47-23
 potassium-sparing, 11-13, 13-21
 pregnancy and, 46-16f
 for RDS, 94-13
 for stroke, 55-7
 weight loss from, 82-6
- Divalproex**
 for aggressive behavior, 100-16
 for schizophrenia, 78-9–78-10
- DMARDs. (see Disease-modifying antirheumatic drugs)**
DMPA. (see Depot medroxyprogesterone acetate)
DMSO. (see Dimethylsulfoxide)
Dobutamine, 18-16, 18-57
 adverse effects of, 21-20
 for AMI, 21-26
 for cardiogenic shock, 21-19, 21-20
 with heart transplantation, 35-2
 heart transplantation and, 35-2
- for HF, 21-22–21-23
 for septic shock, 21-31
- Docetaxel (Taxotere), 88-13f**
 alopecia from, 89-11f
 for breast cancer, 88-22f, 91-6f
 hypersensitivity from, 89-18f
 for lung cancer, 91-12
 nail changes from, 89-11f
 neurotoxicity of, 89-20f
 for non-small-cell lung cancer, 88-22f
 paresthesia from, 89-21
 pulmonary disorders from, 25-2f
 radiation recall reactions from, 89-13f
- Docetaxel, doxorubicin, cyclophosphamide (TAC), 91-4**
Docosanol (Abreva), 72-7
Docusate sodium, for constipation, during pregnancy, 46-32f
Dofetilide (Tikosyn), 19-6f
 amiloride and, 19-11
 amiodarone and, 19-11
 for atrial fibrillation, 19-12
 azole antifungals and, 19-11
 for chemical cardioversion, 19-10–19-11
 cimetidine and, 19-11
 diltiazem, 19-11
 ketoconazole and, 19-11
 megestrol and, 19-11
 metformin and, 19-11
 nefazodone and, 19-11
 prochlorperazine and, 19-11
 quinine and, 19-11
 sulfamethoxazole and, 19-11
 triamterene and, 19-11
 trimethoprim and, 19-11
 zafirlukast and, 19-11
- Dolasetron (Anzemet), 7-6f**
 for PONV, 7-10f, 9-24f
 torsades de pointes and, 19-26f
- Dolobid. (see Diflunisal)**
Domperidone
 for anorexia nervosa, 82-14
 for gastroparesis, 50-77
 for GERD, 93-11
- Donepezil (Aricept), 53-21**
 for AD, 100-7, 100-8f
- Dong quai, for hot flushes, 48-7**
Dopamine, 18-16, 18-57. (see also Dopamine in Subject Index)
 for AMI, 21-26
 for ATN, 30-11–30-12
 for cardiogenic shock, 21-18–21-19, 21-20
 GERD and, 26-23f
 neonates and, 94-7f
 for septic shock, 21-31
- Dopamine agonists**
 for PD, 53-6–53-7, 53-14–53-15
 for RLS, 53-24–53-25
 schizophrenia and, 78-3
 for sleep disorders, 77-6
 sleep disorders from, 77-10f
- Doral. (see Quazepam)**
Doribax. (see Doripenem)
Doripenem (Doribax), 56-8f
 for UTIs, 64-10f
- Dornase alfa (Pulmonzyme), 98-9**
Dorzolamide (Trusopt), 51-6
 adverse effects of, 51-12
 for POAG, 51-10f
- Dovonex. (see Calcipotriene)**
- Doxapram, for apnea, in neonates, 94-39**
Doxazosin (Cardura)
 for BPH, 101-20
 for dementia, 100-13
 for hypertension, 13-10, 31-21
 nasal symptoms from, 24-23f
 sexual dysfunction from, 101-2f
- Doxepin (Sinequan), 8-22, 79-13f**
 for opiate withdrawal, 83-10f
 for sleep disorders, 77-14
 for tension-type headaches, 52-24
- Doxercalciferol (Hectorol), 31-26**
Doxil. (see Doxorubicin)
Doxorubicin (Adriamycin, Doxil, Rubex), 7-4f, 18-19, 88-13f
 adverse effects of, 51-17f
 alopecia from, 89-11f
 for bladder cancer, 88-22f, 91-16
 for breast cancer, 88-22f, 91-6f
 CHF from, 89-23
 dactinomycin and, 91-26
 for gastric cancer, 88-22f
 hand-foot syndrome from, 89-12f
 for head and neck cancer, 88-22f
 for Hodgkin disease, 88-23f, 89-35
 hypersensitivity from, 89-18f
 for lung cancer, 91-12
 for MM, 90-19–90-20
 nail changes from, 89-11f
 pulmonary disorders from, 25-2f, 25-7f
 radiation enhancement reactions with, 89-13f
 skin pigment changes from, 89-11f
 skin ulcers from, 89-15
 for T-cell lymphoblastic lymphoma, 90-36f
- Doxorubicin, cyclophosphamide (AC), 91-4**
Doxorubicin, vincristine, dexamethasone (DVD), 90-21f
Doxycycline (Vibramycin), 39-6f, 56-8f, 75-9
 for acne, 39-5, 39-9–39-10
 for AEBCB, 60-4f
 alcohol interaction with, 84-21f
 for anaerobes, 56-13f
 for aspiration pneumonia, 60-21f
 for CAP, 60-11f, 60-12f
 for *Chlamydia trachomatis*, 65-11
 for cholera, 62-7
 for COPD, 23-12, 23-15
 for gonorrhea, 65-7
 for LGV, 65-12
 for Lyme disease, 75-4f
 for PID, 65-8, 65-9f
 for pneumonia, 60-10f
 pregnancy and, 66-12
 for RMSF, 75-11, 75-13
 for surgery, 57-2f
 for syphilis, 65-15
 for toxoplasmosis, 70-15
- Doxylamine, 99-6f**
 for NVP, 46-8, 46-8f
 pregnancy and, 46-32f
- DPEN. (see D-penicillamine)**
D-penicillamine (DPEN)
 Goodpasture syndrome from, 43-7
 myasthenia gravis from, 43-7
 for RA, 43-5
 SLE from, 43-7
 for systemic sclerosis, 44-4
- DPP-4 inhibitors, 50-51f**
Dramamine. (see Dimenhydrinate)

- Dronabinol (Marinol), 7-6t**
anxiety from, 76-6t
for HIV wasting syndrome, 70-39t
- Droperidol (Inapsine), 7-6t, 7-8**
for acute agitation, 78-14t
for NVP, 46-8t
for PONV, 7-10t, 9-23-9-25, 9-24t
- Drotrecogin. (see Protein C)**
- Drotrecogin alfa, for septic shock, 21-32-21-33**
- DRV. (see Darunavir)**
- DTaP. (see Diphtheria, tetanus, acellular pertussis)**
- DTP. (see Diphtheria and tetanus vaccine)**
- DT-PACE. (see Dexamethasone, thalidomide, cisplatin, doxorubicin, cyclophosphamide, etoposide)**
- Duetact. (see Pioglitazone/glimepiride)**
- Duloxetine (Cymbalta), 8-27, 79-13t, 79-23**
aging and, 99-11t
for anorexia nervosa, 82-14
for DPN, 50-79
for GAD, 76-9-76-10, 76-11
- Duoderm, 41-19**
- Duranest. (see Etidocaine)**
- Duricef. (see Cefadroxil)**
- Dutasteride (Avodart), for BPH, 101-22**
- DVD. (see Doxorubicin, vincristine, dexamethasone)**
- Dyazide, 18-24**
- Dyclonine hydrochloride, 89-7t**
for mucositis, 89-9
- Dymelor. (see Acetohexamide)**
- Dynabac. (see Dirithromycin)**
- DynaCirc. (see Isradipine)**
- Dynapen. (see Dicloxacillin)**
- Dynorphin, 82-8**
- Dyrenium. (see Triamterene)**
- EC. (see Emergency contraception)**
- Ecamsule. (see Terephthalylidene dicamphor sulfonic acid)**
- Echinacea, 3-3t, 3-15-3-17**
adverse drug reactions with, 3-16
for candidiasis, 3-17
chemotherapy and, 3-17
for common cold, 3-15, 72-18
dosing of, 3-16
for HIV, 3-17
metronidazole and, 3-16
for UTIs, 3-17
for wound healing, 3-17
- Echinocandins, 71-4**
for *Candida*, 71-10
- Echothiophate iodide (Phospholine iodide), 51-7**
for POAG, 51-11t
- Ecstasy, 83-11-83-12, 83-17-83-19**
- EDTA. (see Ethylenediamine tetra-acetic acid)**
- Efalizumab, for psoriasis, 40-3t, 40-7**
- Efavirenz (Sustiva), 61-21**
anxiety from, 76-6t
for HIV, 69-9t, 69-14t
mania from, 80-5t
for *Pseudomonas* spp., 66-10
resistance to, 69-23t
- Effexor. (see Venlafaxine)**
- Eflornithine hydrochloride, 47-7**
- Elavil. (see Amitriptyline)**
- Eldepryl. (see Selegiline)**
- Electrolytes, 93-8, 93-8t. (see also Electrolytes in Subject Index)**
for alcohol withdrawal, 84-11
for hyponatremia, 11-8
- Elestrin. (see Estradiol topical emulsion)**
- Eletriptan, for migraine, 53-4**
- Eletriptan (Relpax), 54-8t**
- Elidel. (see Pimecrolimus)**
- Elimite. (see Permethrin)**
- Elitek. (see Rasburicase)**
- Ellence. (see Epirubicin)**
- Eloxatin. (see Oxaliplatin)**
- Elspar. (see Asparaginase)**
- Emadine. (see Emedastine)**
- EMB. (see Ethambutol)**
- Emedastine (Emadine), 24-15t**
- Emend. (see Aprepitant)**
- Emergency contraception (EC), 45-24-45-26**
OC for, 45-25t
- Eminase. (see Anistreplase)**
- EMLA. (see Lidocaine-prilocaine cream)**
- Emollients, for psoriasis, 40-3t**
- Emtricitabine (FTC, Emtriva), 69-4**
didanosine with, for HIV, 69-14t
for HBV, 73-28
for HIV, 69-8t
lamivudine with, 69-15
renal failure and, 33-8t
resistance to, 69-23t
- Emtriva. (see Emtricitabine)**
- E-Mycin. (see Erythromycin)**
- Enablex. (see Darifenacin)**
- Enalapril, 18-12, 18-27, 18-30, 31-7**
anxiety from, 76-6t
cough from, 101-24
for diabetes, 31-12
for MI, 17-6
for mixed hyperlipidemia, 12-32-12-33
psoriasis from, 40-9t
renal failure and, 33-8t
rifampin and, 61-17
systolic dysfunction and, 18-30t
- Enalaprilat (Vasotec)**
for hypertension, 20-3, 20-4t-5t
intravenous, 20-14
- Enbrel. (see Etanercept)**
- Encainide**
for arrhythmia suppression, 19-19
bioavailability of, 33-2
for MI, 17-7
- Encare, 45-25t**
- Enflurane**
chemical stability of, 9-10t
DILI from, 29-3t
properties of, 9-10t
- Enfurvitride. (see Fuzeon)**
- Engerix-B, 73-16-73-18**
- Enjuvia. (see Synthetic conjugated estrogens (Cenestin, Enjuvia))**
- Enoxaparin, 15-15, 16-31**
as adjunct therapy, for myocardial infarction, 17-15
as antithrombotic, 17-22-17-23
with dialysis, 32-6
dosing of, 16-28t
with epidural infusion, 9-32
for MI, 17-15
renal failure and, 33-23
thrombocytopenia from, 87-10
- Enpresse (Tri-Norinyl, Triphasil), 45-5t**
- Ensulizole. (see Phenylbenzimidazole sulfonic acid)**
- Entacapone (Comtan), 53-4t**
for PD, 53-15-53-17
- Entecavir (Baraclude)**
dosing of, 73-28t
for HBV, 73-23t, 73-27, 73-34t
- Entry inhibitors, for HIV, 69-10t**
- Ephedra**
for asthma, 22-38
hazards of, 3-6t
torsades de pointes and, 19-26t
- Epidrine, 3-5**
anxiety from, 76-6t
mania from, 80-5t
- Epical, 41-19**
- Epidermal growth factor receptor antagonists, pulmonary disorders from, 25-8t**
- Epidurals, 8-18-8-20**
for analgesia, 9-29-9-30
- Epinephrine (Glaucon, Eppy/N, Epitrate)**
for anaphylaxis, 4-8, 4-9t
anxiety and, 76-2
for bronchiolitis, 96-11
for cardiac arrest, 19-27t, 19-28
for cardiogenic shock, 21-19
dosing of, 22-17t
for POAG, 51-6, 51-12t
for pulsatile priapism, 101-13
torsades de pointes and, 19-26t
via endotracheal administration, 19-28-19-29
- Epirubicin (Ellence), 7-4t, 88-13t, 89-24**
alopecia from, 89-11t
for breast cancer, 88-22t, 91-6t
with FLU, 90-11
for gastric cancer, 88-22t
hepatotoxicity from, 89-32t
nail changes from, 89-11t
radiation recall reactions from, 89-13t
skin pigment changes from, 89-11t
- Epitrate. (see Epinephrine)**
- Epivir, for HIV, 69-8t**
- Eplerenone, 18-25**
for diabetic nephropathy, 31-12
for HF, 28-6
for hypertension, 13-10, 28-6
for MI, 17-23-17-24
for renal disease, 28-6
- Epoetin- α (Eprex), 31-17-31-18, 87-16-87-17**
for anemia, 89-5
- Epogen. (see Erythropoietin)**
- Epoprostenol. (see Prostacyclin)**
- Eppy/N. (see Epinephrine)**
- Eprex. (see Epoetin- α)**
- EPT. (see Estrogen-progestin therapy)**
- Eptifibatide (Integrilin)**
with PCI, 16-27
thrombocytopenia from, 87-8
- Equetro. (see Carbamazepine)**
- Equine estrogen, 12-31**
- Erbix. (see Cetuximab)**
- Ergonovine maleate (Ergotrate), 46-23**
for migraine, 52-18t
- Ergostat. (see Ergotamine)**
- Ergot alkaloids**
breast-feeding and, 97-7
for migraine, 53-4
for postpartum hemorrhage, 46-23
pulmonary disorders from, 25-2t, 25-6t, 25-7t
- Ergotamine (Cafergot, Ergostat)**
adverse effects of, 52-11
caffeine with, 52-10
for cluster headaches, 52-21-52-22, 52-21t, 52-22t
contraindications for, 52-11
during lactation, 46-39t
for migraine, 52-10-52-11, 52-13t, 53-4
- Ergotrate. (see Ergonovine maleate)**
- Erlotinib (Tarceva), 88-13t**
alopecia from, 89-11t
nail changes from, 89-11t
pulmonary disorders from, 25-2t, 25-5t, 25-9-25-10
- Errin (Micronor), 45-5t**
- Ertapenem (Invanz), 56-8t, 66-8**
for gram-negative aerobes, 56-10t
for HAP, 60-24t
renal failure and, 33-8t
for UTIs, 64-10t
- Erythrocin. (see Erythromycin)**
- Erythromycin (E-Mycin, Erythrocin), 12-29, 39-6t, 56-8t, 67-2, 67-3**
for acne, 39-6
during pregnancy, 46-32t
adverse effects of, 56-15t
alcohol interaction with, 84-21t
antipsychotics and, 78-15
for aspiration pneumonia, 60-21t
benzodiazepines and, 76-16t
buspirone and, 76-20t
for *Campylobacter* spp., 62-3t
for *Campylobacter jejuni*, 62-16
carbamazepine and, 54-25-54-26
for CDAD, 62-19t
for chancroid, 65-18
for cholera, 62-7
for DGI, 65-10t
DILI from, 29-3t, 29-8t
for dyspepsia, 26-9
for erysipelas, 67-7
for gastroparesis, 50-77
for GERD, 93-10t, 93-11
for gram-positive cocci, 56-9t
for LGV, 65-12
for Lyme disease, 75-5-75-6
mania from, 80-5t
neonates and, 94-3, 94-6t, 94-31t
OC and, 45-12t
penetration characteristics of, 58-7t
penicillin resistance and, 60-13t
pregnancy and, 46-32t
proarrhythmic effects of, 19-25
renal failure and, 33-8t
resistance to, 39-6-39-7
for RMSF, 75-13
sildenafil and, 101-11
for surgery, 57-2t
for syphilis, 65-15
for systemic sclerosis, 44-4
torsades de pointes and, 19-26t
- Erythropoiesis stimulating agent (ESA), 31-15, 31-17-31-19**
for anemia, 89-5
with dialysis, 32-2
- Erythropoietin (Epogen, Procrit), for HSCt, 92-6**
- ESA. (see Erythropoiesis stimulating agent)**
- Escitalopram (Lexapro), 79-13t**
aging and, 99-11t
for bulimia nervosa, 82-17
for GAD, 76-10
for panic disorder, 76-22-76-23
for PMS, 47-24
for social anxiety disorder, 76-27

- ESHAP.** (see **Etoposide, methylprednisolone, cytarabine, cisplatin**)
- Esmolol (Brevibloc), 49-32**
for aortic dissection, 20-6*t*
for hypertension, 20-3, 20-4*t*-5*t*
intravenous, 20-14
for MI, 20-6*t*
for pulmonary disease, 17-20
for supraventricular tachycardias, controlling ventricular rate in, 19-8*t*
- Esomeprazole, 26-5-26-6**
for aspiration pneumonitis, 9-5
for end-of-life care, 6-5
for GERD, 93-10*t*
for SRMB, 26-35*t*
for upper GI disorders, 26-4*t*
- Estazolam (ProSom), 76-8*t*, 76-12*t***
- Esterified estrogen (Estratab, Menest), 48-4*t***
- Esters, 9-16*t***
properties of, 9-18*t*
- Estrace.** (see **Micronized estradiol**)
- Estradiol, 12-29, 48-2*t***
- Estradiol acetate (Femtrace), 48-4*t***
- Estradiol hemihydrate (Vagifem), 48-4*t***
- Estradiol topical emulsion (Elestrin, Estragel, Estrasorb), 48-4*t***
- Estradiol transdermal system, 48-4*t***
- Estrasorb.** (see **Estradiol topical emulsion**)
- Estratab.** (see **Esterified estrogen**)
- Estratest.** (see **Ethinylestradiol and methyltestosterone**)
- Estragel.** (see **Estradiol topical emulsion**)
- Estrogen.** (see **Also Estrogen in Subject Index**)
adverse effects of, 51-18*t*
with androgen, 48-4*t*
for anorexia nervosa, 82-14
dementia and, 100-9
for EPT, 48-4*t*
for ET, 48-4*t*
GERD and, 26-23*t*
for hormone-sensitive tumors, 88-25*t*
pioglitazone and, 50-56
with progestin, 48-4*t*
smoking and, 85-23
for urinary incontinence, 101-28
UTIs and, 48-8
for vaginal epithelial thinning, 48-7
- Estrogen therapy (ET), 102-7-102-8**
AMI from, 48-2*t*
breast cancer from, 48-2*t*, 48-3
cardiovascular disease from, 48-3-48-4
colorectal cancer from, 48-2*t*
contraindications for, 48-3*t*
DVT from, 48-2*t*
endometrial cancer from, 48-3
for hot flushes, 48-2
osteoporosis from, 48-2*t*, 48-3
ovarian cancer from, 48-3
PE from, 48-2*t*
stroke from, 48-2*t*
thromboembolic disease from, 48-3

- Flucytosine**
adverse effects of, 56-16†
for cryptococcosis, 71-25
dosing of, 56-19†
fluconazole with, 70-26
HIV and, 70-4
- 5-Flucytosine (5-FC), 71-4**
for fungal endocarditis, 59-22
for gram-negative bacillary endocarditis, 59-23
- Fludarabine (FLU)**
for CLL, 90-11
cyclophosphamide with, 90-11
dosing of, 89-27†
epirubicin with, 90-11
for HSCT, 92-2†, 92-11†
neurotoxicity of, 89-20†, 89-21
pulmonary disorders from, 25-2†
pulmonary toxicity from, 89-30†
refractory, 90-12
rituximab with, 90-11
sensitive, 90-12
- Fludarabine, cyclophosphamide, and rituximab (FCR), 90-12**
- Fludarabine, mitoxantrone, dexamethasone (FND), 90-17**
- Flumadine. (see Rimantadine)**
- Flumazenil, 28-19**
for benzodiazepine toxicity, 5-5, 5-14, 76-17–76-18
- FluMist, 95-11**
- Flunisolide (Nasalide, Nasarel), 24-16†**
for asthma, long-term, 22-27†
for BPD, 94-18
dosing of, 22-23†, 22-24†
- Fluocinonide, 38-8†**
- Fluoride, 89-7†**
for osteoporosis, 44-13
- Fluorometholone, adverse effects of, 51-20–51-21**
- Fluoroquinolones, 63-4, 75-10**
for AECB, 60-4†
anxiety from, 76-6†
for aspiration pneumonia, 60-20
for *Campylobacter jejuni*, 62-16
for CAP, 60-11†, 60-12†
for CDAD, 62-19†
children and, 96-18†, 96-19
for diarrhea, 62-5
DILI from, 29-8†
drug interactions with, 64-8–64-9
for gonorrhea, 65-4
hemolytic anemia from, 87-7
for HSCT, 92-23
for *Legionella* spp., 56-12†
for Lyme disease, 75-5–75-6
for MDRTB, 70-27
for neutropenia, 68-4–68-5, 68-10
penetration characteristics of, 58-7†
penicillin resistance and, 60-13
photosensitive eruptions from, 38-15
for pneumonia, 60-10†
proarrhythmic effects of, 19-25
for *Salmonella* spp., 62-3†, 62-11–62-12
for SBP, 62-5
for *Shigella* spp., 62-3†, 62-9
SJS from, 38-16
for TB, 61-9–61-11
for typhoid fever, 62-12–62-13
for UTIs, 64-5†, 64-8–64-9, 99-13
- Fluorouracil, 88-13†**
adverse effects of, 51-17†
alopecia from, 89-11†
angina pectoris from, 89-25
for breast cancer, 88-22†
for colorectal cancer, 88-22†
for gastric cancer, 88-22†
hand-foot syndrome from, 89-12
- for head and neck cancer, 88-22†
nail changes from, 89-11†
neurotoxicity of, 89-20†, 89-21
radiation enhancement reactions with, 89-13†
skin pigment changes from, 89-11†
UV reactions from, 89-13†
- Fluorouracil, doxorubicin, cyclophosphamide (FEC), 91-4**
- Fluoxetine (Prozac), 79-13†**
adverse effects of, 51-16†
aging and, 99-11†
for anorexia nervosa, 82-14
antipsychotics and, 78-16
benzodiazepines and, 76-16†
for bulimia nervosa, 82-16–82-17
buspirone and, 76-20†
for cataplexy, 77-17
clomipramine and, 76-39
for depression, 100-16
DILI from, 29-8†
for GAD, 76-10
for hot flushes, 48-6†
lithium and, 80-11†
melatonin and, 3-33†
for OCD, 76-34, 76-35
for OSA, 77-17
for panic disorder, 76-22–76-23
for PD, 53-22
for PMS, 47-24
psoriasis from, 40-9†
for PTSD, 76-30
for sleep disorders, 77-12–77-14
sleep disorders from, 77-10†
for social anxiety disorder, 76-27
toxicity from, 5-17
- Fluoxymestron, for hormone-sensitive tumors, 88-25†**
- Fluphenazine (Prolixin), 78-14, 78-26**
adverse effects of, 78-12†
dosing of, 78-17†
long-acting, 78-15
pharmacokinetics of, 78-16†
receptor-binding affinities of, 78-12†
- Flurandrenolide, 38-14**
- Flurazepam (Dalmane), 76-8†, 76-12†, 77-11, 77-21**
dosing of, 77-10†
for opiate withdrawal, 83-10†
properties of, 77-7†
for sleep disorders, 77-2
- Flurbiprofen (Ansaid), 8-9–8-10, 42-5, 43-17†**
for eyes, 51-21, 51-22†
- Flutamide (Eulexin)**
for BPH, 101-22
for hormone-sensitive tumors, 88-25†
- Fluticasone (Flonase), 24-16†, 99-12**
for asthma, long-term, 22-27†
for BPD, 94-18
dosing of, 22-23†, 22-24†
- Fluvastatin (Lescol), 12-24†, 12-25†, 12-28, 50-77**
- Fluvoxamine (Luvox)**
aging and, 99-11†
antipsychotics and, 78-15
benzodiazepines and, 76-16†
for bulimia nervosa, 82-16, 82-17
buspirone and, 76-20†
clomipramine and, 76-39
for depression, 100-16
lithium and, 80-11†
- melatonin and, 3-33†
for OCD, 76-34, 76-35
for panic disorder, 76-22–76-23
for PMS, 47-24
for PTSD, 76-30
smoking and, 85-5†
for social anxiety disorder, 76-27
- FND. (see Fludarabine, mitoxantrone, dexamethasone)**
- Folate inhibitors, 56-8†**
- FOLFIRI, 91-9–91-10**
- FOLFOX, 91-9–91-10**
- Folic acid. (see also Folic acid in Subject Index)**
for atherosclerosis, 16-10
homocysteine and, 2-12
with MTX, 43-25
pregnancy and, 46-7, 46-43
pyrimethamine with, for toxoplasmosis, 70-15
- Fomepizole (Antizol), 10-7**
for methanol toxicity, 5-5
- Fomoterol, for asthma, long-term, 22-29†**
- Fondaparinux (Arixtra), 15-5, 16-31**
dosing of, 16-28†
for MI, 17-15–17-16
for PE, 15-17
thrombocytopenia from, 87-10
UFH and, LMWH and, 15-4†
- Formoterol, for EIA, 22-32**
- Fortaz. (see Ceftazidime)**
- Fortovase. (see Saquinavir)**
- Fosamax. (see Alendronate sodium)**
- Fosamprenavir (fAPV)**
for HIV, 69-14†
NNRTIs and, 69-21†
PI and, 69-19†
resistance to, 69-24†
with ritonavir, 69-16
for HIV, 69-14†
- Foscarnet (Foscavir)**
adverse effects of, 56-17†, 70-21, 72-6†
for CMV, 34-33
retinitis, 70-16–70-18†, 70-19–70-21, 72-5†
dosing of, 70-20†, 70-21
with ganciclovir, 70-21
renal failure and, 33-9†
toxicity with, 70-21
- Foscavir. (see Foscarnet)**
- Fosinopril (Monopril), 18-12, 18-30**
systolic dysfunction and, 18-30†
- Fosphenytoin (Cerebyx), 54-31–54-32**
for neonates, 94-42–94-44
- Fosrenol. (see Lanthanum carbonate)**
- Free hydroxyl radical, 9-20**
- Fresh-pressed juice, 3-4–3-5**
- Frova. (see Frovatriptan)**
- Frovatriptan (Frova), 54-8†**
for migraine, 53-4
- FTC. (see Emtricitabine)**
- Fulvestrant, for hormone-sensitive tumors, 88-25†**
- Fulvicin. (see Griseofulvin)**
- Furazolidone (Furoxone), 75-11**
alcohol interaction with, 84-21†
- Furosemide (Lasix), 13-13, 18-11, 18-20–18-21, 18-25, 99-2–99-3, 99-10**
for ARF, 30-18
for ascites, 28-5–28-6
for BPD, 94-16†
for HRS, 29-21

Furosemide (Lasix) (continued)

for hypercalcemia, 11-22t
for hypertension, 20-9, 31-20,
31-21

NSAIDs and, 99-3
for RDS, 94-13
for SIADH, 11-11
thrombocytopenia from, 87-8

Furoxone. (see Furazolidone)**Fusion inhibitors, 69-4-69-5****Fuzeon (Enfuvirtide, T-20), for HIV, 69-10t****Fuzeon (T-20), 69-4-69-5****Gabapentin (Neurontin), 8-27, 31-29, 54-9**

adverse effects of, 54-11
for alcohol withdrawal, 84-9t,
84-10-84-11

for alcoholism, 84-14t
for DPN, 50-79
for epilepsy, 54-3t
for ET, 53-27t
for hot flushes, 48-6t
for mania, 80-13
mania from, 80-5t
for migraine, 52-18t
nasal symptoms from, 24-23t
OC and, 54-29-54-30
pregnancy and, 46-43
for seizures, 54-5t, 54-12t
for sleep disorders, 77-5
weight gain from, 82-6

Gabitril. (see Tiagabine)**Galantamine (Razadyne), for AD, 100-7-100-9, 100-8t****Gallium nitrate, for hypercalcemia, 11-22t, 11-24****Galvus. (see Vildagliptin)****Ganciclovir (Cytovene)**

adverse effects of, 56-17t, 72-6t
anemia from, 86-18
for CMV, 34-32-34-33, 34-34,
92-24
in neonates, 94-34t, 94-36
for CMV retinitis, 70-16-70-18t,
70-19, 70-23, 72-5t
for CRRT and HD, 56-21t
dosing of, 56-19t, 70-20t
for HIV, 70-6t
for HSV, 51-22
for PTLD, 35-11
renal failure and, 33-9t

Ganglionic blocking agents, glaucoma and, 51-8**Garamycin. (see Gentamicin)****Garlic, 3-3t, 3-7-3-10**

adverse drug reactions with, 3-9
for atherosclerosis, 3-8
for CAD, 3-8
for cancer, 3-9
contact dermatitis from, 3-9
for diabetes, 3-9
dosing of, 3-9-3-10
for hyperlipidemia, 3-7-3-8
for hypertension, 3-8
for hypoglycemia, 3-9
ritonavir and, 3-9
saquinavir and, 3-9

Gastric motility stimulants, for aspiration pneumonia, 9-5**Gatifloxacin**

for TB, 61-9, 61-11t
torsades de pointes and, 19-26t

GBL. (see γ -Butyrolactone)**G-CSF. (see Granulocyte colony-stimulating factor)****Gefitinib**

nail changes from, 89-11t
pulmonary disorders from, 25-2t,
25-5t, 25-9-25-10

Gelclair, for mucositis, 89-9**Gemcitabine (Gemzar), 88-13t**

alopecia from, 89-11t
for bladder cancer, 88-22t
for breast cancer, 91-6t
for non-small-cell lung cancer,
88-22t
pulmonary disorders from, 25-2t,
25-4t, 25-5t, 25-8t,
25-11-25-12
pulmonary toxicity from, 89-30t
radiation enhancement reactions
with, 89-13t
thrombocytopenia from, 87-8-87-9

Gemfibrozil (Lopid), 12-14, 12-14t,**12-15, 12-25t, 12-26, 50-77**

adverse effects of, 12-37
for dyslipidemia, 31-9
for hyperchylomicronemia, 12-39
for hyperlipidemia, with heart
transplantation, 35-7
pioglitazone and, 50-56
psoriasis from, 40-9t
repaglinide and, 50-52
rosiglitazone and, 50-56
with statins, 12-29
for stroke, 55-7

Gemifloxacin (Factive), 56-8t

for CAP, 60-11t

Gentuzumab ozogamicin (Mylotarg), 88-13t

hepatotoxicity from, 89-32t
VOD from, 92-14

Gemzar. (see Gemcitabine)**GenGraf. (see Cyclosporine)****Genora. (see Ortho-Novum)****Gentamicin (Garamycin), 38-9t, 56-8t, 94-48**

for acute osteomyelitis, 66-4t
adverse effects of, 51-16t, 56-15t,
98-10
as aerosol, 60-29
allergic contact dermatitis from,
38-16
for aspiration pneumonia, 60-21t
for CAP, 60-12t
for CF, 98-11t, 98-14
clindamycin with, 62-9
for CNS infections, 58-9t
continuous ambulatory peritoneal
dialysis and, 33-16-33-17
continuous venovenous
hemofiltration and, 33-16
for CRRT and HD, 56-21t
with dialysis, 32-10
dosing of, 56-19t, 59-17-59-18
for endocarditis, 59-8t, 59-18
for *Enterococcus faecium*, 56-11
for gram-negative aerobes, 56-10t
for gram-negative bacillary
endocarditis, 59-23
for HAP, 60-24t, 60-25
hemodialysis and, 33-15-33-16
for *Listeria monocytogenes*, 56-11
for meningitis, 58-18
for MRSE, 59-11
for MSSA, 59-14

for NEC, 94-27

for neonates, 94-8t

for neutropenia, 68-11

penetration characteristics of, 58-7t

for peritonitis, 32-14

pharmacokinetics of, 94-3t

protein binding with, 33-2

for *Pseudomonas* spp., 66-10

renal failure and, 33-9t

resistance to, 59-17

for RMSE, 75-13

for staphylococcal endocarditis,

59-12t

for surgery, 57-2t

for UTIs, 64-10t

for ventriculitis, 55-19

Gentamicin-impregnated**polymethylmethacrylate (PMMA), 66-7-66-8**

for bone infections, 66-8

Gentian, 71-5

toxicity of, 29-17

Geocillin. (see Carbenicillin)**Geodon. (see Ziprasidone)****Germander**

hazards with, 3-6t

toxicity of, 29-17, 29-19t

GHB. (see γ -Hydroxybutyric acid)**Gilead. (see Adefovir)****Ginger root, for NVP, 46-8****Ginkgo, 3-3t, 3-10-3-12**

for AD, 100-10

adverse drug reactions with,

3-11-3-12

for anxiety, 3-11

aspirin and, 3-11-3-12

for dementia, 3-10

dosing of, 3-11

for IC, 14-9

memory and, 3-12

for SSRI-induced sexual
dysfunction, 79-17t

for stress, 3-11

warfarin and, 3-11-3-12

Ginseng, 3-20-3-24

adverse drug reactions with, 3-24

for AIDS, 3-23

for cancer, 3-23

for colds, 3-23

for diabetes, 3-22

dosing of, 3-24

for ED, 3-23-3-24

for hot flushes, 48-7

for hyperlipidemia, 3-22

for hypertension, 3-22

lithium and, 3-24

for MS, 3-23

Glaucon. (see Epinephrine)**Gleevec. (see Imatinib)****Glimepiride (Amaryl), 50-50t,****50-53-50-54, 50-67**

for type 2 diabetes, 50-65t

Glinitides. (see Nonsulfonylurea secretagogues)**Glipizide, 50-67**

DILI from, 29-14

for type 2 diabetes, 50-65t

Glipizide (Glucotrol), 50-50t, 50-53**Glipizide/metformin (Metaglip), 50-51t****GLP-1. (see Glucagonlike peptide-1 receptor agonists)****Glucagon**

for ALF, 73-15

for anaphylaxis, 4-9t

Glucagonlike peptide-1 receptor agonists (GLP-1), 50-57-50-58**Glucocorticoids**

acneiform eruptions from, 38-15
alendronate sodium and, 102-16
for allergic rhinitis, during
pregnancy, 46-32t
calcitonin and, 102-16
chronic steatosis from, 29-16
for COPD, 23-10-23-11
hyperlipidemia from, 12-17t
hypertension from, 44-6
for ITP, 93-18
osteoporosis from, 102-15-102-16
for preterm labor, 46-28
for pruritus, during pregnancy,
46-32t
risedronate sodium and, 102-16
for SLE, 44-8
weight gain from, 82-6

Glucophage. (see Metformin)**Glucosamine, 3-3t, 3-24-3-28**

adverse drug effects of, 2-27-2-28
diabetes and, 2-28
dosing of, 2-27
heparin and, 3-28
ibuprofen and, 3-26
NSAIDs with, 3-26
for OA, 3-24, 43-39-43-40
for psoriasis, 40-8

Glucose, 5-13. (see also Glucose in Subject Index)

for alcohol intoxication, 84-6
with cardioplegia solution, 9-21t
for hypoglycemia, 50-41
for hyponatremia, 11-8

Glucosidase inhibitors, 50-56-50-57

dosing of, 50-57

drug interactions with, 50-57

 α -glucosidase inhibitors, 50-48t, 50-49t**Glucotrol. (see Glipizide)****Glucovance. (see Glyburide/metformin)****Glutamine, 10-1, 36-9**

for mucositis, 89-9

Glyburide (DiaBeta, Glynase, Micronase), 19-5, 50-50t, 50-53, 50-67

acarbose and, 50-57

DILI from, 29-14

ED and, 101-9

miglitol and, 50-57

nateglinide and, 50-52

sexual dysfunction and, 101-9

Glyburide/metformin (Glucovance), 50-51t**Glycerin, 93-6t**

for constipation, during pregnancy,
46-32t

for glaucoma, 51-13t

Glyceryl PABA (Lisdimate), 41-8t**Glycoprotein (GP), for thrombosis, 17-6****Glycoprotein IIb/IIIa inhibitors, 16-26-16-27, 55-14**

for MI, 17-15

for NSTE-ASC, 17-23

for NSTEMI, 17-23

before PCI, 17-23

Glycoprotein IIb/IIIa receptor antagonists (GPRA), thrombocytopenia from, 87-8**Glycopyrrolate (Robinul)**

adverse effects of, 51-15t

as preoperative agent, 9-3t

- Glycosidase inhibitors, 73-28**
Glycyrrhizin (licorice root), for HCV, 73-44
- Glyname. (see Glyburide)**
Glypressin. (see Terlipressin)
Glyset. (see Miglitol)
GM-CSF. (see Granulocyte-macrophage colony-stimulating factor)
Gn-Rh. (see Gonadotropin-releasing hormone)
Gn-Rh agonists, 47-17t
 adverse effects of, 47-18–47-19, 47-19t
 dosing of, 47-18
- Gold (AUR, Auranofin)**
 adverse effects of, 43-22, 51-17t
 DILI from, 29-14
 dosing of, 43-23
 nephrotic syndrome from, 11-5
 pulmonary disorders from, 25-2t, 25-7t
 for RA, 43-5, 43-7, 43-22
- Gold sodium thiomalate (Myochrysin), 43-22**
- GoLYTELY, 5-5**
- Gonadotropin-releasing hormone (Gn-RH), for BPH, 101-22–101-23**
- Gonadotropin-releasing hormone (Gn-RH) agonists, for endometriosis, 47-16**
- Gordolobo yerba, 29-19t**
- Goserelin (Zoladex), 47-17t, 91-19**
 adverse effects of, 47-19t
 dosing of, 47-18
 for hormone-sensitive tumors, 88-25t
- GPRA. (see Glycoprotein IIb/IIIa receptor antagonists)**
- Gramicidin, 38-9t**
- Granisetron (Kytrel), 7-6t**
 for PONV, 7-10t, 9-24t
- Granulocyte colony-stimulating factor (G-CSF, Filgrastim), 90-6**
 for chemotherapy reactions, 89-3–89-4
 for CMV, 92-24
 for HSCT, 92-6
 hyperuricemia from, 42-8t
 for neutropenia, 68-6, 87-13
- Granulocyte-macrophage colony-stimulating factor (GM-CSF, Sargramostim), 90-6**
 for chemotherapy reactions, 89-3–89-4
 for HSCT, 92-6
 for neutropenia, 68-6, 87-13
- Grepafloxacin, torsades de pointes and, 19-26t**
- Griseofulvin (Fulvicin), 3-16, 71-3**
 OC and, 45-12t
- Growth hormone**
 cluster headaches and, 52-19
 for obesity, 82-8
 sleep and, 77-3
- Guaifenesin, for cough, during pregnancy, 46-32t**
- Guanabenz, sexual dysfunction from, 101-2t**
- Guanadrel, for hypertension, 13-10**
- Guanethidine, 14-9**
 adverse effects of, 51-16t
 for hypertension, 13-10
 nasal symptoms from, 24-23t
- Guanfacine, sexual dysfunction from, 101-2t**
- Gynazole. (see Butoconazole)**
Gyne-Lotrimin. (see Clotrimazole)
Gynodiol. (see Micronized estradiol)
Gynol II, 45-25t
- H₂ receptor antagonists (H₂RAs), 26-4–26-5, 26-4t**
 alcohol interaction with, 84-21t
 for ALF, 73-15
 for aspiration pneumonitis, 9-5
 for GERD, 26-28, 93-10t, 93-11
 for *Helicobacter pylori*, 26-13, 26-14t
 with PPI, for GERD, 26-29
 as preoperative agent, 9-3t
 for reflux esophagitis, 46-9
 for SRMB, 26-35
 for systemic sclerosis, 44-5
 for upper GI bleeding, 26-32
- H₂RAs. (see H₂ receptor antagonists)**
- HAART. (see Highly active antiretroviral therapy)**
- Halcinonide, 38-8t**
- Halcion. (see Triazolam)**
- Haldol. (see Haloperidol)**
- Hallucinogens, 83-16–83-19**
 sexual dysfunction from, 101-7t
- Halobetasol propionate, 38-8t**
- Halogens, acneiform eruptions from, 38-15**
- Haloperidol (Haldol), 7-6t, 7-8, 78-19, 78-26**
 for acute agitation, 78-14t
 adverse effects of, 78-12t
 for alcohol withdrawal, 84-9t, 84-11
 buspirone and, 76-20t
 chronic intrahepatic cholestasis from, 29-16
 dosing of, 78-17t
 drug fever from, 4-11
 drug interactions with, 19-25
 for end-of-life care, 6-7
 long-acting, 78-15
 lorazepam and, for acute agitation, 80-14
 myxedema coma and, 49-16
 for OCD, 76-34–76-35
 for PD, 53-22
 pharmacokinetics of, 78-16t
 pregnancy and, 46-32t
 receptor-binding affinities of, 78-12t
 seizures from, 78-25
 smoking and, 85-5t
- Halothane**
 DILI from, 29-3t, 29-9t
 for SE, 54-33
- Hammerhead ribozymes, 73-28**
- HAT. (see Heparin-associated thrombocytopenia)**
- Havrix, 95-10**
 dosing of, 73-7–73-8, 73-7t
 for hepatitis A, 73-7
- Hawthorn, 18-66**
- HbCV. (see Hib polysaccharide conjugate vaccine)**
- HBIG. (see Hepatitis B immunoglobulin)**
- HbOC, 95-7**
- HbOC (HibTITER), 58-14, 95-7**
- HBsAg. (see Hepatitis B-surface antigen)**
- HCl. (see Hydrochloric acid)**
- HCO. (see Hydroxychloroquine)**
- HCTZ. (see Hydrochlorothiazide)**
- Hectorol. (see Doxercalciferol)**
- Hemabate. (see 15-methyl prostaglandin F_{2α}-tromethamine)**
- Hematide, 31-19**
- Hematopoietic growth factors (HGF), 92-6, 92-14**
 for neutropenia, 68-6
- Heparin, 15-3–15-4**
 adverse effects of, 15-11–15-12
 aging and, 99-5
 for ALF, 73-15
 with dialysis, 32-5–32-7
 for DIC, 15-34
 dosing of, 15-8t, 15-10
 duration of, 15-11
 glucosamine and, 3-28
 hemorrhage from, 15-12
 hyperkalemia from, 11-18, 15-12
 hypersensitivity from, 15-12
 for KD, 96-14
 for MI, 17-9t
 monitoring of, 15-10–15-11
 osteoporosis from, 15-12
 for peritonitis, 32-14
 pregnancy and, 46-32t, 46-39–46-40
 protamine and, 15-13
 sensitivity to, 99-5
 smoking and, 85-5t
 for stroke, 55-14
 thrombocytopenia from, 87-9–87-11
 for thrombosis, 89-6
 trial of, 17-14t
 for valve repair, 15-26–15-27
- Heparin-associated thrombocytopenia (HAT), 15-11**
- Heparin-induced thrombocytopenia (HIT), 15-11, 32-6**
- Heparinoids, for stroke, 55-14**
- Hepatitis B immunoglobulin (HBIG), 73-18–73-19, 73-21, 95-5**
 administration of, 73-30
 adverse effects of, 73-30
 dosing of, 73-30
 for HBV, 34-31
 for transplantation, 34-31
- Hepatitis B-surface antigen (HBsAg), 95-4–95-5**
- HepB, 95-4**
- Hepsera. (see Adefovir)**
- Herbs, 3-1–3-38**
 diazepam and, 3-5
 digitalis and, 3-5
 DILI and, 29-17–29-18
 hazards of, 3-5–3-6, 3-5–3-7
 HCTZ and, 3-5
 for HCV, 73-44
 heavy metals in, 3-5
 mania from, 80-5t
 NSAIDs and, 3-5
 steroids and, 3-5
- Herceptin. (see Trastuzumab)**
- Heroin, 83-3**
 HCV and, 83-6
 HIV and, 83-6
 during lactation, 46-39t
 overdose of, 83-5
 pulmonary disorders from, 25-2t, 25-5t
- HES. (see Hydroxyethyl starch)**
- Hetastarch, 21-16**
- HGF. (see Hematopoietic growth factors)**
- Hib polysaccharide conjugate vaccine (HbCV), 95-4, 95-7**
- HibTITER. (see HbOC)**
- HiDAC. (see High-dose cytarabine)**
- HIF. (see Hypoxia-inducible factor stabilizers)**
- High-ceiling diuretics. (see Loop diuretics)**
- High-dose cytarabine (HiDAC), 90-7–90-8**
 for B-cell lymphoma, 90-36
- Highly active antiretroviral therapy (HAART), 69-1, 70-1**
 AMI from, 69-27
 CAD from, 69-27
 combination therapy with, 69-15
 diabetes from, 69-27
 DILI from, 29-11t
 failures with, 69-17–69-18
 HDL and, 69-27
 hypercholesteremia from, 69-27
 hyperlipidemia from, 69-28
 hypertriglyceridemia from, 69-27
 lactic acidosis from, 69-28
 LDL and, 69-27
 osteonecrosis from, 69-28
 osteopenia from, 69-28
- Histrelin (Supprelin), 47-17t**
- HMG-CoA. (see Hydroxymethylglutaryl-coenzyme A reductase inhibitors)**
- Homosalate, 41-8t, 41-10, 41-11**
- Hormone replacement therapy (HRT)**
 for anorexia nervosa, 82-14
 for CAD, 16-23–16-24
 for sexual dysfunction, 101-9
 stroke and, 55-6
- Hormones**
 for acne, 39-7
 SLE from, 44-3
- HPH. (see Neutral protamine hagedorn insulin)**
- HRT. (see Hormone replacement therapy)**
- HS. (see Hypertonic saline)**
- HSD. (see hypertonic saline-dextran)**
- Humalog. (see Insulin lispro)**
- Humalog Mix, 50-17t, 50-19**
- Human erythropoietin, 31-17–31-18**
- Humira. (see Adalimumab)**
- Humulin, 50-19**
- Hyaluronans, for OA, 43-39**
- Hydantoin, SJS from, 38-16**
- Hydralazine (Apresoline), 13-39–13-40, 18-7, 18-59**
 ANA from, 4-2
 anxiety from, 76-6t
 dosing of, 20-14
 for hypertension, 13-10, 20-3, 20-4t–5t, 31-21
 with heart transplantation, 35-6
 with isosorbide dinitrate, 18-27, 18-60
 nasal symptoms from, 24-23t
 neonates and, 94-7t
 pregnancy and, 46-18
 pulmonary disorders from, 25-2t, 25-8t
 race and, 18-60–18-61
 sexual dysfunction from, 101-2t
 SLE from, 4-2, 4-12, 44-3

Hydrochloric acid (HCl), 10-10**Hydrochlorothiazide (HCTZ), 13-10, 13-21, 17-25, 19-5, 20-3, 55-5**

for BPD, 94-16*t*
herbs and, 3-5
nasal symptoms from, 24-23*t*
photosensitive eruptions from, 38-15
pulmonary disorders from, 25-2*t*, 25-5*t*, 25-8*t*
SLE from, 44-3
for stroke, 55-7

Hydrocodone, 8-32

for postoperative pain, 9-33*t*

Hydrocortisone (Cortisol), 38-8*t*, 44-7*t*

administration routes of, 44-9*t*
for BPD, 94-18
sodium and, 44-7
for sunburn, 41-15

Hydrogen peroxide, 9-20**Hydrolyzed starch (Limit), 38-3****Hydromorphone**

with bupivacaine, for epidural infusion, 9-31*t*
histamine and, 4-17-4-18
PCA and, 8-16, 9-28, 9-29*t*
renal failure and, 33-22

Hydroxocobalamin, for cyanide toxicity, 20-10 **γ -Hydroxybutyric acid (GHB), 83-11-83-12****Hydroxychloroquine (HCQ)**

for Lyme disease, 75-5
psoriasis from, 40-9*t*
for RA, 43-5, 43-6-43-7, 43-20-43-21

Hydroxyethyl starch (HES), 21-16**Hydroxymethylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors, 102-17**

for dyslipidemia, 14-6, 31-9
for HCV, 73-44
for hypercholesterolemia, 69-28
pioglitazone and, 50-56
pulmonary disorders from, 25-2*t*, 25-7*t*
for stroke, 55-5, 55-7-55-8

Hydroxypropylones, 71-5**5-hydroxytryptamine 3 (5-HT₃) receptor antagonists, 7-3, 7-5-7-6****Hydroxyurea**

alopecia from, 89-11*t*
hand-foot syndrome from, 89-12
nail changes from, 89-11*t*
radiation enhancement reactions with, 89-13*t*
skin pigment changes from, 89-11*t*

Hydroxyzine (Atarax, Vistaril), 8-24, 24-12*t*, 31-29, 99-6*t*

allergen skin tests and, 24-21*t*
for GAD, 76-10
for NVP, 46-8*t*
for pruritus, 38-10
for sleep disorders, 77-15-77-16

Hypericum. (see St. John's wort)**Hyperosmotic agents, 51-13, 51-13*t*****Hyperstat. (see Diazoxide)****Hypertonic saline (HS), 24-13, 98-9**

hyperkalemia from, 11-18

Hypertonic saline-dextran (HSD), 10-13**Hypnotics, 83-10-83-12**

adverse drug reactions with, 99-6*t*
in drug poisoning, 5-2*t*
mania from, 80-5*t*

OSA and, 77-17

properties of, 77-7*t*

toxicity from, 5-3

Hypoglycemics

alcohol interaction with, 84-21*t*

DILI from, 29-14

ED from, 101-9

photosensitive eruptions from, 38-15

pregnancy and, 46-13

Hypouricemics, adverse effects of, 51-18*t***Hypoxia-inducible factor (HIF) stabilizers, 31-19****Hytrin. (see Terazosin)****Ibandronate (Boniva), 102-10-102-12, 102-13-102-14****Ibritumomab tiuxetan (Zevalin), 88-14*t*****Ibuprofen (Motrin), 8-9-8-10, 8-15, 43-17*t*, 93-15*t***

adverse effects of, 51-15*t*

ARF from, 30-7-30-8

aspirin and, 16-23, 43-15

for CF, 98-13

DILI from, 29-3*t*

for dysmenorrhea, 47-11*t*

for fever, in children, 93-4-93-5

glucosamine and, 3-26

for gout, 42-5

hyperkalemia from, 11-18

for IVH, 94-40

for migraine, 52-13*t*

nephrotic syndrome from, 8-15

for opiate withdrawal, 83-10*t*

for osteoarthritis, 99-14

for PDA, 94-23-94-24

proarrhythmic effects of, 19-25

renal failure and, 33-9*t*

for sunburn, 41-15

for teething, 93-3

Ibutilide (Corvert), 19-6*t*

cardioversion and, 19-9, 19-10

ICE. (see Ifosfamide, carboplatin, etoposide)**Icodextrin (Extraneal), 32-13****Idamycin. (see Idarubicin)****Idarubicin (Idamycin), 7-4*t*, 88-14*t*, 89-24, 90-7**

adverse effects of, 90-6

Idenix. (see Telbivudine)**IDV. (see Indinavir)****Ifex. (see Ifosfamide)****IFN- α fusion protein (Albuzeron), 73-44****Ifosfamide, 7-4*t*, 89-27**

alopecia from, 89-11*t*

for B-cell lymphoma, 90-36

cardiotoxicity with, 89-25

cranial nerve toxicity with, 89-22

dosing of, 89-27*t*

for lung cancer, 91-12

nephrotoxicity with, 89-28-89-29

neurotoxicity of, 89-20*t*, 89-21

renal Fanconi syndrome with, 91-29-91-30

skin pigment changes from, 89-11*t*

Ifosfamide, carboplatin, etoposide (ICE), 90-16, 90-18**IHS. (see Inhalation of hypertonic saline)****IL-2. (see Interleukin-2)****IL-2 receptor antagonists, for heart transplantation, 35-4****IL-3. (see Interleukin-3)****IL-10. (see Interleukin-10)****IL-11. (see Interleukin-11)****Iloprost, 14-12****Imatinib (Gleevec), 7-4*t*, 88-14*t***

for CML, 90-9

hepatotoxicity from, 89-32*t*

HF from, 89-25-89-26

L-thyroxine and, 49-16

pulmonary disorders from, 25-2*t*, 25-5*t*

Imdur. (see Isosorbide mononitrate; Mononitrate)**Imipenem (Primaxin), 56-8*t*, 59-23**

for aspiration pneumonia, 60-21*t*

for CAP, 60-11*t*

cephalosporins and, 4-6

for CF, 98-11*t*

with cilastatin, 62-9, 63-4

for CRRT and HD, 56-21*t*

dosing of, 56-20*t*

for gram-negative aerobes, 56-10*t*

for gram-positive cocci, 56-9*t*

for HAP, 60-24*t*

for neutropenia, 68-10, 68-11

penetration characteristics of, 58-7*t*

renal failure and, 33-9*t*

for *Salmonella* spp., 62-12

for septic shock, 21-28

for UTIs, 64-10*t*

Imipramine (Tofranil), 8-22, 79-13*t*, 99-6*t*

for cataplexy, 77-17

chronic intrahepatic cholestasis from, 29-16

nephrotic syndrome from, 8-15

for narcolepsy, 77-18

for social anxiety disorder, 76-27

for tension-type headaches, 52-24

for urinary incontinence, 101-20*t*, 101-28

Imiquimod

for genital warts, 65-29-65-30

psoriasis from, 40-9*t*

Imitrex. (see Sumatriptan)**Immunization**

for adolescents, 95-11-95-12

allergy and, 95-3

for BCG, 70-26, 70-29

for cervical cancer, 88-6

CF and, 98-10

for children, 95-1-95-12

adverse effects of, 95-4

contraindications for, 95-1-95-3

immunocompromise and, 95-12

schedule for, 95-1, 95-2*f*, 95-3*f*

with COPD, 23-9, 23-12

for *Haemophilus influenzae* type b, 95-3

for HAV, 73-7-73-9, 95-10

for HIV, 70-6*t*

for HAV and HBV, 73-8

for HBV, 73-15-73-18,

73-16-73-17, 73-28-73-29,

for melanoma, 91-17
NSAIDs and, 91-17
pulmonary disorders from, 25-2t, 25-4t, 25-8t
- Interleukin-2 receptor antagonists, for kidney transplantation, 34-10**
- Interleukin-3 (IL-3), 87-16**
- Interleukin-10 (IL-10, Tenovil), for HCV, 73-44**
- Interleukin-11 (IL-11, Neumega), 92-6**
- Intermediate acting insulin, 50-17t, 50-18**
- Intermittent positive-pressure breathing (IPPB), 22-14**
- International normalized ratio (INR), for warfarin, 15-7**
- Intravenous immunoglobulins (IVIG), 93-18**
for GABHS, 96-7
for KD, 96-14
for kidney transplantation, 34-2
for neonates, 94-32-94-33
- Invanz.** (see **Ertapenem**)
- Invega.** (see **Paliperidone**)
- Invirase.** (see **Saquinavir**)
- Iodides, 49-21-49-22, 49-23t, 49-33-49-34**
acneiform eruptions from, 38-15
breast-feeding and, 97-7
- Iodines, 71-5**
- Iodoquinol, 74-3t**
- IOP and, 51-20t**
- Iopanoic acid, 49-24**
- Iopidine.** (see **Apraclonidine**)
- Ipecac, emesis from, 5-3-5-4**
- Iodate, 49-24**
- IPOI, 95-6**
- IPPB.** (see **Intermittent positive-pressure breathing**)
- Ipratropium (Atrovent), 22-13, 24-16t**
albuterol with
for end-of-life care, 6-4-6-5
for BPD, 94-16t, 94-17
for COPD, 23-13
dosing of, 22-17t
- Ipratropium bromide, 24-8-24-9**
- Irbesartan, 31-7**
- Irbesartan/losartan, DILI from, 29-9t**
- Irinotecan (Camptosar), 7-4t, 88-14t**
alopecia from, 89-11t
for colorectal cancer, 88-22t
diarrhea from, 89-10
pulmonary disorders from, 25-2t, 25-8t
- Iron**
anemia and, 2-18, 31-15, 31-16-31-17, 86-3-86-6
laboratory tests for, 86-4f, 86-5
symptoms of, 86-5
therapy with, 86-5-86-8
antacids and, 31-17
blood chemistry reference values for, 2-5t
with dialysis, 32-2
DRI of, 86-4
GERD and, 26-23t
pregnancy and, 46-7
preparations of, 31-16t
quinolone and, 31-17
toxicity with, 5-9-5-13
stages of, 5-12
whole bowel irrigation (WBI) for, 5-11
- Iron saccharate (Venofer), 4-18**
- Iron sucrose (Venofer), 31-17, 86-7**
- Iron sulfate, 49-16**
- Iron-dextran (In-FeD, DexFerrum), 31-17, 86-7**
adverse reactions from, 4-18
- Isentress, for HIV, 69-11t**
- ISMO.** (see **Isosorbide mononitrate**)
- Isoetharine, for anaphylaxis, 4-9t**
- Isoflamide (Ixef), 88-14t**
- Isoflavones, 48-7**
- Isoflurane**
chemical stability of, 9-10t
properties of, 9-10t
for SE, 54-33
- Isothetepene (Midrin), for migraine, 52-12, 52-13t**
- Isoniazid (INH)**
acneiform eruptions from, 38-15
adverse effects of, 51-16t, 61-15-61-16
alcohol interaction with, 84-21t
- anxiety from, 76-6t
CH from, 29-15
desensitization to, 4-21
DILI from, 29-2, 29-3t, 29-9t
dosing of, 56-20t
drug interactions with, 61-16
for HIV, 70-4
mania from, 80-5t
OC and, 45-12t
protein binding with, 33-2
resistance to, 70-27-70-28
rifampin with, 61-17
SLE from, 4-12, 44-3
subacute hepatic necrosis from, 29-16
for TB, 61-8, 61-9t, 61-10t
for tuberculous meningitis, 61-23
- Isoproterenol, 22-15**
anxiety from, 76-6t
GERD and, 26-23t
heart transplantation and, 35-2
melatonin and, 3-33t
for torsades de pointes, 19-26
- Isoptin.** (see **Verapamil**)
- Isopto-Carbachol.** (see **Carbachol**)
- IsoptoCarpine.** (see **Pilocarpine**)
- Isosorbide, for glaucoma, 51-13t**
- Isosorbide dinitrate, 14-4, 18-15, 18-59, 99-10**
hydralazine with, 18-27, 18-60
race and, 18-60-18-61
- Isosorbide mononitrate (ISMO, Monoket, Imdur), 16-13, 18-15**
for variceal hemorrhage, 28-15
- Isotretinoin (Accutane)**
for acne, 39-4, 39-4t, 39-10-39-11
adverse effects of, 39-11
drug-induced hyperlipidemia from, 12-17t
hyperuricemia from, 42-8t
pregnancy and, 46-43-46-44
pulmonary disorders from, 25-2t, 25-7t
teratogenic effects of, 46-31t
- Isoxsuprine, 14-9**
pulmonary disorders from, 25-2t, 25-4t
- Isradipine (DynaCirc), 16-15, 18-16**
for Raynaud's disease, 14-12
- Itraconazole (Sporanox), 12-29, 71-4, 92-25**
adverse effects of, 56-16t
for aspergillosis, 71-24
benzodiazepines and, 76-16t
buspirone and, 76-20t
for CAP, 60-12t
for cryptococcosis, 70-25-70-26
dosing of, 71-7-71-8
for histoplasmosis, 71-10
for HIV, 70-6t
for HSCT, 92-23
for lung transplantation, 35-10
proarrhythmic effects of, 19-25
for sporotrichosis, 71-6-71-7
for tinea unguium, 71-6
- Ivermectin, 74-5t, 74-16**
- IVIG.** (see **Intravenous immunoglobulins**)
- Ivy leaf extract, for asthma, 22-38**
- Janumet.** (see **Sitagliptin/metformin**)
- Januvia.** (see **Sitagliptin**)
- Jin bu huan**
hazards of, 3-6t
toxicity of, 29-17, 29-19t

- Kaletra.** (see Lopinavir/ritonavir)
- Kanamycin**
for MDRTB, 70-72
teratogenic effects of, 46-31*t*
- Kaopectate, 93-9**
- Kariva (Mircette), 45-5*t***
- Kava**
hazards of, 3-6*t*
toxicity of, 29-17
- Keflex.** (see Cephalexin)
- Kepivance.** (see Pulifermin)
- Keppra.** (see Levetiracetam)
- Keratolytics, for psoriasis, 40-3*t***
- Ketalar.** (see Ketamine)
- Ketamine (Ketalar), 8-5, 9-6, 9-6*t*, 9-7*t***
abuse of, 83-15–83-16
adverse effects of, 9-7*t*
for children, 9-8–9-9
glaucoma and, 51-8
as preoperative agent, 9-3*t*
psychosis from, 78-4
for sedation, 93-12*t*, 93-13
- Ketek.** (see Telithromycin)
- Ketoconazole, 12-29, 71-4**
adverse effects of, 56-16*t*
alcohol interaction with, 84-21*t*
antipsychotics and, 78-15
benzodiazepines and, 76-16*t*
for blastomycosis, 71-19
buspirone and, 76-20*t*
for coccidioidomycosis, 71-22
DILI from, 29-9*t*
dofetilide and, 19-11
proarrhythmic effects of, 19-25
renal failure and, 33-9*t*
rifampin and, 70-30
- Ketolides, for AECB, 60-4*t***
- Ketoprofen (Orudis), 8-9–8-10, 43-17*t***
for dysmenorrhea, 47-11*t*
for gout, 42-5
for migraine, 52-12
- Ketorolac (Acular, Toradol), 8-9–8-10, 8-14, 8-24, 24-15*t*, 43-17*t*, 93-15*t***
with epidural infusion, 9-32
for eyes, 51-21, 51-22*t*
for pain, 93-14
for postoperative pain, 9-33*t*
- Ketotifen (Zaditor), 24-15*t***
- Kineret.** (see Anakinra)
- Klonopin.** (see Clonazepam)
- KOH.** (see Potassium hydroxide)
- Koromex, 45-25*t***
- Kwell.** (see Lindane)
- Kytril.** (see Granisetron)
- LABA.** (see Long-acting β_2 -agonist)
- Labetalol (Normodyne, Trandate), 20-11, 20-12–20-13**
for aortic dissection, 20-6*t*
for hemorrhage, 20-6*tg*
for hypertension, 12-25, 20-3, 20-4*t*-5*t*, 20-5, 20-6, 20-7–20-8
for MI, 20-6*t*
for pheochromocytoma, 20-6*t*
pregnancy and, 46-16*t*, 46-18
pulmonary disorders from, 25-2*t*
renal failure and, 33-9*t*
- β -lactam, 56-8*t*, 63-4**
adverse effects of, 56-15*t*, 98-10
for appendectomy, 63-12
for aspiration pneumonia, 60-20
for CAP, 60-11*t*, 60-12*t*
for CF, 98-10
for gram-negative coverage, 66-6
for HAP, 60-24*t*, 60-25
for neutropenia, 68-10
for osteomyelitis, 66-3–66-4
for respiratory acidosis, 10-11
for septic arthritis, 66-11
sodium and, 2-2
- β -lactamase inhibitor, 62-4**
for appendectomy, 63-12
- Lactated ringers, 10-13**
- Lactobacillus, for VVC, 65-22**
- Lactulose, 28-18–28-19, 93-6*t***
for constipation, during pregnancy, 46-32*t*
neomycin and, 28-19
- LAIV.** (see Live, attenuated influenza vaccine)
- LAK.** (see Lymphokine-activated killer cells)
- L-Amb.** (see Liposomal amphotericin B)
- Lamictal.** (see Lamotrigine)
- Lamisil, for labor induction, 46-20**
- Lamivudine (3TC), 69-4**
anemia from, 86-18
didanosine with, for HIV, 69-14*t*
dosing of, 73-28*t*
with FTC, 69-15
for HBV, 73-23*t*, 73-34*t*
for HDV, 73-33
for HIV, 69-8*t*
renal failure and, 33-9*t*
resistance to, 69-23*t*, 73-26
for transplantation, 34-31
- Lamotrigine (Lamictal), 54-9, 54-14, 79-24**
for absence seizures, 54-20*t*
adverse effects of, 54-14–54-15
for alcohol withdrawal, 84-11
for bipolar disorder, 80-4, 80-12*t*, 80-16–80-17
for bipolar disorder depression, 80-15
for DPN, 50-79
for epilepsy, 54-3*t*
for mania, 80-13
mania from, 80-5*t*
for neonates, 94-43
OC and, 54-29–54-30
pharmacokinetic properties of, 54-6*t*
pregnancy and, 46-43
for seizures, 54-5*t*, 54-12*t*
skin rash from, 54-27–54-28
- Lanoxicaps, 18-14**
- Lanoxin.** (see Digitalis)
- Lansoprazole, 26-5–26-6**
for aspiration pneumonitis, 9-5
feeding tubes and, 36-15
for GERD, 93-10*t*
for SRMB, 26-35*t*
for upper GI disorders, 26-4*t*
for ZES, 26-21–26-22
- Lanthanum carbonate (Fosrenol), 31-24–31-25**
- Lantus.** (see Insulin glargine)
- L-arginine, with cardioplegia solution, 9-20–9-21**
- Lasix.** (see Furosemide)
- L-Asparaginase**
encephalopathy from, 89-19–89-20
hypersensitivity from, 89-18*t*
- Latanoprost (Xalatan), for POAG, 51-5, 51-11*t***
- Laxatives, 31-14, 93-5–93-6**
anorexia nervosa and, 82-2
fixed drug eruptions from, 38-17
- L-Carnitine, 14-9, 32-10–32-11**
- L-dopa, for RLS, 77-19**
- LEF.** (see Leflunomide)
- Leflunomide (LEF, Arava)**
cholestyramine with, 43-26
R(Leflunomide), for transplantation, 34-10
for RA, 43-5, 43-6–43-7, 43-25–43-26
- Lenalidomide**
neurotoxicity of, 89-20*t*
paresthesia from, 89-21
thrombosis from, 89-6
- Lenalidomide/dexamethasone, for MM, 90-21*t***
- L-Epinephrine, for croup, 96-10**
- Lepirudin (Refludan), 15-5**
with dialysis, 32-6
for heparin-induced thrombocytopenia, 33-24
renal failure and, 33-10*t*
- Lescol.** (see Fluvastatin)
- Lessina (Levite), 45-5*t***
- Letrozole**
for breast cancer, 91-7
for hormone-sensitive tumors, 88-25*t*
- Leucovorin**
with clindamycin, for toxoplasmosis, 70-14
for colorectal cancer, 88-22*t*
for osteosarcoma, 91-28
for toxoplasmosis, in neonates, 94-36
- Leukotriene modifiers, 24-8**
for allergic rhinitis, 24-9*t*, 24-18–24-19
for asthma, 22-25
- Leukotriene receptor antagonist (LTRA)**
for asthma, 22-11*t*
long-term, 22-28*t*
for dysmenorrhea, 47-12–47-13
for EIA, 22-32
- Leuprolide (Lupron), 47-17*t*, 91-19**
adverse effects of, 47-19*t*
for BPH, 101-22–101-23
dosing of, 47-18
for hormone-sensitive tumors, 88-25*t*
- Levalbuterol (R-albuterol), 22-15**
dosing of, 22-17*t*
- Levemir.** (see Insulin detemir)
- Levetiracetam (Keppra), 54-9, 54-14, 54-15**
adverse effects of, 54-11
for epilepsy, 54-3*t*
for mania, 80-13
OC and, 54-29–54-30
pharmacokinetic properties of, 54-6*t*
pregnancy and, 46-43
renal failure and, 33-10*t*
for seizures, 54-5*t*, 54-13*t*
- Levitra.** (see Vardenafil)
- Levlen.** (see Levora; Portia)
- Levite.** (see Lessina)
- Levobetaxolol (Betaxon), for POAG, 51-4–51-5**
- Levobunolol (Betagan), for POAG, 51-4, 51-10*t***
- Levobupivacaine (Chirocaine), 9-16*t***
properties of, 9-18*t*
- Levocabastine (Livostin), 24-15*t***
- Levocetirizine (Xyzal), 24-12*t***
for allergic rhinitis, 24-10, 24-11
- Levodopa**
anticholinergics and, 53-14*t*
anxiety from, 76-6*t*
benzodiazepines and, 53-14*t*
for DLB, 100-10–100-11
drug interactions with, 53-14*t*
hyperuricemia from, 42-8*t*
mania from, 80-5*t*
methyldopa and, 53-14*t*
metoclopramide and, 53-14*t*
neuroleptics and, 53-14*t*
for PD, 53-6, 53-10–53-11
phenytoin and, 53-14*t*
pyridoxine and, 53-14*t*
for RLS, 53-25
schizophrenia and, 78-3
TCAs and, 53-14*t*
- Levofloxacin (Levoquin), 56-8*t*, 63-4**
for AOM, 96-6*t*
for CAP, 60-11*t*, 60-12*t*
for CRRT and HD, 56-21*t*
dosing of, 56-20*t*
for gonorrhea, 65-4
for gram-positive cocci, 56-9*t*
for HAP, 60-24*t*
for *Helicobacter pylori*, 26-14*t*
for HSCT, 92-23
for MDRTB, 70-27
for neutropenia, 68-4–68-5
for osteomyelitis, 66-7
penicillin resistance and, 60-13*t*
for PID, 65-8
renal failure and, 33-10*t*
for septic arthritis, 66-12
for TB, 61-11*t*
for travelers' diarrhea, 62-17
for UTIs, 64-6*t*, 64-8–64-9, 64-10*t*
- Levonorgestrel-releasing system (IUS, Mirena, Norplant), 45-21, 48-4*t***
for dysmenorrhea, 47-12
- Levoquin.** (see Levofloxacin)
- Levora (Levlen, Nordette), 45-5*t***
- Levorphanol, histamine and, 4-17–4-18**
- Levosimendan (Simdax), 18-7–18-8**
- Levothyroxine.** (see L-thyroxine)
- Levovirin, 73-44**
- Lexapro.** (see Escitalopram)
- LHRH.** (see Luteinizing hormone-releasing hormone)
- LHRH agonists, 91-19**
for prostate cancer, 91-19
- LHRH analogs, for hormone-sensitive tumors, 88-25*t***
- Librax.** (see Chlordiazepoxide)
- Librium.** (see Chlordiazepoxide)
- Licorice root, for HCV, 73-44**
- Lidocaine (Xylocaine), 8-33, 9-16*t*, 19-6*t***
anaphylaxis from, 4-7
anxiety from, 76-6*t*
for cluster headaches, 52-21
for DPN, 50-79
hepatitis and, 73-7
for herpes zoster, 72-10
intravenous, 19-29
for MI, 17-7, 17-9*t*
neonates and, 94-6*t*
properties of, 9-18*t*
protein binding with, 94-5
renal failure and, 33-10*t*

- risks with, 17-18
for SE, 54-33
for sunburn, 41-15
for sustained ventricular tachycardia, 19-21
for teething, 93-3
for torsades de pointes, 19-26
ventricular fibrillation and, 17-18
via endotracheal administration, 19-28-19-29
- Lidocaine-prilocaine cream (EMLA), 8-33**
Life root, hazards of, 3-6†
Lignans, 48-7
Limbitrol. (see Chlordiazepoxide)
Lindane (Kwell), 74-5†, 74-16, 75-17
Linzolid (Zyvox), 56-8†, 59-20-59-21
adverse effects of, 56-16†
for CAP, 60-12†
for endocarditis, 59-16
for gram-positive cocci, 56-9†
for HAP, 60-24†
for neonates, 94-31†
for osteomyelitis, 66-4, 66-7
pancytopenia from, 87-15
penetration characteristics of, 58-7†
for prosthesis infection, 66-9
renal failure and, 33-10†
for sepsis, in neonates, 94-30
for septic arthritis, 66-11
- Linit. (see Hydrolyzed starch)**
Liotrix (Thyrolar), 49-12
Lipase inhibitors, 82-19, 82-21
Lipid-lowering agents, for MI, 17-24
Lipitor. (see Atorvastatin)
Lipopeptides, 71-4
Liposomal amphotericin B (L-AmB), 92-25
5-Lipoxygenase inhibitors, for asthma, long-term, 22-28†
Lisadimilate. (see Glyceril PABA)
Lisinopril (Prinivil, Zestril), 18-12, 18-30, 31-7
CH from, 29-15
systolic dysfunction and, 18-30†
- Lithium, 79-24**
acneiform eruptions from, 38-15
adverse effects of, 80-8†
for bipolar disorder, 80-12†
with depression, 80-14
maintenance for, 80-16
breast-feeding and, 97-7
with carbamazepine, 80-3
CKD and, 31-3
distribution of, 99-3
dosing of, 80-8
drug interactions with, 80-10, 80-11†
ginseng and, 3-24
hyperkalemia from, 11-18
hypothyroidism from, 80-10
during lactation, 46-39†
for mania, 80-7-80-12
monitoring of, 80-7†
with oxcarbazepine, 80-3
pregnancy and, 46-32†, 80-10
refractoriness of, 80-16
renal failure and, 33-10†
for schizophrenia, 78-9
for SIADH, 11-11
sumatriptan and, 54-9
teratogenic effects of, 46-31†
thyroid and, 49-32-49-33
toxicity with, 80-9-80-10
with valproate, 80-3
weight gain from, 82-6
- Lithium carbonate**
for cluster headaches, 52-22, 52-22†
psoriasis from, 40-9†
- Live, attenuated influenza vaccine (LAIV), 60-16**
- Livostin. (see Levocabastine)**
Lixivaptan, 11-12
LMWH. (see Low-molecular-weight heparin)
- Local anesthetics, 9-16-9-18**
allergic reaction to, 9-17
for postoperative pain, 9-33†
properties of, 9-18†
toxicity with, 9-17
- Lodine. (see Etodolac)**
Lodoxamide (Alomide), 24-15†
Logestrin. (see Microgestin)
Lomefloxacin, torsades de pointes and, 19-26†
Lomustine, 89-27
dosing of, 89-27†
hepatotoxicity from, 89-32†
- Long acting insulin, 50-17†, 50-18-50-19**
Long-acting β_2 -agonist (LABA)
adverse effects of, 22-25
for asthma, 22-10†, 22-11†, 22-12†
long-term, 22-29†
with corticosteroids, 22-24-22-25
for EIA, 22-32
for seasonal asthma, 22-22
- Loniten. (see Minoxidil)**
Loop diuretics, 11-13, 13-21, 18-11, 18-20-18-21
adverse effects of, 13-22†
for ARF, 30-18
drug-induced hyperlipidemia from, 12-17†
for hypertension, 13-10, 31-20
hypokalemia from, 11-16†
for neonates, 94-8
for SIADH, 11-11
- Loperamide, 62-5**
for diarrhea, 62-10, 89-10
for DP-IBS, 27-20
for travelers' diarrhea, 62-17
- Lopid. (see Gemfibrozil)**
Lopidine. (see Apraclonidine)
Lopinavir, 69-4
resistance to, 69-24†
with ritonavir, 69-16
for SARS, 72-17-72-18
- Lopinavir/ritonavir (LPV/r, Kaletra), 61-21**
for HIV, 69-10†
NNRTIs and, 69-21†
PI and, 69-19†
- Lopressor. (see Metoprolol)**
Lorabid. (see Loracarbef)
Loracarbef (Lorabid), 56-8†
for AOM, 96-6†
- Loratadine (Claritin), 12-29, 24-12†**
allergen skin tests and, 24-21†
for allergic rhinitis, 24-10
- Lorazepam (Ativan), 7-6†, 7-8, 54-31, 76-8†, 76-12-76-13, 76-12†, 76-13, 78-14-78-15**
for acute agitation, 78-14†
for alcohol intoxication, 84-6
for alcohol withdrawal, 84-8-84-10, 84-8†, 84-9†
for anorexia nervosa, 84-14
for end-of-life care, 6-7
- haloperidol and, for acute agitation, 80-14
hepatitis and, 73-7
for neonates, 94-43, 94-43†
for panic disorder, 76-23
as preoperative agent, 9-3†
for sedation, 93-12†
for sleep disorders, 77-15-77-16
- Losartan, 31-7**
for diabetes, 31-8
for systemic sclerosis, 44-4
- Lotensin. (see Benazepril)**
Loteprednol (Alrex), 24-15†
adverse effects of, 51-21
- Lovastatin (Mevacor), 12-12†, 12-24†, 12-25†, 12-28, 49-16, 50-77**
adverse effects of, 51-17†
DILI from, 29-9†
for end-of-life care, 6-5
- Low-molecular-weight heparin (LMWH), 15-5, 15-13-15-15**
for ACS, 16-31
as antithrombotic, 17-22-17-23
for bridge therapy, 15-27-15-28
with dialysis, 32-6
dosing, 15-14†
for DVT, 15-14
with epidural infusion, 9-32
for MI, 17-9-†, 17-15
with PCI, 16-27
for PE, 15-17
pregnancy and, 15-25, 46-32†, 46-40
renal failure and, 33-23
renal impairment and, 15-14†
for stroke, 55-14
thrombocytopenia and, 87-10
for thrombosis, 17-6
UFH and, Fondaparinux and, 15-4†
- Low-Ogestrel. (see Cryselle)**
Low-Ovral. (see Cryselle)
Loxapine (Loxitane)
adverse effects of, 78-12†
dosing of, 78-17†
pharmacokinetics of, 78-16†
- Loxitane. (see Loxapine)**
LPV/r. (see Lopinavir/ritonavir)
LSD. (see Lysergic acid diethylamide)
L-thyroxine (Levothyroxine), 49-4, 49-12, 49-15-49-16
anticonvulsants and, 49-16
bexarotene and, 49-16
for end-of-life care, 6-5
imatinib and, 49-16
for myxedema coma, 49-17
rifampin and, 49-16
sleep disorders from, 77-9
for thyroid cancer, 49-36
- LTRA. (see Leukotriene receptor antagonist)**
L-tryptophan, eosinophilic myalgia syndrome from, 3-5
Ludiomil. (see Maprotiline)
Lugol's solution, 49-23†
Lumigan. (see Bimatoprost)
Lunelle, 45-21
Lunesta. (see Eszopiclone)
Lupron. (see Leuprolide)
Luteinizing hormone-releasing hormone (LHRH), 91-4
Luvox. (see Fluvoxamine)
Lymphokine-activated killer cells (LAK), for melanoma, 91-17
Lyrica. (see Pregabalin)
- Lysergic acid diethylamide (LSD), 83-16-83-17**
during lactation, 46-39†
mania from, 80-5†
psychosis from, 78-4, 78-4†
- Lytic peptides, 71-5**
- Macerations, 3-4-3-5**
Macrolide-resistant *Streptococcus pneumoniae*, 60-14
Macrolides
adverse effects of, 56-15†
for AECB, 60-4†
for CAP, 60-11†, 60-12†
for CF, 98-13
penicillin resistance and, 60-13
rifampin and, 61-17
- Mafenide acetate (Sulfamylon), 41-20**
Magnesium (Mg), 2-10, 11-1, 11-27-11-29, 19-26
blood chemistry reference values for, 2-3†
with cardioplegia solution, 9-21†
CKD and, 31-14
homeostasis of, 11-27
liver transplantation and, 34-26
for MI, 17-18
for nocturnal leg cramps, 14-14
for PMS, 47-21-47-22
- Magnesium carbonate, 31-23†, 31-25**
Magnesium choline salicylate (Trilisate), 43-17†
Magnesium hydroxide, 31-23†, 31-25, 93-6†
for GERD, 93-10†
pregnancy and, 46-32†
- Magnesium oxide, for hypomagnesemia, 11-28**
Magnesium sulfate
for eclampsia, 46-19
for preterm labor, 46-25-46-26
pulmonary disorders from, 25-2†, 25-4†
- Mag-Tab SR, for hypomagnesemia, 11-28**
Ma-huang, 83-14
mania from, 80-5†
- Major tranquilizers. (see antipsychotics)**
Malathion, 74-16
Mandelol. (see Cefamandole)
Mannitol, 11-14, 51-13†
MAOIs. (see Monoamine oxidase inhibitors)
Maprotiline (Ludiomil)
for tension-type headaches, 52-24
torsades de pointes and, 19-26†
- Maraviroc, for HIV, 69-11†**
Marcaine. (see Bupivacaine)
Mareline. (see Cyclizine)
Margosa oil, toxicity of, 29-19†
Marijuana, 83-19-83-20
for asthma, 22-38
during lactation, 46-39†
mania from, 80-5†
psychosis from, 78-4, 78-4†
sexual dysfunction from, 101-7†
- Marinol. (see Dronabinol)**
Mast cell stabilizers
for allergic conjunctivitis, 24-9, 24-14, 24-15†
for allergic rhinitis, 24-9†
- Mavik. (see Trandolapril)**
Maxalt. (see Rizatriptan)
Maxzide, 18-24
Mazindol, for obesity, 82-19

- MCV4. (see Menactra)**
MDI. (see Metered-dose inhaler)
MDMA, 83-17-83-19
Measles, mumps, rubella (MMR), 95-4, 95-9
 adverse effects of, 95-4
 immunocompromise and, 95-12
Measles, mumps, rubella, varicella (MMRV), 95-8, 95-9
Measurin, for RA, 43-15
Mebendazole (Vermox), 74-3t, 74-4, 75-12
Mechlorethamine, 7-4t
 alopecia from, 89-11t
 cardiotoxicity with, 89-25
 for Hodgkin disease, 88-23t
 toxicity from, 89-3
Mechlorethamine, doxorubicin, etoposide, vincristine, vinblastine, bleomycin, and prednisone (Stanford V regimen), 90-18
Mechlorethamine, vincristine, procarbazine, and prednisone (MOPP), 90-18
Meclizine (Antivert, Bonine), 7-3t
 for NVP, 46-8t
Meclofenamate (Meclomen), 43-17t
 for dysmenorrhea, 47-11t
 for gout, 42-5
Meclomen. (see Meclofenamate)
Medaphalan, pulmonary disorders from, 25-2t
Medroxyprogesterone, 12-31
 for hormone-sensitive tumors, 88-25t
 weight gain from, 82-6
Medroxyprogesterone acetate (MPA, Provera), 48-4t, 48-5
Medrysone, for eyes, 51-20t
Mefenamic acid (Ponstel), 43-15
 for dysmenorrhea, 47-11t
Mefloquine, 74-4t, 74-5t
 anxiety from, 76-6t
 torsades de pointes and, 19-26t
Mefoxin. (see Cefoxitin)
Megestrol
 dofetilide and, 19-11
 for end-of-life care, 6-5
 for HIV wasting syndrome, 70-39t
 for hormone-sensitive tumors, 88-25t
Melatonin, 3-3t, 3-33-3-36
 for cancer, 3-35-3-36
 for cluster headaches, 52-22t
 cluster headaches and, 52-19
 drug effects on, 3-33t
 for insomnia, 3-35, 77-7
 for jet lag, 3-34
 for pediatric insomnia, 77-20
Mellaril. (see Thioridazine)
Meloxicam, 43-17t
Melphalan
 dosing of, 89-27t
 for Hodgkin disease, 88-23t
 for MM, 90-19-90-20
 pulmonary toxicity from, 89-30t
Melphalan, prednisone (MP), 90-21t
Melphalan, prednisone, thalidomide (MPT), 90-21t
Memantine (Namenda)
 for AD, 100-8t, 100-9
 for end-of-life care, 6-5
Menactra (MCV4), 58-14, 95-11
Menest. (see Esterified estrogen)
Menomune (MPS4), 58-14, 95-11
Menthol, 71-5
Menthylanthranilate (Meradimate), 41-8t, 41-11
Meperidine (Demerol), 8-19, 8-27, 8-28, 93-15t
 bradycardia and, 17-21
 hepatic encephalopathy from, 28-18
 hepatitis and, 73-7
 for MI, 17-7, 17-21
 for migraine, 52-13t
 PCA and, 8-16-8-17, 9-28
 renal failure and, 33-10t, 33-21-33-22
 for sedation, 93-12t
Mepivacaine (Carbocaine, Polocaine), 9-16t
 properties of, 9-18t
Meprobamate
 alcohol interaction with, 84-21t
 withdrawal from, 83-10
Mepron. (see Atovaquone)
MER 29, 12-2
Meradimate. (see Menthylanthranilate)
6-mercaptopurine (6-MP), for CD, 27-15
Mercaptopurine (Purinethol), 88-14t, 90-31-90-32
 adverse effects of, 90-37
 hepatotoxicity from, 89-32t
 neonates and, 94-7t
 for T-cell lymphoblastic lymphoma, 90-36t
Merem. (see Meropenem)
Meridia. (see Sibutramine)
Meropenem (Merem), 56-8t, 62-9
 for CNS infections, 58-9t
 for CRRT and HD, 56-21t
 dosing of, 56-20t
 for HAP, 60-24t
 for neonates, 94-31t
 for neutropenia, 68-10, 68-11
 penetration characteristics of, 58-7t
 renal failure and, 33-10t
 for UTIs, 64-10t
Mesalamine (Asacol, Pentasa, Rowasa), 27-9t
 adverse effects of, 27-10
 for IBD, 27-4t
 pulmonary disorders from, 25-2t, 25-7t
Metadate. (see Methylphenidate)
Metaglip. (see Glipizide/metformin)
Metamizole, agranulocytosis from, 87-14
Metamucil. (see Psyllium)
Metaproterenol
 for anaphylaxis, 4-9t
 for BPD, 94-16t, 94-17
 torsades de pointes and, 19-26t
Metered-dose inhaler (MDI), 22-14
 dosing of, 22-17t
Metformin (Glucophage), 50-46, 50-48t, 50-49t
 alcohol and, 50-48
 cimetidine and, 50-52
 for diabetes, 50-10
 dofetilide and, 19-11
 dosage of, 50-52
 efficacy of, 50-52
 nateglinide and, 50-52
 for PCOS, 47-6t, 47-7, 47-8
 toxicity of, 10-6
 for type 2 diabetes, 50-62-50-63, 50-65t
 weight loss from, 82-6
Methodone, 8-23
 breast-feeding and, 83-8
 cimetidine and, 8-31-8-32
 hepatic encephalopathy from, 28-18
 histamine and, 4-17-4-18
 maintenance of, 83-7
 for NAS, 94-46
 neonatal addiction to, 83-8
 for opioid withdrawal, 83-5-83-6
 phenytoin and, 8-31
 pregnancy and, 83-8
 pulmonary disorders from, 25-2t, 25-5t
 torsades de pointes and, 19-26t
 withdrawal from, 83-4
Methamphetamine, 83-14
Methazolamide, for glaucoma, 51-13t
Methergine. (see Methylergonovine maleate)
Methicillin, interstitial nephritis from, 4-14
Methicillin-resistant Staphylococcus aureus (MRSA), 32-14, 33-19
Methicillin-resistant Staphylococcus epidermidis (MRSE), 32-14
Methimazole (Tapazole), 49-23t, 49-24-49-28
 DILI from, 29-14
 for hyperthyroidism, 49-5
Methocarbamol
 for nocturnal leg cramps, 14-14
 for opiate withdrawal, 83-10t
Methohexital (Brevital), 9-6t, 9-7t
 adverse effects of, 9-7t
 for ECT, 9-8
Methotrexate (MTX), 7-4t, 88-14t, 90-31-90-32
 adverse effects of, 43-24
 alopecia from, 89-11t
 for AML, 90-7
 for B-cell lymphoma, 90-36
 for bladder cancer, 88-22t
 for breast cancer, 88-22t
 for CD, 27-13
 DILI from, 29-3t, 29-9t
 dosing of, 89-27t
 folic acid with, 43-25
 for GVHD, 92-18
 hand-foot syndrome from, 89-12
 for heart transplantation, 35-6
 hepatotoxicity from, 89-32t
 for IBD, 27-4t, 27-5
 for JIA, 43-35
 for lung cancer, 91-12
 monitoring of, 90-30
 nephrotoxicity with, 89-27-89-28
 neurotoxicity of, 89-20-89-21, 89-20t
 for osteosarcoma, 91-28
 for psoriasis, 40-3t, 40-6-40-7
 for psoriatic arthritis, 40-12
 pulmonary disorders from, 25-2t, 25-5t
 pulmonary toxicity from, 89-31t
 for RA, 43-3, 43-5, 43-6-43-7, 43-23-43-25
 radiation enhancement reactions with, 89-13t
 renal failure and, 33-11t
 skin pigment changes from, 89-11t
 for T-cell lymphoblastic lymphoma, 90-36t
 teratogenic effects of, 46-31t
 TMP-SMX and, 92-27
 for transplantation, 92-10
 for transplantation rejection, 35-9
 UV reactions from, 89-13t
 VOD from, 29-16
 for Wegener's granulomatosis, 31-32-31-33
Methoxyflurane, for cluster headaches, 52-21
15-methyl prostaglandin F_{2α}-tromethamine (Hemabate), 46-23-46-24
Methyldopa (Aldomet), 13-39, 14-9, 87-7
 CH from, 29-15
 DILI from, 29-3t
 for hypertension, 13-10, 31-21
 levodopa and, 53-14t
 lithium and, 80-11t
 nasal symptoms from, 24-23t
 pregnancy and, 46-16t
 sexual dysfunction from, 101-2t
 SLE from, 4-12, 44-4
 subacute hepatic necrosis from, 29-16
Methylergonovine maleate (Methergine), 46-23
 for cluster headaches, 52-22t
Methylin. (see Methylphenidate)
Methylphenidate (Ritalin, Methylin, Metadate, Concerta), 18-3
 for ADHD, 81-3-81-4
 anxiety from, 76-6t
 for depression, 55-17
 mania from, 80-5t
 for narcolepsy, 77-17, 77-18
 opioids and, 8-31
 schizophrenia and, 78-3
 for SSRI-induced sexual dysfunction, 79-17t
Methylprednisolone (Solu-Medrol), 34-6t, 44-7t
 administration routes of, 44-9t
 for asthma, long-term, 22-27t
 for bronchiolitis, 96-11
 dosing of, 22-18t
 for GVHD, 92-20
 for heart transplantation, 35-6
 for KD, 96-14
 for kidney transplantation, 34-16
 for lung transplantation, 35-8
 for lupus nephritis, 31-31
 for respiratory acidosis, 10-11
 for SLE, 44-9t
 for transplantation, 34-8
 for UC, 27-8-27-9
Methylxanthines
 for apnea, in neonates, 94-37-94-39
 for asthma, long-term, 22-29t
 for BPD, 94-17
Methysergide (Sansert)
 for cluster headaches, 52-22, 52-22t
 for migraine, 52-15-52-16, 52-15t
 pulmonary disorders from, 25-6t, 25-7t
Metipranolol (Optipranolol), for POAG, 51-4, 51-10t
Metoclopramide (Reglan), 7-6t, 7-8
 alcohol interaction with, 84-21t

- for anorexia nervosa, 82-14
 anxiety from, 76-6t
 for aspiration pneumonia, 9-5
 for depression, 99-15
 for dyspepsia, 26-9
 ET from, 53-26
 for gastroparesis, 50-77
 for GERD, 26-29, 93-10t, 93-11
 levodopa and, 53-14t
 for migraine, 52-13t
 MMF and, 34-29
 for NVP, 46-8, 46-8t
 for PONV, 7-10t, 9-24t, 9-25
 safety of, 93-7
 sexual dysfunction from, 101-7t
 for systemic sclerosis, 44-4
 tardive dyskinesia from, 78-20
- Metolazone, 13-13, 18-11, 18-25**
 drug-induced hyperlipidemia from, 12-17t
- Metoprolol (Lopressor, Toprol), 18-13, 18-41-18-42, 99-9**
 for aortic dissection, 20-6t
 for arrhythmia suppression, 19-19-19-20
 after bypass surgery, 19-14
 cardiogenic shock and, 17-19
 vs. carvedilol, 18-43
 diabetes and, 17-19
 dosing of, 16-15
 for hypertension, 31-21
 for MI, 17-18, 17-19t, 20-6t
 after discharge, 17-24
 trial of, 17-15
 for pulmonary disease, 17-20
 renal failure and, 33-11t
 sexual dysfunction from, 101-2t
 for supraventricular tachycardias, controlling ventricular rate in, 19-8t
- Metronidazole (Flagyl), 56-8t, 63-4, 66-7, 74-5t**
 adverse effects of, 65-24
 alcohol and, 65-19, 84-21t
 for aspiration pneumonia, 60-20, 60-21t
 for *Bacteroides* spp., 56-13t, 66-8
 for brain abscess, 58-33
 for BV, 65-19
 for CD, 27-15-27-16
 for CDAD, 62-20
 for *Clostridium difficile*, 56-13t
 for CNS infections, 58-9t
 dosing of, 56-20t
 echinacea and, 3-16
 fixed drug eruptions from, 38-17
 for giardiasis, 74-4t, 75-11
 for *Helicobacter pylori*, 26-14t, 26-16
 for IBD, 27-6
 during lactation, 46-39t
 mania from, 80-5t
 for NEC, 94-27
 for neonates, 94-31t
 for parasitic infection, 74-3t
 penetration characteristics of, 58-7t
 for PID, 65-8
 pregnancy and, 65-19, 65-24
 for trichomoniasis, 65-23-65-24
- Mevacor. (see Lovastatin)**
- Mexiletine (Mexitol), 19-6t**
 for DPN, 50-79
 smoking and, 85-5t
 for torsades de pointes, 19-26
- Mexitol. (see Mexiletine)**
- Mexoryl. (see Terephthalylidene dicamphor sulfonic acid)**
- Mezlocillin, 60-26**
 renal failure and, 33-11t
- Micafungin, 71-4, 92-26**
 adverse effects of, 56-16t
 for HSCT, 92-23
 for neutropenia, 68-6, 68-17
- Miconazole (Monistat), 12-29, 71-4**
 for diaper rash, 93-4
 for VVC, 65-21t
- Microgestin (Logestrin), 45-5t**
- Micronase. (see Glyburide)**
- Micronized estradiol (Estrace, Gynodiol), 48-4t**
- Micronor. (see Errin)**
- Midamor. (see Amiloride)**
- Midazolam (Versed), 9-4, 9-7t, 12-29, 76-12t, 76-13**
 adverse effects of, 9-7t
 dosing of, 77-10t
 for GAD, 76-8
 neonates and, 94-6t, 94-43t
 for pediatric insomnia, 77-20
 as preoperative agent, 9-3t
 for SE, 54-33
 for sedation, 93-12
- Midodrine, for HRS, 29-21**
- Midrin. (see Isometheptene)**
- Miglitol (Glyset), 50-48t, 50-49t, 50-56-50-57**
 drug interactions with, 50-57
 for type 2 diabetes, 50-65t
- Milk of magnesia**
 for constipation, during pregnancy, 46-32t
 for end-of-life care, 6-5
 for hypomagnesemia, 11-28
- Milrinone (Primacor), 18-57-18-58, 21-23-21-24**
 with heart transplantation, 35-2
- Mineral oil, 93-6t**
- Minipill. (see Progesterone)**
- Minipress. (see Prazosin)**
- Minocycline, 39-6t, 56-8t**
 for acne, 39-6
 adverse effects of, 39-6t
 CH from, 29-15
 hypersensitivity vasculitis and, 4-12
 for PD, 53-21
 pulmonary disorders from, 25-2t, 25-7t
 for RA, 43-8
 SLE from, 44-3
 for toxoplasmosis, 70-15
- Minoxidil (Loniten), 13-40**
 for hypertension, 13-10, 20-3, 20-5, 20-6, 20-7-20-8, 31-21
 with heart transplantation, 35-6
- Mircette. (see Kariva)**
- Mirena. (see Levonorgestrel-releasing system)**
- Mirtazapine (Remeron), 79-12, 79-13t, 79-24, 79-26**
 aging and, 99-11t
 for GAD, 76-10
 for hot flashes, 48-6t
 mania from, 80-5t
 for obesity, 82-20
 for panic disorder, 76-23
 for PTSD, 76-30
 for sleep disorders, 77-14
- for SSRI-induced sexual dysfunction, 79-17t
 weight gain from, 82-6
- Misoprostol (Cytotec), 26-4t, 26-6-26-7**
 during lactation, 46-39t
 for NSAID-induced peptic ulcer disease, 46-21-46-22
 for postpartum hemorrhage, 46-23
 teratogenic effects of, 46-31t
 for upper GI disorders, 26-4t
- Mithramycin. (see Pllicamycin)**
- Mitomycin**
 for bladder cancer, 91-16
 dosing of, 89-27t
 for gastric cancer, 88-22t
 hepatotoxicity from, 89-32t
 pulmonary disorders from, 25-2t, 25-4t, 25-6t, 25-8t
 pulmonary toxicity from, 89-31t
 toxicity from, 89-3
 UV reactions from, 89-13t
 VOD from, 29-16
- Mitoxantrone, 89-24, 90-7**
 alopecia from, 89-11t
- Mixed amphetamine (Adderall), 81-4**
- Mizoribine, for transplantation, 34-10**
- MMF. (see Mycophenolate mofetil)**
- MMR. (see Measles, mumps, rubella)**
- MMRV. (see Measles, mumps, rubella, varicella)**
- Moban. (see Molindone)**
- Moclobemide, for social anxiety disorder, 76-27**
- Modafinil, 79-25**
 for ADHL, 81-6
 for narcolepsy, 77-5, 77-18
 for OSA, 77-17
 weight loss from, 82-6
- Modicon. (see Brevicon; Nortel; Ortho-Novum)**
- Moexipril (Univasc), 18-12**
- Molindone (Moban)**
 adverse effects of, 78-12t
 dosing of, 78-17t
 pharmacokinetics of, 78-16t
- Mometasone (Nasonex, Asmanex), 22-23-22-25, 24-16t**
 for asthma, long-term, 22-27t
 dosing of, 22-23t, 22-24t
- Mometasone furoate, 38-8t**
- Monistat. (see Miconazole)**
- Monoamine oxidase inhibitors (MAOIs), 76-35, 79-12, 79-30-79-32**
 for AD, 100-10
 alcohol interaction with, 84-21t
 for anorexia nervosa, 82-14
 for bipolar disorder, 80-4
 for bulimia nervosa, 82-16
 buspirone and, 76-20t
 for GAD, 76-8-76-9
 glaucoma and, 51-8
 mania from, 80-5t
 for panic disorder, 76-22, 76-23
 for PD, 53-4t, 53-17-53-19
 for PTSD, 76-30
 rizatriptan and, 54-9
 sexual dysfunction from, 101-2t
 for sleep disorders, 77-12-77-14
 for social anxiety disorder, 76-27
 SSRIs and, 79-32
 sumatriptan and, 54-9
 zolmitriptan and, 54-9
- Monobactams, 56-8t**
 adverse effects of, 56-15t
 for neutropenia, 68-10
 for UTIs, 64-10t
- Monacid. (see Cefonicid)**
- Monoclonal antibodies, for kidney transplantation, 34-2, 34-12**
- Monoket. (see Isosorbide mononitrate)**
- MonoNessa (Ortho Cyden), 45-5t**
- Mononitrate (Imdur), 15-7**
- Monopril. (see Fosinopril)**
- Monosodium glutamate, anxiety from, 76-6t**
- Montelukast (Singulair), 24-16t**
 for asthma, 22-10f
 long-term, 22-28t
- MOPP. (see Mechlorethamine, vincristine, procarbazine, and prednisone)**
- Moricizine (Ethmozine), 19-6t**
 for arrhythmia suppression, 19-19
 for MI, 17-7
- Morphine, 8-9, 8-21-8-22, 8-28, 93-15t, 94-48**
 adverse effects of, 93-14
 amylase and, 2-15
 bradycardia and, 17-21
 with bupivacaine, for epidural infusion, 9-31t
 dialysis and, 32-3
 for end-of-life care, 6-6-6-7
 for epidural infusion, 9-31t
 hepatic encephalopathy from, 28-18
 lipase and, 2-15
 for MI, 17-7, 17-9-t, 17-21
 for migraine, 52-13t
 myxedema coma and, 49-16
 for NAS, 83-8, 94-46
 nausea and vomiting from, 8-31
 neonates and, 94-7t
 for pain, 8-5, 93-14
 for PCA, 9-28, 9-29t
 PCA and, 8-16, 83-7
 pharmacokinetics of, 94-3t
 for postoperative pain, 9-33t
 as preoperative agent, 9-3t
 psoriasis from, 40-9t
 pulmonary disorders from, 25-2t, 25-5t
 renal failure and, 33-22
 for sedation, 93-12, 93-13
 sustained-release, 8-22
- Motavizumab, 96-13**
- Motrin. (see Ibuprofen)**
- Moxifloxacin (Avelox), 56-8t**
 for CAP, 60-11t
 for HAP, 60-24t
 renal failure and, 33-11t
 for TB, 61-9, 61-11t
 torsades de pointes and, 19-26t
- MP. (see Melfhalan, prednisone)**
- 6-MP. (see 6-mercaptopurine)**
- MPA. (see Medroxyprogesterone acetate)**
- MPS4. (see Menomune)**
- MPT. (see Melfhalan, prednisone, thalidomide)**
- MRSA. (see Methicillin-resistant *Staphylococcus aureus*)**
- MRSE. (see Methicillin-resistant *Staphylococcus epidermidis*)**
- MTX. (see Methotrexate)**
- Multitargeted tyrosine kinase inhibitors, 89-25-89-26**
- Mupirocin, 38-9t, 67-3**

- Muromonab, pulmonary disorders from, 25-2t**
- Muromonab-CD3 (OKT3, Orthoclone), 34-6t**
adverse effects of, 34-17
CMV from, 34-16
for heart transplantation, 35-4
for kidney transplantation, 34-2, 34-12
for transplantation, 34-9-34-10
- Mycelex. (see Clotrimazole)**
- Mycifradin. (see Neomycin)**
- Mycophenolate mofetil (MMF, CellCept), 34-6t**
adverse effects of, 34-29
dosing of, 34-29
drug interactions with, 34-30t
for focal segmental glomerulosclerosis, 31-34
for heart transplantation, 35-3-35-4
for HSCT, 92-11t
for kidney transplantation, 34-2, 34-12
for liver transplantation, 34-28-34-29
for lung transplantation, 35-8
for lupus nephritis, 31-31-31-32
metoclopramide and, 34-29
for transplantation, 34-7-34-8
for transplantation rejection, 35-9
- Mycophenolate sodium (Myfortic), 34-6t**
CNI and, 34-7
drug interactions with, 34-30t
for kidney transplantation, 34-2
for transplantation, 34-7-34-8
- Mycostatin. (see Nystatin)**
- Myfortic. (see Mycophenolate sodium)**
- Myleran. (see Busulfan)**
- Mylotarg. (see Gemtuzumab ozogamicin)**
- Myochrysin. (see Gold sodium thiomalate)**
- Nabilone (Cesamet), 7-6t**
- Nabumetone (Relafen), 8-9-8-10, 8-15, 43-17t**
- NAC. (see N-acetylcysteine)**
- N-acetylcysteine (NAC)**
for acetaminophen toxicity, 5-5, 5-20-5-22
renal-sparing effects of, 30-13
- NaCMC. (see Sodium carboxymethylcellulose)**
- Nadolol, 49-32**
for ET, 53-27t
for hypertension, 31-21
renal failure and, 33-11t
for variceal hemorrhage, 28-14-28-15
- Nadroparin, for stroke, 55-14**
- Nafarelin (Synarel), 47-17t**
adverse effects of, 47-19t
dosing of, 47-18
- Nafcillin (Unipen), 56-8t**
for aspiration pneumonia, 60-21t
for cellulitis, 67-3
for CNS infections, 58-9t
for culture-negative endocarditis, 59-24
dosing of, 56-20t
for gram-positive cocci, 56-9t
for meningitis, 58-11t
for MSSA, 59-14
for neonates, 94-31t
neutropenia from, 87-12
for osteomyelitis, 66-3, 66-4
penetration characteristics of, 58-7t
for PVE, 59-11
renal failure and, 33-11t
for staphylococcal endocarditis, 59-12t
for *Staphylococcus aureus*, 56-11
for *Staphylococcus epidermis*, 56-11
- Naftifine, 71-4**
- Nalbuphine (Nubain), 8-20, 8-29**
- Nalfon. (see Fenoprofen)**
- Nalidixic acid**
adverse effects of, 51-16t
for diarrhea, 62-5
for *Shigella* spp., 62-9
for typhoid fever, 62-12-62-13
- Nalmefene (Revex), 8-26**
- Naloxone (Narcan), 8-19, 83-9**
for alcohol intoxication, 84-6
for opioid toxicity, 5-5, 5-13-5-14, 8-26
pulmonary disorders from, 25-2t, 25-5t
via endotracheal administration, 19-28-19-29
- Naltrexone (Trexan), 83-9, 84-17-84-19**
for alcoholism, 84-14t
with CBT, 84-18
- Namenda. (see Memantine)**
- Nandrolone, for HIV wasting syndrome, 70-39t**
- Naphazoline (Privine), 24-13**
for allergic rhinitis, during pregnancy, 46-32t
- Naphcon-A. (see Pheniramine + naphazoline)**
- Naprosyn. (see Naproxen)**
- Naproxen (Naprosyn), 8-9-8-10, 43-17t, 93-15t**
ARF from, 30-7-30-8
aspirin and, 43-15
for dysmenorrhea, 47-11t
for gout, 42-5
for migraine, 52-12, 52-15t
nephrotic syndrome from, 8-15
PUD from, 26-18-26-21
- Naproxen sodium (Anaprox), 8-9-8-10**
- Naratriptan (Amerge), 54-8t**
for migraine, 53-4
- Narcan. (see Naloxone)**
- Narcotics**
for migraine, 52-12-52-13
for NAS, 94-46
- Nardil. (see Phenelzine)**
- Naropin. (see Ropivacaine)**
- Nasacart AQ. (see Triamcinolone)**
- Nasal corticosteroids, 24-7-24-8, 24-14-24-18**
- Nasal crom. (see Cromolyn)**
- Nasalide. (see Flunisolide)**
- Nasarel. (see Flunisolide)**
- Nasonex. (see Mometasone)**
- Natalizumab, for CD, 27-6**
- Nateglinide, 50-52**
dosage of, 50-53
efficacy of, 50-52-50-53
for type 2 diabetes, 50-65t
- Natrecor. (see Nesiritide)**
- Navane. (see Thiothixene)**
- Navelbine. (see Vinorelbine)**
- NE. (see Norepinephrine)**
- Nebcin. (see Tobramycin)**
- Necon. (see Ortho-Novum)**
- Nedocromil (Alocril), 24-15t**
for asthma, 22-11t, 22-12t, 22-25-22-26
long-term, 22-27t
- Nefazodone (Serzone)**
benzodiazepines and, 76-16t
buspirone and, 76-20t
doxofetilide and, 19-11
for GAD, 76-10
mania from, 80-5t
for panic disorder, 76-23
for PMS, 47-24
for PTSD, 76-30
- Nelarabine, neurotoxicity of, 89-20t**
- Nelfinavir (NFV, Viracept), 61-21, 69-4**
benzodiazepines and, 76-16t
for HIV, 69-9t
NNRTIs and, 69-21t
OC and, 45-12t
PI and, 69-20t
resistance to, 69-24t
- Nembutal. (see Pentobarbital)**
- Neomycin (Mycifradin), 38-9t, 56-8t, 67-3**
allergic contact dermatitis from, 38-16
lactulose and, 28-19
for surgery, 57-2t
- Neomycin-polymyxin-B-gramicidin (Neosporin), 51-14**
- Neoral. (see Cyclosporine)**
- Neosporin. (see Neomycin-polymyxin-B-gramicidin)**
- Neo-Synephrine. (see Phenylephrine)**
- Nepafenac, for eyes, 51-21**
- Nepavanac (Nevanac), for eyes, 51-22t**
- Nephrocaps, 31-15**
- Nesacaine. (see Chlorprocaine)**
- Nesiritide (Natrecor), 18-7, 18-56-18-57, 21-24**
for BNP, 2-12
- Netaglinide (Starlix), 50-47t, 50-49t**
- Netilmicin (Netromycin), 56-8t**
adverse effects of, 56-15t
for peritonitis, 32-14
- Netromycin. (see Netilmicin)**
- Neumega. (see Interleukin-11)**
- Neupogen, for neutropenia, 87-13**
- Neupro. (see Rotigotine)**
- Neurokinin-1 (NK-1) receptor antagonists, 7-7-7-8**
for PONV, 9-24t, 9-25-9-26
- Neuroleptics. (see Antipsychotics)**
- Neuromuscular blocking agents, 9-12-9-16**
action parameters for, 9-14t
adverse effects of, 9-13t
classification of, 9-13t
elimination of, 9-15t
volatile inhalation agents and, 9-11
- Neurotin. (see Gabapentin)**
- Neutral protamine hagedorn insulin (NPH), 14-4, 50-17t, 50-18**
flocculation of, 50-34
with rapid-acting insulin, 50-30
- Neutrexin. (see Trimetrexate)**
- Nevanac. (see Nepavanac)**
- Nevirapine (NVP, Viramune), 61-21**
clarithromycin and, 70-32t
for HIV, 69-9t, 69-14t
NNRTIs and, 69-21t
resistance to, 69-23t
- Nexavar. (see Sorafenib)**
- NFV. (see Nelfinavir)**
- Niacin, 12-14t, 12-15, 12-24t, 12-25t, 12-26t, 12-27t, 50-77**
adverse effects of, 12-27-12-28
for atherogenic dyslipidemia, 12-37
cholesterol and, 12-28t, 12-37
clinical use of, 12-26-12-27
for dyslipidemia, 12-24t
for hyperchylomicronemia, 12-39
for hyperlipidemia, with heart transplantation, 35-7
hyperuricemia from, 42-8t
liver and, 12-37
mechanism of, 12-27
for metabolic syndrome, 12-26
for MI, 17-24
simvastatin with, 12-15
for stroke, 55-5t, 55-7
triglycerides and, 12-28t
- Niaspan, 12-24t, 12-25t, 12-27**
cholesterol and, 12-37
- Nicardipine (Cardene), 16-15, 18-16**
for acute pulmonary edema, 20-6t
for acute renal failure, 20-6t
for angina, 16-16t
for aortic dissection, 20-6t
for cocaine overdose, 20-6t, 20-16-20-17
for hemorrhage, 20-6t
for hypertension, 20-3, 20-4t-20-5t
intravenous, 20-14-20-15
for pheochromocytoma, 20-6t
- Nicotinamide, 12-26-12-27**
for acne, 39-5
for prediabetes, 50-9
- Nicotine**
anxiety from, 76-6t
bulimia nervosa and, 83-5
panic disorder and, 76-24
pharmacology of, 85-3
weight loss from, 82-6
- Nicotin replacement therapy (NRT)**
bupropion and, 85-21-85-22
high-dose, for smoking treatment, 85-23
for smoking treatment, 85-7t, 85-10-85-23
- Nicotinic acid, anxiety from, 76-6t**
- Nifedipine (Adalate, Procardia), 13-31-13-32, 14-9, 16-15, 16-16, 18-16, 93-17**
for angina, 16-16t
digitalis and, 18-63
GITs and, 16-18
HF and, 16-16
for migraine, 52-17-52-18
pregnancy and, 46-16t, 46-18
for Raynaud's disease, 14-11-14-12
renal failure and, 33-11t
rifampin and, 61-17
sexual dysfunction from, 101-2t
sustained release, 16-18
for systemic sclerosis, 44-4
- Nikkomyins, 71-5**
- Nilutamide, for hormone-sensitive tumors, 88-25t**
- Nimbex. (see Cisatracurium)**
- Nimodipine (Nimotop)**
for delayed cerebral ischemia, 55-19
for migraine, 52-17-52-18
for stroke, 55-17
- Nimotop. (see Nimodipine)**
- Nipride. (see Nitroprusside)**

- Niravam.** (see Alprazolam)
- Nisoldipine (Sular)**
for angina, 16-16*t*
for Raynaud's disease, 14-12
- Nitazoxanide**
for CDAD, 62-21
for *Cryptosporidium parvum*, 62-23
for giardiasis, 74-4*t*
- Nitrates, 18-7, 18-15, 18-59, 18-63**
for angina, 16-9, 16-10
with CCB, 16-25
GERD and, 26-23*t*
for MI, 17-9*t*
sildenafil and, 101-11
for silent myocardial ischemia, 16-26
tadalafil and, 101-11
- Nitrazepam, 99-5**
- Nitrendipine, hepatitis and, 73-7**
- Nitric oxide**
with heart transplantation, 35-2
NSAIDs, 43-9
- Nitro-Bid.** (see Nitroglycerin)
- Nitrofurantoin**
adverse effects of, 64-20-64-21
CH from, 29-15
children and, 64-21
DILI from, 29-3*t*, 29-10*t*
pneumonitis from, 64-20
pregnancy and, 46-32*t*, 64-17

- Perindopril (Aceon), 18-12**
for CAD, 16-21
for PAD, 14-7
systolic dysfunction and, 18-30t
- Permethrin (Elimite, NIX), 74-4t, 74-5t, 75-17**
- Perphenazine (Trilafon)**
dosing of, 78-17t
nasal symptoms from, 24-23t
for PD, 53-22
pharmacokinetics of, 78-16t
receptor-binding affinities of, 78-12t
- PES. (see Paditaxel)**
- Petrolatum, 74-16**
- Pfizerpen. (see Penicillin G)**
- Phenacetin, analgesic syndrome from, 31-3**
- Phenazopyridine, 64-12**
- Phencyclidine (PCP), 83-15-83-16**
anxiety from, 76-6t
during lactation, 46-39t
mania from, 80-5t
psychosis from, 78-3, 78-4, 78-4t
- Phendimetrazine, for obesity, 82-19**
- Phenelzine (Nardil), 3-24, 76-35**
for migraine, 52-18t
for panic disorder, 76-23
for PTSD, 76-30
for social anxiety disorder, 76-27
weight gain from, 82-6
- Phenegan. (see Promethazine)**
- Phenindione, during lactation, 46-39t**
- Pheniramine + naphazoline (Naphcon-A), 24-15t**
- Phenobarbital, 93-17**
benzodiazepines and, 76-16t
COC and, 45-12
for febrile seizures, 54-24
GGT and, 2-14
hepatitis and, 73-7
hypersensitivity to, 4-2
for NAS, 83-8, 94-46
for neonates, 94-3, 94-42-94-44, 94-43t
OC and, 45-12t, 54-29-54-30
pharmacokinetic properties of, 54-6t
pharmacokinetics of, 94-3t
pregnancy and, 46-42
protein binding with, 94-5
renal failure and, 33-11t
for SE, 54-33
for sedative withdrawal, 83-11
for seizures, 54-5t
skin rash from, 54-27-54-28
thyroid and, 49-9
vitamin D and, 2-9
- Phenolates, 71-5**
- Phenolphthalein, fixed drug eruptions from, 38-17**
- Phenothiazine, 5-11, 8-24**
adverse effects of, 51-19t
alcohol interaction with, 84-21t
chronic intrahepatic cholestasis from, 29-16
drug fever from, 4-11
EM from, 38-16
hepatic dysfunction from, 78-24
hepatic encephalopathy from, 28-18
for migraine, 52-11
neutropenia from, 87-12-87-13
photosensitive eruptions from, 38-15
for PONV, 9-24t, 9-25
sexual dysfunction from, 101-2t
- Phenoxybenzamine (Dibenzylamine)**
for BPH, 101-19-101-20
for ED, 101-12
sexual dysfunction from, 101-2t
- Phentermine, for obesity, 82-19**
- Phentolamine (Regitine)**
for ED, 101-12t
for hypertension, 20-4t-5t
intravenous, 20-15
nasal symptoms from, 24-23t
papaverine with, 101-12, 101-13
for pheochromocytoma, 20-6t

- Phenylbenzimidazole sulfonic acid (Ensulizole), 41-8t, 41-11**
- Phenylbutazone (Butazolidin)**
adverse effects of, 51-17t
nephrotic syndrome from, 8-15
SJS from, 38-16
- Phenylephrine (Sudafed PE, Neo-Synephrine), 24-13, 24-13t**
anxiety from, 76-6t
for bronchiolitis, 96-11
mania from, 80-5t
for septic shock, 21-30
- Phenylpropanolamine (PPA)**
mania from, 80-5t
for obesity, 82-19
- Phenylephrine (see Phenytoin)**
- Phenytoin (Dilantin, Phenytek), 31-29, 54-15-54-16, 54-31-54-32, 93-17, 99-3-99-4**
adverse effects of, 51-15t, 54-17-54-18
benzodiazepines and, 76-16t
for brain abscess, 58-34
in breast milk, 46-43
COC and, 45-12
DILI from, 29-3t, 29-10t, 29-14
for eclampsia, 46-19
for epilepsy, 54-3t
feeding tubes and, 36-15, 36-16
GGT and, 2-14
hepatitis and, 73-7
hypersensitivity to, 4-2
INH and, 61-16
levodopa and, 53-14t
methadone and, 8-31
for migraine, 52-18t
neonates and, 94-3, 94-6t, 94-42-94-44, 94-43t
for nocturnal leg cramps, 14-14
OC and, 45-12t, 54-29-54-30
pharmacokinetics of, 54-6t, 94-3t
pregnancy and, 46-41
protein binding with, 33-2, 94-5
pulmonary disorders from, 25-2t, 25-8t
renal failure and, 33-11t
rifampin and, 61-17, 70-32t
for seizures, 54-5t, 54-12t, 55-19
sexual dysfunction from, 101-2t
skin rash from, 54-27-54-28
teratogenic effects of, 46-31t
thyroid and, 49-9
vitamin D and, 2-9
- Phosphate (PO₄), 2-10, 11-1**
blood chemistry reference values for, 2-3t
for DKA, 50-44, 50-44t
DKA and, 50-44
for hypercalcemia, 11-22t, 11-24
liver transplantation and, 34-26
neonatal seizures and, 94-41t
- Phosphate enema, 93-6t**
- Phosphate-binding agents, 31-22, 31-23t**
- Phosphodiesterase (PDE) inhibitors, 18-57-18-58, 21-23-21-24**
for AMI, 21-26
for COPD, 23-10
- Phospholine iodide. (see Echothiophate iodide)**
- Phytoestrogens, 48-7**
- Phytonadione. (see Vitamin K)**
- PI. (see Protease inhibitors)**
- Picotin. (see Oxytocin)**
- Pilocarpine (IsoptoCarpine), 51-6, 89-7t**
for POAG, 51-11t
for xerostomia, 89-8
- Pimecrolimus (Elidel), 38-14**
- Pimozide (Orap)**
for anorexia nervosa, 82-14
dosing of, 78-17t
for OCD, 76-34-76-35, 76-35
- Pindolol**
for nonsustained ventricular tachycardia, 19-21
for OCD, 76-35
sexual dysfunction from, 101-2t
- Pioglitazone (Actos), 50-48t, 50-50t, 50-65**
drug interactions with, 50-56
for PCOS, 47-6t, 47-7
weight gain with, 50-55
- Pioglitazone/glimepiride (Duetact), 50-51t**
- Pioglitazone/metformin (ActoPlus Met), 50-51t**
- Piperacillin**
for CAP, 60-11t
for CF, 98-11t
for gram-negative bacillary endocarditis, 59-23
for gram-negative coverage, 66-6
hypokalemia from, 11-16t
for meningitis, 58-17
penetration characteristics of, 58-7t
for *Pseudomonas* spp., 33-19, 66-6
renal failure and, 33-11t
with tazobactam, 63-4
for UTIs, 64-10t
- Piperacillin/tazobactam (Zosyn), 56-8t, 66-8**
for aspiration pneumonia, 60-20
for CRRT and HD, 56-21t
dosing of, 56-20t
for gram-negative aerobes, 56-10t
for gram-positive cocci, 56-9t
for HAP, 60-24t
for neonates, 94-31t
- Piperazine estrone sulfate (Estropiate, Ogen, Ortho-Est), 48-4t**
- Pirbuterol, dosing of, 22-17t**
- Piroxicam (Feldene), 43-17t**
ARF from, 30-7-30-8
for gout, 42-5
SJS from, 38-16
- Platelet aggregation inhibitors, pulmonary disorders from, 25-2t, 25-8t**
- Platelet glycoprotein Ib/IIb inhibitors, pulmonary disorders from, 25-2t, 25-8t**
- Platinol. (see Cisplatin)**
- Plavix. (see Clopidogrel)**
- Plendil. (see Felodipine)**
- Plicamycin (Mithramycin), for hypercalcemia, 11-22t, 11-23**
- PMMA. (see Gentamicin-impregnated polymethylmethacrylate)**
- Pneumococcal polysaccharide vaccine, 60-17-60-18**
- Pneumovax, 95-10**
for COPD, 23-12
- PO₄. (see Phosphate)**
- Podophyllin, for genital warts, 65-29-65-30**
- Podophyllotoxins, pulmonary disorders from, 25-8t**
- POLIOVAX, 95-6**
- Polocaine. (see Mepivacaine)**
- Polyacrylonitrile, 31-21**
- Polycitra, for metabolic acidosis, 31-14**
- Polyclonal antibody, for kidney transplantation, 34-2, 34-12**
- Polyethylene glycol, 5-11**
neonates and, 94-7t
- Polymox. (see Amoxicillin)**
- Polymyxin B, 38-9t, 67-3**
- Polysorbate, 94-50**
- Pontocaine. (see Tetracaine)**
- Poractant (Curosurf), 94-12t, 94-13**
- Portia (Levlen, Nordette), 45-5t**
- Posaconazole (Noxafil), 92-26**
adverse effects of, 56-16t
for lung transplantation, 35-10
for neutropenia, 68-6
- Potassium, 18-22-18-23. (see also Potassium in Subject Index)**
with cardioplegia solution, 9-21-9-22, 9-21t
diuresis and, 5-9
for DKA, 50-44t
GERD and, 26-23t
for metabolic acidosis, 97-6
for nocturnal leg cramps, 14-14
- Potassium channel blockers, 19-5**
- Potassium chloride, 10-9-10-10**
feeding tubes and, 36-15
for hypokalemia, 11-17
- Potassium citrate, for metabolic acidosis, 31-14**
- Potassium hydroxide (KOH), 71-10**
- Potassium iodide, 71-3**
- Potassium permanganate, 38-3t**
- Potassium-sparing diuretics, 13-13**
- PPA. (see Phenylpropanolamine)**
- PPI. (see Proton pump inhibitors)**
- Pralidoxime (Protopam), 54-25**
- Pramipexole (Mirapex), 53-22**
adverse effects of, 53-9-53-10
dosing of, 53-9
for PD, 53-3t, 53-7, 53-8, 53-14-53-15
for RLS, 53-25, 77-19
tardive dyskinesia from, 78-20
- Pramlintide (Symlin), 50-47, 50-51t, 50-59-50-60**
contraindications for, 50-60
drug interactions with, 50-60
precautions with, 50-60
weight loss from, 82-6
- Prandin. (see Repaglinide)**
- Pravachol. (see Pravastatin)**
- Pravastatin (Pravachol), 12-12, 12-12t, 12-24t, 12-25t, 12-28, 50-77**
for heart transplantation, 35-5
for stroke, 55-7
- Praziquantel (Biltricide), 74-4t, 74-5t, 74-14**
adverse effects of, 74-15
- Prazosin (Minipress)**
for BPH, 101-19-101-20
for dyslipidemia, 31-21
for hypertension, 13-10, 20-3, 20-5, 20-7-20-8, 31-21
nasal symptoms from, 24-23t
for PTSD, 76-30
for Raynaud's disease, 14-12
saw palmetto and, 3-19
sexual dysfunction from, 101-2t
- Precef. (see Cefarandide)**
- Precose. (see Acarbose)**
- Prednicarbate, 38-8t**
- Prednisolone, 44-7t**
administration routes of, 44-9t
for asthma, long-term, 22-27t
dosing of, 22-18t
for herpes zoster, 72-9
for SLE, 44-9t
for transplantation, 34-8
- Prednisone (Deltasone), 34-6t, 44-7t**
for acne, 39-7
administration routes of, 44-9t
adverse effects of, 90-37
for ALL, 90-27
for asthma, long-term, 22-27t
for cluster headaches, 52-21, 52-22t
for COPD, 23-15
for croup, 96-10-96-11
for dermatomyositis, 44-6
dosing of, 22-18t
for GVHD, 92-21
for HDV, 73-32
for head and neck cancer, 88-22t
for heart transplantation, 35-3-35-4, 35-6
for herpes zoster, 72-9
for Hodgkin disease, 88-23t
for hyperthyroidism, 49-23t
for ITP, 93-18
for kidney transplantation, 34-2, 34-12, 34-16
leukocytosis from, 44-11
for migraine, 52-13
for nephrotic syndrome, 93-20
for NODAT, 24
osteoporosis from, 102-15-102-16
for PCP, 70-9t
for polymyositis, 44-6
for SLE, 44-8, 44-9t
for sunburn, 41-15
for T-cell lymphoblastic lymphoma, 90-36t
for transplantation, 34-8
weight gain from, 82-6
- Prefest, 48-4t**
- Pregabalin (Lyrica), 8-27, 54-9, 54-14**
adverse effects of, 54-11
for DPN, 50-79
for epilepsy, 54-3t
for herpes zoster, 72-10
OC and, 54-29-54-30
pharmacokinetic properties of, 54-6t
for seizures, 54-5t, 54-12t
weight gain from, 82-6
- Premarin. (see Conjugated equine estrogens)**
- Premphase, 48-4t**
- Prempo, 48-4t**
- Prepidil. (see Prostaglandin E₂)**
- Prenar. (see Conjugate pneumococcal vaccine)**
- Prezista, for HIV, 69-10t**
- Primacor. (see Milrinone)**
- Primaquine phosphate, 75-6-75-7**
- Primaxin. (see Imipenem)**
- Primidone**
COC and, 45-12
for ET, 53-27t
for neonates, 94-43
OC and, 45-12t
for seizures, 54-5t
- Primrose oil, for hot flushes, 48-7**

- Prinivil. (see Lisinopril)**
Privine. (see Naphazoline)
Pro-Banthine. (see Propantheline)
Probenecid (Benemid), 42-9
 for hyperuricemia, 42-9-42-10
- Probiotics**
 for CDAD, 62-21
 for diarrhea, 93-9
 for NEC, 94-28
- Procainamide (Pronestyl, Pronestyl SR, Procan SR), 19-6**
 ANA from, 4-2
 anxiety from, 76-6*t*
 hemolytic anemia from, 87-7
 for MI, 17-7
 neonates and, 94-7*t*
 renal failure and, 33-12*t*, 33-22
 SLE from, 4-2, 44-3
 for sustained ventricular tachycardia, 19-21
 for Wolff-Parkinson-White syndrome, 19-16
- Procaine (Novocain), 9-16*t***
 allergic contact dermatitis from, 38-16
 for aspiration pneumonia, 60-21*t*
 properties of, 9-18*t*
 psoriasis from, 40-9*t*
- Procan SR. (see Procainamide)**
Procarbazine, 7-4*t*
 for Hodgkin disease, 88-23*t*
 hypersensitivity from, 89-18*t*
 neurotoxicity of, 89-20*t*, 89-21
 pulmonary toxicity from, 89-31*t*
- Procardia. (see Nifedipine)**
Prochieve. (see Progesterone vaginal gel)
Prochlorperazine (Compazine), 7-5, 7-6*t*, 7-8
 chronic intrahepatic cholestasis from, 29-16
 dofetilide and, 19-11
 for end-of-life care, 6-7
 for migraine, 52-12, 52-13*t*
 for NVP, 46-8*t*
 for opiate withdrawal, 83-10*t*
 for PONV, 7-10*t*, 9-24*t*
- Procrit. (see Erythropoietin)**
Proferin-ES, 31-17
Progesterone (Minipill, Prometrium), 45-19-45-20, 48-4*t*
 GERD and, 26-23*t*
 psoriasis from, 40-9*t*
- Progesterone vaginal gel (Prochieve, Crinone), 48-4*t***
Progestin, 48-6. (see also Estrogen-progestin therapy)
 dementia and, 100-9
 for endometriosis, 47-16
 for EPT, 48-4*t*
 estrogen with, 48-4*t*
 for ET, 48-4*t*
 for hormone-sensitive tumors, 88-25*t*
 for PCOS, 47-6*t*
- Prograf. (see Tacrolimus)**
Proguanil, 74-5*t*
ProHIBit, 95-7
Prokinetics
 for dyspepsia, 26-9
 for GERD, 26-29, 93-10*t*, 93-11
- Prolixin. (see Fluphenazine)**
Promethazine (Phenergan), 7-3*t*, 7-6*t*, 7-8
 allergen skin tests and, 24-21*t*
 for cough, during pregnancy, 46-32*t*
 for NVP, 46-8*t*
 for PONV, 7-10*t*, 9-24*t*
 safety of, 93-7
- Prometrium. (see Progesterone)**
Pronestyl. (see Procainamide)
Pronestyl SR. (see Procainamide)
Propafenone (Rythmol), 19-6*t*
 anxiety from, 76-6*t*
 for atrial fibrillation, 19-11-19-12
 for chemical cardioversion, 19-10
 digitalis and, 18-48-18-49
 for Wolff-Parkinson-White syndrome, 19-16
- Propantheline (Pro-Banthine), 99-6*t***
 adverse effects of, 51-15*t*
 for urinary incontinence, 101-27
- Propine. (see Dipivefrin)**
Propionic acid, 71-5
Propofol (Deprivan), 9-6, 9-7*t*
 adverse effects of, 9-7*t*, 51-15*t*
 for ambulatory surgery, 9-8
 for DC cardioversion, 19-10
 for SE, 54-33
 for sedation, 93-12, 93-13
- Propoxyphene**
 with acetaminophen, 8-10
 bioavailability of, 33-2
 pulmonary disorders from, 25-2*t*, 25-5*t*
 renal failure and, 33-22
 smoking and, 85-5*t*
- Propranolol (Inderal), 99-9, 99-10**
 for alcohol withdrawal, 84-11
 for benzodiazepine withdrawal, 76-16
 dosing of, 52-14-52-15
 for ET, 53-27-53-28, 53-27*t*
 half-life of, 16-14
 for hypertension, 12-25
 for hyperthyroidism, 49-23*t*
 melatonin and, 3-33*t*
 for MI, 17-18, 17-19*t*
 after discharge, 17-24
 miglitol and, 50-57
 for migraine, 52-14-52-15, 52-15*t*, 53-4
 for mixed hyperlipidemia, 12-32-12-33
 neonates and, 94-6*t*
 for panic disorder, 76-23
 protein binding with, 94-5
 psoriasis from, 40-9*t*
 pulmonary disorders from, 25-2*t*
 renal failure and, 33-12*t*
 for schizophrenia, 78-9
 sexual dysfunction from, 101-2*t*
 smoking and, 85-5*t*
 for social anxiety disorder, 76-28
 for supraventricular tachycardias, controlling ventricular rate in, 19-8*t*
 for tardive dyskinesia, 78-20
 triptans and, 54-9
 for variceal hemorrhage, 28-14-28-15
 weight gain from, 82-6
- Propylthiouracil (PTU), 49-23*t*, 49-24-49-28**
 DILI from, 29-10*t*
 for hyperthyroidism, 49-5
 during pregnancy, 46-32*t*
 pulmonary disorders from, 25-2*t*, 25-8*t*
 subacute hepatic necrosis from, 29-16
- ProQuad, 95-8, 95-9**
Proscar. (see Finasteride)
ProSom. (see Estazolam)
Prosorba, for RA, 43-8-43-9
Prostacyclin (Epoprostenol), 18-8
 for IC, 14-9
 for RA, 43-6
- Prostaglandin**
 for ALF, 73-15
 for eyes, 51-21
 GERD and, 26-23*t*
 for labor induction, 46-20
 for POAG, 51-5
- Prostaglandin E₁ (Alprostadi), 14-12**
 for ED, 11-14-11-15, 101-12*t*
 for sexual dysfunction, 101-9
- Prostaglandin E₂ (Dinoprostone, Prepidil, Cervidil), 46-21**
Prostaglandin inhibitors, for hypercalcemia, 11-24
- Protamine**
 adverse reaction from, 4-18
 heparin and, 15-13
 histamine and, 4-15
- Protease inhibitors (PI), 69-4**
 DILI from, 29-2
 drug effects with, 69-19-69-20*t*
 drug interactions with, 61-21
 for HIV, 69-9-69-10*t*
 resistance to, 69-24*t*
 rifampin and, 61-17
 weight gain from, 82-6
- Protein C (Drotrecogin), 15-34**
Protein synthesis inhibitors, 56-8*t*
Proton pump inhibitors (PPI), 26-5-26-6, 49-16
 alternative administration options for, 26-36*t*
 for aspiration pneumonitis, 9-5
 for Barrett's metaplasia, 26-28
 diarrhea from, 62-2
 for dyspepsia, 26-8-26-9
 for GERD, 26-28, 93-10-93-11, 93-10*t*
 H₂ receptor antagonists with, for GERD, 26-29
 for *Helicobacter pylori*, 26-6, 26-13, 26-14*t*
 for NCCP, 26-30
 for NERD, 26-29-26-30
 pregnancy and, 46-9
 for SRMB, 26-35
 for systemic sclerosis, 44-4-44-5
 for upper GI bleeding, 26-32-26-33
 for upper GI disorders, 26-4*t*
 vitamin B₁₂ and, 26-6
 for ZES, 26-21-26-22
- Protopam. (see Pralidoxime)**
Protopic. (see Tacrolimus)
Protriptyline, for cataplexy, 77-17
Protriptyline (Vivactil), for tension-type headaches, 52-24
- Provera. (see Medroxyprogesterone acetate)**
Prozac. (see Fluoxetine)
PRP-D, 95-7
PRP-OMP (PedvaxHIB), 58-14, 95-7
PRP-T (ActHIB), 58-14, 95-7
- Pseudoephedrine (Sudafed), 24-13*t***
 anxiety from, 76-6*t*
 ET from, 53-26
 mania from, 80-5*t*
 for urinary incontinence, 101-20*t*
- Psilocin, 83-16-83-17**
Psilocybin, 83-16-83-17
Psychotropic agents, SLE from, 44-3
Psyllium (Metamucil), 12-30
 for constipation, during pregnancy, 46-32*t*
- PTH. (see Parathyroid hormone)**
PTU. (see Propylthiouracil)
Pulmonzyme. (see Dornase alfa)
Purinethol. (see Mercaptopurine)
Pygeum, for BPH, 101-23
Pyrantel pamoate (Antiminth), 74-3*t*, 75-12
- Pyrazinamide (PZA)**
 for CAP, 60-12*t*
 dosing of, 56-20*t*
 hyperuricemia from, 42-8*t*
 for TB, 61-8, 61-9*t*, 61-10*t*, 61-13
 for tuberculous meningitis, 61-23
- Pyrethrin, 74-16**
Pyridoxine, 31-15
 levodopa and, 53-14*t*
 melatonin and, 3-33*t*
 for neonates, 94-43*t*
 for NVP, 46-8, 46-8*t*
 for tuberculous meningitis, 61-23
- Pyrimethamine**
 with folic acid, for toxoplasmosis, 70-15
 HIV and, 70-4
 toxicity with, 70-14
 for toxoplasmosis, 70-14
 in neonates, 94-36
- Pyrimethamine/leucovorin, for PCP, 70-11*t***
Pyrimethamine-sulfadoxine (Fansidar), 74-5*t*
- Pyroliizidine alkaloids, 3-5**
PZA. (see Pyrazinamide)
- Quazepam (Doral), 76-8*t*, 76-12, 76-12*t***
Quelicin. (see Succinylcholine)
Questran. (see Cholestyramine)
Quetiapine (Seroquel), 78-10
 adverse effects of, 78-12*t*
 for anorexia nervosa, 82-14
 for autism, 78-30
 for bipolar disorder, 80-12*t*
 depression with, 80-15
 dosing of, 78-17*t*
 drug interactions with, 19-25
 for mania, 80-12
 mania from, 80-5*t*
 NMS from, 78-24
 for OCD, 76-35
 ocular effects from, 78-24
 for PD, 53-22
 pharmacokinetics of, 78-16*t*
 for psychosis, 100-15
 receptor-binding affinities of, 78-12*t*
 weight gain from, 78-22, 82-6
- Quinacrine (Atabrine), 75-11**
 alcohol interaction with, 84-21*t*
 anxiety from, 76-6*t*
- Quinaglate. (see Quinidine)**
Quinapril (Accupril), 18-12, 18-30
 systemic dysfunction and, 18-30*t*
Quinidex. (see Quinidine)

- Quinidine (Quinidex, Quinaglute), 12-29, 19-11, 99-6†**
antipsychotics and, 78-16
for chemical cardioversion, 19-10
digitalis and, 18-47-18-48
DILI from, 29-10†
GERD and, 26-23†
hemolytic anemia from, 87-6-87-7
HF from, 18-19
for malaria, 74-2-74-3
P-glycoprotein and, 88-20
psoriasis from, 40-9†
rifampin and, 61-17
SLE from, 4-12, 44-4
thrombocytopenia from, 87-8
- Quinine**
dofenilide and, 19-11
hepatitis and, 73-7
for malaria, 74-2-74-3
for nocturnal leg cramps, 14-13-14-14
thrombocytopenia from, 87-8-87-9
torsades de pointes and, 19-26†
- Quinolone, 32-15, 56-8†**
adverse effects of, 56-16†
for AECB, 60-4†
AIN from, 30-15
antacids and, 70-32†
ARF from, 30-3†
for CF, 98-12
for COPD, 23-15
for gram-negative aerobes, 56-10†
for gram-negative coverage, 66-6
for HAP, 60-24†
iron and, 31-17
for *Neisseria gonorrhoeae*, 56-13†
for osteomyelitis, 66-7
for PID, 65-8
for *Salmonella typhi*, 56-12†
for *Shigella* spp., 56-12†
theophylline and, 22-26
for UTIs, 64-10†
- Quinupristin-dalfopristin (Synercid), 59-20-59-21, 68-13**
for gram-positive cocci, 56-9†
- R (Lefflumide), for transplantation, 34-10**
- Rabeprazole, 26-5-26-6**
for aspiration pneumonitis, 9-5
for upper GI disorders, 26-4†
for ZES, 26-21-26-22
- Rabies immunoglobulin (RIG), 95-10**
- Radioactive iodine (RAI), 49-5, 49-23†, 49-24, 49-30**
allergic contact dermatitis from, 38-16
for thyroid cancer, 49-36
- Radiocontrast media**
adverse reactions to, 4-17
anaphylaxis from, 4-7
ATN from, 30-12-30-14
histamine and, 4-15
- Radiopharmaceuticals**
breast-feeding and, 97-7
during lactation, 46-39†
- RAI. (see Radioactive iodine)**
- R-albuterol. (see Levalbuterol)**
- Raloxifene (Evista), 49-16, 102-13**
for cancer prevention, 88-5†
cholestyramine and, 102-9
for osteoporosis, 44-13, 102-8-102-10
for osteoporosis prevention, 88-5†
- Raltegravir, for HIV, 69-11†**
- Ramelteon, 77-21**
for insomnia, 77-7-77-8
- Ramipril (Altace), 18-12**
for CAD, 16-21
ED and, 101-9
for PAD, 14-7
systolic dysfunction and, 18-30†
- Ramoplanin, for CDAD, 62-21**
- Ranibizumab, 51-23**
- Ranitidine (Zantac), 26-4-26-5**
for aspiration pneumonitis, 9-5
benzodiazepines and, 76-16†
for GERD, 93-10†
miglitol and, 50-57
pregnancy and, 46-32†
psoriasis from, 40-9†
for reflux esophagitis, 46-9
sexual dysfunction from, 101-7†
for SRMB, 26-35, 26-35†
for upper GI disorders, 26-4†
- Ranolazine**
for angina, 16-9, 16-18-16-20
for chronic stable angina, 16-20†
proarrhythmic effects of, 19-25
torsades de pointes and, 19-26†
- Rapamune. (see Sirolimus)**
- Rapamycin. (see Sirolimus)**
- Rapid-acting insulin, 50-17-50-18, 50-17†**
with insulin glargine, 50-31
NPH with, 50-30
for preprandial hypoglycemia, 50-31
- Rasagiline (Azilect), 53-4†**
for PD, 53-18-53-19
- Rasburicase (Elitek)**
for hyperuricemia, 42-9
for TLS, 90-6
- Razadyne. (see Galantamine)**
- Reclast. (see Zoledronic acid)**
- Recombinant activated factor VII (NovoSeven), 15-34**
- Recombinant cytokines, SLE from, 44-3**
- Recombinant human erythropoietin (rhEPO), 86-15-86-16**
for anemia, 89-5
- Recombivax HB, 73-15, 73-16-73-18**
- Red petrolatum, 41-8†**
- 5 α -reductase inhibitors, for BPH, 101-22**
- Refludan. (see Lepirudin)**
- Regitine. (see Phentolamine)**
- Reglan. (see Metoclopramide)**
- Relafen. (see Nabumetone)**
- Relenza. (see Zanamivir)**
- Relpax. (see Eletriptan)**
- Remeron. (see Mirtazapine)**
- Remicade. (see Infliximab)**
- Renzapride, 27-20-27-21**
- Repro. (see Abciximab)**
- Repaglinide (Prandin, NovoNorm), 50-47†, 50-49†**
dosage of, 50-53
efficacy of, 50-52-50-53
gemfibrozil and, 50-52
for type 2 diabetes, 50-65†
- Replens, for vaginal epithelial thinning, 48-7**
- Requip. (see Ropinirole)**
- Rescriptor. (see Delavirdine)**
- Resin, 12-26†**
cholesterol and, 12-37
- Resorcinol, 71-5**
for acne, 39-5
- Resperine, 13-39, 14-9**
adverse effects of, 51-16†
anxiety from, 76-6†
for hypertension, 13-10
nasal symptoms from, 24-23†
- Restoril. (see Temazepam)**
- Retepase (r-TA), 17-5†**
for MI, 17-4-17-5, 17-15
dosage of, 17-13
for second infarction, 17-17
- Retin-A. (see Transretinoic acid)**
- Retinoic acid. (see Transretinoic acid)**
- Retrovir, for HIV, 69-8†**
- Reverse transcriptase inhibitors, resistance to, 69-23†**
- Revex. (see Nalmefene)**
- Reyataz, for HIV, 69-10†**
- rhEPO. (see Recombinant human erythropoietin)**
- Rhinocort Aqua. (see Budesonide)**
- Rh₀(D) immune globulin, 46-9-46-10**
- Ribavirin (Virazole)**
adverse effects of, 72-6†
for avian flu, 72-17
for bronchiolitis, 96-12
dosing of, 73-42
for HCV, 73-39, 73-39†
hyperuricemia from, 42-8†
with IFN- α
adverse effects of, 73-42-73-43
for HCV, 73-40
for liver transplantation, 73-45
properties of, 72-3†
for RSV, 72-5†, 72-14-72-15
for SARS, 72-17-72-18
- Riboflavin**
for migraine, 52-18†
for nocturnal leg cramps, 14-14
- RIF. (see Rifampin)**
- Rifabutin**
clarithromycin and, 70-32†
drug interactions with, 70-30
fluconazole and, 70-32†
for MAC, 70-34†
with NNRTI, 70-31†
OC and, 45-12†
for TB, 61-10†
- Rifampin (RIF, Rimactane), 32-15**
adverse effects of, 61-16-61-17
AIN from, 30-15
anticonvulsants and, 70-30
antifungals and, 70-32†
atovaquone and, 70-32†
benzodiazepines and, 76-16†
buspirone and, 76-20†
for CAP, 60-12†
clarithromycin and, 70-32†
corticosteroids and, 70-30
desensitization to, 4-21
digoxin and, 70-30, 70-32†
DILI from, 29-10†
dosing of, 56-20†
drug interactions with, 61-17
fluconazole and, 70-30
hepatitis and, 73-7
for HIV, 70-5†
with TB, 70-28†
with INH, 61-17
ketoconazole and, 70-30
L-thyroxine and, 49-16
for Lyme disease, 75-5-75-6
for meningitis, 58-11†
for MRSE, 59-11
for neonates, 94-3
with NNRTI, 70-31†
NSAIDs and, 61-17
OC and, 45-12†
penetration characteristics of, 58-7†
penicillin resistance and, 60-13
phenytoin and, 70-32†
pioglitazone and, 50-56
for prosthesis infection, 66-9
for *Pseudomonas* spp., 66-10
resistance to, 70-27-70-28
rosiglitazone and, 50-56
sulfonyleureas and, 70-30
for TB, 61-8, 61-9†, 61-10†
theophylline and, 70-30, 70-32†
thyroid and, 49-9, 49-34
vitamin D and, 2-9
warfarin and, 70-32†
- Rifapentine, for TB, 61-10†**
- Rifaximin, 28-19**
for diarrhea, 62-5
for IBS, 27-21
for travelers' diarrhea, 62-17, 62-18
- RIG. (see Rabies immunoglobulin)**
- Rimactane. (see Rifampin)**
- Rimantadine (Flumadine)**
adverse effects of, 72-6†
for influenza, 60-14, 72-5†
pharmacokinetics of, 72-4†
properties of, 72-3†
- Rimexolone, adverse effects of, 51-21**
- Riopan, 49-16**
- Risedronate sodium (Actonel), 102-10-102-12, 102-13-102-14**
adverse effects of, 51-17†
glucocorticoids and, 102-16
- Risperdal. (see Risperidone)**
- Risperidone (Risperdal), 78-10, 78-26, 79-33**
for acute agitation, 78-14†
adverse effects of, 51-14, 78-12†
for anorexia nervosa, 82-14
antipsychotics and, 78-16
for autism, 78-30
for bipolar disorder, 80-12†
DILI from, 29-10†
dosing of, 78-17†
drug interactions with, 19-25
long-acting, 78-15
for mania, 80-12
mania from, 80-5†
nasal symptoms from, 24-23†
NMS from, 78-24
for OCD, 76-35
pharmacokinetics of, 78-16†
for psychosis, 100-15
for PTSD, 76-30
receptor-binding affinities of, 78-12†
for schizophrenia, 78-9-78-10
weight gain from, 78-22, 82-6
- Ritalin. (see Methylphenidate)**
- Ritodrine, pulmonary disorders from, 25-2†, 25-4†**
- Ritonavir (RTV, Norvir), 12-29, 61-21, 69-4**
antipsychotics and, 78-15
atazanavir with, 69-16
for HIV, 69-14†
benzodiazepines and, 76-16†
buspirone and, 76-20†
clarithromycin and, 70-32†
darunavir with, 69-16

- fosamprenavir with, 69-16
 for HIV, 69-14*t*
 garlic and, 3-9
 for HIV, 69-9*t*
 indinavir with, 69-16
 lopinavir with, 69-16
 NNRTIs and, 69-21*t*
 OC and, 45-12*t*
 PI and, 69-20*t*
 with saquinavir, 69-16
 for HIV, 69-14*t*
 for SARS, 72-17-72-18
 tripanavir with, 69-16
 weight gain from, 82-6
- Rituxan.** (see **Rituximab**)
- Rituximab (Rituxan), 31-32, 88-15*t***
 for CLL, 90-12
 dosing of, 43-10*t*, 43-31-43-32
 with FLU, 90-11
 hypersensitivity from, 89-18*t*
 for indolent lymphoma, 90-17
 for kidney transplantation, 34-2
 for PTLT, 35-11
 for RA, 43-5-43-6, 43-8, 43-31
- Rivastigmine (Exelon), 53-21**
 for AD, 100-7, 100-8*t*
- Rizatriptan (Maxalt), 54-8*t***
 MAOIs and, 54-9
 for migraine, 53-4
- Robinul.** (see **Glycopyrrolate**)
- Rocaltrol.** (see **Calcitriol**)
- Rocephin.** (see **Ceftriaxone**)
- Rocuronium (Zemuron), 9-13*t***
 action parameters for, 9-14*t*
 adverse effects of, 9-13*t*
 elimination of, 9-15*t*
- Rofecoxib (Vioxx), 4-16**
 for GI tract disorders, 44-13
 PUD from, 26-10-26-11
 for RA, 43-6
- Ropinole (Requip)**
 adverse effects of, 53-9-53-10
 dosing of, 53-9
 for PD, 53-3*t*, 53-7, 53-8-53-9
 for RLS, 53-25
- Ropivacaine (Naropin), 9-16*t***
 properties of, 9-18*t*
- Rosiglitazone (Avandia), 50-48*t*, 50-50*t*, 50-65**
 for PCOS, 47-6*t*, 47-7
 weight gain with, 50-55
- Rosiglitazone/glimepiride (Avanadryl), 50-51*t***
- Rosiglitazone/metformin (Avandamet), 50-51*t***
- Rosuvastatin (Crestor), 12-24*t*, 12-25*t*, 12-28, 50-77**
 for atherogenic dyslipidemia, 12-37
 for metabolic syndrome, 12-26
- RotaShield, 95-5**
- RotaTeq, 95-5**
- Rotigotine (Neupro), 53-3*t***
 for PD, 53-7, 53-10
- Rowasa.** (see **Mesalamine**)
- Roxadimate, 41-8*t***
- Royal jelly, hazards of, 3-6*t***
- r-TA.** (see **Retepase**)
- RTV.** (see **Ritonavir**)
- Rubex.** (see **Doxorubicin**)
- Rythmol.** (see **Propafenone**)
- SABA.** (see **Short-acting β_2 -agonist**)
- Salicylates, 41-12, 71-5, 93-15*t*.** (see **also Aspirin**)
- for acne, 39-5
 alcohol interaction with, 84-21*t*
 for CTDs, 44-2
 DILI from, 29-2, 29-3*t*, 29-6*t*
 diuresis and, 5-9
 for dysmenorrhea, 47-11*t*
 fixed drug eruptions from, 38-17
 glaucoma and, 51-8
 hyperthermia from, 5-9
 hypoprothrombinemia from, 43-16
 for hypothyroidism, 49-9
 for osteoarthritis, 99-14
 protein binding with, 94-5
 pulmonary disorders from, 25-2*t*, 25-5*t*
 seizures from, 5-9
 for SLE, 44-3
 as sunscreens, 41-8*t*
 toxicity of, 5-10, 10-6
 uric acid and, 2-10
- Saline, 10-13**
 for DKA, 50-43, 50-44*t*
 for hypercalcemia, 11-22*t*
- Salmeterol, 22-15**
 for asthma, long-term, 22-29*t*
 torsades de pointes and, 19-26*t*

- Sevelamer hydrochloride, 31-23*t*, 31-24**
- Sevoflurane**
 chemical stability of, 9-10*t*
 properties of, 9-10*t*
- SFUs.** (see **Sulfonyleureas**)
- SGA.** (see **Second generation antihistamines**)
- SGAs.** (see **Second generation antipsychotics**)
- Shark cartilage, 3-3*t*, 3-28-3-29**
 adverse effects of, 3-29
 for arthritis, 3-28
 for cancer, 3-28
 constipation from, 3-29
 for diabetic retinopathy, 3-28
 diarrhea from, 3-29
 dosing of, 3-29
 for glaucoma, 3-28
 hepatitis from, 3-29
 for Kaposi sarcoma, 3-28
 for psoriasis, 3-28
- Shohl's solution**
 for metabolic acidosis, 31-14
 for RTA, 10-6
- Short acting insulin, 50-17*t*, 50-18**
- Short-acting β_2 -agonist (SABA), 22-12-22-21**
 adverse effects of, 22-15-22-20
 for asthma, 22-10*f*, 22-11*t*, 22-12*t*
 with corticosteroids, 22-19-22-20
 dosing of, 22-15
 for EIA, 22-32
 overdose of, 22-21
 with theophylline, 22-19
- Short-contact anthralin therapy (SCAT), 40-4**
- Sho-saiko-to, for HCV, 73-44**
- Sibutramine (Meridia), 82-20-82-21**
 anxiety from, 76-6*t*
 mania from, 80-5*t*
- Sildenafil (Viagra), 101-10-101-11**
 adverse effects of, 51-14, 51-19*t*
 cimetidine and, 101-11
 erythromycin and, 101-11
 with heart transplantation, 35-2
 nasal symptoms from, 24-23*t*
 nitrates and, 101-11
 nitroglycerin and, 101-11
 for Raynaud's disease, 14-12
 for sexual dysfunction, 101-9
 for SSRI-induced sexual dysfunction, 79-17*t*
- Silvadene.** (see **Silver sulfadiazine**)
- Silver nitrate, 38-3*t*, 41-20**
- Silver sulfadiazine (Silvadene), 41-20**
- Silymarin, for HCV, 73-44**
- Simdax.** (see **Levosimendan**)
- Simulect.** (see **Basiliximab**)

- Simvastatin (Zocor), 12-12t, 12-24t, 12-25t, 12-28, 15-7, 50-77**
for atherogenic dyslipidemia, 12-37
for heart transplantation, 35-5
for MI, 17-24
for mixed hyperlipidemia, 12-32-12-33
with niacin, 12-15
pulmonary disorders from, 25-2t, 25-8t
rifampin and, 61-17
for stroke, 55-5
- Sinemet. (see Carbidopa-Levodopa)**
- Sinequan. (see Doxepin)**
- Singulair. (see Montelukast)**
- Sirolimus (SES, Rapamune), 16-28, 34-6t**
adverse effects of, 34-20
dosing of, 34-20
drug interactions with, 34-30t
for heart transplantation, 35-5, 35-6
for hyperlipidemia, with heart transplantation, 35-7
with islet cell transplantation, 50-12
for kidney transplantation, 34-2, 34-9, 34-12, 34-19-34-20
for NODAT, 24
pulmonary disorders from, 25-2t, 25-5t, 25-8t
- Sisomicin, 60-26**
- Sitagliptin (Januvia), 50-47, 50-51t, 50-58-50-59, 50-66, 99-10**
digoxin and, 50-59
for type 2 diabetes, 50-65t
- Sitagliptin/metformin (Janumet), 50-51t**
- Slow Fe, 86-6t**
- Slow Mag, for hypomagnesemia, 11-28**
- SMX. (see Sulfamethoxazole)**
- SNRIs. (see Serotonin norepinephrine reuptake inhibitors)**
- Sodium. (see also Sodium in Subject Index)**
with cardioplegia solution, 9-21t
for DKA, 50-44
lithium and, 80-11t
nephrotic syndrome and, 93-20
for nocturnal leg cramps, 14-14
- Sodium bicarbonate. (see Bicarbonate)**
- Sodium carboxymethylcellulose (NaCMC), 41-19**
- Sodium channel blockers, 19-5**
for CF, 98-14
TCAs as, 5-17
- Sodium chloride, for hyponatremia, 11-8**
- Sodium citrate, for metabolic acidosis, 31-14**
- Sodium citrate/citric acid (Bicitra)**
for aspiration pneumonitis, 9-5
for metabolic acidosis, 31-14
as preoperative agent, 9-3t
- Sodium ferric gluconate (Ferrlecit), 4-18, 31-17, 86-6, 86-6t**
- Sodium fluoride, 89-7t**
- Sodium oxybate (Xyrem), 77-18**
for narcolepsy, 77-5
- Sodium polystyrene sulfonate (SPS), for hyperkalemia, 11-19**
- Sodium stibogluconate, 74-4t**
- Sodium tyropanoate, 49-24**
- Solifenacin (Vesicare), for urinary incontinence, 101-20t, 101-27**
- Solu-Medrol. (see Methylprednisolone)**
- Somatostatin, 26-3**
for cluster headaches, 52-21
sleep and, 77-3
for upper GI bleeding, 26-33
- Somatropin, for HIV wasting syndrome, 70-39t**
- Sonata. (see Zaleplon)**
- Sorafenib (Nexavar), 88-15t**
alopecia from, 89-11t
hand-foot syndrome from, 89-12
nail changes from, 89-11t
- Sorbitol, 93-6t, 94-50**
for constipation, during pregnancy, 46-32t
for drug poisoning, 5-5
for hyperkalemia, 11-19
- Sordarins, 71-5**
- Soriatane. (see Acitretin)**
- Sotalol (Betapace), 19-6t**
for arrhythmia suppression, 19-20
for atrial fibrillation, 19-12
after bypass surgery, 19-13-19-14
vs. implantable defibrillators, 19-23
QTc from, 19-24
for sustained ventricular tachycardia, 19-22
- Sparfloxacin, torsades de pointes and, 19-26t**
- Specifically targeted antiviral therapy (STAT-C), 73-44**
- Spectinomycin**
for DGI, 65-10t
for gonorrhea, 65-4, 65-5, 65-7
- Spectracef. (see Cefditoren)**
- Spectrobid. (see Bacampicillin)**
- Spermicides, 45-25t, 64-3**
- Spirolactone (Aldactone), 13-13, 18-9, 18-25-18-26, 31-13**
for ascites, 28-5-28-6
for BPD, 94-16t
for diabetic nephropathy, 31-12
hyperchloremic metabolic acidosis from, 11-14
hyperkalemia from, 11-18
for hypertension, 13-10
for MI, 17-23-17-24
for PCOS, 47-6t, 47-7-47-8
sexual dysfunction from, 101-2t
- Sporanox. (see Itraconazole)**
- Sprintec. (see MonoNessa)**
- Sprintec (Ortho Cyden), 45-5t**
- SPS. (see Sodium polystyrene sulfonate)**
- SQV. (see Saquinavir)**
- SSRIs. (see Selective serotonin reuptake inhibitors)**
- SSZ. (see Sulfasalazine)**
- St. John's wort, 3-3t, 3-12-3-15**
adverse drug reactions with, 3-13-3-14
buspirone and, 3-13
for depression, 3-12-3-15
dosing of, 3-14
hypertension from, 3-13
mania from, 80-5t
OC and, 45-12t
photosensitization from, 3-13-3-14
serotonin syndrome from, 3-14
SSRIs and, 3-12
TCAs and, 3-12
- Stadol. (see Butorphanol)**
- Stalevo. (see Carbidopa-Levodopa)**
- Stanford V regimen. (see Mechlorethamine, doxorubicin, etoposide, vincristine, vinblastine, bleomycin, and prednisone)**
- Starlix. (see Netaglinide)**
- STAT-C. (see Specifically targeted antiviral therapy)**
- Statins, 12-26t**
adverse effects of, 12-28-12-30
anxiety from, 76-6t
for atrial fibrillation, 19-12
cholesterol and, 12-28t, 12-37
clinical use of, 12-28
for dyslipidemia, 12-24t
gemfibrozil with, 12-29
for hyperchylomicronemia, 12-39
for hyperlipidemia, with heart transplantation, 35-7
mechanism of, 12-28
for metabolic syndrome, 12-26
for MI, 17-6
for osteoporosis, 44-13, 102-17
for septic shock, 21-32
triglycerides and, 12-28t
- Stavudine, 69-4**
for HIV, 69-8t
resistance to, 69-23t
- Stelazine. (see Trifluoperazine)**
- Stephania tetrandra, 3-5**
- Steroids**
anxiety from, 76-6t
for BPD, 94-18
DILI from, 29-6t
herbs and, 3-5
IOP and, 51-20t
kidney transplantation and, 34-21-34-22
for SLE, 44-8
- STI. (see Structured treatment interruptions)**
- Stool softeners, 89-10**
for MI, 17-7
- Streptase. (see Streptokinase)**
- Streptogramin, 59-20-59-21**
- Streptokinase (Streptase), 17-5t**
bleeding with, 17-17
for elderly, 17-17
for MI, 17-4, 17-16
dosage of, 17-13
pregnancy and, 46-32t
repeat dose avoidance of, 17-17
stroke and, 17-17
trial of, 17-14t
- Streptomycin, 56-8t**
allergic contact dermatitis from, 38-16
for CAP, 60-12t
for endocarditis, 59-18
for HIV, with TB, 70-28t
for MDRTB, 70-27
resistance to, 59-17
for TB, 61-11t, 61-13
teratogenic effects of, 46-31t
for tuberculous meningitis, 61-23
for Tularemia, 75-10
- Streptozocin, 89-27**
hepatotoxicity from, 89-32t
- Strontium ranelate, 102-17**
- Structured treatment interruptions (STI), 69-29**
- Sublimaze. (see Fentanyl)**
- Succinylcholine (Anectine, Quelicin), 9-13t**
action parameters for, 9-14t
adverse effects of, 9-13t
contraindications for, 9-15
elimination of, 9-15t
glaucoma and, 51-8
hyperkalemia from, 11-18
- Sucalfate, 26-6, 31-25, 49-16, 89-7t**
feeding tubes and, 36-15
for GERD, 26-29, 93-10t, 93-11
for *Helicobacter pylori*, 26-13
for SRMB, 26-34-26-35, 26-35t
for upper GI disorders, 26-4t
- Sudafed. (see Pseudoephedrine)**
- Sudafed PE. (see Phenylephrine)**
- Sufentanil, histamine and, 4-17-4-18**
- Sular. (see Nisoldipine)**
- Sulbactam**
ampicillin with, 63-4
penetration characteristics of, 58-7t
- Sulfa drugs, ARF from, 30-3t**
- Sulfadiazine, 56-8t**
SLE from, 44-3
for toxoplasmosis, 70-14
in neonates, 94-34t, 94-36
- Sulfadoxine (Fansidar), 56-8t**
- Sulfamethoxazole (SMX). (see also Trimethoprim-sulfamethoxazole)**
dofetilide and, 19-11
hemolytic anemia from, 87-5
neonates and, 94-7t
renal failure and, 33-12t
thrombocytopenia from, 87-8-87-9
for UTIs, 64-6t
- Sulfamylon. (see Mafenide acetate)**
- Sulfasalazine (SSZ, Azulfidine), 27-9t**
for CD, 27-15
desensitization to, 4-21
for IBD, 27-4t
pulmonary disorders from, 25-2t, 25-7t
for RA, 43-5, 43-6-43-7, 43-21
SLE from, 4-12, 44-4
for UC, 27-9
- Sulfipyrzone (Anturane), 42-9-42-10**
for stroke, 55-8
- Sulfisoxazole, thrombocytopenia from, 87-8-87-9**
- Sulfites, pulmonary disorders from, 25-2t, 25-4t**
- Sulfonamides**
adverse effects of, 51-16t, 56-16t
agranulocytosis from, 87-14
AIN from, 30-15
CH from, 29-15
for chancroid, 65-18
DILI from, 29-3t, 29-11t, 29-14
drug hypersensitivity syndrome from, 38-17
EM from, 38-16
erythema nodosum from, 38-17
fixed drug eruptions from, 38-17
interstitial nephritis from, 4-14
OC and, 45-12t
for prostatitis, 64-16
protein binding with, 94-5
psoriasis from, 40-9t
pulmonary disorders from, 25-2t, 25-3t, 25-8t
SJS from, 38-16
sulfonyleureas and, 50-54
vitamin B₁₂ and, 86-10
- Sulfonyleureas (SFUs), 50-47t, 50-49t, 50-53-50-54, 50-66-50-67**
adverse effects of, 50-54
alcohol and, 50-81
contraindications for, 50-54
dosing of, 50-54
drug interactions with, 50-54
efficacy of, 50-54
for elderly, 50-74-50-75

- pharmacokinetics of, 50-53–50-54
photosensitive eruptions from, 38-15
precautions with, 50-54
rifampin and, 70-30
sulfonamides and, 50-54
for type 2 diabetes, 50-65*t*
weight gain from, 82-6
- Sulindac (Clinoril), 8-15, 43-17*t***
ARF from, 30-7–30-8
for gout, 42-5
nephrotic syndrome from, 8-15
- Sulisobenzone (Eusolex 4360), 41-8*t*, 41-11**
- Sumatriptan (Imitrex), 54-8*t***
adverse effects of, 54-8
for cluster headaches, 52-20, 52-21*t*
dosing of, 54-9
drug interactions with, 54-9
headache recurrence with, 54-8–54-9
for migraine, 52-7–52-9, 52-12, 52-13*t*, 53-4
- Sunitinib (Sutent), 88-15*t***
cardiotoxicity with, 89-26
hand-foot syndrome from, 89-12
nail changes from, 89-11*t*
- Sunscreen, 41-8–41-14**
application of, 41-13
chemical, 41-11
chemotherapy and, 89-15
commercially available, 41-10*t*
cross-sensitivity of, 41-13
photosensitive eruptions from, 38-15
physical, 41-12–41-13
SPF of, 41-9, 41-14
substantivity of, 41-9–41-10
UVR and, 41-8*t*
- Superoxide anion, 9-20**
- Supprelin. (see Histrelin)**
- Suprax. (see Cefixime)**
- Surface active agents, for GERD, 93-10*t*, 93-11**
- Surfactants**
complications with, 94-13
for RDS, 94-11–94-14
- Survantam. (see Beractant)**
- Sustiva. (see Efavirenz)**
- Sutent. (see Sunitinib)**
- Symlin. (see Pramlintide)**
- Symmetrel. (see Amantadine)**
- Sympathomimetics, 50-81**
mania from, 80-5*t*
for obesity, 82-19
sexual dysfunction from, 101-2*t*
toxicity from, 5-3
- Synagis. (see Palivizumab)**
- Synarel. (see Nafarelin)**
- Synercid. (see Dalbapristin/quinupristin; Quinupristin-dalbapristin)**
- Syntest. (see Ethinylestradiol and methyltestosterone)**
- Synthetic conjugated estrogens (Cenestin, Enjuvia), 48-4*t***
- T₄. (see Thyroxine)**
- T-20. (see Fuzeon)**
- TAC. (see Docetaxel, doxorubicin, cyclophosphamide)**
- Tacrine (Cognex), 100-6**
for AD, 100-8*t*
smoking and, 85-5*t*
- Tacrolimus (Protopic, Prograf), 34-6*t*, 38-14**
adverse effects of, 34-27
cyclosporine and, 34-26–34-27
dosing of, 34-26, 92-19
drug interactions with, 34-30*t*
for GVHD, 92-18–92-19
for heart transplantation, 35-3–35-4
for HSCT, 92-11*t*
hyperkalemia from, 11-18
hyperuricemia from, 42-8*t*
with islet cell transplantation, 50-12
for kidney transplantation, 34-2, 34-12
for liver transplantation, 34-26
for lung transplantation, 35-8
for NODAT, 24
OC and, 45-12*t*
pioglitazone and, 50-56
rifampin and, 61-17
for transplantation, 34-8–34-9, 92-10
for transplantation rejection, 35-9
- Tadalafil (Cialis), 101-11**
adverse effects of, 51-19*t*
nasal symptoms from, 24-23*t*
nitrates and, 101-11
for sexual dysfunction, 101-9
- Tagamet. (see Cimetidine)**
- Talc, pulmonary disorders from, 25-2*t*, 25-6*t***
- Talwin. (see Pentazocine)**
- Tamiflu. (see Oseltamivir)**
- Tamoxifen, 88-20**
adverse effects of, 51-17*t*
for breast cancer, 91-7
for cancer prevention, 88-5*t*
for hormone-sensitive tumors, 88-25*t*
- Tamsulosin**
adverse effects of, 51-19*t*
for BPH, 101-20–101-21
- Tannic acid, 71-5**
- Tapazole. (see Methimazole)**
- Tarceva. (see Erlotinib)**
- Tasmar. (see Tolcapone)**
- Tavist. (see Clemastine)**
- Taxobactam, for gram-negative coverage, 66-6**
- Taxol. (see Paclitaxel)**
- Taxotere. (see Docetaxel)**
- Tazarotene. (see Transretinoic acid)**
- Tazobactam, piperacillin with, 63-4**
- TCAs. (see Tricyclic antidepressants)**
- TDM. (see Therapeutic drug monitoring)**
- Teas, 3-4**
- Tegaderm, 41-19**
- Tegaserod, for CP-IBS, 27-16**
- Tegopen. (see Cloxacillin)**
- Tegretol. (see Carbamazepine)**
- Telbivudine (Tyzela, Idenix)**
dosing of, 73-28*t*
for HBV, 73-23*t*, 73-27–73-28, 73-34*t*
- Telithromycin (Ketek), 56-8*t***
- Telmisartan, for diabetes, 31-12**
- Temafloracin (Omniflox), hemolytic anemia from, 87-7**
- Temazepam (Restoril), 76-8*t*, 76-12*t*, 77-11, 77-21**
adverse effects of, 77-11
dosing of, 77-10*t*
properties of, 77-7*t*
for RLS, 77-19
for sleep disorders, 77-2
- Temozolamide, 7-4*t***
- Tenecteplase (TNK), 17-5*t***
bleeding with, 17-17
for MI, 17-4–17-5
dosage of, 17-13
for second infarction, 17-17
stroke and, 17-17
trial of, 17-14*t*
- Teniposide**
hypersensitivity from, 89-18*t*
for lung cancer, 91-12
- Tenofovir (Viread), 69-4, 69-15**
for HBV, 73-28
for HIV, 69-8*t*
renal failure and, 33-12*t*
resistance to, 69-23*t*
- Tenofovir/emtricitabine, for HIV, 69-14*t***
- Tenormin. (see Atenolol)**
- Tenovil. (see Interleukin-10)**
- Terazol. (see Terconazole)**
- Terazosin (Hytrin)**
for BPH, 101-20
for dementia, 100-13
for hypertension, 13-10, 31-21
sexual dysfunction from, 101-2*t*
for urinary incontinence, 101-20*t*
weight gain from, 82-6

ciprofloxacin and, 64-9, 70-32*t*
clarithromycin and, 22-26
for COPD, 23-9–23-10
dosing of, 22-30*t*
drug interactions with, 22-26
for EAR, 22-3
ET from, 53-26
GERD and, 26-23*t*
with heart transplantation, 35-3
hepatitis and, 73-7
hyperuricemia from, 42-8*t*
lithium and, 80-11*t*
neonates and, 94-6*t*
norfloxacin and, 64-9
OC and, 45-12*t*
pharmacokinetics of, 94-3*t*
protein binding with, 94-5
quinolone and, 22-26
for respiratory failure, 22-19
rifampin and, 61-17, 70-30, 70-32*t*
SABA with, 22-19
sleep disorders from, 77-10*t*
toxicity with, 22-26, 99-4
weight loss from, 82-6
- Theopy, smoking and, 85-5*t***
- Theradigm-HBV, 73-28**
- Therapeutic drug monitoring (TDM), 69-26–69-27**
- Thiabendazole, 4-1**
chronic intrahepatic cholestasis from, 29-16
- Thiamine, 5-13**
for alcohol intoxication, 84-6
for alcohol withdrawal, 84-11

- Thiazide diuretics, 13-13, 13-17t, 18-11**
 absorption of, 12-25
 with ACEI, 13-25
 adverse effects of, 13-22t, 51-18t
 with ARBs, 13-25
 with β -blockers, 13-25
 for calcium stones, 30-17
 for diabetic nephropathy, 31-12
 drug-induced hyperlipidemia from, 12-17t
 hypercalcemia from, 2-9
 for hypertension, 12-25, 13-8, 13-10, 13-18, 31-20
 hypokalemia from, 11-16t
 hyponatremia from, 11-14
 lithium and, 80-11t
 for neonates, 94-8
 for osteoporosis, 102-12–102-13
 sexual dysfunction from, 101-2t
 thrombocytopenia from, 87-8
- Thiazolidinediones (TZDs), 50-48t, 50-50t, 50-54–50-56, 50-66**
 adverse effects of, 50-55
 CHF and, 50-55
 contraindications for, 50-56
 dosing of, 50-56
 drug interactions with, 50-56
 efficacy of, 50-56
 hypersensitivity with, 50-55
 for PCOS, 47-6t, 47-7
 pharmacokinetics of, 50-55
 precautions with, 50-56
 for type 2 diabetes, 50-65t
 weight gain from, 82-6
- Thioamides, 49-22, 49-24–49-28**
 for hyperthyroidism, 49-5, 49-20
- Thioguanine**
 for AML, 90-7
 hepatotoxicity from, 89-32t
 neonates and, 94-7t
 for T-cell lymphoblastic lymphoma, 90-36t
 UV reactions from, 89-13t
 VOD from, 29-16
- Thiopental (Pentothal), 9-7t**
 adverse effects of, 9-7t
- Thioridazine (Mellaril), 99-6t**
 adverse effects of, 51-19t, 78-12t
 dosing of, 78-17t
 drug interactions with, 19-25
 nasal symptoms from, 24-23t
 pharmacokinetics of, 78-16t
 receptor-binding affinities of, 78-12t
 sexual dysfunction from, 78-25
- Thiotepa**
 alopecia from, 89-11t
 for bladder cancer, 91-16
 neurotoxicity of, 89-20t
 skin pigment changes from, 89-11t
- Thiothixene (Navane)**
 adverse effects of, 78-12t
 dosing of, 78-17t
 pharmacokinetics of, 78-16t
- Third generation agents (TGA), for allergic rhinitis, 24-11**
- Thorazine. (see Chlorpromazine)**
- 3TC. (see Lamivudine)**
- Thrombolytics**
 for AMI, 21-24, 21-25
 bleeding risks of, 17-5t
 for elderly, 17-17
 for KD, 96-14
 for MI, 17-4–17-5, 17-16
 pulmonary disorders from, 25-2t, 25-8t
 readministration of, 17-17
 for stroke, 17-17, 55-15–55-16
 ventricular fibrillation and, 17-17–17-18
- THY. (see Thymoglobulin)**
- Thymoglobulin (THY), 34-13**
 CMV from, 34-16
 for HSCT, 92-2t
 for kidney transplantation, 34-16
- Thymol, 71-5**
- Thymosin, 73-44**
- Thymyoglobulin. (see Antithymocyte globulin)**
- Thyrolar. (see Liotrix)**
- Thyrotropin- α (Thyrogen), 49-36**
- Thyroxine (T₄), 49-12, 49-15**
 absorption of, 12-25
- Tiagabine (Gabitril), 54-9, 54-13**
 for epilepsy, 54-3t
 for mania, 80-13
 OC and, 54-29–54-30
 for panic disorder, 76-23
 pharmacokinetic properties of, 54-6t
 pregnancy and, 46-43
 for seizures, 54-13t
- Ticar. (see Ticarcillin)**
- Ticarcillin (Ticar), 56-8t**
 for aspiration pneumonia, 60-21t
 for CF, 98-11t
 for gram-negative aerobes, 56-10t
 for gram-negative bacillary endocarditis, 59-23
 for gram-positive cocci, 56-9t
 hypokalemia from, 11-16t
 for neonates, 94-31t
 penetration characteristics of, 58-7t
 sodium and, 2-2
- Ticarcillin/clavulanate (Timentin), 56-8t**
 for aspiration pneumonia, 60-20
 for CRRT and HD, 56-21t
 dosing of, 56-20t
 for gram-negative aerobes, 56-10t
 for gram-positive cocci, 56-9t
 for neonates, 94-31t
- Ticlid. (see Ticlopidine)**
- Ticlopidine (Ticlid), 16-22**
 for acute coronary syndromes, 17-22
 aplastic anemia from, 87-15
 for dementia, 100-14
 for PAD, 14-8
 pulmonary disorders from, 25-2t, 25-7t
 for stroke, 55-8, 55-10–55-11
 thrombotic thrombocytopenic purpura from, 87-11
- TIG. (see Tetanus immunoglobulin)**
- Tigecycline**
 adverse effects of, 56-15t
 for gram-negative aerobes, 56-10t
 for gram-positive cocci, 56-9t
- Tikosyn. (see Dofetilide)**
- Timentin. (see Ticarcillin/clavulanate)**
- Timolol (Blocadren, Timoptic)**
 for MI, 17-18, 17-19t
 for POAG, 51-4, 51-10t
 psoriasis from, 40-9t
 pulmonary disorders from, 25-2t
 sexual dysfunction from, 101-2t
- Timoptic. (see Timolol)**
- Tindamax. (see Tinidazole)**
- Tinidazole (Tindamax), 74-3t, 75-11**
 for trichomoniasis, 65-23–65-24
- Tioconazole (Vagistat), for VVC, 65-21t**
- Tiotropium, 23-16**
- Tipranavir, 69-4**
 NNRTIs and, 69-21t
- Tirofiban, with PCI, 16-27**
- Titanium dioxide, 41-8t, 41-10, 41-11**
- TIV. (see Trivalent inactivated influenza vaccine)**
- Tizanidine, OC and, 45-12t**
- TMP. (see Trimethoprim)**
- TMP/dapsone, for PCP, 70-9t, 70-10**
- TMP-SMX. (see Trimethoprim-sulfamethoxazole)**
- TNF- α blockers, for GVHD, 92-20**
- TNK. (see Tenecteplase)**
- Tobramycin (Nebcin), 56-8t**
 adverse effects of, 56-15t, 98-10
 as aerosol, 60-29
 for aspiration pneumonia, 60-21t
 for CF, 98-11t, 98-12
 for CNS infections, 58-9t
 for CRRT and HD, 56-21t
 dosing of, 56-20t
 for gram-negative aerobes, 56-10t
 for HAP, 60-24t, 60-25
 for MSSA, 59-13
 for neutropenia, 68-11
 penetration characteristics of, 58-7t
 for peritonitis, 32-14
 for pneumonia, with CF, 60-28
 for *Pseudomonas aeruginosa*, 98-11
 for Tularemia, 75-10
 for UTIs, 64-10t
- Tocainide (Tonocard), 19-6t**
 for torsades de pointes, 19-26
- Tofranil. (see Imipramine)**
- Tolazamide (Tolinase), 50-50t, 50-67**
 DILI from, 29-14
- Tolazoline, 14-9**
- Tolbutamide (Orinase), 50-50t, 50-67**
 chronic intrahepatic cholestasis from, 29-16
 DILI from, 29-14
 hemolytic anemia from, 87-6
 hepatitis and, 73-7
 SIADH from, 50-54
- Tolcapone (Tasmar), 53-4t**
- Tolectin. (see Tolmetin)**
- Tolvamer, for CDAD, 62-21**
- Tolinase. (see Tolazamide)**
- Tolindate, 71-5**
- Tolmetin (Tolectin), 43-17t**
 for gout, 42-5
 nephrotic syndrome from, 8-15
- Tolterodine (Detrol), for urinary incontinence, 101-20t, 101-26–101-27**
- Tolvaptan, 11-12**
- Tonocard. (see Flecainide; Tocainide)**
- Topamax. (see Topiramate)**
- Topiramate (Topamax), 54-9, 54-13**
 adverse effects of, 51-15t
 for alcohol withdrawal, 84-11
 for alcoholism, 84-14t, 84-19–84-20
 for bulimia nervosa, 82-17
 dopamine and, 84-19
 for epilepsy, 54-3t
 for ET, 53-27t
 for mania, 80-13
 mania from, 80-5t
- for migraine, 52-18t
 for obesity, 82-21
 OC and, 45-12t, 54-29–54-30
 pharmacokinetic properties of, 54-6t
 for seizures, 54-5t, 54-13t
 weight loss from, 82-6
- Topotecan**
 alopecia from, 89-11t
 dosing of, 89-27t
 for lung cancer, 91-12
 toxicity with, 89-2
- Toprol. (see Metoprolol)**
- Toradol. (see Ketorolac)**
- Toremifene, for hormone-sensitive tumors, 88-25t**
- Torselec. (see Tenecteplase)**
- Torsion, 13-13, 18-11**
 for AREF, 30-18
- Tositumomab (Bexxar), 88-15t**
- tPA. (see Alteplase)**
- Tracleer. (see Bosentan)**
- Tracrium. (see Atracurium)**
- Tramadol (Ultram), 8-9, 8-20, 8-32**
 for DPN, 50-79
 mania from, 80-5t
 for OA, 43-39
 paroxetine with, 8-32
 for RLS, 77-19–77-20
- Trandate. (see Labetalol)**
- Trandolapril (Mavik), 18-12**
 for MI, 17-23
 systolic dysfunction and, 18-30t
- Tranexamic acid, for DIC, 15-34**
- Transderm-Scop. (see Scopolamine)**
- Transretinoic acid (ATRA, Retinoic acid, Retin-A, Aldapalene, Differin, Tazarotene, Tretinoin), 39-3, 40-3t, 40-4–40-5, 41-5–41-6**
 for acne, 39-3–39-4
 adverse effects of, 39-5t
 for APL, 90-5
 hyperpigmentation and, 39-10
 pregnancy and, 46-44
 for psoriasis, 40-10
 teratogenic effects of, 46-31t
- Tranxene. (see Clorazepate)**
- Tranylcypromine, for social anxiety disorder, 76-27**
- Trastuzumab (Herceptin), 88-15t**
 for breast cancer, 88-22t
 CHF from, 89-25
 hypersensitivity from, 89-18t
- Travatan. (see Travoprost)**
- Travoprost (Travatan)**
 adverse effects of, 51-12
 for POAG, 51-5, 51-11t
- Trazodone (Desyrel), 79-12**
 CH from, 29-15
 for depression, 100-16
 mania from, 80-5t
 for opiate withdrawal, 83-10t
 for panic disorder, 76-23
 sexual dysfunction from, 101-2t
 for sleep disorders, 77-2
 toxicity from, 5-17
 weight gain from, 82-6
- Tretinoin. (see Transretinoic acid)**
- Trexan. (see Naltrexone)**
- Triacetin, 71-5**
- Triamcinolone (Aristocort, Nasocort AQ, Tri-Nasal), 24-16t, 38-7, 38-8t, 44-7t**
 for acne, 39-7
 administration routes of, 44-9t

- for asthma, long-term, 22-27t
for cluster headaches, 52-22t
dosing of, 22-23t, 22-24t
- Triamterene (Dyrenium), 8-15, 13-13, 18-12, 18-23, 31-13**
for ascites, 28-6
dofetilide and, 19-11
hyperchloremic metabolic acidosis from, 11-14
hyperkalemia from, 11-18
- Triazolam (Halcion), 12-29, 76-8t, 76-12t, 77-11**
dosing of, 77-10t
mania from, 80-5t
neonates and, 94-6t
properties of, 77-7t
for sleep disorders, 77-2, 77-7
- Triazole**
for *Candida*, 71-10
for lung transplantation, 35-10
- Trichloroethylene, alcohol interaction with, 84-21t**
- TriCor. (see Fenofibrate)**
- Tri-Cyden, 39-7**
- Tricyclic antidepressants (TCAs), 8-22-8-23, 8-26-8-27, 31-29, 79-13t, 79-26**
for ADHD, 81-3, 81-5-81-8
adverse drug reactions with, 99-6t
adverse effects of, 51-16t, 79-26-79-27
for anxiety nervosa, 82-14
anxiety from, 76-6t
for bipolar disorder, 80-4
for bulimia nervosa, 82-16
for cataplexy, 77-17
for depression, 79-12
DILI from, 29-11t
for DPN, 50-79
drug fever from, 4-11
ET from, 53-26
for GAD, 76-8-76-9
GERD and, 26-23t
for herpes zoster, 72-10
levodopa and, 53-14t
mania from, 80-5t
for obesity, 82-20
for panic disorder, 76-22, 76-23
photosensitive eruptions from, 38-15
for PP-IBS, 27-20
pregnancy and, 46-32t
sexual dysfunction from, 101-2t
for sleep disorders, 77-14
sleep disorders from, 77-10t
as sodium channel blockers, 5-17
St. John's wort and, 3-12
toxicity from, 5-10, 5-14
sodium bicarbonate for, 5-5, 5-17-5-18
weight gain from, 82-6, 82-8
- Tridil. (see Nitroglycerin)**
- Triethanolamine salicylate, 41-8t**
- Trifluoperazine (Stelazine)**
adverse effects of, 78-12t
dosing of, 78-17t
- Trifluridine**
adverse effects of, 72-6t
for HSV, 51-22
- Trihexyphenidyl (Artane), 99-6t**
adverse effects of, 51-15t
for PD, 53-3t
- TriHIBit, 95-6**
- Triiodothyronine, 49-12, 49-13**
- Trilafon. (see Perphenazine)**
- Trileptal. (see Oxcarbazepine)**
- Tri-Levlen. (see Trivora)**
- Trilisate. (see Magnesium choline salicylate)**
- Trimethadione**
adverse effects of, 51-15t
for seizures, 54-5t
teratogenic effects of, 46-31t
- Trimethaphan (Arfonad)**
for aortic dissection, 20-6t, 20-16t
for hypertension, 20-3, 20-4t-5t, 20-8-20-9
- Trimethobenzamide**
for NVP, 46-8
for opiate withdrawal, 83-10t
safety of, 93-7
- Trimethoprim (TMX, Trimplex), 56-8t**
dofetilide and, 19-11
hyperkalemia from, 11-18
renal failure and, 33-12t
teratogenic effects of, 46-31t
torsades de pointes and, 19-26t
for UTIs, 64-6t, 64-14, 96-18
- Trimethoprim-sulfamethoxazole (TMP-SMX, Bactrim, Cotrimoxazole, Septra), 32-15, 39-6t, 56-8t, 67-2, 93-17, 95-12**
adverse effects of, 64-19
anemia from, 86-18
for AOM, 96-6t
for aspiration pneumonia, 60-21t
for brain abscess, 58-33
for CAP, 60-12t
for CDAD, 62-19t
for cholera, 62-7
chronic intrahepatic cholestasis from, 29-16
for CNS infections, 58-9t
for COPD, 23-12, 23-15
for CRRT and HD, 56-21t
desensitization to, 4-21, 70-10t
for diarrhea, 62-5
DILI from, 29-3t, 29-11t
dosing of, 56-20t
drug fever from, 64-19
drug-induced skin reactions from, 4-14
for endocarditis, 59-15-59-16
folate deficiency and, 64-19-64-20
for gram-negative aerobes, 56-10t
for gram-positive cocci, 56-9t
for GVHD, 92-21-92-22
hemolytic anemia from, 64-19
HIV and, 4-2, 70-4, 70-5t
for HUS, 62-15
hypersensitivity with, 69-25-69-26
for lung transplantation, 35-10
for Lyme disease, 75-5-75-6
mania from, 80-5t
for meningitis, 58-11t, 58-18-58-19
methotrexate and, 92-27
for *Moraxella catarrhalis*, 56-13t
for neutropenia, 68-4
for *Nocardia* spp., 56-13t
OC and, 45-12t
for osteomyelitis, 66-7
for PCP, 70-8, 70-9t, 70-11t
penetration characteristics of, 58-7t
penicillin resistance and, 60-13, 60-13t
rash from, 64-19
for rhabdomyosarcoma, 91-29
- for RMSF, 75-13
for *Salmonella* spp., 62-11
for SBP, 28-10
for *Shigella* spp., 62-9
thrombocytopenia from, 87-8
for transplantation, 34-31
for travelers' diarrhea, 62-17
for typhoid fever, 62-12-62-13
for UTIs, 64-4-64-5, 64-5t, 64-6t, 64-7, 64-13-64-14, 96-17, 96-18, 99-13
warfarin and, 15-28-15-29
for Wegener's granulomatosis, 31-32-31-33
- Trimetrexate (Neutrexin)**
for PCP, 70-9-70-10
for toxoplasmosis, 70-15
- Trimetrexate/leucovorin, for PCP, 70-9t**
- Trimplex. (see Trimethoprim)**
- Tri-Nasal. (see Triamcinolone)**
- Tri-Norinyl. (see Enpresse)**
- Tripanavir**
for HIV, 69-10t
with ritonavir, 69-16
- Tripanavir/ritonavir, resistance to, 69-24t**
- Triphasil. (see Enpresse; Trivora)**
- Triptans**
anxiety from, 76-6t
drug interactions with, 54-9
for migraine, 52-7-52-10
propranolol and, 54-9
- Triptorelin, for hormone-sensitive tumors, 88-25t**
- Trisodium citrate, 32-7**
- Trivalent inactivated influenza vaccine (TIV), 60-16**
- Trivora (Tri-Levlen, Triphasil), 45-5t**
- Troglitazone**
adverse effects of, 50-55
DILI from, 29-11t, 29-14
weight gain with, 50-55
- Trolamine salicylate, 41-8t, 41-11**
- Tromethamine acetate (THAM), 10-8**
- Tropium (Sanctura), for urinary incontinence, 101-20t, 101-27**
- Trovafloxacin (Trovan), 87-7**
- Trovan. (see Trovafloxacin)**
- Trusopt. (see Dorzolamide)**
- Tryptophan**
mania from, 80-5t
melatonin and, 3-33t
- Twinrix, for HAV and HBV, 73-8**
- Tyrosine kinase inhibitor, pulmonary disorders from, 25-9-25-10**
- Tyzela. (see Telbivudine)**
- TZDs. (see Thiazolidinediones)**
- Ubiquinone. (see Coenzyme Q)**
- UFH. (see Unfractionated heparin)**
- Ultram. (see Tramadol)**
- Unasyn. (see Ampicillin/sulbactam)**
- Unfractionated heparin (UFH), 15-3-15-4**
for ACS, 16-31
as antithrombotic, 17-22-17-23
for bridge therapy, 15-27-15-28
dosing of, 16-28t
for DVT, 15-14
LMWH and, Fondaparinux and, 15-4t
for MI, 17-15
with PCI, 16-27
for PE, 15-17
pregnancy and, 15-25
- stroke and, 17-17
for thrombosis, 17-6
- Unipen. (see Nafcillin)**
- Univasc. (see Moexipril)**
- Urea, 11-14**
- Urispas. (see Flavoxate hydrochloride)**
- Urokinase, for MI, 17-5**
- VAC. (see Vincristine, dactinomycin, and cyclophosphamide)**
- Vaccination. (see Immunization)**
- Vaccine-associated paralytic polio (VAPP), 95-6-95-7**
- VAD. (see Vincristine, doxorubicin, dexamethasone)**
- Vagifem. (see Estradiol hemihydrate)**
- Vaginal ring (Femring), 48-4t**
- Vagistat. (see Tioconazole)**
- Valacyclovir (VCV)**
adverse effects of, 72-6t
for CMV, 34-34-34-35
for HSV, 65-26-65-28, 65-27t
for neutropenia, 68-18
pharmacokinetics of, 72-4t
pregnancy and, 65-29
properties of, 72-3t
- Valcyte. (see Valganciclovir)**
- Valdecoxib, 4-16**
PUD from, 26-10-26-11
- Valdecoxib (Bextra), for RA, 43-6**
- Valerian, toxicity of, 29-17, 29-19t**
- Valganciclovir (Valcyte)**
adverse effects of, 72-6t
for CMV, 34-34
retinitis, 70-19, 72-5t
dosing of, 70-20t
for neutropenia, 68-6
pharmacokinetics of, 72-4t
renal failure and, 33-12t
for transplantation, 34-31
- Valganciclovir (VCV), for CMV retinitis, 70-16-70-18t**
- Valium. (see Diazepam)**
- Valproate (Depakene, Depakote), 54-31**
for absence seizures, 54-19, 54-20t
for aggressive behavior, 100-16
for alcohol withdrawal, 84-10
for bipolar disorder, 80-12t, 80-16-80-17
carbamazepine and, 54-26
chronic steatosis from, 29-16
for cluster headaches, 52-22, 52-22t
DILI from, 29-3t, 29-11t
for epilepsy, 54-3t
ET from, 53-26
for febrile seizures, 54-24
lithium with, 80-3
liver damage from, 54-23
for mania, 80-5-80-7
melatonin and, 3-33t
for migraine, 52-15t, 52-17, 53-4
neonates and, 94-7t, 94-43, 94-43t
OC and, 54-29-54-30
for panic disorder, 76-23
pharmacokinetic properties of, 54-6t
pregnancy and, 46-42
protein binding with, 94-5
psoriasis from, 40-9t
for schizophrenia, 78-9-78-10
for SE, 54-33
for seizures, 54-5t, 54-12t
for tardive dyskinesia, 78-20

Valproate (Depakene, Depakote)
(continued)

teratogenic effects of, 46-31*t*
thrombocytopenia from,
54-26–54-27
thyroid and, 49-9
for tonic-clonic seizures, 54-21
weight gain from, 82-6

Valproic acid. (see Valproate)**Valrubicin, for bladder cancer, 91-16****Vancocin. (see Vancomycin)****Vancomycin (Vancocin), 56-8*t*,
58-20–58-21**

for acute osteomyelitis, 66-4*t*
adverse effects of, 4-14–4-15,
56-15*t*
for aspiration pneumonia, 60-20,
60-21*t*
for CAP, 60-12*t*
for CAPD-associated peritonitis,
63-7
for CDAD, 62-20
cefotaxime with, for NEC, 94-27
for CNS infections, 58-9*t*
for *Corynebacterium jeikeium*,
56-11

for croup, 96-11
for CRRT and HD, 56-22*t*
desensitization to, 4-21
dialysis and, 32-3, 33-3
dosing of, 56-20*t*
for endocarditis, 59-8*t*, 59-18
for *Enterococcus faecium*, 56-11
for GABHS, 96-7
for gram-negative bacillary
endocarditis, 59-23

for gram-negative coverage, 66-6
for gram-positive cocci, 56-9*t*
for HAP, 60-24*t*

for heart transplantation, 34-30
hemodialysis and, 33-20
with high-flux dialysis, 32-10
histamine and, 4-15
for meningitis, 58-11*t*
for MRSA, 33-19, 59-14–59-15
for MRSE, 59-11

for MSSA, 59-13
for NEC, 94-27
for neonates, 94-31*t*
for neutropenia, 68-9, 68-12–68-13
neutropenia from, 87-12
for osteomyelitis, 66-3, 66-7

penetration characteristics of, 58-7*t*
penicillin resistance and, 60-13
pharmacokinetics of, 94-3*t*
psoriasis from, 40-9*t*

for PVE, 59-10–59-11, 59-11
renal failure and, 33-12*t*
resistance to, 94-30

for *S. aureus*, 66-6
for septic arthritis, 66-11
for septic shock, 21-28
for staphylococcal endocarditis,
59-12*t*

for *Staphylococcus aureus*, 56-11
for *Staphylococcus epidermis*,
56-11

for surgery, 57-2*t*
thrombocytopenia from, 87-8
for UTIs, 64-5*t*
for ventriculitis, 55-19

**Vancomycin-resistant enterococci (VRE),
33-19, 68-3****Vanlafaxine (Effexor), for PMS, 47-24****Vantin. (see Cefpodoxime proxetil)****VAPP. (see Vaccine-associated paralytic
polio)****Vaptans, 11-12****Vaqta, 95-10**

dosing of, 73-7–73-8, 73-7*t*
for hepatitis A, 73-7

Vardenafil (Levitra), 101-12

adverse effects of, 51-19*t*
nasal symptoms from, 24-23*t*
for Raynaud's disease, 14-12
for sexual dysfunction, 101-9

Varenicline (Chantix), 14-5

adverse effects of, 85-20
dosing of, 85-20
for smoking treatment, 85-7*t*,
85-13, 85-19–85-20

**Varicella immune globulin (VZIG), 95-8,
95-12**

for HIV, 70-5*t*

Varivax, 95-8**Vasocon-A. (see Antazoline +
naphazoline)****Vasoconstrictors**

for allergic conjunctivitis, 24-14
for AMI, 21-25
for POAG, 51-7

**Vasodilators, 13-39–13-40, 16-16,
18-26–18-27**

for cardiogenic shock, 21-16
vs. digitalis, 18-28–18-29
ED from, 101-9
for HF, 21-21–21-22
for hypertension, 13-10, 31-21
for IC, 14-9
for MI, 17-6–17-7
sexual dysfunction from, 101-2*t*
for systemic sclerosis, 44-4

Vasopressin

adverse effects from, 28-12
for cardiac arrest, 19-28
nitroglycerin and, 28-12–28-13
for septic shock, 21-30–21-31

**Vasopressin receptor antagonists (VRA),
11-12****Vasopressors**

for Hantavirus, 72-16
for septic shock, 21-30–21-32

Vasotec. (see Enalapril; Enalaprilat)**VCF, 45-25*t*****VCV. (see Valacyclovir)****Vecuronium (Norcuron), 9-13*t***

action parameters for, 9-14*t*
adverse effects of, 9-13*t*
elimination of, 9-15*t*

Veetids. (see Penicillin V)**Velban. (see Vinblastine)****Venlafaxine (Effexor), 8-27, 79-13*t*,
79-23**

aging and, 99-11*t*
for bulimia nervosa, 82-17
for GAD, 76-9–76-10, 76-11
for hot flushes, 48-6*t*
hypertension and, 79-12
for OCD, 76-34
for panic disorder, 76-23
for PTSD, 76-30
for social anxiety disorder, 76-27

**Venofer. (see Iron saccharate; Iron
sucrose)****VePesid. (see Etoposide)****Verapamil (Isoptin, Calan), 13-31,
16-15, 19-14, 99-10**

with ACEI, 31-12

for angina, 16-10, 16-16*t*

for asthmatics, 19-9

for atrial fibrillation, 13-33

benzodiazepines and, 76-16*t*

bupirone and, 76-20*t*

cilostazol and, 14-9

for cluster headaches, 52-21,
52-22*t*

for cocaine overdose, 20-6*t*,
20-16–20-17

for controlling ventricular rate,
19-9

HF and, 16-16, 18-19

for hypertension, with heart
transplantation, 35-6

intravenous, 20-14–20-15

for MI, 17-7

for migraine, 13-33, 52-15*t*, 52-17,
53-4

neonates and, 94-6*t*

for nocturnal leg cramps, 14-14

for panic disorder, 76-23

for paroxysmal supraventricular
tachycardia, 19-15–19-16

P-glycoprotein and, 88-20

for pheochromocytoma, 20-6*t*

for proteinuria, 31-8

psoriasis from, 40-9*t*

risks with, 19-9

for supraventricular tachycardias,
controlling ventricular rate in,
19-8*t*

sustained release, 16-18

for Wolff-Parkinson-White
syndrome, 19-16

Vermox. (see Mebendazole)**Versed. (see Midazolam)****Vesicare. (see Solifenacin)****Vfend. (see Voriconazole)****Viagra. (see Sildenafil)****Vibramycin. (see Doxycycline)****Vidarabine, 72-2****Videx, for HIV, 69-8*t*****Vigabatrin, adverse effects of, 51-15*t*
Vildagliptin (Galvus, Novartis),
50-58–50-59****Vinblastine (Velban), 93-19**

alopecia from, 89-11*t*
anxiety from, 76-6*t*
autonomic neuropathy from,
89-22

for bladder cancer, 88-22*t*

cranial nerve toxicity with, 89-22

for Hodgkin disease, 88-23*t*, 89-35

neurotoxicity of, 89-20*t*

paresthesia from, 89-21

pulmonary toxicity from, 89-31*t*

radiation recall reactions from,
89-13*t*

UV reactions from, 89-13*t*

VOD from, 29-16

Vinca alkaloids

adverse effects of, 51-17*t*

pulmonary disorders from, 25-4*t*,
25-8*t*

Vincristine (Oncovin), 88-15*t*, 93-19

adverse effects of, 51-17*t*, 90-37

for ALL, 90-27

alopecia from, 89-11*t*

autonomic neuropathy from,
89-22

cranial nerve toxicity with, 89-22

for head and neck cancer, 88-22*t*

for Hodgkin disease, 88-23*t*

for lung cancer, 91-12

for MM, 90-19–90-20

neurotoxicity of, 89-20*t*

paresthesia from, 89-21

for rhabdomyosarcoma, 91-29

for T-cell lymphoblastic

lymphoma, 90-36*t*

toxicity of, 90-27–90-28

VOD from, 29-16

**Vincristine, dactinomycin, and
cyclophosphamide (VAC), 91-29
Vincristine, doxorubicin, dexamethasone
(VAD), 90-21*t*****Vindesine, alopecia from, 89-11*t*****Vinorelbine (Navelbine), 88-15*t***

for breast cancer, 91-6*t*

neurotoxicity of, 89-20*t*

paresthesia from, 89-21

Vioxx. (see Rofecoxib)**Viracept. (see Nelfinavir)****Viramune. (see Nevirapine)****Viread. (see Tenofovir)****Viscosupplements, for OA, 43-39****Vistaril. (see Hydroxyzine)****Vistide. (see Cidofovir)****Vitamin(s). (see also Vitamins in Subject
Index)**

for end-of-life care, 6-5
for kidney disease, 31-15

Vitamin A

for acne, 39-3–39-4

for CF, 98-8*t*

DILI from, 29-3*t*

pelliosis hepatitis from, 29-17

teratogenic effects of, 46-31*t*

Vitamin B₁, for dysmenorrhea, 47-13**Vitamin B₆**

homocysteine and, 2-12

for NVP, 46-8

for PMS, 47-22

pregnancy and, 46-32*t*

Vitamin B₁₂

homocysteine and, 2-12

PPI and, 26-6

sulfonamides and, 86-10

tetracyclines and, 86-10

Vitamin C

for atherosclerosis, 16-10

for hyperlipidemia, 12-39

for hyperuricemia, 42-10

as sunscreens, 41-12

**Vitamin D, 31-22, 31-25–31-26,
31-26–31-27**

for anorexia nervosa, 82-14

for CF, 98-7, 98-8*t*

with corticosteroids, 43-33

with dialysis, 32-2

hypercalcemia from, 2-9

for osteoporosis, 34-25

phenobarbital and, 2-9

phenytoin and, 2-9

rifampin and, 2-9

Vitamin E

for atherosclerosis, 16-10

for CF, 98-8*t*

dialysis and, 32-4

for HCV, 73-44

for hyperlipidemia, 12-39

for IC, 14-9

as sunscreens, 41-12

for tardive dyskinesia, 78-20

**Vitamin K (Phytonadione),
15-22–15-24, 54-30**

for CF, 98-7, 98-8*t*

- for epilepsy, 54-30
feeding tubes and, 36-16
histamine and, 4-15
for neonates, 94-3
thyroid and, 49-20
warfarin and, 15-5, 15-21
- Vivactil. (see Protriptyline)**
- Volatile inhalation agents, 9-9–9-12, 9-11**
 α_2 -agonists and, 9-11
benzodiazepines and, 9-11
costs of, 9-11–9-12
neuromuscular blocking agents and, 9-11
opioids and, 9-11
properties of, 9-10 t
- Voltaren. (see Diclofenac)**
- Voriconazole (Vfend), 71-4, 92-25–92-26**
adverse effects of, 51-17 t , 56-16 t
for aspergillosis, 71-24
for CRRT and HD, 56-22 t
dosing of, 56-20 t
for lung transplantation, 35-10
for neutropenia, 68-6, 68-17
toxicity with, 92-27
- VRA. (see Vasopressin receptor antagonists)**
- VRE. (see Vancomycin-resistant enterococci)**
- VZIG. (see Varicella immune globulin)**
- Warfarin (Coumadin)**
absorption of, 12-25
adverse effects of, 15-19–15-20
AF and, 15-26, 55-5 t
aging and, 99-5
alcohol and, 15-21
alopecia from, 38-15
amiodarone and, 15-29–15-30
aspirin and, 15-19
for atrial fibrillation, 19-12–19-13
bleeding from, 9-2
after cardioversion, 15-26
before cardioversion, 19-9
ciprofloxacin and, 70-32 t
coenzyme Q10 and, 3-37
for dementia, 100-14
dietary supplements and, 15-31–15-32, 15-31 t
dosing of, 15-21, 19-13
algorithm for, 15-18 f
drug interactions with, 15-28–15-31, 15-30 t
exenatide and, 50-58
feeding tubes and, 36-16
ginkgo and, 3-11–3-12
hemorrhage from, 15-19–15-20
hepatitis and, 73-7
hypokinesia and, 17-20
INR of, 15-7, 15-22
for KD, 96-14
for MI, 17-9 t
after discharge, 17-24–17-25, 17-25
nateglinide and, 50-52
neonates and, 94-6 t
NSAIDs and, 15-19, 15-30–15-31
patient education on, 15-20–15-21
for PE, 15-17
pregnancy and, 15-24–15-25, 46-38–46-39
prothrombin time and, 15-7
purple toe syndrome from, 15-20
renal failure and, 033-5
rifampin and, 61-17, 70-32 t
sensitization effects of, 15-17 t , 99-5
skin necrosis from, 15-20
for stroke, 55-11
prevention of, 19-12–19-13
teratogenic effects of, 46-31 t
thyroid and, 49-20
TMP-SMX and, 15-28–15-29
vitamin K and, 15-5, 15-21
- Welchol. (see Colesevelam)**
- Wild yam, 48-7**
- Xalatan. (see Latanoprost)**
- Xanax. (see Alprazolam)**
- Xeloda. (see Capecitabine)**
- Xenical. (see Orlistat)**
- Xibrom. (see Bromfenac)**
- Xolair. (see Omalizumab)**
- Xylocaine. (see Lidocaine)**
- Xylometazoline (Otrivin), 24-13 t**
for allergic rhinitis, during pregnancy, 46-32 t
- Xyrem. (see Sodium oxybate)**
- Xyzal. (see Levocetirizine)**
- Yasmin, 45-5 t**
- Yogurt, for VVC, 65-22**
- Yohimbine, 101-12**
anxiety from, 76-6 t
melatonin and, 3-33 t
for sexual dysfunction, 101-9
for SSRI-induced sexual dysfunction, 79-17 t
- Zaditor. (see Ketotifen)**
- Zafirlukast**
for asthma, long-term, 22-28 t
dofetilide and, 19-11
pulmonary disorders from, 25-2 t , 25-7 t
- Zalcitabine, anemia from, 86-18**
- Zaleplon (Sonata)**
dosing of, 77-10 t
for GAD, 76-8
for insomnia, 77-8–77-9
for pediatric insomnia, 77-20–77-21
properties of, 77-7 t
for sleep disorders, 77-2
- Zanamivir (Relenza)**
adverse effects of, 72-6 t
for avian flu, 72-13
for influenza, 60-14–60-15, 60-17, 72-5 t , 72-12
pharmacokinetics of, 72-4 t
properties of, 72-3 t
- Zantac. (see Ranitidine)**

- Zemuron. (see Rocuronium)**
- Zenapax. (see Dacizumab)**
- Zerit, for HIV, 69-8 t**
- Zestril. (see Lisinopril)**
- Zevalin. (see Ibritumomab tiuxetan)**
- Z-hypnotics**
for insomnia, 77-5, 77-8–77-9
for pediatric insomnia, 77-20–77-21
for sleep disorders, 77-2
- Ziagen, for HIV, 69-9 t**
- Zidovudine (AZT, ZDV), 69-4, 95-12**
anemia from, 86-15, 86-18
bioavailability of, 33-2
DILI from, 29-11 t
GERD and, 26-23 t
hemodialysis and, 33-17
for HIV, 69-8 t
mania from, 80-5 t
renal failure and, 33-12 t
resistance to, 69-23 t
- Zidovudine/lamivudine, for HIV, 69-14 t**
- Zileuton**
for asthma, 22-12 t
long-term, 22-28 t
pulmonary disorders from, 25-2 t , 25-7 t
- Zinacef. (see Cefuroxime)**
- Zinc, 3-3 t , 3-29–3-33**
adverse effects of, 3-31–3-32
for allergic rhinitis, 3-33
for children, 3-32
for common cold, 3-30–3-31, 72-18
deficiency of, 3-32
for diarrhea, 93-9
dosing of, 3-31
lactation and, 3-32
pregnancy and, 3-32
- Zinc oxide, 41-8 t , 41-11, 41-12–41-13**
for burns, 41-20
for diaper rash, 93-4
for pruritis, during pregnancy, 46-32 t
- Zincard. (see Dexrazoxane)**
- Ziprasidone (Geodon), 78-10**
for acute agitation, 78-14 t , 80-14
adverse effects of, 78-12 t
for autism, 78-30
for bipolar disorder, 80-12 t
dosing of, 78-17 t
for mania, 80-12
mania from, 80-5 t
NMS from, 78-24
pharmacokinetics of, 78-16 t
proarrhythmic effects of, 19-25
receptor-binding affinities of, 78-12 t
weight gain from, 78-22
- Zithromax. (see Azithromycin)**
- Zocor. (see Simvastatin)**
- Zofran. (see Ondansetron)**
- Zoladex. (see Goserelin)**

ACID-BASE DISORDERS

SUPPLEMENTAL CASE

1. M.K. is a 45-year-old man who was brought to the ED with a 3-day history of nausea, vomiting, and dizziness. His medical history includes chronic renal failure from polycystic kidney disease requiring hemodialysis. Up until 3 days before his presentation, he was in his usual state of health. Vital signs included the following: temperature, 37°C; respirations, 10 breaths/minute; HR 120 beats/minute; and BP, 80/50 mmHg. His physical examination findings revealed decreased skin turgor and flat neck veins. Laboratory studies included the following: Na, 145 mEq/L; K, 4.2 mEq/L; Cl, 100 mEq/L; BUN 40 mg/dL; creatinine, 3 mg/dL; ABG: pH, 7.40; PaCO₂, 40 mmHg; PaO₂, 88 mmHg; and HCO₃⁻, 24 mEq/L.

Does M.K. have an acid-base disorder?

ACID-BASE DISORDERS

ANSWERS TO SUPPLEMENTAL CASE

1. M.K. is a 45-year-old man who was brought to the ED with a 3-day history of nausea, vomiting, and dizziness. His medical history includes chronic renal failure from polycystic kidney disease requiring hemodialysis. Up until 3 days before his presentation, he was in his usual state of health. Vital signs included the following: temperature, 37°C; respirations, 10 breaths/minute; HR 120 beats/minute; and BP, 80/50 mmHg. His physical examination findings revealed decreased skin turgor and flat neck veins. Laboratory studies included the following: Na, 145 mEq/L; K, 4.2 mEq/L; Cl, 100 mEq/L; BUN 40 mg/dL; creatinine, 3 mg/dL; ABG: pH, 7.40; PaCO₂, 40 mmHg; PaO₂, 88 mmHg; and HCO₃⁻, 24 mEq/L.

Does M.K. have an acid-base disorder?

M.K.'s normal pH implies either no acid-base abnormality or a mixed disorder (steps 1–3). His AG of 21 suggests the presence of a clinically important AG metabolic acidosis (step 4). Because his AG is increased, step 5 instructs us to calculate his corrected HCO₃⁻ value which would be 35 (excess AG of 11 added to his HCO₃⁻ value of 24). Therefore, M.K. has both an AG acidosis and a metabolic alkalosis. Reviewing M.K.'s acute and chronic medical history suggests causes for both acid-base disorders. The metabolic acidosis may be caused by a combination of chronic renal failure and hypovolemia. The metabolic alkalosis was precipitated by vomiting. Treatment should include isotonic fluid and antiemetic administration. Hemodialysis should be temporarily withheld until restoration of his effective arterial circulating volume.
