INTRODUCTION

Approximately 72 million Americans have hypertension, also called high blood pressure (BP).¹ It is estimated that approximately 30% of adult Americans have hypertension, making it the most frequently encountered chronic medical condition.^{2,3} It is also one of the most significant risk factors for cardiovascular (CV) morbidity and mortality resulting from target-organ damage to blood vessels in the heart, brain, kidney, and eyes. These complications can manifest as either atherosclerotic vascular disease or other forms of CV disease. The exact etiology of essential hypertension is unknown; however, lifelong management with lifestyle modifications and pharmacotherapy are needed.

Awareness, treatment, and control of hypertension are not optimal. Based on the most recent data from the National Health and Nutrition Examination Survey (NHANES), 2003–2004, approximately 76% of patients who truly have hypertension are diagnosed with this medical condition, leaving many patients undiagnosed. Similarly, only 65% of people with hypertension are receiving some form of treatment. Ultimately, the most disappointing statistic is that only 37% of patients with hypertension, including those who have undiagnosed hypertension, have controlled BP (liberally defined as both systolic BP <140 mmHg and diastolic BP <90 mmHg).² When just patients with the diagnosis of hypertension are considered, 63% have controlled BP.⁴ Similarly, when only those patients who are treated for hypertension are considered, 57% have controlled BP.² These BP control estimates actually underestimate the magnitude of this problem, because many patients require more aggressive BP control than <140/90 mmHg. Improvements in diagnosing, treating, and overall management of hypertension are desperately needed.

Blood Pressure (BP)

During systole, the left ventricle contracts, ejecting blood systemically into the arteries, causing a sharp rise in arterial BP. This is the systolic BP (SBP). The left ventricle then relaxes during diastole, and arterial BP decreases to a trough value as blood returns to the right atria and ventricle of the heart from the venous system. This is the diastolic BP (DBP). When recording BP (e.g., 120/76 mmHg), the numerator refers to SBP and the denominator refers to DBP. BP has a predictable diurnal rhythm, with fluctuations throughout the day. Values are lowest during the nighttime, sharply rise starting in the early morning, and peak in the late morning to early afternoon. These fluctuations are less pronounced in the black population and may be absent in patients with secondary hypertension.

Mean arterial pressure (MAP) is sometimes used to represent BP. MAP collectively reflects both SBP and DBP, with one-third of the pressure from SBP and two-thirds from DBP. It is calculated using the following equation (Eq. 13-1):

$$\text{MAP} = ([\text{SBP}] \cdot [1/3]) + ([\text{DBP}] \cdot [2/3]) \quad (13-1)$$

The Seventh Report of the Joint National Committee on Detection, Evaluation, and Treatment of High Blood Pressure (JNC7), published in 2003, classifies BP based on systolic and diastolic values (Table 13-1).⁵ Hypertension is defined as an elevated SBP, DBP, or both. A clinical diagnosis of hypertension is based on the mean of two or more properly measured seated

Table 13-1 Classification and Management of Blood Pressure (BP) in Adults^{5,a}

| Classification | SBP ^a (mmHg) | DBP ^a (mmHg) |
|----------------------|-------------------------|-------------------------|
| Normal | <120 | and <80 |
| Prehypertension | 120–139 | or 80–89 |
| Stage 1 hypertension | 140–159 | or 90–99 |
| Stage 2 hypertension | ≥160 | or ≥100 |

^aClassification is determined based on highest BP category.
DBP diastolic blood pressure; SBP, systolic blood pressure.

BP measurements taken on two or more occasions. This mean BP is also used initially to classify and stage hypertension. The JNC7 classification includes normal BP, prehypertension, stage 1 hypertension, and stage 2 hypertension. Qualitative terms (e.g., mild, moderate, high-normal, severe) are not recommended, and should not be used.

Pathophysiology of BP Regulation

Various neural and humoral factors are known to influence and regulate BP.⁶ These include the adrenergic nervous system (controls α - and β -receptors), the renin-angiotensin-aldosterone system (RAAS) (regulates systemic and renal blood flow), renal function and renal blood flow (influences fluid and electrolyte balance), several hormonal factors (adrenal cortical hormones, vasopressin, thyroid hormone, insulin), and the vascular endothelium (regulates release of nitric oxide, bradykinin, prostacyclin, endothelin). Knowledge of these mechanisms is important in understanding antihypertensive drug therapy. BP is normally regulated by compensatory mechanisms that respond to changes in cardiac demand. An increase in cardiac output (CO) normally results in a compensatory decrease in total peripheral resistance (TPR); likewise, an increase in TPR results in a decrease in CO. These events regulate MAP, as is represented in the following equation (Eq. 13-2):

$$\text{MAP} = \text{CO} \cdot \text{TPR} \quad (13-2)$$

Adverse changes in BP can occur when these compensatory mechanisms are not functioning properly. It has been suggested that in hypertension an initial increase in fluid volume increases CO and arterial pressure. Eventually, with long-standing hypertension, it is believed that TPR increases so that CO returns to normal.

The kidney plays an important role in the regulation of arterial pressure, especially through the RAAS. Decreases in BP and renal blood flow, volume depletion or decreased sodium concentration, and an activation of the sympathetic nervous system can all trigger an increased secretion of the enzyme renin from the cells of the juxtaglomerular apparatus in the kidney. Renin acts on angiotensinogen to catalyze the formation of angiotensin-1. Angiotensin-converting enzyme (ACE) converts angiotensin-1 to angiotensin-2 (see Figs. 18-1 and 18-6 in Chapter 18, Heart Failure). Angiotensin-2 is a potent vasoconstrictor that acts directly on arteriolar smooth muscle and also stimulates the production of aldosterone by the adrenal glands. Aldosterone causes sodium and water retention and the excretion of potassium. Several factors influence renin release, especially those that alter renal perfusion. Lastly, the resultant

increase in BP results in suppression of renin release through negative feedback.

Approximately 20% of patients with essential hypertension have lower-than-normal plasma renin activity (PRA), whereas approximately 15% have PRA concentrations that are higher than normal. Those with normal to high PRA should theoretically be more responsive to drug therapies that target the RAAS (e.g., ACE inhibitors or β -adrenergic blockers). Patients with low PRA may be more responsive to diuretic therapy. Measuring PRA is not readily available in most clinical settings, however, and is not advocated as a practical means for selection of drug therapy.

Arterial BP also is regulated by the adrenergic nervous system, which causes contraction and relaxation of vascular smooth muscle. Stimulation of α -adrenergic receptors in the central nervous system (CNS) results in a reflex decrease in sympathetic outflow causing a decrease in BP. Stimulation of postsynaptic α_1 -receptors in the periphery causes vasoconstriction. α -Receptors are regulated by a negative feedback system; as norepinephrine is released into the synaptic cleft and stimulates presynaptic α_2 -receptors, further norepinephrine release is inhibited. This negative feedback results in a balance between vasoconstriction and vasodilatation. Stimulation of postsynaptic β_1 -receptors located in the myocardium causes an increase in heart rate and contractility, whereas stimulation of postsynaptic β_2 -receptors in the arterioles and venules results in vasodilation.

A direct association exists between sodium and BP. Patients with a high dietary sodium intake have a greater prevalence of hypertension than those with a low sodium intake. The mechanism by which hypertension is caused by an increase in sodium intake is hypothesized to involve natriuretic hormone (not to be confused with A- and B-type natriuretic peptides associated with heart failure). Natriuretic hormone is potentially increased to facilitate sodium and water excretion in response to an increase in renal sodium retention and extracellular fluid volume. Natriuretic hormone might also cause an increase in intracellular sodium and calcium, resulting in increased vascular tone and hypertension. This hypothesis has not been definitively proved, however.

Epidemiologic evidence and clinical trials have demonstrated an inverse relationship between calcium and BP. One proposed mechanism for this relationship involves an alteration in the balance between intracellular and extracellular calcium. Increased intracellular calcium concentrations can increase peripheral vascular resistance, resulting in increased BP.

A decrease in potassium has been associated with an increase in peripheral vascular resistance. In theory, diuretic-induced hypokalemia could counteract some of the hypotensive effects of diuretic therapy, but this has not been well studied. It is important, however, that potassium concentrations be maintained within the normal range because hypokalemia increases the risk of CV events, such as sudden death, and increases the risk of metabolic side effects (hyperglycemia) associated with diuretics.

Insulin resistance and hyperinsulinemia also have been associated with hypertension. Kaplan⁶ suggests that insulin resistance is responsible for the frequent coexistence of diabetes, dyslipidemia, hypertension, and abdominal obesity. This is also referred to as the *metabolic syndrome*.⁷ Although the exact role of insulin resistance in the development of hypertension is still

evolving, it is clear that these factors are intertwined and increase CV risk.

The vascular epithelium is a dynamic system in which vascular tone is regulated by numerous substances. As noted previously, angiotensin-2 promotes vasoconstriction of the vascular epithelium. Several other substances regulate vascular tone, however. Nitric oxide (NO) is produced in the endothelium and is a potent vasodilatory chemical that relaxes the vascular epithelium. The NO system has been firmly established as an important regulator of arterial BP. Hypothetically, some patients with hypertension have an intrinsic deficiency in NO release and inadequate vasodilation, which could contribute to hypertension and its vascular complications.

Factors that regulate BP are well understood and continue to evolve, but the cause of essential hypertension is still unknown. It is currently impossible to target therapy to specific abnormalities. Antihypertensive therapy should be determined on outcome-based clinical data that demonstrate reductions in hypertension-associated complications, as is discussed later in this chapter.

Cardiovascular (CV) Risk and BP

Direct correlations between BP values and risk of CV disease have been established based primarily on epidemiologic data. Beginning at a benchmark BP of 115/75 mmHg, the risk of CV disease doubles with every increment of 20/10 mmHg.⁵ There is a significant increase in risk of CV events in patients with prehypertension BP values versus normal BP values.⁸ Clinically, it is important to note that incremental elevations in SBP are more predictive of CV disease than elevations in DBP for patients older than 50 years of age. Within this population, elevated SBP is often the primary BP abnormality. Therefore, SBP is the target of evaluation and intervention for most patients with hypertension.^{5,9} In younger patients with hypertension, elevated DBP may be the only BP abnormality present.

Measuring BP

AUSCULTATORY METHOD

Blood pressure measurement should be standardized to minimize variability in readings. The American Heart Association (AHA) technique for auscultatory BP measurement (Table 13-2) should be used in most patients.¹⁰ Correct BP measurements require that the clinician listen through a stethoscope that is placed over the brachial artery for the appearance of the five phases of the Korotkoff sounds. Each sound has distinct features, which are depicted in Figure 13-1.¹⁰

BP MONITORING OUTSIDE THE OFFICE

Blood pressure values measured outside the office should be considered in the overall treatment of patients with hypertension, but definitive routine use cannot be universally recommended. The major clinical trials that have established that appropriate treatment of hypertension reduces morbidity and mortality rates used office-based BP measurements. Therefore, office-based BP measurements are still considered the gold standard values that guide antihypertensive drug therapy.

Ambulatory blood pressure monitoring (ABPM) typically measures BP every 15 to 30 minutes throughout the day using a monitoring device. This form of specialized monitoring is indicated for patients with suspected white-coat hypertension, and also may be helpful in patients with apparent

Table 13-2 Auscultatory Method for Measuring BP in Adults as Recommended by the AHA¹⁰

- PATIENT:** Patient should be seated for 5 minutes with arm bared, unrestricted by clothing, and supported at heart level. Smoking or food ingestion should not have occurred within 30 minutes before the measurement.
- CUFF:** An appropriately sized cuff should be chosen. The internal inflatable bladder width should be at least 40% and the bladder length at least 80% of the upper arm circumference. The cuff should be wrapped snugly around the arm with the center of the bladder over the brachial artery.
- MONITOR:** Measurements should be taken with a correctly calibrated mercury sphygmomanometer, an aneroid manometer, or a validated electronic device.
- PALPATORY METHOD:** The palpatory method should be used to estimate SBP. The cuff is inflated while simultaneously palpating the radial pulse on the cuffed arm and observing the manometer. The point at which the radial pulse is no longer palpable is the estimated SBP. The cuff is then deflated rapidly.
- KOROTKOFF SOUNDS:** The head of the stethoscope, ideally using the bell, should be positioned over the brachial artery, and each earpiece placed in the clinician's ear. The cuff should then be rapidly inflated to 20 to 30 mmHg above the estimated SBP from the palpatory method. The cuff is slowly deflated at a rate of 2 mmHg per second while simultaneously listening for phase 1 (the first appearance of sounds) and phase 5 (the disappearance of sounds) Korotkoff sounds while the clinician is observing the manometer. When the pressure is 10 to 20 mmHg below phase 5, the cuff can be rapidly deflated.
- DOCUMENTATION:** BP values should always be recorded. The BP values (SBP/DBP) should be recorded using even numbers (rounded up from an odd number) along with the patient's position (seated, standing or supine), arm used, and cuff size.
- REPEAT:** A second measurement should be taken after at least 1 minute in the same arm. If the readings differ by >5 mmHg, additional measurements should be obtained. The mean of these values should be used to make clinical decisions. BP should be taken in both arms at the initial visit with the BP taken in the arm with the higher reading at subsequent visits.

drug resistance, hypotensive symptoms while receiving antihypertensive therapy, episodic hypertension, and autonomic dysfunction.¹⁰ ABPM values are typically lower than office-based measurements. Patients with hypertension have average values of >135/85 mmHg while awake and >120/75 mmHg while asleep. Therefore, the threshold for acceptable values is lower than that obtained during office-based measurements. Evidence indicates that ABPM recordings can predict clinical outcomes, as does traditional office-based and home-based BP measurements. The utility of using ABPM to evaluate antihypertensive treatment is limited, however.¹⁰

Home BP measurements can provide information on response to therapy and may help improve adherence to therapy and goal BP achievement in some patients.^{5,11} Home measurement devices (e.g., electronic monitors, auscultatory monitors) need to be routinely checked for accuracy. As is the case with ambulatory monitoring, patients with average home BP values >135/85 mmHg are considered hypertensive. Wrist or finger devices that measure BP are not accurate and should not be used.

Types of Hypertension

Essential Hypertension

Most patients with hypertension have essential hypertension (also known as primary hypertension), with no identifiable cause for their disorder.

Secondary Hypertension

Patients with secondary hypertension have a specific identified cause for elevated BP (Table 13-3). Although only 5% to 10% of those among the hypertensive population have secondary hypertension, further diagnostic evaluation should occur if physical or laboratory findings are consistent with a secondary cause (Table 13-4). Secondary causes are potentially correctable. Further diagnostic workup also should be considered in patients who do not respond to increasing doses of antihypertensive medication or who have a sudden increase in BP or accelerated or malignant hypertension.^{5,6} A thorough review of prescription medications, nonprescription medications, and supplements should be conducted to rule out potential causes of BP elevations.

Pseudohypertension

The possibility of pseudohypertension should be considered when measuring BP in elderly patients. In pseudohypertension, blood vessels become stiff and thick because of calcification and resist compression from the bladder of the inflatable BP cuff. Greater pressure is then needed to occlude the artery, and this results in an inaccurate overestimation of SBP. Osler's maneuver is used to detect pseudohypertension. A BP cuff is inflated above the SBP while palpating the brachial or radial arteries to determine whether the pulseless artery is still palpable. If the artery is still palpable, the patient might have pseudohypertension. Pseudohypertension is thought to be relatively rare.

White-Coat Hypertension

White-coat hypertension describes patients who have consistently elevated BP values measured in a clinical environment in the presence of a health care professional (e.g., physician's office), yet when measured elsewhere or with 24-hour ambulatory monitoring, BP is not elevated.¹⁰ Home BP monitoring or 24-hour ABPM is warranted in patients suspected of having white-coat hypertension to differentiate this from true hypertension. The commonly used definition is a persistently elevated average office blood pressure of >140/90 mmHg and an average awake ambulatory reading of <135/85 mmHg. The label *white-coat hypertension* applies only to patients without target-organ disease who are not on antihypertensive therapy. It is estimated to be present in 15% to 20% of people with stage 1 hypertension.¹⁰

Significant controversies surround white-coat hypertension. Although this does not represent a clinical diagnosis, patients with white-coat hypertension are at risk for developing clinically relevant hypertension. Moreover, data suggest that patients with white-coat hypertension are at a higher risk for CV disease than normotensive patients.¹² The decision to treat or not treat white-coat hypertension, however, is controversial. Indeed, many patients enrolled in the landmark clinical trials that demonstrated reductions in CV morbidity and mortality with antihypertensive therapy had white-coat hypertension.

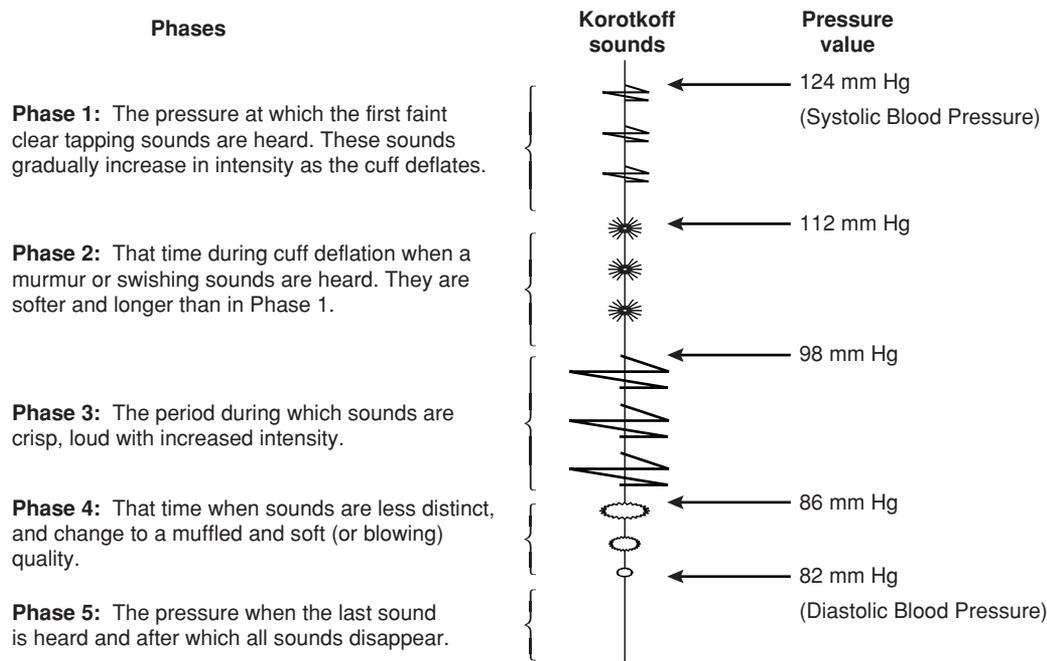

FIGURE 13-1 Phases of the Korotkoff sounds heard when indirectly measuring blood pressure.

At minimum, patients with white-coat hypertension should be treated with lifestyle modifications, and need to be closely monitored with a device that can measure BP outside the clinic environment if they are not treated with antihypertensive drug therapy.

Hypertensive Crises

Hypertensive crises are situations when measured BP values are markedly elevated, typically in the upper range of stage 2 hypertension (>180/110 mmHg). They are classified as either a hypertensive emergency (with acute or progressive target-organ damage) or urgency (without acute or progressive target-

organ damage).⁶ Hypertensive emergencies require hospitalization for immediate BP lowering using intravenous (IV) medications and intraarterial BP monitoring. Examples of acute target-organ damage include encephalopathy, myocardial infarction (MI), unstable angina, pulmonary edema, eclampsia, stroke, head trauma, life-threatening arterial bleeding, aortic dissection, severe retinopathy, or acute kidney failure. Hypertensive urgencies do not require immediate BP lowering; instead, BP should be slowly reduced within 24 hours (but not generally to goal BP so quickly) following drug therapy recommendations for stage 2 hypertension (see Chapter 20, Hypertensive Emergencies). The optimal rate of BP lowering in hypertensive emergencies and urgencies is less clear, however.

Hypertension Management

Hypertension is treated with both lifestyle modifications and pharmacotherapy. The JNC7 has been considered the “gold standard” consensus guidelines for the management of hypertension in the United States. The 2007 American Heart Association (AHA) scientific statement regarding the treatment of hypertension is now considered the most up-to-date and evidence-based guideline.⁹ The AHA 2007 guidelines provide more aggressive BP goals and pharmacotherapy recommendations based on more recent evidence. Of note, the 2007 European Society of Hypertension/European Society of Cardiology also recommend more aggressive BP goals and recommendations, analogous to the AHA 2007 recommendations.¹³ The overall principles common to these guidelines are to implement lifestyle modifications in addition to pharmacotherapy to control BP in patients with hypertension. The presence of specific complications of hypertension or comorbidities (sometime referred to as “compelling indications”) in any given patient should be considered when selecting specific

Table 13-4 Clinical Findings Suggestive of Secondary Hypertension

| <i>Causes</i> | <i>Historical Findings</i> | <i>Physical Examination Finding</i> | <i>Laboratory Finding</i> |
|--------------------------|---|--|---|
| Sleep apnea | Daytime fatigue and somnolence | Large neck circumference; overweight or obese | Abnormal sleep studies with frequent awakenings and anoxic episodes |
| Renovascular disease | Moderate or severe high BP before age 30 or after 55; rapidly progressive hypertension | Abdominal bruits; fundoscopic hemorrhages | Suppressed or stimulated plasma renin activity; IVP (rapid sequence); digital subtraction angiography |
| Renoparenchymal disease | Dysuria, polyuria, nocturia; urinary tract infections; kidney stones; family history of polycystic or other types of kidney disease | Edema | Proteinuria; hematuria; bacteriuria |
| Coarctation of the aorta | Intermittent claudication | Diminished or absent femoral pulses compared with carotids; lower SBP in leg compared with arm | – |
| Pheochromocytoma | Paroxysmal headaches, palpitations, sweating, dizziness, and pallor | Nervousness, tremor, tachycardia, orthostatic hypotension | Clonidine suppression tests ^a ; high urine metanephrine or vanillylmandelic acid |
| Primary aldosteronism | Weakness, polyuria, polydipsia, intermittent paralysis | Orthostatic hypotension | Hypokalemia |
| Cushing's syndrome | Menstrual irregularity | Moon face; truncal obesity; buffalo hump; hirsutism; violet striae | ↑ serum glucose; ↑ plasma cortisol after suppression with dexamethasone |

^aFailure of plasma catecholamines to ↓ by 50% within 3 hr of administration of 0.3 mg clonidine highly suggests pheochromocytoma. BP, blood pressure; IVP, intravenous pyelogram; SBP, systolic blood pressure.

pharmacotherapy to treat hypertension. These issues are discussed later in this chapter.

Goals

The overarching goal of treating hypertension is to reduce associated morbidity and mortality. These manifest as hypertension-associated complications (Table 13-5), which includes atherosclerotic vascular disease and other forms of CV disease. Clinical presentation of such complications can be as an acute CV event (e.g., MI), or development of a chronic medical condition (e.g., chronic kidney disease [CKD]). Hypertension-associated complications are the primary causes of death in patients with hypertension. Several risk factors for complications have been identified. These are considered major CV risk factors that increase the likelihood of developing hypertension-associated complications, not hypertension.

FRAMINGHAM RISK SCORING

Estimating individual risk for CV disease is essential for all patients with hypertension. In the United States, Framingham risk scoring is considered an appropriate way to predict individual 10-year risk for coronary artery disease (CAD), also referred to as coronary heart disease (CHD) (see Fig. 12.7, Chapter 12, Dyslipidemias, Atherosclerosis, and Coronary Heart Disease). All patients with hypertension who do not have a history of hypertension-associated complications (Table 13-5) or diabetes, (considered a CAD risk equivalent condition) should have Framingham risk scoring because their 10-year risk can be low or moderate risk (<10%), moderately high risk (10%–20%), or high risk (>20%).¹⁴ Identifying patients with Framingham risk scores ≥10% is clinically relevant because more aggressive antihypertensive treatment is

Table 13-5 Hypertension-Associated Complications and Major Cardiovascular Risk Factors for Complications

Hypertension-Associated Complications

- Atherosclerotic Vascular Disease:
 - Coronary artery disease (sometimes called coronary heart disease)
 - Myocardial infarction [MI]
 - Acute coronary syndromes
 - Chronic stable angina
 - Carotid artery disease:
 - Ischemic stroke
 - Transient ischemic attack
 - Peripheral arterial disease
 - Abdominal aortic aneurysm
- Other forms of CV disease
 - Left ventricular dysfunction (heart failure)
 - Chronic kidney disease
 - Retinopathy

Major CV Risk Factors

- Advanced age (>55 yr for men, >65 yr for women)
- Cigarette smoking
- Diabetes mellitus
- Dyslipidemia
- Family history of premature atherosclerotic vascular disease (men <55 yr or women <65 yr)
- Hypertension
- Kidney disease (microalbuminuria or estimated GFR <60 mL/min)
- Obesity (BMI ≥30 kg/m²)
- Physical inactivity

BMI, body mass index; CV, cardiovascular; GFR, glomerular filtration rate.

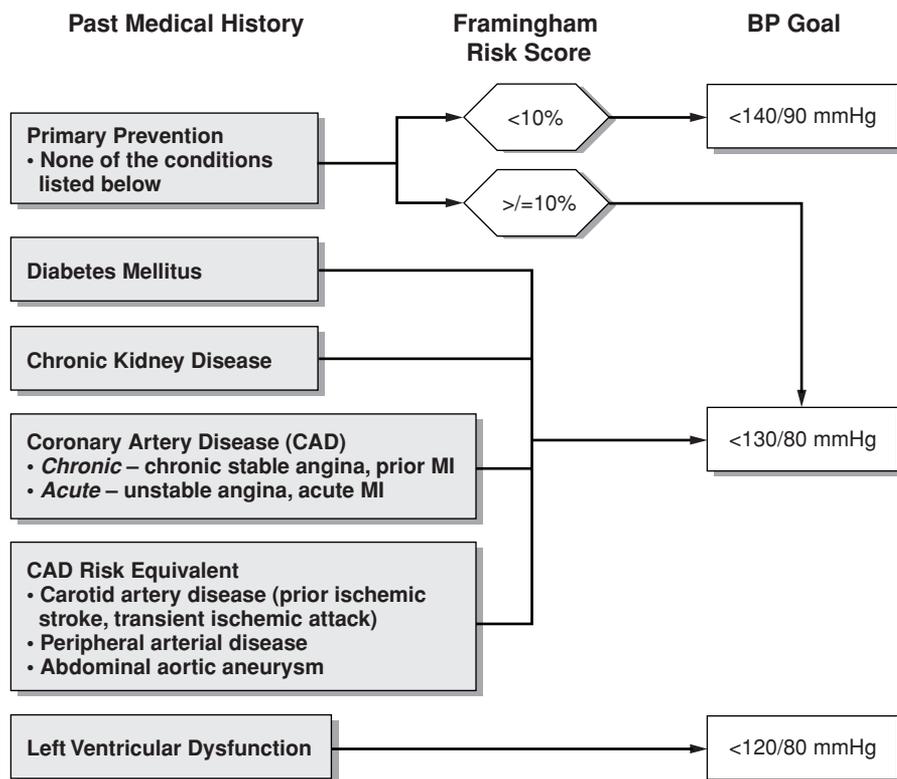

FIGURE 13-2 Goal BP determination based on patient specific history and cardiovascular risk assessment. BP, blood pressure.

needed in this population according to 2007 AHA guidelines.⁹ For patients with hypertension-associated complications or diabetes, Framingham risk scoring is not needed because 10-year risk of CAD is assumed to be $>20\%$.

GOAL BP VALUES

The surrogate goal of treating hypertension is to achieve goal BP values. Patients with hypertension have a BP goal of either $<140/90$, $<130/80$, or $<120/80$ mmHg (Fig. 13-2). Patients with estimated 10-year risk of CAD of $<10\%$, based on Framingham scoring, have a goal BP of $<140/90$ mmHg. In general, all other patients, have a goal BP of $<130/80$ mmHg. More aggressive BP goals are recommended in these patients because they are at higher risk for hypertension-associated complications, and lowering BP to this level has been shown to maximize risk reduction, particularly in patients with diabetes or CKD.^{15,16} If patients have a history of left ventricular dysfunction (also known as systolic heart failure), a BP goal of $<120/80$ mmHg is recommended.⁹ Although elevated SBP is more predictive of CV disease than DBP for most patients,⁵ goal achievement requires reduction of both SBP and DBP to goal values. Control of SBP is imperative and this usually results in control of DBP. Clinicians should follow these recommendations and be appropriately aggressive with therapy despite the tendency to accept BP values that are close to, but not at, the goal.

Lifestyle Modifications

Lifestyle modifications are the cornerstone of management for preventing and treating hypertension. In 2006, the AHA published new guidelines for lifestyle modifications that include

both diet and exercise.^{17,18} These are summarized in Table 13-6. Engaging in these modifications is encouraged for all persons to prevent the development of hypertension; however, they are recommended as a component of first-line therapy in all patients with prehypertension, and in all patients with a diagnosis of hypertension regardless of whether their BP values are at goal or not (Table 13-1).^{5,9} Independent of BP lowering, CV risk may also be reduced.

WEIGHT REDUCTION

Weight loss as small as 5% to 10% of body weight in overweight individuals may significantly lower CV risk. For most patients, an average weight loss of 10 kg can reduce SBP by 5 to 20 mmHg.⁵

DASH EATING PLAN

The DASH (Dietary Approaches to Stop Hypertension) diet is rich in fruits, vegetables, and low-fat dairy foods, coupled with reduced saturated and total fat.¹⁹ This diet can substantially reduce BP (8–14 mmHg in SBP for most patients) and yield similar results to single drug therapy. The low-fat component of this diet is important because weight loss is more readily achieved by a reduced calorie diet (fats contribute more calories per gram than do either carbohydrates or protein) and lowered fat intake also reduces the risk of CV disease by lowering cholesterol.

DIETARY SODIUM RESTRICTION

The average American intake of sodium is >6 g/day. Restricting sodium is reasonable for patients with prehypertension or hypertension, and current recommendations

Table 13-6 Lifestyle Modifications to Prevent and Treat Hypertension^{7,17,18}

| <i>Modification</i> | <i>Recommendation</i> |
|------------------------------------|--|
| Weight management | Lose weight if overweight or obese, ideally attaining a BMI <25 kg/m ² . Maintain a desirable BMI (18.5–24.9 kg/m ²) if not overweight or obese. |
| Adopt DASH-type dietary patterns | Consume a diet that is rich in fruits and vegetables (8–10 servings/day), rich in low-fat dairy products (2–3 servings/day), but has reduced amounts of saturated fat and cholesterol |
| Reduced sodium intake | Reduce daily dietary sodium intake as much as possible; ideally to no more than 65 mmol/day (equal to 1.5 g/day sodium, or 3.8 g/day sodium chloride) |
| Increased dietary potassium intake | Increase daily dietary potassium intake to 120 mmol/day (4.7 g/day), which is also the amount provided in a DASH-type diet. |
| Moderation of alcohol consumption | For patients who drink alcohol, limit consumption to no more than two drinks/day in men and no more than one drink/day in women and lighter-weight persons. ^a Do not recommend alcohol consumption in patients that do not drink alcohol. |
| Regular physical activity | Regular moderate-intensity aerobic physical activity; at least 30 min of continuous or intermittent 5 days/wk, but preferably daily. |

^aNote: one drink is defined as 12 oz of regular beer, 5 oz of wine (12% alcohol), and 1.5 oz of 80-proof distilled spirits.
BMI, body mass index; DASH, Dietary Approaches to Stop Hypertension.

to restrict daily sodium intake to no more than 1.5 g is lower than what has traditionally been recommended. Some clinicians may argue that the efficacy of implementing sodium restriction in patients with hypertension may vary. Evidence from clinical trials has shown, however, that sodium restriction provides mean reductions in BP of 5/2.7 mmHg in patients with hypertension.¹⁸ Some populations (diabetics, blacks, and elderly persons) respond better to sodium restriction than the general population, but all patients with hypertension should be instructed to reduce their sodium intake. They should be counseled not to add salt to foods, and to avoid or minimize ingestion of processed or packaged foods, foods with high sodium content, and nonprescription drugs containing sodium (see Chapter 18, Heart Failure).

INCREASED POTASSIUM INTAKE

A new recommendation from the AHA is to increase dietary potassium intake.¹⁸ Adhering to a DASH eating plan will usually assure an intake of the recommended 4.7 g daily. Dietary supplementation should be the primary strategy to increase potassium. Implementing potassium supplementation outside of dietary sources for the sole purpose of lowering BP should be avoided because of potential harm from hyperkalemia. Moreover, potassium supplementation in patients with hyper-

tension who are treated with either a potassium-sparing diuretic, aldosterone antagonist, angiotensin-converting-enzyme inhibitors (ACEI), or an angiotensin receptor blocker (ARB) may cause hyperkalemia. This can also occur in patients with hypertension and chronic kidney disease who are treated with potassium supplementation.

MODERATE ALCOHOL CONSUMPTION

Explaining the need to limit alcohol consumption is complicated. Whereas data suggest that small daily doses of ethanol are associated with lower CV risk, excessive alcohol intake can elevate BP, decrease the effectiveness of antihypertensive medications, and increase the risk of stroke. Patients who consume three to four drinks a day experience a 3- to 4-mmHg increase in SBP and a 1- to 2-mmHg increase in DBP compared with those who do not drink. These increases are even higher in patients who consume more alcohol. Moderating alcohol consumption of two or fewer drinks daily in men and one or fewer drinks daily in women or lighter weight persons can decrease SBP approximately 2 to 4 mmHg. Patients should be instructed that one drink is equal to 1.5 oz 80-proof whiskey, 5 oz wine, 12 oz beer.

PHYSICAL ACTIVITY

Regular physical activity can reduce SBP by 4 to 9 mmHg in most patients.⁵ Benefits include reducing the incidence of hypertension, promoting weight loss, and improving overall CV fitness. Most patients with hypertension can safely increase their aerobic activity. Those with more severe forms of target-organ damage (e.g., angina, previous MI) may, however, need a medical evaluation before increasing their activity level. Physical activity should occur for at least 30 minutes, at least 5 days of the week, but preferably daily. Aerobic exercise such as walking, running, cycling, swimming, and cross-country skiing, are examples of recommended physical activity.

Pharmacotherapy

Numerous clinical trials have demonstrated that antihypertensive pharmacotherapy generally reduces the risk of hypertension-associated complications (e.g., CV morbidity and mortality).^{5,9} This evidence is the foundation for the 2003 JNC7 and 2007 AHA consensus guidelines, which recommend specific evidence-based pharmacotherapy recommendations based on patient-specific medical history and CV risk (Fig. 13-3).

As is recommended in the 2007 AHA guidelines, evidence supports the use of an ACEI, ARB, calcium channel blocker (CCB), thiazide diuretic, or a two-drug combination for first-line therapy for primary prevention patients.^{9,20} This is in contrast to the 2003 JNC7 guidelines that placed preference on using a thiazide diuretic over other agents for most patients, and also included a β -blocker as a potential first-line option.⁵ Evidence obtained since the 2003 JNC7 guidelines demonstrates, however, that, for first-line treatment in primary prevention patients, β -blocker therapy is not as effective in reducing CV events compared with ACEI, ARB, CCB, or thiazide diuretic therapy.²¹ Moreover, newer evidence also suggests that the reductions in CV events with ACEI, ARB, CCB, or thiazide diuretic are comparable so that one agent is not automatically preferred over another.²⁰

Specific Evidence-Based Pharmacotherapy Recommendations

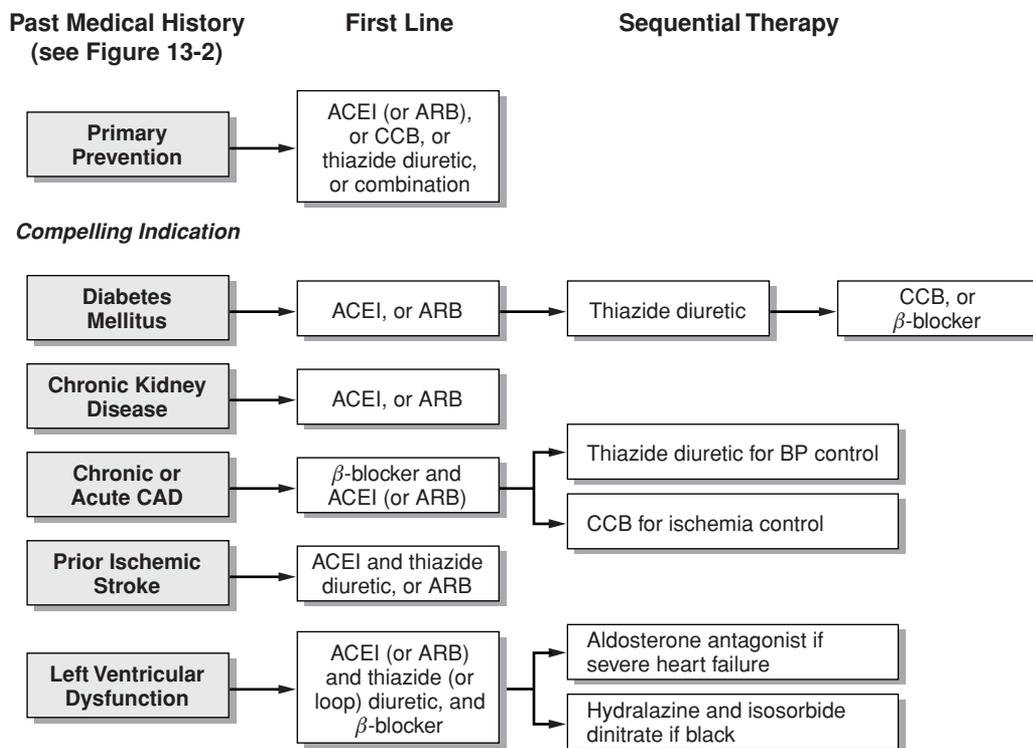

FIGURE 13-3 Recommended pharmacotherapy based on clinical trials evidence demonstrating long term reductions in morbidity and/or mortality in patients with hypertension and specific comorbid conditions and cardiovascular risk. Combination therapy with two antihypertensive drugs is an option for patients with stage 1 hypertension (see Table 13-1) and is strongly recommended in patients with stage 2 hypertension. ACEI, angiotensin converting enzyme inhibitor; ARB, angiotensin receptor blocker; CAD, coronary artery disease; CCB, calcium channel blocker.

Pharmacotherapy has been evaluated in patients with one of several comorbid conditions considered compelling indications for specific pharmacotherapy. The selection of pharmacotherapy in such patients is much more prescriptive than in primary prevention patients, and is outlined in Figure 13-3. These recommendations are based on evidence demonstrating reduced risk of CV events in patients with both hypertension and the compelling indication.

FIRST-LINE AGENTS

Angiotensin Converting Enzyme Inhibitors (ACEIs)

The ACEIs directly inhibit angiotensin-converting enzyme and, therefore, block the conversion of angiotensin-1 to angiotensin-2. This action reduces angiotensin-2-mediated vasoconstriction and aldosterone secretion, and ultimately lowers BP. Because additional pathways exist for the formation of angiotensin-2, ACEIs do not completely block the production of angiotensin-2. These agents generally do not cause metabolic effects. Hyperkalemia is possible, however, and potassium concentrations should be monitored. Patients with chronic kidney disease or volume depletion may be more susceptible to hyperkalemia or to further kidney dysfunction. Bradykinin accumulates in some patients because inhibiting ACE prevents the breakdown and inactivation of bradykinin.

Although this may lead to additive vasodilation by releasing nitrous oxide, bradykinin can also cause a dry cough in some patients. Cough is the most frequent, yet harmless side effect of ACEI therapy.

Angiotensin Receptor Blockers (ARBs)

The newest antihypertensive agents are ARBs. They modulate the RAAS by directly blocking the angiotensin-2 type 1 receptor site. Therefore, they block angiotensin-2-mediated vasoconstriction and aldosterone release. Overall, ARBs are very well tolerated. They do not affect bradykinin and, therefore, do not cause a dry cough as do the ACEI. Because aldosterone is blocked, monitoring of potassium is important to avoid hyperkalemia.

Calcium Channel Blockers (CCBs)

The CCBs are pharmacologically complex. They reduce calcium entry into smooth muscles, cause coronary and peripheral vasodilation, and lower BP. All decrease cardiac contractility (except amlodipine and felodipine). Dihydropyridine CCBs are primarily vasodilators that can cause a reflex tachycardia. Non-dihydropyridine CCBs (verapamil and diltiazem) directly block the AV node, decrease heart rate, decrease cardiac contraction, and have some vasodilatory effects. Side effects depend on the individual CCB used, but can include flushing,

peripheral edema, tachycardia, bradycardia or heart block, and constipation.

Thiazide Diuretics

Diuretics, particularly thiazide diuretics, such as hydrochlorothiazide (HCTZ), have been extensively studied in large clinical trials for hypertension. They have historically been the most commonly prescribed antihypertensive agents in the United States. When initially started, they induce a natriuresis that causes diuresis and decreases plasma volume. Diuresis usually decreases after chronic use with some of these agents, especially with thiazide diuretics. The long-term BP lowering effects are maintained because of a sustained decrease in peripheral vascular resistance (PVR).

Overwhelming evidence from large outcome-based clinical trials indicates that diuretic therapy reduces morbidity and mortality rates.^{5,9,20,22} Diuretics are generally well tolerated, and most can be given once daily. They are especially effective in lowering BP in elderly and black patients. Dose-related metabolic alterations (e.g., hypokalemia, hyperuricemia, hyperglycemia, hypercholesterolemia) can occur with diuretics. These effects were particularly problematic when high doses were used many years ago (e.g., HCTZ 100–200 mg/day), but are drastically minimized by using lower doses that are now considered the standard of care (e.g., HCTZ 12.5–25 mg).^{22,23} Thiazide diuretics can be used in combination with a potassium-sparing diuretic, such as triamterene or amiloride, to minimize any potential potassium depletion, not necessarily to provide a greater reduction in BP. Other biochemical changes in glucose and cholesterol are minimal and mostly transient with low-dose therapy.

SECOND-LINE AGENTS

β-Blockers

β-Blockers have several direct effects on the CV system. They can decrease cardiac contractility and output, lower heart rate, blunt sympathetic reflex with exercise, reduce central release of adrenergic substances, inhibit norepinephrine release peripherally, and decrease renin release from the kidney. All these contribute to their antihypertensive effects. Adverse metabolic effects include altered lipids and increased glucose concentrations. Similar to diuretics, these changes are generally temporary, however, and have minimal to no clinical significance. These agents were considered first-line for the treatment of most patients with hypertension in older JNC guidelines.²⁴ They are now only considered first-line for patients with CAD or left ventricular dysfunction.⁹ In primary prevention patients, they should be used as add-on therapy in combination with the other first-line agents (ACEI, ARB, CCB, or thiazide diuretic).

Aldosterone Antagonists

Spironolactone and eplerenone are aldosterone antagonists, also classified as potassium-sparing diuretics. Potent blockade of the aldosterone receptor inhibits sodium and water retention, and inhibits vasoconstriction. Hyperkalemia, a known dose-dependent effect with these agents, is more prominent in patients with chronic kidney disease or in patients taking a concurrent ACEI or ARB. The incidence of hyperkalemia may be greater with eplerenone compared with spironolactone because eplerenone is a more specific aldosterone blocker.

Gynecomastia is a side effect of spironolactone that does not occur with eplerenone.

OTHER AGENTS

Many older antihypertensive drug classes should primarily be used to provide additional BP lowering after first-line and second-line agents have been implemented. These agents do not have long-term data demonstrating reductions in hypertension-associated complications.

Loop diuretics (furosemide, torsemide) can be used for hypertension. When dosed appropriately, they can provide BP reductions similar to what is seen with a thiazide diuretic. They should be used primarily in patients who do not adequately respond to thiazide diuretic therapy, however, because they are more potent at inducing diuresis compared with thiazide diuretics, and can cause more metabolic side effects (e.g., hypokalemia). Patients with heart failure or severe chronic kidney disease are patients who might require a loop diuretic instead of a thiazide diuretic.

α -Blockers (doxazosin, prazosin, terazosin) attach to peripheral α_1 -receptors, inhibit the uptake of catecholamines in smooth muscle, and cause vasodilation. Although effective in lowering BP, they have more side effects than diuretics, β -blockers, ACEIs, ARBs, or CCBs. The most prominent side effect is hypotension, which is most evident after the first dose and with postural changes (arising from a lying position to a standing position).

Direct vasodilators (hydralazine, minoxidil) work on the arterial vasculature. They are considered last-line therapy, reserved for patients with specific indications or those with very difficult-to-control BP. Fluid retention and reflex tachycardia are frequent side effects. Concomitant therapy with both a diuretic and an agent that lowers heart rate (a β -blocker, diltiazem, or verapamil) is usually needed.

Central α_2 -agonists (e.g., clonidine, methyl dopa) work in the vasomotor centers of the brain where they stimulate inhibitory neurons, and decrease sympathetic outflow from the CNS. The resultant decrease in PVR and cardiac output lowers BP. These agents commonly cause anticholinergic side effects (e.g., sedation, dizziness, dry mouth, fatigue) and possibly sexual dysfunction. Although α_2 -agonists lower BP, they often cause fluid retention and, ideally, they should be used in combination with a diuretic.

Adrenergic antagonists (reserpine, guanadrel, guanethidine) are not frequently used to treat hypertension. Reserpine depletes catecholamines from storage granules to then decrease BP. Potential advantages include low cost and once daily dosing. High doses are associated with more side effects, but low-dose reserpine (0.05–0.1 mg/day), when used as third-line therapy has been shown to be well tolerated. Because of the potential for fluid retention, reserpine requires concurrent diuretic therapy. Guanadrel and guanethidine have numerous significant adverse effects and should be avoided.

NEW ANTIHYPERTENSIVE AGENTS

Aliskiren, approved in 2007, is the first direct renin inhibitor. Other agents within this drug class should become available in the future. Similar to an ACEI or ARB, this agent blocks the RAAS. It is approved for treatment of hypertension, and has been studied in combination with an ACEI or ARB. Because it is a new antihypertensive drug class, however, its exact role in

the treatment of hypertension will continue to evolve as clinical experience is obtained.

CLINICAL EVALUATION

Patient Presentation

1. D.C. is a 44-year-old black man who presents to his primary care provider with a chief complaint that his BP was measured at an employee health screening last month and he was told he has “stage 1 hypertension” at that time. His provider has never told him that he has hypertension. He has been advised, however, to lose weight and exercise more. His medical history is significant for allergic rhinitis. His BP was 144/84 and 146/86 mmHg when measured last year at work during an employee health screening. D.C.’s father had hypertension and died of an MI at age 54. His mother had diabetes and hypertension and died of a stroke at age 68. D.C. smokes one pack per day of cigarettes and thinks that his BP might be high because of job-related stress. He does not believe that he really has hypertension. D.C. does not engage in any regular form of exercise and does not restrict his diet in any way, although he knows he should lose weight.

Physical examination shows he is 175 cm tall, weighs 108 kg (body mass index [BMI], 35.2 kg/m²), BP is 148/88 mmHg (left arm) and 146/86 mmHg (right arm) while sitting, heart rate is 80 beats/minute and regular. Six months ago, his BP values were 152/88 mmHg and 150/84 mmHg when he was seen by his primary care provider for allergic rhinitis. Funduscopic examination reveals mild arterial narrowing, arteriovenous nicking, with no exudates or hemorrhages. The other physical examination findings are essentially normal.

Laboratory examination reveals the following values: blood urea nitrogen (BUN), 24 mg/dL (normal, 7–20 mg/dL); serum creatinine (SrCr), 1.0 mg/dL (normal, 0.5–1.2 mg/dL); fasting glucose, 105 mg/dL (normal, 60–99 mg/dL); potassium (K), 4.4 mEq/L (normal, 3.5–5.2 mEq/L); uric acid, 6.5 mg/dL (normal, 2.0–7.0 mg/dL); total cholesterol 196 mg/dL (normal, <200 mg/dL), low-density lipoprotein cholesterol (LDL-C), 131 mg/dL (normal, <130 mg/dL, optimal <100 mg/dL); high-density lipoprotein cholesterol (HDL-C), 32 mg/dL (normal, >40 mg/dL for men), and triglycerides 170 mg/dL (normal, <150 mg/dL). An electrocardiogram (ECG) and chest radiograph reveal mild left ventricular hypertrophy (LVH). What is the proper assessment of D.C.’s BP based on this information?

D.C. has uncontrolled stage 1 hypertension. He has had elevated BP values, measured in clinical environments, and meets the diagnostic criteria for hypertension because two or more of his BP measurements are elevated on separate days. SBP values are consistently stage 1, whereas DBP values are all in the prehypertension range. The higher of the two classifications is used to classify hypertension.⁵

2. Why does D.C. have hypertension?

D.C.’s has essential hypertension; therefore the exact cause is not known. He has several characteristics (e.g., family history of hypertension, obesity) that may have increased his chance of developing hypertension. Race and sex also influence the prevalence of hypertension. Across all age groups, blacks have a higher prevalence of hypertension than do whites and Mexican Americans.²⁵ Similar to other forms of CV disease, hyper-

tension is more severe, more likely to include hypertension-associated complications, and occurs at an earlier age in black patients.

Patient Evaluation and Risk Assessment

Evaluation of patients with hypertension has multiple purposes. First, the presence and absence of hypertension-associated complications and major CV risk factors (Table 13-5) must be assessed. Second, secondary causes of hypertension (Table 13-3), if present, should be identified and managed accordingly. Third, concomitant medical conditions (e.g., diabetes), and lifestyle habits should be evaluated so that they can be used to guide therapy.

Hypertension-Associated Complications

3. Does D.C. have hypertension-associated complications?

A complete physical examination to evaluate hypertension-associated complications includes examination of the optic fundi; auscultation for carotid, abdominal, and femoral bruits; palpation of the thyroid gland; heart and lung examination; abdominal examination for enlarged kidney, masses, and abnormal aortic pulsation; lower extremity palpation for edema and pulses; and neurologic assessment. Routine laboratory assessment after diagnosis should include the following: ECG; urinalysis; fasting glucose; hematocrit; serum potassium, creatinine, and calcium; and a fasting lipid panel. Optional testing may include measurement of urinary albumin excretion or albumin-to-creatinine ratio, or additional tests specific for secondary causes if suspected.

D.C. does not yet have hypertension-associated complications. He is exhibiting early signs, however, based on his physical examination that, if left untreated, will likely develop into such complications. These early signs have likely evolved from his longstanding, poorly controlled hypertension. D.C.’s ECG revealed LVH indicating early cardiac damage. Although the gold standard for confirming LVH is with echocardiography, this confirmatory procedure is not necessary unless symptoms are present indicating that LVH has progressed to left ventricular dysfunction (e.g., peripheral edema, shortness of breath). His funduscopic examination reveals mild arterial narrowing and AV nicking, early signs of retinopathy and atherosclerosis. D.C.’s serum creatinine is normal, ruling out overt chronic kidney disease. Additional testing for microalbuminuria is needed, however, to confirm that he does not have early stage kidney disease.

4. Which forms of hypertension-associated complications might D.C. develop?

Hypertension adversely affects many organ systems, including the heart, brain, kidneys, peripheral circulation, and eyes. These are summarized in Table 13-5. Damage to these systems resulting from hypertension is termed *hypertension-associated complications*, *target-organ damage*, or *CV disease*. There are often misconceptions about the terms CV disease and CAD. CV disease encompasses the broad scope of all forms of *hypertension-associated complications*. CAD is simply a subset of CV disease and refers specifically to disease related to the coronary vasculature, including ischemic heart disease and MI. Hypertension-associated complications and

major risk factors for developing such complications should be assessed by a thorough patient history, a complete physical examination, and laboratory evaluation.

Hypertension can affect the heart either indirectly, by promoting atherosclerotic changes, or directly, via pressure-related effects. Hypertension can promote CV disease and increase the risk for *ischemic events*, such as angina and MI. Antihypertensive therapy has been shown to reduce the risk of these coronary events. Hypertension also promotes the development of LVH, which is a myocardial (cellular) change, not an arterial change. These two conditions often coexist, however. It is commonly believed that LVH is a compensatory mechanism of the heart in response to the increased resistance caused by elevated BP. LVH is a strong and independent risk factor for CAD, left ventricular dysfunction, and arrhythmias. A finding of LVH does not necessarily indicate the presence of left ventricular dysfunction, but is a risk for progression to left ventricular dysfunction (see Chapter 18, Heart Failure), which is a major cardiac outcome of hypertension. This may be caused by repeated ischemia, excessive ventricular hypertrophy, or pressure overload. Ultimately, left ventricular dysfunction results in a decreased ability to contract (systolic dysfunction) or an inability of the heart to fill (diastolic dysfunction).

Hypertension is one of the most frequent causes of cerebrovascular disease.²⁵ Cerebrovascular signs can manifest as transient ischemic attacks, ischemic strokes, multiple cerebral infarcts, and hemorrhages. Residual functional deficits caused by stroke are among the most devastating forms of hypertension-associated complications. Clinical trials have demonstrated that antihypertensive therapy can significantly reduce the risk of both initial and recurrent stroke.⁵ A sudden, prolonged increase in BP also can cause hypertensive encephalopathy, which is classified as a hypertensive emergency.

The glomerular filtration rate (GFR) is used to estimate kidney function, which declines with aging. This rate of decline is greatly accelerated by hypertension. Hypertension is associated with nephrosclerosis, which is caused by increased intraglomerular pressure. It is unknown whether a primary kidney lesion with ischemia causes systemic hypertension or whether systemic hypertension directly causes glomerular capillary damage by increasing intraglomerular pressure. Regardless, chronic kidney disease, whether mild or severe, can progress to kidney failure (stage 5 chronic kidney disease) and the need for dialysis. Although studies have demonstrated that aggressive BP control is the most important strategy to slow the rate of kidney function decline,²⁶ it may not be entirely effective in slowing the progression of renal impairment in all patients.

Chronic kidney disease is staged based on estimated GFR values.²⁶ Moderate (stage 3) kidney disease is defined as a GFR 30 to 59 mL/minute/1.73 m², severe (stage 4) is 15 to 29 mL/minute/1.73 m², and kidney failure is <15 mL/minute/1.73 m² or the requirement of dialysis. In hypertension, moderate kidney disease or worse (estimated GFR <60 mL/minute) is considered a hypertension-associated complication. An estimated GFR <60 mL/minute corresponds approximately to a serum creatinine concentration of >1.5 mg/dL in an average man and >1.3 mg/dL in an average woman. This level of kidney compromise lowers an individual's BP goal to <130/80 mmHg. The presence of albuminuria (>300 mg albumin in a 24-hour urine collection or 200 mg albumin/g creatinine on a

spot urine measurement) also indicates significant chronic kidney disease. Achieving the more aggressive goal is a strategy to minimize the rate of progression to kidney failure. (Note: These definitions of the stages of kidney disease and albuminuria will be used throughout the remaining cases in this chapter.)

Kidney function can be approximated by calculating a patient's creatinine clearance using the Cockcroft-Gault equation, or by estimating GFR using the Modification of Diet in Renal Disease (MDRD) equation. The Cockcroft-Gault equation is a universally accepted way to estimate kidney function and requires knowledge of the patient's serum creatinine clearance, ideal body weight, and gender (see Fig. 30-1, Chapter 30 Acute Renal Failure). Estimating GFR using the MDRD equation is more reflective of true kidney function, however, and is needed to stage chronic kidney disease (see Fig. 30-2, Chapter 30 Acute Renal Failure).²⁶ Serum creatinine concentration, age, race, and sex are needed with the MDRD equation.^{26,27}

Peripheral arterial disease is another form of atherosclerotic vascular disease that is considered target-organ damage. It is equivalent in CV risk to CAD.⁵ Risk factor modifications, BP control, and antiplatelet agent(s) are needed to decrease progression. Complications of peripheral arterial disease can include infection and necrosis, which in some cases require revascularization procedures or extremity amputation.

Hypertension causes retinopathies that can progress to blindness. Retinopathy is evaluated according to the Keith, Wagener, and Barker funduscopic classification system. Grade 1 is characterized by narrowing of the arterial diameter, indicating vasoconstriction. Arteriovenous (AV) nicking is the hallmark of grade 2, indicating atherosclerosis. Longstanding, untreated hypertension or accelerated hypertension also can cause cotton wool exudates and flame hemorrhages (grade 3). In severe cases, papilledema occurs, and this is classified as grade 4.

Major Risk Factors

5. Which major CV risk factors are present in D.C.?

Hypertension is one of nine major CV risk factors identified by the JNC7. These are not necessarily risk factors for developing essential hypertension; rather, they increase the risk of hypertension-associated complications such as CHD or CAD (Table 13-5). D.C. has multiple CV risk factors: smoking, dyslipidemia, family history of premature atherosclerotic vascular disease, hypertension, obesity, and physical inactivity.

6. What is D.C.'s Framingham risk score and how is this valuable to his overall treatment?

D.C. is considered a primary prevention patient because he does not yet have any hypertension-associated complications or compelling indications. He has multiple major CV risk factors, however, and Framingham risk scoring is needed to determine his BP goal value (Fig. 13-2) and to guide choice of pharmacotherapy (Fig. 13-3) and to provide an overall prognosis for his hypertension. Using the Framingham risk calculator (see Fig. 13.7, Chapter 13, Dyslipidemias, Atherosclerosis, and Coronary Heart Disease), D.C. has an 8% risk of developing CHD (or CAD) over the next 10 years.²⁸ This is considered moderate risk, and because it is <10%, his BP goal is <140/90 mmHg.^{9,14} This risk will increase as he ages, and especially if he does not modify his risk factors. This estimation helps

justify aggressive approaches to reduce CV risk, which includes lifestyle modifications and pharmacotherapy.

Many of D.C.'s risk factors are modifiable. He has a history of cigarette smoking. This significantly increases his CV risk and may reduce the efficacy of antihypertensive therapy. Smoking cessation may not independently lower D.C.'s BP, but it will decrease his overall risk of CV disease. D.C. is obese based on his BMI. His sedentary lifestyle (lack of physical activity) and dietary patterns have likely contributed to his obesity. A more focused patient interview on diet and exercise would be helpful to reinforce the assumption that he has a sedentary lifestyle. D.C.'s abnormal cholesterol values (especially his elevated LDL-C) increase his CV risk and lipid-lowering therapy should be considered because intervention trials have repeatedly shown that lowering LDL-C can decrease the risk of CHD and other forms of hypertension-associated complications (see Chapter 12, Dyslipidemias, Atherosclerosis, and Coronary Heart Disease).^{14,28} Based on Framingham estimates, risk increases with higher SBP values.²⁸ Patients with untreated hypertension have an increased CHD risk related to the degree of BP elevation. Even if D.C.'s BP were controlled with antihypertensive therapy, he would have a lower, but still elevated risk.

Advanced age, depending on sex, is considered a major CV risk factor. Although CV disease in the elderly age is not considered premature, increasing age increases the risk of hypertension-associated complications. Premenopausal women are at low risk for CV disease. CV risk in women increases significantly after menopause, however, similar to the increased risk in men. Therefore, cutoff values for age as a risk factor in men and women are separated by 10 years (>55 years for men, >65 years for women). At age 50, D.C. does not yet have this risk factor. Premature CV disease in first-degree relatives (i.e., parents and siblings) should be identified because it is a major CV risk factor. D.C. has a significant family history of premature CHD as evidenced by his father's death of an MI before the age of 55.

PRINCIPLES OF TREATMENT

Goals of Therapy

7. What are the goals of treating D.C.?

The ultimate overarching goal of therapy is to lower hypertension-associated morbidity and mortality. Control of BP is currently the most feasible clinical endpoint used to guide therapy, which can be thought of as a surrogate goal that is a means to attain the overarching goal. D.C.'s goal BP is <140/90 mmHg because he is a primary prevention patient with a Framingham risk score of 8%, meaning that of 100 patients similar to D.C., 8 will have CAD within the next 10 years. Pharmacotherapy principles to achieve these goals include selecting a treatment regimen with antihypertensive agent(s) that have been proved to reduce morbidity and mortality, complemented by appropriate lifestyle modifications.

Health Beliefs and Patient Education

8. What patient education should be provided to D.C. regarding his disease?

Provision of thorough patient education is needed to ensure that D.C. understands his disease and its complications (Table 13-7). This should comprehensively include information on disease, treatment, adherence, and complications. Several approaches can be effective, but all methods should include direct communication between a clinician and the patient. Multidisciplinary approaches to disease state management in hypertension can effectively utilize a team of different clinicians. Clinicians can be physicians, nurse practitioners, physician assistants, pharmacists, dietitians, or exercise physiologists. Providing education in a face-to-face manner is most common, but the key components in patient education may be delivered via indirect interactions (e.g., on the telephone).

Recommendations should be tailored to the patient's specific needs. For example, some patients are able to comprehend the importance of achieving controlled BP by reading written materials, whereas others understand this only after implementing self-BP monitoring. The patient education process must be continuous throughout the duration of therapy. Not all aspects need to be discussed during each clinical interaction. Careful selection of both written and verbal information is needed so that patients are not overwhelmed or frightened by too much information. It is important that clinicians review all materials provided to patients to identify the source of information, assess ease of reading, and identify omitted information and sources of confusion or anxiety (e.g., drug side effects). Patients' needs can also change over time as their disease or circumstances change, and different strategies might be necessary to enhance education and adherence.

Table 13-7 Patient–Provider Interactions for Hypertension

Patient Education

- Assess patient's understanding and acceptance of the diagnosis of hypertension
- Discuss patient's concerns and clarify misunderstandings
- When measuring BP, inform the patient of the reading both verbally and in writing
- Assure patient understands their goal BP value
- Ask patient to rate (1–10) his or her chance of staying on treatment
- Inform patient about recommended treatment, including lifestyle modification. Provide specific written information using standard brochures when available
- Elicit concerns and questions and provide opportunities for patient to state specific behaviors to carry out treatment recommendations
- Emphasize:
 - the need to continue treatment
 - that control does not mean cure
 - elevated BP is usually not accompanied by symptoms

Individualize Treatment Regimens

- Include the patient in decision-making
- Simplify the regimen to once-daily dosing, whenever possible
- Incorporate treatment into patient's daily lifestyle
- Set realistic short-term objectives for specific components of the medication and lifestyle modification plan
- Encourage discussion of diet and physical activity, adverse drug effects and concerns
- Encourage self-monitoring with validated BP devices
- Minimize the cost of therapy, when possible
- Discuss adherence at each clinical encounter
- Encourage gradual sustained weight loss

BP, blood pressure.

Patients such as D.C. often incorrectly explain BP elevation as stress related. A certain percentage of patients may have an increase in BP because of anxiety, as seen in those with white-coat hypertension. Most patients with essential hypertension, however, will have an elevated BP regardless of their stress level. D.C. should be informed about the cause of his disease and the lack of correlation between stress or symptoms and high BP. Most importantly, D.C. needs to realize that elevated BP is almost always asymptomatic, but can cause serious long-term complications. It is essential that he understand the chronic nature of hypertension and the need for long-term therapy. Otherwise, he may adhere to the prescribed treatment only when he “feels his BP is high” or during stressful events.

Some patients believe they can control their BP by stress management rather than with prescribed therapy (lifestyle modifications and antihypertensive agents). Controlled trials have not consistently proven that stress management is beneficial in hypertension.²⁹ It is important to determine the patient’s health beliefs and attitudes and to educate him or her about the etiology and management of hypertension to promote BP control.

Another common myth patients believe is that treating hypertension commonly leads to fatigue, lethargy, and sexual dysfunction. This misconception can be a limiting factor in appropriate management. Clinical trials have repeatedly reported that quality of life is better with active medication than with placebo.^{30,31} Data have indicated that as many as 27% of men with hypertension have erectile dysfunction.³² Although many believe this to be a side effect of their medication, and incidence rates may vary between certain antihypertensive agents and classes, erectile dysfunction is likely caused by penile arterial changes (probably atherosclerosis), which is related to uncontrolled or untreated hypertension.³²

Benefits of Treatment

9. Does antihypertensive therapy reduce the incidence of hypertension-associated complications?

Without a doubt, antihypertensive therapy reduces the risk of CV disease and CV events in patients with hypertension. Numerous landmark placebo-controlled studies have clearly demonstrated these benefits. The first large-scale trial, published in 1967, was the Veterans Administration (VA) study in men with DBP between 115 and 129 mmHg.³³ This study was prematurely stopped because benefits of treatment were so dramatic. Antihypertensive therapy significantly reduced cerebral hemorrhage, MI, left ventricular dysfunction, retinopathy, and kidney disease. Other landmark placebo-controlled studies, mostly from the 1980s and 1990s, have evaluated antihypertensive therapy in patients with less severe hypertension (DBP, 90–109 mmHg) and have shown a reduced risk of stroke, ischemic heart disease, left ventricular dysfunction, progression to more severe hypertension, and death.^{22,24} Long-term, placebo-control studies evaluating morbidity and mortality in hypertension are not only unnecessary, but are considered unethical because treatment is definitively beneficial.

10. Will D.C.’s early signs of hypertension-associated complications improve or reverse with appropriate BP control?

Most antihypertensive drugs reduce LVH through varying mechanisms. It is logical that regression of LVH is desirable, but this remains unproved. Theoretically, myocardial function might be compromised when hypertrophied muscle regresses in size because of the increased ratio of collagen to muscle. Nonetheless, until proved otherwise, regression of LVH in D.C. is desirable.

Reductions in BP can reverse many of the changes associated with D.C.’s retinopathy. In particular, studies have demonstrated that the risk of retinopathy in diabetic patients increases significantly when the DBP is >70 mmHg and that control of BP can slow this progression. D.C. has an elevated fasting glucose indicating prediabetes, but he does not have diabetes. Regardless, lowering BP is desirable for anticipated beneficial effects on his retinopathy.

HYPERTENSION MANAGEMENT

Lifestyle Modifications

11. Should D.C. start antihypertensive drug therapy, or should lifestyle modifications be his primary treatment?

It is reasonable to assume that lifestyle modifications can partially help D.C. achieve his BP goal. Previous JNC guidelines recommended lifestyle modifications for 6 to 12 months before starting drug therapy in patients with few to no risk factors and no hypertension-associated complications, and no compelling indications (i.e., primary prevention patients with Framingham risk scores of <10%).²⁴ The 2007 European guidelines recommend lifestyle modifications alone to treat hypertension for only “several weeks” before starting drug therapy in patients with stage 1 hypertension who have “moderate” CV risk (i.e., one to two risk factors), and for “several months” in patients with stage 1 hypertension who are at “low” CV risk (i.e., no additional risk factors).¹³ D.C. has several major risk factors for developing hypertension-associated complications, and has early evidence of hypertension-associated complications. Lifestyle modifications are germane to the appropriate treatment of hypertension, but they have not been shown to prevent CV disease in patients with hypertension.⁹ As recommended in the AHA and the European Society of Hypertension/European Society of Cardiology guidelines from 2007, initiation of drug therapy should not be delayed unnecessarily, especially for patients with CV risk factors.^{9,13} Because D.C. has stage 1 hypertension with multiple risk factors, both lifestyle modifications (Table 13-6) and drug therapy should be implemented simultaneously.

Modalities that Lower BP

12. Which lifestyle modifications should be recommended for D.C. to lower his BP?

Weight reduction with dietary modifications and physical activity, sodium restriction, and smoking cessation are the most apparent lifestyle modifications for D.C. A thorough patient interview includes a diet history to quantify his intake of total calories, sodium, fat, and cholesterol. A social history should also be obtained to determine alcohol consumption and to confirm cigarette use. Based on these interviews, customized recommendations can be made.

The DASH diet should be strongly encouraged in D.C. Publications such as Facts About the DASH Eating Plan, are readily available on the National Heart, Lung and Blood Institute (NHLBI) website (<http://www.nhlbi.nih.gov/guidelines/hypertension/index.htm>) and are written in language easily understood by most patients. D.C.'s BMI of ≥ 30 kg/m² classifies him as obese. He needs >16-kg weight loss to lower his weight classification to overweight. As little as a 5% to 10% loss in weight (5–11 kg) will provide global health benefits. Strategies that increase his aerobic activity, in addition to diet, can augment weight loss.

The role of supplementation with calcium, and magnesium in hypertension is unclear. Therefore, these should not be routinely recommended in patients with hypertension for the purpose of lowering BP. Caffeine ingestion has been associated with an acute elevation in BP; however, these elevations appear to be transient. Limitations on caffeine intake are not recommended unless caffeine ingestion is detrimental for other medical reasons (e.g., cardiac arrhythmias, panic attacks).

Other CV Risk Reduction Strategies

13. Aside from treating hypertension, which other CV risk reduction strategies should be recommended in D.C.?

SMOKING CESSATION

Smoking is an important and significant modifiable major CV risk factor. Cigarette smoking independently has been shown to increase CV and overall mortality, and cessation can decrease the incidence of CV disease.³⁴ Although smoking may not chronically alter BP, it can blunt the response to certain antihypertensive medications. Hypertensive smokers should be continually educated about the risks associated with cigarette smoking and directed to behavior modification programs that can assist smoking cessation efforts (see Chapter 85, Tobacco Use and Dependence).

LOW-DOSE ASPIRIN

Low-dose aspirin therapy (81 mg daily) provides antiplatelet effects that reduce the risk of MI. This is available over the counter, and is recommended by consensus guidelines for primary prevention patients with a Framingham risk score of $\geq 10\%$ to reduce the risk of a CV event.³⁵ It is also recommended in all secondary prevention patients who have a history of atherosclerotic vascular disease to reduce the risk of recurrent CV events or CV disease.³⁶ Patients with an absolute contraindication to aspirin therapy (e.g., aspirin allergy, gastrointestinal bleed, aspirin-induced bronchoconstriction) should not receive aspirin therapy. Aspirin can cause an increased risk of bleeding, is subject to many potential drug interactions, and can possibly cause gastrointestinal side effects. Using enteric coated aspirin products, and using low dose can minimize the risk of these potential complications. Based on D.C.'s current Framingham risk score, he is not yet a candidate for low-dose aspirin.

CONTROLLING OTHER COMORBID DISEASES

In addition to treating hypertension and lowering BP to goal, controlling other comorbidities is recommended to further reduce the risk of CV events. When present, dyslipidemia, diabetes mellitus, obesity, and any other forms of CV disease

should be diligently treated and controlled. D.C. does have dyslipidemia (he has elevated LDL-C, low HDL-C, and elevated triglycerides), and his CV risk would be reduced with better control of this condition (see Chapter 12, Dyslipidemias, Atherosclerosis, and Coronary Heart Disease).

Pharmacotherapy for Primary Prevention Patients

Evidence-Based Recommendations

14. Which treatment principles need to be considered when choosing an initial antihypertensive agent for D.C.?

Selecting an antihypertensive drug is difficult considering the numerous choices. All antihypertensive agents can effectively lower BP. Depending on the dose used, pressure reductions are similar.³⁷ BP reduction, however, is only a surrogate endpoint of therapy that does not necessarily reflect overall efficacy. Reducing hypertension-associated complications is the ultimate goal of treatment. Evidence-based medicine is the conscientious, explicit, and judicious use of current best evidence in making decisions about the care of individual patients.³⁸ Practicing evidence-based medicine in hypertension requires a balance between weighing the findings from outcome-based studies showing reduced hypertension-associated complications and considering specific drug therapies for each patient's individual situation.

15. Which antihypertensive agent is appropriate as first-line treatment in D.C.?

The JNC7 report from 2003, supplemented by more recent evidence in the AHA 2007 guidelines, outlines pharmacotherapy recommendations that follow an evidence-based approach.^{5,9} These recommendations are based on the interpretation of clinical trials. Although the JNC7 recommended a thiazide diuretic, either alone or in combination with another antihypertensive (depending on hypertension stage), as the initial drug choice for most patients, recent evidence demonstrates that either an ACEI, ARB, CCB, thiazide diuretic, or certain combinations of these agents is a reasonable first-line drug therapy option for primary prevention patients (Fig. 13-3).^{5,9} This recommendation is based on the propensity of data showing reduced morbidity and mortality with these drug classes.^{20–22} For patients with a *compelling indication* (Fig. 13-3), the choice of pharmacotherapy is more specific, and is discussed later in this chapter. D.C. does not have a compelling indication for specific pharmacotherapy, and is considered a primary prevention patient. Thus, treatment with either an ACEI, ARB, CCB or thiazide diuretic is considered acceptable according to the most recent evidence-based guidelines.⁹

Traditional landmark placebo-controlled hypertension studies conducted in the 1980s (the Systolic Hypertension in the Elderly Program [SHEP],³⁹ Swedish Trial of Old Patients with Hypertension [STOP-hypertension],⁴⁰ and Medical Research Council [MRC]⁴¹) established that treating hypertension produces significant reductions in CV events (e.g., stroke, MI) and mortality. These traditional landmark trials utilized thiazide diuretic-based therapy and, thus, thiazide diuretics have been the quintessential antihypertensive agent for most patients. Subsequently, several clinical trials evaluating newer agents (ACEI, ARB, and CCB) have provided additional evidence on

CV event reduction.^{42–63} Most of these trials do not include a placebo group (because it is unethical to use placebo in long-term studies); rather, they use an active antihypertensive agent as the comparator (usually a thiazide diuretic or β -blocker). In those studies in which newer antihypertensive agents were compared with thiazide diuretics, very similar effects were seen.

16. Should D.C. be placed on a monotherapy or two drug therapy as his initial regimen?

A monotherapy approach is reasonable for D.C., because his BP is classified as stage 1 (Fig. 13-3). Monotherapy with an agent from one of these classes will likely reduce his BP to <140/90 mmHg because his SBP is within 10 mmHg of his goal value. This is not the common scenario; many patients present with stage 2 hypertension and, thus, require two antihypertensive agents from the start. Two-drug therapy using low doses typically lowers BP more effectively than high-dose monotherapy, and may reduce the risk of drug-related side effects compared with high-dose monotherapy.⁶⁴ Initial treatment with two drugs are not needed because D.C. does not have stage 2 hypertension and, in contrast to most patients with hypertension, can feasibly attain goal with one agent.^{5,9}

Special Populations
BLACK PATIENTS

17. D.C. is black. Should his race influence the selection of an antihypertensive regimen?

Black patients have a higher incidence of hypertension, hypertension-associated complications, and an increased need for combination therapy to achieve and maintain BP goals.^{25,65} As monotherapy, it is well documented that a thiazide diuretic or a CCB is highly effective in lowering BP in black patients. Conversely, ACEI, ARB, or β -blocker monotherapy is less effective in lowering BP in black patients compared with white patients. When these agents are used in combination, especially with a thiazide diuretic, BP lowering is greatly improved. This information may aid in selecting one drug option over another in a primary prevention patient, but does not apply to black patients with compelling indications, where choice of therapy follows an evidence-based approach to selection.

The Hypertension in African American Working Group (HAAWG) of the International Society on Hypertension in Blacks has treatment guidelines that are similar to the JNC7 and 2007 AHA hypertension guidelines with respect to lifestyle modifications and pharmacotherapy.^{5,9,65} These guidelines, however, highlight that attaining BP goal values is more challenging in blacks, and usually requires more aggressive initiation of pharmacotherapy. They also identify that black patients are at higher risk of side effects with ACEI (both angioedema and cough) compared with whites.⁴⁵

D.C. does not have any compelling indications for specific antihypertensive drug therapy. His first-line treatment options are an ACEI, ARB, CCB, or thiazide diuretic. Monotherapy with either a thiazide diuretic or a CCB would be very effective in BP lowering; either of these two drugs is an acceptable treatment option for him.

VERY ELDERLY PATIENTS

18. How is treatment of hypertension in an elderly patient different than in a younger patient? Are there any special precautions for lowering BP too much?

Older patients with hypertension (>65 years of age) have the lowest rates of BP control, and this rate decreases in even older populations.²⁵ Very elderly patients (>75 years of age), similar to black patients, respond best to thiazides and CCBs and less to ACEIs, ARBs, and β -blockers. However, it is unclear whether these small differences in BP lowering are clinically significant, so they should be viewed as medical myths rather than definitive realities.

Isolated Systolic Hypertension

Isolated systolic hypertension (ISH) is defined as an elevated SBP (>140 mmHg) with a “normal” DBP (<90 mmHg).⁵ This pattern of hypertension is most common in patients >65 years of age and incurs a significant risk for CV disease. It was once thought that patients with ISH required high SBP to ensure normal perfusion of the heart and brain and that treating ISH would further lower DBP and worsen organ perfusion. Evidence clearly demonstrates, however, that treating ISH reduces the risk of CV events.^{39,42,49}

The care of patients with ISH, including the very elderly, should follow the same general hypertension care principles that apply to all patients, with two exceptions. The first exception is that lower doses should be used when first starting therapy. The second is that initial drug therapy, even with stage 2 hypertension, should only be started with monotherapy. Drug doses can be gradually increased as tolerated and combination therapy subsequently used to achieve recommended BP goals.^{5,9} In earlier JNC recommendations, thiazide diuretics and long-acting dihydropyridine CCB were preferred based on the evidence of reduced hypertension-associated complications.^{39,40,42} The JNC7 recommends that selection of pharmacotherapy in elderly patients be according to the same general treatment philosophies as for other patients with hypertension. Although lower starting doses may be needed to minimize the risk of side effects, elderly patients eventually need standard treatment doses and often require combination therapy to reach and maintain their BP goals.

Few data exist evaluating antihypertensive therapy in the very elderly (i.e., patients >75 years). These patients are underrepresented in most clinical trials. A meta-analysis evaluating landmark clinical trials in hypertension indicates that antihypertensive therapy in patients who were age 80 and older reduced the risk of stroke, but not necessarily all cause mortality.⁶⁶ The Hypertension in the Very Elderly Trial (HYVET) is a placebo-controlled, randomized trial evaluating the effect of antihypertensive pharmacotherapy in patients with hypertension age 80 years and older.⁶⁷ This trial was halted prematurely, after only 1.8 median years, owing to significant reductions in both stroke and overall mortality in the treatment arm.⁶⁸ The HYVET provides the most compelling evidence that treatment of hypertension in the very elderly provides significant benefits.

Absence of a J-Curve

Data from observational studies generated concern that there is a “J-curve” phenomenon where lowering BP too far may

Table 13-8 Additional Considerations in Antihypertensive Drug Choice^a

| Antihypertensive Agent | Situations with Potentially Favorable Effects | Situations with Potential Unfavorable Effects ^b | Avoid Use |
|-------------------------|---|--|---|
| ACEI | Low-normal potassium, prediabetes, microalbuminuria in patients without diabetes | High-normal potassium or hyperkalemia | Pregnancy, bilateral renal artery stenosis, history of angioedema |
| ARB | Low-normal potassium, prediabetes, microalbuminuria in patients without diabetes | High-normal potassium or hyperkalemia | Pregnancy, bilateral renal artery stenosis |
| CCB: dihydropyridine | Raynaud's syndrome, elderly patients with isolated systolic hypertension, cyclosporine induced hypertension | Peripheral edema, left ventricular dysfunction (all except amlodipine and felodipine), high-normal heart rate or tachycardia | |
| CCB: nondihydropyridine | Raynaud's syndrome, migraine headache, arrhythmias, high-normal heart rate or tachycardia | Peripheral edema, low-normal heart rate | Second or third degree heart block, left ventricular dysfunction |
| Thiazide diuretic | Osteoporosis or at increased risk for osteoporosis, high-normal potassium | Gout, hyponatremia, prediabetes (as monotherapy), low-normal potassium | |

^aNever to replace recommendations because of a compelling indication.

^bMay use but requires diligent monitoring.

High-normal refers to patients in the high end of the normal range, but not above the range.

Low-normal refers to patients in the low end of the normal range, but not below the range.

ACEI, angiotensin converting enzyme inhibitor; ARB, angiotensin-2 receptor blocker; CCB, calcium channel blocker.

be harmful.^{69,70} These data found that CAD events were decreased as expected when DBP was reduced to approximately 85 mmHg. Below this level, however, the risk of events actually increased.

The J-curve phenomenon is a medical myth. The data used to establish this phenomenon are observations from retrospective evaluations and, therefore, cannot establish cause and effect. The J-curve has been associated only with CAD events, not stroke or kidney impairment. For stroke prevention and kidney impairment, data consistently suggest that the lower the BP the better, unless BP reductions are too abrupt or are excessive. If the J-curve has any validity, it would occur when BP is reduced much lower than the therapeutic range. Furthermore, patients with very low BP may have other illnesses that predispose them to coronary events (e.g., autonomic dysfunction, volume depletion).

Controlled evidence disputes the J-curve. The Hypertension Optimal Treatment (HOT) trial was a prospective clinical trial designed to evaluate lower BP goals and CV events (challenging the J-curve).¹⁶ More than 18,700 patients were randomized to goal DBP values of <90 mmHg, <85 mmHg, or <80 mmHg. The risks for major CV disease events were the lowest when treatment BP was <139/83 mmHg. The risk for cerebrovascular events was lowest at a treatment BP of <142/80 mmHg. Only in patients with ischemic heart disease and diabetes did the lowest risk occur at a DBP <80 mmHg. A significant increase in events was not seen in patients with lower BP values. Therefore, the HOT trial does not support the concept of a J-curve.

Additional Considerations

19. Multiple pharmacotherapy options are equally recommended in a primary prevention patient. What additional considerations help to select an agent for a specific patient?

It cannot be emphasized enough that selecting pharmacotherapy should follow an evidence-based philosophy. In patients with compelling indications, certain antihypertensive drug classes are recommended in place of other options. In patients without compelling indications, additional factors (e.g., other diseases, cost, serum electrolytes, prior intolerances or allergies) are considered when selecting a drug class (Table 13-8). These are particularly helpful when selecting initial therapy for a primary prevention patient who has more than one acceptable drug class as a therapeutic option. It can also be helpful when selecting add-on therapy to further lower BP. These are discussed later in this chapter.

The costs of treating hypertension and related complications are substantial to patients and health systems.⁷¹ Costs attributed to drug acquisition are small in comparison to expenses for laboratory evaluations, office visits, and medical care for hypertension-associated complications. Whenever possible, affordable regimens that do not compromise efficacy should be designed. Generic antihypertensive products are less expensive than brand-name products, and all first- and second-line antihypertensive classes, except ARB, have generic alternatives. The frequency of administration must also be considered because it can influence patients' adherence to regimens. Once-daily administration maximizes compliance and is most desirable. All major antihypertensive drug classes offer a once-daily product, so optimizing regimen administration is very feasible.

Pharmacotherapy for Patients with Compelling Indications

Throughout the remainder of this chapter the term *compelling indications* will be used frequently. Compelling indications are defined as comorbid diseases for which specific antihypertensive classes are indicated based on evidence from clinical

trials. Although these clinical trials may not have evaluated hypertension-related complications alone, they show significant benefits in reducing CV morbidity or mortality that warrants their use in a hypertensive patient with a given compelling indication (Fig. 13-3). A BP goal of <130/80 mmHg is recommended in patients with a compelling indication, with an even lower goal of <120/80 mmHg recommended if the compelling indication is left ventricular dysfunction.

Diabetes

Kidney disease and CV disease are both considered long-term complication of diabetes and hypertension-associated complications. Patients with diabetes are at high risk for these complications. Evidence shows that treatment with antihypertensive agents (ACEI, ARB, CCB, thiazide diuretics, and even β -blockers) in patients with diabetes reduces risk of CV events, and progression of kidney disease.⁷² When compared head-to-head, ACEI are superior to dihydropyridine CCB at reducing CV events.^{53,54} Subanalyses of larger clinical trials further support CV event reduction with ACEI and ARB^{73,74} (see Chapter 50, Diabetes Mellitus). Therefore, initial antihypertensive therapy for a patient with diabetes should ideally consist of an ACEI or ARB first-line. A thiazide diuretic as add-on agent, followed by either a CCB or β -blocker as the next add-on therapy, should be used to provide additional BP lowering when needed. Aggressive BP control is indicated in diabetes (e.g., <130/80 mmHg) to minimize the risk of hypertension-associated complications.^{5,16,72} To get to this BP goal, however, two or more antihypertensive drugs are almost always needed.^{72,75}

Chronic Kidney Disease

Chronic kidney disease initially presents with microalbuminuria (30–299 mg albumin in a 24-hour urine collection) that can progress over several years to overt kidney failure.²⁶ Progression is accelerated in the presence of both hypertension and diabetes. ACEI or ARB therapy should be used first-line in these patients because both have been shown to reduce the progression of chronic kidney disease in type 1 diabetes,⁷⁶ in type 2 diabetes,^{50,56–58} and in those without diabetes.^{60,75,77} For purposes of hypertension management, patients have chronic kidney disease sufficiently significant to be considered a compelling indication with a goal BP of <130/80 mmHg if they have one of the following three criteria: (a) an estimated GFR <60 mL/minute/1.73 m² based on MDRD calculation (calculator available at: http://www.kidney.org/professionals/KDOQI/gfr_calculator.cfm); (b) a serum creatinine >1.3 mg/dL in women or >1.5 in men because this roughly correlates to a GFR estimation of <60 mL/minute/1.73 m²; or (c) albuminuria (>300 mg/day on a 24-hour urine collection or total protein-to-creatinine ratio >200 mg/g on a spot urinalysis).⁵ These patients typically require three or more antihypertensive agents, within which an ACEI or ARB should be the foundation of the drug therapy regimen.^{60,75}

Chronic and Acute CAD

The two most common forms of chronic CAD, post-MI and chronic stable angina, are considered compelling indications.^{5,9} The American College of Cardiology (ACC)/AHA have guidelines for these conditions that recommend treatment with a β -blocker, followed shortly thereafter by the

addition of an ACEI.^{36,78} β -Blockers (those without intrinsic sympathomimetic activity [ISA]) decrease the risk of a subsequent MI or sudden cardiac death by decreasing the adrenergic burden on the heart,^{79,80} and progression of atherosclerosis.⁸¹ ACEI therapy promotes cardiac remodeling, improves cardiac function, and reduces the risk of CV events.^{82,83} An ARB should be used as an alternative in patients who do not tolerate an ACEI, because fewer data exist that assess the long-term impact of an ARB on CV events compared with an ACEI in this setting.^{9,78} If additional BP reduction is needed, a thiazide diuretic can be added to the core regimen of a β -blocker with an ACEI (or ARB). If an additional agent is needed to treat ischemic symptoms for patients with chronic stable angina, a dihydropyridine CCB can be added to this core regimen. If a β -blocker cannot be used because of intolerance or contraindication, a nondihydropyridine CCB (verapamil or diltiazem) can be used as an alternative.

Acute CAD, also called *acute coronary syndrome*, includes unstable angina, non-ST-segment elevation MI, and ST-segment elevation MI.⁹ The ACC/AHA guidelines for these conditions indicate a β -blocker as first-line pharmacotherapy.^{84,85} Patients must be hemodynamically stable, however, before starting a β -blocker. The addition of an ACEI (or ARB as an alternative) is recommended if an anterior MI is present, if left ventricular dysfunction is present, if the patient has diabetes, or if additional BP lowering is needed.⁹ Most patients with an acute coronary syndrome will have one of these considerations for an ACEI (or ARB). Similar to chronic CAD, a thiazide diuretic can be added for further BP lowering. A dihydropyridine CCB can be added if ischemic symptoms are present. If a β -blocker cannot be used because of intolerance or contraindication, a nondihydropyridine CCB (verapamil or diltiazem) can be used as an alternative.

Prior Stroke

A history of a prior ischemic stroke (the predominant etiology of most cases of stroke) is considered a form of noncoronary atherosclerotic vascular disease and a compelling indication for specific antihypertensive drug therapy to lower the risk of a recurrent stroke. In fact, ischemic stroke is the only form of noncoronary atherosclerotic vascular disease for which specific antihypertensive drug therapy has been shown to reduce recurrent CV events. Lowering BP to goal in patients with a history of stroke is beneficial once patients have stabilized after their acute event. Specifically, the combination of an ACEI with a thiazide diuretic is documented to reduce the incidence of recurrent stroke.⁴⁶ Similarly, an ARB-based regimen has been shown to reduce the incidence of recurrent stroke more effectively than a dihydropyridine CCB-based treatment regimen.⁶³ Therefore, based on these data, either an ACEI with a thiazide diuretic, or ARB-based therapy is considered an appropriate first-line pharmacotherapy option for patients with a history of a prior ischemic stroke. Because dihydropyridine CCB-based therapy has also been shown to reduce the risk of ischemic stroke in patients with hypertension (albeit less than with an ARB),⁴² a dihydropyridine CCB is a good add-on option for combination therapy.

Left Ventricular Dysfunction

Left ventricular dysfunction (sometimes called *systolic heart failure* or *chronic heart failure*) is a common complication of

hypertension in which cardiac contractility is compromised. This compelling indication has the lowest BP goal of <120/80 mmHg. If patients are optimally treated with the combination of pharmacotherapy options recommended by both the 2007 AHA hypertension guidelines and ACC/AHA heart failure guidelines, they will likely attain this strict BP goal and experience reduced CV morbidity and mortality.^{9,86}

Standard first-line therapy for left ventricular dysfunction should include a three-drug combination of an ACEI, a diuretic (either a thiazide or loop, depending on kidney function and need for diuresis), and a β -blocker. ACEI have numerous landmark clinical trials showing reduced morbidity and mortality rates and diuretics provide primarily symptomatic relief of edema.⁸⁶ As left ventricular dysfunction progresses, loop diuretics are almost always needed instead of a thiazide diuretic because they produce more pronounced diuresis. β -Blocker therapy is a component of standard first-line therapy for left ventricular dysfunction because numerous clinical trials have demonstrated reduced morbidity and mortality when added to ACEI with diuretic therapy.^{79,87,88} According to evidence-based medicine principles, only metoprolol, carvedilol, and bisoprolol are indicated for left ventricular dysfunction. Other β -blockers (e.g., atenolol) should not be used in patients with left ventricular dysfunction because they do not have supporting data demonstrating they reduce CV event rates in these patients. Before adding a β -blocker in a patient recently started on an ACEI and diuretic, the patient should be hemodynamically stable. As discussed in detail in Chapter 18 (Heart Failure), it is important to start with very low doses of a β -blocker, then slowly titrating upward over several weeks to the recommended dosing range for left ventricular dysfunction.

Based on evidence demonstrating reduced risk of CV events, additional antihypertensive agents reduce CV risk in this patient population. An aldosterone antagonist (spironolactone, eplerenone) can be added to a standard first-line regimen in patients with severe left ventricular dysfunction.^{9,89,90} Similarly, the combination of hydralazine with isosorbide dinitrate can be added in black patients.⁹¹ An ARB should be used as an alternative for patients intolerant to an ACEI,^{92,93} or in addition to standard first-line treatment for left ventricular dysfunction.⁹⁴ Speculation was that an ARB would be even better than an ACEI in left ventricular dysfunction,⁹⁵ but when compared head-to-head, ACEIs were found to provide better outcomes.⁹⁶

Implementing Pharmacotherapy

Monotherapy

Starting with one drug to treat hypertension is optimal when initial BP is close to goal values. When using a standard dose of a first-line antihypertensive agents (an ACEI, ARB, CCB, or thiazide diuretic), and even with β -blockers, the average reduction in SBP/DBP is only 10/5 mmHg.⁶⁴ This has been termed by some as the “10 over 5” rule.

Two general approaches to monotherapy exist. The stepped-care approach to monotherapy is where a single agent is selected with the dose increased until BP is controlled, the maximal dose is reached, or dose-limiting toxicity occurs. If the goal BP is not achieved, a second drug from a different class is added. Theoretically, this process can be continued, if necessary, until three or even four drugs are used in combination.

The Veterans Affairs (VA) Cooperative Studies Group on Antihypertensive Agents evaluated the ability of a monotherapy in attaining a BP of <140/90 mmHg using one of several antihypertensive agents in patients with stage 1 or 2 hypertension.³⁰ Less than 60% of patients reached a DBP <90 mmHg with this approach when doses were titrated up to the maximal dosage. After 1 year, approximately 50% actually maintained a DBP of <90 mmHg. Therefore, monotherapy is limited in its ability to attain goal BP values for many patients, especially those with higher baseline BP values.

With the sequential therapy approach, monotherapy is initiated and titrated to the maximal dose as needed. If goal BP is not achieved, an alternative agent is selected to replace the first. Combination drug therapy is reserved for patients who do not achieve goal BP values after the second agent. Sequential therapy seems most appropriate when the first drug is either poorly tolerated or results in minimal reduction in BP. The VA Cooperative Studies Group on Antihypertensive Agents also evaluated sequential therapy. Only an additional 49% of the nonresponders to the first agent achieved a DBP <90 mmHg when switched to a second drug.

Combination Therapy

Starting therapy with two drugs is strongly encouraged for patients far from their BP goal, such as patients who have stage 2 hypertension.^{5,9} This approach is also an option for patients closer to their BP goal, who have compelling indications for two drugs, or have BP goals of <130/80 mmHg or <120/80 mmHg. It is justified by the observation that most patients with hypertension have not attained goal BP values, and most patients require two or more agents.⁵ In contrast to high-dose monotherapy, low-dose, two-drug combination therapy provides greater BP lowering with a lower risk of side effects.⁶⁴

IDEAL COMBINATIONS

When selecting a second agent as add-on therapy for BP reduction, a thiazide diuretic should usually be considered if it was not the first drug added. This does not always apply if the second drug is being added to treat a compelling indication, although most patients will respond to a two-drug regimen if it includes a diuretic.⁵ Thiazide diuretics are very effective in lowering BP when used in combination with most other antihypertensive agents. Similarly, the combination of an ACEI or ARB with a CCB is also very effective in lowering BP. By appropriately selecting combination regimens, many patients can achieve a BP goal of <140/90 mmHg with two drugs. It is not uncommon, however, to require three or more drugs to attain a goal BP of <130/80 mmHg or lower.

ORTHOSTATIC HYPOTENSION

Orthostatic hypotension occurs when standing upright results in a SBP decrease >10 mmHg and is accompanied by dizziness or fainting.⁵ This is a risk of rapid BP lowering. Orthostatic hypotension is more frequent in very elderly patients (especially those with ISH), diabetes, autonomic dysfunction, and in patients taking certain drugs (diuretics, nitrates, α -blockers, phosphodiesterase inhibitors use in erectile dysfunction, or psychotropic agents). Combination therapy can still be used in these patients, but close evaluation is needed. Dose titration should be gradual with caution applied to

minimize the risk of hypotension and to avoid volume depletion. Moreover, initial therapy with two drugs should be avoided in this population owing to the increased risk of orthostatic hypotension.

Monitoring Therapy

Four aspects of treatment must always be considered: (a) BP response to attain goal, (b) adherence with lifestyle modifications and pharmacotherapy, (c) progression to hypertension-associated complications, and (d) drug-related toxicity.

Blood pressure control should be evaluated 1 to 4 weeks after starting or modifying therapy for most patients. BP usually begins to fall within 1 to 2 weeks of starting an agent, but steady-state antihypertensive effects typically take up to 4 weeks. If patients have experienced a hypertensive crisis, evaluation should occur sooner. For example, hypertensive emergencies are triaged for hospitalized care, and BP response is evaluated with continuous monitoring. For patients with hypertensive urgency (BP values in the upper range of stage 2 hypertension without signs of acute target-organ damage), BP response to treatment should be assessed ideally within 3 days.

Two BP values should be measured each time to evaluate response, with the average of the two used to make a proper assessment. If dehydration or orthostatic hypotension is suspected, BP measurements should be made in both the seated and standing positions to detect orthostatic changes. For routine monitoring, measuring BP in the seated position is sufficient. Home BP monitoring values should be considered when they are available. They, however, normally are slightly lower (5 mmHg) than clinic values even in patients without white-coat hypertension. For example, patients with a goal BP value of <140/90 mmHg should have home measurements that are <135/85 mmHg.⁵

All patients should be questioned in a nonthreatening manner regarding adherence to lifestyle modifications and drug therapy. This is especially important for complex regimens, when drug intolerance is likely, or when financial constraints hinder acquisition of medications. Medical evaluation to as-

sess hypertension-associated complications and drug side effects is essential. The presence of new hypertension-associated complications may necessitate modification of therapy. Drug therapy may require changes based on the need to treat a compelling indication or attain a new BP goal. The presence of drug-related side effects might similarly result in the need to modify therapy.

CLINICAL SCENARIOS

Diuretics

20. B.A. is a 62-year-old woman who is postmenopausal, does not smoke, and never drinks alcohol. Since being diagnosed with hypertension, she has modified her diet, begun routine aerobic exercise, and has lost 10 kg over the past 18 months. She now weighs 72 kg and is 165 cm tall. Her present BP is 142/94 mmHg (144/92 when repeated) and has consistently remained near this value over the past year. Her BP when first diagnosed was 150/98 mmHg. No evidence is found of LVH or retinopathy. Urinalysis is negative for protein. Other laboratory tests are normal, except for dyslipidemia. B.A. has no health insurance and is concerned about the cost of therapy, and pays full price for all of her medications. Her Framingham risk score is 22%. She takes over-the-counter calcium with vitamin D (she has osteoporosis) and is to start hydrochlorothiazide (HCTZ) for hypertension. Is this an appropriate first-line treatment for her?

This patient has hypertension that is considered uncontrolled. Because of her elevated Framingham risk score, a BP goal of <130/80 mmHg is recommended.⁹ She is a primary prevention patient without compelling indications. An ACEI, ARB, CCB, or thiazide diuretic is acceptable first-line treatment options. A thiazide diuretic is optimal for her. It is the most inexpensive treatment option, and may also benefit her osteoporosis (Table 13-8). Several types of diuretics are used to manage hypertension (Table 13-9). All lower BP, with the primary differences being duration of action, potency of diuresis, and potential for electrolyte abnormalities.

Table 13-9 Diuretics in Hypertension

| Category | Selected Products | Usual Dosage Range (mg/day) | Dosing Frequency |
|------------------------|---|-----------------------------|------------------|
| Thiazide | Chlorthalidone (Hygroton) | 12.5–25 | Daily |
| | Hydrochlorothiazide (Esidrix, Hydrodiuril, Microzide) | 12.5–25 | Daily |
| | Indapamide (Lozol) | 1.25–5 | Daily |
| | Metolazone (Zaroxolyn) | 2.5–10 | Daily |
| | Metolazone (Mykrox) | 0.5–1.0 | Daily |
| Loop | Bumetanide (Bumex) | 0.5–4 | BID |
| | Furosemide (Lasix) | 20–80 | BID |
| | Torsemide (Demadex) | 2.5–10 | Daily |
| Potassium-sparing | Amiloride (Midamor) | 5–10 | Daily to BID |
| | Triamterene (Dyrenium) | 50–100 | Daily to BID |
| Combination | Triamterene/Hydrochlorothiazide (Maxide, Dyazide) | 37.5/25–75/50 | Daily |
| | Spirolactone/Hydrochlorothiazide (Aldactazide) | 25/25–50/50 | Daily |
| | Amiloride/Hydrochlorothiazide (Moduretic) | 5–10/50–100 | Daily |
| Aldosterone antagonist | Eplerenone (Inspra) | 50–100 | Daily to BID |
| | Spirolactone (Aldactone) | 25–50 | Daily to BID |

BID, twice daily.

Thiazides

Thiazide diuretics are the drugs of choice for hypertension based on landmark data using these types of diuretics. Similar to loop diuretics, an initial diuresis is experienced. After approximately 4 to 6 weeks of thiazide diuretic therapy, diuresis dissipates, however, and is supplanted by a decrease in PVR, which is responsible for sustaining antihypertensive effects. HCTZ and chlorthalidone have been used in several major outcome trials, including the ALLHAT.^{5,22,45,47} HCTZ, which is most frequently used in the United States, is very inexpensive and is dosed once daily. Chlorthalidone may be slightly more potent on a milligram per milligram basis, but this difference has questionable clinical relevance. The usual starting dose of HCTZ or chlorthalidone is a low-dose of 12.5 mg once daily. A maintenance dose of 25 mg once daily can effectively lower BP and has a low incidence of side effects.^{22,30,37} The propensity of evidence showing benefit with thiazide diuretics is with low-dose therapy, considered to be the equivalent of HCTZ or chlorthalidone 12.5 to 25 mg daily.²²

Loop Diuretics

Loop diuretics produce a more potent diuresis, a smaller decrease in PVR, and less vasodilation than thiazide diuretics. Therefore, a thiazide is more effective at lowering BP than loop diuretics in most patients. Loop diuretics are usually the diuretics of choice for patients with severe chronic kidney disease (an estimated GFR <30 mL/minute/1.73 m²), left ventricular dysfunction, or severe edema because potent diuresis is often needed in these patients. Furosemide has a short duration of effect and should be given twice daily when used in hypertension, whereas torsemide can be given once daily.

Potassium-Sparing Diuretics

Potassium-sparing diuretics should be reserved primarily for patients who develop hypokalemia while on a thiazide diuretic. With low-dose thiazide diuretics, <25% of patients develop hypokalemia and most cases are not severe. Potassium-sparing diuretics do not provide significant BP-lowering effects when used alone or in combination with a thiazide. Several fixed-dose products are available that include HCTZ with a potassium-sparing agent. Empirically starting all patients with hypertension treated with a diuretic on one of these fixed-dose combination products to avoid hypokalemia is not rational unless baseline serum potassium is in the low-normal range.

21. How should a thiazide diuretic be started in B.A.?

B.A. has stage 1 hypertension and monotherapy with a thiazide diuretic is rational. Evidence supports the use of thiazide diuretics in primary prevention patients, and she has no contraindications to this therapy (Table 13-10). B.A. does have dyslipidemia, but thiazide diuretics are unlikely to have a clinically significant effect on cholesterol when used in low doses.^{23,97} An appropriate starting dose of HCTZ for B.A. is 12.5 or 25 mg daily. She has no additional risks for orthostatic hypotension, so starting at the higher 25 mg daily is safe, and will have a better chance of lowering her BP to <130/80 mmHg than the lower 12.5-mg dose. Most antihypertensive agents provide a 10 mmHg reduction in SBP and 5 mmHg reduction in DBP with a standard starting dose, with less than this amount as additional BP lowering with each dose-doubling thereafter.⁶⁴

Patient Education

22. B.A. is prescribed HCTZ 25 mg daily. How should she be counseled regarding this therapy?

Several counseling points regarding hypertension are summarized in Table 13-7. Some patients disregard lifestyle modifications when they start antihypertensive therapy, so she should be encouraged to continue lifestyle modification to maximize her response to drug therapy. Drug-specific counseling for diuretics includes informing B.A. that diuretics effectively lower BP and risk of CV events. Taking her daily dose at about the same time each morning is best to minimize nocturia and provide consistent effects. Patients experience increased urination when starting this medicine, but this diminishes with time. Missed doses should be taken as soon as possible within the same day, but doubling doses the next day is not recommended. B.A. should be informed of the potential for hypokalemia which is easily identified and managed, and the need for routine monitoring of serum potassium. She should be counseled on the signs and symptoms of electrolyte abnormalities (e.g., leg cramps, muscle weakness) and encouraged to report these to her health care provider if they occur. Increasing dietary intake of potassium-rich foods (i.e., bananas, orange juice) to minimize electrolyte depletion is an option to minimize potassium loss. This should be encouraged only with thiazide and loop diuretics, because a potassium-enhanced diet could contribute to hyperkalemia with potassium-sparing agents.

23. After 4 weeks of HCTZ 25 mg daily, B.A. returns for evaluation without complaints. She has not missed a dose, is still exercising, and is following the DASH diet. Her BP values are 132/82 and 130/84 mmHg. Her serum potassium is 3.8 mEq/L (normal, 3.5–5.2 mEq/L), uric acid is 7.3 mg/dL (normal, 2.0–7.5 mg/dL), fasting glucose is 99 mg/dL (normal, 60–99 mg/dL), and the other laboratory values are unchanged. One month ago, her potassium was 4.0 mEq/L, uric acid was 6.8 mg/dL, and fasting glucose was 95 mg/dL. What is your assessment from the data given regarding efficacy and toxicity?

[SI units: K, 3.8 mmol/L (normal, 3.5–5.2 mmol/L); uric acid, 432 mmol/L (normal, 119–476 mmol/L); and glucose, 5.6 mmol/L (normal, 3.3–6.1 mmol/L)]

Despite significant improvements with lifestyle modifications before starting HCTZ and apparent adherence with taking her HCTZ dose as directed, B.A.'s goal BP of <130/80 mmHg has not been met based on today's BP average of 131/83 mmHg. No new signs of hypertension-associated complications are seen. She should be encouraged to continue with her current efforts, but other interventions are now indicated.

Potassium Loss

Adverse reactions with low-dose thiazide diuretics (e.g., HCTZ 12.5–25 mg daily) are minimal compared with high-dose therapy (HCTZ ≥50 mg daily). Moreover, most side effects with low-dose thiazide diuretic therapy has been shown to be similar to placebo,³⁷ and have similar tolerability compared with other first-line drug therapy options.³⁰ Increased urination usually subsides after the first few weeks of therapy with thiazide diuretics, but this is sometimes a cause for nonadherence,

Table 13-10 Side Effects and Contraindications of Antihypertensive Agents

| | | Side Effects | | |
|-----------------------------------|---|---|---|---|
| | | <i>Innocuous but Sometimes Annoying</i> | <i>Potentially Harmful</i> | <i>Usually Requires Cessation of Therapy, at Least Temporarily</i> |
| | | | | <i>Contraindications</i> |
| Thiazide diuretics | Increased urination (at onset of therapy), muscle cramps, hyperuricemia (without gout), GI disturbances | Hypokalemia, ^a hyperglycemia, hypovolemia, pancreatitis, photosensitivity, hypercholesterolemia, hypertriglyceridemia, hyperuricemia with gout, orthostatic hypotension (more frequent in elderly) | Hypercalcemia, azotemia, skin rash (cross-reacts with only certain sulfonamide allergies), purpura, bone marrow depression, lithium toxicity in patients on lithium therapy | Persistent anuria or oliguria, advanced kidney failure |
| Loop diuretics | Increased urination, muscle cramps, hyperuricemia (less than with thiazides), GI disturbances | Hypokalemia, ^a hyperglycemia, hypovolemia, pancreatitis, hypercholesterolemia, hypertriglyceridemia, hearing loss with large IV doses orthostatic hypotension (more frequent in elderly) | Hyponatremia, hypocalcemia, azotemia, skin rash (cross-reacts with only certain sulfonamide allergies), photosensitivity, lithium toxicity in patients on lithium therapy | |
| ACEI | Dizziness, dry cough | Orthostatic hypotension (more frequent in elderly treated with a diuretic), increased serum creatinine, increased potassium | Angioedema, severe hyperkalemia, increase in serum creatinine >35% | Bilateral renal artery stenosis, volume depletion, hyponatremia, pregnancy, history of angioedema |
| ARB | Dizziness | Orthostatic hypotension (more frequent in elderly treated with a diuretic), increased serum creatinine, increased potassium | Severe hyperkalemia, increase in serum creatinine >35% | Bilateral renal artery stenosis, volume depletion, hyponatremia, pregnancy |
| CCB: dihydropyridines | Dizziness, headache, flushing | Peripheral edema, tachycardia | Significant peripheral edema | Left ventricular dysfunction (not with amlodipine or felodipine) |
| CCB: nondihydropyridines | Dizziness, headache, constipation | Bradycardia | Heart block, left ventricular dysfunction, interactions with certain drugs | Left ventricular dysfunction, second- or third-degree heart block, sick sinus syndrome |
| β-Blocker | Bradycardia, weakness, exercise intolerance | Masking the symptoms of hypoglycemia in diabetes, hyperglycemia, aggravation of peripheral arterial disease, erectile dysfunction, increased triglycerides, decreased HDL-C | Left ventricular dysfunction (not with carvedilol, metoprolol, bisoprolol), bronchospasm in patients with asthma | Severe asthma, second- or third-degree heart block, acute left ventricular dysfunction exacerbation, coronary artery disease for agents with intrinsic sympathomimetic activity |
| Aldosterone antagonist | Menstrual irregularities (spironolactone only) or gynecomastia (spironolactone only) | Increased potassium | Hyperkalemia, hyponatremia | Kidney failure, kidney impairment (for eplerenone: CrCl <50 mL/min, or type 2 diabetes with proteinuria, and elevated or creatinine >1.8 in women, >2.0 in men), hyperkalemia, hyponatremia |

^aRoutine use of potassium supplements and/or concurrent potassium sparing diuretics should be discouraged unless hypokalemia is documented, the patient is taking digoxin, or potassium is in the low-normal range in a patient at risk for prediabetes or diabetes.

ACEI, angiotensin converting enzyme inhibitor; ARB, angiotensin-2 receptor blocker; CCB, calcium channel blocker; CCl, creatinine clearance; GI, gastrointestinal; HDL-C, high-density lipoprotein cholesterol; IV, intravenous.

especially in elderly patients who fear incontinence. Signs and symptoms of metabolic changes, such as hypokalemia, hyperglycemia, or hyperuricemia, should be evaluated. B.A.'s serum potassium has dropped and uric acid has risen. These are small changes that are consistent with thiazide-induced abnormalities. B.A. should be questioned about muscle cramps or weakness, which can be associated with decreases in potassium.

24. Is B.A.'s decrease in potassium concerning? If so, how should this be managed?

Most total body potassium is intracellular (~98%). Thiazide can reduce serum potassium concentrations. This can result in potassium serum concentrations in the low end of the normal range, but overt hypokalemia is not common. Most often, thiazide diuretic-induced hypokalemia is mild, with serum potassium concentrations reaching a nadir within the first month of therapy and generally remaining stable thereafter.^{30,97} HCTZ in doses of 12.5, 25, and 50 mg daily can decrease serum potassium by an average of 0.21, 0.34, and 0.5 mEq/L, respectively.^{23,97}

SUBCLINICAL POTASSIUM DECREASES

The clinical significance of small potassium decreases when serum potassium concentrations are still in the normal range is controversial. B.A.'s potassium has dropped slightly and her current serum concentration is in the low end of the normal range. Patients treated with a thiazide diuretic who experience the greatest decreases in potassium also experience the greatest increases in glucose values.⁹⁸ It is optimal to maintain serum potassium (in milliequivalent per liter [mEq/L]) in the middle to high end of the normal range (e.g., between 4.0 and 5.0 mEq/L in patients treated with thiazide diuretics.⁹⁹ This may minimize the risk, albeit small, of increasing fasting glucose concentrations, and possibly development of type 2 diabetes, which has been demonstrated in patients treated with thiazide diuretics.¹⁰⁰ Keeping serum potassium concentrations in this 4.0 to 5.0 mEq/L range can be accomplished by administering the thiazide diuretic in combination with a potassium-sparing diuretic or an ACEI, ARB, or aldosterone antagonist if additional BP lowering is needed.^{98,99}

B.A.'s BP is still not at goal. Adding either an ACEI or ARB is the most reasonable option to both control her BP and minimize the decrease in potassium. She should be encouraged to continue a low-salt diet. Her potassium and BP should be re-evaluated in 4 weeks.

HYPOKALEMIA

25. When is potassium supplementation needed to manage diuretic-induced hypokalemia?

B.A.'s potassium is still within the normal range. Potassium replacement is not indicated. Diuretic-associated hypokalemia, however, should be treated when serum concentrations are below normal regardless of whether symptoms (weakness and muscle cramps) are present. Serum potassium should be measured at baseline and within 4 weeks of initiating therapy or after increasing diuretic doses. Other conditions, such as chronic diarrhea, high-dose corticosteroid use, and hyperaldosteronism, can contribute to hypokalemia.

Potassium-rich foods (e.g., dried fruit, bananas, potatoes, avocados) may help prevent subclinical decreases in potassium, but they cannot be used as sole therapy to correct hypokalemia. For instance, one medium-size banana has 11.5 mEq of potassium. The usual replacement dose of prescribed potassium chloride is 20 to 40 mEq/day but can range from 10 to more than 100 mEq/day. Potassium chloride, bicarbonate, gluconate, acetate, and citrate salts are available as single ingredients and as components of combination products. Potassium chloride (KCl) preparations are generally preferred, however. Oral potassium supplements are available in liquid, enteric-coated, and slow-release preparations. Slow-release formulations are preferred because they cause fewer gastrointestinal adverse effects than other preparations.

OTHER METABOLIC ABNORMALITIES

26. B.A.'s glucose and uric acid both increased after starting HCTZ. Are these changes clinically significant?

An increase in fasting glucose is a recognized complication of diuretic therapy, but the magnitude of increase is both variable and dose dependent. Patients with diabetes and prediabetes exhibit the greatest glucose increases, and patients without diabetes exhibit the smallest increases. When increases in serum glucose concentration occur in patients without diabetes, they are typically on average 3.6 to 6.7 mg/dL after multiple years of thiazide diuretic therapy.^{30,45,97} It appears that these changes are not clinically relevant because CV events are reduced despite these changes.

Diabetes is not a contraindication to the use of diuretics; rather, it is actually a compelling indication for a diuretic (Fig. 13-3). Risk of CV events is reduced in patients treated with a thiazide who have diabetes.^{5,39,45,75} Altering diet or the dose of diabetes medications can manage hyperglycemia if it occurs in these patients.

B.A. does not have a strong family history of diabetes, and her fasting glucose concentration is still considered normal. Her fasting glucose values should be documented and monitored at least once a year to detect any increases.

Thiazide and loop diuretics can increase serum uric acid concentrations in a dose-dependent fashion. This is more problematic with thiazide diuretics than with loop diuretics. Increased proximal tubular renal reabsorption, decreased tubular secretion, or increased postsecretory reabsorption of uric acid contribute to diuretic-induced hyperuricemia. Thiazide-induced hyperuricemia is usually small (≤ 0.5 mg/dL) and is not clinically significant in most patients.^{23,97} For patients without a history of gout, increases in uric acid serum concentrations are not clinically relevant. For patients with a history of gout, especially those not on preventive antihyperuricemic therapy (allopurinol, probenecid), any increase in serum uric acid usually requires a decrease in dose or possibly discontinuation of the diuretic. If acute gouty arthritis is precipitated, then treatment of gout, discontinuation of the diuretic, or both should be considered. Very few patients have to discontinue a thiazide diuretic secondary to exacerbation of gout.¹⁰¹ A history of gout is not a contraindication to diuretic therapy but is a potentially unfavorable effect. B.A.'s serum uric acid concentration is elevated, but switching to a different agent or

Table 13-11 Reasons for not Attaining Goal Blood Pressure Despite Antihypertensive Pharmacotherapy

| <i>Drug Related</i> | <i>Health Condition or Lifestyle Related</i> | <i>Other</i> |
|--|--|-------------------------------------|
| Nonadherence | Volume overload | Improper blood pressure measurement |
| Inadequate antihypertensive dose | Excess sodium intake | Resistant hypertension |
| Inappropriate antihypertensive combination therapy | Volume retention from chronic kidney disease | |
| Inadequate diuretic therapy | Secondary disease causes (Table 13-3) | |
| Secondary drug-induced causes (Table 13-3) | Obesity | |
| | Excessive alcohol intake | |

lowering the dose of HCTZ is unnecessary because she is not symptomatic.

27. How much will HCTZ alter B.A.'s cholesterol values?

Dyslipidemia is a potential side effect of diuretic therapy. Alterations are characterized by small increases in LDL-C and small increases in triglycerides. Dietary fat restrictions help minimize, but do not necessarily prevent, these effects. Contrary to other biochemical disturbances, diuretic-induced changes in the lipid profile are not dose related, but overall changes are small. Many clinical trials lasting more than 1 year have shown that hypercholesterolemia and hypertriglyceridemia with diuretic therapy is not sustained with prolonged use.^{23,97} Even if these changes are persistent, they are not clinically significant with the doses of thiazide diuretics used for hypertension because the absolute changes are very small. Diuretic therapy should never be avoided in patients with dyslipidemia. B.A. should continue to use her HCTZ.

28. What other metabolic abnormalities should be considered because of B.A.'s thiazide diuretic therapy?

Hyponatremia is a serious, yet infrequent adverse effect of diuretics. Changes in sodium concentrations are usually small, and patients are usually asymptomatic. Decreased renal excretion of free water, inappropriate antidiuretic hormone secretion, urinary sodium loss, and depletion of magnesium and potassium may all contribute to diuretic-induced hyponatremia. Hyponatremia, especially severe hyponatremia (<120 mEq/L), which rarely occurs with diuretic therapy, definitely requires discontinuation of the diuretic when present.

Hypomagnesemia is an often-overlooked metabolic complication of diuretic therapy. Both thiazide and loop diuretics increase urinary excretion of magnesium in a dose-dependent manner. Symptoms of significant hypomagnesemia include muscle weakness, muscle tremor or twitching, mental status changes, and cardiac arrhythmias (including torsades de pointes). Presence of these symptoms would necessitate magnesium supplementation. Hypomagnesemia frequently coexists with hypokalemia. Unless hypomagnesemia is corrected, potassium replacement therapy for hypokalemia can be ineffective, even when high doses of potassium are given.

Thiazide diuretics decrease urinary calcium excretion and have been used to prevent stone formation in patients with calcium-related kidney stones. The resulting systemic retention of calcium does not result in elevated serum calcium concentrations and does not place patients at risk for hypercalcemia. This effect, however, may be beneficial in women at risk for osteoporosis (e.g., postmenopausal) such as B.A. or in patients with osteoporosis. Unlike thiazide diuretics, loop

diuretics increase renal clearance of calcium and are used for acute management of severe hypercalcemia.

Reasons for Inadequate BP Control

29. What are common reasons for inadequate patient response to antihypertensive pharmacotherapy?

The classification of B.A.'s current BP is prehypertension, but this is misleading and not helpful in her treatment at this point. She has uncontrolled hypertension because her BP values are above her goal of <130/80 mmHg. The full antihypertensive effect of HCTZ has been achieved since she has been on her current dose for 4 weeks. She has had a response, but it still is inadequate. Potential reasons for an inadequate response, or lack of attaining BP goal values, with an antihypertensive should be considered before choosing to modify her drug therapy regimen (Table 13-11). Evaluation requires a comprehensive medication history and medical evaluation to rule out identifiable causes, in particular nonadherence to the prescribed dosing regimen. Based on the given information, her BP measurements appear accurate, and the BP reduction she has experienced is typical and predictable. Her kidney function is good and no evidence exists of edema, so volume overload is unlikely. There are no apparent secondary causes of elevated BP. It is reasonable to conclude that B.A. needs additional therapy to achieve her goal BP. It is very common that most patients require two or three antihypertensive agents to attain BP goal values, especially when goal values are <130/80 mmHg.

Modifying Therapy

B.A.'s present dose of HCTZ is appropriate and should not be increased to the maximal recommended dose of 50 mg daily (considered high-dose therapy). An increased risk exists of side effects and minimal to no additional BP lowering occurs when increasing from 25 to 50 mg of HCTZ.^{22,102} B.A.'s potassium dropped to 3.8 mEq/L with HCTZ, and further dosage increases may produce significant hypokalemia (<3.5 mEq/L) requiring supplementation. Her hyperuricemia may also be worsened. Discontinuing HCTZ and starting a different agent is an option, but is not ideal for several reasons. HCTZ lowered her BP; it is known to reduce CV events is inexpensive, and may benefit her osteoporosis. Hypokalemia might lead some clinicians to switch to another agent, possibly because of a higher propensity to increase glucose, but her potassium is still within the normal range, and the addition of an ACEI or ARB will favorably affect her potassium.

Two-Drug Regimens

The role of two-drug regimens in the treatment of hypertension is very clear. Most patients require multiple agents for BP control, especially in populations with BP goals of <130/80 mmHg or lower. Both the JNC7 and AHA guidelines strongly recommend two-drug regimens as initial therapy for patients in stage 2 hypertension, and also cite a two-drug regimen as an option for initial therapy in stage 1 hypertension.^{5,9,65,75}

Adding a second agent to B.A.'s regimen is needed to reduce BP to her goal of <130/80 mmHg. Because she is a primary prevention patient, three potential add-on antihypertensive agents that are considered first-line include an ACEI, ARB, or CCB. Ideally, a combination of two drugs with different mechanisms of action should be selected to produce a complementary effect to lower BP.

COMBINATIONS THAT INCLUDE A THIAZIDE

Thiazide diuretics, when combined with several agents (especially an ACEI, ARB, and even a β -blocker), result in additive antihypertensive effects that are independent of reversing fluid retention. Diuretics reduce BP initially by decreasing fluid volume, but maintain their antihypertensive effects by lowering PVR. BP lowering, however, can stimulate renin release from the kidney and activate the RAAS. This compensatory mechanism is an *in vivo* attempt to neutralize BP changes and regulate fluid loss. An ACEI or an ARB blocks the RAAS, explaining why combinations of these agents with diuretics are additive. One mechanism by which β -blockers reduce BP is by suppressing renin release and activity, resulting in additive BP lowering in combination with a thiazide diuretic. Certain nondiuretic antihypertensive agents (i.e., aliskiren, reserpine, arterial vasodilators, and centrally acting agents) can eventually cause significant sodium retention and increased fluid volume. These agents should ideally be given in combination with a diuretic to maximize BP lowering.

LESS EFFICACIOUS COMBINATIONS

The combination of an ACEI or ARB with a β -blocker provides less additional BP lowering compared with other combination regimens. The primary mechanism of action of an ACEI or ARB is to decrease the effects of angiotensin-2. Less angiotensin-2 is produced when PRA is suppressed by β -blockers. Therefore, if the angiotensin-2-mediated BP effects are suppressed by a β -blocker, adding a β -blocker to an ACEI or ARB might not result in a highly additive effect. Although this combination may not be highly additive, it is often used when multiple conditions or compelling indications require treatment with each of these agents (e.g., hypertension with CAD, left ventricular dysfunction).⁵

Other combinations are only minimally effective at producing significant BP lowering compared with monotherapy. An ACEI in combination with an ARB may be used in left ventricular dysfunction or in patients with certain forms of very advanced chronic kidney disease. Absent these conditions, however, this combination is minimally effective at producing significant BP lowering. Similarly, the use of a dihydropyridine CCB in combination with a nondihydropyridine CCB may lower BP, but the overlapping mechanism of action results in less than ideal reductions in BP. These combinations should be used as last-line alternative combinations when BP reduction is the only purpose for using combination therapy.

FIXED-DOSE COMBINATION PRODUCTS

Several fixed-dose combination products are available (Table 13-12). Although individual dose titration is not easy with fixed-dose combination products, their use can reduce the number of tablets or capsules taken by patients. This can benefit patients by promoting adherence, which may increase the likelihood of achieving or maintaining goal BP values.

Table 13-12 Common Combination Antihypertensive Agents

| Combination Type | Fixed-Dose Combination | Unit Strengths (mg/mg) |
|-----------------------------|---|---|
| ACEI with thiazide diuretic | Benazepril/HCTZ (Lotensin HCT) | 5/6.25, 10/12.5, 20/12.5, 20/25 |
| | Captopril/HCTZ (Capozide) | 25/15, 25/25, 50/15, 50/25 |
| | Enalapril/HCTZ (Vaseretic) | 5/12.5, 10/25 |
| | Lisinopril/HCTZ (Prinzide, Zestoretic) | 10/12.5, 20/12.5, 20/25 |
| | Moexipril/HCTZ (Uniretic) | 7.5/12.5, 15/25 |
| | Quinapril/HCTZ (Accuretic) | 10/12.5, 20/12.5, 20/25 |
| ARB with thiazide diuretic | Candesartan cilexetil/HCTZ (Atacand HCT) | 16/12.5, 32/12.5 |
| | Eprosartan mesylate/HCTZ (Teveten HCT) | 600/12.5, 600/25 |
| | Irbesartan/HCTZ (Avalide) | 150/12.5, 300/12.5, 300/25 |
| | Losartan potassium/HCTZ (Hyzaar) | 50/12.5, 100/12.5, 100/25 |
| | Olmesartan medoxomil/HCTZ (Benicar HCT) | 20/12.5, 40/12.5, 40/25 |
| | Telmisartan/HCTZ (Micardis HCT) | 40/12.5, 80/12.5, 80/25 |
| | Valsartan/HCTZ (Diovan HCT) | 80/12.5, 160/12.5, 160/25, 300/12.5, 300/25 |
| ACEI with CCB | Amlodipine besylate/Benazepril hydrochloride (Lotrel) | 2.5/10, 5/10, 5/20, 10/20, 5/40, 10/40 |
| | Enalapril/Felodipine (Lexxel) | 5/5 |
| | Trandolapril/Verapamil (Tarka) | 2/180, 1/240, 2/240, 4/240 |
| CCB with ARB | Amlodipine/Valsartan (Exforge) | 5/160, 5/320, 10/160, 10/320 |
| | Amlodipine/Olmesartan medoxomil (AZOR) | 5/20, 5/40, 10/20, 10/40 |

ACEI, angiotensin converting enzyme inhibitor; ARB, angiotensin-2 receptor blocker; CCB, calcium channel blocker; HCTZ, hydrochlorothiazide.

Most fixed-dose combinations include a thiazide diuretic and many are available generically. Other fixed-dose combination products combine a CCB with either an ACEI or ARB. These combinations, similar to a thiazide with an ACE or ARB, are highly effective in lowering BP. Use of fixed-dose combination products should continue to increase because the 2007 AHA guidelines recommend lower BP goals for many populations, more combination products are available, and the bottom line is that many patients need multiple agents to attain their BP goal. Clinicians should be comfortable with choosing a fixed-dose combination product in an attempt to simplify regimens and expedite goal achievement. An economic advantage may even exist to using a fixed-dose combination if it allows the patient to receive two drugs for one medication copayment.

B.A. is a candidate for a thiazide-containing fixed-dose combination product. Many options exist because nearly all of these combinations utilize a 12.5 and 25 mg hydrochlorothiazide dose. Cost should be considered because this is a concern for B.A. She has no compelling indications that require selection of a specific second antihypertensive drug class. The most attractive second agent for her is either an ACEI or an ARB. B.A. has no reason to avoid a CCB, and this would be a reasonable second agent. An ACEI or ARB is more reasonable, however, because these agents may blunt some of the potassium loss that she has experienced, and may also delay progression to type 2 diabetes.^{99,100,103} After this second agent is added to her regimen, her BP, serum potassium, and serum creatinine should be reassessed in 2 to 4 weeks.

Step-Down Therapy

30. T.J., a 58-year-old man has a 10-year history of hypertension. He has been treated with lisinopril/hydrochlorothiazide 20/25 mg daily and amlodipine 10 mg daily for more than 2 years and his BP has been well controlled during this time. He has no compelling indications for specific antihypertensive agents and has no hypertension-associated complications. His Framingham risk score is 18% and his BP is 118/74 and 116/72 mmHg. He denies any problems, dizziness, or difficulties with his medications. Should his antihypertensive therapy be changed to reduce his medication doses and/or possibly discontinue some of his medications?

Few patients with hypertension can later have their BP medications slowly withdrawn, resulting in normal BP values for weeks or months following discontinuation of their medications. This is called *step-down therapy*. It is not a feasible option for most patients with hypertension. Primary prevention patients with a goal BP <140/90 mmHg who have very well-controlled BP for at least 1 year might be eligible for a trial of step-down therapy. This option should not be considered for patients who have a Framingham risk score $\geq 10\%$, compelling indications, or hypertension-associated complications.

Step-down therapy consists of attempting to gradually decrease the dosage, number of antihypertensive drugs, or both without compromising BP control. Abrupt or large dosage reductions should be avoided because of the risk of rapid return of uncontrolled blood pressure and even rebound surges in blood pressure. In particular, rapid withdrawal of a β -blocker or an α_2 -agonist (e.g., clonidine) can be problematic owing

to increased receptor sensitivity following long-term receptor up-regulation (see Question 60).

Step-down therapy is most often plausible for patients who have lost significant amounts of weight or have drastically changed their lifestyle. Any attempt at step-down therapy must be accompanied by scheduled follow-up evaluations because BP values can rise over months to years after drug discontinuation, especially if lifestyle modifications are not maintained.

Step-down therapy in T.J. is not an option. Although he does not have compelling indications or hypertension-associated complications, he is considered a high CV risk primary prevention patient based on his Framingham risk score. Although his BP might be viewed as “low,” he does not have symptomatic hypotension, and his BP is considered normal.

ACEI

31. A.R. is a 49-year-old black woman with type 2 diabetes mellitus. She started lisinopril 10 mg daily 4 weeks ago when her BP values were consistently in the high end of the stage 1 hypertension range (156/98 mmHg). Since then, she has had weekly BP measurements and her values have averaged 142/85 mmHg despite strict adherence to her lifestyle modifications. Her BP today is 144/84 mmHg (140/88 when repeated), and her heart rate is 78 beats/minute. She is not a smoker, and her BMI is 29 kg/m² (considered overweight). Her latest hemoglobin A1C was 8.5% (goal for diabetes is <7%). All her laboratory test results, including kidney function, are within normal limits, except that her spot urine albumin-to-creatinine ratio is 80 mg/g (4 weeks ago it was 90 mg/g). How long should A.R. take lisinopril before her BP response is evaluated?

The ACEI lower BP primarily by causing peripheral arterial vasodilation without significant changes in cardiac output, heart rate, or GFR. The principal activity of an ACEI is through inhibition of the RAAS. ACEIs are believed to provide unique CV benefits by improving endothelial function, promoting LVH regression and collateral vessel development, and improving insulin sensitivity.^{104,105} The effects on renal blood flow and glomerular filtration are complex, depending on sodium balance and if renal artery stenosis is present.

Pharmacotherapy Considerations

Several ACEIs are currently marketed for the management of hypertension (Table 13-13). Some agents are primarily renally eliminated (benazepril, enalapril, lisinopril, quinapril, ramipril); others have mixed hepatic and renal elimination (captopril, fosinopril, perindopril, trandolapril), and moexipril is almost completely hepatically eliminated. These characteristics may be important when selecting a product in patients with unstable organ function. Other differences, such as a slower rate of elimination, a longer duration of action, prolonged onset of action with prodrugs, and a slower dissociation from binding sites, have been described. These differences, however, have not been shown to have major clinical importance.

The time to reach steady-state BP conditions is similar to what is seen with other antihypertensive agents. Following the initiation of therapy, it may take several weeks before the full antihypertensive effects of these drugs are observed. Therefore, evaluating BP response 2 to 4 weeks after starting or

Table 13-13 ACEI in Hypertension

| Drug | Usual Starting Dose ^a (mg/day) | Usual Dosage Range (mg/day) | Dosing Frequency |
|--------------------------------|---|-----------------------------|------------------|
| Benazepril (Lotensin) | 10 | 20–40 | Daily to BID |
| Captopril (Capoten) | 25 | 50–100 | BID to TID |
| Enalapril (Vasotec) | 5 | 10–40 | Daily to BID |
| Fosinopril (Monopril) | 10 | 20–40 | Daily |
| Lisinopril (Prinivil, Zestril) | 10 | 20–40 | Daily |
| Moexipril (Univasc) | 7.5 | 7.5–30 | Daily to BID |
| Perindopril (Aceon) | 4 | 4–16 | Daily |
| Quinapril (Accupril) | 10 | 20–80 | Daily to BID |
| Ramipril (Altace) | 2.5 | 2.5–20 | Daily to BID |
| Trandolapril (Mavik) | 1 | 2–4 | Daily |

^aStarting dose may be decreased 50% if patient is volume depleted, in acute heart failure exacerbation, or are very elderly (≥ 75 yrs).

ACEI, angiotensin converting enzyme inhibitor; BID, twice daily; TID, three times daily.

changing the dose of an ACEI is appropriate. A.R. has been taking lisinopril for 4 weeks, and her present BP should be used to determine whether she has attained goal. Both her BP range over the past few weeks and today's average BP are above her goal of $<130/80$ mmHg (because she has diabetes).

Most ACEI are dosed once daily in hypertension (Table 13-13). Captopril is the only one for which at least twice daily dosing is needed. In general, most ACEI, if used in equivalent doses, are considered interchangeable.

32. Why should A.R. have serum potassium and serum creatinine monitored while on lisinopril therapy?

The ACEI can increase serum potassium as a result of aldosterone reduction. Potassium increases with ACEI monotherapy are very small and typically do not result in hyperkalemia. This risk is increased, however, when used in patients with significant chronic kidney disease (estimated GFR <60 mL/minute/ 1.73 m²), or when used in combination with other drugs that can also raise potassium (i.e., an ARB, potassium-sparing diuretics, aldosterone antagonists). ACEI therapy can also cause a small increase in serum creatinine, owing to decreased vasoconstriction of the efferent arteriole in the kidney. This results in a small decrease in GFR that may be realized as a small increase in serum creatinine. One common mistake is to discontinue an ACEI when there is a modest rise in serum creatinine. Increases in serum creatinine of up to 35% from the baseline creatinine value are safe and anticipated. In these patients, the ACEI should be continued because they are more likely to benefit from the renal protective effects.⁷⁵ An ACEI can, however, also cause acute renal compromise (primarily in a small subset of patients with bilateral renal artery stenosis). In these patients, the increase in serum creatinine will be much greater than 35% and would necessitate discontinuing ACEI therapy.

Serum potassium and serum creatinine need to be monitored because of A.R.'s ACEI therapy. This should be done 2 to

4 weeks after starting ACEI therapy or increasing the dose. This is the same time frame at which BP should also be measured.

33. A.R.'s lisinopril dose is increased to 20 mg daily. Although A.R. did not experience hypotension when she first started lisinopril, will this doubling of her dose place her at risk for significant hypotension?

Patients who are either very elderly, volume depleted, or have a heart failure exacerbation may experience a significant first-dose response to an ACEI. This can manifest as orthostatic hypotension, dizziness, or possibly syncope. The increased pretreatment activity of the RAAS, coupled with acute blockade of this system by an ACEI, explains this effect. These patients should initiate ACEI therapy at half the normal dose (Table 13-13), and be slowly titrated up to standard doses.

Concurrent diuretic therapy may predispose some patients to first-dose hypotension. When ACEIs were first approved, dosing guidelines recommended starting at half the standard dose of the ACEI, decreasing the dose of the diuretic, or stopping the diuretic before initiating the ACEI. This was owing to fear that BP would sharply and acutely drop. These recommendations are not necessary unless the patient is hemodynamically unstable (volume depleted, hyponatremic, or poorly compensated heart failure), or very elderly. A.R. does not have any of these characteristics; thus, she did not experience first-dose hypotension. Currently, she does not have these characteristics and can safely increase her dose of lisinopril without fear of significant hypotension.

34. Will an ACEI work in A.R. because she is black?

ACEI monotherapy is more effective at lowering BP in young white patients than in black or elderly patients.³⁰ Elderly and black patients are more likely to have low renin hypertension, which may partially explain some of the differences in response. Nevertheless, many of these patients still respond to ACEI as monotherapy. Combination therapy, especially with a diuretic, can often overcome the race- or age-related differences in BP response to an ACEI. In patients whose conditions do not adequately respond to an ACEI, the addition of a low-dose diuretic (e.g., HCTZ 12.5 mg) can significantly enhance the antihypertensive effect.²⁴ Thiazide diuretic use results in compensatory increases in renin. An ACEI in combination with a thiazide is considered a very additive antihypertensive combination through complementary mechanisms.

When an antihypertensive agent is being selected as initial monotherapy in a primary prevention black patient, an ACEI should generally not be chosen. A thiazide diuretic or CCB is preferred. If a compelling indication, such as left ventricular dysfunction, diabetes, or chronic kidney disease is present, an ACEI is a drug of choice. When selecting initial combination therapy in a primary prevention black patient, a combination of an ACEI with either a thiazide or a CCB can be selected. Of note, black patients have a two- to four-fold increased risk of angioedema and cough compared with whites.⁴⁵ Although this does not preclude ACEI use in black patients, it requires patient education regarding these potential side effects.

A.R. should not be treated as a primary prevention patient. She has type 2 diabetes mellitus, which is a compelling indication for an ACEI. She also has microalbuminuria, which further justifies ACEI use as a first-line therapy. A.R. is also

above her goal BP of <130/80 mmHg. Although an ACEI is ideal treatment, a monotherapy approach is not expected to get her to goal. She has had some BP reduction from lisinopril, and the dose could be increased to the maximum, but she will likely require the addition of a second agent, preferably a thiazide diuretic (Fig. 13-3).

Compelling Indications

Angiotensin-converting enzyme inhibitor therapy is recommended for all compelling indications, either as first-line therapy or as a component of sequential add-on therapy. Evidence has clearly demonstrated reduction in hypertension-associated complications in patients with these medical conditions. ACEIs are also useful as a first-line treatment option for primary prevention patients, including those who may not adequately respond to other therapies, or those who cannot take other first-line agents owing to contraindications or adverse reactions (e.g., patients with asthma, gout).

DIABETES

Angiotensin-converting enzyme inhibitor therapy is strongly recommended first-line to manage hypertension in diabetes based on evidence showing reduced hypertension-associated complications, including CV events and kidney disease.^{5,72} In particular, a substudy of the Heart Outcomes Prevention Evaluation (HOPE) study showed that in 3,577 patients with diabetes, ramipril significantly reduced CV events and overt nephropathy.⁵⁰ Additional clinical trials' data have demonstrated that the combination of an ACEI with a thiazide diuretic significantly reduces the risk of major CV events and death in patients with type 2 diabetes and hypertension.¹⁰⁶ These data further reinforce the role of ACEI in patients with diabetes and hypertension, and also the benefits of combination therapy in this population.

An added benefit of ACEI in diabetes is that they do not have metabolic adverse effects on glucose as may other agents. Moreover, the favorable effects on insulin resistance result in a lower risk of progressing to type 2 diabetes in patients with hypertension who do not have diabetes, when compared with thiazide diuretics, a CCB or β -blockers.¹⁰³

CHRONIC KIDNEY DISEASE

The ACEI protect the kidney from the unrelenting deterioration that occurs with chronic kidney disease, hypertension, and diabetes.^{5,72,75} Therefore, these agents are first-line options in chronic kidney disease. Chronic kidney disease is characterized by increased intraglomerular pressure and mesangial cell proliferation, which leads to proteinuria and a progressive decline in kidney function. Reductions in renal blood flow cause the kidneys to increase renin release, thus activating the RAAs. This action constricts the efferent renal arteriole to preserve glomerular pressure, but may aggravate further renal impairment.

The ACEI preferentially dilate the efferent arteriole, which relieves intraglomerular pressure. Data suggest that ACEI may have unique renal preservation properties, making chronic kidney disease a compelling indication for ACEI therapy. Some of the risk reduction is also related to systemic BP lowering.²⁶

Patients with diabetes are at risk for nephropathy. This is especially true in type 1 diabetes. Evidence indicates that ACEI therapy reduces progression to severe chronic kidney

disease and kidney failure in patients with type 1 diabetes and proteinuria.⁷⁶ ACEI therapy also reduces worsening of proteinuria in patients with type 2 diabetes and proteinuria,⁷⁵ but evidence showing progression to severe chronic kidney disease or failure is not available. Nonetheless, ACEI therapy is considered highly effective and is strongly recommended as a compelling indication in both type 1 and type 2 diabetes.

CHRONIC AND ACUTE CAD

Angiotensin-converting enzyme inhibitor therapy is recommended first-line treatment in all patients with chronic CAD (post-MI, chronic stable angina) and acute CAD (non-ST-segment elevation MI, ST-segment elevation MI).^{36,78,84,85} This is in addition to β -blocker therapy. The benefits of ACEI therapy in patients with CAD is a reduced risk of CV events that is independent of both LV function and BP. ACEI therapy will not provide anti-ischemic effects. Therefore, the role of ACEI therapy in CAD is as an add-on to a β -blocker to reduce CV risk, but not to treat underlying ischemic symptoms.

PRIOR STROKE

The perindopril protection against recurrent stroke study (PROGRESS) was a double-blind, placebo-controlled evaluation of an ACEI in combination with a thiazide diuretic for 4 years in 6,105 patients with a history of stroke or transient ischemic attack.⁴⁶ Hypertensive and nonhypertensive patients were included. The incidence of stroke and total major vascular events were significantly reduced with the combination regimen, and reductions were seen regardless of baseline BP or reduction in BP. These data justify the compelling indication to use an ACEI (in combination with a thiazide diuretic) to reduce recurrence of stroke in patients who have had a stroke.

LEFT VENTRICULAR DYSFUNCTION

Angiotensin-converting enzyme inhibitors reduce morbidity and mortality in patients with left ventricular dysfunction.⁸⁶ Standard therapy for left ventricular dysfunction consists of a diuretic with an ACEI followed by the addition of a β -blocker. Although either an ARB or an aldosterone antagonist can reduce morbidity and mortality in patients with left ventricular dysfunction, either one of these agents may ideally be used in addition to standard therapy. Therefore, ACEI with diuretic therapy is the first-line intervention in patients with hypertension with left ventricular dysfunction. In general, the CV benefit of ACEI therapy in left ventricular dysfunction is considered a class effect, and ACEI are used interchangeably at equivalent dosages in these patients.⁹

Other Considerations

Although an ACEI may not lower BP as well in elderly patients as in young patients, this is also true for black patients when compared with white patients. BP lowering, however, is only a surrogate marker of overall effectiveness of antihypertensive agents. The ability of an ACEI to reduce CV events appears to be equal across all of these patient populations.⁴⁸ Therefore, the overall tendency to avoid ACEI therapy because it might not be as effective in lowering BP should not be a consideration in selecting therapy when an ACEI is compellingly indicated in an elderly patient or in a black patient. This should be a consideration when selecting initial monotherapy to treat hypertension in a primary prevention patient who is either elderly

or black; a thiazide diuretic or CCB would be a better initial agent as monotherapy than an ACEI (or ARB) with respect to BP lowering. When an ACEI (or ARB) is used in combination with a thiazide diuretic or CCB, however, the differences in BP lowering are less apparent because the additive antihypertensive effect of using these combinations neutralizes any differences in response that are based on age or race.⁶⁴

35. A.R. has microalbuminuria based on her spot urine. ACEI therapy may help preserve her kidney function, but is there a risk that ACEI can also cause acute renal dysfunction?

The ACEIs are effective in patients with hypertension-associated renal disease. They are contraindicated, however, in bilateral renal artery stenosis, pregnancy, and volume depletion (Table 13-10). They should be used cautiously in patients who have suspected bilateral renal artery stenosis, or in those who have stenosis in a solitary kidney after nephrectomy. In these patients, high angiotensin concentrations maintain renal blood flow. Acute renal dysfunction can occur when an ACEI is started. Because it is often not known if a patient has bilateral renal artery stenosis, problems with ACEI can be minimized by starting with recommended doses and careful monitoring of serum creatinine within 4 weeks of starting therapy. Modest elevations in serum creatinine that are <35% (for baseline creatinine values <3.0 mg/dL) do not warrant changes.⁷⁵ These changes might even be expected in some patients. If greater increases occur, ACEI therapy should be stopped. Patients with elevated serum creatinine at baseline (up to 3.0 mg/dL) may particularly benefit from the vasodilatory effects of ACEI in the kidney, but definitely require close monitoring. A.R.'s renal function tests were normal after 4 weeks of lisinopril therapy. She is not experiencing any kidney-related adverse effects from lisinopril.

36. What are the risks of using ACEIs in women of childbearing age?

Because ACEI are teratogenic in the second and third trimester,¹⁰⁷ their use in pregnancy is contraindicated. Moreover, their use in women of child-bearing potential is discouraged. If used in this population, patient education should be explicitly clear regarding risks to the fetus, which include potentially fatal hypotension, anuria, renal failure, and developmental deformities. A highly effective form of contraception should be strongly recommended.

ARB

37. Four weeks after increasing lisinopril to 20 mg daily, A.R.'s BP is 126/78 mmHg (128/76 mmHg when repeated). Her serum potassium and creatinine are unchanged from previous values. Her husband states, however, that she has had a persistent dry cough for the past few months that sometimes keeps them both awake at night. She has no additional signs suggesting upper respiratory infection or left ventricular dysfunction. Should A.R.'s lisinopril be replaced with an ARB?

A well-known side effect of ACEI is a nonproductive, dry cough, which can occur in up to 15% of patients.¹⁰⁸ Patients may describe this as a tickling sensation in the back of the throat that commonly occurs late in the evening. This is distinctly different from the cough associated with left ventricular

Table 13-14 ARB in Hypertension

| Drug | Starting Dose ^a (mg/day) | Usual Dosage Range (mg/day) | Dosing Frequency |
|---------------------------------|-------------------------------------|-----------------------------|------------------|
| Candesartan cilexetil (Atacand) | 16 | 8–32 | Daily to BID |
| Eprosartan mesylate (Teveten) | 600 | 600–800 | Daily to BID |
| Irbesartan (Avapro) | 150 | 75–300 | Daily |
| Losartan potassium (Cozaar) | 50 | 25–100 | Daily to BID |
| Olmesartan medoxomil (Benicar) | 20 | 20–40 | Daily |
| Telmisartan (Micardis) | 40 | 20–80 | Daily |
| Valsartan (Diovan) | 80–160 | 80–320 | Daily |

^a Starting dose may be decreased 50% if patient is volume depleted, very elderly, or taking a diuretic.

ARB, angiotensin-2 receptor blocker; BID, twice daily; TID, three times daily.

dysfunction, which is associated with crackles and rales (on auscultation) that may be wet and productive. ACEI-related cough subsides with discontinuation. Many agents have been used to treat an ACEI cough with poor results. The best treatment option for a patient with an intolerable ACEI cough is to switch agents. For A.R., switching to an ARB would likely eliminate the dry cough and still be considered an acceptable first-line treatment option for her hypertension considering her history of diabetes.^{9,72} ARB therapy would also have similar benefits to an ACEI considering her microalbuminuria.

ARBs are considered first-line options for primary prevention patients and have data demonstrating reductions in CV events.^{9,20,22} Seven of these agents are commercially available as brand-name only products (Table 13-14). Fixed-dose combination products with HCTZ are also available (Table 13-12).

38. How exactly do ACEIs and ARBs differ in regard to their mechanism of action?

Pharmacologic Differences between an ACEI and an ARB

Unlike ACEIs, ARBs specifically bind to angiotensin-2 receptors in vascular smooth muscle, adrenal glands, and other tissues. As a result, access of angiotensin-2 to its receptors is blocked and angiotensin-2–mediated vasoconstriction and aldosterone release is prevented, resulting in BP reduction. Reduction in intraglomerular blood flow and pressure is mediated by angiotensin-2 actions in the efferent arteriole of the kidney. ARBs do not affect bradykinin, therefore dry cough does not occur.

Considerable investigation has focused on describing the pharmacologic differences between the angiotensin-2 type 1 and type 2 receptors. Stimulation of the type 1 receptor causes vasoconstriction, salt and water retention, and vascular remodeling. Other deleterious effects from type 1 receptor stimulation include myocyte and smooth muscle hypertrophy, fibroblast hyperplasia, cytotoxic effects in the myocardium, altered gene expression, and possible increased concentrations of plasminogen activator inhibitor. Stimulation of the type 2 receptor results in antiproliferative actions, cell differentiation, and tissue repair when stimulated.

Theoretically, an ideal antihypertensive agent would block only type 1 and not type 2 receptors as is the case with currently marketed ARBs. Therefore, it is possible that an ARB would be superior to an ACEI in reducing hypertension-associated complications because ACEIs ultimately decrease stimulation of both type 1 and type 2 receptors by decreasing production of angiotensin-2. This argument is purely speculative and is not supported by clinical trial data. The Ongoing Telmisartan Alone and in Combination with Ramipril Global Endpoint Trial (ONTARGET) was a prospective, double-blind, randomized controlled trial that directly compared ARB and ACEI therapy.¹⁰⁹ After a median of 56 months, the incidence of CV events was similar with both treatments. Therefore, as a class, ARBs are as effective as other antihypertensive agents for BP lowering. Similar to ACEI, combinations with a thiazide diuretic are highly efficacious in lowering BP.

Compelling Indications

39. Under what circumstances would an ARB be a better initial antihypertensive agent than an ACEI?

DIABETES

Patients with diabetes should be treated with either an ACEI or ARB. ARB-based treatment regimens have been shown in clinical trials to reduce the progression of diabetic nephropathy.⁷² These benefits are similar to what is seen with ACEI, but only among patients with type 2 diabetes who have microalbuminuria. ARB-based therapy contains the only antihypertensive agents for which evidence shows reduced kidney failure in patients with type 2 diabetes who have diabetic nephropathy with albuminuria (not microalbuminuria) and elevated serum creatinine.⁵⁶ Therefore, for patients with type 2 diabetes and advanced nephropathy, evidence supports ARB therapy as the primary antihypertensive agent, ahead of ACEI therapy.

CHRONIC KIDNEY DISEASE

An ARB, similar to an ACEI, minimizes damage that occurs with chronic kidney disease. Both ACEIs and ARBs preferentially dilate the efferent arteriole, which relieves intraglomerular pressure. Thus, chronic kidney disease is a compelling indication for ARB therapy. For nondiabetic kidney disease, less evidence supports ARB use, and these agents should be reserved as alternatives to an ACEI.

CHRONIC AND ACUTE CAD

Angiotensin receptor blocker therapy is a reasonable alternative to ACEI therapy in patients with CAD. Data are very limited, however. For patients post-MI, ARB therapy has been evaluated, and is an option for patients with intolerable side effects from an ACEI. For patients with chronic stable angina or acute coronary syndromes, long-term data evaluating effects on CV events are not available.

PRIOR STROKE

Angiotensin receptor blocker therapy is an evidence-based alternative to the combination of an ACEI with a thiazide diuretic in patients with a history of ischemic stroke or transient ischemic attack. In the Morbidity and Mortality after Stroke Eprosartan Compared with Nitrendipine for Secondary Prevention (MOSES) study, ARB-based therapy reduced the in-

cidence of recurrent stroke more than dihydropyridine CCB-based therapy in a large number of patients with cerebrovascular disease.⁶³ Based on these data, prior stroke (ischemic stroke) is a compelling indication for ARB therapy.

LEFT VENTRICULAR DYSFUNCTION

Pharmacologic blockade of the renin-angiotensin-aldosterone system in left ventricular dysfunction is of paramount importance. An ARB is a reasonable alternative in patients with hypertension and left ventricular dysfunction who cannot tolerate an ACEI (e.g., those who experience cough).⁹³ They should, however, never be empirically used in place of an ACEI, because ACEI therapy is considered superior to ARB therapy in patients with left ventricular dysfunction.⁸⁶ As sequential add-on therapy for patients with left ventricular dysfunction who are already treated with the standard regimen of a diuretic with an ACEI and β -blocker, ARB therapy has been proved to reduce risk of CV events.⁹⁴ Clinicians should be aware that if an ARB is used in combination with an ACEI, a significant increase in risk of side effects exists, particularly hyperkalemia.^{109,110}

Other Considerations

ARB VERSUS ACEI

Monitoring requirements, contraindications, and side effects (other than cough) are the same for ARBs and ACEIs. Because of the potential hyperkalemia and acute renal dysfunction, serum creatinine and potassium should be monitored. Both drug classes are contraindicated in pregnancy and in patients with bilateral renal artery stenosis or volume depletion. Acute hypotension is possible when starting ARB therapy in patients with hyponatremia, volume depletion, or left ventricular dysfunction exacerbation.

40. If A.R. experienced angioedema from lisinopril, would treatment with an ARB be contraindicated?

A history of ACEI angioedema is not a contraindication to ARB therapy. The cross-reactivity between angioedema with an ACEI and ARB is not exactly known. The best available data come from the Candesartan in Heart Failure: Assessment of Reduction in Mortality and Morbidity (CHARM)-alternative study where 39 patients with left ventricular dysfunction and a history of ACEI angioedema were treated long term with ARB therapy.⁹³ Only one of these patients experienced repeat angioedema that required discontinuation of the ARB. This small cross-reactivity rate has been demonstrated in other evaluations.¹¹¹ Therefore, cross-reactivity appears possible, but unlikely.

When the benefits of an agent that blocks the RAAS is needed (e.g., left ventricular dysfunction, diabetes, chronic kidney disease), an ARB is a reasonable alternative for patients with ACEI angioedema. The ACC/AHA guidelines recommend an ARB in patients who have experienced angioedema from an ACEI.⁸⁶ Nonetheless, patients with a history of ACEI angioedema should be counseled regarding the small potential for recurrent angioedema if treated with an ARB.

CCB

41. How do dihydropyridine CCB differ from the nondihydropyridine CCB, verapamil and diltiazem?

Table 13-15 Pharmacologic Actions of CCB

| | Nondihydropyridines | | Dihydropyridines |
|-----------------------------------|---------------------|-----------|------------------|
| | Verapamil | Diltiazem | |
| Peripheral vasodilation | + | + | ++ |
| Heart rate | --- | - | + |
| Cardiac contractility | --- | - | 0/- ^a |
| Atrioventricular nodal conduction | - | - | 0 |
| Coronary blood flow | + | + | ++ |

^aNo significant decreases are seen with amlodipine or felodipine.

+, increase; ++, marked increase; -, decrease; ---, marked decrease; 0, no change. CCB, calcium channel blocker.

Calcium channel blockers are very effective in lowering BP. Elderly and black patients have greater BP reduction with a CCB than with other agents (β -blockers, ACEIs, ARBs). The addition of a diuretic to a CCB provides additive antihypertensive effects. CCBs do not alter serum lipids, glucose, uric acid, or electrolytes and they do not aggravate asthma or peripheral vascular disease.

A heterogeneous drug class, all CCBs inhibit the movement of extracellular calcium, but there are two primary subtypes: dihydropyridines and nondihydropyridines (i.e., diltiazem and verapamil). Each has distinctly different pharmacologic effects that are summarized in Table 13-15.

Dihydropyridines

Dihydropyridines are potent vasodilators of peripheral and coronary arteries. They do not block atrioventricular (AV) nodal conduction and do not effectively treat arrhythmias. Moreover, the potent vasodilation associated with most dihydropyridines can induce a reflex tachycardia. With the exception of amlodipine and felodipine, dihydropyridines can de-

crease cardiac contractility and should be avoided in patients with left ventricular dysfunction. Side effects of dihydropyridines are related to their potent vasodilatory effects, such as reflex tachycardia, headache, flushing, and peripheral edema.

Nondihydropyridines

The nondihydropyridines, diltiazem and verapamil, are similar. Relative to dihydropyridines, they are only moderately potent vasodilators, but they directly decrease AV nodal conduction and have negative inotropic actions. The blockade of AV nodal conduction can slow heart rate and is the basis for their use in treating supraventricular arrhythmias (e.g., atrial fibrillation). Most patients only have a modest decrease in heart rate. However, heart block (first-, second-, or third-degree) is a potential adverse effect, especially with large doses.

Verapamil and diltiazem are considered safe and effective antihypertensives. Both should be avoided in patients with second- or third-degree heart block. Under these circumstances, a dihydropyridine can be used if a CCB is needed. Verapamil and diltiazem should also be avoided in patients with left ventricular dysfunction because they can significantly reduce cardiac contractility. Diltiazem has a lower incidence of constipation than verapamil.

Formulations

Several CCB are available for the treatment of hypertension. They are listed in Table 13-16.

IMMEDIATE-RELEASE NIFEDIPINE

42. A 68-year-old man has a new prescription for immediate-release nifedipine 10 mg three times daily for newly diagnosed hypertension. He has no contraindications to CCB therapy. Why should immediate-release nifedipine not be used to treat his hypertension?

Most dihydropyridines, except amlodipine, are formulated as sustained-release products to provide 24-hour effects.

Table 13-16 CCB in Hypertension^a

| Drug | Usual Dosage Range (mg/day) | Dosing Frequency |
|--|-----------------------------|------------------|
| Nondihydropyridines^b | | |
| Diltiazem, sustained-release (Cardizem CD, Cartia XT, Dilacor XR, Dilt-CD, Diltia XT, Taztia XT, Tiazac) | 120–480 | Daily |
| Diltiazem, extended-release (Cardizem LA) ^c | 120–540 | Daily |
| Verapamil, sustained-release (Calan SR, Isoptin SR, Verelan) | 180–480 | Daily to BID |
| Verapamil, controlled-onset extended-release (Covera HS) ^c | 180–480 | QHS |
| Verapamil, chronotherapeutic oral drug absorption system (Verelan HS) ^c | 100–400 | QHS |
| Dihydropyridines | | |
| Amlodipine, immediate-release tablet (Norvasc) | 2.5–10 | Daily |
| Felodipine, extended-release tablet (Plendil) | 2.5–10 | Daily |
| Isradipine, controlled-release tablet (DynaCirc CR) | 5–20 | Daily |
| Nicardipine, sustained-release capsule (Cardene SR) | 60–120 | BID |
| Nifedipine, sustained-release ^d tablet (Procardia XL, Adalat CC) | 30–90 | Daily |
| Nisoldipine, extended-release tablet (Sular) | 17–34 | Daily |

^aImmediate release (IR) diltiazem, nifedipine, and verapamil should be avoided in hypertension.

^bMany long acting products exist, but vary in release characteristics. Thus, they are not directly interchangeable using a mg/mg conversion.

^c“Chronotherapeutic” agents; because they use different delivery systems, they are not interchangeable products.

^dOnly sustained-release nifedipine is approved for hypertension. Immediate release should be avoided.

BID, twice daily; QHS, every night; CCB, calcium channel blocker.

Nifedipine has a very short half-life, and is available as an immediate-release capsule. It was once used to quickly reduce BP in hypertensive urgencies, but it should never be used for this indication. Immediate-release nifedipine, given sublingually or orally, has been associated with several adverse effects such as severe hypotension, cerebral ischemia, acute MI, fetal distress, conduction abnormalities, and even death. The rapid and potent hypotensive effect can “steal” blood flow from coronary arteries, induce reflex tachycardia, and acutely decrease cardiac contractility. Immediate-release nifedipine is not approved for the treatment of hypertension, and the Cardiovascular Advisory Panel of the U.S. Food and Drug Administration (FDA) concluded that the use of immediate-release nifedipine is neither safe nor efficacious.¹¹² Immediate-release dihydropyridines that are short acting, especially nifedipine, should be avoided. Even with verapamil and diltiazem, once-daily, sustained-release formulations are preferred for hypertension.

SUSTAINED-RELEASE FORMULATIONS

43. C.F. is a 60-year-old man with a history of hypertension, asthma, and type 2 diabetes. His hypertension has been treated with HCTZ 25 mg daily, controlled-onset, extended-release verapamil 240 mg daily (Covera HS), and ramipril 10 mg daily for the past 5 years. Today his BP is 124/74 mmHg (128/72 mmHg when repeated), and his heart rate is 64 beats/minute. C.F. is interested in a generic alternative for his controlled-onset, extended-release verapamil, such as sustained-release verapamil. What are the differences between these two verapamil products, and are they interchangeable?

All CCBs have short half-lives, except amlodipine. Immediate-release forms require multiple daily doses to provide 24-hour effects. Sustained-released formulations are preferred when a CCB is used to treat hypertension. Various sustained-release delivery devices are available. Serum drug concentrations differ between sustained-release CCBs, but the overall BP-lowering effects are usually similar. Nonetheless, most of these products that include the same drug are not AB rated by the Food and Drug Administration (FDA) as equivalent and identical. Insurance formularies often require therapeutic substitution between these agents. Therapeutic interchange with sustained-release diltiazem products or with chronotherapeutic verapamil, however, are not equivalent using a milligram-per-milligram conversion. Therapeutic substitution between these products may result in variable BP-lowering effects if not adjusted appropriately. BP and heart rate monitoring should occur within 2 weeks of interchanging sustained-release CCBs.

CHRONOTHERAPEUTIC CCB

Blood pressure has a predictable circadian rhythm characterized by a sharp rise in pressure starting in the early morning, peaking in the mid to late morning, followed by a gradual decrease to lowest values during early to mid-nighttime. Importantly, MI incidence also has a circadian rhythm in which events are most frequent during the time of the early morning BP surge. Chronopharmacology is the concept of recognizing circadian rhythms of disease and targeting drug delivery to blunt such rhythms. The prevailing assumption is that targeting

BP reduction according to the circadian rhythm can maximally reduce the risk of CV events.

Two sustained-release verapamil products (Covera HS and Verelan PM) and one verapamil product (Cardizem LA) are chronotherapeutically designed to target the circadian BP rhythm. These formulations are dosed primarily at bedtime, have a delayed drug release for a period of hours, followed by slow delivery of drug that starts just before the morning BP surge, with no delivery during the early evening. The two verapamil products use different delivery devices and are not interchangeable with each other or other long-acting verapamil products, using a milligram-to-milligram conversion. Cardizem LA is similarly not interchangeable with other long-acting diltiazem products. Therapeutic substitution between products must involve close monitoring.

The scientific rationale supporting chronotherapy in hypertension is only hypothetical. Evidence from the Controlled Onset Verapamil Investigation of Cardiovascular Endpoints (CONVINCE) trial shows that chronotherapeutic verapamil is similar, but not better than, a thiazide diuretic- or β -blocker-based regimen in reducing hypertension-associated complications.⁴³ C.F. has achieved his goal BP of <130/80 mmHg with his present verapamil product. It is ideal to continue using this product. If a switch occurs, however, his present verapamil 240 mg daily should be changed to sustained-release generic verapamil 240 mg daily. This conversion requires BP and heart rate monitoring in 2 weeks to detect whether BP remains controlled after the switch, because these two products are not identical and are not AB rated as interchangeable.

Compelling Indications DIABETES

44. Why is diabetes a compelling indication for a CCB?

Calcium channel blockers are recommended as options to treat hypertension in patients with diabetes because they have been shown to reduce risk of CV events.^{5,72} They do not affect glucose. Evidence showing reduced CV events with CCB in patients with diabetes is not, however, as convincing as that seen with an ACEI, ARB, or thiazide diuretics. The results of the Fosinopril versus Amlodipine Cardiovascular Events Randomized Trial (FACET) and Appropriate Blood pressure Control in Diabetes (ABCD) trial suggest that ACEI have more CV protection than CCB.^{53,54}

Nondihydropyridine CCB (particularly diltiazem) may slow the progression of chronic kidney disease, although evidence is not as extensive or definitive as it is with an ACEI or ARB. The proposed mechanism is dilation of the afferent and efferent arterioles, which would decrease intraglomerular pressure. Dihydropyridines have unclear effects on progression of kidney disease. The prevailing opinion is that the renal protective effects of an ACEI and ARB are superior to a CCB.

The primary role of a CCB in the management of hypertension in diabetes is ideally as a component of sequential add-on therapy, after an ACEI or ARB and a thiazide diuretic. Because the BP goal in diabetes is <130/80 mmHg, most patients with diabetes need three or more antihypertensives to achieve this goal. A CCB is frequently needed in this population.

CHRONIC CAD

45. A.P. is a 71-year-old man with a BP of 168/90 mmHg (170/90 mmHg when repeated) and a heart rate of 88 beats/minute. He has a history of chronic stable angina that is controlled with sublingual nitroglycerin as needed. He also has severe asthma that is worsened with β -blocker therapy. He currently has no chest pain, and his ECG shows no acute ischemia. Other laboratory results are within normal range, except his serum creatinine is 1.3 mg/dL (normal, 0.5–1.2 mg/dL). Is a CCB appropriate for A.P.? If yes, which type is preferred?

Calcium channel blockers are compellingly indicated in chronic CAD (i.e., chronic stable angina) as an alternative to a β -blocker, or as sequential add-on therapy to a β -blocker for patients who require additional anti-ischemic effects.⁷⁸ Alternatives to β -blockers are needed when contraindications or intolerances to β -blockers are present. Sustained-release CCB formulations or long-acting products (i.e., amlodipine) are always preferred for outpatient management of these patients. A nondihydropyridine is preferred in chronic CAD when used as an alternative to a β -blocker, whereas a dihydropyridine is preferred when CCB therapy is used in addition to a β -blocker.

First developed to treat ischemic heart disease, CCBs were later proved to be effective in hypertension. Nondihydropyridine CCBs decrease myocardial oxygen demand, improve myocardial blood flow, and have negative inotropic and chronotropic effects. All these may benefit patients with CAD. Dihydropyridine CCBs are similar, but do not lower heart rate, and have less negative inotropic effects. They can be used in patients with chronic CAD and possibly acute CAD, but verapamil and diltiazem are preferred when a CCB is used in place of a β -blocker. Moreover, dihydropyridine CCBs are not particularly helpful in patients with acute CAD.

Therapy with a CCB is preferred in A.P., because β -blockers worsened his severe asthma. Verapamil will lower his elevated heart rate and BP as well as treat his angina. Constipation, which may be more prominent in an elderly patient, is the most frequent side effect. Of all the CCBs, constipation is most commonly associated with verapamil, but can be countered with dietary changes or bulk-forming laxatives. Similar to other antihypertensive agents, a low dose (120–180 mg daily) should be used initially and slowly titrated at 2- to 4-week intervals.

Additional Populations

ISOLATED SYSTOLIC HYPERTENSION

46. T.C. is a 76-year-old woman with hypertension and dyslipidemia. Her Framingham risk score is 25%. She has been treated with HCTZ 25 mg daily for several years, and she is very compliant with this regimen. Her BP values are 164/76 mmHg (168/78 mmHg when repeated). She has no other evidence of hypertension-associated complications, and no compelling indications. Her laboratory values and ECG are all normal. Amlodipine 5 mg daily is added to her regimen. What are the benefits of using a CCB to treat T.C.'s hypertension?

T.C. has isolated systolic hypertension. This should be managed according to the general patient care principles for hypertension. Thiazide diuretics have traditionally been considered first-line for this population based on historical data demonstrating CV event lowering in elderly patients with isolated systolic hypertension. The SHEP trial proved that treating ISH in

the elderly is beneficial and established thiazide diuretic-based regimens as first-line agents.³⁹ Long-acting dihydropyridine CCBs have been shown to reduce CV events in patients with isolated systolic hypertension also. The Systolic hypertension in Europe (Syst-Eur) study was similar to the SHEP trial, but used a nitrendipine-based (a long-acting dihydropyridine CCB similar to long-acting nifedipine) regimen instead of a thiazide diuretic-based regimen.⁴² A dihydropyridine CCB is an appropriate add-on therapy for T.C. to control her BP and reduce her risk of CV events.

EDEMA FROM DIHYDROPYRIDINE CCB

47. One month later, T.C.'s BP is down to 148/70 mmHg (150/70 when repeated). She is tolerating her amlodipine, except she has noticed her ankles are both swollen. She has never had this problem before. A complete cardiovascular examination is conducted and no signs found of left ventricular dysfunction or other hypertension-associated complications that would explain this new peripheral edema. Her amlodipine therapy is identified as the cause of this edema. How should her edema be managed? Should her HCTZ be replaced with a loop diuretic, should her amlodipine be stopped, or is there another approach to manage this side effect?

Peripheral edema with CCB therapy, especially a dihydropyridine CCB, is a dose-dependent side effect. It is a direct result of the potent peripheral arterial vasodilation. When there is not equal vasodilation on the venous vasculature, a risk exists for leaking through the capillaries in the legs and, thus, an increased risk of peripheral edema. The best way to manage this side effect is to reduce the dose of the dihydropyridine, or to add an agent that blocks the RAAS to decrease the effects of angiotensin-2, which will result in venous vasodilation. Adding either an ACEI or ARB can be used to accomplish this with the added benefit of further lowering BP. Clinicians should note that using diuretics for the primary purpose of treating peripheral edema that is secondary to CCB use is not recommended, and is not effective.

T.C.'s BP is not at her goal of <130/80 mmHg. Therefore, additional drug therapy is needed. Her best option is to add an ACEI or ARB. This will provide a more balanced pressure gradient across her peripheral vasculature by providing vasodilation of both the arteries and veins. She has otherwise tolerated amlodipine, so no urgent need exists to discontinue this agent. Moreover, lowering the dose of amlodipine to 2.5 mg is an option, but she would still require the addition of a third agent.

ADDITIONAL POPULATIONS

Calcium channel blockers may also have potential benefits for other conditions. Diltiazem and verapamil can be used in atrial fibrillation, atrial flutter, and supraventricular arrhythmias owing to their ability to block the AV node and lower heart rate. Verapamil is effective in migraine prophylaxis. Patients with Raynaud's syndrome can obtain symptomatic relief from the peripheral vasodilation associated with a dihydropyridine CCB. Lastly, CCBs are effective in treating cyclosporine-induced hypertension, but should be used cautiously because verapamil and diltiazem increase cyclosporine concentration.

Table 13-17 Common β -Blockers in Hypertension

| Drug | Usual Dosage Range (mg/day) | Dosing Frequency | Half-life (hr) | β_1 Selectivity | Lipid Solubility |
|--|-----------------------------|--------------------------|----------------|-----------------------|------------------|
| Atenolol (Tenormin) | 25–100 | Daily to BID | 6–7 | ++ | Low |
| Carvedilol (Coreg) | 12.5–50 | BID | 6–10 | 0 | High |
| Carvedilol (Coreg CR) | 10–80 | daily | 6–10 | 0 | High |
| Labetalol (Trandate, Normodyne) | 200–800 | BID | 6–8 | 0 | Moderate |
| Metoprolol tartrate (Lopressor) | 100–400 | BID | 3–7 | + | Moderate to high |
| Metoprolol succinate (Toprol XL) | 25–400 | Daily | 3–7 | + | Moderate to high |
| Nebivolol (Bystolic) | 5–10 | Daily | 12–19 | ++ | High |
| Propranolol (Inderal, Inderal LA, InnoPran XL) | 40–180 | Daily (LA and XL) or BID | 3–5 | 0 | High |

BID, twice daily.

Other Considerations

LEFT VENTRICULAR DYSFUNCTION

48. Why are nondihydropyridine CCB contraindicated in patients left ventricular dysfunction (systolic heart failure)?

Calcium channel blockers, especially nondihydropyridines, decrease cardiac contractility owing to negative inotropic effects. This is most pronounced with verapamil, but is also present with diltiazem and with some dihydropyridines (Table 13-15). In left ventricular dysfunction, the primary physiologic problem is decreased cardiac contractility. Using a CCB in this population can exacerbate left ventricular dysfunction owing to the direct negative inotropic effects, or reveal left ventricular dysfunction that has not yet been diagnosed.

When patients with left ventricular dysfunction require a CCB to treat another condition (i.e., angina or uncontrolled hypertension), amlodipine or felodipine may be used. Amlodipine and felodipine are the only CCB that have been convincingly shown to be safe in left ventricular dysfunction and may be used if needed for either angina or hypertension. Unlike many other antihypertensive agents, they do not, however, protect against left ventricular dysfunction-related mortality.¹¹³

β -Blockers

49. E.K. is a 78-year-old black man with a history of hypertension, who was hospitalized for an acute MI 2 months ago. He has been treated with metoprolol succinate 50 mg daily and lisinopril 20 mg daily since then. Today his BP readings are 148/92 and 146/90 mmHg, and his heart rate is 80 beats/minute. He denies side effects from his medications. Because E.K. is black and elderly, will β -blocker therapy be effective in lowering his BP?

β -Blockers reduce morbidity and mortality in patients with certain compelling indications.^{5,9} These include left ventricular dysfunction, CAD, and diabetes. β -Blocker therapy should not be the primary antihypertensive agent for primary prevention patients, but is an effective alternative add-on agent for primary prevention patients to lower BP. Elderly and black patients may have less BP reduction than young or white patients. E.K. is elderly and might have more BP reduction with another agent (i.e., thiazide diuretic or CCB), but these points are moot in E.K. Age and race should never deter use of a β -blocker when a compelling indication is present. E.K. has

history of a recent MI, which is a compelling indication for a β -blocker as first-line therapy.^{5,9,36,84,85}

Pharmacologic Differences

Many different β -blockers are available (Table 13-17). Clinically important differences relate primarily to cardioselectivity, intrinsic sympathomimetic activity (ISA), relative lipid solubility, and benefit-to-risk in left ventricular dysfunction. These differences might be useful when selecting an individual agent.

CARDIOSELECTIVITY

50. What are the advantages of using a cardioselective β -blocker to treat E.K.'s hypertension?

β_1 -Adrenergic receptors are primarily located in the heart, and β_2 -adrenergic receptors are in the lungs, kidneys, and peripheral arteriolar endothelium. Low-affinity β_1 -receptors are also present in the lung, and low-affinity β_2 -receptors are present in the heart. Some β -blockers demonstrate relative cardioselectivity with greater antagonism of cardiac β_1 -receptors and less activity on β_2 -receptors in the lung or bronchial tissue. Selectivity is not absolute, however, because it is dose-dependent. For instance, asthma has been precipitated even with cardioselective agents when they are used in higher doses, but not with low to moderate doses.

Nonselective β -blockers potentially have the disadvantage of blunting the symptoms of hypoglycemia in patients with diabetes. β_2 -Blockade from nonselective β -blockers can lead to unopposed β_1 -induced peripheral vasoconstriction. This may worsen Raynaud's phenomenon, peripheral arterial disease, or hypertension caused by catecholamine-producing tumors (pheochromocytoma). Despite these shortcomings, nonselective β -blockers are preferred in patients with non-CV indications for β -blocker therapy, such as migraine prophylaxis or essential tremor. Absent these indications, cardioselective β -blockers are preferred. E.K. is taking metoprolol for CV indications (hypertension and post-MI). Metoprolol, being a cardioselective agent, is appropriate therapy for E.K.

INTRINSIC SYMPATHOMIMETIC ACTIVITY

51. Why should acebutolol, carteolol, penbutolol, and pindolol not be used in E.K.?

Pure β -blockers occupy the β -receptor, inhibiting stimulatory catecholamine access while exerting no effect on their

own. β -Blockers with ISA, such as acebutolol, carteolol, penbutolol, and pindolol, partially stimulate β -receptors while attached to this receptor, but much less than a pure agonist. When given to a patient with a slow resting heart rate, ISA β -blockers can increase the heart rate. Conversely, these agents can slow heart rate in patients with resting or exercise-induced tachycardia, because β -blocking properties predominate.

β -Blockers with ISA are theoretically less likely to cause bradycardia, bronchospasm, reduced cardiac output, peripheral vasoconstriction, and increased plasma lipids than nonselective β -blockers. Nonetheless, these agents still might worsen asthma and should never be used in patients with left ventricular dysfunction or CAD because they can worsen these conditions as a result of their agonist properties. No role exists for ISA β -blockers in the treatment of hypertension. Because E.K. has a history of MI, a β -blocker with ISA (e.g., acebutolol) is contraindicated.

LIPID SOLUBILITY

Lipophilic β -blockers (e.g., propranolol) have a larger volume of distribution and undergo more extensive first-pass hepatic metabolism than hydrophilic β -blockers. Highly hydrophilic β -blockers (e.g., atenolol) are primarily excreted by the kidneys and may require lower doses in patients with severe chronic kidney disease. Highly lipophilic agents theoretically penetrate the CNS more extensively and readily than hydrophilic agents. It is possible that lipophilic agents are associated with increased CNS side effects. Comparative studies, however, have not demonstrated significant differences between low to moderate doses of lipophilic and hydrophilic β -blockers. High lipid-soluble drugs are hepatically cleared. A high lipid-soluble β -blocker is desirable for migraine prophylaxis because of better CNS penetration.

Compelling Indications

DIABETES

52. Diabetes is a compelling indication for β -blocker therapy. What role do β -blockers play in treatment and why is caution sometimes recommended when using these drugs in patients with diabetes?

β -Blockers reduce coronary events, progression of kidney disease, and stroke in patients with diabetes.⁷² Their role in treating hypertension in diabetes is as sequential add-on therapy, after an ACEI or ARB and thiazide diuretic. Their role in therapy is similar to that of CCB. These drugs can, however, inhibit insulin secretion and infrequently cause hyperglycemia. In patients with prediabetes, a theoretical higher risk exists of progressing to diabetes than with CCB, ACEI, or ARB therapy based on these changes in insulin sensitivity.¹⁰³ Therefore, in patients with diabetes, unless another compelling indication is present for a β -blocker (e.g., left ventricular dysfunction or CAD), a CCB should be used ahead of a β -blocker.

All β -blockers can mask symptoms of impending hypoglycemia associated with epinephrine release (e.g., palpitations, tremor, hunger), but do not prevent hypoglycemia-related sweating. Although they do not cause hypoglycemia, nonselective β -blockers can worsen a hypoglycemic episode and may prolong recovery from hypoglycemia. The risk of masking and potentiating hypoglycemia is not a contraindication. Although β -blockers are best avoided in insulin dependent type 1 di-

abetes, they can be used if other agents fail or if concurrent diseases are present that justify the use of a β -blocker. Because hypoglycemia is less common in patients with type 2 diabetes who do not require insulin, β -blockers are less likely to create adverse effects in this population.

All patients with diabetes who use β -blockers should be monitored carefully with regular glucose measurements and targeted patient education about how the signs and symptoms of hypoglycemia can change. Nonselective β -blockers should be avoided in patients with tightly controlled diabetes, especially those receiving insulin therapy. If a β -blocker is needed to control BP, or treat a compelling indication in diabetes, a cardioselective agent is preferred.

53. Why are β -blockers so strongly recommended in patients with a history of CAD?

CHRONIC AND ACUTE CAD

Overwhelming evidence supports β -blocker therapy in all forms of CAD.^{5,9,36,78,84,85} β -Blockers prolong survival and reduce the risk of recurrent CV events. These agents are considered first-line agents, but are often underutilized in this population because of perceived contraindications. Patients with relative contraindications to β -blocker therapy (e.g., chronic pulmonary disease), however, do indeed benefit from β -blocker therapy if they have CAD. All patients, even if they have controlled BP, should receive a β -blocker post-MI unless they have demonstrated intolerance or have an absolute contraindication. In addition to lowering BP, β -blockers reduce heart rate, contractility, and myocardial oxygen demand. Therefore, they also relieve ischemic symptoms and β -blocker therapy is essential therapy in many patients with CAD.

LEFT VENTRICULAR DYSFUNCTION

54. β -blockers decrease cardiac contractility. Why then do they benefit patients with left ventricular dysfunction?

β -Blockers decrease cardiac contractility, and reduce cardiac output when first initiated. In patients with left ventricular dysfunction, the primary physiologic abnormality is decreased contractility. Therefore, using a β -blocker seems pharmacologically flawed. Extensive research has shown, however, that slow introduction of certain β -blockers using doses much lower than what is used for BP lowering (i.e., carvedilol 3.125 mg twice daily and metoprolol 12.5 mg daily), followed by very slow and careful titration up to high dose, actually improves cardiac function. Cardiac β -receptor upregulation occurs, and the detrimental compensatory tachycardia and excessive catecholamine release is halted. The end result is decreased morbidity and mortality.⁸⁶ β -Blocker therapy is compellingly indicated in left ventricular dysfunction. β -blockers are the third of three agents that comprise standard therapy for patients with left ventricular dysfunction.

55. Which β -blockers should be used in patients with left ventricular dysfunction?

Metoprolol and carvedilol are FDA approved for left ventricular dysfunction based on evidence showing reduced CV events and mortality.⁸⁶ When β -blockers are used in patients with both hypertension and left ventricular dysfunction, one of these two agents should be selected following dose

recommendations as approved for left ventricular dysfunction (start with a low dose followed by gradual titration upward). Bisoprolol also has been evaluated in left ventricular dysfunction, and demonstrates similar benefits, but is less frequently used.

Additional Considerations

56. Atenolol is the most frequently prescribed β -blocker in hypertension. Why is it not beneficial in left ventricular dysfunction?

When the entire body of evidence evaluating β -blockers and their ability to lower CV events, especially in CAD is examined, a paucity of data are found that independently evaluated atenolol in left ventricular dysfunction.¹¹⁴ Moreover, some data suggests that atenolol is inferior to other β -blockers (e.g., metoprolol) in ability to reduce CV risk.²¹ Perhaps the problem with atenolol is dosing. It is nearly always dosed once daily in hypertension. Its half-life, however, is similar to immediate-release formulations of metoprolol or carvedilol, which are both dosed twice daily (Table 13-17). It is possible that the lack of long-term beneficial data with atenolol might be influenced by improper dosing. Because of this uncertainty, clinicians should select β -blockers, such as metoprolol or carvedilol, instead of atenolol when initiating β -blocker therapy in patients with hypertension. Alternatively, twice daily dosing of atenolol might be a more ideal utilization of this particular agent.

57. How severe are the metabolic side effects associated with β -blocker use?

β -Blockers are associated with adverse metabolic alterations and bothersome side effects that limit their universal use. The incidence of other adverse reactions (e.g., sexual dysfunction) is lower, however, than popular medical myth suggests. Adverse reactions are dose-dependent and are minimized with low to moderate doses.

Nonselective β -blockers have been associated with increased serum triglycerides and reductions in HDL-C. Agents with ISA have little or no effects on lipids, whereas cardioselective β -blockers have intermediate effects. Similar to diuretics, these changes are often not sustained with chronic therapy. β -Blockers have definitively been shown to lower morbidity and mortality, so their effects on cholesterol have little clinical significance. If a β -blocker is indicated in a patient with dyslipidemia, HDL-C and fasting triglyceride values should be monitored.

58. What other noncardiovascular conditions are responsive to β -blockers in patients with concurrent hypertension?

β -Blockers have potential benefits in other conditions. They slow the rate of cardiac conduction, a benefit in patients with paroxysmal supraventricular tachycardia or atrial fibrillation. They are also used in patients with tachycardia and anxiety from mitral valve prolapse, or preoperative hypertension. Finally, β -blockers are effective in treating other noncardiac conditions, such as thyrotoxicosis, essential tremor, and migraine prophylaxis.

59. How should monitoring of heart rate be used to optimize β -blocker therapy?

β -Blockers decrease conduction through both the SA and AV node. Lowering of the resting heart rate can be used

as a marker of response. While receiving β -blocker therapy, heart rate should ideally be controlled to a resting pulse rate of no less than 60 beats/minute to avoid heart block. First-degree heart block may be present when the heart rate is <60 beats/minute, but normal conduction is maintained. β -Blocker therapy should, under most circumstances, be reduced if this occurs. Second- and third-degree heart block result in heart rates typically <55 and <40 beats/minute, respectively, with abnormal cardiac conduction. β -Blocker therapy should be decreased or stopped if either of these two situations occur. Failure to achieve a lowered resting pulse could indicate inadequate dosage (i.e., need for a higher dose) or poor patient adherence to the prescribed regimen. If the BP goal has been obtained, however, this is more important than lowered pulse response.

60. What is the harm associated with abruptly discontinuing β -blocker therapy? How should clinicians treat patients who must have β -blocker therapy discontinued?

Chronic β -blocker therapy upregulates the expression of β -receptors. This does not, however, result in a rise of BP while the β -blocker continues to occupy the receptors. If β -blocker therapy is abruptly stopped, however, rebound hypertension can occur because more β -receptors are available to be activated, causing cardiac stimulation and vasoconstriction. Symptoms of rebound hypertension can include headache, tachycardia, and possibly anxiety. Patients with ischemic heart disease can have significant increases in angina frequency if β -blockers are abruptly stopped. If a β -blocker requires discontinuation, rebound hypertension or ischemia can be avoided by gradually tapering the dose by 50% for 3 days and then another 50% for 3 days. Replacing one β -blocker with another at an equivalent dose should not cause rebound hypertension.

Alternative Antihypertensive Agents

61. R.R. is a 62 year-old man with a long-standing history of hypertension. He has not yet experienced any hypertension-associated complications or target organ damage. He does not have a history of diabetes, does not smoke, and his Framingham risk score is 13%. He has been treated with HCTZ 25 mg daily, amlodipine/valsartan 10/320 mg daily, and carvedilol 12.5 mg twice daily for one year. He is very adherent with these medications, measures his BP at home every day, and follows recommended lifestyle modifications as diligently as possible. He has tried other medications that resulted in intolerances (quinapril caused angioedema, doxazosin caused dizziness, clonidine caused a dry mouth). His BP has never been <130/80 mmHg, which is his goal. All secondary causes of hypertension have been ruled out. His BP today is 150/90 mmHg (152/92 when repeated), heart rate is 60 beats/minute, serum potassium is 4.2 mEq/L, and serum creatinine is 1.1 mg/dL. He is 183 cm tall, and weighs 85 kg. What other options are available for R.R.? Does he have resistant hypertension?

Several alternative agents (Table 13-18) are available to treat difficult-to-control hypertension or resistant hypertension. Resistant hypertension is defined as that in which patients fail to attain their BP goal while treated with a three-drug regimen that utilizes full antihypertensive doses, one of which is a diuretic.⁵ In reality, this represents a hypertensive population that is likely to use four or five drugs to treat hypertension.

Table 13-18 Alternative Antihypertensive Agents

| <i>Drugs/Mechanism of Action</i> | <i>Usual Dosage Range (mg/day)</i> | <i>Dosing Frequency</i> |
|---|------------------------------------|-------------------------|
| Aldosterone Antagonists (see Table 13-9) | | |
| α_1-Blockers | | |
| Doxazosin (Cardura) | 1–8 | Daily |
| Prazosin (Minipress) | 2–20 | BID to TID |
| Terazosin (Hytrin) | 1–20 | Daily to BID |
| Direct Renin Inhibitor | | |
| Aliskiren (Tekturna) | 150–300 | Daily |
| α_2-Agonists (Central) | | |
| Clonidine (Catapres) | 0.1–0.8 | BID |
| Clonidine Transdermal (Catapres TTS) | 0.1–0.3 | Once weekly |
| Methyldopa (Aldomet) | 250–1,000 | BID |
| Arterial Vasodilators | | |
| Hydralazine (Apresoline) | 25–100 | BID |
| Minoxidil (Loniten) | 2.5–80 | Daily to BID |
| Adrenergic Neuron Blockers | | |
| Reserpine (Serpasil) | 0.05–0.25 | Daily |

BID, twice daily; TID, three times daily.

R.R. meets the definition of resistant hypertension. He has already failed to respond to, or tolerate, several drug classes that typically are associated with reductions in hypertension-associated complications. His HCTZ, amlodipine, and valsartan are all at the maximal doses. Carvedilol could be increased to 25 mg twice daily, but this should not be done because his heart rate is 60 beats/minute and increasing this dose would place him at risk for bradycardia. To attain his BP goal of <130/80 mmHg (appropriate because of his elevated Framingham score), an alternate agent, other than clonidine, should be selected because he did not tolerate it in the past.

Alternative agents should not be used as monotherapy in the treatment of nearly all patients' hypertension because they have not been shown to reduce hypertension-associated complications. They should primarily be used as last-line agents in combination with the aforementioned antihypertensive agents that reduce morbidity and mortality.

Aldosterone Antagonists

Spironolactone and eplerenone are aldosterone antagonists. Technically, these are potassium-sparing diuretics and can increase potassium and cause hyperkalemia. When used in hypertension, increases in potassium are small in most patients. This risk increases, however, in patients with chronic kidney disease or when used in combination with an ACEI or ARB.

62. Would it be safe to add spironolactone 25 mg daily to R.R.'s regimen?

Spironolactone is especially useful as an add-on therapy in patients with resistant hypertension. Spironolactone 25 mg daily is a reasonable addition to R.R.'s regimen. His potassium is in the normal range, but could increase after adding spironolactone. Therefore, it should be monitored 2 to 4 weeks after it is started to assure R.R. does not develop hyperkalemia. Eplerenone is more specific than spironolactone in aldosterone blockade. Compared with spironolactone, gynecomastia is not a frequent side effect. The incidence of hyperkalemia is greater with eplerenone, however. When used for hyper-

tension, eplerenone is contraindicated in populations at high risk for hyperkalemia: type 2 diabetes with microalbuminuria, an estimated creatinine clearance <50 mL/minute, or elevated serum creatinine (>1.8 mg/dL in women and >2.0 mg/dL in men).

These agents are indicated for hypertension, but their greatest use is in left ventricular dysfunction. This is considered a compelling indication because of evidence showing reduced morbidity and mortality.^{89,90} In studies to date, eplerenone reduced mortality in patients with left ventricular dysfunction soon after MI, whereas spironolactone was beneficial in patients with more severe left ventricular dysfunction.^{89,90} Although it is logical to add an aldosterone inhibitor to R.R.'s regimen based on the presence of heart failure, the antihypertensive effect may still not be sufficient for him to reach his BP goal.

α -Blockers

63. J.L. is a 64-year-old man with hypertension and peripheral arterial disease. His BP is 138/84 mmHg (136/86 mmHg when repeated). His current antihypertensive regimen is HCTZ 25 mg daily and nifedipine extended release (ER) 60 mg daily. J.L. is not completely adherent with lifestyle modifications, but insists he is doing the best he can. He has been experiencing frequent nocturia, difficulty in starting urination, and a decrease in his urinary flow for the past several months and is diagnosed with benign prostatic hyperplasia (BPH). J.L.'s physician is considering changing one of his antihypertensive agents to an α -blocker. How do α -blockers compare with other agents in reducing CV events?

α -Blockers are not first-line agents in the management of hypertension. The ALLHAT trial, as discussed previously, originally included an α -blocker (doxazosin) treatment arm. Interim results after a mean follow-up of 3.3 years revealed that doxazosin had a statistically higher risk of combined CV disease and heart failure when compared with chlorthalidone.¹¹⁵ Therefore, the ALLHAT data show that thiazide diuretic therapy is more protective against hypertension-associated complications than is α -blocker therapy. This study did not include a placebo group; therefore, to conclude that doxazosin is harmful is inaccurate. For J.L., discontinuing HCTZ or nifedipine to start an α -blocker is not prudent. It may be appropriate, however, to add an α -blocker to his regimen because he is above his goal BP of <130/80 mmHg (appropriate because he has peripheral arterial disease) and is already treated with two first-line agents (thiazide diuretic and CCB). Adding an ACEI or ARB, or even a β -blocker, would be reasonable considerations, but an α -blocker will also provide symptomatic benefit to his BPH.

64. How would adding an α -blocker to J.L.'s treatment regimen affect his BPH?

An α -blocker can potentially improve the symptoms of BPH by reducing urethral tone and alleviating bladder outlet obstruction. Terazosin and doxazosin are both approved for the treatment of symptoms caused by BPH. Prazosin can be used, but requires more frequent dosing. Decreased symptoms of BPH with α -blockers are dose-related, and titration to high doses is often needed. This increases the risk of side effects, such as orthostatic hypotension. In J.L., an α -blocker will lower his BP and might also relieve his urinary symptoms.

65. J.L. prefers to try doxazosin rather than undergo surgery to relieve his symptoms of BPH. How should this agent be started?

For J.L., it would be best to add a low dose of doxazosin to his present two-drug regimen. Based on his tolerance of the new drug and BP response, it can be titrated up. One of his other antihypertensive agents can be decreased if he becomes hypotensive. The initial dose of doxazosin should not exceed 1 mg daily and it should be given at bedtime. This can minimize orthostatic hypotension (i.e., profound hypotension, dizziness, and possible fainting), which is the most frequent side effect of α -blockers. This complication is most pronounced with the first dose, but can persist in some patients. The dose can be increased to symptom control based on BP and tolerability.

66. What patient education should be provided to J.L. about the potential adverse effects of doxazosin?

α -Blockers are relatively well tolerated if dosed appropriately. J.L. could experience side effects, such as drowsiness, headache, weakness, palpitations from reflex tachycardia, and nausea, but these do not occur in all patients. Patients starting an α -blocker should be instructed to take the initial dose at bedtime and to anticipate a first-dose effect, in which they may experience orthostatic hypotension. Specifically, patients should be counseled to rise more slowly from a seated or supine position.

Mixed α/β -Blockers

67. R.P. is a 68-year-old man with hypertension and a history of ischemic stroke (1 year ago). Two months ago, his BP values were 164/94 mmHg and 162/98 mmHg, with a heart rate of 62 beats/min while on atenolol 50 mg daily. He was started on benazepril/HCTZ 10/12.5 mg daily 2 months ago. His BP today is 142/82 mmHg (144/82 mmHg when repeated). All his laboratory values are normal except his serum creatinine, which is 1.9 mg/dL (normal, 0.5–1.2 mg/dL). J.L. has implemented lifestyle modification to the best of his ability. Because R.P.'s BP is still not at goal (<130/80 mmHg because of his history of ischemic stroke), could his atenolol be replaced with an agent such as labetalol and carvedilol?

Labetalol and carvedilol are nonselective β -blockers that also have α_1 -receptor blocking activity. Their antihypertensive effects are only somewhat similar to a combination of a nonselective β -blocker (e.g., propranolol) with an α_1 -antagonist (e.g., terazosin). Dosing recommendations are listed in Table 13-17.

These agents produce vasodilation and can cause more adverse reactions than β -blocker or α -blocker monotherapy. The same precautions and typical contraindications relevant to β -blockers apply to these agents because they basically are nonselective β -blockers (Table 13-10). Unlike pure β -blockers, however, both carvedilol and labetalol may be safer to use in patients with peripheral arterial disease because unopposed peripheral α -constriction does not occur.

Carvedilol is approved for both hypertension and left ventricular dysfunction. Carvedilol has been shown to reduce morbidity and mortality in a wide range of patients with left ventricular dysfunction.^{79,88} Labetalol and carvedilol have no clear advantage over other β -blockers in most patients with hypertension, and patients might experience α -blocker–related side effects (e.g., orthostatic hypotension). If R.P. had the com-

elling indication of left ventricular dysfunction, switching to carvedilol would be reasonable. His heart rate is between 60 and 70 beats/minute, so this indicates he is adherent with atenolol. Increasing the atenolol dose to 100 mg daily is not wise because it may induce heart block. Atenolol is renally eliminated, so his present dose is probably causing more BP lowering than usual doses based on his chronic kidney disease. Increasing his ACEI will help to control both his BP and preserve his kidney function. This can be done without increasing his HCTZ by switching his fixed-dose combination product to benazepril/HCTZ 20/12.5 mg daily or simply increasing both the ACE and HCTZ by doubling his current dose.

Direct Renin Inhibitors

68. How is aliskiren different than an ACEI or ARB?

Aliskiren is the first oral direct renin inhibitor.¹¹⁶ Agents within this new antihypertensive drug class inhibit the RAAS at the first step of this system, which results in reduced plasma renin activity and BP lowering. This is different than both the inhibition of angiotensin-2 production from ACEI therapy and the inhibition of angiotensin-2 seen with ARB therapy. Aliskiren has a 24-hour half-life that allows for once-daily dosing. Its primary route of elimination is through biliary excretion as unchanged drug.

Some similarities and some differences exist among the side effects associated with aliskiren when compared with ACEIs and ARBs. Similarly, aliskiren should not be used in pregnancy because of the known teratogenic effects from blocking the RAAS system. Increases in serum creatinine and serum potassium have been associated with aliskiren similar to ACEI and ARB therapy, mediated by the inhibition of angiotensin-2 vasoconstrictive effects on the efferent arterioles of the kidney, and blocking of aldosterone. Monitoring of serum creatinine and serum potassium should be done in patients treated with aliskiren, particularly in those treated with the combination of aliskiren and an ACEI, ARB, potassium-sparing diuretic, or aldosterone antagonist. Angioedema has been reported in patients treated with aliskiren, but the exact prevalence is unknown.

69. What is the role of aliskiren in treating hypertension? Can patients treated with either an ACEI or ARB have aliskiren added to their drug regimen?

The exact role of aliskiren treatment of hypertension is unclear. It is approved as monotherapy or in combination therapy. The BP reductions with aliskiren as monotherapy are similar to those seen with an ACEI, ARB, or CCB (specifically amlodipine). Aliskiren provides additive BP lowering when used in combination with HCTZ, ACEI, ARB, and CCB. Its efficacy in combination with maximal doses of ACEI is unknown, however. Studies evaluating long-term effects on CV events and progression of diabetic nephropathy are currently underway. Therefore, aliskiren is considered an alternative antihypertensive agent at this time because of unknown long-term effects on hypertension-associated complications.

Central α_2 -Agonists CLONIDINE

70. T.M. is a 37-year-old man. He is a truck driver with a 5-year history of hypertension. His Framingham risk score is <10% and

he does not have hypertension-associated complications or any compelling indications. Secondary causes have been ruled out. His regimen is losartan/HCTZ 100/25 mg daily and sustained-release diltiazem 240 mg daily. Other antihypertensive drugs have failed because of various side effects (captopril and lisinopril caused a dry cough, atenolol and carvedilol caused fatigue, nifedipine and amlodipine caused edema, and terazosin caused orthostasis). T.M. has been adherent to his present medications and lifestyle modification, but has been unable to quit smoking. His clinic and home BP values have been similar and averaged 150/95 mmHg for the past 3 months. Clonidine 0.1 mg twice daily is added to his regimen. How can both an α_2 -agonist and α_1 -antagonists be effective antihypertensive agents?

The antihypertensive effects of α_2 -agonists (Table 13-18) are attributed to their central α_2 -agonist activity. Stimulation of α_2 -receptors in the CNS inhibits sympathetic outflow (via negative feedback) to the heart, kidneys, and peripheral vasculature, resulting in peripheral vasodilation. Although the α_2 -agonists are effective as monotherapy, they are not first-line therapy for the treatment of hypertension because of their potential side effects and a lack of evidence showing reductions in morbidity and mortality.

α_2 -Agonists are most effective when used with a diuretic because they all can cause fluid retention. Ideally, they should be used in combination with agents that have different mechanisms of action and with agents that do not affect other central adrenergic receptors. Clonidine can cause rebound hypertension when abruptly stopped. T.M.'s occupation may place him at risk for this complication if he misses doses because of unusual work hours or prolonged travel.

71. How should T.M.'s clonidine dose be titrated?

Clonidine should be started at a low dosage and gradually increased to achieve optimal BP lowering with minimal side effects. It is started as 0.1 mg twice daily, with 0.1 or 0.2 mg/day increases every 2 to 4 weeks until BP goal is achieved or side effects appear. Clonidine also is available as a transdermal patch, which releases the medication at a controlled rate over 7 days, and may have fewer side effects than the oral dosage form. The onset of initial BP effect may be delayed for 2 to 3 days after application; thus, rebound hypertension might occur when oral clonidine is switched to transdermal. To prevent this, an oral dose should be taken on the first day that the transdermal patch is used. Anticholinergic side effects, such as sedation and dry mouth, are the most frequent and bothersome side effects of clonidine. These are especially problematic in elderly patients.

72. After several weeks, T.M.'s BP is 138/84 mmHg with clonidine 0.2 mg twice daily. However, he is now experiencing daytime somnolence and dry mouth. What other α_2 -agonists are available?

METHYLDOPA

Methyldopa has been extensively evaluated and is considered safe in pregnancy. Therefore, it is recommended as a first-line agent when hypertension is first diagnosed during pregnancy.¹¹⁷ Beyond that, little role exists for methyldopa in the management of hypertension. The usual initial dose is 250 mg administered twice daily up to 2,000 mg/day. Methyldopa causes side effects similar to those associated with clonidine, including sedation, lethargy, postural hypotension, dizziness, dry mouth, headache, and rebound hypertension. These may

decrease with continued use. Other significant side effects include hemolytic anemia and hepatitis. Although these are both rare, they necessitate discontinuing the medication.

OTHERS

Guanfacine and guanabenz have a high incidence of side effects. These agents can cause dry mouth, sedation, dizziness, orthostatic hypotension, insomnia, constipation, and impotence. Guanfacine has a long half-life and may have less rebound hypertension than other α_2 -agonists. The adverse effects of other α_2 -agonists (methyldopa, guanfacine, and guanabenz) are nearly identical to that of clonidine. In general, patients who do not tolerate one α_2 -agonist will not tolerate the others. An antihypertensive agent from a different class (aldosterone antagonist, aliskiren, reserpine or an arterial vasodilator) should be chosen for T.M.

Reserpine

73. What is the role of reserpine in the contemporary management of hypertension?

Reserpine is one of the oldest antihypertensive agents currently available. It is extremely effective in lowering BP when added to a thiazide diuretic. Reserpine is inexpensive, and is dosed once daily. Several of the landmark trials that demonstrated reduced morbidity and mortality with BP lowering in hypertension used reserpine. The SHEP trial used reserpine as a second-step agent added to chlorthalidone in patients who could not take atenolol.³⁹

Low-dose reserpine (0.05–0.1 mg once daily) is effective at lowering BP and has significantly fewer side effects compared with high doses. Reserpine can cause nasal stuffiness in many patients. Gastrointestinal ulcerations have been reported, but they are associated with either parenteral administration or very large doses. T.M. is a candidate for low-dose reserpine. He is already taking a thiazide diuretic, which should always be used with reserpine, and his therapeutic options are limited. Of all the agents remaining for T.M., other than aliskiren, reserpine has the most favorable side effect profile.

Many clinicians avoid reserpine because of the myth that it can cause depression. This fear was generated from case reports in the 1950s when very high doses (0.5–1.0 mg/day) were used. Furthermore, many of the patients described in these cases would not meet modern criteria for depression; rather, they would be described as oversedated. When reserpine is limited to a maximum of 0.25 mg daily, depression is no more frequent than with other antihypertensive agents.

Arterial Vasodilators

HYDRALAZINE

74. C.M. is a 56-year-old woman with a history of hypertension and severe chronic kidney disease (estimated GFR of 14 mL/minute/1.73 m²). Her antihypertensive regimen consists of torsemide 40 mg daily, amlodipine/olmesartan 10/40 mg daily, metoprolol succinate 200 mg daily, and lisinopril 40 mg daily. She started hydralazine 50 mg twice daily 4 weeks ago when her BP was 148/92 and 146/90 mmHg. She has been very compliant, and her BP is now 136/88 mmHg with a heart rate of 82 beats/minute. Her lung fields are clear, with 1+ bilateral pitting edema. Serum electrolytes are within normal limits. Why was hydralazine used in this patient?

Hydralazine causes direct relaxation of arteriolar smooth muscle with little effect on the venous circulation. Arterial vasodilators are infrequently used, except for patients with severe chronic kidney disease. In this population, hypertension is difficult to control and often requires four or five agents. Severe chronic kidney disease results in increased renin release and increased fluid retention. Potent vasodilation, in combination with diuresis, is often effective in lowering BP under these conditions. Potent vasodilation, however, stimulates the sympathetic nervous system and results in a reflex tachycardia, increased PRA, and fluid retention. Thus, the hypotensive effectiveness of direct arterial vasodilators can quickly diminish with time when used as monotherapy. To prevent this effect, arterial vasodilators should always be used in combination with both a β -blocker to counteract reflex tachycardia and a diuretic, often a loop diuretic if used in severe chronic kidney disease, to minimize fluid retention.

75. After 18 months, C.M.'s hydralazine dose is 150 mg twice daily, and her BP is at goal. She now complains of joint pain in both her right and left hands, which extends to the wrists, and generalized weakness with frequent fevers. What is a possible explanation for C.M.'s subjective complaints?

C.M.'s symptoms are consistent with drug-induced lupus (DIL). Hydralazine is one of the most common agents reported to cause DIL. Musculoskeletal pains are the most frequent symptoms, but systemic symptoms (e.g., pericardial effusion and chest pain) and rash may also occur. Hydralazine doses as low as 100 mg/day can cause DIL, and the risk significantly increases when >200 mg/day is used.

76. What objective data can be obtained to confirm the suspicion of DIL?

Laboratory tests are used to establish a diagnosis of DIL. A positive antinuclear antibody (ANA) is a common finding in 70% to 100% of those with long-term hydralazine exposure. Only a small percentage of these patients, however, will experience symptoms of DIL. A positive ANA test without symptoms of DIL does not warrant stopping hydralazine, so routine ANA testing is not necessary. The typical ANA pattern in DIL is diffuse and directed against single-stranded DNA (ss-DNA), not against double-stranded DNA (ds-DNA), as is the case with systemic lupus erythematosus (SLE). Other common laboratory findings include an elevated erythrocyte sedimentation rate (ESR), lupus erythematosus (LE) cells, and a false-positive serologic test finding for syphilis.

Patients with DIL from hydralazine rarely develop serious complications, which include blood dyscrasias such as leukopenia, and thrombocytopenia. Renal complications are

not frequently associated with DIL. Of all causative agents associated with DIL, hydralazine, however, has the highest incidence of kidney dysfunction. A serum creatinine should be obtained to identify any elevations, and a urinalysis should be conducted to monitor for signs of proteinuria and hematuria. In C.M., these tests may not be helpful because she has severe chronic kidney disease.

77. Laboratory findings for C.M. showed a positive ANA (diffuse), a white blood cell count of $3,500/\text{mm}^3$, and an ESR of 45 mm/hour. DIL is diagnosed. How should this drug-induced toxicity be managed?

Hydralazine should be discontinued. Symptoms should begin to subside within days or weeks and complete resolution of symptoms can be expected; however, a positive ANA may persist for several months.

MINOXIDIL

78. How should C.M.'s BP be managed?

C.M.'s BP responded to hydralazine, so she would likely benefit from another arterial vasodilator. Minoxidil, a potent arterial vasodilator, is similar to hydralazine with regard to causing reflex tachycardia, increased cardiac output, increased PRA, and fluid retention. Therefore, concomitant β -blocker and diuretic therapy is required. Minoxidil should be reserved for patients such as C.M. who have severe chronic kidney disease or have resistant hypertension.

79. How should C.M. be counseled regarding the use of minoxidil for her hypertension?

Hypertrichosis is a common adverse effect of oral minoxidil, occurring in 80% to 100% of patients. The hair growth is not associated with an endocrine abnormality and begins within the first few weeks. It commonly occurs on the temples, between the eyebrows, on the cheeks, and on the pinna of the ear. Hair growth can extend to the back of the legs, arms, and scalp with continued use. Some patients, especially women, find the hypertrichosis so intolerable that they stop treatment. Topical minoxidil is an approved therapy for male pattern baldness, but topical administration does not provide BP-lowering effects.

Fluid retention with minoxidil is common, presenting as edema and weight gain. If adequate diuresis is not maintained during minoxidil therapy, left ventricular dysfunction may be precipitated or worsened. This also occurs with hydralazine. The compensatory reflex tachycardia with minoxidil also may precipitate angina in patients who have, or are at risk for, coronary artery disease.

Peripheral Arterial Disease

Peripheral arterial disease (PAD) is a common and sometimes painful complications from stenosis or occlusion in the peripheral arteries of the legs, usually caused by atherosclerosis. Some clinicians and patients have characterized claudication pain as “angina” of the legs. When considering the risk factors and pathology of intermittent claudication (IC), the association with coronary disease becomes clear.

Intermittent claudication is described as aching, cramping, tightness, or weakness of the legs, which usually occurs during exertion. Claudication pain is relieved when the physical activity is discontinued. Numbness or continuous pain in the toes or foot may be present, indicating tissue ischemia, which can lead to ulceration. IC is a painful condition that can severely limit the patient's mobility and lead to tissue necrosis or amputation of the affected limb. Many patients with PAD, however, are asymptomatic or have atypical lower limb symptoms, such as leg fatigue, difficulty walking, or similar nonspecific complaints. Because symptoms of IC develop gradually, patients may not seek medical attention until the condition is advanced.

Epidemiology

Peripheral arterial disease is a relatively common condition that affects men and women equally, with a prevalence of 12%,¹ although men have a twofold increased prevalence of symptomatic IC.² The annual incidence of IC increases dramatically with age (Table 14-1). Most patients with PAD are largely asymptomatic, although their risk of developing symptoms of IC in the future is greatly increased. In a population with only a 2% prevalence of IC symptoms, 11.7% of patients had detectable large vessel atherosclerosis of the lower extremities.³ This disparity between IC symptoms and the presence of PAD contributes to the observation that 50% to 90% of patients

with IC do not mention the symptoms to their physician. Patients attribute the symptoms of IC to normal walking difficulties associated with aging, not a medical condition requiring treatment.⁴

Risk factors for developing occlusive PAD are similar to those for coronary artery disease. Longstanding diabetes is the most significant risk factor, with 30% of patients with diabetes affected by PAD.⁵ PAD is five times more common in patients with diabetes than in patients without diabetes; in diabetics, it develops at a younger age and progresses more rapidly. Each 1% increase in glycosylated hemoglobin is associated with a 28% risk of incident PAD.⁶ Other risk factors include cigarette smoking, hypertension, dyslipidemia, hyperhomocysteinemia, and C-reactive protein.⁷ Hypertriglyceridemia is a more significant risk factor for PAD than for coronary artery disease, and this may partially explain the increased prevalence of PAD in patients with diabetes.⁸

Cigarette smoking has a higher correlation with the development of IC pain than any other risk factor, and the risk increases dramatically with the number of cigarettes smoked per day and the duration of smoking history.⁹ In patients with other cardiovascular risk factors, including hypertension or diabetes, smoking further increases the rate of claudication development. Smoking confers a sevenfold increase in risk for PAD compared with nonsmokers. In contrast, the risk of coronary artery disease is only increased twofold in smokers. Thus, the mechanism by which cigarette smoking causes damage may be different for these two vascular diseases.¹⁰

Epidemiologic studies show that IC is nonprogressive in 75% of patients over a period of 4 to 9 years. The other 25% of patients with IC have worsening painful ischemic episodes over this period. Although rare, more serious complications can occur. Ischemic tissue changes, ulceration, and gangrene can accompany advanced peripheral atherosclerosis. Amputation of the affected limb may be necessary in up to 5% of

Table 14-1 Annual Incidence of Intermittent Claudication by Age³

| Age Group (yr) | Annual Incidence (%) |
|----------------|----------------------|
| 40 | 2.0 |
| 50 | 4.2 |
| 60 | 6.8 |
| 70 | 9.2 |

patients with claudication.¹¹ The presence of two independent risk factors, such as diabetes and cigarette smoking, has an additive effect on the risk for the development of progressive IC and serious limb complications (Table 14-2).

During a relatively short 2-year follow-up of a population with IC, 3.6% of patients died, whereas 22% experienced a nonfatal cardiovascular event (defined as any cardiac, cerebral, or peripheral vascular event). Furthermore, 26% experienced a decline in their walking capability during the same time frame.^{12,13} Although a relatively small fraction of patients died during the 2-year observation period, it is paramount to recognize that severe, short-term morbidity is highly likely in this patient population. IC clearly reflects generalized atherosclerosis and is associated with considerable morbidity.

Pathophysiology

Intermittent claudication, and its associated pain and impaired mobility, is the predominant complication of occlusive PAD. The major cause of occlusive PAD is arteriosclerosis obliterans, defined as the development of atherosclerotic plaques in the peripheral vasculature. These plaques develop as a result of endothelial activation associated with conditions such as dyslipidemia, diabetes mellitus, hypertension, and tobacco use. Plaques result in the proliferation of vascular smooth muscle, with subsequent damage to the vascular structure. The damaged endothelium of the vasculature has impaired vasodilatory capabilities because secretion of nitric oxide, also known as endothelium-derived relaxing factor, is decreased and secretion of vasoconstrictive substances, such as endothelin, are increased. Both defects impede blood flow to the extremities. In addition, growth of atherosclerotic lesions can physically limit blood flow. Exercise may induce IC symptoms in patients who have lesions with >50% stenosis, whereas patients with lesions of >80% stenosis can have pain at rest. The lesions themselves can be unstable and rupture, or adjacent smaller vessels experiencing high hemodynamic pressure caused by nearby plaques may rupture. Either situation can lead to acute vascular occlusion, analogous to unstable angina or acute myocardial infarction (MI) in coronary arteries.¹⁴

Table 14-2 Long-Term Incidence of Outcomes in Patients With Intermittent Claudication^{11,12}

| Patient Population | Abrupt Limb Ischemia (%) | Amputation (%) |
|--------------------|--------------------------|----------------|
| All patients | 23 | 7 |
| Diabetics | 31 | 11 |
| Smokers | 35 | 21 |

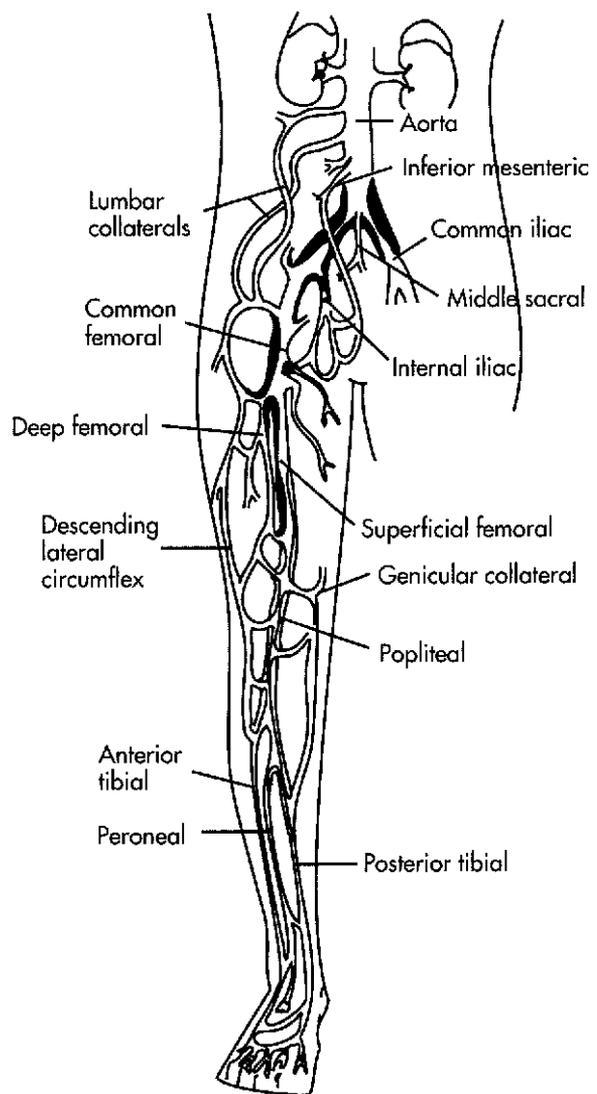

FIGURE 14-1 Common sites of atherosclerosis (shown in black) in the aorta and lower extremities. (From reference 14, with permission.)

Figure 14-1 illustrates the distribution of the major peripheral arteries. Plaques that develop in central vessels (e.g., in the ilioaortic artery) are primarily associated with buttock pain and erectile dysfunction. Those confined to the more distal femoropopliteal arteries characteristically cause thigh and calf pain. Occlusion of the tibial arteries will produce claudication pain in the foot. When more than one artery bed is affected by severe atherosclerosis, symptoms of IC will be diffuse. Symptoms of IC indicate an inadequate supply of arterial blood to peripheral muscles. Exercise, including walking, increases the metabolic demands of the muscles and can lead to claudication pain. Reduced blood supply to the muscles results from changes in perfusion pressures and vascular tone caused by atherosclerosis.

Atherosclerosis can impair the microcirculation of the peripheral muscles by altering the pressure gradient needed for perfusion of the capillaries (Fig. 14-2). When obstruction develops, perfusion of tissue distal to the stenotic lesion relies on collateral blood flow. Collateral circulation consists of new

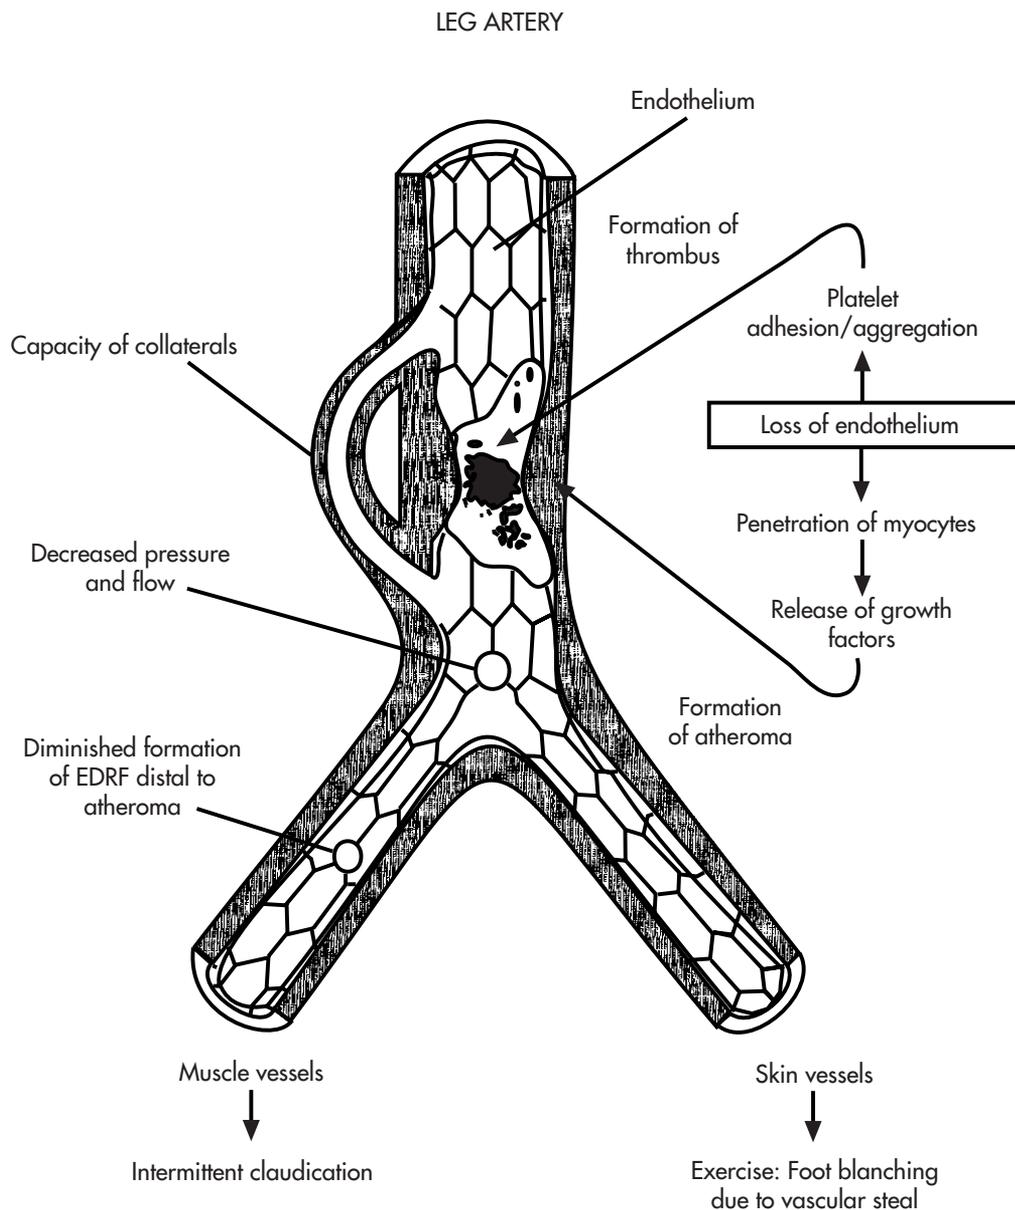

FIGURE 14-2 Consequences of occlusive atherosclerotic disease in the lower limbs. EDRF, endothelium-derived relaxing factor. (From reference 169, with permission.)

blood vessels that develop to carry blood around the occluded area.

Erythrocyte deformability is an important factor for in vitro capillary perfusion.^{15,16} In areas free of compromised blood flow, normal red blood cells (RBCs) have the ability to deform when passing through a small capillary. By aligning themselves in a planar manner, the RBCs also reduce the viscosity of the blood suspension, enabling them to pass smoothly through the capillary. In many patients with IC, RBCs have a marked decrease in this intrinsic ability to deform, which results in increased blood viscosity. This defect is promoted by chronic tissue ischemia and hypoxia caused by increased intracapillary leukocyte adherence, platelet aggregation, and activation of complement and clotting factors.¹⁴ The vascular responses to hypoxia are detrimental because this sequence of events

further inhibits blood flow and oxygen delivery to the tissues (Fig. 14-3).

Clinical Presentation

1. J.S. is a 54-year-old, 100-kg man with a history of type 2, insulin-treated diabetes mellitus, angina, dyslipidemia, and tobacco use. His chief complaint today is right upper thigh pain while walking around the block. The pain has gradually increased over the past 12 months, but only recently has become intolerable. The pain is relieved within minutes after he stops walking. J.S. smokes 1.5 packs of cigarettes a day.

His most recent laboratory results are significant for total cholesterol, 290 mg/dL (optimal, <200 mg/dL); fasting

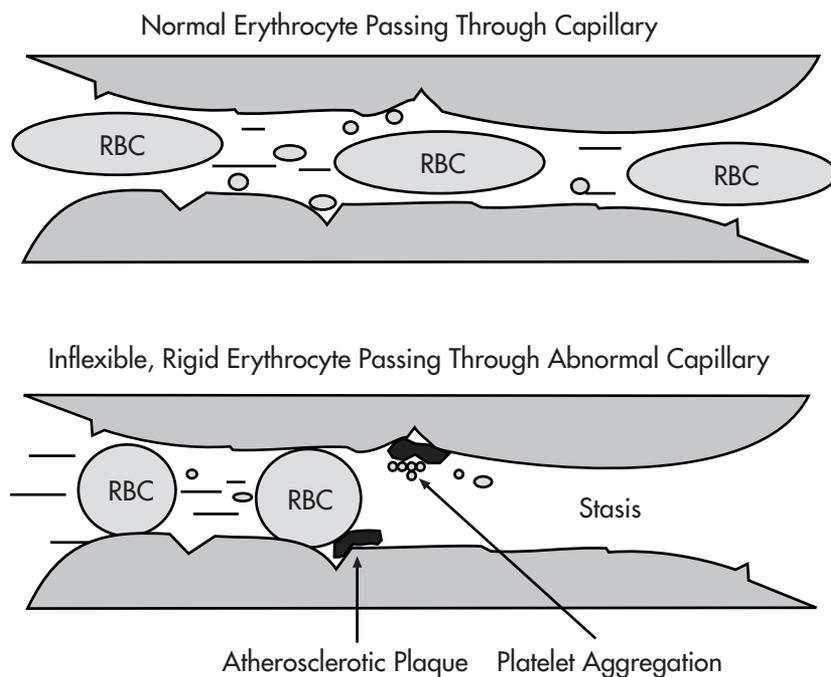

FIGURE 14-3 Erythrocyte inflexibility in intermittent claudication.

triglycerides, 350 mg/dL (optimal, <150 mg/dL); LDL, 188 mg/dL (optimal, <100 mg/dL); and HDL, 32 mg/dL (optimal, >40 mg/dL). His serum creatinine (SrCr) is 1.0 mg/dL (normal, 0.7–1.5 mg/dL), blood urea nitrogen (BUN) 15 mg/dL (normal, 8–20 mg/dL), and hemoglobin (Hgb) A_{1c} 10.0% (normal, 5%–6%), and he has a fasting glucose of 150 mg/dL (normal, 70–115 mg/dL). His blood pressure (BP) is 170/95 mmHg, heart rate (HR) is 89 beats/minute, and his posterior tibial artery pulse is not palpable. A Doppler ultrasound study is performed, and his ankle:brachial index is 0.7 (normal, >0.90).

J.S.'s medication list includes isosorbide dinitrate 20 mg three times daily (TID) (while awake), aspirin 325 mg every day (QD), and enalapril 10 mg twice daily (BID). His insulin doses have progressively increased to neutral protamine hagedorn (NPH) insulin 40 U in the morning and 35 U in the evening. What risk factors and elements of J.S.'s presentation are compatible with a diagnosis of IC?

[SI units: total cholesterol, 7.49 mmol/L (optimal, <3.88 mmol/L); triglycerides, 3.95 mmol/L (optimal, <2.26 mmol/L); LDL, 4.86 mmol/L (normal, <2.58 mmol/L); HDL, 0.83 mmol/L (normal, >1.04 mmol/L); SrCr, 60 mmol/L; BUN, 5.3 mmol/L; HgbA_{1c}, 0.1, glucose 8.3 mmol/L]

J.S.'s medical history illustrates classic risk factors for vascular occlusion and IC, including dyslipidemia (specifically hypertriglyceridemia), diabetes, hypertension, and tobacco use. In particular, his diabetes is not adequately controlled based on elevated HgbA_{1c} and fasting glucose levels, and he is obese. This constellation of disorders is known as the *metabolic syndrome*. These factors, along with smoking, commonly are seen together and have been linked with hyperinsulinemia and accelerated atherosclerosis (Fig. 14-4).^{17,18} The presence of angina indicates coronary artery disease, so it is not surprising that he has peripheral vascular occlusion as well.

The classic pain of IC described by J.S. is associated with exercise of the affected muscle group(s) and subsides with a few minutes of rest and reperfusion. IC pain also can occur at rest; however, this type of claudication pain is less common and is an indication of extensive disease. Other common symptoms of extensive atherosclerosis include cold feet and persistent aching of the feet during rest or sleep. Restricted blood flow to the feet along with pooling of blood secondary to inadequate pressure needed to propel blood back up the leg can lead to rubor (red or purple color of the foot). Other indicators of peripheral atherosclerosis are the loss of hair from the top of the feet, thickening of the toenails, and absence of sweating of the lower legs and feet, all caused by poor circulation.¹⁴

The results of objective studies performed on J.S. are consistent with IC. Doppler ultrasound of the spine is helpful in

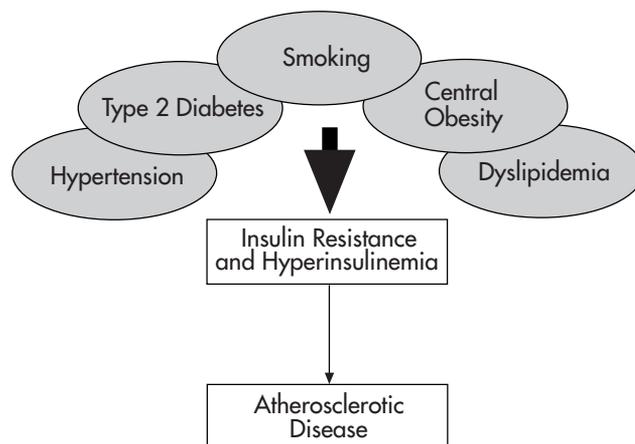

FIGURE 14-4 The metabolic syndrome in atherosclerosis.

Table 14-3 Severity of Arterial Obstruction As Assessed by Ankle:Brachial Index²⁷

| Severity | Ankle:Brachial Index ^a |
|----------|-----------------------------------|
| Normal | >0.90 |
| Mild | 0.70–0.89 |
| Moderate | 0.50–0.69 |
| Severe | >0.50 |

^aAnkle:brachial index is the systolic blood pressure in the ankle divided by the systolic blood pressure in the arm.

excluding pseudoclaudication caused by spinal stenosis and other neurogenic or musculoskeletal causes of leg pain. Ultrasound also is useful to measure BP of the lower extremities. An ankle:brachial index (ABI) of 0.7 means that the ankle systolic BP reading is only 70% of the systolic pressure in the brachial artery supplying blood to the arm. In patients with IC, this is caused by atherosclerotic obstruction of blood flow in the lower limbs and subsequent decreased perfusion pressures in the ankle compared with the arm (Table 14-3). The lower the ABI, the more blood flow to the extremities is compromised and the greater the severity of symptoms. An ABI <0.9 is diagnostic for peripheral arterial disease. Also, loss of the posterior tibial pulse, as seen in J.S., is common in those with peripheral vascular occlusion.

Treatment

Therapeutic Objectives and Nonpharmacologic Interventions

2. What is the therapeutic objective in treating J.S.? What interventions should be initiated to prevent claudication pain and arrest progression of the disease?

The specific treatment goals for J.S. are prevention of further claudication pain, lessening the current pain he experiences, arresting the progression of underlying disease, and decreasing his risk of any cardiovascular event. Achieving these goals will provide J.S. with the best chance of avoiding further mobility impairment, amputation, and cardiovascular events such as stroke or MI. An important concept that should be stressed when explaining these treatment goals to J.S. is that all his diseases are closely interrelated, and that a beneficial intervention for one disease is beneficial for all. Interventions that can be initiated include diet modification and weight loss, control of his diabetes, hypertension therapy optimization, and dyslipidemia therapy. The American College of Cardiology and American Heart Association have published guidelines that thoroughly evaluate the interventions and medications that have been used to treat IC and PAD.⁷ Table 14-4 summarizes these recommendations. The two most important things that J.S. can do for his IC are summed up in five words: “Stop smoking and keep walking.”¹⁹

SMOKING CESSATION

The importance of smoking cessation cannot be overemphasized to patients with IC. It is the most important modifiable factor in preventing the development of rest pain, prolonged limb ischemia, and the need for amputation. Several studies document improved survival and decreased amputa-

Table 14-4 Medical Treatment of Peripheral Arterial Disease and Expected Outcomes^{7,168}

| Intervention | Improve Leg Symptoms? | Prevent Systemic Complications? |

^aAspirin or clopidogrel.

tion rates in patients with IC who stopped smoking compared with patients who continue to smoke.^{20,21} Other benefits, such as improved treadmill walking distance, decreased progression to symptoms, and decreased complications following vascular reconstructive surgery, have been shown in patients who are able to quit smoking compared with patients who continue to smoke.^{7,20,22–24} It is also the intervention that will decrease J.S.’s claudication pain most rapidly. If J.S. is able to stop smoking, his risk of developing rest pain or requiring limb amputation will be very low. He also will decrease his risk of MI and mortality by three- and fivefold, respectively. Table 14-5 summarizes the risk of cigarette smoking and the value of smoking cessation on cardiovascular complications.

Many pharmacologic products and strategies are available to aid patients such as J.S. to stop smoking (see Chapter 84, Treatment of Tobacco Use and Dependence). Many are nicotine replacement products, which can be administered as a nasal spray, chewed as a gum, consumed as a lozenge, or absorbed through a transdermal patch. If these are needed to help him stop smoking, their use is warranted. Nicotine itself has harmful effects on the vasculature via catecholamine release and vasoconstriction, however, and it may play a role in endothelial damage and atherosclerosis progression.²⁵ Medications that do not contain nicotine, such as bupropion (Zyban) and varenicline (Chantix), and smoking cessation counseling or support groups should be used as necessary to help the patient stop smoking.

Table 14-5 Patient Outcomes Based on Smoking Status After Intermittent Claudication Diagnosis^{11,20}

| Amputation | 5 | 11 | 0 |
| Mortality | 10 | 54 | 18 |

^aQuit after intermittent claudication diagnosis.

EXERCISE

An individualized and supervised exercise program has been endorsed for patients with PAD and will benefit J.S.'s other risk factors as well.⁷ The pain associated with IC results in decreased mobility, and because of deconditioning from lack of exercise, patients with IC may slowly become dependent on others for activities of daily living. An exercise program is the most effective way to both preserve and increase mobility. It is more effective than the best pharmacologic therapy currently available.²⁶ The ideal exercise program consists of walking for a minimum of 30 to 45 minutes at least three times a week.⁷ J.S. should walk as fast and far as he can until the pain becomes severe; he should then wait until the pain subsides, and then resume walking.²⁷ At first, J.S. may experience several painful episodes during each exercise session, but these should gradually decrease as the beneficial effects of exercise therapy begin to emerge. Studies have documented that this type of exercise program can more than double the pain-free distance a patient with IC is able to walk.²⁸ Several surgical options are available for patients, including surgical bypass of the affected arteries, in addition to angioplasty and stenting. An appropriate exercise program results in superior outcomes compared with angioplasty and stenting, and equal in terms of walking distance compared with surgery. Significant complications and mortality are associated with surgery, however, and when all outcomes are considered, an exercise program is far more advantageous than surgery.²⁸ For all patients able to walk, an exercise program should be supervised and individually designed, and the patient should understand the importance of exercise to his or her continued mobility.²⁶

Rheologic abnormalities of increased blood viscosity, impaired RBC filterability, hyperaggregation, and polycythemia (elevated hematocrit) have been shown to return to normal in many patients with IC who participate in a regular exercise program.²⁹ Exercise may offset the need for pharmacologic intervention. The potential mechanisms by which exercise benefits patients with IC are listed in Table 14-6.

DYSLIPIDEMIA MANAGEMENT

3. Is lipid-lowering therapy indicated for J.S.?

Because IC is a consequence of atherosclerosis, arresting the progression of J.S.'s atherosclerotic disease is im-

portant (see Chapter 12, Dyslipidemias, Atherosclerosis, and Coronary Heart Disease). The initiation of the nutritional and exercise recommendations outlined in the Therapeutic Lifestyle Changes (TLC) guidelines,³⁰ as well as cholesterol-lowering agents, are the cornerstones for attaining this goal. Considerable data suggest that aggressive dietary and pharmacologic management of dyslipidemia, particularly lowering low-density lipoprotein cholesterol (LDL-C), leads to regression of atherosclerotic lesions in the coronary and carotid vasculature.^{31–33} In contrast, relatively few prospective data exist about the effect of successful lipid-lowering therapy on the regression or stabilization of peripheral lesions, or on clinical events in patients with PAD. A *post hoc* analysis of a large lipid-lowering study in subjects with known coronary artery disease treated with simvastatin, however, demonstrated a significant decrease in new or worsening IC, suggesting that benefit is seen in the prevention of clinically symptomatic PAD in high-risk patients.³⁴ Another study randomized patients with known arterial disease of various types to simvastatin 40 mg daily or placebo. After 5 years, a 15% decrease was found in noncardiac revascularizations, including amputations, among the patients receiving simvastatin.³⁵ Short-term outcomes (e.g., 6 months to 1 year), such as improved walking distance and walking time, have also been documented with simvastatin 40 mg/day.^{36,37}

A meta-analysis of 698 subjects from several small, randomized trials using a variety of lipid-lowering therapies in patients with PAD demonstrated reduced severity of claudication and decreased disease progression as measured by angiography. A decrease in mortality was also seen, but this did not reach statistical significance.³⁸ Limited data suggest high Lp(a) lipoprotein concentrations may be particularly important in the development of PAD.³⁹

All patients with evidence of atherosclerotic disease and a LDL cholesterol > 100 mg/dL (SI: 2.6 mmol/L) are candidates for a lipid-lowering regimen according to the National Cholesterol Education Program (NCEP).³⁰ J.S. has angina and lower extremity atherosclerosis, both of which indicate a need for aggressive lipid lowering. His LDL-C is 180 mg/dL, so a reduction of almost 50% is desired. Lowering triglycerides and raising HDL-C are secondary goals in J.S. and can be reassessed after his LDL goal has been reached and the effect of therapy on these parameters is measured. In addition to an aggressive dietary management program, an hydroxymethylglutaryl-coenzyme A (HMG-CoA) reductase inhibitor agent should be prescribed as initial therapy for J.S. HMG-CoA reductase inhibitors, exercise, and the American Heart Association diet will all improve his LDL-C level. They also have beneficial effects on triglycerides and HDL-C, and the need for additional therapy can be assessed after the impact of these measures is determined. Because of a lack of outcome data with many of the available agents for dyslipidemia, a fibric acid derivative is the best alternative or additional agent if lipid goals are not met with statin therapy.⁷

MANAGEMENT OF HYPERTENSION

4. J.S.'s BP is elevated to 170/95 mmHg despite enalapril therapy. Because he has angina, and his HR is 89, a β -adrenergic blocker is considered. Are there alternative antihypertensive therapies that might be preferable for J.S.?

Table 14-6 Primary Mechanisms of Symptom Improvement With Exercise Therapy in Intermittent Claudication²⁶

| |
|--|
| Decrease of blood viscosity |
| Metabolic changes in the muscle |
| Improved muscle metabolism |
| Improved oxygen extraction |
| Improved endothelial function and microcirculation |
| Decreased occurrence of ischemia and inflammation |
| Atherosclerosis risk factors improved via: |
| Weight loss |
| Glycemic control |
| Blood pressure control |
| Increased high-density lipoprotein (HDL) |
| Decreased triglycerides |
| Decreased thrombotic tendency |

J.S.'s hypertension has likely contributed to the development of his atherosclerosis and PAD. Hypertension has been associated with deficiencies in the synthesis of vasodilating substances, such as prostacyclin, bradykinin, and nitric oxide, by the endothelial cells lining the vasculature. Hypertension also increases concentrations of vasoconstricting substances, such as angiotensin II. An increase in vascular tone can alter local hemodynamics, especially in the presence of a stenotic lesion. Although it has not been determined whether normalization of BP has a positive effect on IC, it is well established that uncontrolled BP, as in J.S., results in vascular complications such as MI and stroke. In light of J.S.'s numerous risk factors for these complications, improved management of his hypertension is warranted.

β -blockers are frequently cited as contraindicated in patients with IC owing to the potential for unopposed α -adrenergic-mediated vasoconstriction during peripheral β -blockade. Evidence to document worsening IC by β -blockade is lacking, however. Overall, controlled studies have been inconclusive, although, a meta-analysis of placebo-controlled trials and studies with control groups concludes that β -blockers do not worsen claudication.⁴⁰

Angiotensin-converting enzyme (ACE) inhibitors are first-line agents in patients with PAD.⁷ Compared with other antihypertensive agents, more data document their beneficial effects in these patient populations. Compared with placebo, walking distance is increased with both perindopril and ramipril in patients with PAD.^{41,42} The Heart Outcomes Prevention Evaluation (HOPE) study of the ACE inhibitor ramipril versus placebo included >4,000 patients with PAD, and this subgroup derived benefit in terms of decreased mortality, MI, and stroke.⁴³

Because J.S. has both hypertension and diabetes, his BP goal is <130/80.⁴⁴ He is already taking an ACE inhibitor, which is an excellent initial antihypertensive choice in a patient with diabetes and PAD. The dose of enalapril could be increased, or a low-dose diuretic, such as hydrochlorothiazide or chlorthalidone, could be added. This combination is synergistic and should be very effective in reducing J.S.'s BP.^{45,46} Other options include a calcium channel blocker or a β -blocker, both of which are useful in patients such as J.S. with angina. If J.S. develops angina symptoms with exercise as a result of sympathetic stimulation, a β -blocker may be required to permit participation in an exercise program that could greatly benefit his IC.

MANAGEMENT OF DIABETES

5. Will improving J.S.'s diabetes control slow the progression of his PAD? What changes in his diabetes management do you recommend?

Patients with type 2 diabetes mellitus are able to minimize macrovascular and microvascular complications of their disease with aggressive pharmacologic glucose control.^{6,47,48} Insulin, sulfonylurea, or metformin therapy have a beneficial effect on slowing the development of the microvascular complications of diabetes, such as retinopathy and nephropathy. Metformin has specifically been shown to further reduce the occurrence of macrovascular complications such as stroke or myocardial infarction compared with therapy with insulin or sulfonylureas in obese patients with type 2 diabetes.⁴⁷

Table 14-7 Effect of Diabetes Mellitus on Intermittent Claudication Outcomes After 5 Years¹⁰

| | Patients With Diabetes (%) | Patients Without Diabetes (%) |
|------------------|----------------------------|-------------------------------|
| Mortality | 49 | 23 |
| Major amputation | 21 | 3 |
| Deterioration | 35 | 19 |

J.S.'s diabetes is a significant risk factor for progression to further ischemic events (Table 14-7). He has a twofold greater risk of death and a sevenfold greater risk of amputation compared with a patient without diabetes. Although a specific benefit on IC has not been demonstrated, it seems prudent to initiate or continue aggressive diabetes management in patients with type 2 diabetes mellitus and IC. The addition of metformin to J.S.'s therapy could improve his blood glucose control and decrease his risk of vascular complications. This agent will favorably affect hepatic glucose production and insulin sensitivity and could result in weight loss. The addition of a short-acting insulin before meals is another possible intervention. It is hoped that J.S. can reach his hemoglobin A1c goal of <7% and a fasting blood glucose of 90 to 130 mg/dL with diet, exercise, and metformin therapy, in addition to his standing dose of insulin.⁴⁹ It would also be helpful to have J.S. check his blood glucose before meals, 1 to 2 hours after meals, and at bedtime and to keep a log of the results. This may help improve understanding of his medication and nutrition therapies and help guide future therapy changes.

J.S. also must take proper care of his feet to prevent ulcerative complications of IC. He should be encouraged to keep his feet warm, dry, and moisturized and to wear properly fitted shoes and perform daily foot inspections.⁷ He should seek medical attention immediately for minor trauma to his feet or legs.⁴ These measures can reduce the incidence of amputation in patients with diabetes.

Pharmacologic Therapies

ANTIPLATELET THERAPIES

6. Is the aspirin that J.S. is taking beneficial for preventing further complications of IC? Would a newer agent such as clopidogrel offer any advantage over aspirin?

Aspirin is one of several antiplatelet agents that may be considered for indefinite use in patients such as J.S. with IC. A paucity of studies has directly addressed the effects of aspirin on IC symptoms. Rather, most available data address the impact of aspirin on overall cardiovascular morbidity and mortality. Aspirin exerts its antiplatelet effect by irreversibly inhibiting cyclooxygenase. This enzyme is essential for the production of thromboxane A₂, a stimulus for platelet aggregation. Although aspirin has no direct effect on plaque regression, it does prevent and retard the role platelets play in the thrombogenic events that occur in the vicinity of atherosclerotic plaques.⁵⁰ Aspirin is an effective antithrombotic agent at dosages ranging from 50 to 1,500 mg daily. The minimal dosages proved to decrease cardiovascular events are 75 to 150 mg daily, with the higher dosage showing benefit in active processes, such as acute ischemic stroke⁵¹ and acute MI.⁵² A dosage of 75 mg daily has

demonstrated benefit in patients with hypertension⁵³ and stable angina.⁵⁴ No evidence indicates that these “low doses” are any more or any less effective than dosages of 900 to 1,500 mg daily.⁵⁵

Aspirin is mandatory in patients with vascular disease of any origin (this includes stroke, MI, PAD, and angina). At dosages of 75 to 150 mg/day, it decreases vascular death by approximately 15% and all serious vascular events (MI, stroke, or vascular death) by approximately 20% in high-risk patients, including those with PAD.⁵⁵ In patients with PAD, aspirin can delay the progression of established lesions as assessed by angiography. When used for primary prevention of cardiovascular disease in men, aspirin decreased the need for arterial reconstructive surgery needed because of PAD.⁵⁶ Whether aspirin has any beneficial effects on walking distance or claudication pain in patients with IC has not been studied, however.

Because all dosages of aspirin are similarly efficacious in decreasing vascular events in this patient population, side effects determine the dose chosen. Although few studies have directly compared varying doses, side effects appear to be dose related. Aspirin 30 mg daily results in less minor bleeding compared with approximately 300 mg daily,⁵⁷ and 300 mg daily results in fewer GI side effects compared with 1,200 mg daily.⁵⁸ Therefore, J.S. should take the lowest effective dose of aspirin; for convenience, 81 mg daily. Of note, J.S.’s hypertension should be controlled before initiating aspirin therapy to decrease the small increased incidence of cerebral hemorrhage associated with its use.⁵⁹

Ticlopidine is a thienopyridine derivative that blocks adenosine 5'-diphosphate (ADP) receptors on platelets, and decreases platelet-fibrinogen binding.⁶⁰ Several studies document its efficacy in patients with PAD on endpoints such as walking distance, cardiovascular death, and the need for revascularization surgery.^{61,62} Diarrhea is a common side effect, however, and hematologic toxicities (neutropenia and rarely, thrombotic thrombocytopenic purpura) further limit its use.^{63,64} Clopidogrel, an antiplatelet agent with the same mechanism of action as ticlopidine but with an improved safety profile, has largely replaced ticlopidine when thienopyridine therapy is desired. The effects of clopidogrel on specific PAD outcomes are not known, but it has been compared with aspirin in patients with known atherosclerotic disease. Dosages of 75 mg daily significantly reduced cardiovascular endpoints by approximately 25% compared with aspirin in this patient population.⁶⁵ In fact, the treatment effect was most pronounced in the subgroup that had PAD, leading to the suggestion that clopidogrel may be preferable in the patient population with PAD. No measure was taken of clopidogrel’s effect on walking distance or claudication pain, however, nor have these results been replicated. The combination of aspirin and clopidogrel was compared with aspirin alone in >15,000 patients at high risk of vascular events, of whom >20% had a history of PAD, and approximately 10% had IC.^{66,67} In this large study that assessed cardiovascular endpoints, no benefit was found to dual antiplatelet therapy with aspirin and clopidogrel.⁶⁷ Thus, clopidogrel is an appropriate alternative to aspirin in patients unable to take aspirin therapy, perhaps owing to a serious allergy.⁷ It should not be used in addition to aspirin, however, because the risk of bleeding and increased cost are not outweighed by any measurable vascular benefit.⁶⁷

CILOSTAZOL

7. Are there any medications that can be used to increase the walking abilities of patients with IC?

Cilostazol is one of the few agents approved by the U.S. Food and Drug Administration (FDA) specifically for the treatment of IC. Several studies have confirmed that at a fixed dose of 100 mg twice daily of cilostazol increases walking distance by approximately 50%,^{68–70} and that discontinuation of cilostazol resulted in a decline in function.⁷¹ This drug possesses antiplatelet and vasodilatory effects mediated by the inhibition of phosphodiesterase III.⁷² Some *in vitro* observations suggest that these pharmacologic effects of cilostazol are particularly pronounced at the blood–vessel interface,⁷² which may explain its particular efficacy in the patient population with PAD. Studies that included quality-of-life measurements have found that cilostazol improved overall quality of life in these patients.^{68,73} Additionally, a small improvement was seen in ABI with chronic cilostazol therapy.⁷⁴ Despite these positive findings with cilostazol, several drawbacks exist to its use. It is contraindicated in patients with heart failure, because other phosphodiesterase inhibitors cause excess mortality in patients with heart failure, presumably owing to increased arrhythmias.⁷⁵ Other common side effects include headache, occurring in up to one-third of patients, and loose stools or diarrhea.^{69,76} Cilostazol is a cytochrome P450 3A4 substrate; therefore, any inhibitor of this enzyme system may substantially increase cilostazol levels.

Cilostazol is an importance advance in the treatment of IC. It is the first pharmacologic agent to demonstrate a consistent effect on a significant source of IC disability: walking and mobility measures. Although no data address its impact on other important endpoints, such as amputation and revascularization procedures or cardiovascular events, it should be added to J.S.’s existing medication regimen at a dosage of 100 mg twice daily to attenuate his symptoms of IC. It is hoped that its addition to smoking cessation, exercise, and optimal blood pressure and glycosylated hemoglobin attainment will result in good long-term symptomatic and vascular event outcomes.

RHEOLOGIC AGENTS

8. Has pentoxifylline been shown to be efficacious in patients such as J.S.? How does this drug benefit patients with IC?

Pentoxifylline, a methylxanthine derivative, is one of the few agents approved by the FDA for the treatment of IC. The exact mechanism of action is unclear; however, it appears to decrease blood viscosity by decreasing fibrinogen, improving the deformability of both red and white blood cells, and eliciting antiplatelet effects.⁷⁷ Although the theoretic and *in vitro* data on pentoxifylline are unique and positive, the data demonstrating clinical usefulness of this agent are controversial. In general, the improvements in walking distances from study to study are unpredictable, and the clinical importance of the sometimes minimal increases in walking distances is not clear (e.g., pain-free walking of approximately 30 m greater than with placebo).⁷⁸ Some experts assert that these potential benefits of questionable clinical significance are not worth the expense of drug therapy or the GI side effects.^{40,79} Because the therapy is of questionable benefit, the expense and potential for side effects are rarely justified.

Pentoxifylline's role in IC therapy is limited. It may have a role in patients who are unable to engage in exercise therapy or in patients with markedly reduced walking distances, in whom any small increase in walking distance would greatly improve the patient's level of activity.⁸⁰ It also may be tried in patients who have not gained the desired benefit from smoking cessation and exercise therapy. A 2-month trial of pentoxifylline is adequate to determine if the patient will benefit from the therapy.²⁷ J.S. is not severely debilitated, and the benefits of smoking cessation, exercise therapy, and cilostazol have not been fully realized. Therefore, pentoxifylline therapy should be withheld until his response to these well-proven therapies has been determined and the need for further improvement in walking distance is established.

VASODILATORS

9. J.S. is already taking isosorbide dinitrate for his angina. Because IC is made worse by vasoconstriction, should another vasodilating agent be added to treat both his hypertension and IC?

The use of vasodilators for J.S. would at first appear to be a logical pharmacologic intervention to prevent claudication pain. Vasodilators, including isosorbide dinitrate, directly or indirectly relax blood vessel walls and increase both skin and muscle blood flow as long as cardiac output is maintained. With obstructive arterial disease, however, vessels are sclerotic and unable to dilate any further. As a result, relatively healthy collateral vessels dilate to a greater extent than diseased vessels and blood flow is redistributed (shunted) away from areas that have the greatest need. Blood pressure and perfusion paradoxically drop even further in the affected tissues. This process is known as the *steal phenomenon*.

Numerous vasodilators (i.e., prostaglandin-E1, prostacyclin, isoxsuprine, papaverine, ethaverine, cyclandelate, niacin derivatives, reserpine, guanethidine, methyldopa, tolazoline, nifedipine, L-carnitine) have been used to treat IC. None, however has convincingly or consistently improved exercise performance, despite earlier beliefs that they were effective.^{81,82} ACE inhibitors are the exception to this rule, as discussed above, and their beneficial effects are likely independent of their vasodilator properties. One small, controlled study demonstrated improvement in walking distance with verapamil, a calcium channel blocker, compared with placebo in patients with IC.⁸³ Thus, although vasodilators have generally been eliminated from the treatment of IC and related obstructive vascular disorders,¹⁴ verapamil may be an agent with vasodilating properties that is useful in patients with IC.

Smoking cessation, an exercise program, and cilostazol are the interventions that should reduce J.S.'s symptoms of IC to the greatest degree. After these three measures have been implemented and the impact of the modified BP regimen, which should definitely continue to include an ACE inhibitor, has been assessed, the addition of verapamil could be considered. Verapamil is a cytochrome P450 3A4 inhibitor, and would be expected to increase concentrations of cilostazol. The magnitude of this interaction has not been characterized, nor has its impact on efficacy and bleeding events been assessed. Based on the necessity of cilostazol therapy in J.S., the poorly characterized benefits of verapamil in IC, and the plethora of other antihypertensive and antianginal agents, avoidance of vera-

pamil is prudent in this patient. If additional BP or antianginal effects are needed, β -blockade or amlodipine can be initiated, or the nitroglycerin dose can be increased (see Chapter 16, Ischemic Heart Disease: Anginal Syndromes).

Other Therapeutic Alternatives

10. The sales clerk at a health food store told J.S. that several nutritional supplements and herbal products would improve his circulation so that he could walk better. He is considering buying ginkgo biloba. Does ginkgo or any other herbals or vitamins really work?

Several herbs and vitamins have been used to treat IC, but most have not been rigorously studied. To complicate matters, many studies are published in foreign journals, making access and interpretation of the data challenging.

Ginkgo biloba is one of the few herbal therapies with double-blind, placebo-controlled trials to support its use. A meta-analysis of eight trials representing data from 385 patients reported a mean increase in pain-free walking of 34 m (a 47% increase) with a median dosage of 160 mg daily for 6 months.⁸⁴ It has been proposed that ginkgo's therapeutic value is related to its antiplatelet properties.⁸⁵ Ginkgo is generally well tolerated with no major side effects, except for an increased risk of bleeding as would be expected with any platelet inhibitor.⁸⁶ Occasionally, mild GI upset or headache have been reported.⁸⁷ Although the treatment benefit is modest, a consistent trend in benefit is seen and the side effects are minor.

Vitamin E has been advocated for the treatment of intermittent claudication for many years.⁸⁸ Only a few very small, poorly controlled studies, however, support its ability to improve blood flow and walking distance.^{89,90} Vitamin E has not prevented cardiovascular events in patients with both established coronary artery disease and risk factors for cardiovascular disease.⁹⁰⁻⁹² Although it is generally not harmful at dosages of 400 to 800 IU/day, vitamin E is unlikely to offer any symptomatic relief or long-term protection from cardiovascular events to J.S.

Patients with IC have decreased intramuscular carnitine levels, and this impairs oxidative metabolism in skeletal muscle.^{93,94} Exogenous propionyl-L-carnitine, 1 to 2 g/day, improves energy production in ischemic muscles. Small studies have demonstrated beneficial effects on walking distances^{95,96} and quality of life⁹⁷ in patients with IC. Although it is not approved by the FDA, similar agents, such as levocarnitine, are available in the United States. Limited data suggest its effects are less than those seen with propionyl-L-carnitine.⁹⁶

With the abundance of proved, therapeutic measures to be initiated in J.S., the use of relatively poorly studied and unsubstantiated alternative products is not warranted. If debilitating symptoms are still present after adequate trials of the proved therapies, then ginkgo biloba may be considered. J.S. should inform his doctors and pharmacist if he uses any of these agents so they can anticipate the inevitable drug interactions (e.g., ginkgo biloba plus antiplatelet drugs) and to allow for appropriate assessment and monitoring.

11. Three years have passed, and J.S. stopped smoking 6 months ago. His symptoms of IC have remained fairly stable, until the recent development of a nonhealing ulcer on his toe. What options

are there for J.S. if nonpharmacologic and pharmacologic interventions are not sufficient?

Surgical intervention eventually may be necessary for persistent and complicated disease. Because success rates for preventing amputation and postsurgical complications vary from institution to institution, surgery should be considered only for severely ischemic limbs and should be performed in a hospital with a good history of success.⁹⁸ Arterial bypass grafting and percutaneous transluminal angioplasty of the femoral or iliac arteries, similar to cardiac revascularization, are two procedures that can be performed. Angioplasty is beneficial in patients with localized disease, especially in the iliac or superficial femoral arteries, and should be considered in patients who truly are incapacitated by their activity limitations.⁹⁹ Angioplasty ± stent deployment, atherectomy, and the use of drug-eluting stents in the peripheral arteries are all options.⁷ The results obtained are based on several factors, including the vascular bed affected, the technique used, and the degree of occlusive disease. Interestingly, angioplasty has not decreased the number of amputations, yet costs for revascularization procedures have doubled.¹⁰⁰ The more invasive reconstructive arterial (bypass) surgery can be used if diffuse lesions preclude the use of localized angioplasty. The true benefits and pitfalls of these skilled interventions remain unclear.

Emergency surgical intervention may be required if acute, persistent ischemia develops. This is frequently owing to a thrombosis associated with advanced atherosclerosis, although other causes, such as cardiac emboli, cannot be excluded.⁸⁰ Both surgical thrombectomy and localized thrombolytic administration¹⁰¹ with tissue-plasminogen activator (t-PA) or urokinase have equal success in alleviating acute limb-threatening ischemia.^{102,103}

RAYNAUD'S PHENOMENON

Raynaud's disease, first described by Maurice Raynaud in 1862,¹⁰⁴ remains largely a medical enigma today. This disorder is essentially an exaggerated vasospastic response to cold or emotion. The digits initially turn white, indicating ischemia; then blue, signaling deoxygenation; and finally, digits appear red when reperfusion occurs.¹⁰⁵ It is usually limited to the skin of the hands and fingers, but can also occur in the feet. Between attacks, the digits may appear cool and moist or normal. This abrupt and discomforting phenomenon can be brought on by exposure to cold or emotional stress, both likely mediated through an exaggerated sympathetic response to the precipitating stimuli. Although both IC and Raynaud's phenomenon are disorders of the peripheral arterial circulation, they differ significantly in that IC results primarily from atherosclerotic obstruction, whereas Raynaud's disease is caused by vasospasm.

Diagnosis

This disorder can be separated into primary Raynaud's phenomenon, indicating an idiopathic origin, and secondary Raynaud's. Secondary Raynaud's consists of signs and symptoms of Raynaud's phenomenon in the presence of an associated disease or condition, most commonly a connective tissue disorder, such as scleroderma, rheumatoid arthritis, or systemic lupus erythematosus. Primary Raynaud's disease is diagnosed only when secondary causes have been excluded.¹⁰⁶ Common cri-

Table 14-8 Diagnosis of Primary Raynaud's Phenomenon¹¹³

| |
|--|
| Vasospastic attacks caused by cold or emotional stress |
| Symmetric attacks involving both hands |
| No evidence of digital ulcerations, pitting, or gangrene |
| Normal nailfold capillaries |
| No suggestion of a secondary cause |
| A negative antinuclear test |
| A normal sedimentation rate |

teria for the diagnosis of primary Raynaud's phenomenon are listed in Table 14-8. The diagnosis is generally a subjective one, consisting of clinical signs and symptoms, and simply reflects cold hands, feet, or both without normal recovery following a cold stimulus or emotional stress.¹⁰⁷ In unaffected individuals, a cold provocation should result in some mottling and cyanotic changes in the hands, with recovery once the stimuli are removed. In patients with Raynaud's phenomenon, however, the same cold provocation causes closure of the digital arteries, which produces a sharply demarcated pallor and cyanosis of the digits that persists despite removal of the stimulus.¹⁰⁷ The most reliable objective method to measure artery closure during an attack is the finger systolic BP¹⁰⁸; however, subjective diagnostic criteria are most commonly and easily employed to diagnose Raynaud's phenomenon.

Epidemiology

In general, the prevalence of Raynaud's phenomenon is about 3% to 4% across several ethnic groups¹⁰⁶; however, it may be as high as 20% in some geographically defined populations.¹⁰⁹ It is more common in women than men, tends to affect young patients, and has a higher prevalence in patients with family members who also experience Raynaud's phenomenon. An onset in the teenage years suggests primary Raynaud's phenomenon, whereas an onset after 30 years of age suggests a secondary cause.¹¹⁰ Secondary Raynaud's phenomenon is usually associated with a connective tissue disorder, but several other conditions may predispose individuals to its development. These include occupational-related exposures to vibratory machinery (e.g., drills, grinders, chain saws) that cause neural damage,¹¹¹ vinyl chloride, or hand trauma.^{112,113} The diagnosis of primary Raynaud's phenomenon is accurate approximately 85% of the time. The remaining 15% will manifest a connective tissue disorder during the next decade, and will most likely occur in individuals with serum antinuclear antibodies and thickened fingers.¹¹⁴ Raynaud's phenomenon can also be associated with medications, including β -adrenergic blocking agents, ergots, cytotoxic drugs, and interferon, all of which can induce vasoconstriction.^{115,116} Although avoidance of β -adrenergic blocking agents in patients with Raynaud's phenomenon appears prudent, no discernible effect, as measured by skin temperature and blood flow, was found with the administration of both selective and nonselective β -blockers to patients with Raynaud's phenomenon.¹¹⁶ Raynaud's phenomenon not associated with a connective tissue disorder is often transient, and does not interfere with daily activities.¹¹⁷ The effect of smoking on Raynaud's phenomenon has yielded conflicting results. Overall, there appears to be a negligible effect of smoking on the prevalence of Raynaud's phenomenon, the incidence of attacks, and digital blood flow.^{118,119}

Pathophysiology

The blood vessels of the digital skin, which have a prime role in the regulation of body temperature, are supplied with vast amounts of sympathetic vasoconstricting nerves.¹⁰⁶ Cold-induced vasospastic attacks in patients with primary Raynaud's phenomenon involve a heightened vasoconstriction of these digital arteries that is mediated by α_2 -adrenergic receptor.¹²⁰ The cause of this exaggerated response to cold stimuli is unknown; however, several plausible mechanisms involving peripheral α_2 -adrenoreceptors could result in an intense vasoconstriction. These include an increased (a) number of α_2 -adrenoreceptors, (b) temperature sensitivity of the α_2 -adrenoreceptors, and (c) activity of the α_2 -adrenergic intracellular signal-transduction pathway.¹¹⁰ The mechanism of secondary Raynaud's phenomenon is also not known, but it is thought to be similar to primary Raynaud's phenomenon. The α_2 -adrenoreceptor aberrancy may be the result of arterial damage induced by an associated disease state, such as a connective tissue disorder.¹¹⁰ It is also possible that serotonin receptors (S_2) play a role in Raynaud's phenomenon. Serotonin agonists have caused decreased finger blood flow and, conversely, antagonists have increased digital blood flow.¹²¹ Clinically, a patient with Raynaud's disease will present with a waxy pallor of one or more of the fingers after the sudden decrease of arterial blood flow. Hemoglobin desaturation occurs with static venous blood flow and causes the digit or digits to have a cyanotic appearance. The attack subsides over time, and the affected arteries vasodilate. As the skin temperature increases, classic rubor, or reddening of the afflicted area, will be seen. Many patients will be observed to have pallor only during the initial attack, in which the digits take on a white or yellow, sometimes patchy, appearance. In most cases, the ischemia produced by the phenomenon does not have important consequences; however, in severe cases, atrophy of the skin, irregular nail growth, and wasting of the tissue pads can occur.¹⁰⁶

Clinical Presentation

12. F.K., a 39-year-old man, presents today with a 4-day history of left hand pain. He notes that the third digit of his left hand is "cold and somewhat blue," especially in the distal area. The other areas of his hand have recovered, but the distal portion of the digit remains cyanotic and numb. He has used acetaminophen and warm-water soaks without success. He is a construction worker who uses his hands "quite a bit" in his work. He has a history of gastroesophageal reflux and has no allergies. His social history is significant for smoking 1.5 packs of cigarettes a day for 19 years. On physical examination, his extremities reveal appropriate sensation of the forearm and hand. Some blue areas are noted on the distal portion on the third phalanx, with no other signs and symptoms. When F.K.'s opposite hand was placed in cold water, several white splotches appeared and he experienced tingling in this hand as a result of the cold-water exposure. He is diagnosed as having Raynaud's phenomenon. Does F.K. present with primary or secondary Raynaud's phenomenon?

F.K. presents with what is most likely secondary Raynaud's phenomenon owing to one of several potential underlying causes. His clinical presentation is classic for Raynaud's phenomenon, with vasospasm, pallor, and a cyanotic overtone. The

diagnosis is confirmed by the cold-water test, which indicates that the vasospastic attack is precipitated by cold exposure. He has a work history that may easily include hand trauma and the use of vibrating machinery, and his age also suggests secondary Raynaud's phenomenon. Because of its association with connective tissue disorders, other laboratory tests such as an antinuclear antibody (ANA) and sedimentation rate should be checked.

Treatment

Nonpharmacologic Management

13. What conservative measures can be taken with F.K. to prevent or decrease the painful vasospasm of Raynaud's disease?

Most patients with both primary and secondary Raynaud's phenomenon will respond to conservative management. Avoiding cold stimuli is the primary treatment. F.K. should be instructed to protect his hands and fingers from exposure by using mittens and insulated wrappers when handling cold drinks. Although protecting his hands is important, he must also protect other parts of the body from cold exposure to prevent a sympathetic response, which may trigger symptomatic vasoconstriction in his hands. This includes layering his clothing when working outside in cold weather. He should avoid medications that can induce vasoconstriction, particularly sympathomimetics, clonidine, serotonin receptor agonists, and ergot preparations.¹¹³ He should be encouraged to stop smoking, which will avoid smoking-induced vasoconstriction and provide an overall positive health benefit. The impact of smoking cessation on Raynaud's phenomenon, however, actually appears to be negligible.^{118,119}

F.K. has new-onset and relatively mild Raynaud's phenomenon. For others who have more severe symptoms and manifestations, especially patients with underlying connective tissue disorders, it is important to immediately and aggressively manage any ulcers that develop on the digits and to be extremely vigilant in detecting infected digits. Antibiotic therapy should be initiated if necessary.¹²²

Calcium Channel Blockers

14. Nifedipine extended-release 30 mg QD is ordered for F.K. What is the rationale for using a calcium channel blocker in this case?

Drugs can be used to treat primary and secondary Raynaud's phenomenon if it interferes with the patient's ability to work or perform daily activities or if digital lesions develop. Most proposed treatments for Raynaud's are, however, variably effective; they introduce the risk for significant side effects and may be expensive. Drug therapy should always be in addition to nonpharmacologic measures.

Calcium channel blockers decrease calcium ion influx and prevent smooth muscle contraction, especially vascular responses evoked by cold exposure. Nifedipine, a potent peripheral vasodilating calcium channel blocker, has become the drug of choice in patients with Raynaud's disease not controlled by conservative measures. In primary Raynaud's phenomenon, ten or more episodes per week are common. Nifedipine therapy results in an approximate 50% decrease in the number of attacks, in addition to a decrease in severity by one-third.¹²³ Patient's

with secondary Raynaud's phenomenon experience a similar decrease in attack severity, and also obtain a decrease in number of attacks with nifedipine therapy. Because their baseline number of attacks per week often exceeds 20, the relative benefit is not as great as with primary Raynaud's phenomenon, averaging approximately a 25% decrease in weekly episodes.¹²⁴ Doses of 10 to 30 mg three times daily of immediate-release nifedipine are beneficial,^{125,126} although higher doses, if tolerated, may be required for maximal benefit.¹²⁷ Most clinicians administer nifedipine as an extended-release formulation to increase convenience and decrease side effects such as dizziness, headache, facial flushing, and peripheral edema, which can occur in up to 50% of patients,¹²⁸ and this practice is supported by several clinical studies.^{129–131} Even the extended-release preparation of nifedipine can cause bothersome edema owing to dilation of the precapillary bed.

Although less thoroughly studied than nifedipine, other vasoselective calcium channel blockers (CCBs), such as amlodipine, felodipine, isradipine, and nisoldipine decrease the frequency and severity of ischemic attacks.^{132–135} Patients who do not benefit from nifedipine likely will not benefit by switching to another CCB. Patients who cannot tolerate the side effects of nifedipine (e.g., ankle edema) might benefit by switching to another CCB.

F.K. should be warned of the potential side effects with nifedipine therapy, especially dizziness associated with hypotension, and should return in 2 weeks for assessment. A 30-mg daily dose of extended-release nifedipine is a reasonable starting dose. He should be instructed to keep a diary documenting the number of attacks he experiences and details surrounding each attack, such as time course and precipitating factors. In addition to the usual side effects mentioned above, F.K. should be aware that his symptoms of gastroesophageal reflux could worsen with nifedipine therapy, which can cause a decreased lower esophageal sphincter pressure. This side effect should be specifically assessed at his follow-up appointment.

Other Therapeutic Agents

15. What other drugs may be tried if F.K. cannot tolerate the calcium channel blocker?

Other than CCBs, no proven therapy for Raynaud's phenomenon exists. Many agents, however, have been used based on minimal data and anecdotal reports. The α_1 -adrenergic antagonists are one such class of drugs. Prazosin, 1 mg three times a day, yielded moderate benefit in two-thirds of patients in two small studies.^{136,137} Side effects of prazosin are significant at maximal doses and include dizziness, edema, fatigue, and orthostasis. The longer-acting α_1 -adrenergic antagonist terazosin was evaluated in one small study and it improved symptomatology as well as objective measures of blood flow.¹³⁸ No sufficient data with this class of drugs exist to routinely recommend their use in patients with Raynaud's phenomenon.

Several therapeutic approaches are being vigorously investigated, and show promise as future therapies for Raynaud's phenomenon. These include the intravenous prostanoids, iloprost and alprostadil, which enhance nitric oxide-mediated vasodilation¹³⁹; endothelin antagonists, such as bosentan¹⁴⁰; and oral phosphodiesterase inhibitors, such as sildenafil¹⁴¹ and vardenafil,¹⁴² which also promote vasodilation. Because of

side effects, extreme cost, and administration difficulties, these agents are only being studied in the most severe secondary Raynaud's phenomenon cases with digital ulcers or other systemic complications associated with connective tissue diseases. If benefit is proved, however, it will shed light onto the pathogenesis of the disorder, and perhaps lead to therapies appropriate for the larger population with Raynaud's phenomenon.

The ACE inhibitors act as vasodilators and have been investigated in several small studies. ACE inhibitors and angiotensin receptor blockers, however, do not appear to have any beneficial effects in patients with Raynaud's phenomenon.¹⁴³ Fluoxetine, a selective serotonin reuptake inhibitor, was shown in one study to reduce the symptoms of Raynaud's phenomenon.¹⁴⁴ It is hypothesized to exert its effect by depleting platelet serotonin, rendering the platelet unable to release a significant amount of the vasoconstrictive serotonin during activation and aggregation.

The application of nitroglycerin (NTG) ointment to the hands of patients with Raynaud's disease has been tried since the mid-1940s. High doses of NTG ointment (3.5 inches) three times a day applied to the hands for 6 weeks resulted in fewer and less severe attacks.¹⁴⁵ Transdermal NTG patches also provide some benefit, although headaches may be a limiting factor.¹⁴⁶ The potential for tolerance developing to the nitrates for this indication has not been studied. Because the data supporting nitrate use in the management of Raynaud's phenomenon are sparse, these agents should be discontinued after 2 to 3 weeks if no benefit is observed.¹²² Alternative therapies, such as ginkgo biloba and L-arginine, have also been studied in small trials with positive results; however, larger trials are needed to confirm the findings before these therapies can be recommended.^{147,148}

All patients with Raynaud's phenomenon should be counseled regarding cold avoidance and other protective measures. A CCB, nifedipine if tolerated, should be initiated if conservative measures are ineffective and titrated to the highest tolerated dose and symptom resolution. Combination therapies have not been investigated, but another agent, such as an α_1 -adrenergic antagonist, may be considered in addition to the CCB if symptom resolution is not satisfactory and side effects permit.

NOCTURNAL LEG MUSCLE CRAMPS

Nocturnal leg muscle cramps are idiopathic, involuntary contractions occurring at rest that cause a visible and palpable knot in the affected muscle. This type of muscle cramp usually afflicts middle-aged to elderly persons and is a distressing and painful condition. Its cause is unknown. The two primary hypotheses that attempt to explain the pathophysiology propose neurologic impairments. One involves a central nervous system impairment of γ -aminobutyric acid (GABA)¹⁴⁹ and the other, an impaired peripheral response to muscle lengthening.¹⁵⁰ Although the incidence of nocturnal cramps is unknown, some data indicate it is very common. In a survey of veterans (95% men averaging 60 years of age), 56% complained of leg cramps, with 12% having cramping nearly every night¹⁵¹; 36% of these veterans were also attempting some type of drug treatment for their symptoms. A survey of a general population revealed that the prevalence of nocturnal leg cramps was 37% in people >50 years of age, and increased to 54% in people

>80 years of age. The prevalence in men and women is equal.¹⁵² Nocturnal leg cramps are associated with lower extremity atherosclerosis, coronary artery disease, and peripheral neurologic deficits.^{152,153}

Clinical Presentation

16. E.A., a 62-year-old woman, complains of cramps in her left calf that began last night around 10 PM. The cramping occurred several times throughout the night and has resolved slowly since she arose this morning. These nighttime cramping episodes occur frequently, are very painful, and cause her calf muscle to become “knotted.” She denies any trauma, fever, or chills, has no other medical problems, and takes no medications. The pain is not associated with walking. The physical examination is unremarkable and her vital signs are stable. An extended chemistry panel and thyroid function tests are within normal limits. E.A. works at an elementary school and walks up and down stairs throughout the day. Her physician associates the pain with nocturnal leg cramps. What characteristics differentiate E.A.’s nocturnal leg cramps from other pain syndromes?

Benign nocturnal leg cramps usually occur in the early hours of sleeping; they are asymmetric and are not exclusive to, but primarily affect, the calf muscle and small muscles of the foot. These cramps are not associated with exercise, specific electrolyte or laboratory abnormalities, or medication use. Nocturnal cramps occurs with the further contraction of a muscle already in its most shortened position. For example, sleeping in the supine position may place the calf and ventral foot muscles in their most shortened and vulnerable position, predisposing these muscles to contract.¹⁵⁴

For diagnosis and treatment, true muscle cramps first should be distinguished from other causes of muscle cramping, including drug-induced cramps (Table 14-9). The onset of cramps at rest is characteristic of ordinary leg cramps and is the primary symptom used for diagnosis. Clinical signs of sodium depletion, hyper- and hypothyroidism, tetany, and lower motor neuron disease should be evaluated. Laboratory measurements such as standard electrolytes and thyroid function tests can help rule out some of these other conditions.

Table 14-9 Other Causes of Muscle Cramps^{154,155,161}

| <i>Drug-Induced Cramps</i> | <i>Biochemical Causes</i> | <i>Other</i> |
|--|---------------------------|-----------------------------|
| Alcohol | Dehydration | Contractures |
| Antipsychotics (dystonia) | Hemodialysis | Diabetes |
| β -agonists (e.g., albuterol, terbutaline, salbutamol) | Hypocalcemia | Lower motor neuron disease |
| Cimetidine | Hypomagnesemia | Peripheral vascular disease |
| Clofibrate | Hyponatremia | Tetany |
| Diuretics | Uremia | Thyroid disease |
| Lithium | | |
| Narcotic analgesics | | |
| Nicotinic acid | | |
| Nifedipine | | |
| Penicillamine | | |
| Statins | | |
| Steroids | | |

Treatment

Therapeutic Objectives and Nonpharmacologic Interventions

17. What are the therapeutic objectives in treating E.A.? What nonpharmacologic recommendations can be made?

The primary treatment goal is to prevent this uncomfortable condition. Sufferers of leg cramps are commonly advised to stretch out the afflicted muscle or perform dorsiflexion of the feet throughout the day and before bedtime, but this therapeutic modality has sparse, uncontrolled data in the literature and cannot be relied on to be helpful.¹⁵⁵ Patients are also warned to avoid plantar flexion while sleeping by hanging the feet over the edge of the bed when sleeping on the stomach. Once a cramp occurs, the goal is to relieve the cramp as quickly as possible. Acute therapy consists of dorsiflexion (grasping the toes and pulling them upward in the opposite direction of the cramp). This can be accomplished with the hands, by walking, or by leaning toward a wall while standing 2 feet away from it, maintaining the feet flat on the floor.¹⁵⁴

Quinine

18. E.A. is amenable to the recommended stretching practices, and will avoid plantar flexion during sleep. She returns in 3 months, and reports a minor decrease in the attack frequency, but not severity. Her sleep is being affected 2 to 3 nights/week, and she feels it is affecting her performance as a teacher. She remembers her aunt taking a “pill” for her leg cramps. Is there any medication that may help relieve her symptoms?

Quinine is the most frequently prescribed medication for nocturnal leg cramps and was once a nonprescription product. In 1995, the FDA stated that quinine was not considered safe and effective for nocturnal leg cramps¹⁵⁶ and discontinued its over-the-counter status. Physicians can still prescribe quinine for the treatment of nocturnal leg cramps because it is commercially available and indicated for the treatment of malaria. The FDA, however, has clearly stated quinine should not be used for nocturnal leg cramps because of an unfavorable risk:benefit ratio.

Quinine has been used to treat nocturnal leg cramps since the 1940s, when four patients suffering from leg cramps experienced marked improvement in symptoms after being treated with quinine.¹⁵⁷ When given placebo, their symptoms apparently worsened. Quinine may exert a beneficial effect by increasing the refractory period of skeletal muscle and by decreasing the excitability of the motor endplate. Despite its frequent use, significant controversy exists over its benefit. Only a few small controlled trials have been conducted, with mixed conclusions. A meta-analysis was published in 1998 that included both published and unpublished data addressing the efficacy of quinine in the treatment of leg cramps.¹⁵⁸ Pooled data from 659 patients indicated that quinine, at 200 to 325 mg/day, reduced the severity and average number of cramps experienced in a 4-week period from 17.1 to 13.5. Thus, the efficacy of quinine is proved; however, the magnitude of benefit is rather small, and the risks associated with quinine therapy for a benign condition must also be considered. Of note, a recent study that randomized patients to quinine cessation reported no effect

on nocturnal leg cramp frequency (e.g., no worsening of symptoms).¹⁵⁹

Before initiating quinine, prophylactic stretching and alteration of sleeping position should be tried and evaluated. Additionally, modifiable causes of cramps should be explored and addressed. If these measures do not result in adequate relief, therapy with quinine can be considered if the patient is fully aware of the risks, appreciates the small benefit she can expect, and has no medications or conditions that place her at increased risk of adverse effects.

Precautions With Quinine

19. What side effect information should both the physician and E.A. know about before initiation of quinine therapy? How long should therapy be continued?

If quinine therapy is successful, E.A. should see a decrease in the severity and frequency of her cramping attacks. Quinine is available in the United States only as the 324 mg sulfate salt, as the brand name Qualaquin. One tablet should be taken in the evening. Cinchonism, a syndrome that includes nausea, vomiting, blurred vision, tinnitus, and deafness, is a dose-related side effect of quinine.¹⁵⁴ Tinnitus alone occurs in up to 3% of patients.¹⁵⁸ With overdose, central nervous system manifestations, such as headache, confusion, and delirium, can occur. Self-limiting rashes that resolve with drug discontinuation have been described.¹⁵⁴ The unpredictable and life-threatening side effect of thrombocytopenia was the impetus for the FDA to ban the over-the-counter status of this preparation. Thrombocytopenia has been estimated to occur in up to 1 of 1,000 patients taking quinine.¹⁵⁶ Care should also be taken with the use of quinine because its clearance is decreased in the elderly,¹⁶⁰ and several drugs decrease its clearance, such as cimetidine, verapamil, amiodarone, and alkalinizing agents.¹⁶¹ Each of these could increase the risk of quinine dose-related side effects, specifically the central nervous system manifestations. Quinine can also produce toxic levels of digoxin, phenobarbital, and carbamazepine¹⁶¹ and is contraindicated in patients with G6PD deficiency.

E.A. should be instructed to take the dose of quinine with food to minimize GI irritation. If a response is not seen within 2 weeks, it should be discontinued in light of the potentially serious side effects.¹⁵⁴ E.A. should be instructed to keep a diary documenting the frequency of the cramping episodes so that its efficacy can be objectively assessed.

Other Therapies

20. Are there other treatment options for E.A.?

Electrolyte replacement (e.g., sodium, potassium, calcium, magnesium) may be indicated if specific deficiencies are noted or if the onset of cramping is associated with a recent initiation or dosage increase of diuretic therapy. Prophylactic use of other pharmacologic agents has been attempted, but their use is mostly anecdotal. Diphenhydramine, riboflavin, carbamazepine, methocarbamol, and phenytoin have been used empirically,¹⁵⁴ but no data support their use in nocturnal leg cramps. Vitamin E has been recommended, but one controlled study with 800 IU/day of vitamin E showed no benefit.¹⁶² Verapamil has been shown in an open-label trial of eight elderly patients to relieve quinine-resistant cramps. A dose of 120 mg of verapamil at bedtime was used, and relief was seen after 6 days of treatment.¹⁶³ Similar results were reported from a similar small study using diltiazem.¹⁶⁴ A small study found benefit associated with vitamin B complex administration for nocturnal leg cramps, but no quantification of a decrease in the number of cramps was provided.¹⁶⁵ Two small crossover studies suggested that chronic magnesium administration is not effective for the treatment of nocturnal leg cramps.^{166,167}

Although nocturnal leg cramps are relatively benign, they do cause considerable discomfort. Nonpharmacologic measures should be maximized before drug therapy is contemplated. If drug therapy is warranted, quinine is the only agent with proved benefit, but the potential for side effects, especially in the elderly population, is very real. Careful patient selection, patient education, and vigilant monitoring for side effects should all be used to minimize the occurrence and progression of adverse effects from quinine.

GENERAL PRINCIPLES

Thrombosis is the process involved in the formation of a fibrin blood clot. Both platelets and a series of coagulant proteins (clotting factors) contribute to clot formation. An *embolus* is a small part of a clot that breaks off and travels to another part of the vascular system. Damage is caused when the embolus becomes trapped in a small vessel, causing occlusion and leading to ischemia or infarction of the surrounding tissue. Normal clot formation maintains the integrity of the vasculature in response to injury, but pathological clotting can occur in many clinical settings. Abnormal thrombotic events include

deep venous thrombosis (DVT) and its primary complication, pulmonary embolism (PE), as well as stroke and other systemic manifestations of embolization of clots that form within the heart. Anticoagulant drug therapy is aimed at preventing pathological clot formation in patients at risk and at preventing clot extension and/or embolization in patients who have developed thrombosis. This chapter emphasizes arterial and venous thromboembolic disease and the use of heparin and warfarin as anticoagulants. Chapters 17, 18, and 55 provide more in-depth discussions of thrombolytic agents and antiplatelet therapy.

Etiology of Thromboembolism

Three primary factors influence the formation of pathological clots and are described in a model referred to as Virchow's triad (Fig. 15-1).¹ First, abnormalities of blood flow that cause venous stasis can result in DVT, which can progress to PE if embolization occurs. Intracardiac stasis of blood can also result in clot formation within the heart chambers, and embolization of intracardiac thrombi may lead to stroke or other systemic manifestations. Abnormalities of blood vessel walls, such as those that occur in injury or trauma to the vasculature, are a second source of thrombus formation. The presence of foreign material within the vasculature, including artificial heart valves and central venous catheters, is also thrombogenic and, like vascular injury, represents the presence of an abnormal surface in contact with blood. Finally, hypercoagulability resulting from alterations in the availability or the integrity of blood-clotting components or naturally occurring anticoagulants also represents a significant risk factor for thromboembolic disease.²

Clot Formation

The intact endothelial lining of blood vessels normally repels platelets and inhibits clot formation through secretion of numerous inhibitory substances. Damage to the endothelium leads to exposure of circulating blood to subendothelial substances, and this results in a complex series of events, including platelet adhesion, activation, and aggregation, followed by activation of the clotting cascade. These events result in formation of a fibrin clot.³

Platelet Adhesion, Activation, and Aggregation

Endothelial damage leads to exposure of blood to subendothelial collagen and phospholipids, resulting in platelet adhesion to the surface. von Willebrand factor serves as the binding lig-

and for platelet adhesion, via the glycoprotein I (GPI) receptor on the platelet surface. Adhered platelets become activated and release numerous compounds, including adenosine diphosphate and thromboxane A₂, which stimulate platelet aggregation. Fibrinogen serves as the binding ligand for platelet aggregation, via the GPIIb/IIIa receptor on the platelet surface.⁴

Clotting Cascade

Transformation of the relatively unstable platelet plug (i.e., the aggregated platelets) to a stable fibrin clot occurs as a result of an imbalance between other procoagulant and anticoagulant factors. In addition to stimulating the platelet response, endothelial damage results in activation of the clotting cascade (Fig. 15-2). The extrinsic pathway of the clotting cascade is activated by the release of thromboplastin (tissue factor) from endothelial cells. Tissue factor converts factor VII to factor VII_a, which mediates the activation of factor X. The intrinsic pathway of the clotting cascade is activated by exposure of factor XII to subendothelial components exposed during vessel injury. The intrinsic pathway mediates factor X activation via a chain of events initiated by factor XI. The distinction between these pathways is primarily an *in vitro* phenomenon; *in vivo*, the two pathways are activated simultaneously.

Once stimulated, both the extrinsic and intrinsic pathways activate the common pathway of the clotting cascade via factor X. Activated forms of factors V and VIII serve independently to accelerate this process. The final steps include conversion of factor II (prothrombin) to factor II_a (thrombin), with eventual formation of a stable fibrin clot.

Naturally occurring inhibitors of clotting factors play a role in localizing fibrin formation to the sites of injury and in maintaining the fluidity of circulating blood. Table 15-1 outlines these clotting inhibitors and their primary actions. In

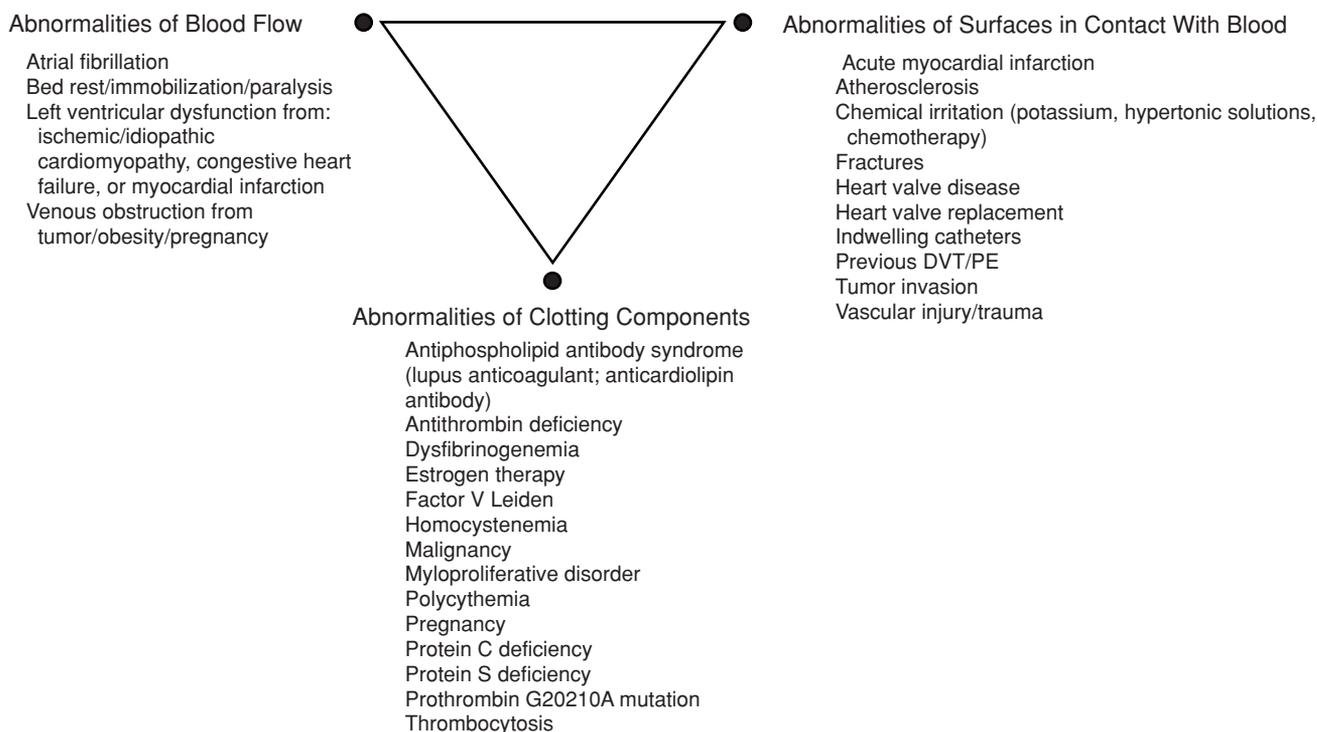

FIGURE 15-1 Risk factors for thromboembolism. DVT, deep venous thrombosis; PE, pulmonary embolism.

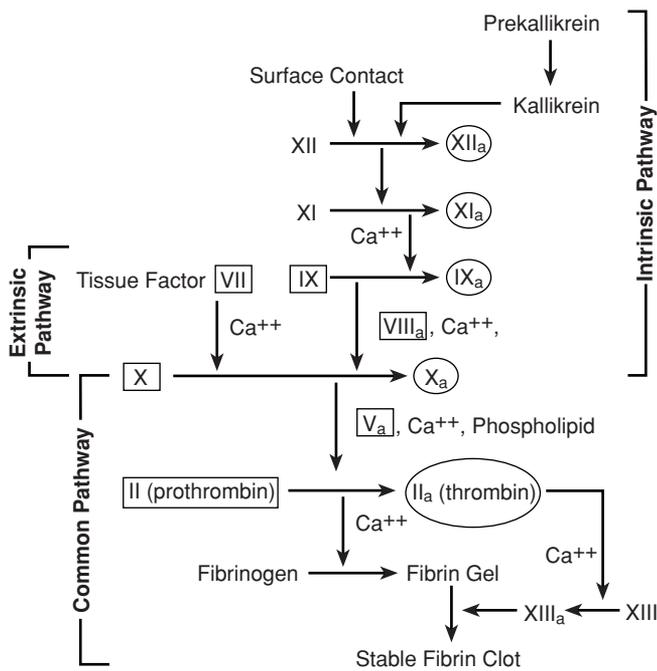

FIGURE 15-2 Simplified clotting cascade. Components in ovals are influenced by heparin; components in boxes are influenced by warfarin.

In addition, the fibrinolytic system is involved in degradation of fibrin clots. The actions of both clotting inhibitors and the fibrinolytic system prevent excessive coagulation. Thus, the process of clot formation is dynamic and involves various factors that can stimulate, inhibit, and dissolve a fibrin clot.

Pathological Thrombi

Pathological thrombi are sometimes classified according to location and composition. Arterial thrombi are composed primarily of platelets, although they also contain fibrin and occasional leukocytes. Arterial thrombi generally occur in areas of rapid blood flow (i.e., arteries) and are typically initiated by spontaneous or mechanical rupture of atherosclerotic plaques (see Chapter 18). Venous thrombi are found primarily in the venous circulation and are composed almost entirely of fibrin and erythrocytes. Venous thrombi have a small platelet head and generally form in response to either venous stasis or vascular injury after surgery or trauma. The areas of stasis prevent dilution of activated coagulation factors by normal blood flow.

The selection of an antithrombotic agent may be influenced by the type of thrombus to be treated. The anticoagulants hep-

arin, low-molecular-weight heparins, factor X_a inhibitors, and warfarin are used in the treatment and prevention of both arterial and venous thrombi. Drugs that alter platelet function (e.g., aspirin), alone and in combination with anticoagulants, are used in the prevention of arterial thrombi. Fibrinolytic agents are used for rapid dissolution of thromboemboli, most notably during myocardial infarction (MI).

Pharmacology of Antithrombotic Agents

Heparin

Heparin is a rapid-acting anticoagulant that is administered parenterally. Standard heparin (unfractionated heparin [UFH]) is a heterogeneous mixture of glycosaminoglycans of varying molecular weights obtained from bovine lung or porcine intestinal mucosa (Table 15-2). The action of heparin is facilitated by its binding to the naturally circulating anticoagulant antithrombin (AT), a serine protease also referred to as heparin cofactor. Binding of heparin to AT accelerates the anticoagulant effect of AT. The heparin-AT complex attaches to and irreversibly inactivates factor II_a (thrombin) and factor X_a, as well as activated factors IX, XI, and XII (Fig. 15-3).⁵ Approximately one-third of the molecules present in UFH bind to AT and provide the anticoagulant properties of heparin. The remaining two-thirds of the heparin molecules bind to plasma proteins and to endothelial cells, saturable processes that contribute to the dose-dependent pharmacokinetic profile of the drug and limit its bioavailability. In addition to its anticoagulant effects, heparin inhibits platelet function and increases vascular permeability; these properties contribute to the hemorrhagic effects of heparin.

In cases of acute DVT or PE, the clotting cascade has been activated, generating abnormal quantities of thrombin and fibrin. In these situations, thrombin must be inactivated directly, a process that may require relatively large doses of heparin. However, when the clotting cascade is in a normal balance, it is possible to indirectly inactivate thrombin with smaller heparin doses by complexing factor X_a. Because of the amplification effect of the clotting cascade, inactivation of relatively small amounts of factor X_a indirectly prevents the production of large quantities of thrombin. This phenomenon is the basis for low-dose heparin prophylaxis after surgery or in cases of prolonged bed rest or immobilization.

Heparin may be administered intravenously (IV) by continuous infusion, or subcutaneously (SC), although its bioavailability is significantly reduced by SC administration. Intramuscular administration should be avoided because of the potential for hematoma formation.

After IV administration, the anticoagulant effect of heparin is noted immediately. During active thromboembolism, the high concentration of clotting factors necessitates a higher concentration of heparin to neutralize them. This increased dosing requirement may also be related to continuing thrombin formation on the surface of the thrombus. Once endothelialization (localization and incorporation of the clot into the vascular endothelium) of the clot begins and the concentration of clotting factors decreases, dosing requirements typically decrease. Considerable variability in dosing requirements among patients necessitates routine therapeutic monitoring to maintain an appropriate intensity of anticoagulation with heparin. The primary laboratory test for monitoring therapeutic heparinization is the activated partial thromboplastin time

Table 15-1 Inhibitors of Clotting Mechanisms

| Inhibitor | Target |
|---------------------------------|---|
| Antithrombin | Inhibits factors IIa, IXa, and Xa |
| Protein S | Cofactor for activation of protein C |
| Protein C | Inactivates factors Va and VIIIa |
| Tissue factor pathway inhibitor | Inhibits activity of factor VIIa |
| Plasminogen | Converted to plasmin via tissue plasminogen activator |
| Plasmin | Lyses fibrin into fibrin degradation products |

Table 15-2 Comparison of Unfractionated Heparin (UFH), Low-Molecular-Weight Heparins (LMWHs), and Fondaparinux

| Property | UFH | LMWH | Fondaparinux |
|---|--|--------------|--------------|
| Molecular weight range ^a | 3,000–30,000 | 1,000–10,000 | 1,728 |
| Average molecular weight ^a | 12,000–15,000 | 4,000–5,000 | 1,728 |
| Anti-X _a :anti-II _a activity | 1:1 | 2:1–4:1 | >100:1 |
| aPTT monitoring required | Yes | No | No |
| Inactivation by platelet factor 4 | Yes | No | No |
| Capable of inactivation of platelet-bound factor X _a | No | Yes | Yes |
| Inhibition of platelet function | ++++ | ++ | No |
| Increases vascular permeability | Yes | No | No |
| Protein binding | ++++ | + | No |
| Endothelial cell binding | +++ | + | No |
| Dose-dependent clearance | Yes | No | No |
| Primary route of elimination | 1. Saturable binding processes 2. Renal | Renal | Renal |
| Elimination half-life | 30–150 min | 2–6 hr | 17 hr |

^aMeasured in daltons.

(aPTT) (see Tests Used to Monitor Antithrombotic Therapy section).

The plasma half-life of heparin varies from 30 to 150 minutes, but the half-life increases with increasing doses. Heparin is cleared by extensive binding to plasma proteins and endothelial cells, saturable processes that explain both its nonlinear kinetics and the variability in dosing requirements among patients. Additional clearance occurs by transfer to the reticuloendothelial system, with ultimate elimination controlled by the kidneys.

Low-Molecular-Weight Heparins

By using chemical or enzymatic depolymerization techniques, UFH can be separated into fragments based on molecular weight.⁶ Several low-molecular-weight heparin (LMWH) molecules have been isolated and commercially marketed as anticoagulants. The LMWH products available in the United States are dalteparin (Fragmin), enoxaparin (Lovenox), and tinzaparin (Innohep). These products have replaced the use of UFH in many clinical situations. These compounds differ substantially from UFH with respect to molecular weight,

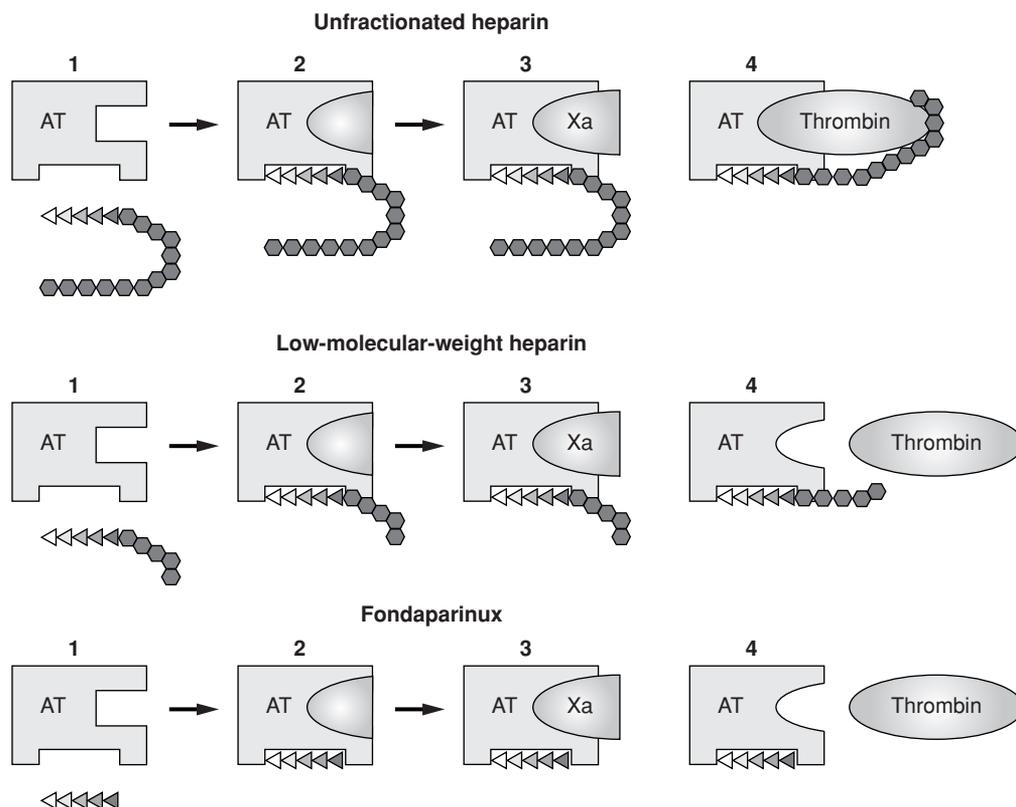

FIGURE 15-3 Mechanism of action of heparin, low-molecular-weight heparins, and fondaparinux (see text for details). Reprinted from reference 5, with permission.

antithrombotic and pharmacokinetic properties, adverse effect profiles, and monitoring requirements (Table 15-2).

To inactivate factor X_a , only the AT component of the heparin–AT complex is required to bind to factor X_a (Fig. 15-3). Both the longer, high-molecular-weight fragments of UFH and the shorter, low-molecular-weight fragments of LMWHs are capable of inactivating factor X_a . However, to inactivate factor II_a (thrombin), both the heparin component and the AT component of the heparin–AT complex are required to bind to factor II_a . This binding requires heparin molecules of at least 18 saccharide units in length, which are less prevalent in LMWHs. Therefore, the anti- X_a properties of LMWHs are more significant than their anti- II_a properties. The resultant antithrombotic effect does not prolong the aPTT, meaning that these compounds do not require laboratory monitoring to ensure a therapeutic effect.

Additional advantages of LMWHs over UFH are explained by their reduced binding affinity for plasma proteins and endothelial cells. These compounds display improved bioavailability after SC injection, a predictable dose response, and a longer pharmacodynamic effect compared with UFH. In general, these compounds are administered subcutaneously every 12 to 24 hours at fixed doses. Many LMWH products have been studied in the prevention and treatment of thromboembolic disease (Table 15-3). They differ significantly in their molecular weight distributions, methods of preparation, and the ratio of anti- X_a :anti- II_a activities, as well as in their pharmacokinetic and pharmacodynamic characteristics.

Fondaparinux

Fondaparinux (Arixtra) is a selective indirect factor X_a inhibitor that is indicated for the prevention of venous thrombosis associated with orthopedic surgery and abdominal surgery, and for the treatment of deep vein thrombosis and pulmonary embolism.^{6,7} It is a synthetic derivative of the five-residue saccharide sequence found in both UFH and LMWH that binds to AT to inactivate factor X_a with no direct impact on factor II_a . This agent has a long elimination half-life, allowing for once-daily SC administration at a fixed dose without the need for routine coagulation monitoring.

Direct Thrombin Inhibitors

Argatroban, lepirudin (Refludan), and bivalirudin (AnGIOmax) are direct thrombin inhibitors that are used as alternative anticoagulants in patients with heparin-induced thrombocytopenia.⁸ (Table 15-4). These agents are administered by continuous infusion and require aPTT monitoring for appropriate dosing adjustments. Bivalirudin is also used in patients undergoing percutaneous coronary intervention. This

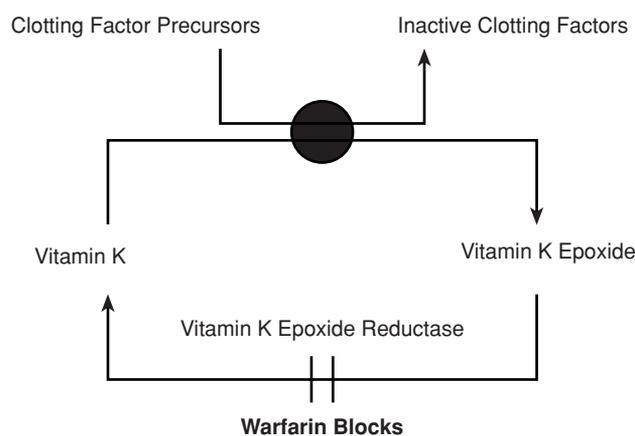

FIGURE 15-4 Mechanism of action of warfarin.

agent appears to be associated with a lower rate of hemorrhagic complications than UFH and may reduce the need for concurrent therapy with glycoprotein IIb/IIIa receptor antagonists⁹.

Warfarin

Warfarin is an oral anticoagulant with a delayed onset of effect that acts as a vitamin K antagonist. Vitamin K is essential for the conversion (carboxylation) of precursors to clotting factors II, VII, IX, and X into inactive clotting factors and for the synthesis of protein C and protein S. During factor conversion, vitamin K is oxidized to inactive vitamin K epoxide (Fig. 15-4). In the nonanticoagulated patient, vitamin K epoxide is in reversible equilibrium with vitamin K, but this equilibrium is disrupted in patients taking oral anticoagulants. Warfarin (Coumadin) interferes with the hepatic recycling of vitamin K by inhibiting vitamin K epoxide reductase (VKOR), the enzyme that converts vitamin K epoxide to vitamin K.¹⁰ The accumulation of vitamin K epoxide reduces the effective concentration of vitamin K and reduces the synthesis of coagulation factors. Concentrations of clotting factors II, VII, IX, and X are diminished gradually at rates commensurate with their elimination half-lives (Table 15-5). Thus, the onset of the anticoagulant effect of warfarin is delayed. It takes approximately 5 to 7 days to reach a steady state of anticoagulation after warfarin therapy is initiated or after dosing changes. Protein C and its cofactor protein S are also vitamin K dependent, and these proteins are depleted by warfarin at rates dependent on their elimination half-lives.

Warfarin is rapidly and completely absorbed in the upper gastrointestinal (GI) tract by passive diffusion, with nearly 100% bioavailability. Peak absorption of warfarin occurs in 60 to 120 minutes. It is approximately 99% bound to serum albumin. The volume of distribution (V_d) for warfarin is 12.5% of body weight. This small volume of distribution is consistent with the extensive binding of warfarin to albumin. The primary laboratory test for monitoring warfarin therapy is the prothrombin time (PT). No correlation appears to exist between PT and the dose of warfarin, the total warfarin concentration, or the free warfarin concentration among individuals, although in individual patients, an increasing dose of warfarin will increase the serum concentration (free and total) and the PT.

Warfarin is administered orally as a racemic mixture containing equal parts of the enantiomers R(+)-warfarin and S(–)-warfarin. The S(–)-isomer is 2.7 to 3.8 times more potent

Table 15-3 Low-Molecular-Weight Heparin Products Available in the United States

| Generic Name | Brand Name | Average Molecular Weight (range) ^a | Anti- X_a :Anti- II_a Activity |
|--------------|------------|---|------------------------------------|
| Dalteparin | Fragmin | 5,000 (2,000–9,000) | 2.0:1 |
| Enoxaparin | Lovenox | 4,500 (3,000–8,000) | 2.7:1 |
| Tinzaparin | Innohep | 4,500 (3,000–6,000) | 1.9:1 |

as an anticoagulant than the R(+)-isomer, has a longer elimination half-life, and is primarily metabolized by cytochrome P450 (CYP)-2C9. Comparatively, R(+)-warfarin is metabolized by primarily by CYP1A2 and CYP3A4. Many drugs interact with warfarin by stereoselectively inhibiting the metabolism of either the R(+)-isomer or the S(-)-isomer (see Drug Interactions section). Genetic expression of CYP2C9 influences the rate of metabolism of warfarin and thus impacts dosing requirements to meet a particular therapeutic end point.¹¹ Variability in genetic expression of VKORC1 (the C1 subunit on the gene that codes for VKOR) also influences dosing requirements in patients taking warfarin.¹² Testing for CYP2C9 and VCORC1 genotype are being evaluated as a method to determine warfarin dosing requirement, but will not ready for clinical use

until randomized controlled trials confirm that this method of dosing improves patient outcomes and is cost effective.

Tests Used to Monitor Antithrombotic Therapy

Before the initiation of antithrombotic therapy, an assessment of coagulation status is necessary. The clinician should obtain a baseline platelet count and hematocrit (Hct), as well as evaluate the baseline integrity of the extrinsic and intrinsic coagulation pathways with PT and aPTT, the tests used to monitor warfarin and heparin, respectively.

Prothrombin Time/International Normalized Ratio

The PT is prolonged by deficiencies of clotting factors II, V, VII, and X, as well as by low levels of fibrinogen and very high

Table 15-5 Elimination Half-Lives of Vitamin K–Dependent Clotting Factors

| Clotting Factors | Half-Life (hours) |
|------------------|-------------------|
| II | 42–72 |
| VII | 4–6 |
| IX | 21–30 |
| X | 27–48 |
| Protein C | 9 |
| Protein S | 60 |

levels of heparin. It reflects alterations in the extrinsic and common pathways of the clotting cascade, but not in the intrinsic system.¹³ The PT is measured by adding calcium and tissue thromboplastin to a sample of plasma from which platelets have been removed by centrifugation. The time to clot formation is detected by automated instruments using light-scattering techniques that measure optical density. The mean normal PT, obtained by averaging a number of PT results from nonanticoagulated subjects, is approximately 12 seconds for most reagents.

The thromboplastins used in PT monitoring are extracted from various tissue sources by a number of techniques and prepared for commercial use as reagents. Unfortunately, thromboplastins are not standardized among manufacturers or among batches of reagent produced by the same manufacturer, leading to significant variability in PT results for anticoagulated patients.¹⁴ To standardize PT results, the World Health Organization developed a system by which all commercially available thromboplastins are compared with an international reference thromboplastin and then assigned an International Sensitivity Index (ISI). This value is used to mathematically convert PT to the international normalized ratio (INR) by exponentially multiplying the PT ratio to the power of the ISI of the thromboplastin being used in the laboratory to measure the test ($INR = [PT\ patient/PT\ mean\ normal]^{ISI}$). The ISI of the international reference thromboplastin is 1.0.

INR is the internationally recognized standard for monitoring warfarin therapy. Current recommendations for intensity of oral anticoagulation therapy for accepted clinical indications are summarized in Table 15-6. Regular-intensity therapy is defined as dosing warfarin to reach a goal INR of 2.5 (range, 2.0–3.0) and is appropriate for most settings that require the prevention and/or treatment of thromboembolic disease. High-intensity therapy is used in mechanical valve replacement and certain situations of thromboembolic recurrence, despite adequate anticoagulation, and is defined as dosing warfarin to reach a goal INR of 3.0 (range, 2.5–3.5).

Activated Partial Thromboplastin Time

The aPTT reflects alterations in the intrinsic pathway of the clotting cascade and is used to monitor heparin therapy.¹⁵ The test is performed by adding a surface-activating agent (kaolin or micronized silica), a partial thromboplastin reagent (phospholipid; platelet substitute), and calcium to the plasma sample. Mean normal values vary among reagents, but typically fall between 24 and 36 seconds.

Like PT, the aPTT is a highly variable test based on differences among commercially available partial thromboplastin

reagents. However, a system equivalent to the INR has not been developed for standardization of aPTT results. Heparinization to prolong the aPTT to 1.5 to 2.5 times the mean normal value historically was considered adequate to prevent propagation or extension of thrombus, but is no longer recommended because it is not appropriate for all reagents and testing systems. Instead, the aPTT should be calibrated for each reagent lot and coagulometer, and a reagent-specific therapeutic range in seconds determined that corresponds to therapeutic heparin levels of 0.3 to 0.7 U/mL by factor X_a inhibition (anti-X_a activity).^{6,16}

Anti-X_a Activity

Although LMWHs do not require coagulation monitoring to ensure an appropriate antithrombotic effect or to adjust dosing, certain clinical situations may require evaluation of the anti-X_a activity of LMWHs.¹⁷ Because these agents are eliminated renally, patients with severe renal failure may accumulate LMWHs, leading to an increased risk of hemorrhagic complications and necessitating evaluation of anti-X_a activity. LMWHs are dosed according to total body weight, but clinical trials have included only limited numbers of obese patients. Therefore, it may be appropriate to monitor anti-X_a activity in these patients. Anti-X_a activity should also be evaluated in patients who experience unexpected bleeding complications secondary to anticoagulation with LMWHs, and in pregnant patients in whom LMWHs are used for treatment or prevention of thrombosis.

Anti-X_a activity is measured using a chromogenic assay that is expensive and of limited availability. Peak activity levels should be obtained approximately 4 hours after a SC dose of LMWH, with empiric dosing adjustments to maintain a level of roughly 0.5 to 1.0 U/mL for therapeutic anticoagulation.^{6,18} Like other measures of hemostasis, results vary considerably, requiring both instrument- and method-specific determination of therapeutic ranges.

DEEP VEIN THROMBOSIS

Clinical Presentation

Signs and Symptoms

1. L.N., a 76-year-old, obese (92 kg, 6 ft tall) man, was admitted to the hospital 3 days ago for management of recurrent angina. He was started on a nitroglycerin drip and confined to bed rest with gradual increases in his oral antianginal medications. On the third day of hospitalization, he noted progressive swelling and soreness of the right calf. He denied shortness of breath (SOB), cough, or chest pain. His medical history includes coronary artery disease, MI at ages 55 and 67, and hypercholesterolemia. His medications are diltiazem CD (Cardizem CD) 360 mg/day PO, isosorbide mononitrate (Imdur) 120 mg/day PO, atenolol (Tenormin) 50 mg/day PO, aspirin 325 mg/day PO, and simvastatin (Zocor) 5 mg PO Q pm. Initial laboratory values include Hct, 36.5% (normal, 42%–52%); PT, 10.8 seconds (INR, 1.0); aPTT, 23.6 seconds (normal, 24–36); and platelet count, 255,000/mm³ (normal, 150,000–300,000). What signs and symptoms demonstrated by L.N. are consistent with DVT?

[SI units: Hct, 0.365 (normal, 0.42–0.52); platelet count, 255 × 10⁹/L (normal, 150–300)]

One of the most reliable, although nonspecific, physical findings of DVT is unilateral leg swelling that often is

Table 15-6 Optimal Therapeutic Range and Duration of Anticoagulation

| <i>Indication</i> | <i>Target INR (Range)</i> | <i>Duration</i> | <i>Comment</i> |
|--|---------------------------|-----------------|--|
| Atrial Fibrillation (AF)/Atrial Flutter | | | |
| Age older than 65 years with no risk factors | None | Chronic | Use aspirin 325 mg QD alone |
| Age 65–75 years with no risk factors | 2.5 (2.0–3.0) | Chronic | Or aspirin 325 mg QD |
| Age older than 75 years OR any risk factor [hx TIA/stroke/TE; HTN; poor LV fxn; mitral valve dz; valve replacement] | | Chronic | |
| Pre cardioversion (AF or flutter >48 hours) | 2.5 (2.0–3.0) | 3 weeks | |

| Following embolic event despite anticoagulation <30% | 2.5 (2.0–3.0) | Chronic | Add antiplatelet therapy |
| Myocardial Infarction (MI) | | | |
| Following anterior MI | 2.5 (2.0–3.0) | 3 months | With aspirin 81 mg QD |
| Following inferior MI with transient risk(s) [AF; CHF, LV dysfxn, mural thrombus, hx TE] | 2.5 (2.0–3.0) | 3 months | With aspirin 81 mg QD |
| Following initial tx with persistent risks | 2.5 (2.0–3.0) | Chronic | With aspirin 81 mg QD |
| Thromboembolism (DVT, PE) | | | |
| Treatment/prevention of recurrence (including calf vein and upper extremity DVT) | | | |
| • Transient risk factors | 2.5 (2.0–3.0) | 3 months | |
| • Idiopathic/first episode | 2.5 (2.0–3.0) | 6–12 months | Consider chronic therapy |
| • Recurrent VTE | 2.5 (2.0–3.0) | Chronic | |
| • With malignancy | 2.5 (2.0–3.0) | Chronic | Preceded by LMWH × 3–6 months |
| • Hypercoagulable state | 2.5 (2.0–3.0) | 6–12 months | Consider chronic therapy |
| • Two or more thrombophilic conditions | 2.5 (2.0–3.0) | 12 months | Consider chronic therapy |
| • Antiphospholipid antibody syndrome | 2.5 (2.0–3.0) | 12 months | Consider chronic therapy |
| • With recurrent VTE or other risk factors | 2.5 (2.0–3.0) | 12 months | Consider chronic therapy |
| Chronic thromboembolic pulmonary hypertension | 2.5 (2.0–3.0) | Chronic | |
| Cerebral venous sinus thrombosis | 2.5 (2.0–3.0) | 3–6 months | |
| Valvular Disease | | | |
| Aortic valve disease | 2.5 (2.0–3.0) | Chronic | |
| • With mobile atheroma or aortic plaque >4 mm | | | |
| Mitral valve prolapse, regurgitation, or annular calcification | | | |
| • With AF or hx systemic embolization | 2.5 (2.0–3.0) | Chronic | |
| • With recurrent TIA despite ASA therapy | 2.5 (2.0–3.0) | Chronic | |
| Rheumatic mitral valve disease | | | |
| • With AF, hx systemic embolization, or LA >5.5 cm | 2.5 (2.0–3.0) | Chronic | |
| • S/p embolic event despite anticoagulation | 2.5 (2.0–3.0) | Chronic | With aspirin 81 mg QD |
| Valve Replacement—Bioprosthetic | | | |
| Aortic | 2.5 (2.0–3.0) | 3 months | Followed by aspirin (or aspirin alone) |
| Mitral | 2.5 (2.0–3.0) | 3 months | Followed by aspirin 81 mg QD |
| Aortic or mitral | | | |
| • With LA thrombus | 2.5 (2.0–3.0) | 3 months | Followed by aspirin 81 mg QD |
| • With prior history systemic embolism | 2.5 (2.0–3.0) | 3–12 months | Followed by aspirin 81 mg QD |
| • With atrial fibrillation | 2.5 (2.0–3.0) | Chronic | |
| Following systemic embolism | 2.5 (2.0–3.0) | Chronic | With aspirin 81 mg QD |

Continued

accompanied by warmth and local tenderness or pain.¹⁹ A tender, cordlike entity caused by venous obstruction can sometimes be palpated in the affected area. L.N. presented with the sudden onset of swelling along with soreness, but without evidence of a cord. Discoloration of the affected limb, including pallor from arterial spasm, cyanosis from venous obstruction,

or a reddish color from perivascular inflammation, may also occur. The presence or absence of a positive Homans' sign (pain behind the knee or calf on dorsiflexion of the foot) is rarely helpful in making the diagnosis because it is present in only about 30% of patients with DVT. Many patients (>50%) can present with asymptomatic disease, but even asymptomatic

patients can have long-term complications such as recurrent DVT or postthrombotic syndrome. Because symptoms of DVT are nonspecific, the diagnosis must be confirmed by objective testing.²⁰

Risk Factors

2. What risk factors does L.N. exhibit that are associated with DVT?

The diagnosis of DVT depends not only on the presenting signs and symptoms, but also on the presence of risk factors. A summary of risk factors for thromboembolism is presented in Figure 15-1. L.N. has presented with obesity and immobilization (i.e., prolonged bed rest), two important risk factors for thromboembolism. It is common for more than one risk factor to be present in patients who develop DVT, and these factors are cumulative in their effect.²¹

Diagnosis

3. How should the final diagnosis of DVT be made in L.N.?

After evaluation of the signs and symptoms of DVT and consideration of risk factors for the development of thrombus, a definitive diagnosis should be made. Diagnostic strategies should include an assessment of pretest clinical probability (clinical suspicion), D-dimer assay (an evaluation of the presence of fibrin degradation products, indicative of clot formation), and noninvasive imaging tests.²²

Despite its limitations as a single diagnostic tool, clinical assessment can improve the diagnostic accuracy of noninvasive testing. A clinical prediction rule, such as the Wells criteria, takes into account signs, symptoms, and risk factors to categorize patients as being at low, intermediate, or high probability of having a DVT (Table 15-7).^{23,24} The D-dimer test can be used in conjunction with clinical evaluation or a clinical prediction rule to help “rule out” DVT in patients with a low clinical suspicion, and thus decrease the need for imaging tests in these patients.²⁵ A D-dimer should not be tested if the clinical suspicion is high because diagnostic imaging is indicated in these patients.

The most common noninvasive test is duplex scanning, which combines B-mode imaging or color flow imaging with Doppler ultrasonography to visualize veins and thrombi while investigating flow patterns.¹⁹ Other noninvasive testing op-

tions include ¹²⁵I-fibrinogen leg scanning (injection of radiolabeled fibrinogen followed by scanning to detect areas of accumulation corresponding to thrombosis), impedance plethysmography (use of pneumatic cuffs to detect leg blood volume changes associated with thrombosis), and Doppler ultrasonography alone (use of a transducer to audibly detect venous flow changes indicative of thrombosis). Each option differs with respect to sensitivity, specificity, and cost. Venography (radiographic visualization of the involved vessels with injection of radiocontrast material), an invasive diagnostic test, is the most sensitive and specific method for diagnosis of DVT, but exposes patients to the risks associated with contrast material.²³

Treatment

Baseline Information

4. What additional baseline data should be obtained before administering anticoagulants to L.N.?

Table 15-7 Clinical Model for Evaluating the Pretest Probability of Deep Vein Thrombosis^a

| Clinical Characteristic | Score |
|--|-------|
| Active cancer (cancer treatment within previous 6 months, or currently on palliative treatment) | 1 |
| Paralysis, paresis, or recent plaster immobilization of the lower extremities | 1 |
| Recently bedridden for ≥3 days, or major surgery within the previous 12 weeks requiring general or regional anesthesia | 1 |
| Localized tenderness along the distribution of the deep venous system | 1 |
| Entire leg swollen | 1 |
| Calf swelling at least 3 cm larger than that on the asymptomatic side (measured 10 cm below tibial tuberosity) | 1 |
| Pitting edema confined to the symptomatic leg | 1 |
| Collateral superficial veins (nonvaricose) | 1 |
| Previously documented deep vein thrombosis | 1 |
| Alternative diagnosis at least as likely as deep vein thrombosis | -2 |

^aClinical probability of DVT: low <0; moderate 1–2; high >3. In patients with symptoms in both legs, the more symptomatic leg is used. Adapted from references 22 and 24.

In addition to assessing the integrity of the clotting process with platelet count, Hct, PT, and aPTT, the patient's baseline renal function should also be evaluated and documented because some anticoagulants are renally eliminated. Generally, it is unnecessary to type and cross-match blood, but if this information is available, it should be recorded. Baseline values are used for comparison with the parameters that will be used in monitoring both therapeutic and adverse effects of anticoagulant therapy.

Initiation of Therapy

5. Duplex scanning reveals clot formation in L.N.'s right calf extending to the right thigh. He does not exhibit signs of PE. What is the appropriate therapy for L.N., and how should it be initiated?

Prompt and optimal anticoagulant therapy is indicated to minimize thrombus extension and its vascular complications, as well as to prevent PE. Treatment options include IV UFH therapy initiated with a loading dose followed by a continuous infusion, adjusted-dose SC UFH, or LMWH or fondaparinux administered by SC injection.²⁶ Because L.N. currently is hospitalized, IV UFH is selected for initial treatment of his DVT.

Heparin

LOADING DOSE

6. L.N.'s medical resident ordered a heparin bolus dose of 5,000 units (U) IV, to be followed by a continuous infusion of 1,000 U/hour. Is this heparin dosing regimen appropriate?

A loading dose of heparin is required for several reasons. Based on pharmacokinetic principles, a therapeutic serum level will be achieved more quickly; thus, pharmacodynamic and therapeutic responses to help prevent progression of clot will occur rapidly. Second, a relative resistance to anticoagulation exists during the active clotting process. Therefore, a larger initial dose generally is necessary to achieve a therapeutic effect.

Although many clinicians historically used standardized doses of heparin for initiation of therapy (e.g., 5,000-U loading dose; 1,000-U/hour maintenance dose), this approach can result in significant delays in reaching a therapeutic intensity of anticoagulation. Body weight represents the most reliable predictor of heparin dosing requirement. For nonobese patients, the use of the actual body weight is recommended to calculate the initial UFH dose. In obese patients, the use of the actual body weight is controversial, and the use of an adjusted-dosing weight is recommended by some experts.²⁷ Compared with standardized dosing, weight-based dosing (80-U/kg loading dose; 18-U/kg/hour initial infusion rate) increases the frequency of therapeutic aPTT at 6 hours and at 24 hours, and decreases the risk of recurrent venous thromboembolism (VTE).^{28–30}

Initial heparin loading doses of 70 to 100 U/kg followed by an infusion rate of 15 to 25 U/kg/hour are commonly recommended. Selection of the lower or upper dosage range is guided by the severity of the patient's symptoms and his or her potential sensitivity to adverse effects. For this 92-kg patient, a midrange loading dose of 7,400 U (92 kg × 80 U/kg), followed by a continuous infusion of 1,700 U/hour (92 kg × 18 U/kg per hour), is recommended. Loading doses are typically rounded to the nearest 500 U and maintenance infusion rates to the nearest 100 U for convenience of administration.

DOSE ADJUSTMENTS

7. The orders for L.N. were rewritten by his attending physician. Based on the data that follow, explain the variability in laboratory results. (At this institution, aPTT values of 60–100 seconds correspond with heparin plasma concentrations of 0.3–0.7 U/mL determined by antifactor X_a assay.)

| Time | APTT (seconds) | Heparin Dosage Order |
|------|----------------|--|
| 0800 | 31 (baseline) | 7,400-U bolus followed by 1,700-U/hour infusion |
| 0900 | 130 | Hold infusion for 30 minutes, then to 1,500 U/hour |
| 1500 | 40 | Rebolus with 2,400 U, then to 1,700 U/hour |
| 2100 | 85 | Continue at 1,700 U/hour; recheck aPTT Q AM |

Although the aPTT drawn 1 hour after the initiation of the maintenance infusion (9 AM) demonstrates excessive prolongation of the aPTT (130 seconds), this value is most likely explained by inappropriate timing of the test. When aPTT values are drawn too soon after a heparin bolus dose (i.e., before the maintenance infusion has achieved a steady-state concentration in serum), they are predictably very high, but are not associated with a bleeding risk and do not accurately reflect the anticipated level of anticoagulation in the patient. To ensure accuracy, the clinician should obtain aPTT values no sooner than 6 hours after a bolus dose or any change in the infusion rate. Even results obtained at 6 hours may be excessively prolonged in some patients because of the dose-dependent pharmacokinetic characteristics of heparin.

L.N.'s heparin dose was decreased at 0900 based on this prolonged, yet inappropriately timed, value. A repeat aPTT at 3 PM was only 40 seconds. The decrease in the dosage to 1,500 U/hour and the repeat aPTT of 40 seconds reflect near steady-state conditions because 6 hours have elapsed since the dosage change. Because the aPTT was subtherapeutic at 3 PM (40 seconds), administration of a smaller repeat bolus dose (2,400 U) and an increase in the maintenance infusion to 1,700 U/hour was the correct course of action. Subsequent aPTT values reflected therapeutic anticoagulation.

Dosing nomograms or protocols have been recommended for adjustment of heparin dosing based on aPTT results.^{6,31} Nomogram-based dosing reduces the time to reach therapeutic range compared with empiric dosing.³¹ After initiation based on patient weight, dosing adjustments may also be weight based or may simply be made in units per hour. A heparin dosing nomogram specific for a reagent with a therapeutic aPTT range of 60 to 100 seconds (and used in the adjustment of heparin doses for L.N.) is illustrated in Table 15-8.

Responses to changes in infusion rates of heparin are not always linear, and to some extent, heparin doses are adjusted by trial and error. As the patient's condition improves after several days and endothelialization of the clot occurs, heparin dosing requirements may decrease.

THERAPEUTIC MONITORING

8. How should L.N.'s heparin therapy be monitored?

Once baseline clotting parameters have been established and a loading dose of heparin has been administered, the aPTT should be measured routinely to guide subsequent dosing adjustments. The aPTT should be evaluated no sooner than

Table 15-8 Heparin Dosing Nomogram^a

- Suggested loading dose
 - Treatment of DVT/PE: 80 U/kg (rounded to nearest 500 U)
 - Prevention, including cardiovascular indications: 70 U/kg (rounded to nearest 500 U)
- Suggested initial infusion
 - Treatment of DVT/PE: 18 U/kg/hr (rounded to nearest 100 U)
 - Prevention, including cardiovascular indications: 15 U/kg/hr (rounded to nearest 100 U)
- First aPTT check: 6 hours after initiating therapy
- Dosing adjustments: per chart below (rounded to nearest 100 U)

| aPTT ^b (seconds) | Heparin Bolus | Infusion Hold Time | Infusion Rate Adjustment | Next aPTT |
|-----------------------------|---------------|--------------------|--------------------------|-----------|
| <40 | 4,000 U | 0 | Increase by 200 U/hr | In 6 hr |

| >120 | 0 | 30 minutes | Decrease by 200 U/hr | In 6 hr |

^aUniversity of Washington Medical Center.

^bBased on aPTT reagent-specific therapeutic range of 60–100 sec corresponding to a plasma heparin concentration of 0.3–0.7 U/mL determined by antifactor X_a activity.

6 hours after the loading dose or after any changes in infusion rate, as noted previously. If dosing is stable, the aPTT should be evaluated once daily (Table 15-8).

Additional monitoring parameters for heparin therapy include evaluation for potential adverse reactions and possible therapeutic failure. Hct and platelet count should be checked every 1 to 2 days. L.N. should be examined for signs of bleeding, as well as for signs and symptoms associated with thrombus extension and PE. Finally, if unusual or unexpected aPTT results are reported, the clinician should consider the possible influence of solution preparation errors, infusion pump failure, infusion interruption, and administration or charting errors in the assessment of L.N.'s heparin therapy.³²

DURATION OF THERAPY

9. How long should heparin therapy be continued in L.N.?

Adherence of a thrombus to the vessel wall and subsequent endothelialization usually takes 7 to 10 days. However, anticoagulation therapy must generally continue for 3 to 6 months to prevent recurrent thrombosis.²⁶ Warfarin is preferred for this long-term anticoagulation because it can be administered orally, and it is generally initiated on the same day as heparin. The long elimination half-life of warfarin and the long elimination half-lives of clotting factors II and X necessitate a prolonged period of overlap between warfarin and heparin. Heparin is, therefore, continued for ≥ 5 days and until the INR is >2 and stable. Heparin therapy should not be discontinued before at least 5 days even if the INR is therapeutic before then because of the time required for adequate elimination of factors II and X by warfarin and the time required to reach its full antithrombotic potential. Shortening the duration of heparin therapy is associated with an increased risk of recurrent thrombosis.

ADVERSE EFFECTS

10. On day 2 of heparin therapy, L.N.'s complete blood count reveals a platelet count of 180,000/mm³, decreased from 255,000/mm³ at baseline. What is a reasonable explanation for this thrombocytopenia, and how should it be managed?

Thrombocytopenia

Thrombocytopenia induced by heparin has two distinct presentations.⁸ Heparin-associated thrombocytopenia (HAT) occurs as a direct effect of heparin on platelet function, causing transient platelet sequestration and clumping with reductions in platelet count, but usually remaining $>100,000/\text{mm}^3$. This reversible form of thrombocytopenia occurs within the first several days of heparin therapy. Patients remain asymptomatic, and platelet counts return to normal even when heparin therapy is continued. L.N.'s reduction in platelet count is somewhat modest and likely represents HAT. His platelet count should be monitored daily, and heparin therapy should be continued.

Reductions in platelet count of $>50\%$ from baseline suggest the development of heparin-induced thrombocytopenia (HIT), a more severe immune-mediated reaction with a typical delay in onset of 5 to 14 days after the initiation of heparin therapy. In contrast, "immediate-onset" HIT can occur rapidly (within 24 hours of UFH initiation) in patients previously exposed to heparin. In addition, delayed-onset HIT has also been reported, where the development of thrombocytopenia begins several days after heparin has been stopped in patients naive to UFH.³³

In the immune-mediated reaction, heparin binds to an IgG antibody to form a heparin-antibody complex that then binds to platelets, leading to significant platelet aggregation. The observed thrombocytopenia is the result of drug-induced platelet aggregation as opposed to platelet destruction or bone marrow suppression. The diagnosis of immune-mediated HIT is made based on clinical findings supplemented by laboratory tests confirming the presence of antibodies to heparin or platelet activation induced by heparin.⁸

The overall incidence of HIT is $<3\%$ after 5 days of UFH use, but the cumulative incidence can be as high as 6% after 14 days of continuous heparin use. HIT occurs more frequently with bovine lung heparin than with heparin derived from porcine gut mucosa, and also with prolonged IV UFH use versus SC UFH.^{8,33} Despite its low incidence, HIT is a life-threatening condition with high morbidity and mortality. Platelet aggregation secondary to HIT can lead to significant

venous and arterial thrombosis, as well as thromboembolic stroke, acute MI, skin necrosis, and thrombosis of other major arteries. Amputation is necessary in up to 25% of patients, and mortality approaches 25% to 30% (see Chapter 87).

In patients who develop HIT, heparin therapy should be stopped immediately, and treatment with an alternative anticoagulant should be initiated.^{8,33} Although associated with a lower risk of HIT (<1%) than UFH, LMWH products are contraindicated in patients with HIT because of a high incidence of immunologic cross-reactivity with heparin.⁸ The future use of heparin in patients with HIT, especially in the first 3 to 6 months following the diagnosis, should be avoided. Treatment options include the direct thrombin inhibitors argatroban, lepirudin and bivalirudin, although only the first two are U.S. Food and Drug Administration (FDA) approved for this indication. The dose of lepirudin and argatroban should be titrated based on aPTT testing, and both are administered by IV infusion. Although some clinicians prefer argatroban because it has a shorter half-life and lower cost when compared to lepirudin, both agents are considered equally suitable for the initial treatment of HIT. Bivalirudin also appears to be a promising emerging alternative for the treatment of HIT due to its short-half life, low immunogenicity, minimal effect on INR, and enzymatic metabolism. Various patient-related factors—such as the presence of renal or hepatic dysfunction; prior exposure to lepirudin; and drug availability, cost, and institutional preference—should be used to select the most appropriate agent^{8,34} (Table 15-4).

11. On day 3 of heparin therapy, L.N.'s Hct has dropped from a baseline of 36.5% to 29%, and blood is noted in his urine. Describe an approach to evaluate and interpret this event.

Hemorrhage

Bleeding is the most common adverse effect associated with heparin. A summary of eight inception cohort studies reporting heparin-associated bleeding found the absolute frequency of fatal, major, and all (major or minor) bleeding to be 0.4%, 6%, and 16%, respectively.³⁵ The corresponding average daily frequencies were 0.05% for fatal bleeding, 0.8% for major bleeding, and 2% for major or minor bleeding; cumulative risk increased with the duration of therapy. The most common sites for heparin-associated bleeding are soft tissues, the GI and urinary tracts, the nose, and the oral pharynx.

In addition to length of therapy, many factors influence the risk of bleeding during heparinization, including advanced age, serious comorbid illnesses (heart disease, renal insufficiency, hepatic dysfunction, cerebrovascular disease, malignancy, and severe anemia), and concomitant antithrombotic therapy.³⁶ The incidence of UFH-associated bleeding complications is minimal with SC prophylactic doses, but higher (2%–4%) with therapeutic doses given via IV infusion. Soft tissue bleeding commonly occurs at sites of recent surgery or trauma. Previously undiagnosed abnormalities, including malignancy and infection may be identified in some patients with GI or urinary tract bleeding associated with heparin therapy.

The influence of the intensity of heparinization on bleeding risk is controversial. Although an elevated aPTT has historically been considered a risk factor for bleeding complications, several investigators have been unable to substantiate a relationship between supratherapeutic aPTT values and hemor-

rhagic effects.³⁶ In addition, bleeding episodes can occur when coagulation test results are within the therapeutic range. These conflicting results may be explained in part by the influence of additional risk factors for bleeding and by the effect of heparin on platelet function and vascular permeability.

L.N. has developed hematuria despite an acceptable intensity of anticoagulation. He should be questioned and examined for the presence of nose bleeding (epistaxis), increased tendency to bruise (ecchymosis), bright red blood in the stool (hematochezia), black or tarry stool (melena), or coughing up of blood (hemoptysis). Blood pressure and pulse, both sitting and standing, should be obtained to determine whether orthostasis representing blood loss is present. A thorough evaluation of the urinary tract may reveal a previously unknown abnormality that will explain the bleeding episode.

12. What other side effects of heparin should be considered in L.N.?

Osteoporosis

The development of osteoporosis has been associated with administration of >20,000 U/day of heparin for 6 months or longer.³⁷ Various mechanisms have been suggested, but the underlying pathophysiology of this rare adverse effect remains unclear. Affected patients may present with bone pain and/or radiographic findings suggestive of fractures. The possibility of osteoporosis should be considered in patients receiving long-term, high-dose heparin therapy such as pregnant patients or elderly patients.

Hyperkalemia

Although rare, hyperkalemia has been attributed to heparin-induced inhibition of aldosterone synthesis. Hypoaldosteronism leading to hyperkalemia has been described with both high-dose and low-dose heparin therapy, may occur as quickly as within 7 days after initiation of heparin therapy, and appears to be reversible after discontinuation of heparin.⁶ Patients with diabetes or renal failure may be at greatest risk.

Hypersensitivity Reactions

Other rarely occurring adverse effects associated with heparin include generalized hypersensitivity reactions, such as urticaria, chills, fever, rash, rhinitis, conjunctivitis, asthma, and angioedema, as well as priapism and a reversible temporal alopecia.⁶

ADJUSTED-DOSE SUBCUTANEOUS ADMINISTRATION

13. By day 4 of heparinization, IV access for L.N. has become difficult. What alternatives can be considered?

The most common strategy for treatment of venous thrombosis in hospitalized patients without IV access is the use of SC LMWH (see question 15). Another alternative is SC administration of unfractionated heparin with adjustment of dosing to maintain a therapeutic aPTT.^{26,38} Typically, SC heparin is administered at 12-hour intervals, and aPTT is monitored at the mid-dosing interval (i.e., 6 hours after a dose). Due to lower bioavailability if the SC route of administration is used, the initial SC UFH dose should be approximately 10% to 20% higher than the corresponding IV dose required to maintain therapeutic effect.

Table 15-9 Heparin Protocol for Adjusted-Dose Subcutaneous Administration^a**Initial Dosage**

1. Initial therapy with adjusted-dose SC heparin
 - a. Give SC heparin 240 U/kg STAT.
 - b. Check first aPTT 6 hours after first dose.
 - c. Adjust dosing per chart below.
2. Conversion from continuous infusion heparin to adjusted-dose SC heparin
 - a. Calculate total 24-hour heparin requirement necessary to maintain therapeutic aPTT.
 - b. Divide 24-hour heparin requirement by 2 and increase this dose by an additional 10%–20% to determine initial Q 12 hours SC dosing requirement.
 - c. Discontinue IV heparin and administer initial Q 12 hr SC dose within 1 hr.
 - d. Check first aPTT 6 hr after first dose.
 - e. Adjust dosing per chart below.
3. Conversion from warfarin to adjusted-dose SC heparin
 - a. Discontinue warfarin.
 - b. Give 240 U/kg SC heparin within 24 hr.
 - c. Check first aPTT 6 hr after first dose.
 - d. Adjust dosing per chart below.

Dosing Adjustments

| aPTT ^b (seconds) | Dosing Adjustment ^c | Next aPTT |
|-----------------------------|--------------------------------|-----------------|
| <40 | Increase by 48 U/kg Q 12 hr | 6 hr after dose |
| 40–59 | Increase by 24 U/kg Q 12 hr | 6 hr after dose |
| 60–100 | No change | Q am |
| 101–120 | Decrease by 12 U/kg Q 12 hr | 6 hr after dose |
| 121–140 | Decrease by 24 U/kg Q 12 hr | 6 hr after dose |
| >140 | Decrease by 36 U/kg Q 12 hr | 6 hr after dose |

^aUniversity of Washington Medical Center.

^bBased on aPTT reagent-specific therapeutic range of 60–100 sec corresponding to a heparin concentration of 0.3–0.7 U/mL determined by antifactor X_a activity.

^cRounded to nearest 500 U.

SC, subcutaneous; aPTT, activated partial thromboplastin time; Q, every; IV, intravenous.

For L.N., whose current heparin dosage is 1,700 U/hour, the initial SC heparin dose would be 22,500 U (1,700 U/hour × 12 hours plus a 10% increase and rounded to the nearest 500 U). L.N.'s aPTT should be checked 6 hours after the first dose, with adjustment of dosing as necessary. A weight-based dosing nomogram, specific for a reagent with a therapeutic aPTT range of 60 to 100 seconds, is described in Table 15-9.

More recent data support the efficacy of weight based SC UFH (initial dose of 333 U/kg followed by 250 U/kg every 12 hours) *without routine aPTT monitoring* for the treatment of acute VTE. Although not yet ready for wide implementation because data are only based on one trial, the use of weight-based, unmonitored SC UFH has the potential to simplify the way acute VTE is treated.³⁹

REVERSAL OF EFFECT

14. P.B. is a 64-year-old woman with DVT. On day 4 of heparin therapy, she received 25,000 U of heparin during a 1-hour period as a result of an infusion pump malfunction. The infusion was stopped and within 30 minutes, she became diaphoretic and hypotensive. Bright red blood was evident on rectal examination, and a large retroperitoneal mass was noted. How should the excessive heparin effect be reversed?

P.B. has definite signs of hemorrhage from the GI tract, a site of bleeding associated with considerable mortality. Heparin should be discontinued immediately, and treatment should include maintenance of fluid volume and replacement of clot-

ting factors with whole blood, fresh frozen plasma, or clotting factor concentrates. If hemorrhage had not been present and the only manifestation of overdose had been a prolonged aPTT, administration of heparin simply could have been discontinued, permitting the effects to clear within a few hours.

Protamine can be used to neutralize heparin by forming an inactive protamine–heparin complex.⁴⁰ Protamine has a rapid onset of action, with effects lasting about 2 hours. Protamine sulfate is infused slowly over 3 to 5 minutes, as a 1% solution at a dose of 1 mg for each 100 U of heparin administered, but only if it is given within 30 minutes of discontinuation of heparin administration. The maximum single recommended dose of protamine is 50 mg, but doses may be repeated if bleeding persists. If protamine therapy is delayed, dosing should be based on the estimated amount of heparin remaining, taking into consideration the elimination half-life of heparin. Response to protamine therapy can be assessed by a return of the aPTT to baseline. Adverse effects associated with protamine include systemic hypotension secondary to rapid administration; anaphylaxis characterized by edema, bronchospasm, and cardiovascular collapse; and catastrophic pulmonary vasoconstriction⁴¹ (see Chapter 4).

LOW-MOLECULAR-WEIGHT HEPARIN

15. H.K. is a 32-year-old woman who presents to the emergency department (ED) complaining of right calf pain of 1 day's duration. She denies trauma to the calf but reveals that she has just

Table 15-10 Dosing of Low-Molecular-Weight Heparin and Fondaparinux for the Treatment of Venous Thromboembolism

| Dalteparin | Enoxaparin | Tinzaparin | Fondaparinux |
|--|--|---------------------|---|
| 100 U/kg SC Q 12 hr OR 200 U/kg SC Q 24 hr | 1 mg/kg SC Q 12 hr OR 1.5 mg/kg SC Q 24 hr | 175 U/kg SC Q 24 hr | 5 mg SC Q 24 hr if weight <50 kg 7.5 mg SC Q 24 hr if weight 50–100 kg 10 mg SC Q 24 hr if weight >100 kg |

returned to the United States from Australia on a lengthy flight. She has no significant medical history, has no family history of clotting disorders, and takes no medications. A duplex ultrasound is positive for DVT, and immediate anticoagulation is indicated. What therapeutic alternative to hospitalization for UFH is available for this patient?

Historically, UFH was the initial treatment of choice for acute DVT. However, LMWHs have now emerged as more convenient and practical treatment alternatives to UFH.²⁶ In addition, meta-analysis data suggest that LMWH results in fewer deaths, major hemorrhages, and recurrent VTE when compared to UFH.⁴² Weight-based, once- or twice-daily SC dosing of LMWHs provides a consistent anticoagulant effect that does not require aPTT monitoring.⁴³ Based on these advantages, outpatient use of LMWH has become the most common approach to treatment of uncomplicated DVT. Home treatment is safe and effective and improves the overall physical and social functioning of patients being treated for DVT.⁴⁴ The drug costs associated with LMWH treatment are much higher than the costs of UFH, but overall costs to health care systems are significantly reduced when patients can be treated at home rather than in the hospital.⁴⁵ The synthetic pentasaccharide, fondaparinux, can be considered as an alternative treatment option to the LMWHs as it has been shown to be as effective and safe as LMWH in the treatment of DVT.⁴⁶ Fondaparinux has the benefit that, to date, HIT has not been associated with its use.⁴⁷

For H.K. to be treated at home with LMWH, she or a family member must be willing and able to administer SC injections, and she must be able to return for frequent follow-up visits, particularly during the first week while warfarin therapy is initiated. In addition, her health care insurance should cover the cost of the drug, or she must be able to pay out of pocket. Contraindications to home treatment of DVT include a pre-existing condition that requires hospitalization, clinical symptoms of PE and/or hemodynamic instability, recent or active bleeding, and end-stage renal disease.

H.K. meets the eligibility requirements for home treatment and is interested in self-injection of LMWH at home, with support from her partner, for initial treatment of DVT. Possible treatment options and doses for H.K. are listed in Table 15-10. However, most institutional formularies carry only a single LMWH product, with formulary decisions based on FDA-approved indications and clinical data supporting use for treatment and prevention of thromboembolism in various settings. In this case, enoxaparin is the LMWH available for use. The usual dosing of enoxaparin for treatment of DVT is 1 mg/kg total body weight SC Q 12 hours, rounded to the nearest 10-mg increment. Once-daily dosing, at 1.5 mg/kg SC Q 24 hours is also an option, but this strategy is inferior to twice-daily dosing in patients with malignancy or obesity.⁴⁸ In addition, results from a meta-analysis suggest that hemorrhage and recurrent VTE are less likely to occur with twice-daily dosing of LMWH as compared to once-daily dosing, thus raising further controversy around the routine use of once-daily dosing.⁴³

Because LMWHs are eliminated renally, patients with significant renal impairment require dose reductions.⁴⁹ The degree of drug accumulation can vary between the various LMWH preparations, thus specific guidelines for dose adjustments will be agent specific^{50–52} (Table 15-11). Some experts suggest monitoring of antifactor X_a activity to rule out accumulation of LMWHs in patients with renal impairment.^{53,54} Fondaparinux is also renally excreted and is contraindicated in patients with creatinine clearance <30 mL/minute. Data with the use of LMWH and fondaparinux for the prevention and treatment of VTE in patients on hemodialysis is lacking; thus, UFH is the recommended treatment option in these patients.

16. What systems must be in place for H.K.'s home treatment to be successful? What is the role of the pharmacist or other caregiver in her therapy?

H.K. should be weighed to determine her dose of enoxaparin. Because she is not obese and does not have a malignancy, a 1.5-mg/kg dose once daily can be considered for convenience

Table 15-11 Dosing of Low-Molecular-Weight Heparins (LMWHs) in Patients With Renal Impairment (CrCL <30 mL/min^a)

| LMWH | Dalteparin | Enoxaparin | Tinzaparin |
|---|--|---|---|
| Product information recommendations | Use with caution | Prophylaxis—30 mg SC daily Treatment—1 mg/kg SC daily | Use with caution |
| Dosing suggestions based on agent-specific pharmacokinetic observations | CrCL <30 ^a mL/min: no dose adjustment needed up to 1 week For use longer than 1 week, consider monitoring of anti-X _a activity and adjust dose if accumulation is noted CrCL 30–50 mL/min: no dose adjustment needed | CrCL <30 ^a mL/min: Consider a 40%–50% dose decrease and subsequent monitoring of anti-X _a activity CrCL 30–50 mL/min: Consider a 15%–20% dose decrease with prolonged use (longer than 10–14 days) and subsequent monitoring of anti-X _a activity | CrCL <30 ^a mL/min: consider a dose decrease of 20% and subsequent monitoring of anti-X _a activity CrCL 30–50 mL/min: no dose adjustment needed |

^aIn patients with a CrCL <20 mL/min, data are very limited and use of unfractionated heparin is suggested.

of administration. Dosing is typically rounded to the nearest 10 mg based on the availability of prefilled syringes. At 64 kg, H.K. will receive 100 mg SC Q 24 hours. Warfarin therapy is initiated concurrently to expedite the conversion to oral treatment.

H.K. must be taught to self-administer enoxaparin by SC injection. Patient education resources, including videotaped instructions and written materials, should supplement hands-on instruction. H.K. will administer the first dose of enoxaparin in the ED with the assistance of a pharmacist. She should also be given prescriptions for enoxaparin and warfarin that must be filled immediately at the pharmacy of her choice.

H.K. should be instructed regarding the potential adverse effects of LMWH therapy (bleeding, thrombocytopenia, pain and bruising at the injection site), required laboratory monitoring, and the expected duration of anticoagulation. At baseline, Hct, INR, renal function, and platelet count should be determined. Platelets will continue to be monitored at least every 2 to 3 days while the patient is receiving LMWH therapy. Platelet counts will be monitored up to 10 to 14 days or for as long as the patient is receiving LMWH therapy, whichever is sooner. H.K. can expect to continue enoxaparin therapy for a minimum of 5 days. If by day 5 her INR is therapeutic and stable, enoxaparin can be discontinued. Oral anticoagulation with warfarin will continue for 3 to 6 months.²⁶

To ensure the safety and efficacy of home treatment, H.K. should be provided with the names and telephone numbers of the health care providers who will assume responsibility for her care, including her primary physician and her anticoagulation management team. No patient should be sent home with LMWH without an adequate follow-up plan.

Prevention

17. D.F., a 63-year-old obese woman, is to undergo elective abdominal surgery for treatment of diverticulitis. She has a medical history significant for mild hypertension, currently controlled by enalapril 10 mg QD (blood pressure, 135/85 mmHg), and peripheral vascular disease. What therapeutic interventions might decrease the risk of DVT or PE in D.F.?

Surgical procedures represent a significant risk factor for DVT formation. All hospitalized patients, including both surgical and nonsurgical patients, should be stratified for risk of DVT based on the presence of various factors.^{21,55,56} Risk stratification is used to select the most appropriate therapeutic interventions to prevent DVT, and thereby reduce the risk of fatal PE. These interventions include both mechanical and pharmacologic strategies.

Nonpharmacologic Measures

Mechanical interventions aimed at preventing venous stasis and increasing venous return include the use of elastic compression stockings, as well as leg elevation, leg exercises, and early postoperative ambulation. Intermittent pneumatic compression (IPC) of the leg muscles, using inflatable cuffs applied to the calf and thigh, represents another alternative for the prevention of DVT.²¹

Pharmacologic Measures

Fixed, low-dose unfractionated heparin (LDUFH), administered as 5,000 U SC Q 8 to 12 hr depending on the indication, is

an inexpensive and effective pharmacologic approach to DVT prevention in the setting of venous stasis, in medical patients, or after certain surgical procedures. Because low-dose heparin inactivates factor X_a without a direct effect on factor II_a, the aPTT is not prolonged, and therefore, aPTT monitoring is unnecessary. Bleeding complications are minimized using this dosing regimen.

Fixed-dose SC LMWH and fondaparinux are alternative approaches for preventing DVT. Enoxaparin 30 mg SC Q 12 hr or 40 mg SC once daily, dalteparin 2,500 to 5,000 IU SC once daily, and fondaparinux 2.5 mg SC once daily are effective strategies, although enoxaparin has been studied for a larger number of indications. Current recommendations for prevention of VTE based on risk stratification are presented in Table 15-12.²¹

D.F. is at high risk for DVT and PE, not only because of general surgery, but also because of her age (older than 40 years) and the presence of other risk factors for VTE (obesity, peripheral vascular disease, and probable postoperative immobilization). Options for DVT prevention include SC heparin at 5,000 U Q 8 hr or a LMWH (enoxaparin 40 mg SC QD, or dalteparin 2,500 IU initial dose followed by 5,000 IU SC QD). The first dose should be administered several hours preoperatively, and dosing should continue postoperatively until she is fully ambulatory. If bleeding risk is of concern, IPC could be used as an alternative.

PULMONARY EMBOLISM

Clinical Presentation

18. D.J. is a 38-year-old, 90-kg man. Several days ago, he developed a swollen left calf, which was painful and warm. This swelling gradually increased, affecting the entire left leg to the groin and prompting him to seek medical attention. In the ED, he also notes the recent onset of right-sided pleuritic chest pain without SOB or hemoptysis. His medical history includes a gastric ulcer 4 years ago, treated medically without recurrence. Physical examination reveals a pleasant, obese man with an enlarged left leg and mild to moderate tenderness in the entire leg. Chest examination reveals a loud, pulmonary heart sound (P₂). Vital signs include blood pressure, 150/85 mmHg; heart rate, 100 beats/minute; and respiratory rate, 28 breaths/minute and regular. Laboratory data include Hct, 26.7% (normal, 45%–52%); SCr 1.1 mg/dL (normal, 0.8–1.2); and arterial blood gases (on room air) PO₂, 72 mmHg (normal, 75–100); PCO₂, 30 mmHg (normal, 35–45); and pH 7.48 (normal, 7.35–7.45). The chest radiograph and lung scan (ventilation-perfusion [V/Q] scan) are highly suggestive of PE. An angiogram was not performed. The electrocardiogram (ECG) shows sinus tachycardia. The venogram is positive for defects in the iliofemoral vein. Coagulation test results include PT, 11.2 seconds (INR, 1.0); aPTT, 28 seconds; and platelet count, 248,000/mm³ (normal, 150,000–350,000). What subjective and objective evidence in D.J. is compatible with PE?

[SI units: Hct, 0.267 (normal, 0.45–0.52); platelets, 248 × 10⁹/L (normal, 150–300)]

Signs and Symptoms

The clinical diagnosis of PE is often difficult to make because of the nonspecificity of symptoms.⁵⁷ The most commonly observed subjective symptoms are dyspnea, pleuritic

Table 15-12 Prevention of Venous Thromboembolism (VTE)²¹

| | |
|--|--|
| General surgery | |
| Low risk | Early ambulation |
| Moderate risk | LDUH Q 12 hr, LMWH QD, IPC, or GCS |
| High risk | LDUH Q 8 hr, LMWH QD, or IPC |
| Highest risk | LMWH QD, Fondaparinux QD, Warfarin (INR 2–3), or IPC/GCS + LDUH/LMWH |
| Gynecologic surgery | |
| Brief procedures (<30 min) | Early ambulation |
| Laparoscopic surgery with additional VTE risk factors | LDUH Q 12–Q 8 hr, or LMWH QD, or IPC/GCS |
| Major surgery for benign disease and no other risk factors | LDUH Q 12 hr, LMWH QD, or IPC |
| Major surgery for malignancy, or additional VTE risk factors | LDUH Q 8 hr; or LMWH QD; or IPC; or LDUH/LMWH + IPC/GCS. |
| Urologic surgery | |
| Low-risk procedures | Early ambulation |
| Major open procedures | LDUH Q 12–Q 8 hr, LMWH QD, IPC/GCS |
| Highest-risk patients | LDUH Q 12–Q 8 hr or LMWH QD + IPC/GCS |
| Orthopedic surgery | |
| Hip replacement | Fondaparinux, or LMWH QD or BID, or warfarin (INR 2–3) |
| Knee replacement | Fondaparinux, or LMWH BID, or warfarin (INR 2–3) |
| Hip fracture surgery | Fondaparinux, or LMWH BID, or warfarin (INR 2–3); IPC/GCS if anticoagulation therapy is contraindicated. |
| Trauma | LMWH BID; IPC/GCS if anticoagulation is delayed or contraindicated. |
| Acute spinal cord injury | LMWH BID, or LMWH/LDUH + IPC/GCS |
| Neurosurgery | IPC/GCS ± LDUH Q 12 hr, or LMWH QD |
| Acutely medically ill | LDUH Q 8–12 hr or LMWH QD |

LDUH, low-dose unfractionated heparin (5,000 U SC Q 8–12 hr); LMWH, low-molecular-weight heparin (enoxaparin 40 mg SC QD or 30 mg SC Q 12 hr; dalteparin 2,500–5,000 IU SC QD); Fondaparinux (2.5 mg SC QD); GCS, graduated compression stockings; IPC, intermittent pneumatic compression.

Low risk: minor surgery, age younger than 40 years, and no additional risk factors for VTE. Moderate risk: minor surgery and additional risk factors for VTE; surgery, age 40–60 years, and no other risk factors for VTE. High risk: surgery with age older than 60 years, or age 40–60 years with additional risk factors for VTE. Highest risk: surgery in patients with multiple risk factors for VTE (age older than 40 years, cancer, prior VTE); orthopedic surgery, trauma.

chest pain, apprehension (anxiety or a feeling of impending doom), and cough. Hemoptysis occurs occasionally. The objective signs most commonly observed are tachypnea at a rate of ≥ 20 breaths/minute, tachycardia of ≥ 100 beats/minute, accentuated pulmonary component of the second heart sound (P_2), and rales. DVT precedes PE in 80% or more of patients. A combination of these signs and symptoms provides further evidence for acute PE. D.J. has presented with pleuritic chest

pain, tachycardia, tachypnea, loud P_2 , and a decrease in PO_2 ; therefore, he may have developed PE.

Diagnosis

Because the clinical signs and symptoms of PE are difficult to distinguish from many other medical conditions, further evaluation is necessary.^{57,58} Chest radiograph, ECG, and arterial blood gas (alveolar-arterial oxygen gradient [A-a gradient]) abnormalities are often present in patients with PE, but like clinical signs and symptoms, they are somewhat nonspecific. Although pulmonary angiography has been considered the gold standard for diagnosis of PE, it is an invasive procedure that is expensive and technically difficult to perform. In addition, the contrast material used can be toxic or irritating, and some patients are unable to tolerate the procedure. Noninvasive tests such as V/Q lung scans and computed tomography (CT) scans are useful and the most frequently used diagnostic procedures to document the presence of PE. Lung scans that incorporate an assessment of perfusion, or regional distribution of pulmonary blood flow, and ventilation are referred to as V/Q scans; they involve both the injection and the inhalation of radiolabeled compounds. Test results are expressed as a high, intermediate, or low probability of PE. When ventilation (air movement) is normal over an area that shows abnormal perfusion (blood flow), a V/Q mismatch exists, and PE is highly probable. If a matched defect is noted (abnormal ventilation over an area of abnormal perfusion), another disease state, such as chronic obstructive airway disease, is more likely.

As in the case of DVT, clinical assessment can improve the diagnostic accuracy of noninvasive tests such as CT or VQ scanning.^{23,58} Validated assessment tools can be used to stratify patients into high, moderate, and low probability of a PE⁵⁹ (Table 15-13). In patients with a low clinical probability of PE, measuring a high-sensitivity D-dimer can be considered, and if negative, PE can be ruled out eliminating the need of further imaging studies.^{23,60} In patients with a moderate to high clinical probability of PE, diagnostic imaging studies should be performed.²³

A positive lung scan (D.J. had one highly suggestive of PE) or a positive pulmonary angiogram would confirm the presence of a PE. If the results of the clinical assessment and the noninvasive scan are discordant, angiography should be performed to aid in making the definitive diagnosis. Nonetheless, when the diagnosis of PE is suspected, anticoagulation should be initiated immediately while awaiting results of more definitive

Table 15-13 Clinical Model for Evaluating the Pretest Probability of Pulmonary Embolism (PE)^a

| Clinical Characteristic | Score |
|---|-------|
| Cancer | +1 |
| Hemoptysis | +1 |
| Previous PE or deep vein thrombosis (DVT) | +1.5 |
| Heart rate > 100 beats/min | +1.5 |
| Recent surgery or immobilization | +1.5 |
| Clinical signs of DVT | +3 |
| Alternative diagnosis less likely than PE | +3 |

^aClinical probability of PE: low, 0–1; moderate, 2–6; high, ≥ 7 . From reference 58.

diagnostic procedures. Mortality associated with PE has been documented to be as high as 17.5% over 3 months.⁶¹

Treatment

19. What anticoagulant strategy should be initiated for D.J.?

Treatment options for PE include IV UFH therapy initiated with a loading dose followed by a continuous infusion, or a LMWH or fondaparinux administered by SC injection.^{26,62} UFH therapy could be started in D.J. with a loading dose of 7,200 U (80 U/kg × 90 kg), followed by continuous infusion of 1,600 U/hour (18 U/kg/hour × 90 kg). Monitoring of the aPTT would be used to adjust dosing to maintain treatment within the therapeutic range (Table 15-8).

The alternative to UFH for treatment of PE is the use of a SC LMWH^{63,64} or SC fondaparinux⁶⁵ (Table 15-10). D.J. could receive fixed-dose enoxaparin 90 mg SC Q 12 hr (1 mg/kg Q 12 hr–90 kg). Generally, PE should not be treated on an outpatient basis.⁶³ In this case, LMWH or fondaparinux would be used during the complete hospital course, or only for partial outpatient therapy in selected lower-risk and stable patients who may be discharged early.

The use of thrombolytic therapy should be reserved for patients with acute massive embolism, who are hemodynamically unstable (SBP <90 mmHg) and at low risk for bleeding.²⁶

Warfarin

TRANSITION FROM HEPARIN/LMWH THERAPY

20. When should warfarin be administered, and how should the transition be accomplished?

Either heparin or LMWH/fondaparinux therapy should be continued for at least 5 days in the setting of PE, and until warfarin therapy is therapeutic and stable. Warfarin should be started on the first day of hospitalization and continued for a minimum of 3 to 6 months or longer, if indicated. However, a delay in the initiation of warfarin may be acceptable in the setting of an anticipated extended hospitalization, recent or anticipated surgery or other invasive procedures, or a medical condition with the potential for uncontrolled bleeding.^{26,63}

There are several reasons to overlap heparin and warfarin therapy. The onset of warfarin activity depends not only on its inherent pharmacokinetic characteristics (half-life >36 hours), but also on the rate of elimination of circulating clotting factors. Although warfarin inhibits production of the vitamin K–dependent clotting factors, previously synthesized clotting factors must be eliminated at rates that correspond with their elimination half-lives (Table 15-5). Approximately four half-lives are required for these factors to reach a new steady state after their production is inhibited, so the effect of warfarin can be delayed for several days. Initial increases in the INR reflect only reductions in factor VII activity, but full anticoagulation with warfarin requires adequate suppression of factors II and X, which have significantly longer elimination half-lives. By overlapping a quick onset anticoagulant such as heparin or LMWH with warfarin therapy, adequate anticoagulation can be continued with heparin/LMWH until warfarin therapy reaches a therapeutic intensity.^{10,66}

In addition to suppressing the synthesis of the vitamin K–dependent clotting factors, warfarin also inhibits the formation

of the naturally occurring anticoagulant protein C and its cofactor, protein S. In patients with congenital protein C or protein S deficiency, initial warfarin therapy can suppress these proteins to concentrations that may result in hypercoagulability with possible thrombus extension, unless concurrent heparin therapy provides adequate anticoagulation.⁶⁷ To prevent these complications, heparin and warfarin therapy should overlap.

Heparin therapy has been observed to prolong the INR,⁶⁸ and warfarin can prolong the aPTT by several seconds.⁶⁹ Thus, interference with laboratory tests should be considered in the evaluation of the intensity of anticoagulation during the overlap of heparin and warfarin therapy.

INITIATION OF THERAPY

21. In an effort to discharge D.J. from the hospital as soon as possible, an initial dose of warfarin 10 mg PO Q pm for 3 days has been ordered. Is such a “loading dose” reasonable? What would be a more appropriate approach to initiating therapy?

Initiation of warfarin dosing is complex because dosing requirements vary significantly among individuals. Daily doses as low as 0.5 mg and as high as 20 mg or more may be required in individual patients to reach a therapeutic INR.⁷⁰ Two methods for initiation of warfarin therapy have been developed.⁷¹ The average daily dosing method relies on an understanding that although dosing requirements for warfarin vary significantly among patients, an average dosing requirement of 4 to 5 mg/day of warfarin is necessary to maintain an INR of 2.0 to 3.0. When the average daily dosing method is used for initiation of warfarin therapy, patients are typically started at 4 to 5 mg daily, with dosing adjustments as necessary until the therapeutic goal is reached. However, patients who may be more sensitive to the effects of warfarin (Table 15-14) are expected to require lower dosages of warfarin. In these patients, therapy should be initiated at 1 to 3 mg daily, with subsequent dosing adjustments as necessary. Several dosing algorithms, using a 4- to 5-mg initiation dose, have been developed to aid with dosing decisions after the first few doses of warfarin have been administered.^{72–74} Another popular dosing algorithm used a 10-mg initiation dose for the first 2 days, with the INR on day 3 used to guide dosing on days 3 and 4, and the INR on day 5 used to guide the next three doses⁷⁵ (Fig. 15-5). Although

using this dosing algorithm helps achieve a therapeutic INR more quickly than using a 5-mg initial dose, these findings may not be generalizable to all patient populations because the patients evaluated were relatively healthy, young outpatients.⁷⁶ The 10-mg initiation dose may lead to overanticoagulation and heightened bleeding risk in elderly and ill patients with multiple medical problems.⁷⁷ Average daily dosing is often used to initiate therapy in ambulatory patients; in this case, the first INR should be evaluated within 3 to 5 days of initiation of warfarin therapy. In hospitalized patients, it is more common to evaluate the INR daily during initiation of therapy.

Flexible initiation of warfarin is an alternative approach for starting therapy that is based on evaluating the rate of increase in the INR and making daily dosing adjustments based on daily INR evaluation, with a goal of determining the eventual maintenance dosing requirement. A popular flexible initiation nomogram is presented in Table 15-15.^{78,79} Using this nomogram, warfarin can be initiated with either a 10-mg or a 5-mg starting dose, with daily dosing adjustments based on the rate of increase in the INR. Flexible initiation does not necessarily shorten the time to reach the goal INR, and initiating therapy with a 10-mg dose as described in some protocols may be associated with an increased risk of early overanticoagulation in certain patients. Nonetheless, these methods offer a more individualized approach to initiation of therapy.

The baseline INR for D.J. was 1.0. Using the flexible initiation protocol presented in Table 15-15, the first dose of warfarin should be 10 mg administered in the evening on the first day of hospitalization. Subsequent INR values obtained daily will guide dosing requirements until a therapeutic INR is reached. The order for warfarin 10 mg orally every evening for three doses should be discontinued and replaced with daily orders for warfarin and INR monitoring.

Table 15-15 Flexible Initiation Dosing Protocol for Warfarin Dosing, Including 10- and 5-mg Starting Dose Options

| Day | INR | 10-mg Initiation Dose | 5-mg Initiation Dose |
|-----|---------|-----------------------|----------------------|

INTENSITY OF THERAPY

22. What is the goal INR for D.J., and how long should anticoagulation be administered?

In patients with DVT or PE, warfarin doses that prolong the PT to an INR of 2.0 to 3.0 is defined as “low-intensity therapy.” This therapeutic range is recommended to maximize the antithrombotic effect of warfarin while minimizing potential bleeding complications associated with excessive anticoagulation.¹⁰

DURATION OF THERAPY

Once formed, clots adhere to the vessel wall. Thus, the first step in resolution of a thrombus involves covering the clot with a layer of endothelial cells to prevent additional platelet aggregation at the site of vessel injury. This endothelialization process generally takes 7 to 10 days to be completed. Initial anticoagulant treatment is used to prevent clot extension while allowing adequate endothelialization to occur. Continued anticoagulation prevents further clotting.

The appropriate duration of warfarin therapy is based on the likelihood of a recurrent venous thromboembolic event and also the risk of bleeding in each patient. The presence of concurrent risk factors for VTE and the specific circumstances that triggered the initial thrombotic event all have to be taken into account. Patients with unprovoked (idiopathic) DVT or PE, like in the case of D.J., should be treated for at least 6 to 12 months, but considered for indefinite therapy as their likelihood of having a recurrent event can be as high as 30% over 5 years.^{26,63} Patients with DVT or PE associated with transient

Table 15-16 Duration of Anticoagulation Therapy in Patients With Venous Thrombosis (Deep Vein Thrombosis and/or Pulmonary Embolism)

| <i>Patient Characteristic</i> | <i>Duration of Therapy</i> | <i>Comments</i> |
|---|--|---|
| First episode of venous thromboembolism (VTE) secondary to a transient (reversible) risk factor | At least 3 months | Recommendation applies to both proximal and calf vein thrombosis |
| First episode of VTE and cancer | 6 months (indefinite therapy or until cancer is resolved should be considered) | Low-molecular-weight heparin is recommended over warfarin |
| First episode of idiopathic VTE with or without a documented hypercoagulable abnormality | At least 6–12 months (indefinite therapy may be considered) | Continue warfarin therapy after 12 months if patient is low risk for bleeding |
| First episode of VTE with documented antiphospholipid antibodies or two or more thrombophilic abnormalities | 12 months to indefinite | The risk–benefit of indefinite therapy should be reassessed at periodic intervals |
| First episode of VTE with documented deficiency of antithrombin, protein C, protein S, factor V Leiden or prothrombin 20210 gene mutation, homocystinemia, elevated factor VIII | 6–12 months; indefinite for idiopathic thrombosis | The risk–benefit of indefinite therapy should be reassessed at periodic intervals |
| Second episode or recurrent VTE | Indefinite | |

Adapted from reference 26.

or reversible risk factors are usually treated for 3 to 6 months, as the risk of recurrence is lower (approximately 10% over 5 years). In patients with recurrent DVT/PE and patients with persistent risk factors, including AT deficiency, protein C or protein S deficiency, factor V Leiden, prothrombin gene mutation, antiphospholipid antibody syndrome, or other hypercoagulable states, including malignancy, warfarin treatment should be continued indefinitely^{26,63} (Table 15-16).

ADVERSE EFFECTS

23. What possible adverse effects from warfarin therapy should be considered in D.J., and how should they be monitored?

Hemorrhage

Bleeding is the most common adverse effect associated with warfarin. A summary of experimental and observational inception cohort studies determined that the average annual frequency of fatal, major, and all (major or minor) bleeding in patients treated with warfarin was 0.6%, 3%, and 9.6%, respectively.³⁵ However, wide variation in bleeding frequencies has been reported, probably because of differences in patient characteristics, treatment protocols, and the definition and assessment of bleeding among trials.

Warfarin-associated bleeding most commonly occurs in the nose, oral pharynx, and soft tissues, followed by the GI and urinary tracts. Hemarthrosis (bleeding into joint spaces) and retroperitoneal and intraocular bleeding represent less common hemorrhagic complications of warfarin therapy.^{35,36} As with heparin, GI and urinary tract bleeding associated with warfarin is often caused by previously undiagnosed lesions. Menstrual blood flow may be increased and prolonged in patients taking anticoagulants. This problem may be clinically significant if there is an underlying pathological condition (ovarian cysts, uterine fibroids, or polyps) resulting in abnormal vaginal bleeding.

Although it is uncommon, intracranial bleeding resulting in hemorrhagic stroke represents the most common cause of fatal bleeding associated with warfarin therapy. Rates of intracranial hemorrhage associated with anticoagulants have been estimated to range from 0.3% to 2%, and up to 60% are fatal.⁸⁰

Many factors influence the risk of hemorrhagic complications associated with warfarin. The frequency of bleeding is higher in the first 3 months of therapy than during subsequent months.⁸¹ Unlike heparin, the intensity of anticoagulation with warfarin directly influences the risk of bleeding, including intracranial hemorrhage.⁸² Other patient-specific variables that influence the risk of warfarin-associated bleeding include a history of GI bleeding, serious comorbid disease (including malignancy), and concomitant therapy with aspirin or non-steroidal anti-inflammatory drugs (NSAIDs).^{35,36}

The influence of age on bleeding risk is controversial. Older patients are known to require lower dosages of warfarin than younger patients to reach a therapeutic intensity of anticoagulation.⁸³ Inherent vitamin K deficiency or age-related differences in stereoisomeric disposition of warfarin may explain why older patients are more sensitive to the effects of warfarin and, therefore, require lower dosages than younger patients. This increased sensitivity to the effect of warfarin is not the result of differences in pharmacokinetic characteristics of warfarin between older and young patients, including protein binding and metabolism. It is also not related to gender, weight, underlying medical conditions, or the presence of interacting drugs. Nonetheless, increased sensitivity to warfarin does not imply an increased bleeding risk if older patients are managed appropriately.

Some studies have reported that age is an independent risk factor for bleeding, whereas others have suggested that age alone does not increase bleeding risk.⁸⁴ However, in two studies in which comprehensive anticoagulation monitoring and follow-up were provided through anticoagulation management services, elderly patients did not experience an increased incidence of major bleeding.^{85,86} However, other reports suggest that advanced age is linked to an increased risk of warfarin-related intracranial hemorrhage, even when patients are managed in an anticoagulation clinic setting.⁸²

Hemorrhagic risk assessment can be used to predict bleeding risk during anticoagulant therapy. A popular bleeding index scoring system assigns level of risk based on the presence of age older than 65 years, history of GI bleeding, history of stroke, and one or more of four comorbid conditions: recent MI, anemia (Hct <30), renal insufficiency (Scr >1.5), and diabetes.⁸⁷

The cumulative risk of major bleeding at 48 months in low-, intermediate-, and high-risk patients was 3%, 12%, and 53%, respectively. The bleeding index can be useful in making decisions about management of drug interactions, overanticoagulation, bridge therapy for invasive procedures, and other issues that may present during anticoagulant therapy.

Bleeding complications in D.J. can be minimized by careful attention to the signs and symptoms of bleeding by the patient and his caregivers, maintenance of the INR within the therapeutic range, avoidance of therapy with concomitant drugs known to increase the risk of bleeding or to increase the INR, and routine outpatient follow-up for INR monitoring and clinical assessment.

Skin Necrosis

Warfarin-induced skin necrosis is a rare, but serious adverse effect of oral anticoagulation, occurring in approximately 0.01% to 0.1% of patients treated with warfarin.^{88,89} Patients present within 3 to 6 days of the initiation of warfarin therapy with painful discoloration of the breast, buttocks, thigh, or penis. The lesions progress to frank necrosis with blackening and eschar. Skin necrosis appears to be the result of extensive microvascular thrombosis within subcutaneous fat and has been associated with hypercoagulable conditions, including protein C or protein S deficiency. In these patients, rapid depletion of protein C before depletion of vitamin K–dependent clotting factors during early warfarin therapy can result in an imbalance between procoagulant and anticoagulant activity, leading to initial hypercoagulability and thrombosis. Adequate heparinization during initiation of warfarin can prevent the development of early hypercoagulability.

Warfarin therapy should be discontinued in patients who develop skin necrosis. However, subsequent warfarin therapy is not necessarily contraindicated if it is required for treatment or prevention of thromboembolic disease.⁸⁸ In patients with protein C or protein S deficiency and a history of skin necrosis, warfarin therapy can be restarted at low dosages as long as therapeutic heparinization has been achieved. Therapy is maintained until the INR has been within the therapeutic range for 72 hours. Supplementation of protein C through administration of fresh frozen plasma also may be indicated.

Purple Toe Syndrome

Purple toe syndrome is a rarely reported adverse effect that typically occurs 3 to 8 weeks after the initiation of warfarin therapy and is unrelated to intensity of anticoagulation.⁸⁹ Patients initially present with painful discoloration of the toes that blanches with pressure and fades with elevation. The pathophysiology of this syndrome has been related to cholesterol microembolization from atherosclerotic plaques, leading to arterial obstruction. Because cholesterol microembolization has been associated with renal failure and death, warfarin therapy should be discontinued in patients who develop purple toe syndrome.

PATIENT EDUCATION

24. B.H. is a 30-year-old woman newly diagnosed with idiopathic DVT. Before anticoagulation is initiated, appropriate laboratory tests are drawn to evaluate the possibility of a hypercoagulable state. She will be treated as an outpatient with enoxaparin 1.5 mg/kg SC QD and started on warfarin 4 mg PO QD using

the average daily dosing method. Her primary care physician would like her to receive follow-up care in the medical center's pharmacist-managed anticoagulation clinic. What information should B.H. receive regarding the benefits of formal anticoagulation management services?

One of the keys to successful oral anticoagulant therapy is appropriate outpatient management. In comparison with routine medical care, management of warfarin therapy by anticoagulation clinics is associated with significant reductions in bleeding and thromboembolic complications, with reductions in the rates of warfarin-related hospital admissions and ED visits, and with outcome-based cost savings for health care organizations.^{90,91} Pharmacist-managed anticoagulation clinics offer many benefits for the management of anticoagulation therapy, including improved dosing regulation, continuous patient education, early identification of risk factors for adverse events, and timely intervention to avoid or minimize complications. B.H.'s referral to a pharmacist-managed anticoagulation clinic is likely to improve her overall satisfaction with care and to improve her clinical outcomes.

25. At her initial visit to the anticoagulation clinic, B.H. will receive extensive education about her warfarin therapy. What information should be conveyed to her by her anticoagulation provider to ensure the safety and efficacy of warfarin therapy?

Successful warfarin therapy depends on the active participation of knowledgeable patients.¹⁰ The anticoagulant effect of warfarin is influenced by various factors, and fluctuations in the intensity of the anticoagulant effect of warfarin can increase the risk of both hemorrhagic complications and recurrent thromboembolism.⁹² Pharmacists and other providers can improve adherence to the medication schedule, as well as ensure the safety and efficacy of warfarin therapy, by providing appropriate education to patients treated with this agent.

Key elements that form the basis of a thorough patient education program for warfarin therapy are listed in Table 15-17.

Table 15-17 Key Elements of Patient Education Regarding Warfarin

| |

INR, international normalized ratio.

This information may be conveyed through written teaching materials, videotaped instruction, individual or group discussion, or a combination of these approaches. Many useful educational tools are available from the manufacturers of warfarin.

B.H. should receive extensive education about warfarin therapy in an individual teaching session or an organized education program. A wallet card, medical bracelet, or alternative method of identifying her as a patient treated with warfarin should be provided. The health care provider who assumes responsibility for her outpatient warfarin therapy will need to provide continuing reinforcement of the essential elements of medication information at each follow-up visit.

FACTORS INFLUENCING DOSING

26. After receiving 6 days of enoxaparin therapy and six doses of warfarin 4 mg/day PO, B.H.'s INR is 2.4. Enoxaparin is discontinued, and B.H. is instructed to continue her current dosage of warfarin. She is scheduled to return to the anticoagulation clinic in 1 week for re-evaluation. At that time, her INR is 1.7. What factors might account for this change in the intensity of anticoagulation?

Patients should always be questioned about their understanding of the prescribed dose and their adherence to the prescribed regimen. Questions might include, "what dose of the medication have you been taking?", or "what time of the day do you take your medication?", or "how many times in the last week did you miss a dose of your medication?" If there is no evidence of misunderstanding of the correct dose or of noncompliance, numerous other factors should be considered that are known to influence warfarin dosing requirements in individual patients during both initiation and maintenance phases of therapy. Changes in dietary vitamin K intake, alcohol use, underlying disease states, genetic factors, and concurrent medications can significantly change the intensity of therapy, resulting in the need for dosing adjustments to maintain the INR within the therapeutic range.

Dietary Vitamin K Intake

The two primary sources of vitamin K in humans are the biosynthesis of vitamin K₂ (menaquinone) by intestinal bacteria and dietary intake of vitamin K₁ (phytonadione). The U.S. recommended daily allowance for vitamin K is 70 to 140 mcg/day, and the typical Western diet provides approximately 300 to 500 mcg/day.⁹³ Vitamin K is found in high concentrations in certain foods, including green leafy vegetables (asparagus, broccoli, Brussels sprouts, cabbage, cauliflower, chick peas, collard greens, endive, kale, lettuce, parsley, spinach, and turnip greens), soy milk, certain oils, certain nutritional supplements, and multiple vitamin products. Green tea and chewing tobacco are other significant sources of vitamin K.

Variations in vitamin K intake have been linked to INR fluctuations in patients taking warfarin.^{94,95} In addition, diets high in vitamin K content have been associated with acquired warfarin resistance, defined as excessive warfarin dosing requirements to reach a therapeutic INR range.⁹⁶ Numerous cases have also been reported in which patients previously stabilized with warfarin experienced elevations in INR with or without hemorrhagic complications when dietary sources of vitamin K were eliminated. Conversely, reductions in INR with or without

thromboembolic complications have been reported in patients in whom dietary sources of vitamin K have been added.

These data illustrate the potential clinical significance of dietary changes in patients taking warfarin. To minimize these potential effects, B.H. should be counseled to maintain a *consistent* intake of dietary vitamin K.⁹⁷ Her final warfarin maintenance dose will be partially influenced by her typical diet. However, restriction of dietary vitamin K intake is unnecessary, except in cases of significant resistance to the anticoagulant effect of warfarin. B.H. should be aware of the types of foods and supplements that contain large quantities of vitamin K, and should be counseled to maintain a consistent diet, to avoid bingeing with foods high in vitamin K content, and to report significant dietary changes to her health care provider. Appropriate assessment and follow-up are essential to prevent hemorrhagic or thromboembolic complications that may arise from changes in INR resulting from dietary alterations.

Alcohol Ingestion

Chronic alcohol ingestion has been associated with induction of the hepatic enzyme systems that metabolize warfarin. Therefore, warfarin dosing requirements are sometimes higher in alcoholic patients. Conversely, acute ingestion of large amounts of alcohol can slow warfarin metabolism through competitive inhibition of metabolizing enzymes, leading to elevations in INR and an increased risk of bleeding complications.^{98,99} Despite some reports linking low amounts of alcohol to an elevated INR,¹⁰⁰ in general it is believed that moderate intake of alcoholic beverages is not associated with alterations in the metabolism or the therapeutic effect of warfarin as measured by INR. Patients taking warfarin should be educated to limit their alcohol consumption to less than one to two alcoholic beverages per day. Chronic drinkers should be counseled to limit their drinking and maintain a regular pattern to avoid fluctuations in INR.⁹⁷ B.H. does not need to abstain from drinking alcoholic beverages in moderation, but she should be counseled to avoid the sporadic ingestion of large amounts of alcohol.

Underlying Disease States

The presence or exacerbation of various medical conditions can also influence anticoagulation status.¹⁰¹ Diarrhea-associated alterations in intestinal flora can reduce vitamin K absorption, resulting in elevations in INR. Fever enhances the catabolism of clotting factors and can increase INR. Heart failure, hepatic congestion, and liver disease can also cause significant elevations in INR because of a reduction in warfarin metabolism. End-stage renal disease is associated with decreased CYP2C9 activity, resulting in lower warfarin dose requirements.

Thyroid function can influence warfarin therapy significantly. Hypothyroidism decreases the catabolism of certain clotting factors, increasing their availability and producing a relative refractoriness to warfarin therapy. This results in the need for increased dosages to reach a therapeutic INR. The addition of thyroid supplementation in these patients reverses the influence of hypothyroidism and can lead to significant elevations in INR unless the warfarin dose is reduced. Conversely, hyperthyroidism increases the catabolism of clotting factors, leading to an increased sensitivity to warfarin. Frequent monitoring of and adjustments in warfarin therapy are necessary in patients with changing thyroid function.

Genetic Factors

Cytochrome-P450 2C9 genotype^{102,103} and VKOR^{12,104} haplotype have been shown to correlate with the dose of warfarin required for effective anticoagulation. Patients with variant expression of CYP2C9 have a lower warfarin dose requirement and their risk of overanticoagulation is higher during therapy. Dosing algorithms that incorporate CYP2C9 genotype and VKOR1 haplotype along with other patient characteristics to predict warfarin maintenance doses are being tested.¹⁰⁵ It still remains to be determined whether pharmacogenomic-based dosing will improve clinical outcomes.

Other Factors That Influence Warfarin Dosing Requirements

Acute physical or psychological stress has been reported to increase INR.¹⁰⁶ Increased physical activity has also been reported to increase the warfarin dosing requirement.¹⁰⁷ Smoking can induce CYP1A2, which may increase warfarin metabolism in certain patients, resulting in increased dose requirements.¹⁰⁸ Due to its high vitamin K content, chewing smokeless tobacco can suppress the INR response.¹⁰⁹

27. How should B.H. be assessed and evaluated at this clinic appointment?

At each clinic visit, regardless of the INR result, all factors that may influence B.H.'s anticoagulation status should be evaluated carefully, including adherence with the warfarin dose schedule. A patient assessment nomogram (Fig. 15-6) is a helpful tool to assist with patient evaluation.

The accuracy and reliability of the INR test should be also considered. B.H. should be assessed thoroughly for signs and symptoms of thromboembolism and hemorrhage. Detailed questions should be asked to determine whether any changes in diet, alcohol intake, underlying disease states, concurrent medications, or other factors have occurred.

DOSING ADJUSTMENTS**28. After a thorough assessment, it is determined that B.H. has adhered to her prescribed warfarin dosage schedule and that there is no apparent explanation to account for her reduction in INR. How should her warfarin dosage be adjusted?**

When overanticoagulation or underanticoagulation is verified, an adjustment in warfarin dosing may be necessary. Figures 15-7 and 15-8 describe approaches to warfarin dosing adjustments for both regular-intensity and high-intensity maintenance therapy. Typically, dosing adjustments of 5% to 20% of the total daily dose (or the total weekly dose) are appropriate to reach the therapeutic range.¹¹⁰ Because warfarin does not follow linear kinetics, small adjustments in dose can lead to large INR changes, thus large dose adjustments (i.e., greater than or less than 20% of the total weekly dose) are not recommended. These maintenance dosing guidelines should only be applied to patients who have reached a steady-state dose and not in the initiation phase of therapy.

Because B.H. is currently taking 4 mg daily, an adjustment of 10% would increase her dosage to approximately 4.5 mg/day. This dosing adjustment can be made by having her take one 4-mg tablet and half of a 1-mg tablet each day (same daily dosing) or by having her take 6 mg 2 days per week and 4 mg all other days of the week (alternate-day dosing). Patient preference and the likelihood of confusion about different tablet sizes versus

different doses on different days of the week should be the primary considerations when selecting a dosing method.¹¹¹

FREQUENCY OF FOLLOW-UP**29. B.H. agrees to increase her warfarin dosage to 4.5 mg/day. A new prescription for 1-mg tablets is written for her, and she is instructed about the use of these tablets. When should her INR be reassessed and her anticoagulation status, including physical assessment, be re-evaluated?**

It will take several days for her warfarin level to reach a new steady state because of the long elimination half-lives of both warfarin and the vitamin K-dependent clotting factors. Her INR should be rechecked approximately 1 week after a dosing adjustment has been made. Once a stable dose has been reached, patient assessment and INR monitoring should occur every 4 to 6 weeks. However, if B.H. displays any signs of medical instability or nonadherence, a follow-up schedule of every 1 to 2 weeks is indicated (Table 15-18).

MANAGEMENT OF OVERANTICOAGULATION**30. E.M., who has been taking warfarin for 6 months with good laboratory control, noted a slight pink color to his urine. In the ED, an INR of 5.6 was reported. His Hct and hemoglobin (Hgb) were both within normal limits, as were his vital signs. A stool Hemocult test was negative, but urinalysis revealed >50 red blood cells per high-power field. How should this adverse effect of warfarin be treated in E.M.?**

Management of overanticoagulation depends on the clinical presentation of the patient. In the case of an elevated INR without bleeding complications, interruption of warfarin therapy by holding one or two doses until the INR returns to the therapeutic range is usually sufficient.¹¹² Minor bleeding complications accompanied by an elevated INR can be also managed by withholding warfarin therapy for a short period until bleeding resolves. In either case, the patient should be questioned to determine a possible cause for overanticoagulation, including intake of extra doses of warfarin, changes in diet or alcohol intake, changes in underlying medical conditions, or the use of other medications. In some cases, no apparent explanation is identified. Depending on the cause, a reduction in the maintenance dosing of warfarin may be necessary.

The time required for INR to return to the therapeutic range after warfarin is withheld depends on several patient characteristics. Advanced age, lower warfarin maintenance dose requirements, and higher INR are associated with increased time for INR correction.¹¹³ Other factors that can prolong the time for INR to return to the therapeutic range include decompensated heart failure, active malignancy, and recent use of medications known to potentiate warfarin.

To shorten the time to correction of overanticoagulation, an alternative approach is to withhold warfarin and administer a small dose of vitamin K (phytonadione)¹⁰ (Table 15-19). An oral dose of 1 to 2.5 mg can correct overanticoagulation in 24 to 48 hours without causing prolonged resistance to warfarin therapy, a problem commonly seen with larger (10-mg) doses of vitamin K.¹¹⁴ Intramuscular administration is contraindicated due to the risk of hematoma formation, and SC administration of vitamin K is not recommended because of variable absorption.¹¹⁵

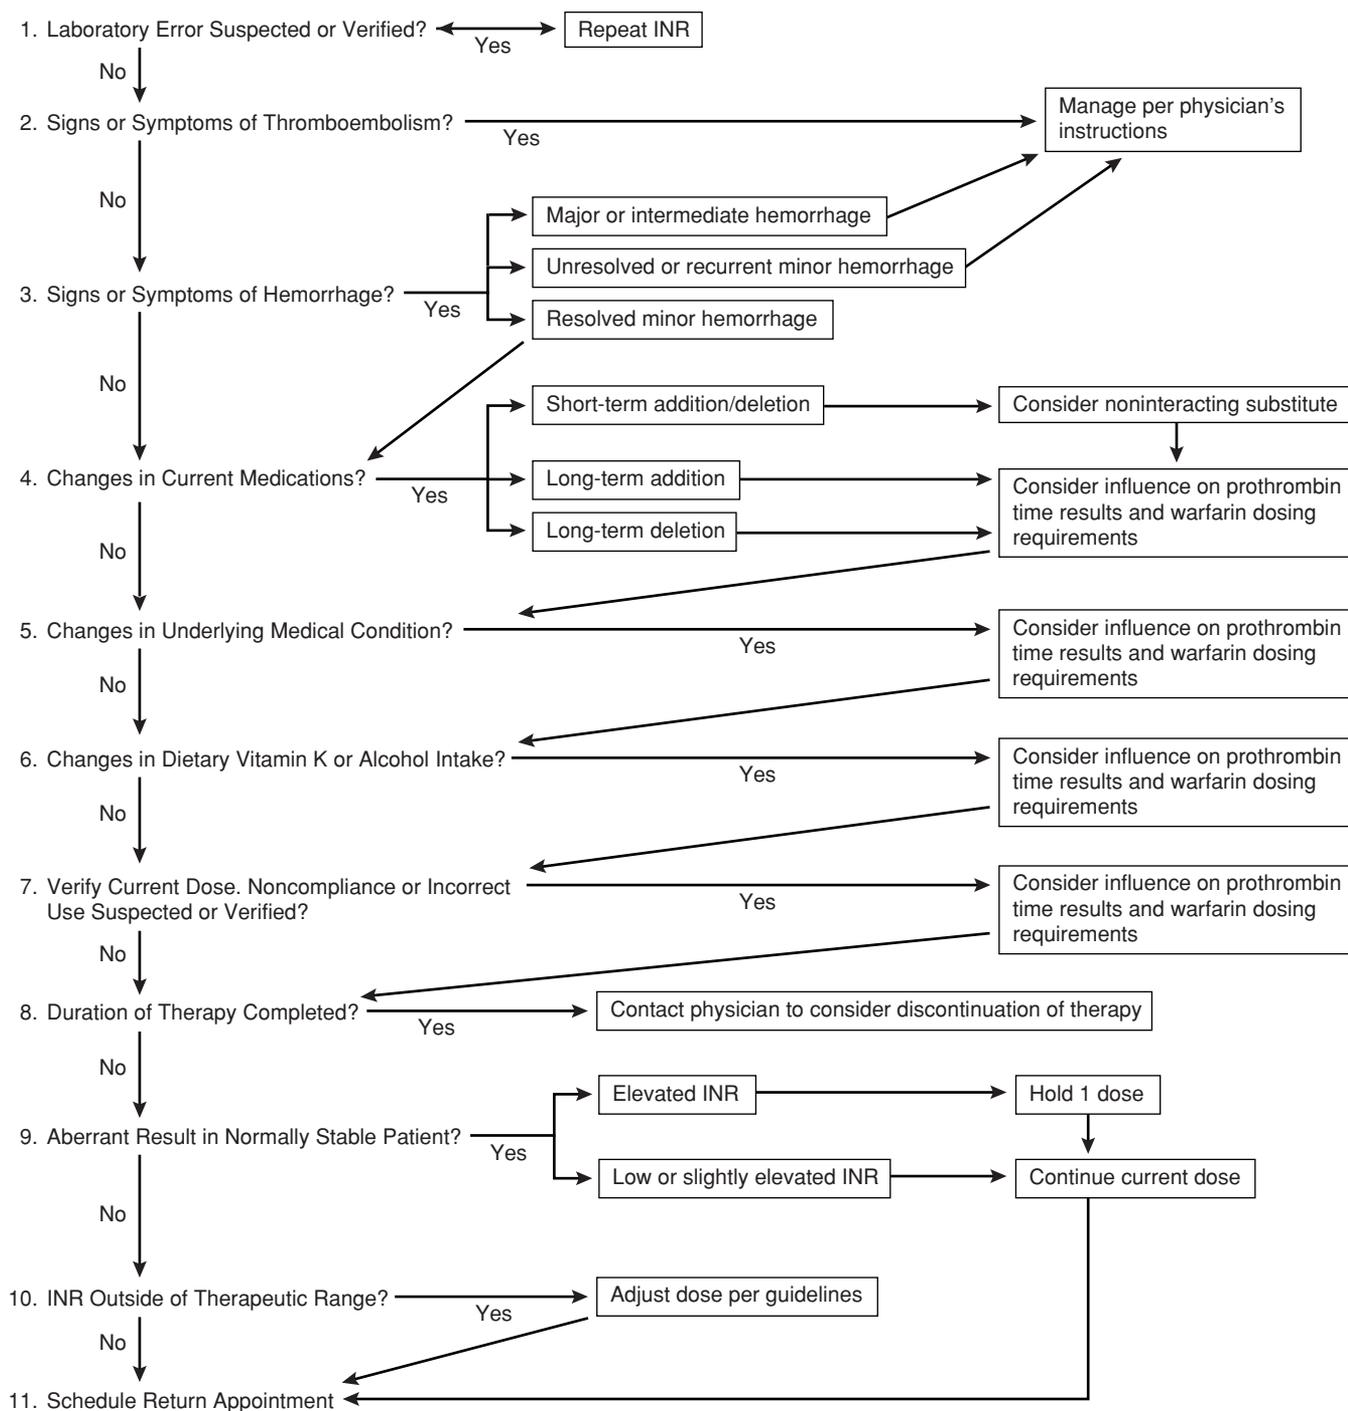

FIGURE 15-6 Assessment nomogram for patients taking warfarin.

IV doses of 0.5 to 1 mg of vitamin K can correct overanticoagulation within 24 hours.¹¹⁶ This approach is also useful for reversal of therapeutic anticoagulation prior to invasive procedures and can be used to correct overanticoagulation in high-risk cases. IV vitamin K should be diluted and administered by slow infusion over 30 to 60 minutes to prevent flushing, hypotension, and cardiovascular collapse.¹¹⁷ Although these symptoms resemble anaphylaxis, the mechanism of this adverse response is unclear: it is not known if it is caused by phytonadione or by the vehicle in which phytonadione is

formulated. If this adverse reaction occurs, administration of epinephrine may be indicated, as well as other standard measures to support blood pressure and maintain the airway.

Rapid reversal of warfarin therapy is indicated in the setting of major, life-threatening bleeding. Fresh frozen plasma or factor concentrates to replace clotting factors will decrease the INR for 4 to 6 hours and should be administered as needed with careful monitoring of volume status. Supplementation with high-dose IV vitamin K (10 mg) may also be indicated. IV administration will reverse the effects of warfarin within

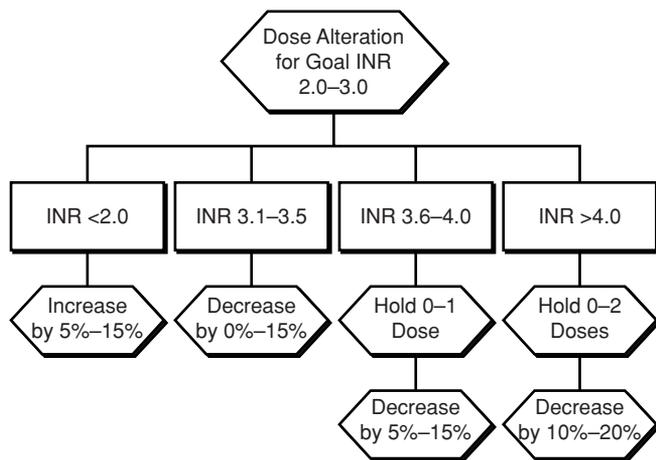

FIGURE 15-7 Warfarin maintenance dosing protocol for goal international normalized ratio (INR) 2.0–3.0.

6 to 12 hours. However, if continued warfarin therapy is indicated when bleeding resolves, anticoagulation with heparin may be necessary for as long as 7 to 14 days until the effect of high-dose vitamin K is diminished and warfarin responsiveness returns.

Hematuria may be an early sign of more serious bleeding, but in many cases this condition is associated with only minor bleeding episodes. In a reliable patient, discontinuing warfarin until the INR returns to a therapeutic level usually suffices. A more rapid return to normal can be accomplished if low-dose vitamin K is administered. Because E.M. appears to be bleeding only into the urine and is hemodynamically stable, withholding warfarin and administering a low dose of oral vitamin K (1–2.5 mg) is appropriate. A thorough workup to evaluate the source of bleeding is indicated.

USE IN PREGNANCY

31. E.S., a 30-year-old woman, has been taking warfarin for continuing therapy of a resolved PE. She has just learned she is pregnant. What effects might warfarin have on the fetus? Are UFH or LMWHs safer alternatives in this situation?

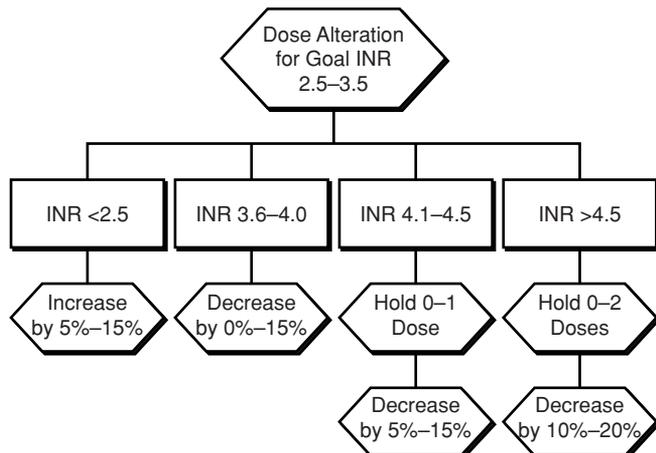

FIGURE 15-8 Warfarin maintenance dosing protocol for goal international normalized ratio (INR) 2.5–3.5.

Table 15-18 Frequency of International Normalized Ratio Monitoring and Patient Assessment During Warfarin Therapy

Initiation Therapy

| | |
|-----------------------------|--|
| Flexible initiation method | Daily through day 4, then within 3–5 days |
| Average daily dosing method | Within 3–5 days, then within 1 week |
| After hospital discharge | If stable, within 3–5 days; if unstable, within 1–3 days |
| First month of therapy | Every 1–4 days until therapeutic, then weekly |

Maintenance Therapy

| | |
|--|------------------|
| Dose held today | In 1–2 days |
| Dosage change today | Within 1–2 weeks |
| Dosage change <2 weeks ago | Within 2–4 weeks |
| Routine follow-up of medically stable and reliable patients | Every 4–6 weeks |
| Routine follow-up of medically unstable or unreliable patients | Every 1–2 weeks |

Coumarin anticoagulants cross the placental barrier and may place the fetus at risk for hemorrhage and teratogenic effects.¹¹⁸ Up to 30% of pregnancies that involve exposure to coumarin result in abnormal liveborn infants, and up to 30% in spontaneous abortion or stillbirth. Congenital abnormalities such as stippled calcifications and nasal cartilage hypoplasia primarily occurred in infants born to mothers receiving warfarin during the first trimester of pregnancy, with the highest risk during weeks 6 to 12. Other abnormalities, involving the central nervous system and eyes, are more likely to occur when the mother is taking warfarin later in the pregnancy. In addition, because warfarin crosses the placenta, fatal bleeding complications may occur.

Women of childbearing age who require anticoagulation should be counseled about options for contraception. Patients

Table 15-19 Guidelines for Reversal of an Elevated International Normalized Ratio (INR)

| INR | Recommendation |
|--------------------------------|---|
| <5 | Lower or hold dose. |
| 5–8.9 | Hold one or two doses, or hold dose and give vitamin K (<5 mg orally). If more rapid reversal is required, use 2–4 mg. Repeat vitamin K (1–2 mg orally) if INR is still elevated at 24 hr. |
| ≥9 | Hold warfarin and give vitamin K (5–10 mg orally). Use additional vitamin K, if necessary. |
| Serious bleeding with high INR | Hold warfarin and give vitamin K (10 mg slow IV infusion) supplemented with fresh frozen plasma, prothrombin complex concentrate, or recombinant factor VIIa. May repeat vitamin K every 12 hr, if necessary. |
| Life-threatening bleeding | Hold warfarin and give prothrombin complex concentrates or recombinant factor VIIa supplemented with vitamin K (10 mg slow IV infusion). Repeat as necessary. |

From reference 10.

Table 15-20 Recommendations for Anticoagulation During Pregnancy

| Clinical Situation | Peripartum Options | Postpartum |
|--|--|---|
| 1. Prophylaxis | | |
| Known hypercoagulable state with no prior history of VTE | <ul style="list-style-type: none"> • Surveillance • Minidose UFH • Prophylactic LMWH | Warfarin to INR 2–3 for 4–6 weeks with UFH/LMWH overlap until INR >2.0 |
| Single prior episode of VTE associated with transient risk factors, not receiving long-term anticoagulants | <ul style="list-style-type: none"> • Surveillance | Warfarin to INR 2–3 for 4–6 weeks with UFH/LMWH overlap until INR >2.0 |
| Single prior episode of idiopathic or thrombophilia-related VTE, not receiving long-term anticoagulants | <ul style="list-style-type: none"> • Surveillance • Minidose UFH • Moderate-dose UFH • Prophylactic LMWH | Warfarin to INR 2–3 for 4–6 weeks with UFH/LMWH overlap until INR >2.0 |
| Multiple prior episodes of VTE and/or receiving long-term oral anticoagulants for VTE | <ul style="list-style-type: none"> • Adjusted-dose UFH • Prophylactic LMWH • Full-dose LMWH | Long-term warfarin to INR 2–3 with UFH/LMWH overlap until INR >2.0 |
| Long-term oral anticoagulants for mechanical valve replacement | <ul style="list-style-type: none"> • Adjusted-dose UFH • Full-dose LMWH | Long-term warfarin to prior INR goal with UFH/LMWH overlap until INR above lower limit of therapeutic range |
| 2. Treatment of VTE that occurs during pregnancy | | |
| | <ul style="list-style-type: none"> • IV UFH for ≥5 days, followed by adjusted-dose UFH • Full-dose LMWH | Warfarin to INR 2–3 for a minimum of 6 weeks with UFH/LMWH overlap until INR >2.0 |

VTE, venous thromboembolic disease; UFH, unfractionated heparin; LMWH, low-molecular-weight heparin; INR, international normalized ratio.

Minidose UFH: 5,000 U SQ Q 12 hr. Moderate-dose UFH: adjusted to 0.1–0.3 U/mL anti-X_a activity. Adjusted-dose UFH: adjusted to maintain therapeutic aPTT at mid-dosing interval. Prophylactic LMWH: enoxaparin 40 mg SQ QD or dalteparin 5,000 U SQ QD. Full-dose LMWH: enoxaparin 1 mg/kg SQ Q 12 hr or dalteparin 200 IU/kg and adjusted throughout pregnancy to maintain 4-hour postinjection anti-X_a activity level of 0.5–1.2 U/mL (VTE) or approximately 1.0 U/mL (mechanical valves).

who become pregnant while receiving warfarin should be informed of the risks of continued anticoagulation to the fetus, as well as the risk to themselves of discontinuing anticoagulation.

Other options for pregnant women who require anticoagulation include UFH and LMWHs.¹¹⁸ Because these agents do not cross the placenta, they are preferred over warfarin for use in pregnancy. UFH is typically recommended because it has been used extensively during pregnancy. However, many clinical trials have validated the safety and efficacy of LMWHs in the prevention and treatment of DVT and PE during pregnancy.¹¹⁹ These agents represent an alternative to UFH, with advantages as previously described. When used at full doses for the treatment of VTE during pregnancy, dosing must be adjusted throughout the pregnancy to account for the expected increase in the body weight of the mother and the reported increase in clearance of LMWH during pregnancy.¹²⁰

In pregnant patients with mechanical heart valves, there is controversy regarding the use of LMWHs.¹²¹ Several cases of valvular thrombosis and of maternal and fetal death have been reported. These cases may be the result of underdosing of LMWH and UFH.¹¹⁸ Table 15-20 describes recommendations for anticoagulation during and after pregnancy for various conditions.

After being informed of the risks associated with warfarin, E.S. decided to continue her pregnancy and to begin anticoagulation with UFH. Warfarin therapy should be discontinued immediately and UFH initiated using SC treatment doses as previously described, or by continuous IV infusion. Dosing adjustments may be required throughout pregnancy as determined by aPTT monitoring. Potential adverse effects of UFH

use, including hemorrhage, thrombocytopenia, and osteoporosis, should be monitored appropriately.

SC heparin should be discontinued 24 hours before elective induction of labor and resumed as soon as bleeding from delivery has been controlled. IV heparin should be discontinued 6 hours before delivery. Warfarin therapy can then be safely reinitiated. If spontaneous labor occurs, protamine can be used to reverse the effect of UFH. Warfarin is not secreted in breast milk; therefore, E.S. can safely breast-feed.

PREVENTION OF CARDIOGENIC THROMBOEMBOLISM

Atrial Fibrillation

Anticoagulation Before Cardioversion

32. C.D., a 68-year-old woman with hypertension, presents to the cardiology clinic complaining of several days of fatigue and a “racing heart.” On physical examination, her pulse is irregularly irregular, and her heart rate is approximately 120 beats/minute. Using ECG, a diagnosis of atrial fibrillation is made and cardioversion planned. Should C.D. be anticoagulated before cardioversion?

In atrial fibrillation, compromised atrial activity and atrial enlargement causes stasis of blood within the atria and the left atrial appendage, often resulting in atrial thrombus formation. Atrial thrombus formation increases the risk of systemic embolization; clinical manifestations include arterial embolization of the extremities or embolization of the splenic, renal, or abdominal arteries. However, the most prevalent site of embolization is the cerebral arterial system, resulting in transient

ischemic attack or stroke with potentially devastating neurologic and functional impairment.¹²²

Both direct current cardioversion and pharmacologic cardioversion using antiarrhythmic drugs expose patients with atrial fibrillation to an initial short-term increase in stroke risk from embolization secondary to resumption of normal atrial mechanical activity (see Chapter 20). Data from a prospective cohort study of 437 patients noted a stroke incidence of 5.3% in patients with atrial fibrillation who were cardioverted without prior anticoagulation, but a significant reduction in stroke incidence to 0.8% was noted if patients who had received cardioversion were anticoagulated.¹²³ In addition to preventing the development of new atrial thrombi, anticoagulation allows any thrombus that may be present to endothelialize and adhere to the atrial wall so that the thromboembolic risk is minimized. Based on the assumed time course of thrombus development, as well as the presumed time course of clot endothelialization, patients who have been in atrial fibrillation for 48 hours should receive 3 weeks of therapeutic anticoagulation with warfarin to a target INR of 2.5 (range, 2.0–3.0) before cardioversion is attempted.¹²² Despite a lower risk of stroke than that associated with atrial fibrillation, patients with atrial flutter should be treated similarly.

Whether C.D. has been in atrial fibrillation for 48 hours is not known; therefore, she requires a 3-week course of therapeutic anticoagulation with a goal INR range of 2.0 to 3.0 before cardioversion is attempted. If C.D. cannot tolerate her heart symptoms despite control of the ventricular response rate, her medical team might consider immediate cardioversion without anticoagulation if transesophageal echocardiography (TEE) is used to rule out left atrial thrombi. TEE is much more sensitive than transthoracic echocardiography to visualize the left atrium and the left atrial appendage.

In a clinical trial, 1,222 patients with atrial fibrillation of more than 2 day's duration were randomly assigned to either treatment guided by TEE findings or to conventional precardioversion anticoagulation.¹²⁴ Patients assigned to conventional treatment and patients in the TEE group in whom thrombus was detected received a 3-week course of warfarin prior to cardioversion. Patients without detectable thrombus by TEE were cardioverted without precardioversion anticoagulation. All patients received 4 weeks of postcardioversion anticoagulation. Thromboembolic rates were identical between patients who received conventional treatment and those whose treatment was guided by TEE (0.5% vs. 0.8%, $p = 0.5$).

Anticoagulation After Cardioversion

33. After 3 weeks of regular-intensity warfarin therapy, C.D. is successfully cardioverted. Should warfarin be discontinued?

Despite normalization of atrial electrical activity, restoration of effective atrial mechanical activity after cardioversion of atrial fibrillation can be delayed for up to 3 weeks. In addition, a significant number of patients with atrial fibrillation who initially are successfully cardioverted revert to atrial fibrillation during the first month. Both of these factors contribute to the recognized delay in stroke presentation after cardioversion in patients with atrial fibrillation. For these reasons, anticoagulation with warfarin should be continued after cardioversion for a minimum 4 weeks.

Anticoagulation for Paroxysmal, Permanent, or Persistent Atrial Fibrillation

34. Two weeks after successful cardioversion, C.D. presents to the ED with chest palpitations and light-headedness. An ECG is evaluated, and atrial fibrillation is diagnosed again. What decisions regarding anticoagulation need to be made?

ANTICOAGULATION IN VALVULAR ATRIAL FIBRILLATION

Atrial fibrillation secondary to valvular heart disease has historically been recognized as a significant risk factor for stroke. Patients with atrial fibrillation who have a history of rheumatic mitral valve disease have a 17-fold higher incidence of stroke than in matched controls. Patients with valvular atrial fibrillation require long-term, regular-intensity anticoagulation to a target INR of 2.5 (range, 2.0–3.0) to prevent thromboembolism and stroke.^{122,125}

ANTICOAGULATION IN NONVALVULAR ATRIAL FIBRILLATION

Nonvalvular heart disease is the most common cause of atrial fibrillation and, like valvular heart disease, represents a significant risk for stroke in patients with atrial fibrillation. Five clinical trials have substantiated the role of warfarin in the primary prevention of systemic embolization and stroke in chronic, nonvalvular atrial fibrillation.¹²⁶ All five trials compared warfarin with a placebo and were terminated before completion because of the substantial benefit of warfarin. In comparison with a placebo, warfarin significantly reduced the risk of stroke from approximately 5% per year to approximately 2% per year, with an average relative risk reduction of 67%. Based on the results of these trials, long-term anticoagulation with warfarin to a goal INR of 2.5 (range, 2.0–3.0) is recommended in patients like C.D., who have atrial fibrillation secondary to nonvalvular heart disease.^{122,125}

Several clinical trials have attempted to define the comparative efficacy of warfarin versus aspirin in the prevention of stroke associated with atrial fibrillation.¹²⁷ Compared with a placebo or control, aspirin decreases the risk of stroke in patients with atrial fibrillation. However, that reduction is not as substantial as the reduction seen with warfarin. In clinical trials comparing warfarin and aspirin, the risk reduction associated with warfarin is significantly larger than that of aspirin. However, aspirin may be appropriate in certain patients at low risk for stroke associated with atrial fibrillation (Table 15-6).

The decision to continue long-term anticoagulation with warfarin in C.D. should be based on an evaluation of the likelihood that her atrial fibrillation will become chronic with a paroxysmal, persistent, or permanent presentation, as well as an assessment of her risk of stroke compared with her risk of warfarin-associated bleeding complications. Because of her age and history of hypertension, the appropriate strategy should be long-term warfarin therapy with a goal INR of 2.5 (range, 2.0–3.0).

Cardiac Valve Replacement

Mechanical Prosthetic Valves

35. D.L., a 56-year-old woman with a history of rheumatic mitral valve disease, has undergone mitral valve replacement. A St. Jude (bileaflet mechanical) valve has been implanted, and heparin

therapy is initiated postoperatively. Does D.L. require continued anticoagulation with warfarin?

Mechanical prosthetic valves confer a significant thromboembolic risk by providing a foreign surface in contact with blood components on which platelet aggregation and thrombus formation can occur. Valvular thrombosis can impair the integrity of valve function and can lead to embolization with systemic manifestations, including stroke.¹²⁸ The incidence of thromboembolic complications depends on the type of artificial valve (caged ball [Starr-Edwards] > tilting disk [Medtronic-Hall; Bjork-Shiley] > bileaflet [St. Jude]), as well as the anatomical position of the replacement (dual valve replacement > mitral > aortic).¹²⁹

Long-term anticoagulation is required in patients with mechanical valve replacement because it significantly reduces the risk of stroke and other manifestations of systemic embolization. Trials comparing different intensities of oral anticoagulation with warfarin in mechanical valve replacement helped identify the intensity of anticoagulation that protects against thromboembolic risk, while reducing the incidence of hemorrhagic complications.^{129,130} Patients with a St. Jude bileaflet valve in the aortic position should receive long-term anticoagulant therapy with warfarin to a target INR of 2.5 (range, 2.0–3.0).^{128,131} For all other mechanical valve types in the aortic position, and for any mechanical mitral valve replacement, chronic warfarin therapy with a target INR of 3.0 (range, 2.5–3.5) is recommended.^{128,131} The concurrent use of low-dose aspirin (81 mg daily) is recommended for patients with additional risk factors for systemic embolization (atrial fibrillation, left ventricular dysfunction, a history of prior systemic embolism, or a hypercoagulable condition), unless the patient has a significant risk for bleeding or a history of aspirin intolerance.

Bioprosthetic Valves

36. E.K., an 86-year-old woman with a history of symptomatic aortic stenosis, has received a bioprosthetic (mammalian) aortic valve replacement. Is anticoagulant therapy required in E.K.?

Prosthetic heart valves extracted from mammalian sources (porcine or bovine xenografts; homografts) are significantly less thrombogenic than mechanical prosthetic valves. The period of greatest thromboembolic risk appears to be during the first 3 months after implantation. Therefore, short-term, regular-intensity, preventive anticoagulation to an INR of 2.5 (range, 2.0–3.0) is recommended.^{128,131} After this period, long-term aspirin therapy (minimum dose, 162 mg/day) is indicated. However, oral anticoagulation should be continued long term in patients with concurrent atrial fibrillation, a history of systemic embolism, or evidence of atrial thrombus at surgery.

BRIDGE THERAPY

Management of Anticoagulation Around Invasive Procedures

37. C.G. is a 43-year-old woman with a history of valvular heart disease associated with Marfan syndrome. She has a St. Jude mitral valve replacement and is anticoagulated with warfarin 7.5 mg once daily to a goal INR range of 2.5 to 3.5. Recently, she has

complained of episodic rectal bleeding despite adequate anticoagulation. She is scheduled for colonoscopy in several weeks. Her gastroenterologist calls you at the anticoagulation clinic to determine the most appropriate plan for reversal of her warfarin prior to the procedure. What are the options?

When an invasive procedure is planned, it is often necessary to reverse the effects of warfarin to minimize the risk of bleeding complications associated with the procedure, which can be worsened by the presence of an anticoagulant. It can take several days for the anticoagulant effect of warfarin to be reversed after discontinuation of the drug, but in that period of time, a patient may be at risk for thromboembolic complications associated with underanticoagulation. *Bridge therapy* is the term that refers to the use of a relatively short-acting injectable anticoagulant (UFH, LMWH) as a substitute for warfarin prior to and immediately following an invasive procedure.¹³² Because UFH and LMWH have shorter elimination half-lives than warfarin, they can be stopped just prior to the invasive procedure without increasing the risk of bleeding associated with the procedure. In addition, because of their shorter onset of effect, they can be used when warfarin is restarted and until the INR reaches the therapeutic range.

Although bridge therapy has not been studied in randomized clinical trials, there are multiple options, many of which have been evaluated in case series, observational studies, and nonrandomized trials involving patients with various indications for anticoagulation, including valve replacement.^{133–135} The choice of a bridge therapy strategy depends on the risk of bleeding associated with continued anticoagulation for the surgery or procedure to be performed and on the risk of thromboembolism associated with underanticoagulation in the patient in question. Individualized risk assessment and bridge therapy planning are necessary for each patient who may require temporary discontinuation of warfarin.

Because the use of IV UFH for bridge therapy requires hospitalization, there has been considerable interest in using LMWH on an outpatient basis for this purpose. Clinical outcomes in patients bridged with LMWH or UFH are similar, and overall costs are lower for LMWH because of the avoidance of hospital admission, despite higher drug costs.¹³⁶ UFH, however, may be appropriate in patients with significant renal impairment, or in patients without third-party prescription coverage who cannot afford the drug cost of LMWH. A guideline for bridge therapy based on the risk of thromboembolism and on renal function is presented in Table 15-21.

Because C.G. has a mechanical mitral valve replacement, her risk of thromboembolism associated with underanticoagulation is considered high. Therefore, warfarin should not simply be withheld; instead, she should receive bridge therapy with an injectable anticoagulant. Her renal function is normal, and her health care insurance covers injectable drugs. Therefore, her plan will include early discontinuation of warfarin 3 to 5 days prior to the procedure, and substitution with enoxaparin 1 mg/kg Q 12 hr when the INR falls below the lower limit of the therapeutic range. The last dose of enoxaparin should be given no later than 24 hours prior to the procedure to minimize the risk of bleeding at the time of the procedure. After the procedure, warfarin should be restarted at her usual dose, and enoxaparin should be continued until the INR is >2.5.

Table 15-21 Bridge Therapy Guidelines for Invasive Procedures

| Thrombotic Risk | Renal Function | Bridge Therapy |
|---|----------------|--|
| HIGH <ul style="list-style-type: none"> • Afib with moderate/high stroke risk per CHAD2 score, or with concurrent valve replacement or mitral stenosis • Hx stroke/TIA • Any hypercoagulable state • Mechanical valve • hx DVT/PE <3 months ago | CLcr >30 | <ul style="list-style-type: none"> • Hold warfarin for 3–5 days preprocedure (decision predicated on age, dosing requirement, and other comorbid conditions associated with prolonged time for reversal) OR hold warfarin 2–3 days preprocedure and administer vitamin K 2.5 mg PO 2 days preprocedure (may repeat on day 1) • Initiate UFH SQ/IV or LMWH when INR falls below lower limit of therapeutic range • Stop IV UFH 6 hr preprocedure or stop SQ UFH/LMWH 24 hr preprocedure • Resume UFH/LMWH 12–24 hr postprocedure (decision predicated on postop assessment of bleeding risk) and continue until INR above lower limit of therapeutic range • Resume warfarin 12–24 hr postprocedure at usual maintenance dose (decision predicated on postprocedure assessment of bleeding risk) |
| | CLcr <30 | <ul style="list-style-type: none"> • Last dose of warfarin on day 3 preprocedure • Vitamin K 2.5 mg PO on day 2 preprocedure • Admit on day 1 preprocedure and begin IV UFH (70 U/kg bolus, 15 U/kg/hr infusion and adjust per inpatient protocol) • If INR above 1.5 on day 1, give vitamin K 1 mg IV • Stop IV UFH 6 hr preprocedure • Resume UFH 12–24 hr postprocedure (decision predicated on postprocedure assessment of bleeding risk) and continue until INR above lower limit of therapeutic range • Resume warfarin 12–48 hr postprocedure at usual maintenance dose (decision predicated on postop assessment of bleeding risk) |
| LOW <ul style="list-style-type: none"> • Afib with low/moderate stroke risk per CHADS2 score • Dilated cardiomyopathy with no hx thrombosis • hx DVT/PE >3 months ago | All patients | <ul style="list-style-type: none"> • Hold warfarin for 3–5 days preprocedure OR hold warfarin for 2–3 days preprocedure and administer vitamin K 2.5 mg PO 2 days preprocedure (may repeat on day 1) • Resume warfarin 12–48 hr postprocedure at usual maintenance dose (decision predicated on postop assessment of bleeding risk) |

Management of Anticoagulation Around Dental Procedures

38. J.Y. is a 76-year-old man with a history of hypertension, hypercholesterolemia, adult-onset diabetes, and atrial fibrillation. He receives warfarin 2.5 mg on Monday, Wednesday, and Friday and 5 mg on all other days for stroke prevention. He is scheduled to have a tooth removed, and his dentist has recommended that warfarin be withheld for 5 days prior to the procedure. He calls his anticoagulation provider for advice. What is your response?

Based on his medical history, A.V. is considered at moderate to high risk for stroke. If his warfarin were to be discontinued for 5 days prior to this dental procedure, he would require bridge therapy with inpatient UFH or outpatient LMWH prior to the procedure, and afterward until his INR reached 2.0. However, for many dental procedures, it is often not necessary to withhold warfarin.¹³⁷ Oral bleeding can be prevented or controlled using a combination of local measures, including cold water rinse, local pressure (biting on gauze or tea bags [which release tannins, causing local vasoconstriction]), additional suturing, or electrocautery. Other options include packing the site with gelatin sponges (Gelfoam) or absorbable oxycellulose (Surgicel), or applying microcrystalline collagen (Avitene), topical thrombin, or a fibrin adhesive.

A mouth rinse of 5% tranexamic acid or 5% aminocaproic acid can also be used to control oral bleeding.¹³⁸ Patients are instructed to hold 10 mL of the rinse in their mouths for 2 minutes, 30 minutes prior to the procedure, and then to repeat

every 2 hours as needed afterward until bleeding is resolved. Table 15-22 describes guidelines for the management of warfarin around dental procedures based on the bleeding risk of the procedure.

The simple extraction planned for A.V. does not require discontinuation of his warfarin therapy. The anticoagulation clinic provider should call the dentist to offer suggestions regarding local prevention and control of oral bleeding. A.V. should be cautioned to avoid hot liquid, vigorous mouthwashes, hard foods, and NSAIDs and other antiplatelet agents during the first 24 to 48 hours after his tooth extraction.

DRUG INTERACTIONS

Interactions With Legend Drugs

39. D.G., a 72-year-old man, received a Bjork-Shiley tilting disk mitral valve prosthesis 5 years ago. He has been anticoagulated with warfarin 6 mg/day with good control. He is allergic to ampicillin and has gastric intolerance to tetracycline. Yesterday, he was seen in an acute-care clinic with symptoms of an acute prostatic infection and prescribed one double-strength tablet of trimethoprim-sulfamethoxazole (TMP-SMX) BID for 10 days. How will the combination of warfarin and TMP-SMX (Bactrim, Septra) affect D.G.'s anticoagulation control? Should his warfarin dosage be adjusted or another drug substituted for TMP-SMX?

Drug interactions with warfarin occur by a number of different mechanisms and can have a significant impact

Table 15-22 Suggestions for Anticoagulation Management Before and After Dental Procedures^a

| | Low Bleeding Risk | Moderate Bleeding Risk | High Bleeding Risk |
|--------------------|---|---|---|
| Procedure | <ul style="list-style-type: none"> • Supragingival scaling • Simple restorations • Local anesthetic injections | <ul style="list-style-type: none"> • Subgingival scaling • Restorations with subgingival preparations • Standard root canal therapy • Simple extractions • Regional injection of local anesthetics | <ul style="list-style-type: none"> • Extensive surgery • Apicoectomy (root removal) • Alveolar surgery (bone removal) • Multiple extractions |
| Suggestions | <ul style="list-style-type: none"> • Do not interrupt warfarin treatment • Use local measures to prevent/control bleeding | <ul style="list-style-type: none"> • Interruption of warfarin treatment is not necessary • Use local measures to prevent or control bleeding <p><i>Consult with dentist to determine comfort with use of local measures to prevent bleeding when anticoagulation is not interrupted</i></p> | <ul style="list-style-type: none"> • May need to reduce international normalized ratio or return to normal hemostasis • Follow bridge therapy guidelines for invasive procedures based on risk of thromboembolism |

^aUniversity of Washington Medical Center Anticoagulation Clinics.

on the anticoagulant effect of warfarin.^{139–141} Elevations or reductions in INR have been observed when interacting drugs are added to or discontinued from the medication regimens of patients taking warfarin or when used intermittently. Clinically significant hemorrhagic or thromboembolic complications can result. Careful selection of both prescription and nonprescription medications, appropriate INR monitoring, and detailed patient education regarding drug interactions are important interventions for pharmacists caring for patients taking warfarin. A summary of drugs that interact with warfarin, including mechanisms of interaction and effect on INR, is provided in Table 15-23.

Although warfarin is highly bound to protein, primarily to albumin, and can be displaced from protein-binding sites by a number of weakly acidic drugs, these interactions typically do not result in clinically significant elevations in PT/INR.¹⁴² Warfarin displaced from protein-binding sites is readily available for elimination by hepatic metabolism, resulting in increased clearance without a significant change in the free drug concentration.

Other types of interactions with warfarin are much more significant. Pharmacodynamic interactions are those that alter the physiology of hemostasis, particularly interactions that influence the synthesis or degradation of clotting factors or that increase the risk of bleeding through inhibition of platelet aggregation. Pharmacokinetic interactions influence the absorption and metabolism of warfarin, and many clinically significant interactions with warfarin occur when warfarin metabolism is induced or inhibited. Interactions involving agents known to influence the hepatic microsomal enzyme systems responsible for the metabolism of the more potent S(–)-warfarin (CYP2C9) are potentially more significant than those that influence the enzymes that metabolize R(+)-warfarin (CYP1A2, CYP3A4).¹⁴¹

Sulfamethoxazole can increase the effect of warfarin significantly by stereoselectively inhibiting the metabolism of the more potent S(–)-enantiomer of warfarin.¹³⁹ Potentiation of warfarin activity after inhibition of metabolism usually takes several days, and the effect may be slow to resolve once the offending agent is discontinued. In addition, fever associated with the infection for which TMP-SMX has been prescribed may enhance the catabolism of vitamin K–dependent clotting factors, resulting in an accentuated hypoprothrombinemic response. This effect will dissipate as the fever abates with antibiotic therapy.

For D.G., the best choice would be to discontinue TMP-SMX. Because ampicillin and tetracycline are contraindicated, either a first-generation cephalosporin or TMP alone may be used. Oral quinolones should be avoided because they also carry the risk of potentiating the anticoagulant effect of warfarin. Careful monitoring of the INR should continue because the introduction of any changes in treatment, as well as the acute illness, may alter the patient's response to warfarin therapy.

If noninteracting alternatives are not clinically appropriate, the concomitant use of interacting agents is not an absolute contraindication in patients taking warfarin. TMP-SMX can be prescribed if D.G. is monitored frequently and carefully, with adjustment of warfarin dosages as necessary to maintain his INR within the therapeutic INR range of 2.5 to 3.5 and with attention to potential hemorrhagic complications. No initial change in the dosage of warfarin should be made because it may take several days for the interaction to become apparent. The INR should be repeated within 3 days, with warfarin dosing adjustments and subsequent monitoring guided by initial INR results.

40. D.R. is a 39-year-old woman recovering from unexplained ventricular fibrillation several weeks ago with significant, but improving, neurologic deficits. A defibrillator system has been implanted, with amiodarone 400 mg/day added for suppressive antiarrhythmic therapy. As a result of being immobile during her hospitalization, she developed a DVT and has been receiving heparin for 5 days. A full 3-month course of anticoagulation is indicated. How will amiodarone influence D.R.'s anticoagulation?

Amiodarone appears to inhibit the hepatic metabolism of warfarin, resulting in significant increases in the INR in patients previously stabilized on warfarin therapy and in whom amiodarone is added.¹⁴³ Elevations in INR typically occur within 1 week and stabilize after approximately 1 month of combination therapy. These patients require frequent monitoring with downward adjustments in warfarin dose by as much as 50% or more.

In the case of D.R., warfarin is to be added to pre-existing amiodarone therapy. The use of a drug known to interact with warfarin is not an absolute contraindication to the addition of warfarin. Warfarin therapy should begin using a flexible initiation protocol or average daily dosing method, but with the expectation that D.R.'s INR will likely increase at a rate

Table 15-23 Drug Interactions

| <i>Mechanism</i> | <i>Effect on International Normalized Ratio</i> | <i>Drugs/Drug Classes</i> | |
|---|---|--------------------------------|-----------------------------------|
| Increased synthesis of clotting factors | Decreased | Vitamin K | |
| Reduced catabolism of clotting factors | Decreased | Methimazole | Propylthiouracil |
| Induction of warfarin metabolism | Decreased | Alcohol(chronic use) | Fosphenytoin ^a |
| | | Aminoglutethimide | Glutethimide |
| | | Barbiturates | Griseofulvin |
| | | Bosentan | Nafcillin |
| | | Carbamazepine | Phenytoin ^a |
| | | Dicloxacillin | Primidone |
| | | Ethchlorvynol | Rifampin |
| Reduced absorption of warfarin | Decreased | Cholestyramine | Sucralfate |
| | | Colestipol | |
| Unexplained mechanisms | Decreased | Ascorbic acid | Corticosteroids |
| | | Azathioprine | Cyclosporin Mercapto purine |
| Increased catabolism of clotting factors | Increased | Thyroid hormones | |
| Protein binding displacement | Increased | Chloral hydrate | |
| Decreased synthesis of clotting factors | Increased | Cefamandole | Cefoperazone |
| | | Cefotetan | Moxalactam |
| | | Cefmetazole | Vitamin E |
| Impaired vitamin K production by GI flora | Increased | Broad-spectrum antibiotics | |
| Inhibition of warfarin metabolism | Increased | Acetaminophen | Isoniazid |
| | | Alcohol (acute use) | Macrolide antibiotics |
| | | Allopurinol | Metronidazole |
| | | Amiodarone | Omeprazole |
| | | Azole antifungals | Phenytoin ^a |
| | | Capecitabine | Propafenone |
| | | Celecoxib | Quinidine |
| | | Chloramphenicol | Rofecoxib |
| | | Cimetidine | SSRIs |
| | | Disulfiram | Statins |
| | | Fluoroquinolone antibiotics | Sulfa antibiotics |
| | | Fluorouracil | Zafirlukast |
| | | Fosphenytoin ^a | |
| Additive anticoagulant response | Increased | Direct thrombin inhibitors | Low molecular weight heparins |
| | | Heparin | Thrombolytic agents |
| Unexplained mechanism | | Androgens | Gemcitabine |
| | | Clofibrate | Gemfibrozil |
| | | Cyclophosphamide | Influenza virus vaccine |
| | | Fenofibrate | Mesalamine |
| Increased bleeding risk | No effect | Aspirin/acetylated salicylates | Cyclo-oxygenase 2 inhibitors |
| | | Clopidogrel/ticlopidine | Glycoprotein IIb/IIIa antagonists |
| | | | NSAIDS |

^aReported to both increase and decrease PT/INR.

faster than if she were not taking amiodarone and that her maintenance dosing likely will be significantly lower than if she were not taking amiodarone concurrently. Frequent monitoring will be required for D.R. to establish a maintenance dose because she may not yet have a steady-state amiodarone level.

If amiodarone therapy is discontinued while D.R. is anticoagulated, frequent monitoring will also be necessary. However, the effect of amiodarone on warfarin metabolism can

continue for several months after amiodarone is discontinued because of amiodarone's long elimination half-life and large volume of distribution. Gradual increases in warfarin dosing requirements over weeks to months have been observed after discontinuation of amiodarone.

41. M.G., a 67-year-old woman, was recently diagnosed with bursitis of the right shoulder. A course of anti-inflammatory medication is recommended by her doctor. M.G. is taking warfarin

12.5 mg/day for a history of chronic atrial fibrillation. What could be prescribed for M.G.'s shoulder pain that would not significantly interact with the warfarin she is taking?

This question illustrates one of the most difficult therapeutic dilemmas for a patient taking warfarin. All NSAIDs have the potential to cause gastric irritation by inhibiting cytoprotective prostaglandins, thereby providing a focus for GI bleeding. In addition, most NSAIDs inhibit platelet aggregation, which compromises effective clotting and can lead to bleeding complications.¹⁴⁴ Some NSAIDs (phenylbutazone, sulfipyrazone, mefenamic acid) may also have specific pharmacokinetic interactions with warfarin that can increase the hypoprothrombinemic effect of warfarin.

These effects can increase the risk of hemorrhagic complications significantly in patients taking warfarin who are prescribed concurrent NSAID therapy. In a retrospective cohort study of patients age 65 years or older, the risk of hospitalization for bleeding peptic ulcer disease was approximately three times higher for patients taking concurrent warfarin and an NSAID versus patients taking either drug alone, and almost 13 times higher than in patients taking neither warfarin nor an NSAID.¹⁴⁵ Warfarin therapy is considered a relative contraindication to NSAID use.

In patients like M.G. who require combination therapy, clinical experience suggests that ibuprofen (Motrin), naproxen (Naprosyn), or nabumetone (Relafen) are somewhat better tolerated than other NSAIDs with respect to additive hemorrhagic complications, particularly for short-term use. Alternative agents include the nonacetylated salicylates such as salsalate or choline salicylate. These agents have minimal effect on platelet aggregation compared with other salicylates. However, all patients requiring combined warfarin and NSAID therapy should be followed closely and observed routinely for signs and symptoms of bleeding, with frequent stool testing for GI bleeding. Patients should be counseled to avoid additional NSAID use, including use of aspirin, and to seek assistance from a pharmacist to prevent inadvertent NSAID use when selecting over-the-counter medications.

The analgesic and antipyretic of choice in patients taking warfarin is acetaminophen, which has not been consistently shown to increase the risk of bleeding. However, in a controversial case-control study of patients taking warfarin, acetaminophen use of >2,275 mg/week was an independent risk factor for developing an INR >6.0.¹⁴⁶ Controls were matched for age, gender, and race, but patients had a higher frequency of febrile illness and reduced oral intake, factors that may influence the INR independently as well as account for acetaminophen use. Acetaminophen may increase the INR by inhibition of CYP1A2 metabolism of R(+)-warfarin, but this effect has not been reported consistently.¹⁴⁷ Appropriate monitoring and assessment of patients taking concurrent warfarin and acetaminophen, either routinely or as needed, is sufficient to detect any potential interaction.

Interactions With Natural Products/Dietary Supplements

42. K.P. is a 32-year-old woman who developed a left lower extremity DVT after sustaining a skiing injury 1 month ago. She

has been taking warfarin 5 mg on Monday, Wednesday, and Friday and 7.5 mg on all other days of the week. She has maintained stable INRs between 2.0 and 3.0 for the last 2 weeks. She has no known medical problems and takes no other medications. However, she has felt increasingly lethargic since her accident and feels that she cannot participate fully in physical therapy because of fatigue. She is interested in taking an herbal supplement to increase her level of energy. How should she be counseled?

Dietary supplements, including herbal medicinals, amino acids, and other nonprescription products, are not tested before marketing for interactions with other medications, including warfarin.⁹⁷ Little is known about their interactive properties, other than published case reports of varying quality. In addition, dietary supplements are not required to meet *United States Pharmacopeia* standards for tablet content uniformity. Therefore, the actual ingredients and quantity of ingredients of a given product may change from batch to batch, and different products produced by different manufacturers may also differ substantially. These limitations influence the availability and reliability of information regarding potential interactions between warfarin and dietary supplements.

Table 15-24 lists dietary supplements reported to influence INR or suspected to interact with warfarin based on known or implied properties.¹⁴¹ Because of limited information regarding the full extent of possible interactions with dietary supplements, including herbal medicinals, it is appropriate to counsel patients taking warfarin to avoid use of these products. However, a large percentage of patients may not report their use of dietary supplements to health care providers. Ongoing, detailed evaluation of all current medications including dietary supplements is necessary to prevent potential adverse effects

Table 15-24 Drug Interactions with Dietary Supplements

| Mechanism | Effect | Supplement |
|------------------------------------|--------------------|---|
| Inhibition of warfarin metabolism | Increased INR | Chinese wolf berry Cranberry juice Grapefruit juice |
| Contain coumarin derivatives | Increased INR | Dan shen Dong quai Fenugreek |
| Unknown | Increased INR | Curbicin Devil's claw Glucosamine-chondroitin Melatonin Papaya extract Quilnggao |
| Inhibition of platelet aggregation | Increased bleeding | Garlic Ginger Ginkgo |
| Contain vitamin K/derivatives | Decreased INR | Coenzyme q10 Green tea Some multivitamins |
| Induction of CYP3A4 | Decreased INR | St. John's wort |
| Unknown | Decreased INR | Ginseng Melatonin |

associated with interactions between warfarin and dietary supplements.

DISSEMINATED INTRAVASCULAR COAGULATION

Pathophysiology

43. W.K., a 63-year-old woman, was admitted to the intensive care unit with respiratory failure secondary to acute PE. She required ventilatory support until 48 hours ago, when she was extubated. At that time, aspiration was suspected, but no antibiotic coverage was prescribed. Within the last 24 hours, W.K. developed tachycardia (heart rate, 120 beats/minute), tachypnea (respiratory rate, 30 breaths/minute), and a fever to 39°C. Sepsis was suspected, broad-spectrum antibiotic coverage was started, and W.K. was reintubated. Because of the sudden appearance of bright red blood per rectum and through her nasogastric tube, a coagulation screen was ordered. Until this time, all coagulation parameters had been within normal limits. Now the results show platelets, 43,000/mm³ (normal, 150,000–350,000); PT, 24 seconds (mean normal, 12); aPTT, 76 seconds (mean normal, 34); thrombin time, 48 seconds (normal, 16–27); fibrinogen, 60 mg/dL (normal, 150–400); and fibrin degradation products, 580 ng/mL (normal, <250). The diagnosis of disseminated intravascular coagulation (DIC) is made. How does the pathophysiology of DIC explain these hematologic abnormalities?

[SI units: platelets, $43 \times 10^9/L$ (normal, 150–300), and fibrinogen, 0.6 g/L (normal, 1.5–4)]

Thrombosis in response to endothelial damage or the presence of an altered surface in contact with blood components is a localized phenomenon. Thrombus formation occurs at the site of injury or abnormality, where procoagulant and anticoagulant mechanisms, as well as fibrinolytic and antifibrinolytic mechanisms, are regulated. The term *localized extravascular coagulation* describes the site-specific nature of venous and arterial thrombosis.

In contrast, DIC is a diffuse response to systemic activation of the coagulation system (Fig. 15-9).¹⁴⁸ Circulating thrombin converts fibrinogen to fibrin, resulting in fibrin deposition within the microcirculation. Clinical manifestations of microvascular thrombosis are the result of tissue ischemia resulting from thrombotic occlusion of small and midsize vessels.

The presence of systemic circulating thrombin causes simultaneous systemic activation of the fibrinolytic system, resulting in circulating plasmin within the systemic circulation. Plasmin causes systemic lysis of fibrin to fibrin degradation products and results in hemorrhagic complications.

Bleeding manifestations of DIC occur not only as a result of systemic fibrinolysis, but also secondary to thrombocytopenia, clotting factor deficiency, and platelet dysfunction. Circulating thrombin promotes platelet aggregation, resulting in thrombocytopenia as platelet aggregates deposit in the microcirculation. Circulating plasmin degrades clotting factors as well as fibrin, and the presence of fibrinogen degradation products from fibrinolysis inhibits platelet function. Normal mechanisms of platelet and clotting factor synthesis are unable to compensate for this consumption. In essence, the patient shows paradoxical bleeding secondary to overactivation and eventual consumption of available clotting factors and platelets.

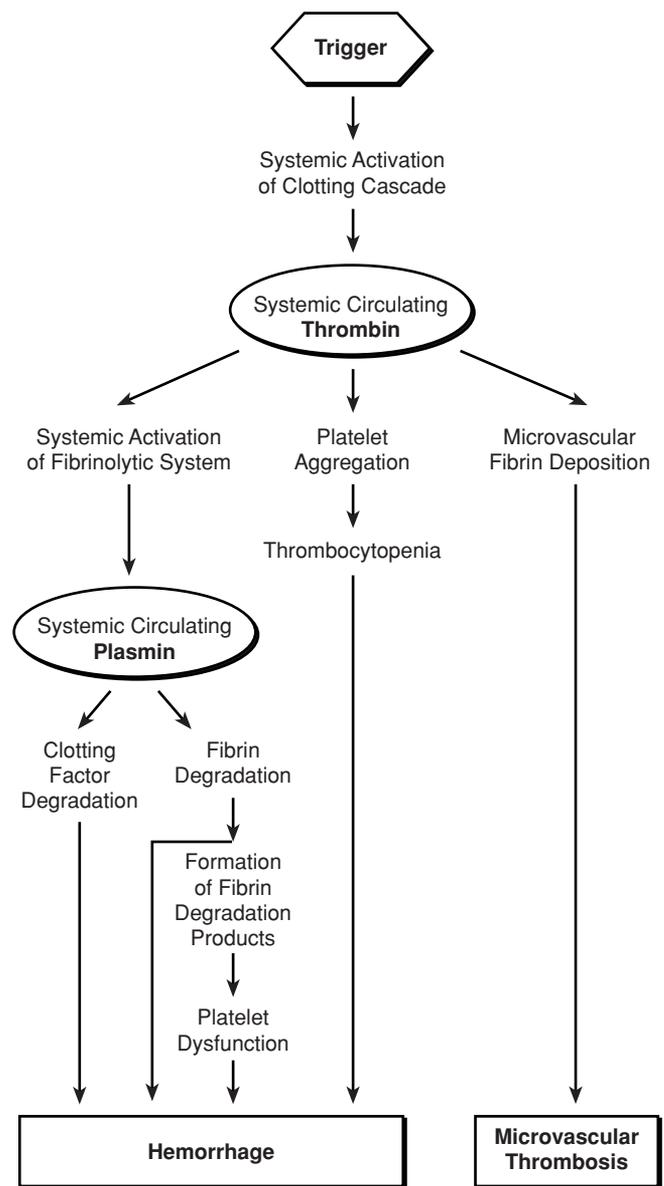

FIGURE 15-9 Pathophysiology of disseminated intravascular coagulation.

Clinical Presentation

44. What subjective and objective evidence in W.K. is consistent with the diagnosis of acute DIC?

Laboratory Findings

Many coagulation laboratory abnormalities occur in DIC.¹⁴⁹ The PT/INR, aPTT, and thrombin time are increased because clotting factors, as well as antithrombin and proteins C and S, are consumed more quickly than they can be replenished by hepatic synthesis. Platelet count is diminished secondary to thrombin-mediated platelet aggregation. Fibrinogen is reduced as a result of plasmin-mediated fibrinolysis, with an elevation in fibrinogen degradation products including D-dimer, indicative of a fibrinolytic state. A peripheral smear will often show thrombocytopenia and red blood cells fragmented by exposure to microcirculatory fibrin (schistocytes).

Table 15-25 International Society on Thrombosis and Haemostasis Disseminated Intravascular Coagulation (DIC) Scoring System

Does the patient have an underlying disorder known to be associated with DIC? (if YES, continue with scoring)

| Laboratory Test | Result | Point Score |
|------------------------|-------------------|---|
| Platelet count | >100,000 | 0 |
| | <100,000 | 1 |
| | <50,000 | 2 |
| Fibrin-related markers | No increase | 0 |
| | Moderate increase | 2 |
| | Strong increase | 3 |
| PT (vs. baseline) | <3 seconds | 0 |
| | 3–6 seconds | 1 |
| | >6 seconds | 2 |
| Fibrinogen | >1 g/L | 0 |
| | <1 g/L | 1 |
| TOTAL SCORE | ≥5 | Compatible with over DIC (repeat daily) |
| | <5 | Suggestive but nonaffirmative for nonovert DIC (repeat in 1–2 days) |

PT, prothrombin time.
From reference 150.

The International Society of Thrombosis and Haemostasis Overt DIC Scoring System, based on laboratory values observed in patients suspected of having DIC, is used in the diagnosis of DIC (Table 15-25).¹⁵⁰ There is a strong correlation between increasing DIC score and 28-day mortality.¹⁵¹

Hemorrhagic Manifestations

As illustrated by W.K., hemorrhagic manifestations are the predominant clinical finding in DIC.¹⁴⁸ Bleeding can occur at sites of injury, including surgical incisions, venipuncture sites, nasogastric tubes, or gastric ulcers. However, spontaneous bleeding also occurs from intact sites or organ systems. Spontaneous ecchymosis, petechiae, epistaxis, hemoptysis, hematuria, and GI bleeding are commonly encountered. Intracranial, intraperitoneal, and pericardial bleeding may also occur.

Thrombotic Manifestations

Thrombotic manifestations of DIC result in the obstruction of blood flow to multiple organ systems. The resultant ischemic damage to end organs, including the skin, kidneys, brain, lungs, liver, eyes, and GI tract, can result in multisystem failure. Despite the severity of hemorrhagic complications, microvascular thrombosis represents a significant cause of morbidity and mortality in patients with acute DIC.

Precipitating Events

45. What events may have precipitated the development of DIC in W.K.?

DIC is a pathological syndrome triggered by disease states or conditions that activate coagulation systemically rather than locally.¹⁴⁹ The presence of thrombin within the systemic circulation can be triggered by systemic endothelial damage (e.g.,

Table 15-26 Clinical Conditions Associated With Disseminated Intravascular Coagulation

| | |
|---------------------------------|-------------------------------------|
| Infectious Diseases | Obstetric States |
| Aspergillosis | Amniotic fluid embolism |
| Bacterial infections | Eclampsia |
| Candidiasis | Retained dead fetus |
| Cytomegalovirus | Septic or saline abortion |
| Fungal infections | Tissue Injury |
| Gram-negative sepsis | Burns |
| Gram-positive sepsis | Crush injuries |
| Hepatitis | Extensive surgery |
| Histoplasmosis | Multiple trauma |
| Miscellaneous infections | Vascular Disorders |
| Mycobacteria malaria | Aortic aneurysm |
| Mycoplasma | Giant hemangioma |
| Psittacosis | Miscellaneous |
| Rocky Mountain spotted fever | Acidosis |
| Varicella | Anaphylaxis |
| Viral infections | Acute respiratory distress syndrome |
| Intravascular Hemolysis | Cardiopulmonary bypass |
| Hemolytic transfusion reactions | Hematologic disorders |
| Massive transfusions | Heat stroke |
| Minor hemolysis | Hepatic disease |
| Malignancy | Hypoperfusion |
| Myeloproliferative diseases | Hypovolemia |
| Solid tumor | Severe allergic reaction |
| | Snake bites |
| | Transplant rejection |

bacterial endotoxin), by systemic contact activation of the clotting cascade (e.g., cardiopulmonary bypass), or by the release of procoagulants into the systemic circulation (e.g., malignancy). Table 15-26 presents an abbreviated list of disorders associated with the development of DIC. Although the most likely stimulus for DIC in W.K. is sepsis, both hypoxia and acidosis associated with respiratory compromise may also have contributed.

Treatment

46. Over the course of several hours, W.K. has developed more severe GI bleeding. Her Hct has fallen from 43% to 35%. What treatment course should be pursued? Should heparin therapy be given?

The most important element of treatment in patients with DIC is alleviation of the underlying cause to eliminate the stimulus for continued thrombosis and hemorrhage.¹⁵² For W.K., this involves appropriate antibiotic therapy, as well as supportive measures to correct or prevent the hemodynamic, respiratory, and metabolic manifestations of shock. Fluid replacement, maintenance of blood pressure and cardiac output, and adequate oxygenation are essential components of the treatment of patients with DIC.

The selection of other therapies aimed at correcting the hemorrhagic or thrombotic manifestations of DIC are controversial and to some extent depend on whether hemorrhagic manifestations or thrombotic complications predominate in the clinical presentation. Initial treatment in patients with hemorrhage involves replacement of clotting components that have been consumed in DIC, guided by coagulation laboratory data.¹⁵³

Transfusion of platelets, fresh frozen plasma (containing all clotting factors), and/or cryoprecipitate (containing factor VIII and fibrinogen) may be necessary, with close monitoring of platelet count and fibrinogen level.

Several approaches to restoring the inherent anticoagulant pathways that are disrupted in DIC have been attempted. Transfusion of AT concentrates may improve survival in DIC associated with sepsis.¹⁵⁴ Recombinant thrombomodulin was associated with a higher degree of resolution of DIC compared to heparin in a randomized clinical trial, but it is not yet commercially available.¹⁵⁵ Recombinant activated protein C (drotrecogin), which lowered mortality in patients with sepsis in the Prowess Trial, had its most significant impact on mortality in the subgroup of sepsis patients who had DIC.^{156,157}

Anticoagulation with heparin in patients with DIC is controversial. In theory, because the initial pathological event in DIC is activation of the clotting system with formation of intravascular thrombin, the antithrombin activity of heparin

should prevent further fibrin deposition and subsequent activation of fibrinolysis. However, randomized trials have not been conducted to confirm this potential benefit, and the role of heparin remains controversial. Emerging anticoagulants that are targeted more specifically at the underlying pathophysiology of thrombosis in DIC, recombinant tissue factor pathway inhibitor, and recombinant nematode anticoagulant protein c2 are being studied in phase II and phase III clinical trials, but are not yet part of routine care of patients with DIC.¹⁵²

Finally, the use of the antifibrinolytic agents tranexamic acid and aminocaproic acid to control bleeding is relatively contraindicated. These agents may worsen the thrombotic complications of DIC, particularly if heparin is not used concurrently. However, antifibrinolytic therapy or recombinant activated factor VII (NovoSeven) may be used in patients with life-threatening bleeding who fail to respond to replacement of clotting components or to heparinization.

| Clinical Presentation | 16-30 |
| Management | 16-31 |

Angina pectoris, whether stable or unstable, is one common manifestation of coronary heart disease (CHD). Other manifestations can include myocardial infarction (MI), heart failure (HF), arrhythmias, as well as sudden cardiac death. By far the most common cause of CHD is narrowing of the coronary arteries through the presence of atherosclerotic plaques, or coronary artery disease (CAD). Because angina is a marker for underlying heart disease, its management is of great importance.

Definitions

Angina pectoris is a “clinical syndrome characterized by discomfort in the chest, jaw, shoulder, back, or arm.”^{1,2} Although angina is typically brought on by exertion and relieved by nitroglycerin (NTG), its presentation is variable. At one extreme, angina occurs predictably with strenuous exercise; at the other, angina can develop unexpectedly with little or no exertion.

Patients who have a reproducible pattern of angina that is associated with a certain level of physical activity have *chronic stable angina* or exertional angina. In contrast, patients with unstable angina experience new-onset angina or a change in their angina intensity, frequency, or duration.³ Both chronic stable angina and unstable angina often reflect underlying atherosclerotic narrowing of coronary arteries. Classic Prinzmetal’s variant angina, or vasospastic angina, occurs in patients without CHD; it is caused by a spasm of the coronary artery that decreases myocardial blood flow.^{3,4} When coronary vasospasm occurs at the site of a fixed atherosclerotic plaque, mixed angina can result.³

Silent (asymptomatic) myocardial ischemia, which can result in transient changes in myocardial perfusion, function, or electrical activity, is detected on an electrocardiogram (ECG) in most patients with angina.^{3,5} The patient, however, does not experience chest pain or other signs of angina (e.g., jaw pain,

shortness of breath [SOB]) during these episodes. Silent myocardial ischemia also can occur in patients with no angina history (see Chapter 18, Myocardial Infarction).

Epidemiology

Cardiovascular disease (CVD) is the leading cause of death in the United States (U.S.), and death caused by CHD is responsible for approximately half of all deaths from CVD. *Chronic stable angina* is the first clinical sign of CHD in approximately 50% of patients.^{3,6} CVD remains the leading cause of death in the U.S. despite a decline in the death rate from CVD in the late 20th century. The incidence of angina is difficult to assess because it often is unrecognized by patients and physicians. Current estimates are that of the 16,000,000 patients with CHD, approximately 9,100,000 have chronic stable angina.⁶

Although CHD accounts for one of every five deaths in the United States, individual mortality varies according to the patient's age, gender, cardiovascular risk profile, myocardial contractility, coronary anatomy, and specific anginal syndrome. The annual mortality rate increases as the number of coronary vessels with high-grade atherosclerotic lesions increases. Patients with left main coronary artery disease have an increased mortality rate compared with patients without left main CAD. Similarly, patients with diminished left ventricular (LV) function (ejection fraction [EF] <50%) have higher mortality rates compared with patients without impaired LV function.

In addition to the high morbidity and mortality associated with CHD, the economic cost to the U.S. health care system is substantial. Total direct and indirect costs associated with CHD are estimated to be \$156.4 billion.⁶

Coronary Anatomy

Figure 16-1 illustrates the normal distribution of the major coronary arteries, although variation is common from individual to individual. The anterior and lateral portions of the left ventricle receive blood flow from the left coronary artery, usually the largest diameter and shortest of all coronary arteries. From its main stem, the left coronary artery divides into its two major branches: the left anterior descending (LAD) coronary artery and the circumflex. The LAD further subdivides into the first diagonal, the first septal, the right ventricular, the minor septals, the second diagonal, and the apical branches. Similarly, the circumflex subdivides into four or five branches, the largest branch being the obtuse marginal.⁷

The right coronary artery (RCA) supplies blood flow to most of the right ventricle as well as the posterior part of the left ventricle. As with the LAD, the RCA branches into major vessels, which supply blood flow to specific areas of the heart. In order of origin, the RCA divides into the conus branch, sinus node branch, right ventricular branches, atrial branch, acute marginal branch, atrioventricular (AV) node branch, posterior descending, LV, and left atrial branches.⁷ Because of wide variation in coronary artery distribution and the need to confirm the precise location of atherosclerotic plaques, most patients with angina undergo coronary arteriography. Patients with severe left main CAD are at higher risk because obstruction of this large coronary artery jeopardizes almost the entire left ventricle. Similarly, patients with three-vessel CAD are at higher

risk than patients with single-vessel disease (see Chapter 17, Myocardial Infarction).

Pathophysiology

Angina pectoris typically occurs when myocardial oxygen demand exceeds myocardial oxygen supply (perfusion). The underlying pathologic condition of this mismatch invariably is the presence of atherosclerosis in one or more of the epicardial coronary arteries (conductance vessels).¹⁻³ If the size of the atherosclerotic plaque obscures <50% of the diameter of the vessel, coronary blood flow can be augmented sufficiently during exertion by the intramyocardial arterioles (resistance vessels), and the patient is pain free. In patients with chronic stable angina, most coronary artery stenoses are >70%. A linear decrease in coronary blood flow occurs as the plaque occupies more of the arterial lumen until high-grade (>80%) obstruction develops. At this point, the decrease in blood flow is out of proportion to plaque size.⁸ The impaired blood flow with atherosclerotic lesions may be adversely affected by vasomotor dysfunction leading to inappropriate vasoconstriction and further reduction in blood supply.⁹ Functionally, coronary blood flow is absent when lesions obstruct >95% of the vessel lumen.⁸

Collateral blood vessels (i.e., side branches of a coronary artery that join one of the three principal arteries or connect two points along the same artery) may offer protection against myocardial ischemia. The distribution and extent of collateral vessels are variable. These usually are very small and have no function in the normal heart. If blood flow is obstructed, however, collateral vessels assume more importance and can restore some myocardial blood flow. When myocardial oxygen demand is increased excessively, however, collateral blood flow usually is insufficient, and angina or other myocardial ischemia syndromes develop.^{3,10}

A thorough understanding of the determinants of myocardial oxygen supply and demand is needed to better comprehend the rationale for the use of traditional pharmacotherapeutic agents in the treatment of stable and unstable anginal syndromes.

Myocardial Oxygen Supply and Demand

The oxygen demand of the heart is determined by its work load. The major determinants of myocardial oxygen consumption are heart rate, contractility, and intramyocardial wall tension during systole (Fig. 16-2; also, see Chapter 18, Heart Failure). Intramyocardial wall tension, which is the force the heart is required to develop and sustain during contraction, is affected primarily by changes in ventricular chamber pressures and volume. Both enlargement of the ventricle and increased pressure within the ventricle increase the systolic wall force and consequently myocardial oxygen demand. Increases in contractility and heart rate also result in increased oxygen demand. Pharmacologic control of angina is, in part, directed toward decreasing the myocardial oxygen demand by decreasing heart rate, myocardial contractility, or ventricular volume and pressures.⁸

Of the many factors that affect oxygen supply to the heart (Fig. 16-2), coronary blood flow and oxygen extraction are most important. Oxygen extraction by heart cells is high (~70%–75%) even at rest. When extra demand is placed on the heart, myocardial oxygen extraction increases slightly and

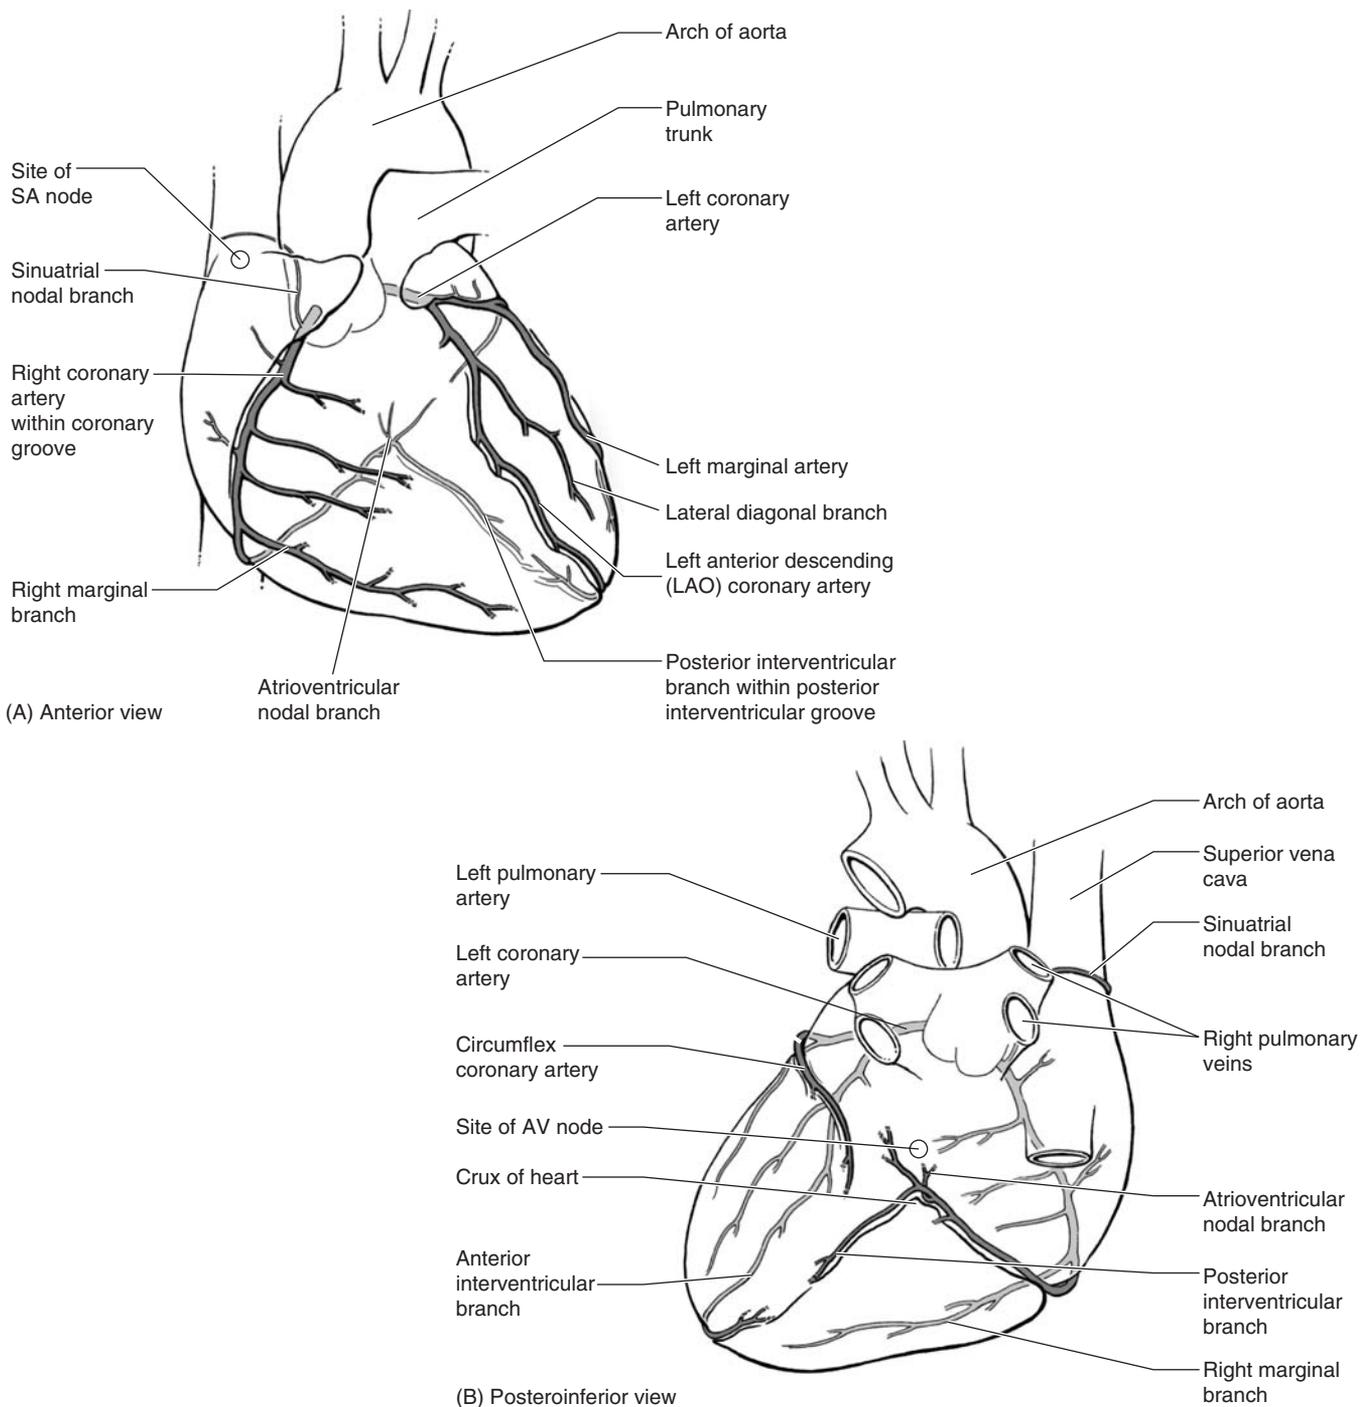

FIGURE 16-1 Coronary arteries. The right coronary artery (RCA) originates from the aorta and courses in the atrioventricular (coronary) groove to reach the posterior surface of the heart. The left coronary artery splits into the circumflex branch that supplies blood to the lateral and posterior walls of the left ventricle, and a left anterior descending (LAD) branch, which supplies blood to the anterior wall of the left ventricle.

plateaus at approximately 80%. Because oxygen extraction is increased only modestly when the heart is heavily stressed, high oxygen demands must be met by increases in coronary blood flow. Sudden increases in oxygen demand lead to a rapid decrease in coronary vascular resistance and an increase in coronary blood flow. The mechanisms by which coronary artery resistance is decreased during increased demand are not

completely understood, but likely involve various mediators, such as adenosine and nitric oxide (NO) released from the myocytes and endothelium.⁸ The oxygen content of arterial blood also is important. Therefore, the hematocrit (Hct), hemoglobin (Hgb), and arterial blood gases (ABG) should be monitored. In a similar fashion to targeting determinants of myocardial oxygen demand, pharmacologic control of angina is directed at

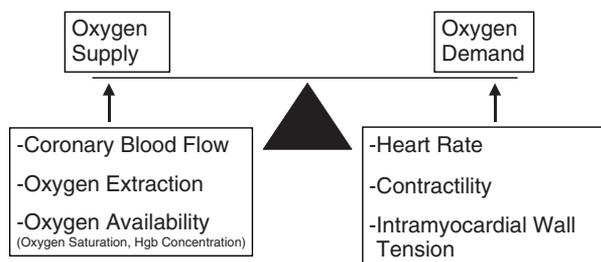

FIGURE 16-2 Determinants of myocardial oxygen supply and demand.

improving oxygen supply through vasodilation of the epicardial coronary arteries.

Ischemia

Ischemia in the myocardium develops when there is a mismatch between myocardial oxygen supply and demand. This imbalance is often caused by a reduction in blood flow as a result of increased coronary arterial tone or thrombus formation. This condition is known as *supply ischemia* or *low-flow ischemia* and typically is present during acute coronary syndromes (ACS) such as unstable angina or MI. Under different conditions, ischemia can result from increased myocardial oxygen demand in the presence of a fixed supply. This condition is known as *demand ischemia* or *high-flow ischemia* and typically exists in the setting of chronic stable angina where patients have a fixed supply to the myocardium and undergo exercise or experience stress.^{3,8}

Although it is useful to consider these mechanisms separately to facilitate understanding of how myocardial ischemia develops, in reality most patients with either chronic stable angina or ACS develop ischemia from both an increase in oxygen demand and a reduction in oxygen supply. As discussed, in diseased segments of the coronary arteries where atherosclerotic lesions have developed, vasomotor function of the arterial wall is often abnormal secondary to endothelial dysfunction. This can lead to inappropriate vasoconstriction on top of a flow-limiting atherosclerotic plaque, resulting in the precipitation or worsening of ongoing ischemia in patients with chronic stable angina.⁸ In the setting of ACS, coronary blood flow is often acutely decreased or completely interrupted secondary to the development of a pathologic thrombus superimposed on a flow-limiting atherosclerotic plaque. Coronary vasoconstriction can be present in these acute coronary syndromes as well.^{11,12}

Intracellular Sodium and Calcium Handling

Recent investigations highlight the role of the late sodium current (I_{Na}) in the development and maintenance of myocardial ischemia. Most sodium enters the myocardium in phase 0 of the action potential. Under normal conditions, however, a small amount of sodium will enter the cell during phase 2 (plateau phase) of the action potential.¹³ When ischemia is present, sodium handling is altered such that a substantial increase occurs in the late I_{Na} . The increase in intracellular sodium triggers an increase in the influx of calcium through the reverse mode of the sodium-calcium exchanger. The net result of the alterations in intracellular ion handling is intracellular calcium overload.^{14,15} Increases in intracellular calcium impair

myocardial relaxation, increase intramyocardial wall tension, decrease perfusion to the myocardium owing to compression of the small arterioles feeding the myocardium, as well as increase myocardial oxygen demand.¹⁶ Ultimately these pathologic changes in sodium and calcium handling serve to perpetuate and worsen ischemia once it develops and can be thought of as the consequences of myocardial ischemia development. Targeting this pathologic process has led to the development of new anti-anginal medications (e.g., ranolazine) with a distinct, novel mechanism of action as compared to traditional anti-anginal agents (i.e., nitrates, β -blockers, and calcium channel blockers).

Atherosclerotic Vascular Disease

Although understanding the determinants of myocardial oxygen supply and demand are important in treating CHD, of equal importance is understanding how atherosclerotic plaques develop (Fig. 16-3). Through this understanding, the rationale for certain pharmacotherapy options is revealed, and the process of atherosclerosis may be halted or prevented.

Atherosclerosis was once thought of as a simple disease involving excess lipid accumulation in the arterial wall. Today,

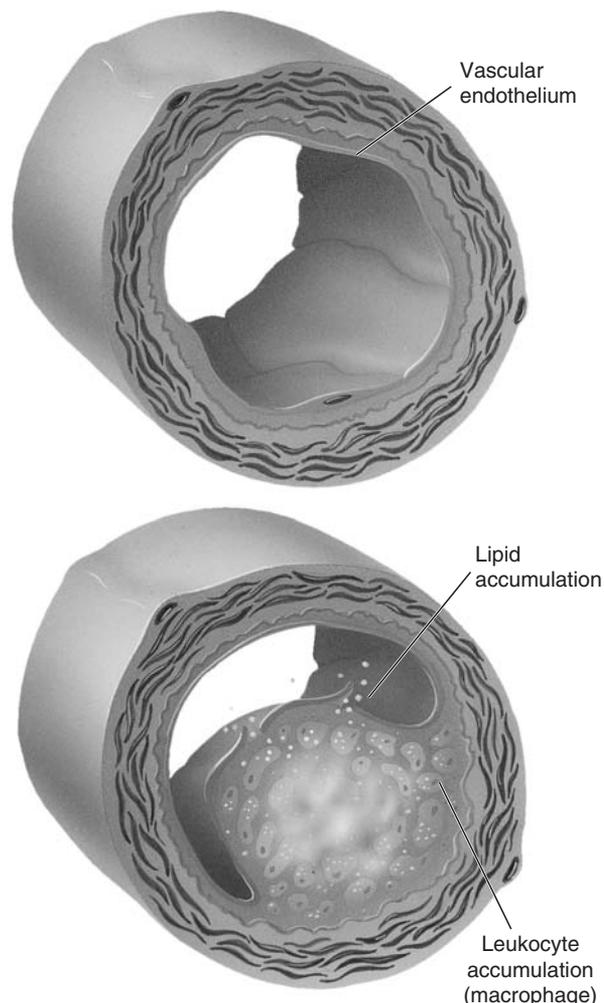

FIGURE 16-3 Process of atherosclerosis. (Copyright © Anatomical Chart Co., Hagerstown, MD.)

atherosclerosis is recognized as a complex and lifelong process. Recent advances in vascular biology demonstrate that inflammation plays a fundamental role in all stages of the atherosclerotic process. Examination of atherosclerotic lesions demonstrates that each plaque contains elements of inflammation and a fibroproliferative response. Although the initial stages of atherosclerosis remain speculative, it is generally thought that the first step is lipid accumulation (primarily low-density lipoprotein cholesterol [LDL-C]) in the vascular wall and subsequent oxidation of LDL lipoproteins. This is followed by leukocyte recruitment and accumulation in the vessel wall. Early lesions (fatty streaks) are present in all people at a young age and primarily consist of activated macrophages and T lymphocytes. Once within the arterial wall, the leukocyte can take up oxidized cholesterol and become a lipid-laden macrophage (foam cell). As lesions progress, smooth muscle cells (SMC) migrate, proliferate, and secrete large amounts of extracellular matrix (collagen), promoted by the release of several proinflammatory cytokines produced by leukocytes. The end result is the presence of an elevated plaque, which occludes the vessel lumen (also see Chapter 12, Dyslipidemias, Atherosclerosis, and Coronary Heart Disease). The inflammatory process is not only involved in the initiation and a development of atherosclerosis, but also is directly involved in the acute thrombotic complications of atherosclerosis, such as MI or unstable angina. Cytokines produced by activated macrophages induce the production of proteolytic enzymes, which break down the extracellular matrix and render the plaque more susceptible to rupture.^{17,18}

A key factor in plaque formation is the functional status of the vascular endothelium (Fig. 16-4). Historically, the endothelium was thought to act simply as the inner barrier of blood vessels. This single-cell layer, however, has several functions, including the synthesis and secretion of many different substances and the regulation of the local vascular environment. One of the key substances synthesized is endothelium-derived relaxing factor (EDRF), identified as nitric oxide. Nitric oxide has vasodilatory, antithrombotic, anti-inflammatory, and growth-inhibiting properties. In the response to injury hypothesis, the endothelium is damaged and loses the ability to secrete NO and the ability to regulate the vascular environment. Without NO, the endothelium facilitates inflammation, throm-

boses, and extracellular growth. In this setting, atherosclerotic plaques can develop.^{19,20}

Traditional risk factors, such as smoking, hypertension, hyperlipidemia, diabetes, and obesity, are linked to the process of atherosclerosis through their ability to produce oxidative stress within the vasculature. Increased oxidative stress leads to progressive decreases in NO levels and endothelial dysfunction, providing the substrate for atherosclerosis to develop.¹⁸ In addition, dietary patterns typically seen in western industrialized countries have been linked to increased oxidative stress within the vasculature. This may partially explain the link between dietary patterns and development of atherosclerosis.²¹ Recent research provides a more in-depth understanding of the link between obesity and the development of CAD. Adipose tissue, rather than just being a passive storage vehicle, is a metabolically active organ that secretes a number of active cytokines that promote inflammation and oxidative stress within the vasculature.²² Adiponectin levels are also decreased in obesity, which further serves to promote atherosclerosis development.²³ The role of a healthy lifestyle and dietary pattern are both more crucial than ever in preventing the development or progression of CAD.

Although traditional risk factors have long been appreciated as the underlying cause for the development of CAD, continuing research efforts have attempted to identify novel risk factors to refine risk assessment for the development of CAD. The novel risk factors include C-reactive protein, homocysteine, fibrinogen, and lipoprotein(a), among others.²⁴ Findings from the INTERHEART study indicate, however that little may be gained from identifying additional risk factors.²⁵ In this large case-control international study, nine clinical risk factors were strongly associated with the development of first ever MI and accounted for >90% of the risk for developing CAD (Table 16-1). Importantly the results were consistent across gender, geographic regions, and ethnic groups, suggesting strategies to reduce the incidence of CAD can be applied universally.

Platelet Aggregation and the Formation of Thrombi

Although plaque rupture and the formation of a superimposing thrombus are commonly considered in the pathophysiology of ACS,¹¹ platelet activation and thrombus formation also are integral to the chronic atherosclerotic process. Advances in

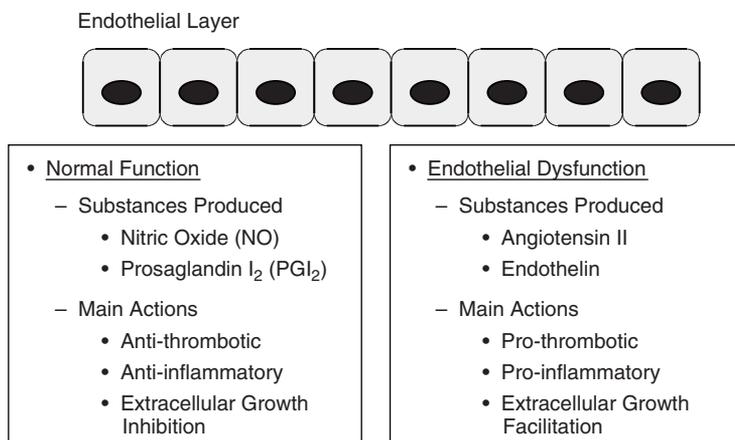

FIGURE 16-4 Endothelial function.

Table 16-1 Risk Factors for First Time Myocardial Infarction From the INTERHEART Study²⁵

| Risk Factor | Adjusted Odds Ratio (99% CI) |
|----------------------------|------------------------------|
| ApoB-to-Apo A-1 ratio | 3.25 (2.81–3.76) |
| Current smoking | 2.87 (2.58–3.19) |
| Psychosocial | 2.67 (2.21–3.22) |
| Diabetes | 2.37 (2.07–2.71) |
| Hypertension | 1.91 (1.74–2.10) |
| Abdominal obesity | 1.62 (1.45–1.80) |
| Moderate alcohol intake | 0.91 (0.82–1.02) |
| Exercise | 0.86 (0.76–0.97) |
| Vegetable and fruits daily | 0.70 (0.62–0.79) |
| All combined | 129.2 (90.2–185.0) |

vascular biology have demonstrated that platelets can both be a source of inflammatory mediators, as well as be activated by generalized inflammation within the vasculature.²⁶ In response to arterial vessel wall injury (e.g., an atherosclerotic lesion), platelets aggregate and release granular contents.¹⁷ These activities further enhance platelet aggregation, vasoconstriction (dynamic obstruction), and in many cases, thrombus formation. Although coronary atherosclerosis is the underlying mechanism for most patients with anginal syndromes, thrombotic factors commonly play a key role in the pathogenesis of myocardial ischemia. Both blood flow turbulence and stasis can cause intermittent platelet aggregation or intermittent coronary artery thrombosis. Thus, platelet-active agents are used in the treatment of chronic stable angina and unstable angina, primary prevention of MI, secondary prevention of myocardial ischemia and acute MI, and in patients after coronary angioplasty or coronary artery bypass grafting (CABG).

Approach to a Patient With Anginal Symptoms

The medical management of anginal syndromes always should be individualized. The first step for any given patient is a detailed history and physical examination. Once this information is available, an estimate can be made of the probability of CAD being present (low, intermediate, high). The probability estimate will often help direct which diagnostic tests are appropriate to perform, as well as the utility of the results obtained (positive predictive value).^{1,2} In addition, it is important to discern as soon as possible whether the patient's reported chest discomfort is consistent with chronic stable angina, or represents the presence of ACS. Patients presenting with ACS often are at high short-term risk of MI or death and warrant hospitalization with aggressive treatment strategies.^{11,12} Regardless of whether a patient is experiencing chronic stable angina or ACS, patients often receive medications to alleviate or prevent ischemia, medications that prevent pathologic thrombus formation and may alleviate or prevent the progression of atherosclerosis (vasculoprotective agents), as well as undergo revascularization procedures such as percutaneous coronary intervention (PCI) or CABG. In addition, all patients with anginal syndromes should receive instructions on changes to adopt a healthy lifestyle and dietary pattern, as well as appropriate control of risk factors for CAD.

CHRONIC STABLE EXERTIONAL ANGINA

Signs and Symptoms

1. J.P., a 62-year-old retired dairy farmer, is hospitalized for evaluation of chest pain. About 3 weeks before admission, he noted substernal chest pain brought on by lifting heavy objects or walking uphill. He describes a crushing or viselike pain that never occurs at rest and is not associated with meals, emotional stress, or a particular time of day. When J.P. stops working, the pain subsides in about 5 minutes.

J.P.'s mother and brother died of a heart attack at ages 62 and 57, respectively; his father, who is alive at age 86, has survived one heart attack and one stroke. Family history (except for J.P.) is negative for diabetes mellitus. J.P. is 5'10" tall and weighs 235 lb; he drinks two or three beers per day and does not smoke or chew tobacco.

J.P.'s other medical problems include a 10-year history of hypertension, diabetes for 4 years, and traumatic amputation of the right hand. Until 3 weeks ago, J.P. could perform all his farm chores without difficulty, including heavy labor. He follows a no-added-salt diet, but consistently eats at fast-food establishments with his favorite meal consisting of two cheeseburgers and French fries.

J.P.'s medication history reveals the following: metoprolol (Toprol XL) 100 mg every day, glipizide (Glucotrol) 5 mg twice daily (BID) and losartan (Cozaar) 50 mg every day. He rarely uses over-the-counter medications. He has a history of an allergic reaction to sulfa drugs.

On admission to the cardiac ward, J.P. appears his stated age and is in no apparent distress. Resting vital signs include supine blood pressure (BP), 164/98 mmHg (normal, 120/80); regular pulse, 73 beats/minute (normal, 65–75); and respiratory rate, 12 breaths/minute (normal, 8–14). He has no peripheral edema or neck vein distention, and lung auscultation is within normal limits. Abdominal examination is unremarkable and he is alert and oriented $\times 3$. Cardiac auscultation reveals a regular rate and rhythm with a normal S₁ and S₂; third or fourth heart sounds and murmurs are not noted. A 12-lead ECG reveals normal sinus rhythm at a rate of 75 beats/minute without evidence of previous MI. All intervals are within normal limits.

Admitting laboratory values include the following: Hct, 43.5% (normal, 40%–45%); white blood cell (WBC) count, 5,000/mm³ (normal, 5,000–10,000); sodium (Na), 140 mEq/L (normal, 136–144); potassium (K), 4.7 mEq/L (normal, 3.5–5.3); magnesium (Mg), 1.9 mEq/L (normal, 1.7–2.7); random blood glucose, 152 mg/dL (normal fasting, 65–110); blood urea nitrogen (BUN), 27 mg/dL (normal, 10–20); serum creatinine (SrCr), 1.4 mg/dL (normal, 0.5–1.2). Chest radiograph is within normal limits.

What signs and symptoms of angina pectoris does J.P. exhibit? Can his symptoms be categorized on a measurement scale?

[SI units: Hct, 0.435 (normal, 0.40–0.45); WBC count, $5 \times 10^9/L$ (normal, $5-10 \times 10^9/L$); Na, 140 mmol/L (normal, 136–144); K, 4.7 mmol/L (normal, 3.5–5.3); Mg, 0.95 mmol/L (normal, 0.85–1.35); random blood glucose, 6.16 mmol/L (normal, 3.6–6.1); BUN, 9.6 mmol/L of urea (normal, 3.57–7.14); SrCr, 124 $\mu\text{mol/L}$ (normal, 44.2–106)]

J.P.'s description of his chest pain includes several common characteristics of angina pectoris (Table 16-2).^{1–3} The substernal location of J.P.'s chest pain is typical, although some patients describe pain radiating down the left arm or pain that

Table 16-2 Characteristics of Angina Pectoris¹⁻³

| <i>Symptoms</i> | <i>Duration of Symptoms</i> |
|--|---|
| Sensation of pressure or heavy weight on chest alone or with pain | 0.5–30 min |
| Pain described variably as feeling of tightness, burning, crushing, squeezing, vicelike, aching, or “deep” | Electrocardiogram |
| Gradual increase in intensity followed by gradual fading away (distinguished from esophageal spasm) ^a | ST-segment depression >2 mm |
| SOB with feeling constriction about the larynx of upper trachea | T-wave inversion |
| Location of Pain or Discomfort | Precipitating Factors |
| Over the sternum or very near to it | Mild, moderate, or heavy exercise, depending on patient |
| Anywhere between epigastrium and pharynx | Effort that involves use of arms above the head |
| Occasionally limited to left shoulder and left arm | Cold environment |
| Rarely limited to right arm | Walking against the wind |
| Lower cervical or upper thoracic spine | Walking after a large meal |
| Left interscapular or suprascapular area | Emotions: fright, anger, or anxiety |
| Radiation of Pain | Coitus |
| Medial aspect of left arm | Nitroglycerin Relief^a |
| Left shoulder | Relief of pain occurring within 45 sec to 5 min of taking nitroglycerin |
| Jaw | |
| Occasionally, right arm | |

^aEsophageal spasm and other gastrointestinal disorders occasionally mimic anginal pain and also can be relieved by nitroglycerin.

SOB, shortness of breath.

is referred to the shoulder area or jaw. J.P.’s pain is described as crushing or viselike in quality, which also is common; a fullness in the throat or jaw may occur simultaneously or in lieu of chest pain. In some cases, the patient may not consider these sensations as pain, describing them instead as a sense of pressure or heaviness. Many patients complain of shortness of breath (SOB), J.P.’s symptoms are related to exercise and exertion—both known precipitating factors of angina. Most episodes of exertional angina last several minutes in duration and are relieved with rest. Because J.P. has never sought medical attention for his chest pain, his response to NTG cannot be determined.

After getting a detailed description of J.P.’s symptom complex, his physician can characterize his chest pain and make a global assessment. Initially, the chest pain should be classified as either typical angina, atypical angina, or noncardiac chest pain. Furthermore, angina should also be classified as either stable or unstable. This distinction is important because it indicates whether his short-term risk of an acute coronary event could be life-threatening. Attempts to categorize J.P.’s anginal symptoms on an objective measurement scale (e.g., Canadian Cardiovascular Society Grading Scale) can be misleading.²⁷ For example, a sedentary 65-year-old patient’s class II symptoms may be tolerable, but the same symptoms could significantly disable an active 50-year-old patient.

J.P.’s chest pain is of a quality and duration characteristic of angina, provoked by exertion, and relieved by rest; therefore, J.P.’s constellation of symptoms can be classified as typical chest pain. J.P.’s symptoms do not occur at rest, however, so they can be classified as stable angina.¹⁻³

2. Assess J.P.’s physical examination. What signs and symptoms are relevant to the angina?

The physical examination typically provides little information about the presence of CAD. The most useful findings

pertain to the cardiovascular system where heart rate and BP can be increased during an acute anginal episode. J.P.’s physical examination is characteristic for a man of his age with angina.³ He is obese and hypertensive, but his cardiac examination is normal. The presence of murmurs would have required further workup; the absence of a third heart sound suggests that the left ventricle may be functioning normally. (See Chapter 18, Heart Failure, for a description of third heart sounds.) The absence of a fourth heart sound in J.P. is indicative of a low probability of either CHD or a cardiac end-organ damage resulting from systemic hypertension. His chest radiograph, which is normal, does not present evidence of other complications commonly associated with myocardial ischemia (e.g., enlarged heart, heart failure).

J.P.’s physical examination should also evaluate the possibility of peripheral vascular disease and abdominal aortic aneurysm. The presence of xanthomas would suggest severe hypercholesterolemia, but these were not noted in J.P.

Diagnostic Procedures

3. J.P.’s medical history and family history support the diagnosis of chronic stable angina. What other objective diagnostic procedures are helpful to confirm CHD and angina?

A 12-lead ECG reading should be obtained in all patients with symptoms suggestive of angina pectoris, although it will be normal in >50% of patients. Although not useful in establishing a definitive diagnosis of CAD, the ECG will be useful at detecting important information regarding conduction abnormalities, left ventricular hypertrophy, ongoing ischemia, or evidence of a previous myocardial infarction. Chest radiography is typically not useful except in patients with symptoms of heart failure, valvular disease, or pericardial disease. In these selected patients, echocardiography may also be used to better (a) evaluate the structure and function of the cardiac valves,

(b) characterize the extent of ischemia during pain, or (c) assess global left ventricular systolic function.³ Electron beam computerized tomography (EBCT) is evolving as a potential non-invasive approach to detecting significant CAD through identification of coronary artery calcification. Although an attractive alternative to other invasive diagnostic measures, current information suggest that a sufficient level of variability exists in repeated measure of coronary calcium by EBCT and that the specificity of the procedure remains poor. Current guidelines do not recommend the routine use of EBCT in the diagnosis of chronic stable angina.²⁸

Exercise Tolerance Test

An exercise tolerance test or treadmill test would be helpful in the diagnosis of CAD in J.P. Under controlled circumstances, J.P. would exercise to a preset level, and the test would be indicative of CAD on the development of angina, ECG signs of ischemia, arrhythmias, abnormal heart rate, or abnormal BP response. The product of the heart rate and systolic BP (i.e., *the rate–pressure or double product*) correlates well with myocardial oxygen demand. The rate–pressure product normally rises progressively during exercise, with the peak value best describing the cardiovascular response to stress. Often, patients with stable angina experience chest pain at a consistent rate–pressure product.²⁹

Abnormal responses of either BP or heart rate may signal CAD. A normal BP response to exercise is a gradual rise in systolic BP with the diastolic BP (DBP) remaining unchanged. A rise or fall of DBP > 10 mmHg is considered abnormal. A fall in systemic BP (SBP) during exercise is especially ominous because this indicates that the cardiac output cannot increase sufficiently to overcome the vasodilation in the skeletal muscle vascular bed.

During exercise, the heart rate increases steadily until it reaches a plateau. The maximal heart rate depends on age, drug therapy, and cardiovascular fitness. Some patients exhibit an abnormal slowing of heart rate, especially when taking β -blockers. Therefore, β -blockers should be tapered off (i.e., gradually discontinued) before treadmill testing when the test is being used for diagnosis or risk stratification. Similarly, digoxin can also interfere with the results of exercise testing, and other testing modalities are recommended if digoxin cannot be safely discontinued before treadmill testing. In patients with a history such as J.P.'s, the exercise tolerance test helps to confirm the presence of CAD and provides a risk stratification that may be helpful in determining whether he is a candidate for revascularization therapy.²⁹

Myocardial Imaging

Stress imaging studies, either echocardiographic or nuclear, are preferred over the exercise tolerance test in patients with left bundle-branch block, electronically paced ventricular rhythm, prior revascularization (percutaneous coronary intervention or coronary artery bypass surgery), pre-excitation syndrome, > 1 mm ST-segment depression at rest, or other ECG conduction abnormalities. In addition, many patients are not able to develop an appropriate level of cardiac stress through exercise; pharmacologic stress testing is preferred in these patients.¹

Pharmacologic stress may be achieved through the use of dipyridamole, adenosine, or dobutamine. Each of these agents is used to induce changes in the balance between myocardial

oxygen supply and demand, similar to walking on a treadmill during the exercise stress test. Vasodilators (dipyridamole and adenosine) promote vasodilation in normal coronary segments, but have no effect in arteries affected by atherosclerosis. The net result is shunting of blood away from diseased coronary arteries and the development of ischemia that may be detected by changes in blood pressure, heart rate, or ECG changes. These agents are typically used in conjunction with myocardial perfusion scintigraphy. Stress thallium-201 myocardial perfusion imaging provides a dynamic picture of the heart. The radionuclide is injected at peak stress and an image is obtained within several minutes. A defect in myocardial uptake of the thallium indicates an area of ischemia or possible infarction.¹

Dobutamine is a positive inotrope and typically is used with echocardiography. Administration of dobutamine leads to an increase in myocardial oxygen demand secondary to increases in heart rate and contractility. If demand exceeds available oxygen supply, ischemia develops. Subsequent to the infusion of dobutamine, defects or decreases in the wall motion or thickening of the left ventricle are indicative of ischemia.¹

Cardiac Catheterization

4. Should J.P. undergo cardiac catheterization? How will the results of this invasive procedure influence future therapy?

Coronary artery disease can be diagnosed definitively only by coronary catheterization and subsequent angiography. In addition, angiography is the most accurate means of identifying less common causes of chronic stable angina, such as coronary artery spasm.^{1,30} Cardiac catheterization is a procedure used to provide vascular access to the coronary arteries. Once access is gained with an intravascular catheter, a number of procedures (angiography, ventriculography, percutaneous coronary intervention) can be performed. Access to the vasculature is usually obtained percutaneously through the brachial or femoral arteries. From this point, the catheter is advanced through the vasculature until the coronary arteries are accessible. After the tip of the catheter is advanced into the coronary arteries, radiocontrast dye is injected into the coronary arteries and the location and extent of atherosclerosis can be determined. Approximately 75% of patients with chronic stable angina, such as J.P., are noted to have one-, two-, or three-vessel disease by this procedure (approximately equally divided).³

The results of angiography will be useful in determining the risk of death or MI in J.P. and, subsequently, the course of needed treatment. For example, patients who have a significant stenosis in the left main coronary artery are at high risk of death and should undergo CABG.³¹

Risk Stratification and Prognosis

5. J.P. is found to have two-vessel CAD with obstructive lesions of 55% and 70%; the LAD coronary artery is not involved. What is his prognosis?

The prognosis of patients with stable angina is variable and dependent on the presence of other factors and comorbid conditions. Developing a level of risk for a particular patient helps determine the appropriate treatment strategy. The extent of CAD, quantification of ventricular function, the response to

stress testing, as well as the initial clinical evaluation all help to provide a estimate of risk in a given patient.

J.P.'s history and physical examination suggest he does not have HF; poor LV function would be an ominous concurrent finding. J.P. also does not have three-vessel disease or blockage of the LAD artery.¹ Overall, he probably will do well with medical therapy. His life expectancy depends on progression of the disease and development of other complications of CHD (e.g., HF, MI, sudden cardiac death). Medical therapy is a reasonable treatment strategy for J.P., but revascularization via percutaneous transluminal coronary angioplasty (PTCA) is an equally viable option. Although PTCA with or without stent placement would offer no mortality advantage over medical therapy at this time, it has been shown to decrease the incidence of recurrent symptoms.¹ Both strategies, including both pros and cons, should be offered to J.P. so that an informed decision can be made in accord with his wishes.

Presently, J.P. is not a candidate for CABG because the usual indications for surgical therapy include presence of left main CAD, presence of three-vessel disease (especially if LV function is impaired), or ineffectiveness of medical therapy.^{30,31}

Overview of Medical Management

6. After consultation, J.P. and his cardiologist elect to control his angina medically. What are the goals of his therapy and how can they be achieved?

Two major pharmacotherapeutic goals exist for treating all patients with angina. The first goal includes relief of symptoms and reduction of myocardial ischemia to improve quality of life. The second goal, and more important overall, is to prevent major complications of CAD such as acute MI and death. Therapies that prevent death (vasculoprotective agents) should receive priority. As with any chronic disease, education of the patient and his or her family are important objectives. The ultimate goal of patient education is a better quality of life through improved understanding of the disease and its therapy. Every effort should be made to reverse J.P.'s modifiable risk factors (i.e., obesity, hypertension, and diabetes). He also could receive one or more of the following: a nitrate, calcium channel blocker (CCB), β -adrenergic blocker, ranolazine, angiotensin-converting enzyme (ACE) inhibitor, or antiplatelet drug.¹ J.P. should continue metoprolol therapy because it will be helpful in treating both his hypertension and angina. Compliance to metoprolol should be assessed because his BP was elevated on admission. His BUN and creatinine are slightly elevated (probably as a consequence of his hypertension), and he developed angina symptoms despite use of a β -blocker. Reduction of precipitating factors may be difficult, given J.P.'s work. He should be counseled, however, to avoid sudden bursts of physical activity. Moderate exercise should be encouraged, such as a walking program. J.P.'s family members should be screened for smoking because passive (secondhand) smoke can aggravate angina.

GENERAL MANAGEMENT

Patients and family members should receive education regarding the nature of chronic stable angina, the progressive nature

of CAD, as well as specific information regarding potential complications and overall prognosis. All patients should be able to recite specific instructions for how to deal with exertional angina attacks. These include immediate cessation of the provoking activity, rest, as well as the use of sublingual (SL) nitroglycerin for immediate relief. All patients with CAD and angina should have a prescription for SL nitroglycerin, as well as receive instructions for the appropriate use and storage of the medication.³² If rest or SL nitroglycerin does not provide adequate relief from angina after the first dose, patients should be instructed to immediately call for medical assistance.^{2,11,12}

Risk Factors and Lifestyle Modifications

7. What independent risk factors for CAD are present in J.P.? Which of these may be altered?

The first step in the treatment of any patient with chronic stable angina, or CAD for that matter, should be the modification of any existing risk factors and the adoption of a healthy lifestyle. By addressing the underlying circumstances which likely led to the development of CAD, a significant impact can be made at halting the progression of the disease and preventing complications of CAD. Current recommendations for the goals for risk factor management are listed in Table 16-3.³³ In addition to specific risk factor goals, attention should be paid to evidence that may favor specific drug therapies that have evidence supporting reductions in morbidity and mortality. Examples would include the use of metformin³⁴ or pioglitazone³⁵ in the treatment of type 2 diabetes, the use of 3-hydroxy-3-methylglutaryl co-enzyme A inhibitors (HMG-CoA reductase inhibitors) in the treatment of hyperlipidemia,^{1,2,33} as

Table 16-3 AHA/ACC Guidelines for the Secondary Prevention for Patients with Coronary and Other Atherosclerotic Vascular Disease³³

| Risk Factor | Intervention and Goal |
|-----------------------|---|
| Smoking | Complete cessation No exposure to environmental tobacco smoke |
| Blood pressure | <140/90 mmHg <130/80 mmHg if patient has diabetes or chronic kidney disease |
| Lipid management | LDL-C <100 mg/dL If triglycerides >200 mg/dL, non-HDL-C should be <130 mg/dL |
| Diabetes | Hemoglobin A _{1C} <7% |
| Physical activity | At least 30 min of moderate intensity aerobic activity (e.g., brisk walking) for minimum of 5 days/wk |
| Weight management | BMI between 18.5–24.9 kg/m ² Waist circumference men <40 in Waist circumference women <35 in |
| Influenza vaccination | Patients with CAD should have an annual influenza vaccination BMI, body mass index; CAD, coronary artery disease; HDL-C, high-density lipoprotein cholesterol; LDL-C, low-density lipoprotein cholesterol. |

well as the use of ACE inhibitors for the treatment of hypertension.³⁶

J.P. has several risk factors for CAD, some of which cannot be altered, such as middle age, male gender, and a strong family history of CAD. Risk factors, such as hypertension, obesity, hypercholesterolemia, smoking, and possibly stress, can potentially be modified to decrease the likelihood of adverse sequelae for J.P. His hypertension should be controlled and his serum cholesterol concentration should be tested and fractionated for LDL, high-density lipoprotein (HDL), and triglycerides (TG) (see Chapter 12, Dyslipidemias, Atherosclerosis, and Coronary Heart Disease). A fasting hemoglobin A_{1c} should be drawn with a goal of <7% (see Chapter 50, Diabetes Mellitus). Dietary modification and weight reduction for J.P. are mandatory, because they positively influence several risk factors. J.P., however, does not smoke cigarettes, which would significantly increase his cardiovascular risk.¹ J.P.'s active lifestyle may influence his prognosis favorably.³⁷

Dietary Interventions

8. J.P. states he had heard that antioxidants such as vitamin E could benefit him along with a daily B vitamin. Are there other dietary changes he could make that would benefit his cardiovascular disease?

Because oxidation of LDL in the arterial wall was identified as a key step in the atherosclerotic process, considerable interest exists in the theory that supplementation with high doses of antioxidants, such as vitamin E, vitamin C, and β -carotene, might mitigate this process and slow the progression of atherosclerosis. Early observational studies of dietary patterns high in these antioxidants seemed to confirm this theory. Multiple large randomized studies, however, have shown no positive effect from supplemental intake of antioxidants, such as vitamin E, on the incidence of cardiovascular outcomes including MI or death. These findings were observed in both primary and secondary prevention of cardiovascular events. J.P. should be informed that supplemental intake of vitamin E will not have any positive effect on his cardiovascular disease. (See Chapter 12 Dyslipidemias, Atherosclerosis, and Coronary Heart Disease, for further discussion.)^{38,39}

Interest in the use of supplemental intake of folic acid and B vitamins stems from their ability to lower homocysteine levels. It is well established that elevated levels of homocysteine are associated with a higher incidence of cardiovascular disease.^{40,41} Despite this association, the great majority of appropriately designed, randomized, placebo-controlled studies have demonstrated that supplemental ingestion of folic acid and B vitamins has no impact in reducing hard cardiovascular outcomes such as MI or death in patients with CAD.⁴² Therefore, similar to the advice for vitamin E, J.P. should be counseled that folic acid and B vitamin supplementation will not provide him any tangible cardiovascular benefit.

In contrast to the data regarding specific dietary interventions, such as vitamin E or folic acid, several healthy dietary patterns have compelling evidence to support their implementation to prevent the development or progression of CAD. These include the substitution of nonhydrogenated saturated fats for saturated fats and trans-fats in the diet; consumption of omega-3 fatty acids (primary source is fish); and con-

sumption of a diet high in fruits, vegetables, nuts, and whole grains.⁴³ When patients post-MI were randomized to a traditional western diet or a Mediterranean diet high in fruits, vegetables, cereals, beans, nuts, and olive oil as the primary source of fat intake, a 50% to 70% lower risk was seen of recurrent heart disease (which includes cardiac death and non-fatal MI).^{44,45} These dietary alterations are in line with the current dietary guidelines from the American Heart Association.⁴³ Additional trial data have demonstrated a beneficial effect of either increasing weekly fish consumption, or taking omega-3 fatty acid fish oil supplements on reducing cardiovascular morbidity and mortality.^{46–48} J.P. can make a number of dietary changes that can significantly benefit his cardiovascular disease, and he should be encouraged to do so. J.P. should be asked if he regularly consumes alcohol and counseled to limit his intake to one to two drinks per day if he does.⁴³

ANTI-ISCHEMIC DRUG THERAPY

Organic Nitrates

Nitrates are commonly used in the treatment of all anginal syndromes. They are effective in treating all forms of angina because they decrease venous return to the heart and, therefore, decrease cardiac work load. Nitrates also promote coronary vasodilation, even in the presence of atherosclerosis. Nitrates generally are well tolerated. To prevent loss of effect over time, however, they must be scheduled to provide a nitrate-free interval of 10 to 12 hours. Therefore, nitrates should be combined with a β -blocker or a CCB (e.g., verapamil, diltiazem). The individual nitrate products differ primarily in their onset and duration of action.

Mechanism of Action

9. During the first hospital day, J.P. decides to walk up three flights of stairs when returning to his room from the cafeteria instead of taking the elevator. Midway through the third flight of stairs J.P. develops chest pain. After quickly performing a 12-lead ECG, the physician instructs J.P. to place a 0.4-mg sublingual NTG tablet (Nitrostat) under his tongue. This relieves the pain. J.P.'s physician elects to continue metoprolol and add both short- and long-acting nitrates. What is the mechanism by which NTG relieves angina? Why should J.P. continue his metoprolol therapy?

The mechanism of action of NTG and the other nitrate esters is not completely understood, although they have been used for >100 years. The overall benefits of nitrates result from a reduction in myocardial oxygen demand caused by venodilation and some arteriolar dilation.^{1,2,32} Nitrates produce vasodilation by at least two mechanisms: stimulation of cyclic guanosine monophosphate (cGMP) production and inhibition of thromboxane synthetase. Organic nitrates are converted into NO. Nitric oxide is identical to EDRF, an endogenous vasodilator. Nitric oxide reacts with sulfhydryl groups in the vascular smooth muscle to produce S-nitrosothiols, which subsequently activate guanylate cyclase and increase the intracellular concentration of cGMP. cGMP controls the amount of vascular smooth muscle calcium available for muscle contraction by binding to calmodulin and phosphorylating myosin light chain

kinase. The cGMP enhances calcium uptake into the sarcoplasmic reticulum, or inhibits its cellular influx. Because less calcium is available, dilation occurs.^{32,49}

The peripheral effects of sublingual NTG in J.P. include dilation of both veins and arteries. Venous dilation is more pronounced because relaxation of arterial smooth muscle requires higher plasma NTG levels. By dilating the veins and reducing preload to the heart, filling pressures in the ventricles are reduced. This, in turn, reduces myocardial oxygen demand, thereby relieving J.P.'s angina.^{32,49} (See Chapter 18, Heart Failure, for a more detailed discussion of preload.)

Metoprolol should be continued in J.P. because it both lowers BP and exerts antianginal effects. In addition, administration of nitrates must include a daily nitrate-free interval; metoprolol will provide continued protection from ischemia during this time.⁴⁹ The addition of long-acting nitrates will provide J.P. additional protection against developing angina, and short-acting NTG will provide J.P. acute relief when an anginal attack occurs.

Short-Acting Preparations

Sublingual Nitroglycerin

DOSING

10. How should J.P.'s dose of sublingual NTG be determined? Can NTG be used prophylactically?

Because sensitivity to NTG varies among patients, the dosage should be individualized (Table 16-4). Most patients, however, use a dose of 0.4 mg. An optimal dosage relieves pain and produces an objective hemodynamic response, such as a 10-mmHg fall in systolic BP or a 10-beat/minute rise in heart rate. High doses can cause intolerable orthostatic hypotension, however.⁴⁹

The administration of sublingual NTG is also useful in patients who have a good understanding of what level of exertion produces their chest pain. About 5 to 10 minutes before J.P. is about to undergo heavy exertion, he can take a sublingual NTG tablet to prevent angina.¹

Table 16-4 Commonly Prescribed Organic Nitrates

| Drug | Dosage Form | Duration | Onset (min) | Usual Dosage |
|--------------------------------|--------------------------------|----------------------|-------------|--|
| Short-acting | | | | |
| Nitroglycerin (NTG) | Sublingual (SL) | 10–30 min | 1–3 | 0.4–0.6 mg ^{a,b} |
| NTG | Translingual spray | 10–30 min | 2–4 | 0.4 mg/metered spray ^{a,b} |
| NTG | Intravenous (IV) | 3–5 min ^c | 1–2 | Initially 5 mcg/min. Increase every (Q) 3–5 min until pain is relieved or hypotension occurs |
| Long-acting^d | | | | |
| NTG | Sustained release (SR) capsule | 4–8 hr | 30 | 6.5–9 mg Q 8 hr |
| NTG | Topical ointment ^e | 4–8 hr | 30 | 1–2 inches Q 4–6 hr ^f |
| NTG | Transdermal patch | 4–>8 hr | 30–60 | 0.1–0.2 mg/hr to start; titrate up to 0.8 mg/hr ^f |
| NTG | Transmucosal | 3–6 hr | 2–5 | 1–3 mg Q 3–5 hr ^f |
| ISDN ^g | SL | 2–4 hr | 2–5 | 2.5–10 mg Q 2–4 hr ^f |
| | Chewable | 2–4 hr | 2–5 | 5–10 mg Q 2–4 hr ^f |
| | Oral | 2–6 hr | 15–40 | 10–60 mg every 4–6 hr ^f |
| | SR | 4–8 hr | 15–40 | 40–80 mg Q 6–8 hr ^f |
| ISMN ^h | Tab (ISMO, Monoket) | 7–8 hr | 30–60 | 10–20 mg twice daily (BID) (morning and midday) to start; titrate to 20–40 mg BID ^f |
| | SR tablet (Imdur) | 8–12 hr | 30–60 | 60 mg every day (QD) to start; titrate to 30–120 mg QD |

^aWhen using sublingual or translingual spray forms of NTG, patients should administer the dose while sitting to minimize tachycardia, hypotension, dizziness, headache, and flushing. The optimal dose relieves symptoms with <10–15 mmHg drop in systolic blood pressure or <10 beat/min rise in pulse. Pain relief is rapid (onset 1–2 min; relief in 3–5 min), but up to three doses at 5-min intervals may be given. After this, medical assistance should be summoned.

^bSublingual NTG tablets are degraded rapidly by heat, moisture, and light. They should be stored in a cool, dry place; do not leave the lid open or refrigerate. Tablets should be stored in the original manufacturer's container or a glass vial because the tablets volatilize and bind to many plastic vials and cotton. Previously, stinging of the tongue was an indicator of fresh tablets, but newer formulations only cause stinging in ~75% of patients.

^cDuration after infusion discontinued.

^dLonger-acting forms of nitrates are effective drugs, but it is important to understand their limitations to optimize effectiveness. Sublingual isosorbide dinitrate (ISDN) tablets display an onset and duration intermediate between that of sublingual NTG and oral ISDN. Because of high presystemic (1st-pass) metabolism of the oral forms of both NTG and ISDN, very large doses may be required compared with SL or chewable dosage forms. Small oral doses (2.5 mg NTG, 5 mg ISDN) are probably not effective; doses as large as 9 mg NTG and 60 mg ISDN are not uncommon. Despite claims for longer activity, ointments and oral forms are often only effective for 4–8 hr, even when given as SR preparations. Also, continued daily use leads to rapid development of tolerance (see f).

^eSqueeze 1" to 2" of ointment onto the calibrated paper enclosed in the package with tube. Carefully spread the ointment on chest in a thin layer ~2"–2" in size. Keep area covered with applicator paper. Wipe off previous dose before adding new dose or if hypotensive. If another person applies the ointment, avoid contact with fingers or eyes to prevent headache or hypotension.

^fDosage regimens should maintain a nitrate-free interval (e.g., bedtime) to decrease tolerance development. Give last oral dose or remove ointment or transdermal patch at 7 P.M. Give last dose of SR ISDN in early afternoon.

^gISDN, isosorbide dinitrate.

^hISMN, isosorbide monohydrate, major active metabolite of ISDN; 100% bioavailable; no first-pass metabolism, but tolerance may still occur. Rapid release (ISMO, Monoket) as 10- and 20-mg tablets. SR form (Imdur) as 60-mg tablets. OK to cut Imdur in half, do not crush or chew.

PATIENT INSTRUCTIONS

11. What instructions should J.P. receive with regard to the use and storage of sublingual NTG? How rapidly will sublingual NTG relieve J.P.'s chest pain?

When angina occurs, J.P. should sit down immediately and place the NTG tablet under his tongue; he should not swallow it. Many patients experience dizziness and lightheadedness, which is minimized by sitting. The onset of action is within 1 to 2 minutes, and pain usually is relieved within 3 to 5 minutes. If he needs more than one tablet, he can take a maximum of three tablets over 15 minutes. If the pain persists or is unimproved 5 minutes after the first dose of NTG, the patient should call 9-1-1 as they may be experiencing an MI.^{11,12}

The tablets should be dispensed in the original, unopened manufacturer's container and stored in the original brown bottle. Because sublingual NTG tablets are degraded by heat, moisture, and light, they should be stored in a cool, dry place, but not refrigerated. The bottle should be closed tightly after each opening. Safety caps are not necessary, although patients should be cautioned to keep all medications out of the reach of children. The cotton plug sometimes is difficult to remove. Therefore, it should be discarded on initial receipt of the prescription and should not be replaced. Use of cotton other than that supplied by the manufacturer should be discouraged because NTG tablets are volatile and are adsorbed by household cotton. This results in a significant loss in tablet effectiveness. Expiration dating should be monitored closely, and tablets should be replaced immediately if they are exposed to excessive light, heat, moisture, or air. Once a container is opened, the tablets should be used for only a limited time—usually from 6 months to 1 year.⁴⁹ A tablet left out of the bottle on a table will lose its effectiveness in just a few hours.

Long-Acting Nitrates

12. J.P. does well over the next several months, but he is still bothered by occasional angina episodes, ranging from one to four times per week. He was changed to the translingual spray form of NTG (0.4 mg/spray) because he had difficulty with storage of the tablets. The attacks usually are precipitated by strenuous work and are relieved by rest and two or three NTG sprays. The quality and location of the pain are unchanged, although the duration has increased by 1 or 2 minutes. He follows a low-cholesterol, no-added-salt diet.

Physical examination is unchanged except for a 20-lb weight loss. Vital signs include the following: supine BP, 119/76 mmHg; heart rate, 65 beats/minute; and respiratory rate, 12 breaths/minute. J.P.'s cardiologist elected to start a long-acting prophylactic nitrate (isosorbide mononitrate) as well as continuing his β -blocker and angiotensin-receptor blocker (ARB) therapy. What therapeutic endpoints should be used to evaluate the efficacy of long-acting nitrates? Could a CCB have been used instead of the long-acting nitrate?

Long-acting nitrates occupy a key role in the prevention of angina of all types. Their mechanism of action is the same as that of short-acting NTG. The goals of therapy are to decrease the number, severity, and duration of J.P.'s anginal attacks.

A CCB could be prescribed for J.P. instead of isosorbide mononitrate because he has no contraindications to this class

of drugs. A CCB would have been a good alternative if his BP had remained elevated, but for now, J.P.'s BP and pulse are within a desired range. Because sublingual nitrates were well tolerated by J.P., a long-acting nitrate would be acceptable. A CCB (e.g., amlodipine) is an alternative as long as J.P.'s BP is not unduly decreased by this combination of drugs. Ultimately, the decision is based on the prescriber's personal choice and past experience, as well as the entire spectrum of the patient's disease complex.

Nitrate Tolerance

13. Will J.P. develop tolerance to the long-acting nitrate?

Early evidence for the development of nitrate tolerance and dependence came from the munitions industry. Workers in this industry were constantly exposed to NTG and ethylene glycol dinitrate, components of explosives.⁵⁰ Tolerance can develop in as few as 24 hours after continuous exposure to nitrate preparations, however, the degree of tolerance may be variable in terms of percentage of efficacy lost. Tolerance can be limited by maintaining a nitrate-free interval of about 10 to 12 hours daily. Nitrate dosing schedules should be arranged to permit a nitrate-free interval during which time the patient may receive angina protection from β -adrenergic blockers or CCB. Most often, this nitrate-free interval is arranged during the night because angina is more likely to occur during the work day. Patients with nocturnal angina should arrange their nitrate-free interval during the day.⁵¹ Because long-acting nitrates must be dosed intermittently to avoid tolerance, metoprolol therapy will provide J.P. with continuous protection, even during the nitrate-free interval. Although J.P. uses a long-acting nitrate, he still will respond favorably to sublingual NTG. No evidence indicates that use of long-acting nitrates leads to resistance or tolerance to the effects of sublingual NTG.

MECHANISM OF ACTION

14. What is the mechanism of action for nitrate tolerance?

Several mechanisms of nitrate tolerance have been proposed, including the depletion of sulfhydryl groups, which are necessary for the biotransformation of nitrate to NO; neurohormonal activation; plasma volume expansion; and abnormalities in NO signal transduction. More recent investigations, however, have identified that chronic nitrate administration produces a state of oxidative stress, leading to dysfunction of mitochondrial aldehyde dehydrogenase, which is the enzyme responsible for biotransformation of nitrates to NO.^{52,53}

One potential consequence of this current theory is that long-term administration of organic nitrates, by producing neurohormonal activation and endothelial dysfunction, may have long-term detrimental effects. Further research is needed to confirm this hypothesis for nitrate tolerance and its long-term consequences on patient outcomes.⁵⁴

INTERMITTENT APPLICATION OF TRANSDERMAL NITROGLYCERIN

15. Are all nitrate delivery systems capable of inducing nitrate tolerance? How can tolerance be minimized?

All organic nitrates exhibit similar hemodynamic effects through a common pharmacologic mechanism; yet, the differing pharmacokinetic profiles of the nitrate delivery systems lead to a variation in the development of tolerance.⁴⁹

Short-acting formulations (e.g., sublingual NTG, oral NTG spray, and sublingual isosorbide dinitrate) are not likely to induce tolerance given their rapid onset of action and short duration of effect. Oral nitrates and transdermal products, both having an extended duration of action, are likely to induce tolerance.

Intermittent application of transdermal NTG can limit tolerance development in patients with both chronic stable angina and HF. The effects of continuous (24 hours/day) and intermittent (16 hours/day) transdermal NTG (10 mg/day) were compared in 12 men with chronic stable angina who also were being treated with β -blockers or CCB.⁵⁵ Nitrate efficacy was maintained with intermittent treatment and an 8-hour nitrate-free interval. Tolerance to the antianginal effects occurred, however, with continuous transdermal NTG treatment. Twelve-hour intermittent patch therapy also prevents tolerance.⁵⁶ The minimal time necessary for a nitrate-free interval is unknown.

Intravenous (IV) NTG, a cornerstone therapy in management of patients with unstable angina and severe HF, is associated with nitrate tolerance if it is administered as a sustained infusion. The immediate hemodynamic benefits observed with NTG infusions in patients with severe chronic heart failure were greatly reduced 24 to 48 hours after continuous IV therapy. Tolerance to IV NTG was prevented by infusing NTG for only 12 hours followed by a 12-hour nitrate-free interval.⁵⁷ Intermittent NTG infusions for patients with unstable angina appear reasonable, but have not been fully evaluated.

Isosorbide Dinitrate

16. J.P. ultimately receives a prescription for oral isosorbide dinitrate (Isordil) 30 mg three times daily (TID). How should he be instructed to take his medication so that he is nitrate free for 10 to 12 hours?

Despite the availability of nitrate preparations that can be dosed once or twice a day (isosorbide mononitrate), oral isosorbide dinitrate is still commonly used in the treatment of angina. J.P. should take his oral nitrate at 7 AM, noon, and 5 PM because his exercise-induced angina is likely to occur during daylight hours. He may need to adjust this schedule if he arises earlier than 7 AM because early-morning angina is common. Some physicians prescribe isosorbide dinitrate twice a day at 7 AM and noon for patients with less severe anginal syndrome.

17. Does isosorbide mononitrate offer any distinct advantages over other nitrate preparations for angina prophylaxis?

Isosorbide mononitrate (ISMO, Monoket, and Imdur) is the primary metabolite of isosorbide dinitrate. In fact, most of the clinical activity of isosorbide dinitrate is due to the mononitrate. Therefore, both drugs share a similar pharmacology. Isosorbide mononitrate does not undergo first-pass metabolism and has no active metabolites. Its oral bioavailability is almost 100%, and its overall elimination half-life is about 5 hours.⁴⁹ Maximal serum concentrations are observed 30 to 60 minutes after a dose. To minimize the potential development of nitrate tolerance, isosorbide mononitrate should be used in a twice-daily, asymmetric dosing regimen in which the first dose is taken on awakening and the second dose about 7 hours later. Because of this unconventional dosing pattern and the avail-

ability of the sustained-release (SR) product, which can be taken once a day, most use of isosorbide mononitrate is in the form of the SR preparation (Imdur).

General precautions and adverse reactions for isosorbide mononitrate are similar to those for the other nitrates. Potential advantages for the clinical use of isosorbide mononitrate are less dosage fluctuation because of the absence of presystemic clearance and an effective once- or twice-daily dosing schedule, which could perhaps lead to improved patient dosing adherence. Nevertheless, isosorbide dinitrate is effective clinically when administered two or three times a day and is a viable alternative.

Transdermal Patches

18. J.P. likes the idea of using topical nitrates instead of an oral agent. Are the transdermal patches a viable alternative?

Transdermal NTG patches originally were designed to provide angina protection with once-daily application. The concept of a compact, easy-to-apply transdermal NTG patch prompted pharmaceutical manufacturers to design a number of products, which the U.S. Food and Drug Administration (FDA) subsequently approved based on plasma level data, not clinical efficacy studies. Subsequently, the shortcomings of plasma level data have become apparent and prompted numerous clinical efficacy studies.

Transdermal NTG therapy has been shown to increase exercise duration and maintain an anti-ischemic effect for 12 hours after patch application. These beneficial responses remained consistent throughout 30 days of therapy. No significant nitrate tolerance or rebound was noted when the patch was applied for not more than 12 of 24 hours.⁴⁹

Although the various patches use different pharmaceutical delivery systems, clear-cut advantages of one over another are not apparent. Despite variations in surface area and NTG content, the most important common denominator of the transdermal NTG systems is the amount of drug released per hour expressed as the release rate (e.g., 0.2 mg/hour). Each product label includes this information. Low dosages (0.2 to 0.4 mg/hour) may not produce sufficient plasma and tissue concentrations to produce a clinically significant effect³; however, it is still recommended to start with a low-dose patch and titrate upward as needed. Because the skin is the major factor influencing NTG absorption rate, product release characteristics do not favor one system over another. Contact dermatitis has been reported with the transdermal patches. Patient instructions are included with the patches and should be reviewed with the patient, emphasizing the appropriate time for application and removal of the patch.

Adrenergic Blockers

MECHANISM OF ACTION

19. T.I. has a 5-year history of chronic stable angina. Cardiac catheterization 3 months ago showed two-vessel coronary artery disease with obstructions of 55% and 65% in the right coronary and circumflex coronary arteries, respectively. Despite appropriate use of sublingual NTG tablets (0.4 mg) and oral isosorbide dinitrate (40 mg at 6 AM, noon, and 5 PM), T.I. is having four to five angina attacks per week. His physician writes a prescription

for atenolol (Tenormin) 50 mg every day. How do β -adrenergic blockers prevent angina?

β -Adrenergic blockers reduce myocardial oxygen demand by decreasing catecholamine-mediated increases in heart rate, BP, and, to some extent, myocardial contractility.^{58–60} As such, β -blockers have been demonstrated to be very effective at reducing anginal symptoms and ischemia, including silent myocardial ischemia.^{1,2} β -Blockers might also favorably affect myocardial metabolism, coronary microvasculature, collateral blood flow, myocardial blood flow, and oxygen-hemoglobin affinity.⁶¹

In patients with chronic angina, current guidelines recommend β -blockers be administered before a nitrate or a CCB when long-term therapy is indicated.^{1,2} Although β -blockers significantly reduce anginal symptoms, increase exercise tolerance, as well as time to ST-segment depression during exercise testing, few randomized controlled trials have assessed the impact of β -blockers on clinical outcomes in patients with chronic stable angina.⁶⁰ Several cohort and case-control studies have demonstrated, however, that β -blockers do improve clinical outcomes, including reductions in mortality in patients with chronic stable angina or CAD.^{62–66} In addition, recent evidence indicates that β -blockers may also slow the progression of atherosclerosis.⁶⁷ In a meta-analysis of clinical trials that compared the three classes of anti-ischemics, differences in long-term mortality were not noted. β -Blockers, however, were more effective in lowering the incidence of anginal episodes.⁶⁸ β -Blockers are generally considered the most effective class of agents at preventing silent myocardial ischemia.³ In addition, β -blockers clearly lower morbidity and mortality in patients with hypertension,⁶⁹ acute MI,^{11,12} and heart failure.⁶⁰ Although mortality benefits have not been demonstrated specifically in patients with chronic angina, the body of literature available supports the recommendation that all patients with angina should receive a β -blocker as initial therapy unless contraindicated.³⁶ (See Chapter 13, Essential Hypertension, and Chapter 18, Heart Failure, for more in-depth information on β -blocker product availability, dosage forms, pharmacology, and dosing.)

Judging Therapeutic Endpoint

20. How can the efficacy of the atenolol be assessed?

All patients receiving antianginal drugs should be monitored for frequency of angina attacks and NTG consumption. Nevertheless, this provides only an estimate of therapeutic efficacy because the patient's exercise and stress levels change from day to day. Traditionally, clinicians have monitored the reduction in resting heart rate and have progressively increased the β -blocker dose until the resting heart rate was 55 or 60 beats/minute. Heart rates <50 beats/minute may be acceptable, provided the patient is asymptomatic and heart block is not present. This approach does not take into account, however, that although the initial β -blocker dose reduces heart rate, subsequent increases in dose may only slightly reduce the resting heart rate. Variations in resting heart rate are normal and subject to the influence of the endogenous sympathetic nervous system and other exogenous factors, such as drugs, tobacco, and caffeine-containing beverages. β -Blockers with intrinsic

sympathomimetic activity (e.g., pindolol) will not reduce the resting heart rate as much as β -blockers lacking this activity.⁵⁹

Exercise testing is probably the most accurate, but least practical method of documenting the adequacy of β -blocker therapy. During an exercise tolerance test, atenolol should substantially increase the time T.I. walks before developing angina. There also may be a reduction in ST-segment depression during exercise, indicating less myocardial ischemia. The heart rate-SBP product probably will be markedly lowered, reflecting a decrease in both heart rate and systolic wall tension.⁵⁸ β -Blocker dosages needed to achieve these effects are highly variable. Therefore, therapy should be initiated with the lowest possible effective dosage and titrated upward. Continuous assessment of T.I.'s exercise tolerance is advisable.

Dosing Frequency

21. Is once-daily dosing of atenolol sufficient to provide T.I. with 24-hour protection? How often should immediate-release propranolol be administered?

The pharmacodynamic effects of β -blockers are longer than their plasma half-lives, and β -blockers can be dosed once or twice a day for angina. The half-life of atenolol is about 10 hours during chronic dosing; however, clinical studies support a once-a-day dosing schedule.⁶¹

Propranolol has a relatively short plasma half-life of 2 to 3 hours, yet clinicians have observed that a single dose lowers the heart rate and BP for at least 12 hours. Subsequent studies have confirmed the efficacy of twice-daily dosing for propranolol in the treatment of angina. (See Chapter 13, Essential Hypertension, for detailed pharmacokinetic and pharmacodynamic discussion of β -blockers.)⁶¹

β -Blocker Cardioselectivity

Contraindications

22. R.O. is a 65-year-old man with a 40-pack-year smoking history and a 13-year history of insulin-dependent diabetes mellitus. His ability to walk is limited by peripheral vascular disease and claudication, as well as by exertional angina. A β -blocker is to be initiated for treatment of chronic angina. Which β -blocker would be preferable for this patient?

Although all β -blockers are equally effective in the treatment of angina, R.O.'s medical history poses several relative contraindications to the use of some β -blockers. His smoking history may have caused some degree of chronic obstructive pulmonary disease (COPD) with a bronchospastic component despite the absence of a medical history. His history of diabetes and peripheral vascular disease will influence the selection of a β -blocker for management of his angina. A cardioselective β -blocker offers several advantages in R.O.⁵⁹ Drugs such as acebutolol (Sectral), atenolol, and metoprolol (Lopressor) primarily inhibit β_1 -receptors in the heart and produce less blockade of β_2 -receptors in the bronchial and vascular smooth muscle. In patients with asthma and obstructive lung disease, β_2 -receptors mediate airway responsiveness and blockade of β_2 -receptors can cause severe bronchospasm and respiratory difficulty. In one meta-analysis, cardioselective β -blockers were not found

to produce clinically significant adverse respiratory effects in patients who had mild to moderate reactive airway disease.⁷⁰

Cardioselective β -blockers also are less likely to inhibit β_2 -mediated vasodilation in the peripheral arterioles. Therefore, cardioselective β -blockers are preferred over nonselective β -blockers for patients with peripheral vascular disease and Raynaud's disease. Blockade of peripheral β_2 -receptors would permit unopposed α -mediated vasoconstriction and could decrease R.O.'s walking tolerance markedly.

Although β -blockers can alter glucose metabolism and mask the symptoms of hypoglycemia, their use has clearly been demonstrated to lower overall mortality in diabetic patients after acute MI.^{11,12} In addition, diabetic patients in general develop more severe CAD and overall have a worse prognosis than patients without diabetes. Because of the significant beneficial effects on mortality with β -blockers, diabetes should not be considered a contraindication to β -blocker therapy.

Adverse Effects

23. If R.O. receives a cardioselective β -blocker, could he still experience more difficulty breathing or walking?

Cardioselectivity is not an all-or-none response; instead, it is a dose-dependent phenomenon. As the dose is increased, cardioselectivity is lost. The dose at which cardioselectivity will be lost in R.O. cannot be predicted, however; even a very small dose (e.g., metoprolol 37.5 mg) could cause wheezing.^{59,61} Some evidence suggests that atenolol may have a larger window of dosing than metoprolol before cardioselectivity is lost. Similarly, a cardioselective drug could worsen R.O.'s claudication. If R.O. experiences worsening control of COPD or peripheral vascular disease, a better alternative may be a CCB either alone or with intermittent nitrate therapy.

Abrupt Withdrawal

24. J.F., a 76-year-old retiree with a long history of chronic stable angina controlled with oral isosorbide mononitrate 90 mg every day, and atenolol 100 mg every day, stopped his atenolol 36 hours ago when he forgot to get his prescriptions refilled. He is transported to the hospital emergency department (ED) for treatment of angina unresponsive to five NTG tablets. How could J.F.'s situation have been avoided?

The β -blocker withdrawal syndrome places patients with CAD at high risk for adverse cardiovascular events, which may include acute MI and sudden cardiac death. After J.F.'s angina has been controlled with medications during this particular hospitalization and before reinstitution of β -blocker therapy, he should be warned not to precipitously discontinue his β -blockers in the future. Failure to renew prescriptions and financial hardship are common reasons for abrupt discontinuation, and clinicians need to have sufficient professional rapport with patients to understand when patients encounter difficulties in obtaining medications.

The β -blocker withdrawal syndrome is a rebound phenomenon resulting from heightened β -receptor density and sensitivity (i.e., upregulation) subsequent to receptor blockade. An "overshoot" in heart rate, as a consequence of sympathoadrenal activity from abrupt β -blocker withdrawal increases myocardial oxygen demand and platelet aggregation. Withdrawal

syndromes may be less severe in patients taking β -blockers with partial agonist activity.^{56,58}

If β -blockers are to be discontinued, a gradual tapering schedule (preferably over 1 to 2 weeks) should be used. Shorter periods for β -blocker withdrawal (e.g., 2–3 days) have been proposed, although the optimal strategy for discontinuation is not known. Ensuring that β -blockers are tapered and that the patient is reasonably monitored for adverse events for the duration of the taper is imperative. Patients should limit physical activity throughout the β -blocker withdrawal period and seek prompt medical attention when angina symptoms become apparent.

Calcium Channel Blockers

Classification

Calcium channel blockers are highly diverse compounds. They differ markedly in chemical structure as well as specificity for cardiac and peripheral tissue. Using these characteristics, it is possible to classify calcium antagonists into several major types (Table 16-5).^{71,72}

Both diltiazem and verapamil exert qualitatively similar effects on myocardial and peripheral tissue. They slow conduction and prolong the refractory period in the AV node. Ventricular refractory period is not affected. Therefore, the antiarrhythmic utility of these drugs is limited to controlling the ventricular rate in supraventricular tachyarrhythmias. Both agents can depress myocardial contractility and should be used with caution in patients with LV dysfunction (heart failure). They are moderate peripheral vasodilators and potent coronary artery vasodilators.^{71,72}

Nifedipine is the prototype compound of the dihydropyridine derivatives. Although amlodipine, felodipine, isradipine, and nicardipine are second-generation dihydropyridines, only nicardipine and amlodipine currently are approved for the treatment of chronic stable angina pectoris. In addition, amlodipine is indicated for vasospastic angina. In contrast to diltiazem or verapamil, the dihydropyridines do not slow cardiac conduction and, therefore, have no antiarrhythmic action. They, however, are more potent peripheral vasodilators and are associated with a reflex increase in the heart rate. All dihydropyridines have negative inotropic effects in vitro, but these effects, clinically, are overshadowed by the reflex sympathetic activation and decreased afterload. The net effect of these actions essentially results in no depression of myocardial function (see Chapter 18, Heart Failure).^{71,72} The dihydropyridines also can dilate coronary arteries, but vary in their potency.

Pharmacology

Depending on the agent, CCBs decrease myocardial oxygen demand and increase myocardial blood supply.^{71,72} By inhibiting smooth muscle contraction, CCBs dilate blood vessels and decrease resistance to blood flow. Dilation of peripheral vessels reduces systemic vascular resistance and BP, thus decreasing the work load of the heart. Coronary artery dilation improves coronary blood flow. Diltiazem and verapamil also decrease the myocardial contractile force (negative inotropic effect) as well as heart rate. All these actions can reduce angina symptoms.

Table 16-5 Calcium Channel Blockers in Anginal Syndromes^a

| Drug Name | FDA Approved ^a | Usual Dose for Chronic Stable Angina ^b | Product Availability ^c |
|----------------------------|-----------------------------------|--|--|
| Dihydropyridines | | | |
| Amlodipine | Angina, hypertension | 2.5–10 mg QD | 2.5, 5, 10 mg tab |
| Felodipine | Hypertension | 5–20 mg QD | 5, 10 mg ER tab |
| Isradipine | Hypertension | 2.5–10 mg BID 5–10 mg QD | 2.5, 5 mg IR cap 5, 10 mg CR tab |
| Nicardipine | Angina (IR only), Hypertension | 20–40 mg TID 30–60 mg BID | 20, 30 mg IR cap 30, 45, 60 mg SR cap |
| Nifedipine | Angina, Hypertension | 10–30 mg TID 30–180 mg QD | 10, 20 mg IR cap 30, 60, 90 mg ER tab |
| Nisoldipine (Sular) | Hypertension | 20–60 mg QD | 10, 20, 30, 40 mg ER tab |
| Diphenylalkylamines | | | |
| Verapamil | Angina, hypertension, SVT | 30–120 mg TID/QID 120–240 mg BID 120–480 mg Q HS | 40, 80, 120 mg IR tab 120, 180, 240 mg SR tab 180, 240 mg DR, ER tab 120, 180, 240, 360 mg ER cap 100, 200, 300 mg DR, ER tab |
| Benzothiazepines | | | |
| Diltiazem | Angina, hypertension, SVT | 30–120 mg TID/QID 60–180 mg BID 120–480 mg QD | 30, 60, 90, 120 mg IR tab 60, 90, 120, 180 mg SR cap 120, 180, 240, 300, 360 mg cap 120, 180, 240 mg ER cap 120, 180, 240, 300, 360, 420 mg ER cap |

^aFDA-approved indications vary among IR and ER products. However, most all have been used clinically for both angina and hypertension. Avoid IR release products in hypertension.

^bBecause of short half-lives, most of these drugs are given TID if using IR tabs or caps. Amlodipine has a long half-life and is given PD.

Also see Tables 14-15 and 14-16 in Chapter 14: Essential Hypertension.

Cap, capsules; CD, controlled diffusion; CR, controlled release; DR, delayed release; ER, extended release; FDA, U.S. Food and Drug Administration; HS, bedtime; IR, immediate release; Q, every; QID, four times a day; SR, sustained release; SVT, supraventricular including atrial fibrillation, atrial flutter, and reentry; Tab, tablets; XL and XR, extended release.

Potent arterial (peripheral) vasodilators, such as nifedipine, markedly reduce peripheral vascular resistance,⁷¹ and reflexively stimulate the sympathetic nervous system to cause a slight to moderate increase in heart rate and perhaps increase myocardial oxygen demand (Table 16-6). The cardiodepressant effect of verapamil- and diltiazem-like drugs prevents reflex tachycardia. Verapamil and diltiazem are more likely to worsen ventricular function in patients with HF secondary to systolic dysfunction.⁷² Two dihydropyridines, amlodipine and felodipine, have been studied in the setting of LV dysfunction and found to be relatively safer than other calcium blockers in heart failure, but have a negligible effect on mortality.⁷¹ Therefore, these two drugs are available options in patients with HF who have other disease states that would benefit from CCB therapy. Diltiazem and verapamil should be avoided in HF. Individualization of CCB therapy must consider the drug's overall pharmacologic effect and side effect profile.

Indications for Use

25. B.N., a 56-year-old man, has just undergone cardiac catheterization, which showed two-vessel CAD. He refuses to take nitrates because they cause severe headaches. His medical history includes asthma and hyperlipidemia. His physician

begins antianginal therapy with oral diltiazem 120 mg every day. Are the calcium channel blockers indicated for all types of angina?

Calcium channel blockers are effective in both vasospastic and classic exertional angina. These drugs relieve vasospasm of the large coronary arteries and, as a result, are effective in treating Prinzmetal's variant angina. Their beneficial effect in chronic stable (effort-induced) angina is the result of multiple factors. Their vasodilatory effects in the coronary circulation increase myocardial oxygen supply, whereas dilation of the peripheral arterioles leads to a reduction in myocardial oxygen demand. Because coronary vasospasm can occur at the site of an atherosclerotic plaque, a CCB is particularly useful in patients who have a vasospastic component to their angina.

Although β -blockers are considered the drugs of choice when instituting antianginal therapy, recent data indicate that the selection of a heart rate-lowering CCB may also be a reasonable first-line choice as well. Calcium channel blockers and β -blockers appear to provide equivalent efficacy in head-to-head trials of chronic stable angina.^{73,74} In addition, the available head-to-head trials with sufficient numbers also suggest that CCBs and β -blockers produce similar effects on cardiovascular outcomes and mortality in patients with chronic stable angina.^{75,76} In addition, several recent trials in the setting of hypertension have demonstrated that CCBs can produce meaningful reductions in mortality.^{77–79} It would appear that either

Also see Tables 13-15 and 13-16 in Chapter 13: Essential Hypertension.

^aDihydropyridine derivatives U.S. Food and Drug Administration (FDA) approved for angina: amlodipine (Norvasc), nicardipine (Cardene), and nifedipine (Adalat, Procardia). See Table 13-6 for others that are approved for hypertension but have been used clinically for angina. Investigational: nitrendipine (Baypress).

^bPeripheral and coronary vasodilation helpful for angina, hypertension, and possibly HF, but peripheral dilation is the basis for side effects of flushing, headache, and hypotension.

^cAtrioventricular (AV) node suppression is helpful for controlling supraventricular arrhythmias, but this property plus the negative inotropic effect may worsen HF. Nifedipine has less negative inotropic effect than verapamil and diltiazem, but still may worsen HF. Amlodipine may have the least negative inotropic effect.

^dAll have poor bioavailability owing to high first-pass metabolism and all are eliminated primarily by hepatic metabolism; intra- and interindividual variability in bioavailability and metabolism is extensive. Diltiazem, nifedipine, nicardipine, and verapamil have short half-life (<5 hr) requiring frequent dosing or use of sustained release (SR) products. Amlodipine, isradipine (8 hr), and felodipine (10–20 hr) have longer half-life.

^eSee Table 13-6 and Tables 13-16 in Chapter 13: Essential Hypertension.

^gHypotension and reflex tachycardia most with immediate release nifedipine, occasional with immediate-release diltiazem and verapamil, minimal with sustained release products or intrinsically long-acting agents.

^hDiltiazem and verapamil, weak CYP 3A4 inhibitors and strong P-glycoprotein inhibitors. Increase cyclosporine and digoxin bioavailability via increased gastrointestinal (GI) transport and possibly less gut metabolism. Case reports of cyclosporine renal toxicity when combined with diltiazem. Bradycardia and heart failure risk with combined verapamil and digoxin via additive AV block and negative inotropic effects. Risk of interaction with drugs metabolized by CYP 3A4 not known.

a heart rate-lowering CCB, or a β -blocker, may be considered relatively equal options and initial therapy for chronic stable angina. The selection of a particular class will likely be dictated by patient characteristics.

In the case of B.N., his asthma may be worsened by the addition of a β -blocker. Although a cardioselective β -blocker could be tried to see if B.N. could tolerate it, a heart rate-lowering CCB is a good alternative to a β -blocker for the treatment of angina in this situation. The choice of a CCB as initial therapy in this patient is appropriate because of B.N.'s previous intolerance to nitrates and because nitrate therapy requires the scheduling of a nitrate-free period.¹ Patients with significant peripheral arterial disease, or demonstrated exercise intolerance to β -blockers, are also likely good candidates for CCB monotherapy for chronic angina. For patients with a history of MI or who have HF, β -blockers would likely be preferred because of the substantial literature demonstrating improved outcomes in these patient populations. In the absence of any patient-specific characteristics to help guide selection, it is pertinent to recognize that current guidelines still recommend β -blockers as the primary initial antianginal therapy.^{1,2}

Although the selection of a heart rate-lowering CCB may be generally preferred, the distinct pharmacologic and adverse event profiles of the various classes may also help dictate agent selection. Some side effects of CCBs reflect an extension of their hemodynamic and electrophysiologic profiles and, there-

fore, are predictable (Table 16-6). Dihydropyridine-induced hypotension and dizziness occur in approximately 15% of patients. Patients also may complain of light-headedness, facial flushing, headache, and nausea. Swelling of the lower legs and ankles (peripheral edema) is related to the potent peripheral vasodilating effects of these agents. Verapamil and diltiazem have similar side effect profiles, although diltiazem appears to be better tolerated. The lower incidence of side effects reported with diltiazem, compared with verapamil, may reflect a true difference or, perhaps, less aggressive dosing regimens. Both drugs can cause sinus bradycardia and worsen already existing conduction defects and heart block.⁶⁵ Neither should be used in patients with sick sinus syndrome or advanced degrees of heart block unless a functioning ventricular pacemaker is present. Patients should be monitored for signs of worsening HF, such as SOB, weight gain, and peripheral edema. Verapamil-induced constipation can be particularly troublesome to the elderly. Rare instances of fecal impaction requiring surgery illustrate the need for the aggressive use of stool-softening agents and, often, bulk-forming laxatives.

Generalized fatigue and nonspecific gastrointestinal (GI) complaints can occur with any of the calcium channel blockers. In rare instances, elevations of hepatic enzymes and acute hepatic injury have occurred with CCBs. Appreciation for the individual side effect profiles helps determine preference for one CCB over another. B.N. is not likely to experience major side effects with either verapamil or diltiazem.

Pharmacokinetics

26. Do any of the calcium channel blockers require dosage adjustment in patients with renal or hepatic disease?

Currently available calcium channel antagonists demonstrate similar pharmacokinetic properties.⁷¹ With the exception of amlodipine and the SR formulations, all are absorbed rapidly after oral administration and generally reach peak concentrations within 1 to 2 hours. Peak concentrations for amlodipine usually are achieved within 6 to 9 hours after administration. Although calcium channel antagonists are well absorbed, bioavailability generally is low owing largely to first-pass metabolism. In addition, calcium channel antagonists tend to have high metabolic clearances; their pharmacokinetic parameters are related to hepatic blood flow and intrinsic clearance, and they are metabolized almost exclusively by the liver. Furthermore, intraindividual and interindividual variations in bioavailability and total body clearance for most calcium channel antagonists are great. Therefore, dosage adjustment probably is necessary in patients with severe hepatic impairment, but not in those with renal disease.

Sustained-Release Calcium Channel Blockers

27. L.M., a 45-year-old female surgeon with a 3-year history of hypertension, recently was switched to sustained release verapamil 240 mg BID. As newly diagnosed with chronic stable angina, she wonders if studies support the use of SR calcium channel blockers in angina.

Nifedipine, diltiazem, and verapamil all were originally introduced into the United States as immediate-release preparations. As a consequence, dosing regimens called for TID or four times daily (QID) administration. SR CCBs are attractive alternatives to immediate-release products. The SR formulations of verapamil, diltiazem, and nifedipine offer promise in improving patient drug adherence and, thereby, better control of anginal episodes. L.M. uses the first SR CCB marketed in the United States. SR verapamil is absorbed more slowly than immediate-release verapamil, thus providing more constant serum levels. The SR formulation, with a bioavailability of 0.9, extends the verapamil elimination half-life to 12 hours compared with about 6 hours observed with the immediate-release product.⁸⁰ Although some patients experience adequate control with once-daily SR verapamil, most patients require twice-daily dosing.⁶⁷ Another SR verapamil product (Verelan) uses beaded capsules and can be dosed reliably once a day. Therefore, SR verapamil and Verelan should not be interchanged. The side effect profiles for immediate-release and SR verapamil are similar, with constipation being frequent.

Diltiazem SR also exhibits slowed absorption and a prolonged half-life compared with immediate-release diltiazem. As with verapamil SR, twice-daily dosing of diltiazem SR is appropriate for most patients. A newer version of SR diltiazem (Cardizem CD available as 180-, 240-, and 300-mg capsules) may be given once daily. It is important that the Cardizem SR and Cardizem CD products are not confused. Another SR diltiazem product (Dilacor SR) uses yet another delivery system. Although verapamil SR and diltiazem SR and CD are FDA approved for treatment of hypertension only, many clinicians use these drugs to treat angina.

Sustained-release nifedipine (Procardia XL) uses a unique drug delivery system based on the osmotic pump principle. The GITS (GI system) nifedipine tablet consists of a semipermeable membrane that surrounds an active drug core. The core is composed of two layers: an active drug layer and an inert, but osmotically active push layer. Water entering the tablet from the GI tract activates the osmotic pump mechanism and pushes the active nifedipine out through a laser-drilled hole in the tablet's active layer. The inert components eventually are eliminated in the feces as a shell. The tablet should not be crushed, divided, or chewed. It should be taken at the same time each day and may be taken either with food or on an empty stomach.

The GITS nifedipine provides consistent (zero order rate), 24-hour serum nifedipine levels independent of pH or GI motility. Although this formulation decreases the vasodilatory effects observed with immediate-release nifedipine, dose-related edema is a common adverse experience occurring in 10% to 30% of patients. Headache is another common adverse effect. Limited experience suggests that patients switched from immediate-release nifedipine to GITS nifedipine will experience fewer angina episodes and side effects. Another form of extended-release tablets (Adalat CC) can be administered once daily and appears to be therapeutically equivalent to GITS nifedipine. Nevertheless, when patients are converted to any SR CCB, reassessment of therapeutic efficacy is necessary. Because variations in SR products exist, they should not be substituted for one another without prior approval and patient counseling. The cost of the SR CCB is similar to the equivalent immediate-release doses. At one time, the use of generic immediate-release products was considered a cost-saving alternative, but now generic SR products are marketed as well.

Any of the SR preparations of nifedipine, verapamil, or diltiazem are reasonable choices for patients with chronic stable angina. Immediate-release preparations of CCBs should be reserved for situations in which rapid titration of the dose is needed or desired, such as in patients with supraventricular arrhythmias. As stated, use of immediate-release nifedipine should be discouraged in any situation owing to the risk of reflex sympathetic drive and potential precipitation of myocardial ischemia. (See Chapter 13, Essential Hypertension, for further discussion of SR dosage forms of calcium channel blockers.)

Ranolazine

Approved by the FDA in early 2006, ranolazine is the first new antianginal agent marketed in nearly 20 years. The need for additional agents to modify and treat myocardial ischemia is illustrated by the fact that many patients have contraindications to one or more traditional antianginal agents, or may not tolerate larger therapeutic doses of a specific drug used as monotherapy. Others may have intolerance to the additive hemodynamic effects of combination therapy, as well as incomplete relief of symptoms from revascularization therapy. For example, despite the effectiveness of PCI at relieving symptoms of angina, 10% to 25% of patients still have angina and 60% to 80% require antianginal therapy 1 year after the procedure.^{81,82} Therefore, a need clearly exists for new antianginal agents to complement existing pharmacologic and revascularization strategies.

Mechanism of Action

Unlike traditional antianginal agents, such as β -blockers, CCBs, and long-acting nitrates, ranolazine does not have any appreciable effects on heart rate, arterial resistance vessels, the inotropic state of the myocardium, or coronary blood flow. When administered clinically, no changes in blood pressure or heart rate are observed.⁸³ As such, ranolazine does not affect myocardial oxygen supply or demand in the traditional sense. Early preclinical work identified inhibition of fatty acid oxidation as the probable mechanism for antianginal efficacy.^{84,85} Subsequent investigations revealed, however, that these effects only occur at plasma concentrations of ranolazine substantially higher than those obtained with current approved doses.^{86,87} It is now known that ranolazine's anti-ischemic effects are modulated through inhibition of the late sodium current (I_{Na}).^{16,83} By inhibiting late sodium entry, and hence calcium overload during ischemia, ranolazine effectively inhibits the consequences of ischemia such as decreased microvascular perfusion, as well as increased myocardial oxygen demand. This novel mechanism of action offers the possibility of complementary effects when added to more traditional antianginal agents which act through their hemodynamic actions.

Pharmacokinetics and Dosing

Initial investigations of ranolazine involved an immediate-release product that necessitated three times/day dosing. Because of the short half-life of the parent drug, the peak-to-trough ratio in clinical studies were suboptimal, with significant loss of therapeutic efficacy at the end of the dosing interval.⁸⁸⁻⁹¹ Consequently, ranolazine is marketed as an extended-release tablet formulation that should be dosed twice daily. Maximal plasma concentrations are observed 4 to 6 hours after administration of the extended-release formulation with a terminal half-life of 7 hours. With twice-daily dosing of the extended-release preparation, a more favorable peak-to-trough fluctuation of 1.6 is observed.⁸³ Steady-state is typically reached within 3 days and oral bioavailability is in the 30% to 55% range. Ranolazine is primarily metabolized by the liver through cytochrome P450 (CYP) 3A4 (70%–85%), and CYP2D6 (10%–15%). Ranolazine also is a substrate for P-glycoprotein.^{16,83} Patients should initially be started at an oral dose of 500 mg twice daily, which can be titrated up to a maximal dose of 1,000 mg twice daily.

Place in Therapy

28. A.E., a 65-year-old man, has been treated for chronic angina pectoris for 4 years. He refuses cardiac catheterization and revascularization; however, his coronary risk factors include a strong family history of cardiovascular disease and hyperlipoproteinemia. He experienced rheumatic fever at age 12; 5 years ago, his mitral valve was replaced. At that time, he had two-vessel CAD with 80% and 85% occlusion and an LV EF of 30% (normal, 55%). Current medications include a prescription for SL nitroglycerin; warfarin 5 mg for 5 days/week and 2.5 mg for 2 days/week; metoprolol 50 mg every day; enalapril 10 mg every day; digoxin 0.125 mg/day (serum digoxin concentration drawn 18 hours after the last dose is 0.7 ng/mL); oral simvastatin 40 mg every day; and furosemide 40 mg/day. At his regular follow-up visit with his cardiologist, A.E. reports an increase in weekly anginal attacks over the last 2 months during his daily routine of working in his yard.

Current vital signs include a blood pressure of 110/60 mmHg and a resting heart rate of 60 beats/minute. What therapeutic options would be available for A.E. for additional control of his chronic stable angina? Would ranolazine be an option?

As discussed, monotherapy for chronic stable angina typically starts with a β -blocker or, in select patients, a heart rate-lowering CCB. These agents are typically titrated up based on both efficacy and tolerance. Once a maximal dose of the initial agent is reached, additional antianginal agents can be added, if needed, for additional symptom control. The choice of which agent to add on is likely dictated by the specific characteristics of the patient. In a patient on a β -blocker who needs additional blood pressure control, the addition of a dihydropyridine CCB would seem prudent. A nondihydropyridine agent may be an option, however, if additional heart rate control is also needed. Conversely, in a patient maximized on β -blocker therapy, with adequate blood pressure control and also a history of heart failure, the addition of a long-acting nitrate may be preferred. Triple therapy with a β -blocker, a CCB, and a nitrate is also an option in patients whose condition is difficult to control, but careful attention must be paid to the additive hemodynamic effects to minimize intolerance.

In the setting of additional antianginal therapy, ranolazine should be considered. Several large, randomized studies with ranolazine have been conducted, all demonstrating it is effective at reducing ischemia and angina when added on to existing therapy. Although not FDA approved as monotherapy in the treatment of chronic stable angina, the Monotherapy Assessment of Ranolazine in Stable Angina (MARISA) trial randomized patients in a crossover fashion who had met screening exercise treadmill criteria to either escalating doses of ranolazine (500 mg BID, 1,000 mg BID, 1,500 mg BID) or placebo. All other antianginal agents, except for SL nitroglycerin, were discontinued before start of the study. Ranolazine significantly increased exercise duration, time to onset of angina, and to 1 mm ST-segment depression during exercise treadmill testing.⁸⁶ Similar results were seen in the Combination Assessment of Ranolazine in Stable Angina (CARISA) trial where ranolazine (500 mg BID, 750 mg BID, 1,000 mg BID) was added onto antianginal monotherapy that consisted of either atenolol 50 mg/day, diltiazem 180 mg/day, or amlodopine 5 mg/day.⁸⁷ The Efficacy of Ranolazine in Chronic Angina (ERICA) trial assessed the effects of ranolazine when added to the maximal dose of an existing antianginal agent, in this case amlodopine 10 mg/day. Importantly, up to one-half of the patients enrolled in ERICA were also on a long-acting nitrate. Patients were randomized to either ranolazine 500 mg/day for 1 week and then had their dose increased to 1,000 mg/day for an additional 6 weeks, or placebo. Patients receiving 1,000 mg/day of ranolazine had a significant reduction in both the number of weekly anginal attacks, as well as the number of SL nitroglycerin tablets used on a weekly basis.⁹² Ranolazine was well-tolerated in the CARISA, MARISA, and ERICA trials with the most common side effects being dizziness, constipation, nausea, and headache. The incidence of adverse effects increased with increasing doses. No other significant adverse effects were noted, although it is important to note the duration of these trials was limited.⁸³

A.E. is at goal heart rate and his blood pressure is well controlled on his current regimen, but he continues to have

Table 16-7 Considerations for the Use of Ranolazine If Patients With Chronic Stable Angina^{16,83}

| Clinical Issue | Recommended Management Strategy |
|---|--|
| Renal insufficiency | Ranolazine plasma levels may increase up to 50%. Caution with dose titration to maximal recommended dose. |
| Hepatic insufficiency | Ranolazine is contraindicated in patients with Child-Pugh Classes A, B, or C hepatic impairment. |
| Drug interactions: Effects on ranolazine | |
| CYP 3A4 inhibitors | Plasma concentrations of ranolazine are significantly elevated when combined with potent inhibitors of CYP3A4. Ketoconazole, diltiazem, verapamil, and other potent or moderately potent inhibitors of CYP 3A4 should not be coadministered with ranolazine. |
| CYP 3A4 inducers | Rifampin coadministration should be avoided owing to significant decreases in ranolazine plasma concentrations. Coadministration with other CYP 3A4 inducers should also be avoided. |
| P-glycoprotein inhibitors | Caution should be exercised when coadministering ranolazine with P-glycoprotein inhibitors. |
| Drug interactions: effects on other medications | |
| Simvastatin | Plasma levels of simvastatin are increased twofold with coadministration with ranolazine through CYP 3A4 inhibition by ranolazine. Closely monitor for adverse effects (e.g., myositis) from simvastatin. |
| Digoxin | Ranolazine coadministration increases plasma concentrations of digoxin by 1.5 times. Adjust dose of digoxin accordingly to maintain desired therapeutic level and response. |
| CYP 2D6 substrates | Ranolazine can inhibit the activity of CYP 2D6 and thus the metabolism of drugs metabolized by this enzyme may be impaired. The dose of these medications may need to be reduced. |
| QTc prolongation | Use of ranolazine is contraindicated in patients with pre-existing QTc prolongation. Use of ranolazine is contraindicated in patients receiving other QTc prolonging medications. |

anginal symptoms. Because of the lack of hemodynamic effects, ranolazine is a reasonable option for A.E., in addition to continuing metoprolol. A long-acting nitrate is also an option, but this could lower his blood pressure more than is desired. A CCB should not be given because A.E. has evidence of poorly controlled heart failure (EF of 30%). His initial dose of ranolazine should be 500 mg orally two times/day and titrated up to 1,000 mg twice daily if needed for additional efficacy.

29. Is ranolazine safe for long-term use in A.E.?

Initial information regarding the safety of ranolazine in patients with longer drug exposure came from the Ranolazine Open Label Experience (ROLE) program,⁹³ which followed patients from the MARISA and CARISA trials who continued participation in an open-label extension program. A total of 746 patients initially entered the 6-year run-on safety program. At the time of publication, the mean duration of therapy was 2.82 years, with 23.3% of patients discontinuing therapy. One-half of the withdrawals were because of adverse events, but the incidence of common adverse effects did not seem to change from that seen in the randomized portions of the clinical trials. Mortality rates at both 1 year (2.8%) and 2 years (5.6%) indicate no adverse risk of ranolazine on overall mortality.

Additional safety data are now available from the Metabolic Efficiency with Ranolazine for Less Ischemia in Non-ST-Elevation Acute Coronary Syndrome (MERLIN)-TIMI 36 trial.⁹⁴ Patients in the MERLIN trial were randomly assigned to ranolazine or placebo in the setting of non-ST-segment ACS. Ranolazine was administered as an IV infusion for 12 to 96 hours, then converted to 1,000 mg twice daily. Patients were assessed for clinical endpoints during the acute hospitalization, then every 4 months thereafter. Treatment was continued for a median of 348 days. The primary endpoint of the trial (cardiovascular death, MI, or recurrent ischemia) trended lower with patients on ranolazine, but was not statistically significant (23.5% placebo, 21.8% ranolazine, $P = 0.11$). The incidence of recurrent ischemia was significantly

reduced, however, with ranolazine (4.2% vs. 5.9%, $P = 0.02$), providing additional support for the efficacy of ranolazine in treating chronic stable angina. Although ranolazine appeared to offer no benefit in the setting of ACS, significant long-term safety data were seen in the trial. Importantly, the risk of mortality, sudden cardiac death, or symptomatic arrhythmias was not increased with ranolazine versus placebo. In fact, the incidence of arrhythmias in the first 7 days as documented by Holter monitor was significantly lower with ranolazine than with placebo.⁹⁵ This was an important finding given ranolazine produces a dose-dependent increase in the QT interval.^{16,83} As QT prolongation activity has been associated with proarrhythmia in other medications, results from the MERLIN trial are reassuring that ranolazine appears to be safe to use for chronic treatment of patients with stable angina.

30. Are there special considerations for the use of ranolazine in A.E.?

Although ranolazine is a promising new option in the treatment of chronic stable angina, careful patient selection is required for the drug to be used safely and effectively. Table 16-7 summarizes significant issues which should be evaluated when the drug is being considered for a patient. For A.E., the main issues are the potential for ranolazine to increase plasma concentrations of both simvastatin (twofold increase) and digoxin (1.5 times increase). A.E. should be monitored closely for possible increased adverse effects from both simvastatin (myalgias, liver toxicity), as well as digoxin (heart block, GI intolerance) after the initiation of ranolazine. The dose of each medication ultimately may need to be decreased.

VASCULOPROTECTIVE DRUG THERAPY

Angiotensin-Converting Enzyme Inhibitors

31. E.R., a 62-year-old woman with a long history of angina pectoris, has survived one out-of-hospital cardiac arrest and two

MIs. She is not considered a surgical candidate for CABG because of severe COPD. Her current medications include oral isosorbide mononitrate 60 mg every day, oral metoprolol 50 mg BID, oral diltiazem CD 240 mg every day, fluticasone two puffs BID, albuterol two puffs as needed (PRN), NTG spray 0.4 mg PRN chest pain, and enteric-coated aspirin 325 mg/day. Would the addition of an ACE inhibitor be beneficial for E.R. at this time?

Historically, ACE inhibitors have not been thought of as having anti-ischemic properties. Recent information indicates, however, that ACE inhibitors have a prominent role in the overall treatment of patients with CAD.

As a class, ACE inhibitors have demonstrated significant benefits on morbidity and mortality in a number of patient groups, such as those with HF, acute MI, and diabetes mellitus.⁹⁶ Interest in these agents for the treatment of chronic angina stems from results of studies investigating ACE inhibitors in patients with HF. Overall, ACE inhibitors decreased the risk of MI by approximately 23% in patients with HF.^{97,98} This set the stage for the investigation of ACE inhibitors in patients with CAD who do not have LV dysfunction or who are status post MI.

In a large, randomized, placebo-controlled trial of 9,297 patients with chronic CAD and no HF (the HOPE study), ramipril significantly decreased the incidence of death, MI, stroke, need for revascularization, and worsening angina. All patients were on appropriate medical therapy for angina, and the benefit appeared to be independent of any antihypertensive effect of ramipril in the treatment group.⁹⁹ Although the direct mechanism of action is unclear, it is thought that ACE inhibitors have a number of beneficial effects relative to the atherosclerosis process. These include antagonizing the growth-mediating properties of angiotensin-2 on smooth muscle cells, preventing the rupture of atherosclerotic plaques by reducing inflammation, reducing LV hypertrophy, and improving endothelial function.¹⁰⁰

The results of the European trial on reduction of cardiac events with perindopril in stable coronary artery disease (EUROPA) replicated the benefits seen in the HOPE study with the administration of perindopril in 12,218 patients with stable coronary heart disease and no apparent heart failure. Perindopril use (target dose 8 mg every day) for an average of 4.2 years resulted in a 20% relative risk reduction in the combined incidence of cardiovascular death, myocardial infarction, or cardiac arrest.¹⁰¹ The results of the Prevention of Events with Angiotensin Converting Enzyme Inhibitors (PEACE), however, did not produce similar results as the HOPE and EUROPA trials. In PEACE, the addition of trandolapril 4 mg/day to standard therapy in patients with CAD did not reduce the rate of the primary endpoint, a composite of cardiovascular death, MI, or coronary revascularization.

Several plausible explanations exist for the different results seen in these three trials. The first is that patients in the PEACE trial appeared to be at much lower risk for a cardiovascular event than the patients enrolled in HOPE and EUROPA as evidenced by an event rate in the placebo group in PEACE that was lower than the treatment arm of the HOPE trial. Furthermore, patients in the PEACE trial were in general receiving more intensive risk factor modification as compared with those in the other two trials. Secondly, an inherent difference may exist in the three ACE inhibitors used, or the dosages used in the

clinical trials. The results of the PEACE trial call into question whether all patients with CAD should receive an ACE inhibitor. ACE inhibitors are well established in the treatment of patients with HF, MI, and diabetes, however, so it is certainly prudent to treat patients with stable angina and the other compelling indications with an ACE inhibitor.³⁶

While in theory angiotensin-receptor blockers (ARBs) should produce the same beneficial effects as ACE inhibitors in patients with atherosclerosis, there are no clinical trials available documenting whether this is indeed true. However, given the similar results ARBs have shown to ACE inhibitors in patients with HF and post-MI, and the significant beneficial effects with ARBs seen in treating patients with hypertension and diabetes, the administration of an ARB in patients with CAD and intolerance to ACE inhibitors seems reasonable.³⁶

Antiplatelet Therapy

Aspirin

32. E.R. is taking enteric-coated aspirin every day. She wants advice to why she is being given this drug and if it is safe for her stomach. What is the most appropriate dose?

Platelet activation produces coronary occlusion either by formation of a platelet plug or through release of vasoactive compounds from the platelets. Two indices of platelet activity that have been studied intensely in patients with CAD are thromboxane A₂ and prostacyclin. Thromboxane A₂ is a cyclooxygenase-catalyzed product of arachidonic acid metabolism and a potent vasoconstrictor. Prostacyclin (PGI₂), another arachidonic acid metabolite produced under the influence of cyclooxygenase, counterbalances the effect of thromboxane A₂. It is a potent inhibitor of platelet aggregation and a vasodilator. Although PGI₂'s production is increased in USA and acute MI, the amount produced is insufficient to fully offset the effects of elevated thromboxane A₂ levels.¹⁰²

The mechanism of action for aspirin's antiplatelet effect is inhibition of cyclooxygenase (see Chapter 15, Thrombosis). By acetylating the active site of cyclooxygenase, aspirin blocks the formation of prostaglandin endoperoxides from arachidonic acid. This inhibits the formation of both thromboxane and prostacyclin. Researchers have tested various aspirin doses hoping to find a dose that inhibits thromboxane synthesis but does not inhibit formation of prostacyclin. A single 100-mg aspirin dose virtually eliminates thromboxane A₂ production, whereas doses below 100 mg result in a dose-dependent reduction in thromboxane A₂ synthesis. Therapeutic benefit has been demonstrated with doses as low as 30 mg/day.¹⁰³

Recent research has attempted to determine the effect of aspirin doses on the thromboxane A₂ to PGI₂ balance. PGI₂ production recovers within hours of aspirin administration because the endothelial cell can resynthesize cyclooxygenase. In contrast, the inhibition of platelet cyclooxygenase is irreversible. Selective inhibition of platelet-generated thromboxane A₂ synthesis has been shown with 75 mg of controlled-release aspirin daily.¹⁰²⁻¹⁰⁴ This aspirin formulation undergoes extensive first-pass metabolism forming salicylic acid, a weak and reversible cyclooxygenase inhibitor. Theoretically, administration of 75 mg aspirin daily in a controlled-release formulation

may selectively spare vascular endothelial PGI₂ production, but at the same time still inhibit platelet cyclooxygenase. Controlled clinical trials on this proposed aspirin dosage regimen are lacking, however. Therefore, the proposed biochemical selectivity of aspirin on platelet function versus the vascular endothelium is difficult to achieve clinically.

Because of the lack of precise understanding of the pharmacodynamic effect of aspirin, it is not surprising that controversy exists regarding the optimal dose of aspirin to be used in patients with angina, as well as post-MI and as secondary prevention of stroke. It has been believed that higher doses of aspirin would produce a higher level of efficacy than low doses; however, all available literature indicates that low dosages of aspirin (75–325 mg/day) are as effective as higher dosages (625–1,300 mg/day) in the treatment of patients with angina.¹⁰⁴ Conversely, as the aspirin dosage increases, the incidence of adverse effects, especially GI bleeding, increases as well. Therefore, current guidelines recommend a daily dosage of 75 to 162 mg orally for the prevention of MI and death in patients with CAD.¹⁰⁴ Given this information, E.R. should be advised to lower her daily dose of aspirin to 81 mg/day to maintain efficacy but decrease the risk of adverse effects.

Aspirin remains the most commonly prescribed antiplatelet agent for the treatment of cardiovascular disease. Essentially all patients with a history of angina or CAD, especially if they have also experienced an MI, should take aspirin daily. Further discussions of aspirin use in the secondary prevention of MI, combined therapy with thrombolytics in the treatment of acute MI, atrial fibrillation, prosthetic valves, and postoperative CABG are discussed in Chapter 17, Myocardial Infarction, Chapter 15, Thrombosis, and Chapter 19, Cardiac Arrhythmias. Aspirin also is a key drug in treating cerebrovascular disease as presented in Chapter 51, Cerebrovascular Disorders.

Clopidogrel

33. As noted in Question 31, E.R. was taking 325 mg/day of enteric-coated aspirin. This was later reduced to 81 mg/day based on the discussion above. Last week she was hospitalized for rapidly worsening angina, diagnosed as unstable angina. She is being discharged today with a new prescription for oral clopidogrel 75 mg every day. Is the combined use of aspirin and clopidogrel appropriate? How long should clopidogrel be continued?

Clopidogrel (Plavix), a thienopyridine, inhibits platelet function *in vivo*. Its mechanism of action has not been identified, although it appears to be a noncompetitive antagonist of the platelet adenosine diphosphate (ADP) receptor. Stimulation of the ADP receptor produces platelet activation similar to thromboxane A₂. Clopidogrel at a dosage of 75 mg orally every day was demonstrated in one study to be slightly more effective than aspirin in the secondary prevention of MI and death in patients with various manifestations of atherosclerotic vascular disease.¹⁰⁵ The magnitude of difference in benefit seen with clopidogrel was quite small and not sufficient to justify its broad scale use in the treatment of CAD. Based on this study, the role of clopidogrel historically was to serve as an alternative antiplatelet agent in patients with a true contraindication to aspirin and it is still used in this fashion.^{1,2,33}

The combination of aspirin and clopidogrel was compared with aspirin alone in patients with acute coronary syndromes without ST-segment elevation in the CURE study. Patients received combination antiplatelet therapy acutely while in the hospital and continued it for an average of 9 months. The combination of aspirin and clopidogrel significantly reduced the occurrence of death from cardiovascular causes, nonfatal MI, or stroke.¹⁰⁶ The results of the CURE study were confirmed in the Clopidogrel for Results of Events During Observation (CREDO) trial where patients with acute coronary syndromes who were treated with percutaneous coronary intervention with stent placement received aspirin plus clopidogrel acutely in the hospital and then for 1 year. Patients receiving both aspirin and clopidogrel for 1 year had a lower incidence of death, MI, and stroke in comparison to patients who only received aspirin.¹⁰⁷ Based on the results of these two studies, it appears appropriate for E.R. to receive the combination of aspirin and clopidogrel for up to 1 year after her recent episode of ACS. The occurrence of bleeding should be closely monitored because bleeding events were significantly increased in patients receiving combined antiplatelet therapy in both the CURE and CREDO study.^{106,107} Dual therapy with aspirin and clopidogrel has not been investigated beyond 1 year; therefore, the combination should be limited to a duration of 1 year in patients who have experienced an acute coronary event.

Given the beneficial effects seen in patients with recent ACS, as well as data supporting the use of dual antiplatelet therapy in patients with PCI plus stent placement, investigators hypothesized that dual therapy with aspirin plus clopidogrel would be superior to aspirin in the treatment of chronic stable CAD. In the Clopidogrel for High Atherothrombotic Risk and Ischemic Stabilization, Management, and Avoidance (CHARISMA) trial, 15,063 patients with documented vascular disease (CAD, cerebrovascular, peripheral arterial disease), or no documented vascular disease but with multiple cardiovascular risk factors, were assigned to aspirin alone or aspirin plus clopidogrel for an average of 28 months duration.^{108,109} Unlike the results from ACS studies, however, the combination of aspirin plus clopidogrel did not reduce the incidence of the primary endpoint (risk of death, MI, stroke, or coronary revascularization) as compared with aspirin alone. In a secondary analysis of patients who entered the trial with documented vascular disease, dual therapy did produce statistically significant reductions in the primary endpoint as compared with aspirin. Further trials should be conducted, however, to further elucidate the role of dual antiplatelet therapy outside the setting of ACS or PCI, and at this time combination therapy cannot be recommended as treatment strategy for patients with chronic stable CAD.

Ticlopidine (Ticlid) is a related thienopyridine antiplatelet agent that is similar to clopidogrel in both structure and mechanism of action and is a potential alternative to aspirin for E.R. Ticlopidine compares unfavorably with clopidogrel, however, because of a lack of any data examining its use in ischemic heart disease (IHD) and its side effect profile. Of particular concern is a roughly 2% incidence of neutropenia, which may be life-threatening.¹⁰² Because of these factors, ticlopidine should not be considered as a potential alternative to aspirin now that clopidogrel is available.

Oral anticoagulation with warfarin represents another alternative to aspirin in patients with angina. Although the efficacy of warfarin (international normalized ratio [INR] 2.0–3.0) appears to be similar to aspirin in the prevention of MI and death, the need for monitoring and the risk of bleeding relegate this mode of therapy as second line behind antiplatelet strategies.³³

Primary Prevention

34. E.R. returns to the pharmacy 1 week later with her brother who wants to know if he should be taking an aspirin a day to prevent heart disease. His only medical history consists of hypertension for which he is taking oral hydrochlorothiazide 25 mg every day. Is primary prevention of CAD with aspirin appropriate for E.R.'s brother?

The question of whether aspirin is valuable in the primary prevention of cardiovascular events has been debated for more than 20 years. Meta-analyses indicate that aspirin reduces the risk of a serious vascular event (nonfatal MI, nonfatal stroke, or death from vascular causes) by 25%; however, low-dose aspirin also doubles the risk of major extracranial bleeding (mostly GI), including hemorrhagic stroke. As these proportional changes for both efficacy and safety apply to any given category of patients with vascular disease, the absolute risk-to-benefit ratio for aspirin in the primary prevention arena will depend on the overall absolute risk of vascular ischemic events.^{110,111}

In 2002, the U.S. Preventative Services Task Force developed guidelines for aspirin use in primary prevention based on the results of five large randomized studies.¹¹² In patients who have a high risk of developing cardiovascular disease (>1.5% per year), the benefits of aspirin in preventing cardiovascular events far outweigh the bleeding risks. In patients at low risk (<0.6% per year), the risk of bleeding events negates any potential benefit in cardiovascular outcomes. Patients at intermediate risk (0.6%–1.4% per year) derive some benefit in preventing cardiovascular events. The magnitude of benefit is not sufficiently large, however, to recommend routine administration of aspirin for primary prevention. In these circumstances patients should be informed about the risks and benefits of aspirin use to make an informed decision about whether they wish to take aspirin to prevent the occurrence of cardiovascular disease.¹¹² The recommendations from the U.S. Preventative Services Task Force are consistent with recommendations from the American College of Cardiology (ACC), American Heart Association (AHA), American College of Chest Physicians (ACCP), and the American Diabetes Association (ADA).¹¹¹

Recently, the value of aspirin for primary prevention of CAD in women has come under question owing to the overall results of the Women Health Study which did not find a statistically significant reduction in the composite outcome of nonfatal MI, nonfatal stroke, or death.¹¹³ A statistically significant reduction in the risk of ischemic stroke was found, however. A recent meta-analysis that included 51,342 women and 44,114 men found that low-dose aspirin reduced the risk of a composite of cardiovascular events (MI, stroke, cardiovascular mortality) in both men and women. In men, the primary benefit was a

reduction in first time MI, whereas a reduction of first time ischemic stroke was observed in women.¹¹⁴

For E.R.'s brother, the first step is to calculate what is his risk of developing cardiovascular disease. This can be done by using a validated risk assessment scoring system, such as the Framingham risk score (see Chapter 12, Dyslipidemias, Atherosclerosis, and Coronary Heart Disease).¹¹¹ Once his risk is known, an appropriate recommendation can be made regarding his use of aspirin for primary prevention.

Drug Interactions with Nonsteroidal Anti-Inflammatory Drugs

35. During the discussion with E.R. regarding her brother, she is noticed buying a bottle of over-the-counter ibuprofen. On further questioning, it is learned that E.R. suffers from occasional back and knee pain and uses ibuprofen three to five times a week for pain relief. How should E.R. be educated on regarding the use of ibuprofen and aspirin concomitantly?

In 2006, the FDA released a warning statement on the concomitant use of both aspirin and ibuprofen. The impetus for the statement was the growing recognition that nonsteroidal anti-inflammatory drugs (NSAIDs), in particular ibuprofen, may attenuate the antiplatelet effects of low-dose aspirin. This FDA warning was then followed by an updated scientific statement from the AHA.¹¹⁵ The mechanism behind this interaction is that both aspirin and nonselective NSAID bind to the same acetylation sites of the cyclo-oxygenase enzyme. Although aspirin does this in a nonreversible fashion, binding by an NSAID occurs in a reversible fashion. If an NSAID, such as ibuprofen, is present, aspirin will be unable to bind to its site of action, and will be rapidly cleared from the plasma. The result is the patient will not receive the antiplatelet benefit of aspirin.

E.R. should be counseled on the nature and consequences of the interaction between her low-dose aspirin and ibuprofen. Additionally, if she can avoid or at least minimize (both dose and duration) the use of ibuprofen, the effect on her cardiovascular health would be optimized. If occasional use of ibuprofen cannot be avoided, it should be administered in such a fashion as to minimize the potential for interacting with her low-dose aspirin. This would include taking ibuprofen at least 2 hours after her daily dose of aspirin, as well as taking her daily aspirin dose at least 8 hours after the last dose of ibuprofen. Although similar concerns exist for other nonselective NSAIDs (naproxen, diclofenac), no formal recommendations exist on how to manage concomitant use of these agents with aspirin.

Hormone Replacement Therapy

36. E.R. returns to the pharmacy 4 months later to obtain refills of her isosorbide mononitrate, metoprolol, diltiazem, albuterol, lisinopril, and clopidogrel. She mentions that a few years back she remembers that her mother was put on estrogen by her doctor to help prevent heart disease and is wondering if she should be on estrogen replacement as well?

Epidemiologic evidence initially supported the notion that hormone replacement therapy (HRT) in postmenopausal women would prevent cardiovascular events. When put to the

test of a randomized, placebo-controlled trial, the benefits of HRT on cardiovascular disease, however, were not seen and potential harm was noted.^{116,117} One of these studies was the Women's Health Initiative (WHI), which sought to answer the question of whether administering estrogen alone (in women without a uterus) or estrogen plus progesterone (in women with a uterus) would prevent the development of CAD in healthy (without history of CAD) postmenopausal women. Unexpectedly, a 29% increase was found in the incidence of CAD in those women on estrogen plus progesterone compared with placebo after an average treatment duration of 5 years. No increase was noted in women on estrogen alone; that part of the trial is still ongoing.¹¹⁸ Based on the negative results seen in clinical trials of HRT, the AHA released a specific recommendation in 2001 not to initiate HRT for prevention of cardiovascular disease.^{33,119,120}

Recent information indicates, however, that HRT may have varying effects, depending on the age and time from menopause for women.¹²¹ When the WHI trial was analyzed in terms of timing of HRT initiation, women in whom HRT was started in close proximity to menopause actually derived a cardiovascular benefit. If HRT was initiated at a time remote from menopause, an increase in cardiovascular events was noted. The results from this analysis need to be confirmed in an appropriately designed trial, but it may be plausible that HRT is safe to use in the first few years after menopause for other indications without any increased risk of cardiovascular events. In the case of E.R., because she is 62 years of age and likely more than 10 years past menopause, she should be educated that the current body of knowledge does not support the use of HRT in the treatment of cardiovascular disease.

VARIANT ANGINA (CORONARY ARTERY SPASM)

Clinical Presentation

37. A.P., a 35-year-old woman, is hospitalized for evaluation of severe chest pain, which occurs almost daily at about 5 AM. A.P. ranks the severity of pain as 7 to 8 on a scale of 1 to 10. It is associated with diaphoresis and is not relieved by change in position. A.P. has no cardiovascular risk factors, and her hobbies include triathlon competition and rock climbing, neither of which has caused chest pain. She follows a strict vegetarian diet and takes no medications. Admission ECG reveals sinus bradycardia at 56 beats/minute. Serum electrolytes, chemistry panel, and cardiac enzymes are all within normal limits.

At 6 AM the next morning, A.P. is awakened abruptly by severe chest pain. Her vital signs include the following: heart rate, 55 beats/minute; supine BP, 110/64 mmHg; and respiratory rate, 12 breaths/minute. An immediate ECG shows sinus bradycardia with marked ST-segment elevation. The pain is relieved within 60 seconds by one NTG 0.4-mg sublingual tablet. During the day, she completes an exercise tolerance test without complication or evidence of CAD.

On the second day, A.P. undergoes cardiac catheterization, and no coronary atherosclerosis is visualized. An ergonovine provocation test is performed during cardiac catheterization. At 3-minute intervals, escalating IV ergonovine maleate bolus doses are given: 0.05, 0.10, and 0.25 mg. After the 0.25-mg dose, A.P. de-

velops severe chest pain associated with an ST-segment elevation of 0.3 mV. The cardiologist observes almost complete vasospasm of the RCA and immediately injects 200 mcg NTG into the coronary artery along with administering two lingual sprays of NTG. A.P.'s chest pain resolves within 60 seconds, and the ECG normalizes within 3 minutes. A.P. is diagnosed as having Prinzmetal's variant angina. Discharge medications include oral amlodipine 10 mg every day at 11 PM and NTG lingual spray 0.4 mg PRN chest pain. Is A.P.'s presentation typical for Prinzmetal's variant angina?

A.P. presents with a classic picture of variant (Prinzmetal's) angina, with transient total occlusion of a large epicardial coronary artery as a result of severe segmental spasm. Clinical manifestations include chest pain occurring at rest, often in the morning hours. As with A.P., patients with Prinzmetal's variant angina generally are younger than patients with chronic stable angina and do not carry a high-risk profile. Other vasospastic disorders, such as migraine attacks or Raynaud's phenomenon, may be present; smoking and alcohol ingestion can be important contributing factors.¹²²

The hallmark of variant angina is ST-segment elevation on the ECG, which denotes rapid and complete occlusion of the coronary artery. Many patients also have asymptomatic episodes of ST-segment elevation. Transient arrhythmias and conduction disturbances may be observed during pain, depending on the severity of the myocardial ischemia. In contrast to chronic stable angina in which the heart rate–BP product often is elevated with pain, no hemodynamic factors appear to contribute to Prinzmetal's variant angina.¹²²

As documented by angiography, A.P. has vasospasm of the large RCA. This transient, reversible narrowing probably is caused by increased coronary vascular resistance. It can occur in the absence of atherosclerosis, as illustrated by A.P., or it can occur in the presence of CAD. One possible explanation for vasospasm occurring more commonly at night or during the early morning hours is increased vasomotor tone secondary to diurnal variations in catecholamines.

Ergonovine Stimulation Test

38. Why was the ergonovine test used? Was intracoronary NTG necessary to reverse the effects of ergonovine?

Because Prinzmetal's variant angina does not occur predictably, spasm must be induced under controlled circumstances. Ergonovine maleate, an ergot alkaloid that stimulates α -adrenergic and serotonergic receptors, exerts a direct vasoconstrictive effect on the vascular smooth muscle. The ergonovine maleate provocation test is highly specific and sensitive, especially in patients with normal coronary arteries. The risks of the test, which often discourage some physicians from using ergonovine, include arrhythmias (heart blocks, ventricular tachycardia, ventricular fibrillation) and possible MI.¹²²

The vasospasm induced by ergonovine should be reversed promptly. Although sublingual NTG tablets or lingual spray might relieve the episode, the coronary vasospasm could be unresponsive to these agents. Direct injection of NTG into the coronary arteries immediately reverses the vasoconstrictor action of ergonovine.

Therapy

39. Oral amlodopine 10 mg every day was ordered for A.P. Would long-acting nitrates or β -adrenergic blockers be alternatives to amlodopine for A.P.? Is one CCB preferable to another for treatment of Prinzmetal's variant angina?

Because of their antispasmodic effects and low incidence of side effects, CCBs are generally selected over nitrates or β -blockers for nocturnal vasospastic angina. All CCBs appear equally effective in preventing Prinzmetal's variant angina.¹²² Intrinsically long-acting or SR forms are preferred, however, and some patients may respond better to one agent than to another.

In patients who continue to experience pain using maximal CCB doses, combination therapy with a nitrate should be tried.¹²² Nitrates cause vasodilation by a different mechanism than CCBs and are effective in treating Prinzmetal's variant angina.¹²² To avoid tolerance, the nitrate-free interval for A.P. should be scheduled during the day so that the early morning hours when vasospasm occurs are covered by NTG. For example, if needed, A.P. could apply a transdermal NTG patch at bedtime and remove it on awakening. Aspirin therapy is indicated for A.P.

β -Blockers are likely to worsen A.P.'s angina because blockade of the β_2 -receptors that mediate vasodilation may allow unopposed α_1 -mediated vasoconstriction. A cardioselective β -blocker also could worsen Prinzmetal's variant angina. Therefore, a CCB or nitrate is preferable.

40. Will A.P. require treatment for the remainder of her life?

During the first year of therapy, up to 50% of patients experience spontaneous remission by an unknown mechanism. This occurs most often in patients who have had a short duration of symptoms or who have normal or mildly diseased coronary arteries (i.e., isolated vasospasm without atherosclerosis). If A.P. is pain free and not experiencing significant arrhythmias or silent ischemic episodes of Prinzmetal's angina after 1 year, amlodopine could be tapered and discontinued. It is also possible, however, that she will require treatment indefinitely. Modification of smoking and ethanol ingestion may promote remission of Prinzmetal's angina.¹²²

41. Can variant angina lead to acute MI or death?

Variant angina, particularly in patients with multivessel coronary artery spasm, can lead to acute MI or death. In a study of 159 consecutive patients with variant angina in Japan who required hospitalization, 76% of patients experienced a cardiac event (acute MI in 19 patients, sudden death in 5 patients, and coronary artery bypass graft in 1 patient) within 1 month of onset of angina.¹²² These patients had greatly improved outcomes if treated aggressively with calcium antagonists, nicorandil, and NTG infusion during the early stages. If variant angina persisted, revascularization of coronary arteries with underlying critical lesions was indicated.

MICROVASCULAR ISCHEMIA (SYNDROME X)

42. K.G., a 50-year-old female executive, has undergone an extensive cardiovascular workup for exertional angina associated with a 3-mm ST-segment depression. A recent cardiac catheteri-

zation did not reveal any atherosclerosis, and an ergonovine stimulation test did not produce observable coronary vasospasm. The cardiologists believe K.G. has microvascular ischemia. What drug therapy might be indicated for K.G.?

Syndrome X, increasingly known as *microvascular angina*, is a syndrome of angina or anginalike chest pain in the setting of a normal coronary arteriogram. Several theories exist regarding the mechanism of pain production, including microvascular dysfunction producing ischemia or chest discomfort without ischemia in patients who may have an abnormal perception of pain. Microvascular dysfunction can be the result of either diminished responsiveness to vasodilating stimuli (e.g., endothelial relaxation factor [NO], kinins, atrial natriuretic peptide or prostaglandin I₂) or increased sensitivity to vasoconstricting stimuli (e.g., catecholamines, vasopressin, angiotensin-2 or thromboxane A₂). Patients who display a heightened perception of pain may have an awareness of pain in response to atrial stretch or changes in heart rate. Ischemia is not universally present in patients with syndrome X; therefore, different mechanisms may be responsible for symptoms in different patients.^{3,123}

Microvascular angina differs substantially from variant angina. Although spasm-causing variant angina may be visible with coronary angiography, the microvascular coronary circulation is not visible. The changes in coronary artery tone are in the distal coronary arteries and perhaps the collateral vessels. Some patients with microvascular ischemia have other smooth muscle disorders, such as esophageal motility disorders. A definite link is found between coronary vasoconstriction and mental or psychological stress.³

By symptoms alone, K.G.'s presentation does not significantly differ from that of a patient with exercise-induced angina secondary to atherosclerosis. Of concern is the finding of a 3-mm ST-segment depression on K.G.'s ECG, which raises concern of severe CAD. The negative findings from her cardiac catheterization and ergonovine stimulation testing, however, rule against both CAD and coronary artery spasm as a cause of her symptoms, and help to confirm the diagnosis of syndrome X. Overall, the prognosis for patients with syndrome X appears to be good. Long-term survival is no different from age-matched controls. Most patients, however, continue to experience symptoms and control of anginal pain is the main goal in therapy.³

Treatment with a nitrate, CCB, or β -blocker all appear to offer some relief, but overall the response to therapy in these patients is poor. The choice of agent will likely depend on specific patient characteristics. Sublingual NTG, however, is often ineffective at treating acute attacks, although it should still be prescribed.

SILENT MYOCARDIAL ISCHEMIA

Definition

43. Y.G., a 60-year-old man who has had his first complete physical examination in 12 years, is found to have Q waves on ECG, indicating a previous MI. Physical findings are normal except for borderline LV hypertrophy. Abnormal laboratory studies include moderately elevated total serum cholesterol and TG. His medical history is remarkable for hypertension controlled with oral

hydrochlorothiazide 25 mg every day. Y.G. does not recall ever experiencing angina, nor has he ever been told he had a heart attack. What characteristic syndrome does Y.G. exhibit, and how does it differ from angina pectoris?

Y.G. had a silent MI, often the first indicator of silent myocardial ischemia.⁵ Silent myocardial ischemia is unrecognized by the patient because there are no symptoms of angina. It can occur in totally asymptomatic persons (type 1), in asymptomatic postinfarction patients (type 2), and in patients with angina (type 3).¹²⁴ The prevalence of silent myocardial ischemia is difficult to estimate because it often is undetected. An estimated 1 to 2 million totally asymptomatic men have silent myocardial ischemia, and approximately 50,000 new cases of postinfarction silent ischemia occur each year. Most patients with angina also appear to have episodes of silent ischemia, with the silent episodes occurring two to three times more often than the anginal episodes. The pathogenesis of silent ischemia is not fully defined. An abnormality in pain threshold may exist so that the anginal warning system is not triggered, or it may represent varying activation of coronary vasomotor tone or platelet activity.³

Prognosis

44. What is Y.G.'s prognosis?

Y.G.'s prognosis depends on the extent of his underlying CAD, ventricular function, and arrhythmia status. If Y.G. has multivessel disease, he is more likely to develop adverse cardiac events (reinfarction, unstable angina, sudden death) than if he has single-vessel disease. Silent myocardial ischemia is especially ominous in patients with unstable angina.¹²⁴

Diagnosis

45. What diagnostic tests will be used to evaluate Y.G.'s total ischemic burden both before and after therapy is started?

The total ischemic burden, the sum of painful and painless ischemic episodes that occur, is assessed with exercise testing and 24-hour ambulatory electrocardiographic (Holter) monitoring. Both tests measure ST-segment depression, the usual abnormal ECG response to ischemia. ST-segment depression >2 mm at low levels of exercise or ST-depression with hypotension or arrhythmias is a strong indicator of disease. Radionuclide procedures help confirm ECG responses.¹²⁴

Management

46. What management goals and techniques are likely to apply to Y.G.?

Treatment of patients with silent myocardial ischemia is unresolved, but modification of risk factors is mandatory. Y.G.'s cholesterol and hypertension should be corrected and the aim of pharmacotherapy is to abolish all ECG evidence of ischemia. The same drugs used to treat angina (nitrates, β -blockers, CCBs, and aspirin) also prevent silent myocardial ischemia if used at sufficiently high doses or in appropriate combinations. β -Blockers may be the most effective agents in decreasing the episodes of silent ischemia. Calcium antagonists are useful, but

dihydropyridines are less efficacious than verapamil and diltiazem. Aspirin and nitrates also are key therapies in treating silent myocardial ischemia. Each patient requires careful titration to reduce both symptomatic and asymptomatic ischemic episodes. Although many questions remain unanswered about silent myocardial ischemia, it is no longer acceptable to treat painful ischemic episodes only.^{3,124}

REVASCULARIZATION

Percutaneous Coronary Intervention

47. T.T., a 54-year-old man, had a recent onset of angina that was precipitated by exertion. His current medications include oral isosorbide mononitrate 30 mg every day, oral atenolol 50 mg every day, NTG SL 0.4 mg PRN for chest pain, and enteric-coated aspirin 81 mg/day. After discussions with his cardiologist, he elects to undergo revascularization with PCI for symptom relief. What is the current standard for prevention of acute complications during PCI?

Percutaneous coronary intervention (PCI), also known as angioplasty, involves the percutaneous insertion of a balloon catheter into the femoral artery in a similar fashion to angiography. The catheter is advanced up the aorta and into the coronary arteries at the coronary sinus. PCI, which was introduced in 1977, initially involved the inflation of a catheter-borne balloon that mechanically dilated a coronary artery obstruction through arterial intimal disruption, plaque fissuring, and stretching of the arterial wall. Balloon inflations were repeated until the plaque was compressed and coronary blood flow resumed. Since then, alternative devices have been developed, including rotational blades designed to remove atheromatous material, lasers to ablate plaques, and intracoronary stents that are designed to maintain the patency of the vessel after it is reopened.¹²⁵ Stents can be of the bare metal (BMS) variety, or contain a drug impregnated on the surface of the stent to prevent restenosis (drug-eluting stent or DES). It is estimated that more than 1,265,000 PCI procedures are performed in the United States each year. An overwhelming majority of these procedures involve placement of a BMS or DES (Fig. 16-5). PCI is indicated in patients with single- or multivessel disease and who are either symptomatic or asymptomatic.^{125,126}

Because of mechanical disruption of the atherosclerotic plaques and exposure of plaque contents to the bloodstream during PCI, potent antiplatelet and antithrombotic strategies are needed to prevent acute thrombotic events such as MI and death. Initially, strategies involved the use of high-dose unfractionated heparin and aspirin. Current strategies involve the administration of aspirin, clopidogrel, an antithrombin agent, as well as a glycoprotein (Gp) IIb/IIIa receptor antagonist in selected patients. In patients not taking aspirin on a daily basis, 300 to 325 mg of aspirin should be given at least 2 hours before the procedure. Patients currently on daily aspirin therapy should receive 75 to 325 mg of aspirin before PCI is performed. A 600-mg loading dose of clopidogrel on or before the time of the procedure is currently recommended, producing an antiplatelet action within 2 hours.^{11,126}

With the development of the Gp IIb/IIIa receptor antagonists, significant improvements were made in patient outcomes during and after PCI.¹²⁶ Currently, three agents are available

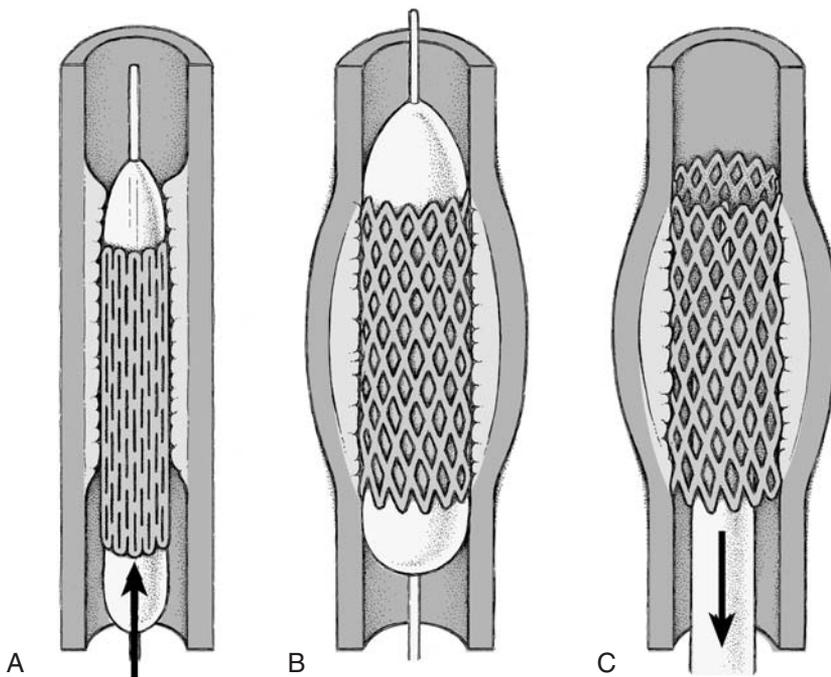

FIGURE 16-5 Vascular stent. **A:** A balloon catheter positions stent at site of arterial stenosis. **B:** inflation of balloon dilates artery and expands stent. **C:** balloon is collapsed and withdrawn, leaving expanded stent in position. (Illustration by Neil O. Hardy, Westpoint, Conn.)

in the United States (Table 16-8). Abciximab, a human-murine monoclonal antibody fragment, was the first agent available. Subsequently eptifibatide (cyclic heptapeptide) and tirofiban (nonpeptide mimetic) have become available.¹²⁶ These agents, when administered IV during PCI and for 12 to 24 hours afterward, significantly decrease the risk of death, acute MI, or need for repeat PCI. Major adverse effects include bleeding and thrombocytopenia. Therefore, hematocrit and platelet counts should be monitored appropriately. Clearance of both eptifibatide and tirofiban is renal, and dose adjustments should take place accordingly.¹²⁷

In addition to appropriate use of the antiplatelet agents (aspirin, clopidogrel and Gp IIb/IIIa inhibitors), patients having PCI should also receive adequate antithrombin therapy during the procedure. Available options include unfractionated

heparin (UFH), the low-molecular weight heparin (LMWH) enoxaparin, and the direct thrombin inhibitor bivalirudin. Any of the available agents may be initiated at the time of the procedure, or may be continued with appropriate dose adjustment if administered to the patient before PCI. See Table 16-9 for information regarding appropriate dosing and management strategies for each agent. Current guidelines do not specify a preference for any particular antithrombin agent during the course of PCI. Therefore, the choice of agent will likely depend on local practice variations. Antithrombin agents are typically discontinued immediately after the PCI procedure unless a compelling separate indication exists for therapeutic anticoagulation. Of note, significant interest exists in using direct thrombin inhibitors, such as bivalirudin, in place of heparin during PCI. One advantage for this approach is that most

Table 16-8 Indications and Dosing of Glycoprotein IIb/IIIc Receptor Antagonists

| Indication | Abciximab (ReoPro) | Eptifibatide (Integrilin) | Tirofiban (Aggrstat) |
|---|--|--|--|
| Percutaneous transluminal coronary angioplasty (PCTA) | 0.25 mg/kg IV bolus, then 0.125 mcg/kg/min IV infusion × 12 hr | 180 mcg/kg IV bolus, then 2.0 mcg/kg/min IV × 20–24 hr Repeat 180 mcg/kg IV bolus 10 mins after first bolus | Not approved use |
| Coronary stent placement | 0.25 mg/kg IV bolus, then 0.125 mcg/kg/min IV infusion × 12 hr | Same dose as for PCTA | Not approved use |
| Acute coronary syndrome (unstable angina and non-Q-wave MI) | Not approved use | 180 mcg/kg IV bolus, then 2.0 mcg/kg/min IV × 20–24 hr | 0.4 mcg/kg/min IV load × 30 mins, then 0.1 mcg/kg/min IV infusion × 48–102 hr Reduce dose by 50% if CrCl <30 mL/min |

CrCl, creatinine clearance; IV, intravenous.

Table 16-9 Dosing of Antithrombin Agents in Different Settings 11,126

| <i>Antithrombin Agent</i> | <i>Dosing Strategy</i> |
|--|---|
| Unfractionated Heparin | |
| Acute coronary syndromes: Medical management | 60 U/kg IV bolus, 12 U/kg/hr IV continuous infusion, titrated to goal aPTT |
| PCI: Therapy initiated at time of procedure | With IV Gp IIb/IIIa: 60–70 U/kg bolus, target ACT of 200 sec Without IV Gp IIb/IIIa: 100–140 U/kg bolus, target ACT of 250–350 sec |
| PCI: Continuation of prior therapy | Provide additional boluses if needed to meet specified ACT goals above |
| Enoxaparin | |
| Acute coronary syndromes: Medical management | Loading dose of 30 mg IV may be given 1 mg/kg SQ twice daily Reduce to 1 mg/kg QD in patients with CrCL <30 mL/min <i>Do not use in renal failure, dialysis</i> |
| PCI: Therapy initiated at time of procedure | 0.5 to 0.75 mg/kg IV bolus |
| PCI: Continuation of prior therapy | If last SQ dose <8 hr ago; no additional medication required If last SQ dose 8–12 hr ago; give one-time additional 0.3 mg/kg IV bolus |
| Bivalirudin | |
| Acute coronary syndromes: Medical management | 0.1 mg/kg IV bolus, then 0.25 mg/kg IV infusion <i>Use only with an interventional strategy</i> |
| PCI: Therapy initiated at time of procedure | 0.75 mg/kg IV bolus 1.75 mg/kg IV infusion for duration of the procedure <i>Preferred agent if HIT present or suspected</i> |
| PCI: Continuation of prior therapy | Give additional 0.5 mg/kg IV bolus, then increase IV infusion to 1.75 mg/kg/hr |
| Fondaparinux | |
| Acute coronary syndromes: Medical management | 2.5 mg SQ QD <i>Contraindicated in patients with a CrCL <30 mL/min</i> |
| PCI: Therapy initiated at time of procedure | Not recommended |
| PCI: Continuation of prior therapy | Give 50–60 mg/kg IV bolus of UFH for adequate protection during PCI procedure |

ACT, activated clotting factor; HIT, heparin-induced thrombocytopenia; IV, intravenous; PCI, percutaneous coronary intervention; QD, every day; SQ, subcutaneous; UFH, unfractionated heparin.

patients receiving bivalirudin during PCI do not require a Gp IIb/IIIa receptor antagonist. This strategy has the potential to reduce overall medication costs, as well as decrease the incidence of bleeding in association with PCI.¹²⁸

48. T.T. undergoes PCI plus placement of a drug-eluting stent (sirolimus) to address a 75% lesion in his proximal left circumflex artery. What advantages and disadvantages are there in the decision to place a DES versus a BMS in T.T.?

The overall success of any procedure is directly related to the experience of the operator, patient factors (such as LV function or number of vessels treated), and the equipment used. In patients receiving balloon angioplasty alone (without stent placement), repeat revascularization procedures (either repeat angioplasty or surgery) may be required in as many as 32% to 40% of cases because of the reoccurrence of plaque at the angioplasty site. The process is known as *restenosis*.¹²⁵ Many pharmacologic strategies have been studied in an attempt to reduce the risk of restenosis. The outcome with most methods has been disappointing. The only strategy that has been associated with a decrease in restenosis is the use of intraluminal stents.¹²⁵ Stents are essentially metal scaffolding devices placed into the vessel after balloon inflation has taken place. They provide a physical barrier to the reoccurrence of a significant stenosis at the site. One of the early drawbacks of the use of stents was the need for complicated anticoagulation reg-

imens, including aspirin, heparin, dipyridamole, and warfarin, to prevent in-stent thrombosis. Dual antiplatelet therapy—a combination of clopidogrel and aspirin—is effective at reducing in-stent thrombosis and is now recommended for use after stent placement.¹²⁶ The duration of dual antiplatelet therapy will depend on the type of stent used, as well as other clinical characteristics of the patient.

Recently, stents that elute antiproliferative agents such as sirolimus (SES) or paclitaxel (PES) have been shown in clinical trials to reduce the incidence of restenosis compared with BMS.^{129,130} Restenosis rates in clinical trials with these DES were in the single digit range, as compared to 15% to 20% with traditional BMS. Soon after their introduction to the U.S. market, DES use grew to the point that >90% of stent use was DES. This trend abruptly halted in the fall of 2006 when several reports indicated a higher than expected incidence of stent thrombosis a year or more after DES placement. Although late stent thrombosis had previously been reported with BMS usage, the incidence was rare.¹³⁰ Shortly after these initial reports, an explosion of scientific literature emerged on the topic. Many potential explanations exist for the occurrence of late stent thrombosis in a patient receiving a DES, but perhaps the most relevant from a pharmacotherapy standpoint is the delayed healing response seen with DES compared with BMS. After placement of an intracoronary stent, a healing process typically occurs resulting in growth of a protective layer of endothelial cells over the stent surface, removing the stent

surface from blood exposure and drastically reducing the stimulus for thrombosis. In the case of DES coated with paclitaxel or sirolimus, cellular growth may be inhibited, significantly impairing endothelialization of the stent surface. In a small number of patients, endothelialization does not seem to occur at all. In this scenario, the stent structure remains continually exposed to flowing blood and is a potent stimulus for thrombosis.¹³¹ Because of the concerns of late stent thrombosis, the usage of DES has dramatically decreased. Some use of DES is likely to continue, however owing to the tangible benefits in reduction of revascularization procedures in some patients. Therefore, practitioners will need to continue to stay abreast of evolving information regarding appropriate strategies to prevent late stent thrombosis.

Although there has been speculation to the causes of late stent thrombosis with DES as described above, one critical issue that has been identified is the premature discontinuation of dual antiplatelet therapy consisting of aspirin and clopidogrel. Previous recommendations called for varying durations of combined therapy, depending on the type of stent used. Because of the recognition of a delayed healing response to DES, current guidelines recommend at least 1 year of dual antiplatelet therapy in patients receiving a DES if patients are not at an elevated risk of bleeding. For BMS placement, dual antiplatelet therapy should continue for a minimum of 1 month, and up to 1 year ideally, but this extended duration is not as critical as it is in the setting of DES placement. The dose of aspirin during dual antiplatelet therapy should be 162 to 325 mg/day, and then decreased to 81 mg/day once dual antiplatelet therapy is discontinued. When administered, the dose of clopidogrel should be 75 mg/day.¹²⁶

For T.T. the decision of placing a DES versus a BMS will likely be a lower risk of needing a repeat revascularization for restenosis within 6 to 9 months. He will, however, need to take dual antiplatelet therapy for at least a year, significantly increasing the costs of his prescriptions as well as putting him at an increased risk of bleeding in the long run. Regardless, it is vital that T.T. be educated about the importance of maintaining his therapy with aspirin and clopidogrel is to prevent complications. This discussion should commence before the PCI procedure to assess whether T.T. has the economic resources to comply with the needed therapy, or whether there

may be any planned upcoming surgery necessitating the discontinuation of antiplatelet therapy. If these present a problem for T.T., placement of a BMS is a viable option. T.T. should also be counseled to alert his cardiologist if another health care professional wishes to discontinue antiplatelet therapy for any reason.¹³²

49. Would revascularization therapy with coronary artery bypass grafting have been a better option for T.T. than PCI and stent placement?

Coronary Artery Bypass Graft Surgery

Coronary artery bypass grafting is a complicated surgical procedure during which an atherosclerotic vessel is “bypassed” using either a patient’s saphenous vein or internal mammary artery (IMA; Fig. 16-6). The “graft” (i.e., the saphenous vein or IMA) then allows blood to flow past the obstruction in the native vessel. The goals of antianginal therapy, whether medical (pharmacologic) or revascularization, remain unchanged: (a) to prolong life, (b) to prevent MI, and (c) to improve the quality of life.

The outcomes of medical therapy, PCI, and revascularization with CABG have been compared, and current guidelines are available.³¹ Of interest to practitioners and patients are the relative effects of each treatment modality on mortality, occurrence of symptoms, and quality of life. When compared with medical treatment in patients who would not be considered high risk, PCI in general offers no improvement in the long-term incidence of MI or cardiovascular death, but significantly reduces symptoms.^{1,126} Because of his escalating symptoms on triple drug therapy, the choice of PCI for T.T. is justified.

Certain high-risk patient subgroups clearly have an improved outcome with CABG. These include (a) patients with significant left main coronary disease; (b) patients who have three-vessel disease, especially with LV dysfunction; (c) patients with two-vessel disease with a significant proximal LAD lesion; (d) patients who have survived sudden cardiac death; and (e) patients who are refractory to medical treatment. In patients who do not meet these criteria, either medical treatment, or PCI is a viable option.^{1,31} Because T.T. does not fall into one of these categories, PCI is preferable at this time owing to the

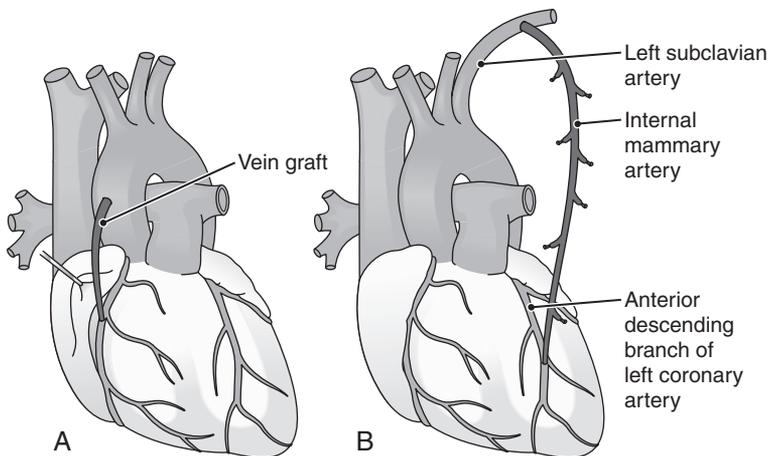

FIGURE 16-6 Coronary artery bypass graft (CABG). **A:** A segment of the saphenous vein carries blood from the aorta to a part of the right coronary artery that is distal to an occlusion. **B:** The mammary artery is used to bypass an obstruction in the left anterior descending (LAD) coronary artery. less invasive nature of the procedure and the equivalent outcomes that are seen in long-term prognosis. These results were recently confirmed in the Clinical Outcomes Utilizing Revascularization and Aggressive Drug Evaluation (COURAGE) trial.¹³³ Patients with CAD were randomized to aggressive medical treatment with optimization of medical therapy and risk factors, or aggressive medical treatment plus PCI. Over a 4.6-year period, no significant difference was noted between the groups in cardiovascular outcomes (death, MI, stroke, hospitalization for ACS). The only difference noted was better control of anginal symptoms early on with PCI, but that difference was no longer significant at the end of the study. These results highlight the crucial role of optimizing medical therapy (including diet, lifestyle changes, risk factor modification) for patients with CAD, regardless of whether revascularization is performed.

ACUTE CORONARY SYNDROMES: UNSTABLE ANGINA AND NON-ST-SEGMENT ELEVATION MYOCARDIAL INFARCTION

50. E.G., a 54-year-old man, is brought to the ED by helicopter for treatment of severe, unrelenting chest pain of 2 hours' duration. He has no history of CAD, but cardiac risk factors include a strong positive family history of CAD, a 45-pack-year smoking history, and a 5-year history of hypertension. He is taking oral metoprolol 100 mg BID. Physical examination reveals a middle-aged man in obvious distress with the following vital signs: heart rate, 110 beats/minute; BP, 176/108 mmHg; respiratory rate, 18 breaths/minute; and temperature, 37°C. Normal lung and heart sounds are heard, with the exception of an S₄ gallop. Examination of E.G.'s abdomen and extremities is unremarkable, as is the fundoscopic examination. E.G. has received 10 mg morphine sulfate IV and three sublingual 0.4 mg NTG tablets and is still experiencing severe pain that is associated with ST-segment depression.

He is placed on oxygen (2 L by nasal prongs) and an NTG infusion (5 mcg/minute). Rapid upward titration of the NTG to 60 mcg/minute alleviates the chest pain. His admitting diagnosis is acute coronary syndrome. What general guidelines exist for the treatment of acute coronary syndromes?

Clinical Presentation

Acute coronary syndromes include unstable angina (also known as *preinfarction angina*, *crescendo angina*, and *angina at rest*), non-ST-segment elevation myocardial infarction (NSTEMI), and ST-segment elevation myocardial infarction (STEMI). On presentation, the ultimate diagnosis usually cannot be determined because the diagnosis of MI requires the presence of biomarkers such as creatinine kinase (CK) or troponin. Often these results are not available for the first 12 to 24 hours. Because of this delay in the determination of the final diagnosis, initial treatment must be driven by other factors. One critical factor during the acute presentation is the initial ECG and, more specifically, whether ST-segment elevation is present on the initial ECG. Patients who have ST-segment elevation acute coronary syndromes (e.g., acute MI) are candidates for immediate reperfusion therapy and are discussed in detail in Chapter 17, Myocardial Infarction. Treatment of patients who present with non-ST-segment elevation acute coronary syndromes (this includes patients presenting with ST-segment depression, T-wave inversions, or no ECG changes) is discussed briefly here.¹¹

Unstable angina is a syndrome falling between chronic stable angina and MI. The prognosis of patients with unstable angina is variable, and classification systems have been developed to determine whether a patient is at low, intermediate, or high risk for acute MI and death in the short term (Table 16-10).¹¹ Patients at intermediate or high risk should be hospitalized for acute treatment and assessment of potential long-term treatment strategies. Patients at low risk may be treated without

Table 16-10 Short-Term Risk of Death or Nonfatal Myocardial Infarction (MI) in Patients With Unstable Angina

| Feature | High Risk (at least one of the following must be present) | Intermediate Risk (no high-risk features, but must have one of the following) | Low Risk (no high- or intermediate-risk features, but may have any of the following) |
|-------------------|---|--|---|
| History | Accelerating tempo of ischemic symptoms in preceding 48 hr | Prior MI, peripheral or cerebrovascular disease, or CABG, prior aspirin use | |
| Character of pain | Prolonged ongoing (>20 min), rest pain | Prolonged (>20 min) rest angina, now resolved, with moderate or high likelihood of CAD | New-onset angina ³² CCS class III or IV angina in the past 2 wk without prolonged (>20 min) rest pain, but with moderate or high likelihood of CAD |
| Clinical findings | Pulmonary edema New or worsening MR murmur S ₃ or new/worsening rales Hypotension, bradycardia, tachycardia Age >75 yr | | |
| ECG | Angina at rest with transient ST-segment changes >0.05 mV Bundle-branch block, new or presumed new | T-wave inversions >0.2 mV Pathologic Q waves | Normal or unchanged ECG during episode of chest discomfort |
| Cardiac markers | Markedly elevated (e.g., TnT or TnI >0.1 ng/ml) | Slightly elevated (e.g., TnT >0.01 but <0.1 ng/mL) | Normal |

CABG, coronary artery bypass graft; CAD, coronary artery disease; CCS, Canadian Cardiovascular Society; ECG, electrocardiogram; MR, mitral regurgitation; S₃, third heart sound; TnI, troponin I; TnT, troponin T.

admission to the hospital. F.G. is a high-risk patient because he has ST-segment depression at rest or with pain.

Management

Coronary arteriographic studies of patients with USA usually reveal severe atherosclerotic disease complicated by the rupture of an atherosclerotic plaque with the formation of a superimposing thrombus.¹¹ Therefore, the pathophysiology of USA is closely related to that of MI, and similar treatment strategies are used in both disease states. The treatment of USA in recent years has evolved to include medical therapy as well as revascularization procedures. Typically, revascularization with PCI is reserved for patients who are considered intermediate to high risk for developing adverse cardiovascular outcomes in the next 30 days or whose condition does not stabilize with medical therapy.¹¹

The immediate challenge in the treatment of USA is relief of pain and control of all ischemic episodes. Hospitalization, bedrest, diagnosis, and treatment of underlying precipitating factors, such as infection, anemia, hypertension, heart failure, and arrhythmias, are essential. Pharmacologic therapy is targeted at relieving ischemia and at attenuating the thrombotic process.

As with patients experiencing an acute MI, β -blockers should be administered acutely because they have been demonstrated to prevent the progression to MI and death. Nitrates, both sublingually and then intravenously, are effective for relieving pain and acutely treating ischemia. CCBs are effective for treating ischemia in patients with USA, but should be reserved for patients who have ischemia refractory to β -blockade.¹¹

A 325-mg dose of chewable aspirin should be administered to all patients because it has been shown to prevent the progression to MI and death. In addition, the combined use of aspirin (81–325 mg daily) and clopidogrel (300 mg load, 75 mg orally every day) acutely and for up to 1 year in patients with USA/NSTEMI has been shown to decrease the risk of cardiovascular death, MI, or stroke at 30 days and up to 1 year.^{106,107} Based on these results from the CURE and CREDO studies, aspirin and clopidogrel should be administered to all patients with USA/NSTEMI who are unlikely to undergo PCI acutely. In patients who will undergo emergent PCI for treatment of USA/NSTEMI, clopidogrel administration can be delayed until the procedure is completed and then continued for up to 1 year, depending on the course of events during PCI.

Historically UFH has been the primary antithrombin used in the treatment of ACS. The beneficial effects of UFH are additive to aspirin in the prevention of acute MI and death.¹¹ Several new antithrombotic strategies have become available, which may improve on the results seen with aspirin and UFH. These include LMWH, the synthetic pentasaccharide fondaparinux, as well as the direct thrombin inhibitor bivalirudin. Each of these agents has demonstrated efficacy in the setting of non-ST-segment ACS and the choice of agent will likely be determined by cost, physician preference, and overall treatment strategy (invasive versus conservative management).

Several LMWHs have been investigated in the setting of USA and non-Q-wave MI and, as a group, are considered at least as effective as UFH at improving clinical outcomes. Results for individual agents have not been uniform, however. Trials comparing enoxaparin with UFH have consistently shown

that enoxaparin is superior to UFH in preventing cardiovascular events. Trials investigating other LMWH have only demonstrated equivalency to UFH. Based on these results from clinical trials, the current ACC/AHA guidelines specifically recommend enoxaparin as the LMWH of choice to be used during ACS.¹¹

In patients who are at low risk and being treated with a conservative medical strategy, UFH, enoxaparin, and fondaparinux all represent reasonable options for antithrombin therapy. Enoxaparin or fondaparinux are preferred, however, owing to demonstrated superiority for enoxaparin in clinical trials as compared with UFH,¹³⁴ as well as equivalence of enoxaparin and fondaparinux in the Organization to Assess Strategies in Acute Ischemic Syndromes (OASIS)-5 study.¹³⁵ In the conservative management setting, bivalirudin is not an option because trial data in this setting are lacking, as well as the prohibitive cost associated with a prolonged infusion duration. UFH is typically continued for 48 hours, whereas enoxaparin and fondaparinux can be continued for up to the duration of hospitalization.

In patients who present with non-ST-segment ACS, and who are at high risk requiring aggressive intervention with early angiography (with or without PCI), UFH, bivalirudin, enoxaparin, and fondaparinux all are reasonable options. Support for bivalirudin comes from the ACUTY trial, which demonstrated similar outcomes with a reduced incidence of bleeding for bivalirudin as compared with heparin (UFH or enoxaparin).¹³⁶ Although fondaparinux is listed as an option in association with an invasive strategy, the need for an additional antithrombin agent with anti-IIa activity during PCI makes this a less attractive strategy.¹¹ Dosing strategies for various antithrombin agents can be found in Table 16-9.

The Gp IIb/IIIa receptor antagonists are potent antiplatelet agents that provide significantly improved outcomes in patients with USA/NSTEMI who are being treated medically or who undergo revascularization via PCI.¹³⁷ These agents have a unique mechanism of action in that they block the final common pathway in platelet aggregation. Platelets can be stimulated by a number of different agonists (e.g., epinephrine, serotonin, ADP, thromboxane A₂), some of which may be inhibited by aspirin (thromboxane A₂) or clopidogrel. Blockade of one or more of these agonists by aspirin or clopidogrel still leaves the platelet susceptible to stimulation via other agonists. Regardless of the initial stimulus, the end result is the expression of the Gp IIb/IIIa receptor. This receptor is critical because it binds and cross-links fibrin, which stabilizes the clot. This process is blocked with the receptor antagonists. Because of their mechanism of action, the Gp IIb/IIIa antagonists are significantly more potent in terms of their antiplatelet effects than aspirin or clopidogrel.

These agents, in addition to aspirin, clopidogrel, and antithrombin therapy, significantly decrease the composite risk of death, acute MI, and urgent revascularization in patients with USA/NSTEMI. The Gp IIb/IIIa receptor antagonists currently are recommended as options in patients with USA/NSTEMI in one or more of the following groups: (a) in whom catheterization and PCI is planned; (b) who have continuing ischemia despite treatment with aspirin, UFH/LMWH/fondaparinux/bivalirudin, nitrates, β -blockers, and clopidogrel; and/or (c) who have other high risk features, such as elevated troponin or ST-segment changes on the initial ECG.¹¹

LIFESTYLE MODIFICATIONS 17-25**SUMMARY 17-25**

Acute myocardial infarction (AMI), now referred to as ST segment elevation myocardial infarction (STEMI), is a manifestation of ischemic heart disease characterized by cellular death or necrosis occurring in the setting of severe or prolonged ischemia. STEMI is believed to be the result of complete occlusion in a coronary artery.

STEMI is a medical emergency requiring immediate intervention. Until the 1980s, patients with AMI were treated symptomatically. Their pain was controlled; arrhythmic complications were treated; and bed rest, nitrates, and β -blockers minimized the amount of oxygen required by the heart. In 1980, an angiographic study by DeWood et al. found total occlusion in a coronary artery in 87% of patients who were examined by angiography within the first 4 hours of symptoms.¹ This study stimulated interest in using thrombolytics to interrupt the progression of myocardial necrosis. Thrombolytics and percutaneous coronary intervention (PCI) are now considered first-line therapies unless a contraindication is present. A committee composed of representatives from the American College of Cardiology (ACC) and the American Heart Association (AHA) periodically review the literature and publish practice guidelines to aid health care practitioners in selecting the most effective treatments for patients with STEMI.^{2,3}

Epidemiology

The estimated annual incidence of STEMI is 565,000 for new and 300,000 for repeat attacks.⁴ Twenty to 30% of patients die before reaching a hospital, presumably as a result of ventricular fibrillation.⁴ Prompt recognition and treatment of AMI have dramatically reduced event-related mortality since the 1990s. In-hospital and 30-day mortality rates have been estimated to be 8.8% and 18.4%, respectively.⁵ Treatment disparities and access to care exist for women, blacks, and patients who are at least 75 years of age.^{6–8}

Pathophysiology

The majority of AMIs results from occlusion of a coronary artery secondary to thrombus formation overlying a lipid-rich atheromatous plaque that has undergone fissuring or rupture. Damage to the plaque results in blood being exposed to collagen and fatty acids; this in turn activates platelets, the first step in thrombosis and formation of a fibrin clot. Rarely, coronary artery spasm may cause an AMI in a patient with normal coronary arteries, particularly in the setting of cocaine abuse. More likely, spasm occurs before, during, or after the AMI and further compromises blood flow in an already stenotic artery.⁹

Most infarctions are located in a specific region of the heart and are described as such (e.g., anterior, lateral, inferior). Some patients develop permanent electrocardiographic abnormalities (Q waves) following an AMI. In the past, patients with Q-wave infarctions were generally believed to have more extensive necrosis and a higher in-hospital mortality rate. Patients with a non-Q-wave infarct were believed to have a greater likelihood of experiencing postinfarction angina and early reinfarction. More recently, however, these distinctions have come into question. Some cardiologists now believe that there is no difference in prognosis. The terminology has changed: Q-wave MI is now called STEMI and non-Q-wave MI is now called non-ST segment elevation MI (NSTEMI) or non-ST segment elevation acute coronary syndrome (NSTEMI-ACS). An anterior wall infarction carries a worse prognosis than an inferior or lateral wall infarction.¹⁰

Clinical Presentation

It is important to make the diagnosis of STEMI as quickly as possible so appropriate action may be taken. Patients may complain of prolonged substernal chest pain or pressure, shortness of breath, diaphoresis, nausea, and vomiting. In some patients, the symptoms may be confused with indigestion or other gastrointestinal (GI) complaints. The pain may be atypical in nature and location. The pain might be described as burning, and it may occur in the arms, shoulder, neck, jaw, or back.^{2,3} Presentation may differ by gender and age. Men commonly complain of chest pain, whereas women present with nausea and diaphoresis.¹¹ Elderly patients may present with hypotension or cerebrovascular symptoms rather than chest pain. However, not all STEMIs are symptomatic: An estimated 20% of STEMIs are “silent,” and this presentation tends to occur more frequently in the elderly and people with diabetes.

The physical examination is not particularly helpful in making the diagnosis of STEMI, but the findings are important in guiding initial therapy. Signs of severe left ventricular or right ventricular dysfunction may be present (see Chapter 19). The patient may have severe hypertension due to pain or, conversely, may be hypotensive. Significant tachycardia (heart rate >120 beats/minute) suggests a large area of damage. On cardiac auscultation, a fourth heart sound (S₄) may be heard, denoting an ischemia-induced decrease in left ventricular compliance. New cardiac murmurs may be heard, resulting from papillary

muscle dysfunction. The cerebral and peripheral vasculature should be assessed. Patients with a history of cerebrovascular disease may not be eligible for thrombolytic therapy. Peripheral pulses should be examined to assess perfusion and to obtain a baseline before invasive procedures are instituted.

Diagnosis

Failure to make the appropriate diagnosis in STEMI can lead to disastrous results. The list of other medical conditions that mimic the presentation of STEMI is extensive (Table 17-1). In addition to the patient’s history and presentation, the diagnosis of STEMI is based on the ECG and laboratory results in a cardiac injury profile. Usually two of the three criteria (history, ECG changes, and cardiac injury profile findings) should be consistent with STEMI before the diagnosis is made.^{2,3}

The electrocardiogram (ECG) is an indispensable tool in the diagnosis of STEMI and has become the key point in the decision pathway. The presence of ST segment elevation is used to identify patients who will benefit from thrombolytic therapy. The 12-lead ECG is helpful in determining the location of an infarct. The presence of a new Q wave, new bundle branch block, or ST segment elevation is consistent with a STEMI. The electrocardiographic diagnosis of a STEMI is extremely difficult in the presence of a left bundle branch block. Figures 17-1 and 17-2 show the ECG in a patient presenting with STEMI before and after successful thrombolysis.¹²

Patients presenting with ischemic chest pain but without ST segment elevation and without laboratory evidence of

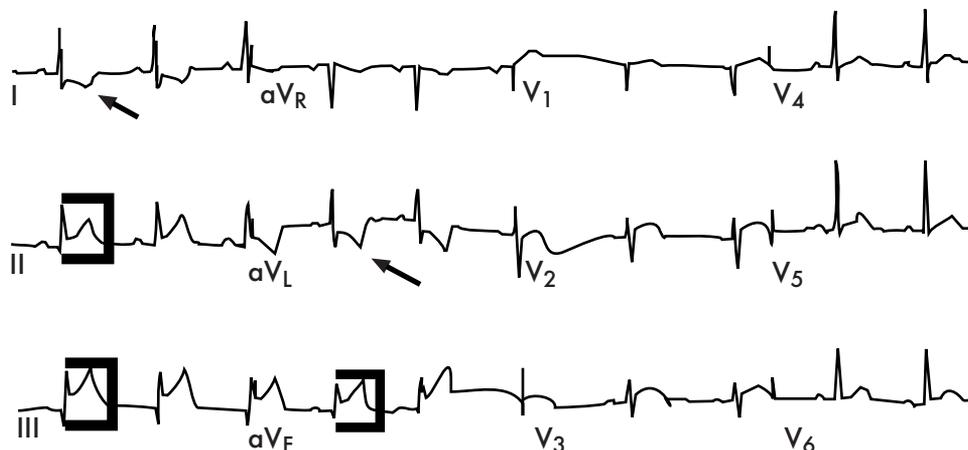

FIGURE 17-1 On this admission electrocardiogram (ECG), note the extensive ST segment elevation in leads II, III, and aV_F (brackets), indicating an inferior wall AMI. The patient also displays reciprocal ST segment depression in I and aV_L (arrows), which are the lateral ECG leads and are opposite the inferior leads.

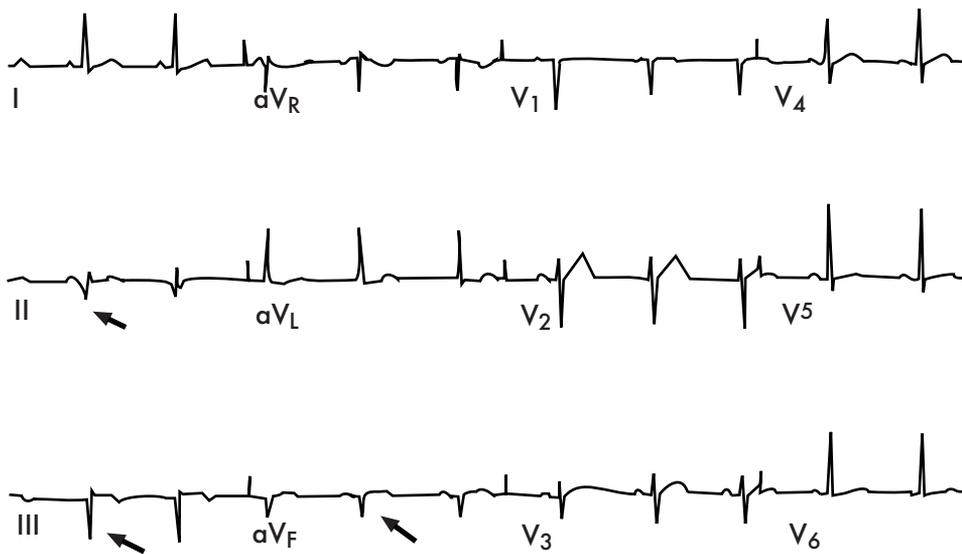

FIGURE 17-2 After successful thrombolysis, the electrocardiogram shows no ST segment changes suggestive of ischemia, but evolution of new Q waves in leads II, III, and aVF (arrows) is apparent.

infarction are classified as having unstable angina, part of the acute coronary syndrome spectrum. Patients with a history consistent with ischemic chest pain, without ST segment elevation, but who develop a positive cardiac injury profile (i.e., elevated troponin) within hours of presentation are also given the diagnosis of AMI (referred to as NSTEMI or NSTEMI-ACS). Patients with NSTEMI and unstable angina continue to have some blood flow, although limited, through the affected coronary artery. Patients with NSTEMI usually have partial occlusion of the artery and/or thrombi that are comprised largely of platelets and fibrinogen. Thrombolytic therapy is not beneficial in these patients and is a major point of differentiation.³ Figure 17-3 shows the relationship between different forms of acute coronary syndromes (ACSs).

Laboratory Changes

When a cardiac cell is injured, enzymes are released into the circulation. The measurement of cardiac enzymes is routine in making the diagnosis of AMI. One of the enzymes used for the laboratory diagnosis of AMI is creatine kinase (CK).

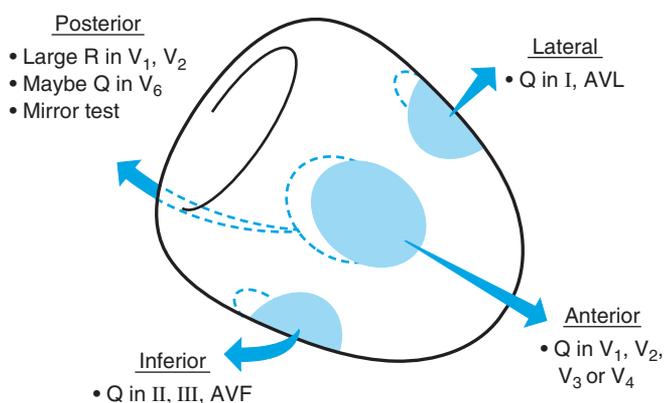

FIGURE 17-3 Diagnosis and presentation of the acute coronary syndromes. Source: Reprinted with permission from Dubin D. Infarction. In Dubin D, ed. Rapid Interpretation of EKGs. 6th Ed. Tampa. COVER Publishing Co., 2000:290.

There are three isoenzymes of CK: the BB, MM, and MB bands. Of these, the CK-MB isoenzyme is the most specific for the diagnosis of AMI. It can appear in the serum within 3 to 6 hours after myocardial damage, and levels generally peak in 12 to 24 hours.^{2,3} Serum enzymes are normally determined at admission and then repeated at least once 12 hours after the onset of chest pain. The magnitude of rise of peak CK is related to the size of the infarct, but the peak may be missed if admission is delayed. There are several conditions other than AMI in which CK-MB may be elevated (Table 17-2).¹³ CK is usually reported as enzymatic activity (U/L), and CK-MB is reported as mass (ng/mL) in either plasma or serum. CK-MB is often reported as percentage of activity.

The most sensitive markers of damage to cardiac muscle are the troponins I and M. The troponins are enzymes that normally

Table 17-2 Conditions Where CK-MB Isoenzyme May Be Elevated

regulate the interaction of actin and myosin within the cardiac cell. When cell death occurs, they diffuse into the peripheral circulation. Although troponins are more sensitive than CK and CK-MB, they have a similar lag time before they can be detected in the blood following an acute coronary occlusion. Elevation of troponins has been associated with subsequent cardiac events.¹³

Another laboratory change that may be seen is an increase in lactate dehydrogenase (LDH). The increase in LDH generally appears 24 to 48 hours after the onset of chest pain and peaks in 3 to 6 days. Measurement of LDH may be helpful in patients who present with a history of chest pain that began several days before admission. In these cases, the CK may have already returned to normal before the patient is evaluated. Increases in LDH are also seen in liver disease, hemolysis, leukemia, pulmonary embolism, myocarditis, and skeletal muscle disease. LDH is comprised of five isoenzymes. Because the heart muscle contains LDH₁, a ratio of LDH₁ to LDH₂ >1 may be helpful in distinguishing AMI from other disorders. Because troponins are known to remain elevated in patients who have sustained myocardial necrosis, they have replaced the less specific LDH enzyme. Other nonspecific laboratory changes that occur in AMI include hyperglycemia and increases in aspartate aminotransferase, the white blood cell count, and C-reactive protein.¹³

Complications

The primary complications of AMI can be divided into three major groups: pump failure, arrhythmias, and recurrent ischemia and reinfarction. Depression of cardiac function following an AMI is related directly to the extent of left ventricular damage. As a result of decreased cardiac output and decreased perfusion pressure associated with left ventricular dysfunction, a number of compensatory mechanisms become activated. The levels of circulating catecholamines increase in an attempt to increase contractility and restore normal perfusion. In addition, the renin-angiotensin-aldosterone system is enhanced, leading to an increase in systemic vascular resistance and sodium and water retention. These compensatory mechanisms can eventually worsen the imbalance between myocardial oxygen supply and consumption by increasing the myocardial oxygen demand.

Signs and symptoms of heart failure are common in patients who have abnormal wall motion affecting 20% to 25% of the left ventricle. If 40% or more of the left ventricle is damaged, cardiogenic shock and death can occur.¹⁴ In addition to systolic dysfunction, patients who have suffered an AMI may also have diastolic dysfunction. Scar formation following an AMI may lead to a decrease in ventricular compliance, resulting in abnormally high left ventricular filling pressures during diastole. (See Chapter 18 for further discussion on systolic dysfunction versus diastolic dysfunction.)

Decreased contractility and a compensatory increase in left ventricular end-diastolic volume and pressure lead to increased wall stress within the left ventricle. Left ventricular enlargement is an important determinant of mortality after AMI. Over a period of days to months following an AMI, the infarcted area may expand as a result of dilatation and thinning of the left ventricular wall. These changes are known as *ventricular remodeling*. In addition, hypertrophy of the noninfarcted myocardium

occurs. Administration of oral angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers, and/or aldosterone antagonists may limit remodeling and will attenuate the progression of left ventricular dilatation.¹⁵

During the peri-infarction period, the heart is irritable and subject to ventricular arrhythmias. The continuous monitoring of patients in a coronary care unit has reduced the in-hospital mortality rate related to ventricular arrhythmias. However, patients who have had an AMI have an increased risk of sudden cardiac death for 1 to 2 years following hospital discharge. The most important predictor for sudden cardiac death is an abnormal ejection fraction (EF). During the first 30 days after an AMI, each 5% decrease in EF will increase the risk of sudden death by 21%.¹⁴ Other factors associated with an increased risk for sudden cardiac death are complex ventricular ectopy, frequent (>10/hour) premature ventricular complexes, and the identification of late potentials on a signal-averaged ECG.

OVERVIEW OF DRUG AND NONDRUG THERAPY

Thrombolytics

In the management of patients with AMI, emphasis has shifted from preventing or managing complications (arrhythmias, pain, and blood pressure [BP] control) to limiting the extent of myocardial necrosis and preventing reinfarction. The 2004 update of the ACC/AHA guidelines for the management of patients with STEMI addressed the most significant advances made in the prior 2.5 years and should be used in conjunction with the 1999 guidelines.²

Because the majority of STEMI cases result from the sudden occlusion of a coronary artery due to the formation of a thrombus, the therapeutic priority is to open the occluded artery as quickly as possible. This is accomplished by administering a thrombolytic that enhances the body's own fibrinolytic system or by mechanically reducing the obstruction with PCI.

Large clinical trials have proven that administration of a thrombolytic agent reduces mortality. Early mortality from STEMI has been reduced by approximately one-third (from 10%–15% to 6%–10%) with the advent of thrombolytic therapy.¹⁶

The thrombolytics currently used for STEMI patients in the United States are streptokinase, anistreplase, alteplase (t-PA), reteplase (r-PA), and tenecteplase (TNK). Streptokinase is a polypeptide derived from β -hemolytic streptococcal cultures. It binds to plasminogen to form an active plasminogen-streptokinase complex that cleaves other molecules of plasminogen to form plasmin. Plasmin, which is an active fibrinolytic enzyme, then acts on a fibrin clot to enhance its dissolution. Anistreplase, also known as anisoylated plasminogen streptokinase activator complex, is a combination of streptokinase and plasminogen with an anisoyl group reversibly placed within the catalytic center of the plasminogen moiety. This moiety is deacylated in the circulation at a controlled rate.

Alteplase, or t-PA, is a naturally occurring enzyme produced commercially by recombinant DNA technology. t-PA cleaves the same plasminogen peptide bond that urokinase cleaves. However, t-PA has a binding site for fibrin, which allows it to bind to a thrombus and preferentially lyse it over the circulating plasminogen.

Table 17-3 Pharmacologic Comparison of Available Thrombolytic Agents

| Drug | Enzymatic Efficiency for Clot Lysis | Fibrin Specificity | Potential Antigenicity | Average Dose | Dosing Administration | Cost |
|---------------------------|-------------------------------------|--------------------|------------------------|---|--|----------|
| Streptokinase (Streptase) | High | Minimal | Yes | 1.5 MU | 1 hr IV infusion | Low |
| Anistreplase (Eminase) | High | Minimal | Yes | 30 U | 2–5 min IV infusion | Moderate |
| Alteplase (Activase) | High | Moderate | No | 100 mg | 15 mg IV bolus, 50 mg over 30 min, then 35 mg over 60 min ^a | High |
| Retepase (Retavase) | High | Moderate | No | 10+10 U | 10 U IV bolus, sec bolus 30 min later | High |
| Tenecteplase (TNK) | High | High | No | 30–50 mg (based on weight) ^b | Bolus over 5–10 sec | High |

^aFor patients = 65 kg; reduced doses for patients weighing <65 kg.

^bFor patients <60 kg, 30 mg; 60–69 kg, 35 mg; 70–79 kg, 40 mg; 80–89 kg, 45 mg; 90 kg, 50 mg.

Adapted from references 2, 3, 16, and 17.

Retepase is a genetically modified plasminogen activator that is similar to t-PA. Retepase has a longer half-life, allowing it to be administered as two bolus injections 30 minutes apart, rather than as a bolus plus infusion.

TNK is a genetically modified form of t-PA. Compared to t-PA, TNK has a longer plasma half-life, better fibrin specificity, and higher resistance to inhibition by plasminogen-activator inhibitor. The pharmacologic properties of these agents are compared in Table 17-3.^{2,3,17}

Urokinase, although available in the United States, has not gained widespread use as a thrombolytic agent for patients with STEMI. The ideal thrombolytic would be thrombus specific, easily administered, highly efficacious, inexpensive, and rapid acting, and the incidence of reocclusion and side effects would be low. Unfortunately, such an ideal thrombolytic does not exist. Three problems common to all thrombolytics are the inability to open 100% of coronary artery occlusions, inconsistent ability to maintain good blood flow in the infarcted artery after it is opened, and bleeding complications. Good blood flow is commonly defined as thrombolysis in myocardial infarction (TIMI) grade 3 flow, which is complete reperfusion of the vessel.

To minimize the risk of bleeding complications, contraindications to the use of thrombolytics must be evaluated prior to administration (Table 17-4).^{2,3} There are relatively few absolute contraindications to thrombolytic therapy, but each patient should be assessed carefully to ascertain whether the potential benefit outweighs the potential risk. Because of the serious nature of intracerebral hemorrhage associated with thrombolytic therapy, patients should be selected carefully before receiving these agents.² Generally, the diagnosis of STEMI must be ensured, with a history consistent with ischemic heart disease, presence of ST segment elevation in two contiguous leads, or a new left bundle branch block on the ECG. Once the diagnosis is made, the thrombolytic should be administered immediately if there are no contraindications.

The benefit derived from thrombolytic therapy is directly related to the time from the onset of chest pain to the time of administration. The 2004 guidelines recommend initiation of thrombolytic therapy within 12 hours from the onset of chest

pain. However, data from clinical trials suggest that mortality reduction is greater when thrombolytic therapy is initiated within 0 to 2 hours of symptom onset compared to treatment begun more than 2 hours after symptoms have begun (44% vs. 20%, respectively, $p = 0.001$).^{2,3} The guidelines recommend a “door-to-needle time” of 30 minutes, meaning the diagnosis of STEMI and initiation of thrombolytic therapy should ideally take place within 30 minutes from the time the patient arrives at the hospital door.

Table 17-4 Risk Factors Associated With Bleeding Complications Secondary to Thrombolytic Use

| | |
|--|---|
| Major (thrombolytics contraindicated) | Intracranial tumor (primary or metastatic) Prior intracranial hemorrhage Recent head/face trauma within 3 months Suspected aortic dissection Ischemic stroke within 3 months, EXCEPT acute ischemic stroke within 3 hr Active internal bleeding or bleeding diathesis (excluding menses) |
| Important (relative contraindication) | Uncontrolled hypertension on presentation (SBP >180 mm, DBP >110 mmHg) Chronic, severe, poorly controlled hypertension Prior ischemic stroke >3 months, dementia, or known intracranial pathology Puncture of a noncompressible vessel Cardiopulmonary resuscitation for >10 min Major surgery (<3 wk) Recent internal bleeding within 24 wk Active peptic ulcer Current use of anticoagulants (the higher the INR, the greater the risk for bleeding) Pregnancy For streptokinase or anistreplase: prior exposure (>5 days) or prior allergic reaction |

DBP, diastolic blood pressure; INR, international normalized ratio; SBP, systolic blood pressure.

From reference 2.

Antiplatelet and Anticoagulant Drugs

When thrombolysis occurs, whether due to the administration of a thrombolytic agent or through activation of the body's own fibrinolytic system, the fibrin clot begins to disintegrate. As the clot dissolves, there is a paradoxical increase in local thrombin generation and enhanced platelet aggregability, which may lead to rethrombosis. Aspirin, unfractionated heparin (UFH), and low-molecular-weight heparin (LMWH) have been used to minimize repeat thrombosis. LMWH may offer advantages over heparin due to its ease of administration, improved bioavailability, and less need for monitoring. Bivalirudin, lepirudin, and argatroban are thrombin inhibitors that bind directly to thrombin and inactivate it. Unlike UFH, the direct thrombin inhibitors (DTIs) offer better protection against thrombin reactivation after therapy discontinuation. When used with early invasive treatment (<72 hours), DTIs appear to reduce the rate of death or reinfarction to a greater extent than UFH (9.50% vs. 13.86%, respectively, $p < 0.05$).¹⁸ The 2004 ACC/AHA guidelines recommend DTIs, specifically bivalirudin, as an alternative to heparin in patients with heparin-induced thrombocytopenia.²

Another class of agents being used is the glycoprotein (GP) IIb/IIIa inhibitors. GP IIb/IIIa receptors are abundant on the platelet surface. Platelets become activated when patients are having an acute ischemic coronary event or are undergoing a PCI. With platelet activation, the GP IIb/IIIa receptor undergoes a conformational change that increases its affinity for binding to fibrinogen. The binding of fibrinogen to receptors on platelets results in platelet aggregation, which can lead to thrombus formation. The GP IIb/IIIa receptor inhibitors prevent platelet aggregation by preventing fibrinogen from binding to GP IIb/IIIa receptor sites on activated platelets. The GP IIb/IIIa inhibitors are more often used in conjunction with aspirin and UFH in patients with ischemic chest pain, usually without ST segment elevation (ACS patients) and in patients undergoing PCI. When used in conjunction with thrombolytic agents for patients with STEMI, the dose of thrombolytic drug is reduced by one-half.

β -Blockers

In addition to antiplatelet, antithrombotic, and thrombolytic agents, β -blockers are fundamental in the management of AMI. Before the advent of thrombolytics, β -blockers were shown to decrease infarct-associated morbidity and mortality. These benefits are additive to those of thrombolytics. β -blockers decrease myocardial oxygen consumption, limit the amount of myocardial damage, and reduce some of the complications of MI, specifically sudden death attributed to ventricular fibrillation. During the prethrombolytic era, 28 randomized clinical trials involving more than 27,000 patients with AMI were conducted to evaluate β -blocker use. A retrospective analysis of these studies suggests that β -blockers reduce mortality by 14% with a 19% reduction in nonfatal reinfarction and a 19% reduction in nonfatal cardiac arrest during the first week in hospital. These short-term benefits are also seen with long-term use in the post-MI period. Unless there are contraindications to their use, β -blocking agents should be prescribed for all patients having an AMI, and they should be continued indefinitely.^{2,3}

Statins

HMG-CoA reductase inhibitors or statins reduce long-term morbidity and mortality in patients with cardiovascular disease. What is less clear is whether statins provide short-term benefit when started immediately after hospitalization for AMI. Beyond their lipid-lowering properties, statins are believed to exhibit pleiotropic effects, which include plaque stabilization, anti-inflammation, antithrombogenicity, enhancement of arterial compliance, and modulation of endothelial function.¹⁹ Data regarding early intensive statin therapy in patients with STEMI or NSTEMI exist with atorvastatin, simvastatin, pravastatin, and fluvastatin.²⁰ Debate continues to exist over which statin to initiate, the dosage, and the timing²¹ (see Chapter 13).

Vasodilators

Other strategies for minimizing myocardial damage include the use of vasodilators in the peri-infarction period. Progressive left ventricular dilatation ("remodeling") occurs in some patients following an AMI and has become an important marker for prognosis. Vasodilators reduce oxygen demand and myocardial wall stress by reducing afterload and/or preload and can halt the remodeling process. Some vasodilators may increase the blood supply to the myocardium by enhancing coronary vasodilatation.

ACE inhibitors have been assessed in a large number of clinical trials, and all trials using oral agents have demonstrated a benefit in reducing mortality.^{2,3} Only one trial has not shown a benefit. Enalapril was studied in the Cooperative New Scandinavian Enalapril Survival Study (CONSENSUS-II) trial. In this study, more than 6,000 patients were randomized to either placebo or enalapril, which was started within 24 hours from the onset of chest pain. Enalapril was initiated by intravenous (IV) administration, followed by oral enalapril administration 6 hours later. In this trial, enalapril did not improve 6-month survival, but this may be because hypotension was more common in the enalapril-treated group. It appears that early IV administration of ACE inhibitors results in excessive hypotension, offsetting their potential benefits. The benefit of ACE inhibitors is greatest in patients with anterior infarction, signs of heart failure, tachycardia, or a history of previous infarction. Ideally, oral ACE inhibitors should be started within 24 hours of diagnosis, after BP has stabilized. Initial doses should be low and then titrated as quickly as possible.^{2,3}

The effects of nitrates have been evaluated in AMI patients. Pooled effects from several studies show a small but statistically significant benefit in reducing mortality in patients receiving nitrates. Nitroglycerin (NTG) is more beneficial than nitroprusside in this population. IV NTG is recommended for routine use during the first 24 to 48 hours in most patients with STEMI, particularly those with large anterior wall infarctions.^{2,3}

Another class of vasodilators that has been investigated in the treatment of AMI is the calcium channel blockers. There are several proposed mechanisms whereby a calcium channel blocker might be beneficial. As a group, they dilate coronary and peripheral vessels. They could alleviate some of the coronary vasospasm present at the time of coronary thrombosis. In addition, they are effective anti-ischemic agents through

their action in improving coronary blood supply and reducing myocardial oxygen demand. Because intracellular calcium overload has been observed in the ischemic myocardium, it was believed that calcium channel blockers would protect cardiac cells during the peri-infarction period. Despite these theoretical benefits, the outcomes of clinical trials have varied, depending on the individual drug used and the timing of administration resulting in a decline in use.^{2,3}

There have been two trials evaluating diltiazem in the setting of AMI. The first study evaluated the effect of oral diltiazem, started 24 to 72 hours after the onset of chest pain, on reinfarction rates in patients with non-Q-wave AMI. There was a 51% reduction in the reinfarction rate in the diltiazem group compared to placebo after 14 days of follow-up. Diltiazem also reduced the frequency of postinfarction angina. Another trial initiated oral diltiazem (240 mg daily) 3 to 15 days after infarction in patients with both Q wave and non-Q wave. Diltiazem was continued indefinitely, and patients were followed for 12 to 52 months. Overall, there was no difference in mortality between the two groups. However, patients assigned to diltiazem who did not have pulmonary congestion at the time of randomization had a reduced number of cardiac events compared to placebo patients. In contrast, patients who had signs of pulmonary congestion at the time of randomization had an unfavorable response to diltiazem (i.e., more deaths from cardiac causes or nonfatal reinfarction). Diltiazem may be used to lower the heart rate or decrease angina in patients who cannot tolerate a β -blocker. However, diltiazem should be avoided in patients with signs or symptoms of pulmonary congestion because its negative inotropic properties may worsen systolic function.^{2,3}

The Danish Verapamil Infarction Trial (DAVIT-II) study showed a trend toward a reduction in mortality at 18 months in patients receiving verapamil (11.1% vs. 13.8% in the placebo group). In patients who did not have heart failure at the time of randomization, verapamil showed a statistically significant benefit in reducing mortality (7.7% vs. 11.8% in the placebo group). In contrast to the diltiazem trial, verapamil had neither a demonstrable benefit nor a detrimental effect in patients with heart failure. It has been suggested that the use of verapamil and diltiazem should be limited to patients who do not tolerate β -blocker therapy and who do not have systolic dysfunction.^{2,3}

Analgesics

It is important to abolish the patient's pain as quickly as possible because the pain and anxiety associated with an AMI will contribute to increased myocardial oxygen demand. If the pain is not relieved by the thrombolytic and anti-ischemic medications (e.g., nitrates, β -blockers), then additional analgesia may be necessary. Morphine and meperidine are the two most commonly prescribed analgesics.

Oxygen

Many patients are modestly hypoxemic during the initial hours of an AMI. Oxygen should be administered via nasal cannula to all patients suspected of having ischemic pain. Patients with severe hypoxemia or pulmonary edema may require intubation and mechanical ventilation.^{2,3}

Antiarrhythmics

Ventricular arrhythmias, including ventricular fibrillation, are common complications associated with myocardial ischemia and AMI. Lidocaine, procainamide, and amiodarone are the drugs of choice for the treatment of ventricular arrhythmias in the peri-infarction period. The routine use of prophylactic lidocaine or other antiarrhythmic agents to prevent ventricular tachycardia and ventricular fibrillation is not recommended. Although the routine use of lidocaine may reduce the number of episodes of ventricular fibrillation, it may contribute to an increased number of episodes of asystole (see Chapter 20).^{2,3}

Suppression of ventricular ectopy following an AMI with the chronic use of oral antiarrhythmic agents is not recommended. Results of Cardiac Arrhythmia Suppression Trial (CAST)-I and CAST-II demonstrated an increase in mortality in asymptomatic patients with ventricular ectopy following an AMI who were treated with flecainide, encainide, or moricizine.^{2,3}

Stool Softeners

It is common to administer agents such as docusate to prevent constipation in AMI patients because straining causes undesirable stress on the cardiovascular system. Table 17-5 summarizes the common adjunctive therapy used in patients with AMI.

Nondrug Therapy

PCI is an attractive alternative to thrombolytic therapy. PCI consists of the insertion of a guidewire through a catheter into the occluded coronary vessel. Using fluoroscopy, the wire is directed and manipulated across the stenosis. A balloon angioplasty catheter is then progressed across the guidewire to the stenosis and inflated, which mechanically compresses the plaque in the vessel to increase lumen size. However, when balloon angioplasty alone is employed, reocclusion (9%–20%), reintervention (10%–20%), and restenosis (31%–45%) of the affected coronary artery occur. To correct these problems, a bare metal or drug-eluting stent may be placed in the coronary lumen (Fig. 17-4).²² Specific guidelines have been published by the ACC/AHA addressing PCI and stent use in AMI.²³

PCI is preferred only if a skilled interventional cardiologist and catheterization laboratory are available, if the procedure can be performed within 90 minutes after initial medical contact, and/or a contraindication for a thrombolytic exists.²³ Thrombolytic therapy is preferred for patients whose first medical contact occurs less than 3 hours after symptom onset but for whom PCI is not immediately available, those who seek medical attention less than 1 hour after onset of symptoms, and those with a history of anaphylaxis to radiographic contrast material.

The disadvantages of PCI include the longer amount of time needed to mobilize the personnel needed to prepare the catheterization laboratory and its initial higher cost. A potential advantage of PCI is the greater ability to achieve TIMI grade 3 flow in the affected vessel (90% vs. 50%–60%, respectively).²² Pooled data from major trials comparing PCI to thrombolysis have found PCI to be associated with fewer major adverse cardiac events, irrespective of patient presentation time.

Table 17-5 Adjunctive Therapy for Acute Myocardial Infarction

| Drug | Indication | Dose and Duration | Therapeutic End Points | Precautions | Comments |
|------------------------------------|---|--|--|---|--|
| ACE inhibitors ^a | AMI with EF <40% | Usual captopril dose 12–50 mg TID; then start longer-acting ACE inhibitor. Duration indefinite. | Titrate to usual doses and maintain systolic BP >90–110 mmHg | Avoid IV therapy within 48 hr of infarct | Oral therapy in patients with EF <40%. |
| Aldosterone antagonists | AMI with EF <40% with symptomatic HF or DM currently receiving ACE inhibitors | Spirolactone 12.5–50 mg daily or eplerenone 25–50 mg daily. | Titrate to heart failure symptom control without evidence of hyperkalemia | Hyperkalemia | Avoid if potassium ≥ 5 mEq/L or Scr ≥ 2.5 mg/dL for men and 2.0 mg/dL for women. Dose can be increased every 4–8 weeks. |
| Aspirin ^a | AMI and ischemic heart disease | 160–325 mg during AMI, then 75–325 mg/day for an indefinite period. | No firm end point | Active bleeding, thrombocytopenia | Unless clear contraindication exists, aspirin should be given to all AMI patients. |
| β -blockers ^a | General use in all AMI patients to reduce reinfarction and improve survival | Variable; titrate to HR and BP. Immediate IV therapy preferable. Duration indefinite. See Table 17–8 for specific dosing recommendations. | Titrate to resting HR approx. 60 beats/min, maintain systolic BP >100 mmHg | Usual β -blocker contraindications. Observe HR and BP closely when given IV | Unless clear contraindication exists, β_1 -selective agents such as metoprolol and atenolol should be given to all AMI patients. In patients with systolic dysfunction, metoprolol or carvedilol can be considered. |
| Calcium channel blockers | Postinfarction angina, non-Q-wave AMI | Usual doses of calcium channel blockers are used. Duration dictated by clinical scenario (see Chapter 17). | Titrate to usual doses and maintain systolic BP >90 mmHg | Usual calcium channel blocker contraindications. Avoid in patients with pulmonary congestion or EF <40% | a) In patients with good EF, most calcium channel blockers will exert beneficial effects. b) Some data support use of verapamil or diltiazem for non-Q-wave AMI, but not dihydropyridine types. |
| Clopidogrel ^a | For patients with aspirin allergy | 75 mg/day | No firm end point | Active bleeding, thrombotic thrombocytopenia purpura (rare) | |
| Clopidogrel + aspirin ^a | For STEMI, prior to thrombolytic therapy or PCI | 300 mg load 10–45 minutes before thrombolytic therapy, followed by 75 mg daily and continued to the day of angiography; aspirin 150–325 mg on first day, then 75–162 mg daily. | No firm end point | Active bleeding, thrombotic thrombocytopenia purpura (rare) | Whether administered before thrombolytic or PCI, clopidogrel + aspirin reduced CV death, MI, or ischemia at 30 days. The 600 mg load should be considered if a GIIb/IIIa is not used. Aspirin + clopidogrel should be continued for at least 1 month after placement of a BMS and at least 1 year for DES. |
| | For STEMI | 75 mg daily; aspirin 162 mg daily. | No firm end point | | Initial clopidogrel dose should be started within 24 hr of symptoms and continued until hospital discharge. |
| | For NSTEMI and unstable angina patients | 300 mg load, followed by 75 mg daily for 1–9 months; aspirin 75–325 mg daily. | No firm end point | Clopidogrel + aspirin reduced death, reinfarction, or stroke through index hospitalization | |

Table 17-5 Adjunctive Therapy for Acute Myocardial Infarction (Continued)

| Drug | Indication | Dose and Duration | Therapeutic End Points | Precautions | Comments |
|-----------------------|--|---|---|---|--|
| Factor Xa inhibitor | To replace UFH or LMWH in ACS and STEMI | STEMI Fondaparinux: 2.5 mg SQ daily for 8 days or discharge. | No firm end point | Active bleeding | In STEMI, fondaparinux reduced mortality and reinfarction without increased bleeds or strokes compared to UFH, but only in patients not undergoing PCI. In ACS, fondaparinux was at least as effective as enoxaparin but exhibited less bleeding. Can possibly be used in HIT. |
| | | ACS Fondaparinux: 2.5 mg SQ daily for 6 days. | No firm end point | | |
| Heparin ^a | Acute anticoagulation, patients undergoing reperfusion with t-PA | Variable; 60 U/kg loading at initiation of t-PA, then 12 U/kg/hr. Usual duration 24–48 hr. | aPTT ratio 1.5–2.5 patient's control value | Active bleeding, thrombocytopenia | Unless clear contraindication exists, UFH should be given to all AMI patients who do not receive thrombolytic therapy. |
| Lidocaine | Treatment of VT, VF | Variable, 1.5 mg/kg loading dose, then 14 mg/min. Use for <48 hr. | Cessation of arrhythmia | Bradycardia. Observe for CNS toxicity. | Some data indicate increased mortality with generalized use. |
| LMWH ^a | To replace UFH in STEMI and ACS | STEMI Enoxaparin: 30 mg IV bolus (optional), then 1 mg/kg SQ twice daily for 7–8 days Dalteparin: 100 U/kg SQ prior to thrombolytic, then 120 U/kg twice daily. ACS Enoxaparin: 1 mg SQ twice daily for 28 days. Dalteparin: 120 U/kg SQ twice daily for 6 days. | No firm end point | Active bleeding | In ACS, enoxaparin was superior to UFH for reducing mortality and ischemic events. In STEMI, compared to UFH, LMWHs may lower coronary reocclusion with variable effects on mortality. |
| Morphine | Treatment of severe chest pain; venodilator | 2–5 mg IV Q3–5 min PRN. | Decreased chest pain and HR | Bradycardia, right ventricular infarct | Good choice for acute pain relief along with NTG. |
| Nitrates ^a | General use in most AMI patients | Variable; titrate to pain relief or systolic BP. 5–10–200 mcg/min typical regimen. Usually maintain IV therapy for 24–48 hr after infarct. | Titrate to pain relief or systolic BP > 90 mmHg | Use cautiously in right ventricular infarct or large inferior infarct because of effects on preload | Use acetaminophen, NSAIDs, narcotics for headache. NTG should be tapered gradually in ischemic heart disease patients. |
| Warfarin | Left ventricular thrombus | Variable; titrate to INR. Duration usually for several months. | INR 2–3 patient's control value | Usual warfarin problems such as noncompliance, bleeding, diatheses | May be useful in the presence of a left ventricular thrombus to prevent embolism. |

^aIndicates specific drug therapies that are known to reduce morbidity and/or mortality.

ACE, angiotensin-converting enzyme; ACS, acute coronary syndrome; AMI, acute myocardial infarction; aPTT, activated partial thromboplastin time; BMS, bare metal stent; BP, blood pressure; CNS, central nervous system; CV, cardiovascular; DES, drug-eluting stent; DM, diabetes mellitus; EF, ejection fraction; GIIb/IIIa, glycoprotein 2b3a inhibitor; HF, heart failure; HIT, heparin-induced thrombocytopenia; HR, heart rate; INR, international normalized ratio; IV, intravenously; LMWH, low-molecular-weight heparin; NSAIDs, nonsteroidal anti-inflammatory drugs; NSTEMI, non-ST segment elevation myocardial infarction; NTG, nitroglycerin; PCI, percutaneous coronary intervention; PRN, as needed; Q, every; Scr, serum creatinine; SQ, subcutaneously; STEMI, ST segment elevation myocardial infarction; TID, three times a day; t-PA, tissue plasminogen activator; UFH, unfractionated heparin; VF, ventricular fibrillation; VT, ventricular tachycardia.

Unfortunately, many hospitals do not have the facilities or skilled personnel to complete this procedure in the necessary time frame.²²

SIGNS AND SYMPTOMS OF ACUTE MYOCARDIAL INFARCTION

1. P.H., a 65-year-old, 80-kg man, is being admitted to the emergency department (ED) after experiencing an episode of sustained chest pain while mowing his yard. After waiting 5 hours, he called 911 and was transported to the ED. Physical examination reveals a diaphoretic man who appears ashen. Heart rate and rhythm are regular and no S_3 or S_4 sounds are present. Vital signs include BP 180/110 mmHg, heart rate 105 beats/minute, and respiratory rate 32 breaths/minute. P.H.'s chest pain radiates to his left arm and jaw, and he describes the pain as "crushing" and "like an elephant sitting on my chest." He rates it as a "10/10" in

intensity. Thus far, his pain has not responded to five sublingual (SL) NTG tablets at home and three more in the ambulance. His ECG reveals a 3-mm ST segment elevation and Q waves in leads I and V_2 to V_4 . Based on this, P.H. is diagnosed with an anterior infarction. Laboratory values include sodium (Na), 141 mEq/L (normal, 135–145); potassium (K), 3.9 mEq/L (normal, 3.5–5); chloride (Cl), 100 mEq/L (normal, 100–108); CO_2 , 20 mEq/L (normal, 24–30); blood urea nitrogen (BUN), 19 mg/dL (normal, 8–25); serum creatinine (SrCr), 1.2 mg/dL (normal, 0.6–1.5); glucose, 149 mg/dL (normal, 70–110); magnesium (Mg), 1.3 mEq/L (normal, 1.5–2); CK, 1,200 U/L (normal, 60–370), with a 12% CK-MB fraction (normal, 0%–5%); troponin-I, 60 ng/mL (normal, <2); cholesterol, 259 mg/dL (normal, <200); and triglycerides, 300 mg/dL (normal, 40–150). P.H. has a prior history of coronary artery disease (CAD). A previous cardiac catheterization 2 years ago revealed a lesion in his middle left anterior descending coronary artery (75% stenosis) and in the proximal left circumflex artery (30% stenosis). His ventriculogram at the time showed an EF of 58%. These lesions were deemed suitable for medical

management. He also has a history of recurrent bouts of bronchitis with bronchospastic disease for 10 years, diabetes mellitus treated with insulin for 18 years with fair control, and mild hypertension with fair control for 20 years. His father died of an MI at age 70. His mother and siblings are all alive and well. P.H. has smoked one pack of cigarettes a day for 30 years, and he drinks approximately one six-pack of beer a week. He has no history of IV drug use. On admission, P.H.'s medications include insulin glargine 40 U daily; albuterol inhaler, PRN; hydrochlorothiazide, 25 mg daily; NTG patch, 0.2 mg/hour; and NTG SL, 0.4 mg PRN chest pain. What signs and symptoms does P.H. have that are consistent with the diagnosis of AMI?

[SI units: Na, 141 mmol/L (normal, 135–145); K, 3.9 mmol/L (normal, 3.5–5.0); Cl, 100 mmol/L (normal, 100–108); CO₂, 20 mmol/L (normal, 24–30); BUN, 6.8 mmol/L (normal, 2.9–8.9); SrCr, 72 mmol/L (normal, 36–90); glucose, 8.3 mmol/L (normal, 3.9–6.1); Mg, 0.65 mmol/L (normal, 0.75–1.0); CK, 20 and 33.34 kat/L, respectively (normal, 1.0–6.7); cholesterol, 6.7 mmol/L (normal, <5.2); triglycerides, 3.9 mmol/L (normal, 0.45–1.7)]

P.H. described his pain as a pressure sensation, which is common with ischemic heart disease. The chest discomfort associated with AMI is described more often as pressure or as a tight band around the chest rather than pain. Although P.H. was involved in physical exertion when his chest pain began, this is not always the case. It can begin at rest and, frequently, in the early morning hours. At least 20% of patients with AMI have no pain or discomfort; these are described as having “silent” MIs. Presentations range from asymptomatic to shortness of breath, hypotension, heart failure, syncope, or ventricular arrhythmias. Silent or atypical infarctions occur more commonly in people with diabetes or hypertension and in the elderly. P.H. is diaphoretic, a common finding, but other common symptoms such as nausea and anxiety are not present. He also describes his pain as “10/10” in intensity, or perhaps “the worst pain I’ve ever experienced,” which is typical of an AMI. The typical patient with an uncomplicated AMI has few useful physical findings. The diagnosis primarily lies in the symptoms, the ECG, and the laboratory findings.

The history of diabetes, hypertension, smoking, and a positive family history in P.H. are all risk factors for coronary disease. His admission BP is high, which could indicate poor underlying control or anxiety and stress related to his AMI. The blood sugar of 140 mg/dL is high, again indicating either poor control or a stress response. Measurement of glycosylated hemoglobin is indicated during his hospitalization to better assess his diabetes control.^{2,3}

Laboratory Abnormalities

2. What laboratory abnormalities can you expect to see in P.H.?

P.H. demonstrates several laboratory abnormalities commonly seen in AMI. His CK was high on admission and the CK-MB of 12% (normal, <5%) is indicative of myocardial necrosis. CK-MB rises acutely over the first 12 to 24 hours and returns to normal in 2 to 3 days. The troponin level is also increased, which is consistent with myocardial necrosis. Several other nonspecific laboratory findings should be monitored in P.H. Hyperglycemia may develop because P.H. is a diabetic, but this can also occur in nondiabetic patients. Total cholesterol and HDL cholesterol concentrations may fall

dramatically within a few days following an AMI; therefore, it is best to check serum lipid profiles within 24 to 48 hours. Leukocytosis and an increase in the erythrocyte sedimentation rate may also be observed with AMI.^{2,3}

ST Segment Elevation Myocardial Infarction versus Non-ST Segment Elevation Myocardial Infarction

3. P.H. was noted to have “ST segment elevation and Q waves” on the ECG. What are the implications of a ST segment elevation versus non-ST segment elevation MI?

Perhaps the most important diagnostic test in someone who is suspected to have an AMI is the ECG. The ECG is an important tool because it is noninvasive, can be performed rapidly, is readily available in most clinical settings, and adds valuable clues as to where the AMI is located (i.e., anterior, inferior, lateral) (Fig. 17-4). It is valuable in determining whether a thrombolytic should be administered. Although enzyme profiles are helpful, the results are often not available for hours, or the patient may present to the hospital before the cardiac enzymes are present in the serum. Therefore, enzymes allow one to confirm “retrospectively” the presence of an AMI, but do not necessarily influence the immediate therapeutic course for the patient. P.H. has classic ECG changes such as ST segment elevation and Q waves. Their presence in the anterior ECG leads (V₂–V₄) indicates which part of the heart is affected and also points to the coronary arteries that are likely to be blocked. P.H.'s previous left anterior descending lesion may have had a plaque rupture leading to thrombosis of the vessel.

The presence of ST segment elevation in two contiguous leads indicates severe ischemia and occlusion of the coronary artery. Every effort should be made to open the infarct-related artery as soon as possible. If the ECG showed ST segment depression instead of elevation, P.H. would not be eligible for thrombolytic therapy.

Anterior versus Inferior Infarction

4. What are the prognostic implications of an anterior versus an inferior MI?

Damage to the anterior section of the heart is more likely to be associated with increased morbidity (e.g., left ventricular dysfunction) and mortality. The patients at highest risk of death are those with an anterior AMI, left ventricular dysfunction, and complex ventricular ectopy.¹⁰ P.H. is at an increased risk because he has sustained an anterior AMI.

Risk Stratification

5. What is P.H.'s initial risk of mortality based on his presenting signs and symptoms?

Much of the information used to stratify patients is based on their physical findings, test results, and past medical history. Risk stratification should be conducted on initial diagnosis and repeated or modified as needed based on an initial response to therapy and results of laboratory findings.

The first risk stratification method was introduced in 1967 by Killip et al. and found to be a useful, easy tool for early risk stratification for patients with STEMI.^{24,25} Higher Killip class was found to be associated with increased in-hospital and 1-year mortality (Table 17-6). The TIMI risk score was introduced in 2000 and can be used with either STEMI or NSTEMI.^{26,27} For STEMI, the higher the risk score, the greater the 30-day mortality rate. In the case of NSTEMI, the higher the risk score, the greater the 14-day risk of death or MI. Table 17-6 describes the various risk factors and corresponding percentage risks.

P.H. has a TIMI risk score of 7 based on his age (2 points); history of angina, hypertension, and diabetes (1 point); heart rate (2 points); location of his MI (1 point); and time to reperfusion therapy (1 point). P.H. has a 30-day mortality rate of 23%, thereby highlighting the serious nature of his heart disease and the importance of adherence to medications.

TREATMENT

Therapeutic Objectives

6. What are the immediate and long-term therapeutic objectives in treating P.H.?

The immediate therapeutic objectives in treating P.H. are to minimize the amount of myocardial necrosis that develops, to alleviate his symptoms, and to prevent his death. These objectives are achieved primarily by restoring coronary blood flow (administering a thrombolytic and/or performing a PCI) and lowering myocardial oxygen demand. Any life-threatening ventricular arrhythmias that develop must be treated. The long-term therapeutic objectives are to prevent or minimize recurrent ischemic symptoms, reinfarction, heart failure, and sudden cardiac death. The specific therapeutic regimens are discussed in the questions that follow.

Thrombolytic Therapy

7. Is P.H. a candidate for thrombolytic therapy? Is any one agent preferred?

AMI is a medical emergency and rapid administration of drug therapy is crucial to save myocardial tissue. The results of several major trials have shown unequivocally that if used appropriately, thrombolytics can reduce the mortality associated with an AMI.^{2,3} Because mortality benefit is greatest when thrombolytic therapy is administered within 2 hours of symptom onset, many institutions are employing early prehospital thrombolytic therapy, in which trained paramedics administer the thrombolytic in the field.¹⁶

Controversy still exists over which thrombolytic should be used, the best dosing regimen, the most appropriate adjunctive therapy, and whether the risk outweighs the benefit in some subpopulations of patients (e.g., those with an inferior AMI). Each issue is discussed in subsequent cases.

P.H. has a history of hypertension, and at presentation, his BP is 180/110 mmHg. A BP this high is a relative contraindication to thrombolytic therapy because of an increased risk of cerebral hemorrhage; however, P.H. has an anterior MI and is likely to benefit from thrombolytic therapy. In this case, he should receive IV NTG immediately because the onset of blood

Table 17-6 Risk Stratifications Tools for Acute Myocardial Infarction

| TIMI Risk Score ^a | | | |
|---|--|---|---------------|
| STEMI | | NSTEMI | |
| Risk Factor | No. of Points | Risk Factor | No. of Points |
| Age 65–75 yr | 2 | Age ≥65 yr | 1 |
| Age ≥75 yr | 3 | ≥3 risk factors for CAD ^b | 1 |
| SBP <100 mmHg | 3 | Prior history of CAD ^c | 1 |
| Heart rate >100 beats/min | 2 | Aspirin use in past 7 days | 1 |
| Killip class II–IV | 2 | ≥2 anginal events in past 24 hr | 1 |
| Weight <67 kg | 1 | ST segment deviation ≥0.5 mm | 1 |
| History of HTN, diabetes, or angina | 1 | Elevation of cardiac markers ^d | 1 |
| Time to reperfusion therapy >4 hr | 1 | | |
| Anterior ST segment elevation or left bundle branch block | 1 | | |
| Killip Class^e | | | |
| Class | Symptoms | In-Hospital and 1-yr Mortality (%) | |
| I | No heart failure | 5 | |
| II | Mild heart failure, rales, S ₃ , congestion on chest radiograph | 21 | |
| III | Pulmonary edema | 35 | |
| IV | Cardiogenic shock | 67 | |

^aTIMI risk score data from refs. 26 and 27. A risk score is calculated by adding the total number of risk factors. Total points for STEMI are 0–14, in which risk scores of 0, 2, 4, 6, 7, and >8 correspond to a 30-day mortality rate of 0.8%, 2.2%, 7.3%, 16%, 23%, and 36%, respectively. Total points for NSTEMI are 0–7, in which scores of 0 or 1, 3, 5, and 7 correspond to a 3%, 5%, 12%, or 19% risk of death or repeat MI at 14 days, respectively.

^bRisk factors include smoking, diabetes, hypertension, family history of coronary artery disease, and hypercholesterolemia.

^cDefined as a prior coronary stenosis ≥50%; history of previous MI, percutaneous coronary intervention, or coronary artery bypass graft; or chronic stable angina pectoris associated with a positive exercise tolerance test or pharmacologically induced nuclear imaging or echocardiographic changes (positive nuclear imaging or echocardiographic changes required if female).

^dEither troponin I or T or CK-MB.

^eKillip class data from reference 25.

CAD, coronary artery disease; HTN, hypertension; NSTEMI, non-ST segment elevation myocardial infarction; SBP, systolic blood pressure; STEMI, ST segment elevation myocardial infarction; TIMI, thrombolysis in myocardial infarction.

pressure control with this agent usually occurs within minutes. Once his systolic BP is <180 mmHg and the diastolic is <110 mmHg, a thrombolytic can be administered. The NTG will also reduce the workload on his heart and may provide pain relief.

Because P.H. has severe pain and ECG changes consistent with an anterior AMI, he is at great risk for substantial

morbidity and/or mortality. Alteplase is more rapid acting and effective in restoring TIMI grade 3 blood flow than streptokinase; however, the slightly increased risk of stroke and the increase in cost with t-PA may outweigh its advantages. The argument for or against a specific thrombolytic is probably less important than the decision to use an agent and to administer the medication as soon as possible after the onset of symptoms. P.H. is fortunate because he has presented within 5 to 6 hours of the onset of chest pain.

Dosage Regimens

8. “Alteplase 100 mg infused over 90 minutes” is ordered for P.H. Is this an appropriate dosage? If streptokinase, anistreplase, reteplase, or tenecteplase had been ordered, what would be an appropriate regimen?

To enhance reperfusion while minimizing bleeding complications, accelerated dosage regimens of t-PA are recommended. The recommended regimen is a 15 mg bolus followed by a 50 mg infusion over 30 minutes and then the remaining 35 mg over 60 minutes. The Global Utilization of Streptokinase and t-PA for Occluded Arteries (GUSTO) trial used this accelerated or front-loaded regimen for administration of t-PA. In this trial, t-PA was compared to streptokinase and a combination of streptokinase and t-PA. The results showed that t-PA alone was the most effective in reducing mortality. The 30-day mortality rate for the accelerated t-PA group was 6.3% compared to 7.3% in the streptokinase group. In GUSTO, the t-PA regimen was also weight adjusted, such that after the 15 mg bolus dose, the infusion was 0.75 mg/kg over 30 minutes followed by 0.5 mg/kg over 60 minutes. The maximum dose received was 100 mg.

Most of the large trials with streptokinase have used an IV infusion of 1.5 MU administered over 60 minutes. There have been some trials in which the infusion was shortened to 30 minutes; however, there have been no large studies that have compared a 30-minute infusion to a 60-minute infusion.

Anistreplase is usually given intravenously as 30 U over 2 to 5 minutes. This convenient dosing schedule is the major advantage of this agent. As mentioned previously, it has been suggested that prehospital administration of anistreplase by emergency services personnel would reduce the amount of time from the onset of chest pain to the administration of this life-saving drug.

Reteplase was compared to t-PA in the GUSTO-III trial. Reteplase has a slower clearance from the body, allowing the drug to be given as a bolus without the need for a constant infusion. In the GUSTO-III trial, reteplase was administered in two bolus doses of 10 MU, given 30 minutes apart. The mortality rate and incidence of stroke were the same in the two groups of patients.

TNK was compared to t-PA in the Second Assessment of Safety and Efficacy of a New Thrombolytic (ASSENT-2) trial. TNK was administered as a bolus of 30 to 50 mg over 5 to 10 seconds, based on body weight (Table 17-3). No difference existed between TNK and t-PA in 30-day mortality and stroke.

Many institutions have streptokinase in addition to one of the more expensive, fibrin-selective agents (t-PA, reteplase, or TNK) on their formulary. Choice of the later is based on contract pricing, ease of administration, and simplicity of dosing regimen. From GUSTO and GUSTO III, t-PA and reteplase

are effective therapies for achieving early coronary reperfusion, providing an advantage over streptokinase. The 2004 ACC/AHA guidelines recommend t-PA or reteplase for patients who present early after onset of chest pain and in those with a large area of injury (e.g., anterior infarction) who have a low risk for an intracranial bleed. However, based on the ASSENT-2 trial, TNK appears to be just as effective as t-PA with fewer bleeding complications. Compared to t-PA, both TNK and reteplase can be administered as bolus doses.^{2,3}

Once P.H.'s BP is controlled, he should receive a thrombolytic as quickly as possible. Because he appears to be having a large anterior infarction, the added cost of t-PA, r-PA, or TNK versus streptokinase may be justified. Table 17-7 summarizes the major thrombolytic trials. With regard to medication safety, the thrombolytic dose should always be carefully checked because over- and underdosing of thrombolytics has been associated with higher 30-day mortality.^{2,3,28}

Adjunct Therapy

9. Orders are written for UFH 5,000 U IV bolus, followed by 1,000 U/hour by continuous infusion. Also prescribed is aspirin 325 mg STAT. Are both agents necessary?

The Second International Study of Infarct Survival (ISIS-2) trial showed that aspirin 160 mg/day alone and in combination with streptokinase reduced mortality in patients with AMI by 23% and 42%, respectively, when compared to a control group of patients who received neither aspirin nor streptokinase. In doses of 160 mg or more, aspirin generates a prompt clinical antithrombotic effect as a result of its inhibition of thromboxane A₂ production. Thus, immediate administration of 160 to 325 mg of aspirin in patients diagnosed with AMI, regardless of whether they receive thrombolytics, is indicated. In the acute setting, aspirin should be chewed because it is absorbed more quickly. All patients should receive 75 to 325 mg of daily aspirin indefinitely following AMI. If patients have a contraindication to aspirin, clopidogrel can be substituted.^{2,3}

The use of UFH as adjunct therapy to prevent reocclusion has been evaluated in many studies (Table 17-7). Overall, it appears that UFH administration offers no benefit to patients receiving streptokinase or anistreplase.^{2,3} However, because P.H. will receive t-PA, due to his anterior wall infarct, an IV UFH bolus followed by a continuous infusion should be started before the end of the t-PA infusion. The 2004 ACC/AHA guidelines recommend a 60 U/kg bolus of UFH at the initiation of t-PA, followed by a maintenance infusion of 12 U/kg/hour or a maximum of a 4,000 U bolus, followed by 1,000 U/hour. The target activated partial thromboplastin time should be 1.5 to 2.0 × control (generally 50–75 seconds). UFH should always be considered in patients at high risk for systemic or venous embolism.

10. Would P.H. benefit from the addition of clopidogrel to his current drug regimen?

Recent studies have defined the potential role of in-hospital clopidogrel as an integral part of reperfusion therapy in patients with STEMI. Although the data with clopidogrel are quite promising, the risk and cost of chronic therapy of the drug must be weighed against its benefits.

The Clopidogrel as Adjunctive Reperfusion Therapy-Thrombolysis in Myocardial Infarction 28 (CLARITY-TIMI

Table 17-7 Summary of Major Thrombolytic Trials

| <i>Trial</i> | <i>Thrombolytics</i> | <i>Heparin, Aspirin, LMWH</i> | <i>Number of Patients</i> | <i>Duration of Symptoms</i> | <i>Results</i> |
|--------------------------|---|---|------------------------------|-----------------------------|---|
| ISIS-2 1988 | Streptokinase 1.5 MU over 1 hr vs. placebo | Also randomized to aspirin 160 mg/day or no aspirin. Heparin not specified. | 17,187 | <24 hr | Streptokinase, aspirin, streptokinase + aspirin all reduced mortality compared to placebo. Most benefit from streptokinase + aspirin. Aspirin alone and in combination with streptokinase reduces mortality. Some benefit from aspirin and/or streptokinase even administered late. |
| ISG 1990 | t-PA 100 mg over 3 hr vs. streptokinase 1.5 MU over 1 hr | Also randomized to heparin SQ or no heparin. All patients received aspirin and atenolol unless contraindicated. | 20,891 | <6 hr | No significant difference in hospital mortality between streptokinase and t-PA. More episodes of major bleeding with streptokinase and more strokes with t-PA. Results questioned due to the use of SQ heparin. |
| ISIS-3 1992 | t-PA (alteplase) 0.6 MU over 4 hr vs. streptokinase 1.5 MU over 1 hr vs. APSAC 30 U over 3 min | Also randomized to SQ heparin or no heparin. All patients received aspirin 162 mg/day. | 41,299 | <24 hr | No significant difference in mortality between thrombolytics. More episodes of major bleeding with heparin and more strokes with t-PA. Results questioned due to the use of SQ heparin. |
| GUSTO 1993 | t-PA 1.25 mg/kg (100 mg) over 90 min vs. streptokinase 1.5 MU over 1 hr vs. t-PA 1 mg/kg + streptokinase 1 MU over 1 hr | Aspirin 160–325 mg/day to all patients. Heparin IV with t-PA groups. Heparin IV or SQ in streptokinase groups. | 41,021 | <6 hr | Statistically significant decrease in 30-day mortality in the t-PA group (6.3%) vs. streptokinase (7.3%). More strokes in t-PA groups. |
| GUSTO-III 1997 | t-PA 100 mg over 90 min vs. r-PA 10 + 10 U | Aspirin 160 mg immediately, then daily. Heparin 5,000 U bolus, 1,000 U/hr. | 15,059 No upper age limit | <6 hr | Mortality rate at 30 days was 7.47% in r-PA vs. 7.24% in t-PA ($p = \text{NS}$). Stroke occurred in 1.64% of r-PA patients vs. 1.79% of t-PA patients ($p = \text{NS}$). |
| ASSENT-2 1999 | TNK 30–50 mg over 5–10 sec vs. t-PA 1.25 mg/kg over 90 min | Aspirin 150–325 mg and heparin 4,000 U bolus, 800 U/hr for patients 67 kg or 5,000 U bolus, 1,000 U/hr >67 kg. | 16,949 | <6 hr | No significant difference in 30-day mortality, death or nonfatal stroke, or intracranial bleeding between thrombolytics. TNK had significantly fewer bleeding complications. |
| GUSTO-V 2001, 2002 | r-PA two 10 U boluses vs. r-PA two 5 U boluses + abciximab 0.25 mg/kg bolus, 0.125 mcg/kg/min for 12 hr | Aspirin 150–325 mg orally or 250–500 mg IV immediately, then 75–325 mg daily. For r-PA alone: heparin 5,000 U bolus, 1,000 U/hr. (≥ 80 kg) or 800 U bolus, 800 U/hr. (< 80 kg). For combination therapy, heparin 60 U/kg bolus, 7 U/kg/hr. | 16,588 | <6 hr | No significant difference between groups in all-cause mortality at 30 days and 1 year, confirmed cerebrovascular events, or nonfatal disabling strokes. Combination therapy had a statistically significant higher rate of bleeding complications ($p < 0.0001$). |
| ASSENT-3 2001 | TNK 30–50 mg over 5 sec vs. TNK 15–25 mg over 5 sec + abciximab 0.25 mg/kg bolus, 0.125 mcg/kg/min for 12 hr | Aspirin 150–325 mg orally. For full-dose TNK, patients were randomized to either enoxaparin 30 mg bolus, 1 mg/kg Q 12 hr 7 days or IV heparin 60 U bolus, 12 U/kg/hr 48 hr. For combination therapy, 40 U bolus, 7 U/kg/hr. | 6,095 | <6 hr | For the composite end point of 30-day mortality, reinfarction, or refractory ischemia, event rates were 6.1% for full-dose TNK + enoxaparin, 5.2% for half-dose TNK + abciximab, 8.8% for full-dose TNK + heparin ($p < 0.0001$). No significant difference in 30-day mortality between groups. More major bleeding ($p = 0.0002$) and transfusions ($p = 0.001$) in the abciximab group compared to heparin. |
| ASSENT-4 2006 | Standard PCI vs. pretreatment with TNK 30–50 mg over 5 sec, 1–3 hr before PCI | Aspirin 150–325 mg orally and single heparin bolus (70 U/kg for PCI group, 60 U/kg for TNK group). | 1,667 | <6 hr | Study terminated early due to increased in-hospital mortality in the TNK group (6%) compared to standard PCI (3%) ($p = 0.0105$). Patients receiving TNK had more strokes ($p < 0.0001$) and 90-day reinfarction ($p = 0.0279$) and repeat revascularizations ($p = 0.0041$). |

APSAC, anisoylated plasminogen streptokinase activator complex; IV, intravenously; LMWH, low-molecular-weight heparin; NS, nonsignificant; TNK, tenecteplase; PCI, percutaneous coronary intervention; r-PA, reteplase; SQ, subcutaneously; t-PA, tissue plasminogen activator.

From reference 2, 3, and 28.

28) evaluated 3,497 patients (18–75 years of age) with STEMI who received standard thrombolytic therapy, aspirin, and UFH, and were scheduled for angiography within 2 days. Patients received either clopidogrel (300 mg loading dose, followed by 75 mg daily) or placebo within 10 minutes of thrombolytic administration. Clopidogrel was continued up to and including the day of angiography and stopped. The primary end point was the composite of an occluded infarct-related artery on predischARGE angiography or death or an MI up to the start of coronary angiography. Compared to placebo, patients in the clopidogrel group demonstrated a 36% reduction in the primary end point ($p < 0.001$). By 30 days, the clopidogrel treatment group had a 20% reduction in cardiovascular death, recurrent MI, or recurrent ischemia ($p = 0.03$). No difference in the rate of major bleeding was seen between groups.²⁹

Similar results were seen in the Adjunctive Reperfusion Therapy (PCI-CLARITY) study in which STEMI patients scheduled for PCI received pretreatment with either placebo or clopidogrel (300–600 mg load, then 75 mg daily) up to and including the day of angiography.³⁰ Those receiving clopidogrel had a 38% reduction in the MI or stroke prior to PCI ($p = 0.028$), as well as a 46% reduction in the incidence of cardiovascular death, MI, or stroke 30 days following the procedure ($p = 0.008$). No difference in the rate of major bleeding was seen between groups.

Finally, the Clopidogrel and Metoprolol in Myocardial Infarction Trial (COMMIT) evaluated the effect of administering either clopidogrel 75 mg daily with no loading dose or placebo in 45,852 patients presenting with STEMI.³¹ The initial clopidogrel dose was given within 24 hours of symptom onset and continued until hospital discharge or up to 4 weeks in the hospital. Compared to placebo, the allocation to clopidogrel was associated with a 9% reduction in death, reinfarction, or stroke ($p = 0.002$) and a 7% reduction in all-cause mortality ($p = 0.03$). No significant excess in bleeding was noted in the treatment group or in those who received concomitant thrombolytic therapy or who were younger than 70 years.

Based on the data from COMMIT, P.H. could safely receive clopidogrel 75 mg daily as an inpatient. However, long-term clopidogrel use in patients with STEMI remains questionable, unless the patient receives a stent. As discussed later in the chapter, most of the data with maintenance clopidogrel use are documented in patients with acute coronary syndromes (NSTEMI-ACS) and PCI.

11. Would P.H. benefit from a LMWH, factor Xa inhibitor, or a GP IIb/IIIa inhibitor added to his thrombolytic regimen?

The replacement of UFH with a LMWH, factor Xa inhibitor, or the addition of an antiplatelet agent such as a GP IIb/IIIa inhibitor to thrombolytic therapy has been evaluated in patients with STEMI.

In the Enoxaparin and Thrombolysis Reperfusion for Acute Myocardial Infarction Study-25 (ExTRACT-TIMI 25), 20,506 patients with STEMI scheduled for thrombolytic therapy were randomized to receive either enoxaparin throughout the index hospitalization or continuous infusion UFH for 48 hours.³² Enoxaparin was dosed according to age and renal function. For patients younger than 75 years, enoxaparin was dosed as a fixed 30 mg bolus followed 15 minutes later by 1 mg/kg subcutaneously (SQ) twice daily. For patients older than 75 years, the

bolus was eliminated, and the dose reduced to 0.75 mg/kg SQ twice daily. If the creatinine clearance was < 30 mL/minute, the dose was modified to 1.0 mg/kg SQ daily. UFH was dosed according to weight (60 U/kg bolus, followed by 12 U/kg/hour) and adjusted to achieve an aPTT 1.5 to 2.0 \times control. The composite end point of death or nonfatal MI through 30 days occurred in 12.0% in the UFH group and 9.9% in the enoxaparin group, representing a 17% risk reduction ($p < 0.001$). Although no difference was noted in mortality between the two groups, treatment with enoxaparin did reduce the 30-day risk of nonfatal reoccurrence of AMI by 33% compared to UFH ($p < 0.001$). However, major bleeding was higher in the enoxaparin group compared to those receiving UFH (2.1% vs. 1.4%, respectively, $p < 0.001$).^{2,3}

The TIMI-14 trial demonstrated enhanced reperfusion (TIMI 3 flow) using reduced-dose t-PA combined with abciximab (0.25 mg/kg bolus, then 12-hour infusion of 0.125 mcg/kg/minute) compared to full-dose t-PA alone. This improvement occurred without an increase in the risk of major bleeding.³³ Similar rates of enhanced reperfusion have also been observed with the combination of double-bolus dose eptifibatidE (180/90 mcg/kg, 10 minutes apart) with a 48-hour infusion (1.33 mcg/kg/minute) plus half-dose t-PA (50 mg).^{2,3}

In the GUSTO-V trial, 16,588 patients with STEMI were randomized to standard-dose reteplase or half-dose reteplase plus full-dose abciximab. There was no difference in death rates between the groups at 30 days or 1 year. The combination group had less reinfarction and recurrent ischemia, but this benefit was offset by more episodes of moderate and severe bleeding, especially in the elderly.^{2,3}

The ASSENT-3 trial randomized 6,095 AMI patients to full-dose TNK + enoxaparin, half-dose TNK + UFH, and a 12-hour infusion of abciximab, or full-dose TNK + UFH. The addition of either abciximab or enoxaparin to TNK reduced the composite end point of 30-day mortality, in-hospital reinfarction, or ischemia compared to UFH. More major bleeding complications were seen with abciximab compared to UFH.^{2,3}

The Enoxaparin as Adjunctive Antithrombin Therapy for ST-Elevation Myocardial Infarction (ENTIRE-TIMI 23) trial evaluated the use of a thrombolytic in combination with a GP IIb/IIIa inhibitor and either UFH or LMWH. In this trial, 483 AMI patients were randomized to full-dose TNK or half-dose TNK + abciximab. Each group was then randomized to receive either UFH or enoxaparin. Patients receiving full-dose TNK plus enoxaparin exhibited lower 30-day mortality/recurrent MI rates compared to those receiving TNK + UFH. Rates of major bleeding were highest with the TNK, abciximab, and enoxaparin combination.^{2,3}

The Organization for the Assessment of Strategies for Ischemic Syndromes (OASIS) 6 was a complex, randomized double-blind trial of 12,092 patients with STEMI designed to assess the effect of early initiation of fondaparinux with primary PCI and medical therapy.³⁴ The study compared the effects of fondaparinux (2.5 mg/day for up to 8 days) with two different control arms: stratum 1, in which placebo was used if UFH was not indicated; and stratum 2, in which UFH was administered for up to 48 hours followed by placebo for up to 8 days. Each control group included a mix of the different treatment strategies, with essentially all primary PCI patients receiving UFH. Compared to the control group, those receiving fondaparinux had a significant reduction in the composite of

death or reinfarction at 30 days (11.2% vs. 9.7%, respectively, $p = 0.008$). Significant reductions in this end point were also observed at 9 days (7.4% for the fondaparinux group vs. 8.9% for the controls, $p = 0.003$), and at the end of the study (13.4% vs. 14.8%, $p = 0.008$). Specifically, in stratum 1, fondaparinux reduced the incidence of death or MI compared to the control group (11.2% vs. 14.0%, $p < 0.05$), but in stratum 2, demonstrated no difference in this end point when compared to UFH. Fondaparinux did not appear to offer benefit in patients who were managed with primary PCI. Although the rates of death, MI, and severe bleeds did not differ in these patients, there was a higher rate of catheter thrombosis with fondaparinux.

In a meta-analysis of 11 trials involving 27,115 STEMI patients who received adjunctive abciximab in addition to either PCI or thrombolytic therapy, use of abciximab was associated with a significant reduction in 30-day ($p = 0.047$) and 6- to 1-month mortality ($p = 0.01$) in patients undergoing PCI but not in those receiving thrombolytic therapy. Although both reperfusion strategies demonstrated a significant reduction in 30-day reinfarction ($p < 0.05$), only those patients receiving abciximab with a thrombolytic had an increased risk in major bleeding ($p < 0.001$).³⁵

For P.H., enoxaparin could be substituted for UFH based on the ExTRACT-TIMI 25 trial. However, P.H. will have a higher risk for bleeding and will need to be monitored closely. Because P.H. is not undergoing PCI, he may not benefit from the addition of a GP IIb/IIIa at this time. GP IIb/IIIa inhibitors are used primarily in NSTEMI and PCIs. If a GP IIb/IIIa inhibitor was to be used in conjunction with a thrombolytic agent for patients with STEMI, the dose of the thrombolytic agent is reduced by one-half.

Determination of Reperfusion

12. How can you monitor for successful reperfusion in P.H. after he has received thrombolytic therapy?

Performing coronary angiography following thrombolytic therapy will reveal whether the infarcted artery is open, how vigorous the blood flow is, and the extent of residual stenosis. There are several clinical indicators that correspond with reperfusion, one of which is the resolution of chest pain. Some investigators have found the development of “reperfusion arrhythmias” to be associated with infarct-related artery patency, but neither of these clinical markers is very reliable.

Two other methods used to estimate reperfusion are the ECG and laboratory changes. Because the extent of the reduction of ST segment elevation may be related to the extent of patency, 12-lead ECGs should be obtained frequently. ECGs have the advantage of being readily available and noninvasive.

Early peaking of total CK and the CK-MB isoenzyme levels may also differentiate patients who have achieved reperfusion from those in whom thrombolytic therapy has failed. Lewis et al. found an absolute rise in CK activity of 480 U/L or a relative rise of 34% within the first hour following successful thrombolysis. CK-MB activity was found to have a relative rise of 27% during the first hour. In the absence of reperfusion, CK activity was only increased by 15 U/L or had a relative rise of 3% over the first 2.5-hour period.^{2,3}

Some hospitals routinely evaluate regional wall motion using echocardiography. Unfortunately, it may take several days before improvement in wall motion is seen; therefore, it is

difficult to use this test to assess the initial success of thrombolysis.

It is important to determine whether thrombolysis has been successful because the prognosis of the patient appears to be related to the presence or absence of an open infarct-related artery. If thrombolytic therapy fails to open the infarct-related artery, then the patient may benefit from mechanical revascularization such as PCI or a coronary artery bypass graft (CABG) surgical procedure.^{2,3,22}

Overall, coronary angiography is expensive, and although rare, it does carry the risk of major bleeding, stroke, and renal dysfunction. To minimize expense and complications, P.H. should undergo a 12-lead ECG to evaluate reperfusion.

Time From Onset of Chest Pain

13. If P.H.’s arrival at the hospital had been delayed >6 hours from the onset of his chest pain, should he still have received a thrombolytic?

Although efforts should be directed toward administering a thrombolytic as early as possible, many patients present several hours after the onset of chest pain. There are several theoretical reasons why the late administration of a thrombolytic may be helpful. Some patients present with a “stuttering” MI, which is chest pain that waxes and wanes over a period of hours or days, presumably from recurrent or ongoing ischemia. These patients should be considered candidates for thrombolytic therapy or angiographic evaluation. The magnitude of left ventricular dilatation may be diminished by reperfusion of the infarct-related artery, even if it is late. Another potential advantage of opening an infarct-related artery, even hours after an MI, is that the opened artery could become a source of collateral blood flow in the future. The Gruppo Italiano per lo Studio della Streptochinasi nell’Infarto Miocardico (GISSI)-1 trial enrolled patients within 12 hours from the onset of chest pain. After 12 months of follow-up, the cumulative survival rate showed a statistically significant benefit from the administration of streptokinase compared to placebo. However, a subgroup analysis showed no benefit for the patients who received streptokinase after 6 hours from the onset of chest pain.^{2,3}

The ISIS-2 trial expanded patient enrollment to include patients admitted within 24 hours from the onset of chest pain. In that trial, there was a 17% reduction in vascular death at 5 weeks in the streptokinase group treated 5 to 24 hours from the onset of chest pain, compared to a 35% reduction in the group who received streptokinase within 4 hours from the onset of pain. Although the benefit was reduced, a statistically and clinically significant benefit was still present.^{2,3}

Overall, there appears to be a statistically significant benefit associated with administering a thrombolytic up to 12 hours from the onset of chest pain and a trend toward benefit when given between 13 and 24 hours. Late administration may be most beneficial in patients at the highest risk for mortality. This would include the elderly, patients with large infarctions, and those with continuing pain or hypotension.³⁶ P.H. still may benefit from thrombolytic therapy even if he presents beyond the 6-hour time frame. If he is still having symptoms, he probably has viable myocardium at risk that may be salvaged. Streptokinase is the most cost-effective drug and the thrombolytic that has been shown to be effective in this situation.

Readministration of Thrombolytic Agents

14. This is P.H.'s first infarction. If he had a history of a previous MI that was treated with a thrombolytic agent, would he still be eligible for thrombolysis?

The need to administer a thrombolytic for a second infarction is becoming common. Many patients who are admitted to a hospital with AMI have a history of a previous infarction. Both streptokinase and anistreplase are associated with the formation of neutralizing antibodies within several days following administration and up to 4 years with streptokinase. Unfortunately, the clinical significance of these antibodies on thrombolytic efficacy remains unknown. Based on observations made in ISIS-2, repeat doses of streptokinase were associated with allergic reactions (4.4% of individuals) consisting of shivering, pyrexia, or rashes, which were resistant to use of prophylactic corticosteroids.³⁷ If P.H. was presenting with a second infarction within a year and had received streptokinase for his first infarction, the thrombolytic of choice would be t-PA, TNK, or reteplase.

15. P.H. was stable initially following thrombolysis, but 48 hours later he experienced recurrent chest pain and ECG changes consistent with extension of his infarct. The attending cardiologist would like to readminister t-PA at this time. Is this a reasonable course of therapy?

Reocclusion of the infarct-related artery following initial successful thrombolysis is a major setback for this therapeutic strategy. If reocclusion occurs, mechanical intervention (e.g., PCI) is often attempted. Debate has existed between whether to readminister the thrombolytic or refer the patient for PCI.³⁸ In a meta-analysis of eight trials composed of 1,177 patients with STEMI who failed thrombolytic therapy, patients receiving rescue PCI showed no significant reduction in all-cause mortality, but had a 27% risk reduction in heart failure ($p = 0.05$) and 42% reduction in reinfarction ($p = 0.04$) when compared with conservative treatment. Repeat fibrinolytic therapy was not associated with significant improvements in all-cause mortality or reinfarction. Both treatment strategies demonstrated a significant increase in minor bleeding, but PCI was associated with an increase in stroke.³⁹

In the case of P.H., a repeat infusion with t-PA would probably be safe, but it may not be effective. As discussed in question 12, repeat doses of streptokinase should be avoided. If facilities for either PCI or surgery exist at the institution, many cardiologists would choose an invasive strategy at this time for P.H.

Use in the Elderly

16. B.T., an 85-year-old woman, presents to the ED with a history and examination that are nearly identical to P.H.'s. Should an elderly person (older than 70 years) be treated any differently with regard to thrombolytic therapy?

Some of the early trials with thrombolytic therapy excluded the elderly. Although the elderly may have a higher prevalence of relative contraindications such as severe hypertension or history of stroke at presentation, they also have a higher incidence of mortality following an AMI. The 30-day mortality rate following an AMI is 19.6% for patients between 75 and 85 years of age and 30.3% for those who are 85 years of age.⁴⁰

In a trial using streptokinase, a higher incidence of bleeding in patients older than age 70 was reported. However, in the ISIS-2 trial, the greatest reduction in mortality occurred in the elderly subgroup. There are no controlled trials in which thrombolytic therapy has increased mortality in the elderly. If B.T. had no contraindications to thrombolytic therapy, she should receive it. However, in a high-risk cohort of elderly female patients (older than 75 years, <67 kg), the ASSENT investigators demonstrated that, compared with bolus and infusion of t-PA, TNK was associated with lower rates of major bleeding (15.15% vs. 8.33%) and intracerebral hemorrhage (3.02% vs. 1.14%).^{2,3,36}

Strokes Associated With Thrombolysis

17. G.M., a 45-year-old man, presents with signs and symptoms consistent with an anterolateral AMI. On admission, he received t-PA (100 mg over 90 minutes). He developed nystagmus, blurred vision, dysarthria, and paresthesias in his right hand 18 hours after the infusion. How often are stroke symptoms observed in patients with AMI? Is there a difference in the risk of stroke among the various thrombolytic agents?

Stroke is a serious but infrequent complication of AMI. In the prethrombolytic era, thrombotic stroke occurred in 3.7% of AMI patients. In recent years, the number of ischemic strokes has diminished to <0.6%, with a 17% mortality rate.⁴¹ The risk factors identified for stroke associated with AMI include large, akinetic segments of myocardium and the presence of a left ventricular mural thrombus. Other comorbid conditions can also increase stroke risk such as atrial fibrillation, hypertension, diabetes, CABG, and previous stroke. An estimated one third of patients with anterior wall infarction who do not receive a thrombolytic will develop a mural thrombus, usually within the first week of the event.⁴¹ Echocardiograms are recommended before discharge in patients who have had an anterior wall infarction to rule out a mural thrombus.

The risk of stroke was analyzed from the GISSI-2 and International Study trials, where streptokinase was compared to t-PA with and without SQ UFH. Of the 20,768 patients who had complete records, 236 had a stroke while in the hospital. Thirty-one percent of the cases were intracerebral hemorrhage, 42% were ischemic stroke, and 26% were not classified. More hemorrhagic and ischemic strokes occurred in patients receiving t-PA (1.33% vs. 0.94% for streptokinase). Elderly patients (older than age 70) had a stroke rate of 2.6% with t-PA and 1.6% with streptokinase. Patients older than age 75 had a higher incidence of death and stroke compared to patients younger than 75 in the GUSTO trial. Patients older than 75 who were randomized to the t-PA group had a higher incidence of hemorrhagic stroke (2.08%) versus those randomized to either streptokinase group (1.23%). This has prompted some to suggest that patients older than age 75 should receive streptokinase rather than t-PA.⁴⁰ Furthermore, Van De Graaff et al. suggested that administration of thrombolytic therapy within 15 minutes of hospital arrival is associated with a 42% lower risk of in-hospital stroke ($p < 0.05$).⁴¹

Risk of Ventricular Fibrillation

18. After thrombolysis, P.H. is in normal sinus rhythm with rare premature ventricular contractions (PVCs). Should he receive prophylactic lidocaine?

Ventricular fibrillation is a major cause of death in patients who are having an AMI. More than half of the episodes of ventricular fibrillation that occur with an AMI are within 1 hour of the onset of symptoms. Because ventricular fibrillation is estimated to occur in 2% to 19% of patients with AMI, prophylactic lidocaine has been used in an attempt to reduce this complication.⁴² It was assumed initially that ventricular ectopy such as frequent PVCs or short runs of ventricular tachycardia would precede any episodes of ventricular fibrillation. However, it was noted that not all patients who developed ventricular fibrillation had warning arrhythmias, so it became routine to give all patients with AMI prophylactic infusions of lidocaine. Subsequent meta-analyses of the use of prophylactic lidocaine in AMI found that while lidocaine was associated with a 35% reduction of ventricular fibrillation, no significant reduction in all-cause mortality was noted. In fact, early mortality and asystole, although not significant, were detected in the lidocaine-treated patients.⁴³ Nonetheless, as ventricular fibrillation is treated readily with defibrillation in an intensive care unit, the risk of prophylactic lidocaine in all patients may exceed the benefit. Because electrical cardioversion is an unpleasant experience, it is reasonable to use prophylactic lidocaine in patients at highest risk for ventricular fibrillation (see Chapter 19).

Risks of Using Lidocaine

19. How should lidocaine be given, and if so, for how long? How should lidocaine be monitored?

Lidocaine should be given as a loading dose followed by a continuous infusion. Loading doses of 1 mg/kg (maximum 100 mg) are used, followed by a constant infusion of 20 to 50 mcg/kg/minute. Patients should be monitored for the side effects of lidocaine; the most common are those associated with central nervous system toxicity. Symptoms may include drowsiness, dizziness, tremor, paresthesias, slurred speech, seizures, and coma. Massive overdoses may cause respiratory depression. Lidocaine may suppress ventricular escape mechanisms, leading to atrioventricular block or asystole. The overall incidence of side effects in studies has been approximately 15%.^{42,43}

Plasma Concentrations

20. What factors following an AMI may complicate the measurement of lidocaine plasma concentrations?

The likelihood of developing adverse effects from lidocaine is dose related; however, side effects are frequently reported when plasma concentrations are within the therapeutic range. The elderly and patients with heart failure and hepatic dysfunction have reduced clearance of lidocaine and may be predisposed to lidocaine toxicity. Lidocaine is bound to α_1 -acid glycoprotein (AAG) and albumin in the serum. AAG plasma concentrations have been shown to increase within 36 hours of the time of infarction.⁴⁴ Patients with AMI have an increased binding of lidocaine to AAG and a rise in total lidocaine plasma concentrations, but a reduced percentage of free lidocaine. This could result in a patient with a plasma lidocaine concentration that is above the “therapeutic range” without signs of toxicity. Therefore, plasma lidocaine concentrations may be difficult to interpret in the setting of AMI. (See Chapter 19 for a complete discussion of lidocaine dosing and toxicity.)

Magnesium

21. Will the administration of IV magnesium be beneficial for P.H.? How is magnesium administered?

There has been considerable debate regarding the use of magnesium in the setting of AMI. The potential mechanisms by which magnesium may benefit a patient include an antiarrhythmic effect, an antiplatelet effect, reversal of vasoconstriction, reduction of catecholamine secretion, and enhancement of adenosine triphosphate production.

In the Second Leicester Intravenous Magnesium Intervention Trial (LIMIT-2), a randomized, placebo-controlled, double-blind trial of 2,316 patients with suspected AMI, IV magnesium was found to decrease mortality at 28 days by 24%. However, in the Magnesium in Coronaries (MAGIC) trial, 6,213 patients with AMI were randomized to 2 g of IV magnesium sulfate given as a bolus followed by a 17 g infusion over 24 hours or matching placebo. Early administration of magnesium did not reduce 30-day mortality. There was no benefit seen in the ISIS-4 study.^{2,3}

At this time, most clinicians do not routinely administer IV magnesium to AMI patients. However, because P.H. has a low serum magnesium concentration (1.3 mEq/L), he could benefit from the drug. Increasing P.H.’s serum magnesium concentration to 2.0 mEq/L could reduce his risk for potential arrhythmias. Based on trials using magnesium in AMI, P.H. should receive 8 mmol over 5 to 15 minutes followed by 65 to 72 mmol, or 8 to 9 g, given as an IV infusion over 24 hours.^{2,3}

β -Blockers

22. The physician has written orders for IV metoprolol 5 mg Q 5 minutes for three doses. What are some of the benefits of administering β -blockers to P.H.? Should they be given early in his therapeutic course as IV therapy or simply started as oral therapy a few days after the infarct?

As with thrombolytics, β -blockers offer significant benefits to the MI patient in both the acute infarct period and/or several days later as initial oral therapy. Several large trials were designed to give early IV β -blockers (up to 24 hours after symptom onset), followed by oral therapy; other studies used oral therapy alone beginning days after the infarct. Early IV administration appears to be most beneficial, with a reduction of mortality of around 25% in the first 2 days when the results of these trials are pooled. However, late oral therapy alone, up to 21 days post-MI in the β -Blocker in Heart Attack Trial, was also associated with a substantial reduction in mortality (around 10%).^{2,3}

Propranolol, metoprolol, timolol, and atenolol have been studied extensively. All have been given by early IV administration. Typically, metoprolol and atenolol are used in the acute setting due to their β -1 selectivity, ease of dosing and administration, and weight of evidence. Oral carvedilol, a nonselective β - and α -blocker, has been used in the peri-infarction period, specifically in patients with left ventricular dysfunction. In the Carvedilol Post-Infarction Survival Control in Left Ventricular Dysfunction (CAPRICORN) trial, carvedilol reduced all-cause and cardiovascular mortality as well as recurrent nonfatal MI.^{2,3}

In general, if a patient has transient cardiac decompensation (e.g., hypotension, bradycardia, or worsening symptoms

of heart failure) during the acute infarct period, early IV β -blockers are withheld. The patient's condition is then observed for a few days; if it stabilizes, oral therapy is initiated and titrated slowly. Data from COMMIT highlight the importance of tailored β -blockade therapy.⁴⁵ In this study, 45,852 patients were randomized to receive placebo or metoprolol (up to 15 mg IV, then 200 mg orally daily) within 24 hours of AMI. Although metoprolol use reduced reinfarction ($p < 0.001$) and ventricular fibrillation rates ($p < 0.001$) compared to placebo, the drug was also associated with a significant increase in episodes of cardiogenic shock ($p < 0.00001$). In a subgroup analysis, patients with hemodynamic instability at randomization appeared to bear the brunt of early cardiogenic shock associated with metoprolol.

Because P.H. has experienced an uncomplicated MI and is stable, he is a candidate for early IV therapy. Acute and chronic dosing regimens for β -blockers are listed in Table 17-8.^{2,3}

Use in Diabetes

23. What are some reasons for concern about the use of a β -blocker in P.H. (refer to the data presented in question 1)? How should this therapy be monitored?

Recall that P.H. has a long-standing history of hypertension and diabetes and that his admission BP was 180/110 mmHg and heart rate was 100 beats/minute. Historically, the presence of diabetes was a relative contraindication for β -blockade due to the adverse effects on insulin release and blunting of the hypoglycemia-associated tachycardia. However, diabetics comprise a large portion of AMI patients, and many β -blocker trials contained diabetic AMI patients. Gottlieb et al. found that post-MI diabetic patients treated with β -blockers experience a 36% reduction in mortality.⁴⁶

Furthermore, data from the Glycemic Effects in Diabetes Mellitus: Carvedilol-Metoprolol Comparison in Hypertensives (GEMINI) trial suggest that in hypertensive, diabetic patients receiving RAS blockade, carvedilol does not affect glycemic control and may improve insulin sensitivity compared to metoprolol.⁴⁷ Due to these positive data, β -blockers would have to possess major negative effects on the diabetic condition to be considered contraindicated. Diabetic patients

who are given β -blockers should receive nonintrinsic sympathomimetic activity, cardioselective agents (e.g., metoprolol, atenolol) or a more cardioselective α - β blocker (e.g., carvedilol). Patients should be advised to monitor their blood glucose levels carefully for both hypo- and hyperglycemia after the β -blocker is initiated, making adjustments to their insulin or oral hypoglycemic therapy as needed.

In a patient like P.H., a low dose of metoprolol 25 mg twice a day (BID) or carvedilol 3.125 mg BID can be given and titrated to either adequate β -blockade or loss of diabetic control. At these doses, the relative β_1 selectivity will be more likely to remain intact and is less likely than some of the nonspecific β -blockers to affect his diabetes.

Use in Hyperlipidemia

P.H. has elevated serum cholesterol (259 mg/dL) and triglyceride (300 mg/dL) levels. His low-density lipoprotein (LDL) and high-density lipoprotein (HDL) cholesterol levels are unknown. Although β -blockers have undesirable effects on plasma lipids (they decrease HDL and increase total cholesterol and triglycerides), the evidence in support of their use in MI patients is compelling (see Chapter 13). β -blockers have reduced post-MI morbidity and mortality in hyperlipidemic patients. An appropriate lipid-lowering treatment plan should be developed and initiated as soon as possible.

Use in Heart Failure

Years ago, heart failure was considered a contraindication to β -blockade, but that is no longer the case. There are several factors to consider before withholding β -blockers. In general, patients who receive early IV β -blockade will benefit from this therapy. If the patient has a relative contraindication to β -blockade, one could consider using esmolol (500 mcg/kg IV bolus over 1 minute followed by a maintenance infusion of 50 to 300 mcg/kg/minute), which has a short duration of action. IV β -blockade should be withheld only if the patient has signs and symptoms of moderate to severe left ventricular dysfunction. However, chronic, oral therapy should be initiated before discharge (see Chapter 19). β -blockade should be given to P.H. because he has no heart failure symptoms and his previous EF was $> 50\%$.

Table 17-8 Dosing Summary of β -Blockers in Acute Myocardial Infarction

| β -Blocker | IV Dose | Chronic Dose |
|-----------------------|---|--|
| Atenolol (Tenormin) | Administer 5 mg IV over 5 min, followed by 5 mg IV 10 min later; after second IV dose, immediately begin 50 mg PO, followed by 50 mg PO 12 hr later. ^a | 50–100 mg PO daily ^a |
| Carvedilol (Coreg) | None | 6.25–25 mg PO twice daily ^a |
| Metoprolol (Toprol) | Administer 5 mg IV over 2 min for three doses; 15 min after the last IV dose, begin 50 mg PO Q 6 hr for eight doses. ^a | 50–100 mg PO twice daily ^a |
| Propranolol (Inderal) | Administer 58 mg IV over 5 min, followed by 40 mg PO 2 hr apart, then Q 4 hr for seven doses. ^a | 180–240 mg PO daily in 24 divided doses ^a |
| Timolol (Blocadren) | Administer 1 mg IV, followed by 1 mg IV 10 min later; 10 min after the second IV dose, begin constant infusion of 0.6 mg/hr for 24 hr; on completion of infusion, begin 10 mg PO twice daily. | 10 mg PO twice daily ^a |

^aFDA-approved dose.

IV, intravenously; PO, orally; Q, every.

Use in Pulmonary Disease

P.H.'s acute situation is complicated by his history of intermittent pulmonary problems. In deciding whether to attempt use of β -blockers in patients with pulmonary disease, one must determine the nature of the pulmonary problem (i.e., reactive airways or restrictive lung disease). It also would be helpful to determine P.H.'s need for routine use of β -agonists to help quantify the severity of his disease. By history, P.H. does not use β -agonist bronchodilators routinely. No history is given regarding his pulmonary function tests or the degree of reversibility of his airway disease with bronchodilators. β_1 -selective antagonists are the drugs of choice in these patients, but at higher doses (e.g., metoprolol doses >100 mg/day), the relative β_1 selectivity may be lost. Similar to the argument regarding diabetes, a patient would need to experience significant worsening of the pulmonary disease to justify avoiding β -blockers. A better history of P.H.'s pulmonary problems should be obtained; if they are minor, low doses of metoprolol or atenolol (started in the hospital so he may be monitored closely) should be considered.

Weighing the risk versus benefit of β -blockers, one could make a case for cautiously administering IV agents to him at this time. His dose of IV metoprolol (5 mg Q 5 minutes for three doses) is a typical treatment plan. He must have frequent monitoring of heart rate, BP, and respiratory status. Therapy should be discontinued if P.H.'s heart rate drops below 60 beats/minute, systolic BP falls below 100 mmHg, or any respiratory distress is noted. Oral metoprolol therapy could begin at 25 to 50 mg a few hours after his last IV dose. Substituting the ultra-short-acting agent esmolol for metoprolol is an option for P.H. because any adverse effects would be relatively short lived. Unfortunately, there are no data to support the use of esmolol for an AMI.

Objective evidence of adequate β -blockade consists of a resting heart rate of 50 to 60 beats/minute, an exercise heart rate of <120 beats/minute, and/or a resting systolic BP of 100 to 120 mmHg. Therefore, P.H. needs a significant reduction in heart rate and BP from his admission values (100 beats/minute and 180/110 mmHg, respectively) to be considered as having achieved adequate β -blockade.⁴⁸

24. Several days later, a routine echocardiogram is performed on P.H. that shows hypokinesis of the anterior and lateral left ventricular walls, a slightly enlarged left ventricle, no valvular abnormalities, EF 35% to 40%, and the appearance of a thrombus in the left ventricle. Clinically, he has no signs or symptoms of heart failure. What are the therapeutic and prognostic implications of this echocardiogram?

Hypokinesis of the infarcted areas of the heart is not unusual. P.H. may have an area of "stunned" or "hibernating" myocardium; it could take several weeks to recover some of the wall motion if the area is still viable.⁴⁹ Therefore, P.H. may recover some of the wall motion and EF over time.

The presence of a thrombus in the left ventricle is a risk factor for embolization. Several studies have shown that this may increase P.H.'s risk of experiencing a later embolic event. If P.H. is believed to be compliant with his medications, he would be a candidate for warfarin therapy (titrated to an international normalized ratio [INR] of 2 to 3) for 1 to 3 months because of this thrombus. This should be enough time for the thrombus

to organize and become less of an embolic threat. Because of his reduced EF, P.H. is an ideal candidate for treatment with an ACE inhibitor and β -blocker.

Nitroglycerin

25. A.J., a 75-year-old man, presents to the ED with complaints of dizziness and chest discomfort. He is a poor historian, but it appears that his symptoms have been ongoing for >12 hours. His physician is concerned that the symptoms represent an STEMI. He had a GI bleed 6 weeks ago and has chronic obstructive pulmonary disease with a bronchospastic component. The ECG is consistent with a new anterolateral AMI. His vital signs are BP, 150/94 mmHg; heart rate, 55 beats/minute; and respiratory rate, 20 breaths/minute. Physical examination reveals wheezing. What is the best treatment strategy for A.J.?

Because of the time delay since symptoms first appeared and his history of recent GI bleeding, A.J. is not a good candidate for thrombolysis. β -blockers also should be avoided in A.J. because of his serious pulmonary disease and current heart rate. Thus, symptomatic management with IV NTG is indicated, and PCI should be considered. NTG lowers the left ventricular filling pressure and systemic vascular resistance, thereby reducing myocardial oxygen consumption and myocardial ischemia. At lower doses (<50 mcg/minute), IV NTG preferentially dilates the venous capacitance vessels, which leads to a decrease in left ventricular filling pressure.^{2,3} For patients who have signs of pulmonary congestion, IV NTG is of particular value. (See Chapter 16 for further discussion of NTG pharmacology.)

26. How should IV NTG be administered to A.J.? How should it be monitored?

IV NTG should be initiated with a small bolus dose of 15 mcg. A constant infusion is then delivered by a controlled infusion device, starting with 5 to 10 mcg/minute, which is then increased by an additional 5 to 10 mcg/minute every 5 to 10 minutes.^{2,3} Many cardiologists routinely give patients an infusion of NTG for the first 24 to 48 hours following an AMI. Increasing doses may be required over this period to maintain the desired hemodynamic effect due to tolerance that occurs from prolonged nitrate exposure. However, if >200 mcg/minute is needed to achieve the desired response, another vasodilator such as nitroprusside or an ACE inhibitor may be needed. NTG is typically administered in combination with thrombolytics in patients who require relief of myocardial ischemia. Two studies have reported that concurrent administration of NTG may impair the thrombolytic effects of t-PA, but these data have been questioned.^{50,51}

Some patients may have a problem with increased sensitivity to NTG, described as development of mean BP <80 mmHg. Of the patients who become hypotensive, many have an inferior AMI. Ferguson et al. noted that hypotension following NTG infusion was a common complication in patients with right ventricular infarction.⁵²

NTG readily migrates into many plastics; therefore, manufactured solutions are available only in glass containers. Some filters may absorb NTG, so they should be avoided. Polyvinyl chloride (PVC) tubing may absorb NTG, especially during the early phases of infusion. Some institutions use non-PVC

tubing for NTG infusions to minimize this problem. However, if standard PVC tubing is used, the usual starting dose of nitroglycerin is 25 mcg/minute and should be titrated to hemodynamic response.^{2,3}

A.J.'s BP should be monitored closely during this infusion. On admission, his BP was elevated at 150/94 mmHg, and his pulse rate was low at 55 beats/minute. After starting NTG, we would expect to see his BP decline; the pulse rate may or may not increase. The NTG dose should be titrated to relieve pain while avoiding hypotension. In patients with evidence of heart failure, NTG can reduce left ventricular filling pressure (preload), as well as improve orthopnea and pulmonary congestion. However, excessive doses of IV NTG can reduce left ventricular filling pressure and potentially decrease cardiac output, especially in patients like A.J. who do not have signs of heart failure. The end points for dose titration include relief of pain or other symptoms. The systolic BP should be kept equal to 90 mmHg. Nitrate tolerance can be minimized by providing a nitrate-free interval to the patient. If A.J. later receives chronic nitrate therapy with either an oral agent or a transdermal delivery system, a nitrate-free interval should be used (see Chapter 16).

27. Because A.J. has an elevated BP (154/94 mmHg), should he receive nitroprusside instead of NTG?

NTG is preferred over nitroprusside in the setting of an AMI. Although the drugs have similar hemodynamic effects, nitroprusside has been shown to increase ST segment elevation, whereas NTG decreases ST segment elevation.⁵³ Others have shown similar results and have proposed that nitroprusside may redistribute coronary blood flow away from the ischemic area, causing a worsening of the injury, known as coronary steal.⁵⁴

Analgesic Use

28. A.J.'s chest pain becomes increasingly severe despite NTG, and the physician is considering use of a potent analgesic. Which analgesic would be best for A.J.?

The pain associated with AMI is due to continuing tissue ischemia surrounding the area of infarcted tissue. The relief of pain should involve efforts to optimize the myocardial blood supply and minimize myocardial oxygen demand. Pain is usually relieved with successful thrombolysis. Other interventions can include oxygen, nitroglycerin, and β -blockers. As noted previously, A.J. is not a candidate for either thrombolysis or β -blockade. If his pain continues despite administration of IV NTG, he will need an analgesic. A.J. may also need to undergo emergency revascularization with either PCI or bypass surgery.

Morphine sulfate is usually the analgesic of choice in patients with AMI. In addition to diminishing pain and anxiety, morphine also has beneficial hemodynamic effects. By reducing pain and anxiety, the release of circulating catecholamines is diminished, possibly reducing the associated arrhythmias. Morphine also causes peripheral venous and arterial vasodilatation, which reduces preload and afterload, and consequently, the myocardial oxygen demand. Morphine is administered in small (2- to 4-mg) IV doses as often as every 5 minutes if needed. Cumulative doses of 25 to 30 mg may be

required. The risks associated with morphine use include hypotension, bradycardia, and respiratory depression. Because A.J. already has bradycardia, meperidine may be used because it has vagolytic properties.

POSTINFARCTION ARRHYTHMIAS

29. D.T., a 45-year-old man who is recovering from an AMI (onset 12 hours ago), is noted to have sustained ventricular tachycardia on the telemetry monitor in the coronary care unit. During the episode, he was hemodynamically unstable (BP 80/40 mmHg, heart rate >200 beats/minute). The arrhythmia was terminated with a 100-J countershock. He now is in sinus rhythm and clinically stable. Would D.T. be a candidate for further workup of the arrhythmia? If so, what tests are appropriate?

In the past, it was assumed that ventricular ectopy in the immediate post-MI period would be a negative prognostic factor, especially for sudden cardiac death. Overall, ventricular arrhythmias detected during hospitalization have not been helpful in identifying patients at high risk for sudden cardiac death on long-term follow-up.⁵⁵ Because D.T.'s arrhythmia occurred within the first 48 hours after the infarct (i.e., the peri-infarct period, when some residual ischemia may be occurring), he is not a candidate for any further specific arrhythmia workup, such as electrophysiologic testing. D.T. should receive a β -blocker and aspirin during hospitalization and after discharge to prevent reinfarction and reduce mortality.

30. Two weeks after D.T.'s AMI, he returns to the clinic for routine follow-up. A Holter monitor (continuous ambulatory ECG monitoring) is ordered for him because he states that he has had several "skipped beats" since the MI. This is a new finding. The results of the Holter indicate that he is having >30 PVCs/hour that are asymptomatic to mildly symptomatic. What is the appropriate antiarrhythmic therapy at this time?

It has been known for some time that frequent PVCs in patients with organic heart disease (e.g., post MI) are indicators for an increased risk of sudden cardiac death. However, the CAST showed that when PVCs were suppressed with flecainide, encainide, or moricizine, survival was significantly worse than in patients treated with placebo. This may be related to the proarrhythmic effects of these drugs (see Chapter 20). Therefore, treatment of asymptomatic or mildly symptomatic PVCs with antiarrhythmics (other than β -blockers) in this type of MI patient is not recommended. A pooled-data analysis of class I antiarrhythmic trials in these patients also supports these conclusions. Therapies should be aimed at correcting the patient's underlying ischemia and/or coexisting heart failure rather than administering antiarrhythmics. D.T. should not be given any of the class I antiarrhythmics.^{2,3}

Amiodarone has been extensively studied in post-MI patients. The largest trials to date have been the Canadian Amiodarone Myocardial Infarction Arrhythmia Trial (CAMIAT) and European Myocardial Infarction Amiodarone Trial (EMIAT) studies. CAMIAT enrolled 1,202 patients between 6 and 45 days post MI who had ≥ 10 PVCs/hour. EMIAT enrolled 1,486 patients between 5 and 21 days post MI with a documented EF <40%. CAMIAT found a nonsignificant reduction in total mortality rate but a 38% reduction ($p = 0.03$) in the rate of ventricular fibrillation or arrhythmic death. EMIAT

also found no difference in total mortality rate, but a 32% reduction ($p = 0.05$) in arrhythmic death and resuscitated cardiac arrest. The Amiodarone Trials Meta-Analysis Investigators evaluated data from 6,553 post-MI patients enrolled in 13 randomized trials. These investigators found that amiodarone significantly reduced the total mortality rate by 13% and the arrhythmic/sudden death rate by 29%.^{2,3}

Outside amiodarone, randomized trials also strongly support implantable cardioverter-defibrillators (ICDs) as an option for secondary prevention in patients with prior life-threatening arrhythmias and as primary prophylaxis for those with a low EF and CAD⁵⁶ (see Chapter 20).

At this time, D.T. should not receive empiric amiodarone or an ICD because his symptoms are mild and treatment would not prolong his life.

ACUTE CORONARY SYNDROMES

31. J.W. is a 55-year-old man who presented to the ED with chest tightness and shortness of breath. He gives a history of similar symptoms the prior day that lasted 15 minutes. He was given aspirin 325 mg and started on an IV NTG infusion, which was increased to 80 mcg/minute; at that time, his BP was 100/60 mmHg, and his heart rate was 88. His ECG continued to show ST segment depression in the anterior leads. His shortness of breath was relieved, but he still complained of chest tightness. His past medical history is unremarkable, and he was on no medications prior to admission. He has smoked a pack of cigarettes per day for the past 30 years. Blood is drawn for troponin and CK as well as routine chemistries. Based on his symptoms and ECG, the diagnosis is presumed unstable angina. Should J.W. receive an additional oral antiplatelet agent?

J.W. is presenting with signs and symptoms consistent with ACS. If his cardiac enzymes come back positive, his diagnosis will be NSTEMI. If they remain unchanged, his diagnosis will be unstable angina. Regardless of the diagnosis, clopidogrel should be added to aspirin as soon as possible on admission. It should be administered for 1 month and may be given for up to 9 months in patients who are not at a high risk for bleeding.

In hospitalized patients with unstable angina or NSTEMI who do not require early interventional therapy, clopidogrel may be used in combination with aspirin. In the Clopidogrel in Unstable Angina to Prevent Recurrent Ischemic Events (CURE) trial, 12,562 patients with NSTEMI presenting within 24 hours were randomized to receive placebo + aspirin (75–325 mg) or clopidogrel (300 mg, immediately followed by 75 mg daily) plus aspirin. After 9 months, cardiovascular death, MI, or stroke occurred in 11.5% of patients in the placebo group and 9.3% in those receiving clopidogrel ($p < 0.001$). Clopidogrel was associated with reductions in severe ischemia and revascularization. Compared to placebo, an increase in major and minor bleeding was seen with clopidogrel. Based on these data, clopidogrel with aspirin should be administered immediately on admission and continued for at least 1 month and up to 9 months.^{2,3}

In the PCI-CURE study, 2,658 patients from the CURE trial undergoing PCI were randomized to receive clopidogrel or placebo in addition to aspirin. Patients were treated prior to the PCI with aspirin and study medication for a median of 10 days. After the PCI, patients received open-label clopidogrel

or ticlopidine for about 2 to 4 weeks, after which the study drug was restarted for a mean of 8 months. In the clopidogrel group, there was a statistically significant reduction in the composite of cardiovascular deaths, MIs, or urgent target-vessel revascularizations within 30 days of the PCI compared to placebo (4.5% vs. 6.4%, $p = 0.03$). Overall, patients receiving clopidogrel exhibited a 31% reduction in cardiovascular death or MI compared to those receiving placebo ($p = 0.002$).^{2,3}

Based on these data, in patients with unstable angina or NSTEMI receiving aspirin and undergoing PCI, clopidogrel should be administered prior to the procedure, followed by 1 month and possibly up to 12 months of additional treatment. In patients undergoing elective CABG or other surgery, clopidogrel should be discontinued for 5 to 7 days prior to the procedure.

32. What other antithrombotic medications should be considered for J.W.?

The ACC/AHA guidelines recommend the use of either LMWH or UFH for the treatment of unstable angina/NSTEMI.^{2,3} Enoxaparin is preferred over UFH unless CABG is anticipated within 24 hours. In the Efficacy and Safety of Subcutaneous Enoxaparin (ESSENCE) study, enoxaparin (1 mg/kg SQ twice daily) was compared to UFH (5,000 U IV bolus followed by continued infusion titrated to an activated partial thromboplastin time of 55–86 seconds) administered for 48 hours to 8 days. The composite outcome of death, MI, or recurrent angina at 14 days was 19.8% in the UFH group versus 16.6% in the enoxaparin group, a 20% relative risk reduction. This benefit was maintained over 1 year.

In the TIMI-11B trial, enoxaparin (30 mg IV bolus followed by 1 mg/kg SQ twice daily for 8 days) compared to UFH (70 U/kg bolus followed by 15 U/kg/hour for 3–8 days) reduced the composite end point of death, MI, or need for urgent revascularization at 8 days ($p = 0.048$) and 43 days ($p = 0.048$).

In the Superior Yield of the New Strategy of Enoxaparin, Revascularization and Glycoprotein IIb/IIIa Inhibitors (SYNERGY) trial, 9,978 high-risk NSTEMI patients were randomized to receive either enoxaparin (1 mg/kg SQ twice daily) or weight-based UFH (60 U/kg bolus followed by 12 U/kg/hour adjusted to an aPTT 1.5 to 2 × control) prior to an early invasive strategy. Enoxaparin was found to be as efficacious as UFH in reducing 30-day all-cause mortality or nonfatal MI but was associated with a significant risk of major bleeding ($p = 0.008$).⁵⁷ Bleeding was especially problematic in those patients who crossed-over from one treatment to the other during the trial.

Finally, enoxaparin has been compared with the factor Xa inhibitor fondaparinux. In the OASIS-5 trial, 20,078 NSTEMI patients were randomized to receive either fondaparinux (2.5 mg SQ daily) or enoxaparin (1 mg/kg SQ twice daily) for a mean of 6 days and evaluated at 9 days for the primary end point of death, MI, or refractory ischemia. No difference existed between groups for the primary end point; however, compared to enoxaparin, fondaparinux demonstrated a significantly lower incidence of major bleeding at 9 days ($p < 0.001$) and a greater reduction in mortality at 30 days ($p = 0.05$).⁵⁸

The addition of a LMWH with a GP IIb/IIIa inhibitor for the initial management of unstable angina/NSTEMI has been evaluated in small trials. The major finding was that major

hemorrhage rarely occurred in the combination arms (0.3%–1.8%). Although not powered to detect a difference, the rates of ischemic events were noted to be similar between the LMWH and UFH groups.⁵⁹ Similar findings have also been seen when a DTI, bivalirudin, has been added to a GP IIb/IIIa.⁶⁰

33. What is the role of a GP IIb/IIIa inhibitor in patients with NSTEMI-ACS or NSTEMI?

The ACC/AHA guidelines recommend that a platelet GP IIb/IIIa inhibitor be administered, in addition to aspirin and/or clopidogrel and UFH or LMWH, to patients in whom PCI is planned.²³ A GP IIb/IIIa inhibitor may also be administered just prior to PCI. Eptifibatid or tirofiban, when used in combination with aspirin and UFH or LMWH, is also approved for the medical management of patients with NSTEMI-ACS. When used to treat patients medically, the GP IIb/IIIa inhibitors (in combination with the other drugs previously mentioned) are generally given for 2 to 3 days.

The GUSTO-IV-ACS trial enrolled 7,800 patients with unstable angina/NSTEMI in whom early (<48 hours) revascularization was not intended. All patients received aspirin and either UFH or LMWH. They were randomized to placebo, an abciximab bolus and 24-hour infusion, or an abciximab bolus and 48-hour infusion. At 30 days, death or MI occurred in 8.0% of patients taking placebo, 8.2% of patients receiving 24-hour abciximab, and 9.1% of patients receiving 48-hour abciximab ($p = \text{NS}$). At 48 hours, death occurred in 0.3%, 0.7%, and 0.9% of patients in these groups, respectively (placebo vs. abciximab at 48 hours, $p = 0.008$). Abciximab should be used only if a patient is planning to undergo PCI; it should be avoided if only medical management is intended. Major trials have been done with other GP IIb/IIIa inhibitors in patients with ACS, showing them to be useful for the medical management of NSTEMI-ACS.^{61,62}

LONG-TERM THERAPY

Angiotensin-Converting Enzyme Inhibitors

34. A patient with an uncomplicated MI has no signs or symptoms of heart failure. An order is written for captopril 12.5 mg three times a day (TID). Is this appropriate? If so, how should the therapy be monitored?

After an AMI, the heart undergoes processes that initially compensate for the loss of contractile function but may increase the long-term risk for development of heart failure. This is referred to as “remodeling” of the ventricle. (See Chapter 18 for a more detailed description of ventricular remodeling.) The increase in the number of survivors of AMI has increased the number of heart failure patients.

In the SAVE (Survival and Ventricular Enlargement) trial, captopril (up to 50 mg TID) had a statistically significant beneficial effect on mortality when given to asymptomatic patients with an EF <40% who were 3 to 16 days post MI. This 4-year follow-up study also showed significant decreases in morbidity from heart failure and recurrent AMI in the captopril group. Data from the ISIS-4, GISSI-3, Trandolapril cardiac evaluation (TRACE), Infarction Ramipril Efficacy (AIRE), and Second Survival of Myocardial Infarction Long-term Evaluation (SMILE) trials have also shown a benefit with the use of ACE inhibitors post MI.^{2,3}

Based on these studies, oral ACE inhibitor therapy should be started within the first 24 hours of an AMI, preferably after completion of thrombolytic therapy and BP stabilization (systolic BP >100 mmHg). ACE inhibitor therapy is particularly beneficial in patients with an anterior infarction and an EF <40% (even if asymptomatic) or clinical evidence of heart failure.^{2,3} ACE inhibitors may be used to prevent the occurrence of heart failure symptoms or for treatment of heart failure in the AMI patient. However, unlike β -blockers, the use of IV ACE inhibition therapy is not recommended by the ACC/AHA guidelines.^{2,3} Captopril could be given on postinfarct day 2 or 3, beginning with a test dose of 6.25 mg and then titrated to a maintenance dosage of 25 to 50 mg TID. BP should be monitored closely, with the systolic BP maintained above 90 mmHg. Renal function and serum potassium levels should be followed closely during the first few months of therapy. In diabetics, an ACE inhibitor may also benefit long-term renal function.⁶³ Once it is established that the patient can tolerate an ACE inhibitor, he or she can be switched to a longer-acting agent such as lisinopril or enalapril to simplify the regimen. (See Chapter 18 for ACE inhibitor dosing recommendations.)

If the patient cannot tolerate an ACE inhibitor due to cough, an ARB may be an alternative. In the Optimal Therapy in Myocardial Infarction with the Angiotensin II Antagonist Losartan (OPTIMAAL) Trial and Valsartan in Acute Myocardial Infarction Trial (VALIANT), losartan and valsartan demonstrated similar reductions in all-cause mortality compared to captopril, with a nonsignificant trend in favor of captopril. Dual therapy of captopril with valsartan offered no additional benefits but increased side effects.^{2,3}

Aldosterone Antagonists

35. Should this patient receive an aldosterone antagonist?

Like angiotensin II, aldosterone also plays an important role in left ventricular remodeling. (See Chapter 18 for further discussion of aldosterone.) Inhibiting aldosterone directly in addition to ACE inhibitor therapy was first evaluated in the heart failure patients in the Randomized Aldactone Evaluation Study (RALES).⁶⁴ Patients who received spironolactone exhibited a 30% reduction in mortality compared to placebo ($p < 0.001$). Another aldosterone antagonist, eplerenone, is a selective inhibitor of the mineralocorticoid receptor with fewer sexual side effects.

In the Eplerenone Post Acute Myocardial Infarction Heart Failure Efficacy and Survival Study (EPHESUS), 6,600 patients with AMI and an EF <40% were allocated to optimal medical therapy with either eplerenone or placebo. After 16 months, a 15% risk reduction in mortality ($p = 0.008$), 13% reduction in sudden death ($p = 0.002$), and 21% reduction in cardiovascular death or hospitalization ($p = 0.02$) was seen in the eplerenone group compared to placebo.⁶⁴

Based on these data, the 2004 ACC/AHA guidelines recommend an aldosterone antagonist in STEMI patients without significant renal dysfunction (creatinine <2.5 mg/dL in men and <2.0 mg/dL in women) or hyperkalemia (potassium <5 mEq/L) who are already receiving therapeutic doses of an ACE inhibitor, have an EF <40%, and have either symptomatic heart failure or diabetes.^{2,3}

Because our patient does not have heart failure or diabetes, he is not a candidate for aldosterone antagonism. However, if his EF was <40%, either spironolactone or eplerenone would be an option. Serum potassium and renal function would need to be carefully checked 3 days and at 1 week after therapy initiation and every month for the first 3 months. ACE inhibitor and potassium supplement doses may need to be adjusted.⁶⁴

β -Blockers

36. Should the previous patients receive a β -blocker upon discharge?

The 2004 ACC/AHA guidelines recommend β -blocker therapy indefinitely for all patients following an AMI.^{2,3} The benefits of β -blockers in reducing reinfarction and mortality are believed to outweigh the risk, even in patients with asthma, insulin-dependent diabetes, severe peripheral vascular disease, first-degree heart block, and moderate left ventricular dysfunction. Due to his bronchospastic disease, P.H. should be carefully titrated on a β -blocker to see if he can tolerate it. Propranolol, metoprolol, and atenolol are available as generics, making any of them a cost-effective alternative. Metoprolol or carvedilol are considered first-line choices in patients with heart failure, whereas atenolol or metoprolol should be considered in patients with stable asthma or bronchospastic pulmonary disorder.

Lipid-Lowering Agents

37. Should AMI patients be started on a lipid-lowering agent? When should it be initiated?

Although the results of a complete fasting lipid panel were not made available, P.H. had elevated total cholesterol and triglycerides as part of his routine screening laboratory tests. A complete fasting lipid profile would be helpful and should be completed within 24 hours of presenting with an AMI. This is often overlooked or not done because the patient is not fasting. Most patients will require a low-cholesterol, low saturated fat diet in addition to lipid-lowering therapy. The goal for P.H. will be to reduce his LDL to <100 mg/dL, with an ideal goal of <70 mg/dL with a statin (see Chapter 12). When triglycerides are >200 mg/dL, drug therapy with niacin or a fibrate is beneficial.^{2,3} Hormone replacement therapy is not beneficial for secondary prevention in postmenopausal women. If a patient is receiving hormone replacement therapy, it should be discontinued during the acute event (see Chapter 12).

The Myocardial Ischemia Reduction with Aggressive Cholesterol Lowering (MIRACL) trial, which enrolled NSTEMI patients, reported a 16% lower rate of death and nonfatal major cardiac events at 4 months follow-up in patients receiving atorvastatin 80 mg/day within 24 to 96 hours of hospitalization when compared with placebo ($p = 0.048$). The A to Z trial, showed a favorable trend toward major cardiovascular event reduction during 624 months follow-up in AMI patients receiving an intensive simvastatin regimen (40 mg/day for 1 month followed by 80 mg/day thereafter) initiated within 12 hours of stabilization when compared with those receiving a less intensive regimen (placebo for 4 months followed by simvastatin 20 mg/day).^{2,3,65}

In the case of P.H., a statin should be administered during his hospitalization. Statin choice and dose should be based on current published evidence, cost, and potential drug interactions (see Chapter 12).

Antithrombotic Agents

38. Three days before P.H.'s anticipated discharge, the medical team is discussing the need to administer long-term anticoagulant therapy with warfarin in addition to antiplatelet therapy with aspirin. Is either therapy indicated for P.H. at this time?

In addition to its use in the setting of AMI, aspirin is routinely prescribed for post-MI patients. The prophylactic role of aspirin in asymptomatic patients has also been established by such trials as the Physicians' Health Study as well as in patients with chronic stable angina.^{66,67}

Antiplatelet therapy should be lifelong because of its effects on secondary prevention of reinfarction. There appears to be no difference in efficacy over a wide range of aspirin doses (75–1,500 mg/day), although higher doses may increase the incidence of side effects. Much interest exists in using lower doses of aspirin for cardiovascular disease. Most clinicians use dosages of 81 to 325 mg daily or every other day.^{68,69}

Long-term warfarin may be beneficial in some patients, but clinical judgment is needed to decide whether the benefit is likely to exceed the risk. Kaplan reviewed data for the development of left ventricular thrombi in AMI and found an incidence of approximately 35% in patients who suffered an anterior infarct.⁷⁰ Although anticoagulation will decrease the incidence of stroke, <3% of patients will develop a cerebrovascular accident following an AMI if not anticoagulated. The ACC/AHA guidelines recommend warfarin for post-MI patients unable to take aspirin or clopidogrel, patients with a left ventricular thrombus, and those with persistent atrial fibrillation.^{2,3} There is also consensus that post-MI patients with extensive wall motion abnormalities and those with paroxysmal atrial fibrillation will benefit from anticoagulation. Data have suggested that the use of high-intensity warfarin (INR 3–4) or moderate intensity warfarin (INR 2–2.5) with low-dose aspirin (75–100 mg) may significantly reduce subsequent cardiovascular events and death post MI compared to aspirin (100–160 mg).⁷¹

P.H. is probably a good candidate for 1 to 3 months of warfarin therapy titrated to an INR of 2 to 3 because of his left ventricular thrombus. The use of low-dose aspirin in conjunction with warfarin will probably not increase his risk of bleeding.

39. Is clopidogrel more effective than aspirin in reducing the risk for further cardiovascular events?

In patients with STEMI and NSTEMI, clopidogrel (Plavix) may be used when aspirin is contraindicated or not tolerated; however, it is significantly more expensive than aspirin. In the Clopidogrel Versus Aspirin in Patients at Risk of Ischemic Events (CAPRIE) trial, 19,185 patients with atherosclerotic vascular disease such as ischemic stroke, MI, or peripheral arterial disease were randomized to clopidogrel 75 mg once daily or aspirin 325 mg once daily and followed for 1 to 3 years. On completion of the study, an intention-to-treat analysis demonstrated a lower risk for the combined end points of ischemic stroke, MI, or vascular death in the clopidogrel group compared to aspirin (5.32% vs. 5.83%, $p = 0.043$). A post hoc

analysis of these data found a lower rate of AMI in patients receiving clopidogrel compared to aspirin (4.2% vs. 5.04%, $p = 0.008$).^{2,3} (See Chapters 16 and 55 for further discussion of anticoagulants and antiplatelet drugs.) However, the 2004 ACC/AHA guidelines still recommend aspirin over clopidogrel, except when aspirin is contraindicated or if a patient is undergoing PCI with stent placement.^{2,3}

40. How would you summarize the long-term therapy needed by P.H. on discharge?

Appropriate discharge medications for P.H. include a β -blocker, aspirin 81 mg/day, an ACE inhibitor, and warfarin to achieve an INR of 2 to 3. He also should receive a prescription for sublingual NTG to carry with him for use as needed. Some clinicians also might choose to continue his low-dose chronic nitrate therapy. These agents should be continued long term except for the warfarin, which should be discontinued after a few months. P.H. can be started on a statin drug to reach his LDL goal of <100 mg/dL, ideally 70 mg/dL. Routine liver function tests should be obtained prior to initiation of therapy and periodically thereafter. His previous hydrochlorothiazide may be discontinued because his hypertension will likely be controlled with the β -blocker and ACE inhibitor. His insulin should be continued, and his blood glucose monitored closely. The goal is to achieve a state of β -blockade that will allow P.H. to maintain a systolic BP of >100 mmHg; therefore, the clinician must balance the hypotensive effects of the ACE inhibitor and the β -blocker. If P.H. experiences postinfarction angina, then the addition of a calcium channel blocker such as diltiazem and/or chronic nitrate therapy would be indicated.

LIFESTYLE MODIFICATIONS

41. What types of lifestyle modifications should P.H. be encouraged to pursue to reduce his risk factors?

P.H. must be encouraged to stop smoking; this may be the most important intervention. Rosenberg et al. showed that the risk of AMI in men who quit smoking was reduced to that of nonsmokers within a few years after quitting⁷² (see Chapter 85). Weight management, diabetic treatment, and serum lipid control are also important risk factors to address. (See Chapters 13 and 50 for further information on lipid-lowering drugs and diet therapy.)

SUMMARY

The use of thrombolytics and PCI has significantly improved the survival of patients with STEMI. Despite the overwhelming results favoring thrombolytic therapy in all subgroups, it is believed that these agents remain underused in patients with STEMI. The major risk associated with thrombolysis is bleeding, especially within the central nervous system. Another problem associated with thrombolytic therapy is re-occlusion of the artery that was initially opened. Coronary angioplasty is more effective than thrombolytic therapy; however, it is available only in hospitals with experienced invasive cardiologists, thereby limiting its availability to many patients.

Aspirin should be given to all patients with AMI; unless there is a contraindication, β -blockers and statins should be administered as well. Clopidogrel is often used in conjunction with aspirin, especially in patients receiving stents. ACE inhibitors and aldosterone antagonists have been shown to be beneficial in patients who have left ventricular dysfunction (EF <40%) and are also recommended for secondary prevention. Nitrates are also useful, but care must be taken to maintain an adequate perfusion pressure. Secondary prevention emphasizing a healthy lifestyle and aggressive lipid lowering are important components to the overall treatment plan.

INTRODUCTION

The descriptive terminology, diagnostic techniques, and treatment of heart failure (HF) have undergone significant change in the past 15 to 20 years. Since 1994, a series of consensus and evidence-based practice guidelines have been published in an effort to standardize HF management. The first was from an expert panel appointed by the Agency for Health Care Policy and Research (AHCPR) and the RAND Corporation.¹ At about the same time, the American College of Cardiology (ACC)/American Heart Association (AHA) Task Force on Practice Guidelines published their initial recommendations.² The recommendations from both groups were remarkably similar and included three key principles: differentiation of HF into systolic and diastolic dysfunction, recommendation of ejection fraction measurement to determine type of HF, and establishing angiotensin-converting enzyme (ACE) inhibitors as the gold standard for the treatment of HF. The Heart Failure Society of America (HFSA) Guidelines were first released in 1999,³ and updated in 2006.⁴ The European Society of Cardiology (ESC) published updated guidelines in 2005.⁵ Important additions from these later guidelines include recommendation of β-adrenergic blockers for all patients with New York Heart Association (NYHA) class II and III HF and use of low-dose spironolactone (Aldactone) in class IV HF. The ACC/AHA guidelines were updated in 2001 and revised again in 2005.^{6,7} These revised guidelines continue to adhere to the four disease stages of HF first assigned by the ACC/AHA 2001 guidelines. The guidelines also incorporate the latest clinical trials and continue to emphasize the role of neurohumoral drug therapy. Furthermore, the updated guidelines recognize the large growing geriatric population and end-of-life issues and how these will impact the management of advanced HF. It is highly recommended that practitioners look at least annually for the most recently published guidelines to be aware of the rapidly evolving treatment strategies for HF.

Epidemiology of Heart Failure

Heart failure “is a complex clinical syndrome that can result from any structural or functional cardiac disorder that impairs the ability of the ventricle to fill with or eject blood.”⁶ As a consequence the heart fails to pump sufficient blood to meet the body’s metabolic needs. “The cardinal manifestations of HF are dyspnea (breathlessness) and fatigue, which can limit exercise tolerance; and fluid retention, which can lead to pulmonary congestion and peripheral edema.”⁶ Congestive heart failure (CHF) is a specific subset of HF characterized by left ventricular systolic dysfunction and volume excess present-

ing as an enlarged, blood-congested heart. Because of wide variability in the causes and clinical presentation of HF, it is recommended that the term congestive heart failure be abandoned.

It is estimated that 5 million people in the United States (1.5% to 2% of the population) have HF.^{7,8} The prevalence continues to increase, with 550,000 new cases diagnosed each year. A recent analysis by an Olmstead county (Minnesota) epidemiologic group showed that, although the prevalence of systolic HF did not change significantly, the recognition of diastolic HF has increased.⁹ HF incidence approaches 10 per 1,000 population after age 65 and is the most common cause of hospitalizations in the elderly population in the United States. In 2004, approximately 1 million people were hospitalized for HF. Direct and indirect health care costs of HF in 2007 are estimated to be \$33.2 billion. HF is the number one discharge diagnosis in the Medicare population (70,000 hospitalized for HF). In the last 10 years the reported HF visits rose to 3.4 million. In the year 2001, Medicare expended \$5,912 per discharge for Medicare beneficiaries with HF.⁸ More aggressive treatment of hypertension may have contributed to the lower incidence of HF in some populations, whereas improved survival after myocardial infarction (MI) may leave others at greater risk of developing post-infarction HF. As the size of the geriatric population increases, HF likely will become a more frequently encountered clinical entity.

Quality of life is adversely affected by progressive functional disability. Of greater consequence is the high mortality rate. Of men and women under age 65 who have HF, 80% and 70%, respectively, will die with in 8 years.⁸ Despite earlier diagnosis and aggressive medical management, the prognosis is poor.

Etiology

Low-Output Versus High-Output Failure

Traditionally, HF has been described as being either *low-output* or *high-output failure*, with a predominance (>90%) of cases being low-output failure (Table 18-1). In both types, the heart cannot provide adequate blood flow (tissue perfusion) to meet the body’s metabolic demands, especially during exercise. The hallmark of classic low-output HF is a diminished volume of blood being pumped by a weakened heart in patients who have otherwise normal metabolic needs.

In high-output failure, the heart itself is healthy and pumps a normal or even higher than normal volume of blood. Because of high metabolic demands caused by other underlying medical disorders (e.g., hyperthyroidism, anemia), the heart becomes exhausted from the increased workload and eventually cannot

Table 18-1 Classification and Etiology of Left Ventricular Dysfunction

| Type of Failure | Characteristics | Contributing Factors | Etiology |
|---|--|--|--|
| Low output, systolic dysfunction (dilated cardiomyopathy) ^a (60%–70% of cases) | Hypofunctioning left ventricle; enlarged heart (dilated left ventricle); ↑left ventricular end-diastolic volume; EF <40%; ↓stroke volume; ↓CO; S ₃ heart sound present | 1. ↑Contractility (cardiomyopathy) 2. ↓Afterload (elevated SVR) | 1. Coronary ischemia, ^b MI, mitral valve stenosis or regurgitation, alcoholism, viral syndromes, nutritional deficiency, calcium and potassium depletion, drug induced, idiopathic 2. Hypertension, aortic stenosis, volume overload |
| Low output, diastolic dysfunction (30%–40% of cases) | Normal left ventricular contractility; normal size heart; stiff left ventricle; impaired left ventricular relaxation; impaired left ventricular filling; ↓left ventricular end-diastolic volume; normal EF; ↓SV; ↓CO; exaggerated S ₄ heart sound | 1. Thickened left ventricle (hypertrophic cardiomyopathy) 2. Stiff left ventricle (restrictive cardiomyopathy) 3. ↑Preload | 1. Coronary ischemia, ^b MI hypertension, aortic stenosis and regurgitation, pericarditis, enlarged left ventricular septum (hypertrophic cardiomyopathy) 2. Amyloidosis, sarcoidosis 3. Sodium and water retention |
| High-output failure (uncommon) | Normal or ↑contractility; normal size heart; normal left ventricular end-diastolic volume; normal or ↑EF; normal or increased stroke volume; ↑CO | ↑Metabolic and oxygen demands | Anemia and hyperthyroidism |

^aSame as congestive heart failure if symptoms also present.

^bHeart failure caused by coronary artery ischemia or myocardial infarction classified as “ischemic” etiology. All other types combined as “nonischemic.”
CO, cardiac output; EF, ejection fraction; K, potassium; MI, myocardial infarction; SV, stroke volume; SVR, systemic vascular resistance.

keep up with demand. The primary treatment of high-output HF is amelioration of the underlying disease. The remainder of this chapter focuses on the treatment of low-output HF.

Left Versus Right Ventricular Dysfunction

Simple classification of HF as being low-output failure does not adequately describe the complex nature of this disorder. Consequently, low-output HF is further divided into left and right ventricular dysfunction, or a combination of the two (biventricular failure). Because the left ventricle is the major pumping chamber of the heart, it is not surprising that *left ventricular dysfunction* is the most common form of low-output HF and the major target for pharmacologic intervention. Right ventricular dysfunction may coexist with left ventricular HF if damage is sustained by both sides of the heart (e.g., after MI) or as a delayed complication of progressive left-sided HF (see Question 1).

Isolated right-sided ventricular dysfunction, which is relatively uncommon, is usually caused by either primary or secondary *pulmonary arterial hypertension* (PAH). In these conditions, elevated pulmonary artery pressure impedes emptying of the right ventricle, thus increasing the workload on the right side of the heart.^{10,11} Primary PAH is idiopathic, caused by stenosis or spasm of the pulmonary artery of unknown etiology. Secondary causes include collagen vascular disorders, sarcoidosis, fibrosis, exposure to high altitude, drug and chemical exposure, and cor pulmonale. Drug-induced sources include opioid overdoses (especially heroin), 5 hydroxytryptamine 2B (5HT-2B) agonists (e.g., dexfenfluramine, fenfluramine, and pergolide), and pulmonary fibrosis caused by intravenous (IV) injection of poorly soluble forms of methylphenidate (e.g., IV drug users injecting partially dissolved Ritalin tablets). Cor pulmonale is defined as pulmonary hypertension, and sec-

ondary right-sided failure as a complication of chronic obstructive pulmonary disease (COPD).

Systolic Versus Diastolic Dysfunction; Ischemic Versus Nonischemic Heart Failure

Left ventricular dysfunction is further subdivided into systolic and diastolic dysfunction, with mixed disorders also being encountered (Table 18-1). In both forms, the *stroke volume* (SV) (i.e., the volume of blood ejected by the heart with each systolic contraction; normal, 60–130 mL) and the subsequent 1-minute *cardiac output* (CO) (i.e., SV × heart rate; normal, 4 to 7 L/minute) are reduced. In diagnosing HF, a critical marker differentiating systolic from diastolic dysfunction is the *left ventricular ejection fraction* (LVEF), defined as the percentage of left ventricular end-diastolic volume expelled during each systolic contraction (normal, 60%–70%).

In *systolic dysfunction*, the LVEF is <40%, dropping to <20% in advanced HF. Thus, systolic dysfunction is synonymous with low ejection fraction (EF) heart failure and is almost always caused by factors causing the heart to fail as a pump (decreased myocardial muscle contractility). The heart dilates as it becomes congested with retained blood, leading to an enlarged hypokinetic left ventricle.

Heart failure caused by damage to heart muscle or valves because of chronic coronary ischemia or after MI is classified as *ischemic*, with all other types grouped as *nonischemic*. Coronary artery disease is the cause of HF in approximately two thirds of patients with left ventricular systolic dysfunction. Other causes of left ventricular pump failure include persistent arrhythmias, post-streptococcal rheumatic heart disease, chronic alcoholism (alcoholic cardiomyopathy), viral infections, or unidentified etiology (idiopathic dilated cardiomyopathy). Chronic hypertension, and certain cardiac

valvular disorders (aortic or mitral stenosis), also precipitate systolic HF by increasing resistance to CO (i.e., a high afterload state).

In contrast, left ventricular diastolic dysfunction refers to impaired relaxation and increased stiffness of the left ventricle; ejection fraction may or may not be abnormal and the patient may or may not be symptomatic. The terms *diastolic dysfunction* and *diastolic heart failure* are not synonymous. Diastolic dysfunction is one diagnostic criterion for diastolic heart failure. Diastolic HF is defined as “a clinical syndrome of HF characterized by a normal ejection fraction and abnormal diastolic function.”^{12–16} In this form of HF, cardiac muscle function (contractility) is *not* impaired and, most importantly, the EF remains $\geq 45\%$. The SV and CO, however, are still reduced because the end-diastolic ventricular volume is less than normal. In simple terms, a high fraction of a low volume is ejected. Possible causes for diastolic failure include coronary ischemia, long-standing uncontrolled hypertension, left ventricular wall scarring after an MI, ventricular wall hypertrophy, hypertrophic cardiomyopathy (formerly known as idiopathic hypertrophic subaortic stenosis), constrictive pericarditis, restrictive cardiomyopathy (e.g., amyloidosis and sarcoidosis), and valvular heart disease (mitral stenosis, acute aortic regurgitation, mitral regurgitation). These factors lead to left ventricular stiffness (reduced wall compliance), an inability of the ventricle to relax during diastole, or both, which result in an elevated resting pressure within the ventricle despite a relatively low volume of blood in the chamber. In turn, the elevated pressure impedes left ventricular filling during diastole that would normally occur by passive inflow against a low resistance pressure gradient. Heart size is usually (but not always) normal. To summarize, in diastolic dysfunction regardless of the EF, the SV and CO are deficient because of impaired ventricular filling and a relatively small left ventricular volume. It is estimated that 20% to 60% of patients with HF may have normal LVEF and reduced ventricle compliance.^{1,7,12–16} Because coronary ischemia, MI, and hypertension are contributors to both systolic and diastolic failure, many patients have symptoms of a combined disorder.

The pathology of systolic dysfunction most closely resembles what has historically been referred to as “congestive heart failure”; nevertheless, in the strictest sense, CHF only exists if the patient has both systolic dysfunction and the classic symptoms of HF. Tremendous variability exists in the clinical presentation of both systolic and diastolic dysfunction, however, and both disorders can have essentially identical symptoms.^{6,12} For example, some patients with either systolic or diastolic dysfunction exhibit exercise intolerance, but have little evidence of fluid retention. Others may have significant edema with few complaints of exercise intolerance or shortness of breath. It is also possible to have no symptoms in the early stages of both forms of HF. For all these reasons, it is best to avoid the abbreviation *CHF*, especially because CHF has also been used to denote *chronic heart failure*. In the meantime, clinicians are strongly encouraged to obtain an EF measurement in all patients with suspected HF to help define the clinical state more fully.^{1–6}

Some drugs used to treat systolic dysfunction, such as digoxin, can worsen symptoms in diastolic dysfunction. Conversely, negative inotropes (β -adrenergic blockers and calcium channel blockers) may be beneficial in diastolic dysfunction by

slowing the heart and allowing the ventricles to fill more fully at low pressures.

Cardiac Workload

A common factor to all forms of HF is increased cardiac workload. Four major determinants contribute to left ventricular workload: preload, afterload, contractility, and heart rate (HR).

PRELOAD

Preload describes forces acting on the *venous* side of the circulation to affect myocardial wall tension. The relationship is as follows: as venous return (i.e., blood flowing into the heart) increases, the volume of blood in the left ventricle increases. The volume is maximal when filling finishes at the end of diastole (left ventricular end-diastolic volume). This increased volume raises the pressure within the ventricle (left ventricular end-diastolic pressure), which in turn increases the “stretch,” or wall tension, of the ventricle. Peripheral venous dilation and decreased peripheral venous volume diminish preload, whereas peripheral venous constriction and increased peripheral venous volume increase preload.

Elevated preload can aggravate HF. For example, rapid administration of blood plasma expanders and osmotic diuretics or administration of large amounts of sodium (Na) or sodium-retaining agents can increase preload. A malfunctioning aortic valve (aortic stenosis, aortic insufficiency), resulting in regurgitation of blood back into the left ventricle, also can increase the volume of blood that must be pumped. A malfunctioning mitral valve (mitral regurgitation) can cause retrograde ejection of blood from the left ventricle back into the left atrium, with a resultant decrease in EF. In patients with systolic failure, ventricular blood is ejected less efficiently because of a hypofunctioning left ventricle; the volume of blood retained in the ventricle is thus increased, and preload becomes elevated. In diastolic failure with a stiffened left ventricle, relatively small increases in end-diastolic volume from sodium and water overload can lead to exaggerated increases in end-diastolic pressure, despite normal or even reduced end-diastolic volumes.

AFTERLOAD

Afterload is the tension developed in the ventricular wall as contraction (systole) occurs. The tension developed during contraction is affected by intraventricular pressure, ventricular diameter, and wall thickness. More simply, afterload is regulated by the systemic vascular resistance (SVR) or impedance against which the ventricle must pump during its ejection and it is chiefly determined by arterial blood pressure (BP). Hypertension, atherosclerotic disease, or a narrowed aortic valve opening increases arterial impedance (afterload), thereby increasing the workload on the heart. Hypertension is a major etiologic factor in the development of both systolic and diastolic HF. The Framingham group found that 75% of patients who developed HF had a history of hypertension.^{17,18} The risk of developing HF was six times greater for hypertensive than for normotensive patients.

CARDIAC CONTRACTILITY

The terms *contractility* and *inotropic state* are used synonymously to describe the myocardium’s (cardiac muscle’s) inherent ability to develop force and shorten its fibers independent

of preload or afterload. Myocardial contractility is decreased when myocardial fibers are diminished or poorly functioning as may occur in patients with primary cardiomyopathy, valvular heart disease, coronary artery disease, or following an MI. Defects in contractility play a major role in systolic HF, but are not a component of pure diastolic dysfunction. Occasionally, drugs, such as nonselective β -adrenergic blockers or doxorubicin (Adriamycin), induce HF by decreasing myocardial contractility. (See Questions 4 and 5 for a more complete discussion of drug-induced HF.) As summarized in Table 18-1, the major contributors to systolic failure are decreased contractility and increased afterload, whereas structural abnormalities and increased preload play a greater role in diastolic failure.

HEART RATE

An increased heart rate is a reflex mechanism to improve CO as EF declines. As discussed below, the sympathetic nervous system is the major mediator of this response. The workload and energy demands of a rapid heart rate ultimately place undo strain on the heart, however, and can eventually worsen HF.

Pathogenesis

When the heart begins to fail, the body activates several complex compensatory mechanisms in an attempt to maintain CO and oxygenation of vital organs. These include increased sympathetic tone, activation of the renin-angiotensin-aldosterone system (RAAS), sodium and water retention, other neurohormonal adaptations, and cardiac “remodeling” (ventricular dilation, cardiac hypertrophy, and changes in left ventricular lumen shape). The long-term consequences of these adaptive mechanisms can create more harm than good, however (Fig. 18-1). The relative balance of each of these adaptive processes can vary depending on the type of HF (systolic versus diastolic dysfunction) and even from patient to patient with the same

type of disorder. An understanding of the potential benefits and adverse consequences of these compensatory mechanisms is essential to understanding the signs, symptoms, and treatment of HF.¹⁹

Sympathetic (Adrenergic) Nervous System

Stroke volume, CO, or both are low in both systolic and diastolic left ventricular dysfunction, resulting in decreased tissue perfusion. The body’s normal physiologic response to a decreased CO is generalized activation of the adrenergic (sympathetic) nervous system as evidenced by increased circulating levels of norepinephrine (NE) and other catecholamines. The inotropic (increased contractility) and chronotropic (increased HR) effects of NE initially maintain near-normal CO and preserve perfusion of vital organs such as the central nervous system (CNS) and myocardium. Catecholamine-mediated vasoconstriction in the skin, gastrointestinal (GI) tract, and renal circulation, however, decreases perfusion of these organs and ultimately increases the workload on the heart by increasing SVR. Other adverse consequences of NE activation include impaired sodium excretion by the kidneys, restricted ability of coronary arteries to supply blood to the ventricular wall (myocardial ischemia), increased automaticity of cardiac tissue to provoke arrhythmias, hypokalemia, and oxidative stress to trigger programmed cell death (apoptosis).⁶

In the long term, high levels of NE or its metabolites are potentially harmful to heart muscle because they decrease β_1 -receptor sensitivity and reduce β_1 -receptor density on the surface of myocardial cells by as much as 60% to 70% in severe HF.^{20–25} The normal ratio of β_1 : β_2 receptors in the heart is 75 to 80:20 to 25. As a negative feedback response to overstimulation, this balance is shifted to a ratio of 60 to 70:30 to 40 in the failing myocardium by downregulation of β_1 subtype receptors. This selective downregulation of β_1 -receptors is accompanied by a complex phenomenon of “uncoupling of the

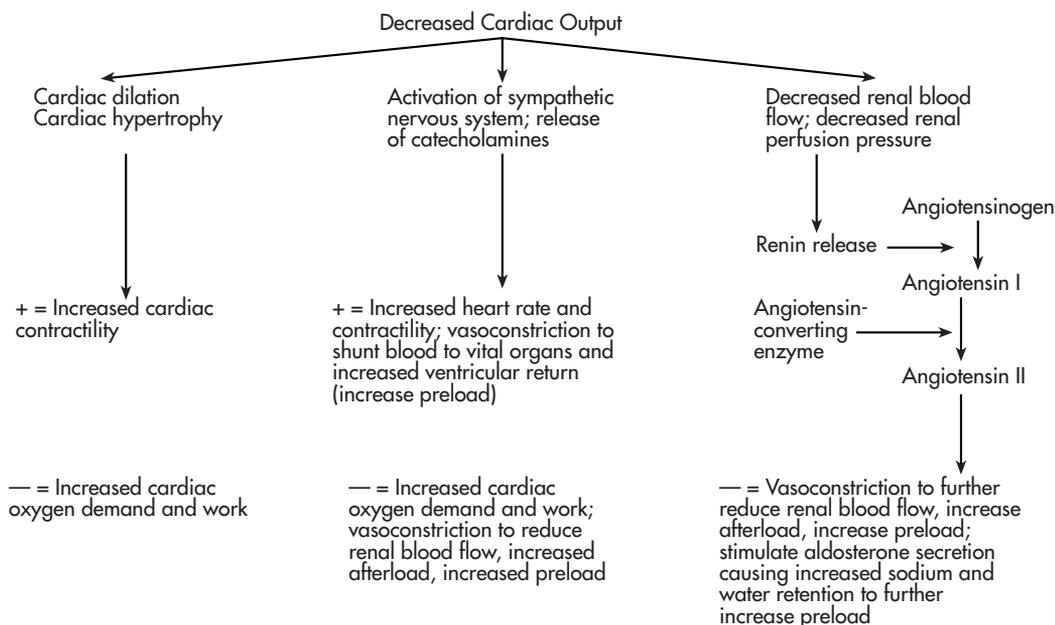

FIGURE 18-1 Adaptive mechanisms in systolic heart failure (HF). +, beneficial results; -, negative (detrimental) effects.

β_1 - and β_2 -receptor activity,” whereby the number of β_2 -receptors are unchanged and the responsiveness of these receptors in eliciting a response can be reduced by 30%.²⁰ Over time this leaves the myocyte less responsive to adrenergic stimuli and further decreases contractile function. At the same time, the postsynaptic β_1 subtype is upregulated in the failing heart resulting in cell growth (hypertrophy) and a positive inotropic effect. β_2 receptors on the presynaptic side of the sympathetic nerve act to suppress NE release, providing a partial protective mechanism from adrenergic overstimulation.

Alterations in sympathetic adrenergic receptors in the heart during HF are complex and partially determined by genetic phenotype. Interestingly, among black patients with HF is seen a disproportionately high incidence of polymorphisms for variants of the β_1 -receptor that are associated with increased function. Additionally, a variant of the β_2 -receptor with defective response to adrenergic overstimulation is also seen. These combined defects are found less often in whites, perhaps partially explaining a higher incidence of HF in blacks. A better understanding of α and β receptor phenotyping may someday lead to improved prevention and treatment strategies for HF.²⁶

Renal Function and the Renin-Angiotensin System

The combined actions of the decreased CO and vasoconstriction secondary to sympathetic tone in HF causes decreased renal blood flow (RBF). This, in turn, sets off a complex chain of events leading to sodium and water retention and, eventually, increased blood volume. Renal vascular resistance is increased and the glomerular filtration rate (GFR) is decreased. As the GFR decreases, more sodium is reabsorbed in the proximal tubule. Additionally, the glomerular filtrate may be preferentially shunted to nephrons with long loops of Henle, increasing the surface area for sodium reabsorption. A diminished effective circulating plasma volume and angiotensin II also stimulate release of antidiuretic hormone (ADH) from the pituitary, resulting in the retention of free water in the renal collecting ducts.

The kidney releases the enzyme renin when renal perfusion pressure is decreased. Renin acts to convert a substrate present in the blood called *angiotensinogen* into the inactive decapeptide, *angiotensin I*. Angiotensin I is further metabolized to the active decapeptide, *angiotensin II*, under the influence of circulating *ACE* (Fig. 18-1). Angiotensin II has multiple effects favoring sodium and water retention: Its vasoconstricting effects may further decrease GFR, and it stimulates the adrenal glands to secrete aldosterone, a hormone that increases sodium reabsorption in the distal tubule. Further, angiotensin II stimulates increased synthesis and release of vasopressin, thereby increasing free water retention and stimulation of thirst centers in the CNS. Finally, angiotensin II may directly stimulate NE release. The net result of the kidney and angiotensin II effects is detrimental. Increased sodium and water retention increase preload, whereas angiotensin II-induced vasoconstriction increases SVR and afterload.

Of further concern is recent evidence that angiotensin II and aldosterone can have other adverse effects that contribute to the pathophysiology of HF independent of their renal and electrolyte mechanisms.²⁷ These effects include coronary and vascular remodeling, endothelial cell and baroreceptor dysfunction, and inhibition of myocardial NE uptake. Morphologic studies indicate that a chronic excess of aldosterone (plus

salt loading), as occurs in HF, can cause fibrosis in the atria and ventricles, kidneys, and other organs in animals and humans.²⁷ Thus, aldosterone may promote the remodeling of organs and fibrosis, independent of angiotensin II.

Other Hormonal Mediators

ENDOTHELINS

Several other regulatory hormones and cytokines have been identified as playing a role in the pathogenesis and adaptation to HF. The first of these are the endothelins, a family of 21 amino acid peptides.^{28,29} Within this family, endothelin-1 (ET-1) is the most active. ET-1 was first isolated from vascular endothelial cells, but it is also synthesized by vascular and airway smooth muscle, cardiomyocytes, leukocytes, and macrophages. Serum concentrations of ET-1 are elevated in HF, pulmonary hypertension, MI, ischemia, and shock and are implicated in causing vasoconstriction, potentiation of cardiac remodeling, and decreased renal blood flow and glomerular filtration. Although these effects of ET-1 are detrimental in HF, its pharmacology is complex and dependent on the relative balance of two distinct G protein-coupled receptor subtypes referred to as ET_A and ET_B. As illustrated in Table 18-2, ET-1 can elicit opposing effects from each receptor, with the net effect being dependent on the relative density of the two receptors.

Synthesis of ET-I begins with a precursor protein called pre-proendothelin (PPET-1) and involves several enzymatic steps and intermediates. Key enzymes in its synthesis are dibasic specific endopeptidase, carboxypeptidase, and endothelin-converting enzyme. Possible therapeutic implications of understanding this synthetic pathway are development of specific inhibitors of one or more of the enzymes to prevent activation of ET-1. Alternatively, selective inhibitors of ET_A receptors could shift responses toward the favorable aspects of ET_B receptor activation. Currently, no such drugs exist, but bosentan (Tracleer) and tezosentan are investigational nonselective dual ET_A/ET_B antagonists. Bosentan has U.S. Food and Drug

Table 18-2 Biological Effects of Endothelin-1

| Organ System | Effect |
|----------------|---|
| Blood vessels | Potent vasoconstriction via ET _A receptors Collagen deposition via ET _A receptors Vasodilation via release of nitrous oxide and prostacyclin in endothelial cells via ET _B receptors |
| Heart | ↑Heart rate. Positive or negative inotropism under varying conditions Hypertrophy, remodeling via ET _A receptors |
| Lungs | Bronchoconstriction via ET _A receptors |
| Kidney | Afferent and efferent vasoconstriction via ET _A receptors ↓Renal blood flow and GFR via ET _A receptors Natriuresis, diuresis via tubular ET _B receptors |
| Neuroendocrine | Stimulate release of catecholamines, renin, aldosterone, atrial natriuretic hormone |

ET_A, endothelin A; ET_B, endothelin B; GRF, glomerular filtration rate.

Administration (FDA) approval for the treatment of pulmonary hypertension and is being investigated for use in HF.^{10,11}

NATRIURETIC PEPTIDES

Natriuretic peptides are a family of peptides containing a common 17 amino acid ring. A-type natriuretic peptide (ANP), previously referred to as either atrial natriuretic peptide or atrial natriuretic factor, is secreted by the atrial myocardium in response to dilation and stretch. Similarly, B-type natriuretic peptide (BNP), formerly referred to as brain natriuretic peptide, is produced by the ventricular myocardium in response to elevations of end-diastolic pressure and volume. Type-C (CNP) is secreted by lung, kidney, and vascular endothelium in response to shear stress. Collectively, the natriuretic peptides have been referred to as “cardiac neurohormones” and are generally considered to be a favorable form of neurohormonal activation. Among their positive attributes are antagonism of the renin-angiotensin system, inhibition of sympathetic outflow, and endothelin-1 antagonism. The net effect is peripheral and coronary vasodilation to decrease preload and afterload on the heart. As their name implies, they also have diuretic or natriuretic properties with improved renal blood flow and glomerular filtration resulting from afferent arteriolar dilation and possibly efferent arteriolar constriction. Sodium reabsorption is blocked in the collecting duct by virtue of an indirect aldosterone inhibition. Natriuretic peptides also inhibit vasopressin secretion from the pituitary gland and block “salt appetite” and thirst centers in the CNS. Each of these CNS effects contributes further to diuresis. Of note, type-C has minimal diuretic properties.

Earlier research on natriuretic peptides centered on ANP, but BNP is now receiving greater attention both for diagnostic and treatment purposes. BNP precursor is cleaved to produce the biologically active C-terminal fragment (BNP) and an inactive N-terminal fragment (NT-proBNP). Plasma level measurement of either BNP or NT-proBNP can be used as a biologic marker to differentiate HF-induced acute dyspnea from other causes of respiratory distress (e.g., chronic bronchitis).^{30–32} BNP levels >200 pg/L indicate a high probability of HF. Higher concentrations correlate to severity of heart failure, with a mean plasma level of 241 pg/mL in NYHA class I patients and >800 pg/mL in NYHA class IV HF. Similarly, clinical resolution of symptoms is often accompanied by a decline in BNP concentration. (Also see Question 9 later in this chapter).

Possible therapeutic implications are synthesis of natriuretic hormone analogs or inhibitors of their metabolism as possible drug therapies. Nesiritide (Natrecor) is a recombinant produced human B-type natriuretic peptide approved by the FDA for IV management of acute HF exacerbations in hospitalized patients.^{33,34} Downregulation of natriuretic peptide receptors, however, occurs during chronic HF, reducing the protective benefit of their actions and possibly limiting their usefulness as therapeutic entities.

Metabolism by neutral endopeptidase (NEP) and receptor sequestration are the primary modes of clearance of natriuretic peptides. NEP is a plasma membrane-bound zinc-metalloprotease enzyme found primarily in renal tubular cells, but also in the lung, GI tract, adrenal gland, heart, brain, and peripheral vasculature. This enzyme also assists in the degradation or metabolism of bradykinin and possibly of angiotensin II. It is speculated that drugs formulated to inhibit NEP (and

thus maintain protective natriuretic peptide levels) might have additive effects to ACE inhibitors in the treatment of HF and hypertension. On the other hand, administering an NEP inhibitor in the absence of a concurrent ACE inhibitor, theoretically, could be counterproductive by leaving unopposed angiotensin II activity. No selective NEP inhibitors are being actively investigated.

VASOPRESSIN RECEPTOR ANTAGONISTS

To date, all standard therapies to relieve acute decompensated heart failure (ADHF) have had disappointing outcomes. These agents have either caused serious side effects or increased mortality in HF. The potent vasoconstrictor antidiuretic hormone arginine vasopressin, which modulates volume homeostasis, is elevated in HF. Early studies with tolvaptan (selective vasopressin subtype V2 receptor antagonist) demonstrated improvement in congestive symptoms of HF and overall hemodynamic profile.³⁵

Recent publication of the findings in the EVERST trial, which studied the efficacy of vasopressin antagonism in heart failure, provides evidence for another possible drug in the war chest of HF.^{36,37} Tolvaptan was tested in 4,133 patients with ADHF with NYHA class III-IV and LVEF of <40%. All patients also received standard therapy (ACE inhibitors, angiotensin receptor blockers [ARB], β -blockers, diuretics, nitrates, and hydralazine). The patients were randomized within 48 hours of hospitalization to 30 mg/day tolvaptan or placebo. The trial was a composite of three distinct analyses. The primary endpoint for the two identical short-term trials was to assess the change in global clinical status and body weight at day 7 or the day of discharge, whichever came earlier. The primary outcome for the long-term trial was all cause mortality and cardiovascular (CV) death or HF hospitalizations. The results of the short-term trial showed only modest improvement in the global clinical score compared with placebo. The most clinical benefit was seen in change in body weight. The long-term trial failed to show any statistical significance between the study drug and placebo in achieving the primary endpoints. Common side effects that resulted in the discontinuation of tolvaptan were dry mouth and thirst. In a small number of patients, hyponatremia was corrected. In conclusion, the results of EVERST trials suggest a novel drug with a potential role in ADHF. Because long-term benefits are lacking, the use of tolvaptan should be restricted to patients with similar characteristics as the original study design.

CALCIUM SENSITIZERS

Calcium sensitizers represent another new class of drugs under investigation for the treatment of ADHF. They exert positive inotropic effects by stabilizing the calcium troponin C-complex and facilitating actin-myosin cross-bridging without increasing myocardial consumption of adenosine triphosphate.³⁸ Levosimendan (Simdax), the prototype for this drug class, has a dual mechanism of action to increase myocardial contractility and induce vasodilation. Unlike other inotropic agents, it does not affect the intracellular calcium concentrations and, therefore, has a lower potential for inducing proarrhythmias. The safety and efficacy of levosimendan in ADHF has been evaluated in placebo-controlled trials and in comparative trials with dobutamine. In patients with decompensated HF, levosimendan significantly reduced the incidence

Ventricular remodeling in diastolic and systolic heart failure

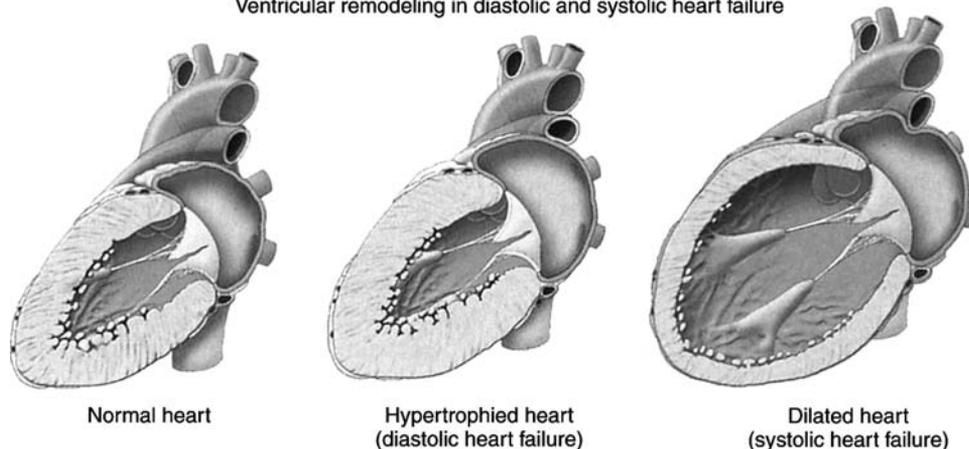

FIGURE 18-2 Cardiac remodeling. (Reprinted with permission from Jessup M, Brozena S. Medical progress: heart failure. *N Engl J Med* 2003;348:2007. Copyright 2003 Massachusetts Medical Society. All rights reserved.)

of worsening HF, and improved hemodynamic indices.^{39–41} In addition, mortality was lower in the levosimendan group. These trials, however, were not powered to show a difference in mortality as an endpoint. A recent trial comparing levosimendan with dobutamine in acute HF, designed to confirm the beneficial effects on morbidity and mortality, did not reduce all-cause mortality, which contrasts with earlier studies.⁴² The most common adverse effects associated with levosimendan are headache and hypotension. Currently it is only approved in Europe for ADHF.

INFLAMMATORY CYTOKINES, INTERLEUKINS, TISSUE NECROSIS FACTOR, PROSTACYCLIN, AND NITROUS OXIDE

Vascular endothelial cells release various other proinflammatory cytokines, vasodilator, and vasoconstrictor substances, including interleukin cytokines (IL-1 β , IL-2, IL-6), tumor necrosis factor (TNF- α), prostacyclin, and nitrous oxide (NO) (also known as endothelium-derived relaxing factor).^{43–45} The exact role of these mediators in the pathogenesis of HF is unclear. Recent studies have shown that patients with HF have elevated levels of the proinflammatory cytokines IL-1 β , IL-6, and TNF- α that correlate with the severity of disease.^{45–47} Initial enthusiasm for use of the TNF- α receptor antagonist etanercept (Enbrel) as a treatment of HF has been abandoned after disappointing results in larger phase 2 and 3 clinical trials.⁴⁸ Of even greater concern, at least 47 spontaneous adverse event reports were made to the FDA describing new onset HF or exacerbation of existing HF with etanercept and infliximab in patients being treated for either Crohn disease or rheumatoid arthritis.⁴⁹

Other investigators have tried using either NO or prostacyclin (epoprostenol) as therapeutic vasodilators with mixed success.^{50–52} A particular concern with prostacyclin was a trend toward increased death rates despite an improved hemodynamic status in treated patients during the Flolan International Randomized Survival Trial (FIRST).⁵²

Cardiac Remodeling

Progression of HF results in a process referred to as *cardiac remodeling*, characterized by changes in the shape and mass of the ventricles in response to tissue injury.⁵³ The three primary manifestations of cardiac remodeling are chamber dilation, left

ventricular cardiac muscle hypertrophy, and a resulting spherical shape of the left ventricular chamber (Fig. 18-2). Cardiac remodeling, which starts months to years before the appearance of clinical symptoms, contributes to the progression of the disease despite treatment.

CARDIAC DILATION

Cardiac dilation results when the ventricles fail to pump an adequate volume of blood with each contraction. This is most evident in systolic dysfunction. If the rate at which blood is delivered to the heart (preload) remains the same, but the rate at which it is pumped to other tissues diminishes, residual blood will begin to accumulate in the ventricles. Thus, end-diastolic volume increases, myocardial fibers are stretched, and the ventricle(s) become dilated. In the healthy heart, the end-diastolic volume is about 180 to 200 mL. With an EF of 60%, the SV is approximately 100 mL, leaving an end-systolic residual volume in the ventricle of 80 to 100 mL. Early in HF, a near normal SV of 100 mL is maintained, although the EF may be low (e.g., 33%). This leaves a 200- to 300-mL end-systolic residual volume in the ventricle. Over time, an enlarged heart will become evident on a chest radiograph, and the body cannot completely compensate. Cardiac dilation is less evident in diastolic dysfunction because normal contractility is maintained and the stiffened left ventricle is resistant to filling and not likely to enlarge (Fig. 18-2).

FRANK–STARLING CURVE

The Frank-Starling ventricular function curve (Fig. 18-3) implies a curvilinear relationship between left ventricular myocardial muscle fiber “stretch” (wall tension) and myocardial work. As stretch increases, the volume of blood ejected with each systolic contraction (stroke volume) increases. In systolic HF, the work capacity for any degree of stretch is diminished. A simple analogy is drawn using a balloon. The greater amount of air blown into a balloon, the more it stretches and, if released, the farther it flies around a room. As the balloon gets old, it loses its elasticity and thus has less recoil when stretched. Similarly, dilation of the ventricles initially may serve as an effective compensating mechanism in systolic failure, but it becomes inadequate as the elastic limits of the myocardial muscle fibers are reached. HR may also increase to maintain CO if SV is low. The downside of cardiac dilation is increased myocardial

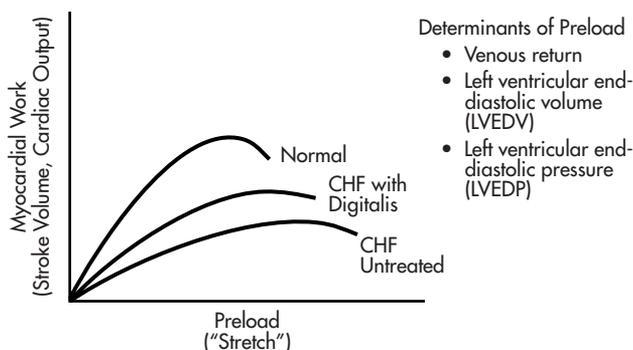

FIGURE 18-3 Representation of Frank-Starling ventricular function curve.

oxygen demand. Theoretically, as cardiac dilation progresses beyond a certain point, CO could decrease (as visualized on the descending limb of the Starling curve), but this rarely is observed clinically.

CARDIAC HYPERTROPHY

Cardiac hypertrophy, a long-term adaptation to increased diastolic volume in systolic failure, represents an absolute increase in myocardial muscle mass and muscle wall thickness (Fig. 18-2). This is somewhat analogous to increased muscle mass in skeletal muscle in response to weight lifting or other forms of exercise. Cardiac hypertrophy should not be confused with cardiac dilation. Of the two, hypertrophy provides more desirable effects, but its absolute benefit is inadequate in severe disease.

Functional Limitation Classification and Stages of Heart Failure

NEW YORK HEART ASSOCIATION CLASSIFICATION

The NYHA classification scheme identifies four categories of functional disability associated with HF. Patients in class I are well compensated with no physical limitations and lack symptoms with ordinary physical activity. In class II, ordinary physical activity results in mild enhancement of symptoms

and imparts slight limitations on exercise tolerance. Patients in class III are comfortable only at rest; even less than ordinary physical activity leads to symptoms. In class IV, symptoms of HF are present at rest and no physical activity can be undertaken without symptoms. Determination of class placement for a specific patient is highly subjective and will vary between observers. In some cases, subdivisions such as class III_A or III_B may be used to further individualize grading of severity.

A shortcoming of the NYHA classification scheme is that it does not include asymptomatic individuals who are at high risk for developing HF and who may benefit from preemptive lifestyle changes and drug therapy. The 2001 ACC/AHA Practice Guidelines introduced a new staging algorithm that can be used in conjunction with the NYHA classifications.⁶ Patients in stage A have hypertension, coronary artery disease, diabetes mellitus, or other conditions that, if left untreated, can result in the development of overt HF. HF symptoms or identifiable abnormalities of the myocardium or heart valves are absent in stage A. Patients in stage B remain asymptomatic but have structural defects within the heart (e.g., left ventricular hypertrophy, dilation, or valve disease) that indicate the existence of impending HF. Patients in stage C exhibit varying degrees of HF symptoms corresponding to NYHA classes I–III along with structural changes in the heart consistent with systolic or diastolic HF. Stage D in the ACA/AHA scheme roughly correlates to NYHA class IV. Patients in this latter category are frequently hospitalized, dependent on IV therapy, and could be considered to have end-stage disease. Table 18-3 summarizes these two classification schemes and how they overlap.

Treatment Principles

The 2005 ACC/AHA Task Force Practice Guidelines serve as the primary basis for recommendations within this chapter.⁷ A clinical algorithm reprinted from the ACC/AHA guidelines is found in Figure 18-4.⁷ The ACC/AHA Task Force recommends that most patients with HF should be routinely treated with a combination of the following classes and drugs: a diuretic, an ACE inhibitor, a β -adrenergic blocker, and (usually) digitalis.⁷

Table 18-3 American College of Cardiology-American Heart Association (ACC/AHA) Staging and New York Heart Association (NYHA) Classification of Heart Failure

| ACA-AHA Stage | NYHA Functional Class |
|---|---|
| A. At high risk for heart failure, but without structural heart disease (normal heart exam) or symptoms of heart failure (e.g., patients with hypertension, coronary heart disease, diabetes, alcoholism, or strong family history) | No corresponding category |
| B. Structural heart disease present (e.g., LV hypertrophy, dilation, fibrosis, old MI), but without symptoms of heart failure | I. Asymptomatic or no limitations on normal physical activity, but symptoms with strenuous exercise. |
| C. Structural heart disease with prior or current symptoms of heart failure | II. Symptoms of heart failure with normal activity or with moderate exertion III. Symptomatic with minimal exertion; marked limitations in physical activity including activities of daily life (e.g., bathing, dressing) (or III _B). Symptoms of heart failure at rest. |
| D. Refractory heart failure requiring specialized interventions | IV (or IV _B). Symptoms of heart failure at rest and requiring hospitalization or intravenous inotropic support |

An aldosterone antagonist (e.g., spironolactone) is a fifth class of drug recommended for patients with advanced HF.

The objectives of therapy for all forms of HF are to abolish disabling symptoms, avoid complications such as arrhythmias, and improve the quality of the patient's life. Increased walking distance during a 6-minute treadmill test or transition to a lower NYHA symptom class is used as a rough measure of success for these objectives. Specific quality of life questionnaires are also available. The ultimate goal is to prolong survival in individuals and reduce mortality rates within the population of patients with HF. Short of a heart transplant, none of the treatment measures are curative.

Nonspecific medical management of systolic HF includes addressing CV risk factors, correcting underlying disease states (e.g., hypertension, ischemic heart disease, arrhythmias, lipid disorders, anemia, or hyperthyroidism), moderate physical activity as tolerated, immunization with influenza and pneumococcal vaccines to reduce the risk of respiratory infections, and discontinuing possible drug-induced causes. A sodium-restricted diet and diuretics are required if fluid retention is

evident. Pharmacotherapeutic interventions include ACE inhibitors, certain β -blocking drugs (e.g., carvedilol and metoprolol), digoxin, and other vasodilators (nitrates, hydralazine, or angiotensin receptor blockers). Amiodarone is indicated in the treatment of symptomatic ventricular tachycardia and atrial fibrillation (AF) associated with HF. The role of natriuretic peptides, endothelin inhibitors, vasopressin receptor antagonists, and calcium sensitizers continue to be investigated. Nondigitalis inotropic agents and TNF- α inhibitors, although theoretically valuable, have yielded disappointing results and significant complications, including arrhythmias and increased mortality rates.

Treatment of diastolic failure is less well defined.¹²⁻¹⁶ The term *heart failure with normal left ventricular ejection fraction* has been proposed instead of diastolic heart failure. A sodium-restricted diet and diuretics are indicated for symptomatic relief of shortness breath or edema. ACE inhibitors are frequently used, although controlled trials of effectiveness are lacking. Negative inotropes such as nonselective β -blockers (e.g., propranolol) and calcium blockers (especially verapamil) are

often advocated to slow HR and allow more efficient ventricular filling during diastole. Digitalis is relatively contraindicated, especially in patients with ventricular septal hypertrophy.

Physical Activity

Patients should be encouraged to maximize their activities of daily life and exercise to maintain physical conditioning. Edema can be minimized by use of elastic hosiery, which increases interstitial pressure and helps mobilize fluid into vascular spaces. During acute exacerbations, bed rest and restricted physical activity decrease the metabolic demands of the failing heart and minimize gravitational forces contributing to the formation of edema. Renal perfusion is increased in the prone position, resulting in diuresis and eventual mobilization of edema fluid.

Sodium-Restricted Diet

Reduction of dietary salt is prudent in patients with hypertension or evidence of fluid retention, but is not required in all patients. No evidence indicates that salt restriction in normotensive or asymptomatic patients will prevent the onset of HF. It is convenient to remember that 1 g of sodium (Na) is equivalent to 2.5 g of salt (NaCl), and that one level teaspoon of salt weighs approximately 6 g. Similarly, 1 g Na = 43 mEq Na and 1 g NaCl = 17 mEq Na. In patients with clinically evident HF, moderate sodium restriction (<3 g/day Na) may allow patients to use lower doses of diuretics by decreasing blood volume and offsetting abnormal retention of sodium by the kidneys. If the kidney's ability to excrete sodium is not severely compromised, it is possible to approach normal balance by restricting sodium intake to match excretion. Although <1 g of sodium chloride (NaCl) is required to meet physiologic needs, the average U.S. diet contains 10 g. Dietary sodium can be reduced to 2 to 4 g of NaCl by eliminating cooking salt. This diet is more palatable and leads to better adherence than a severely salt-restricted diet.

Diuretics: Clinical Use and Renal Pharmacology

Only those points salient to the treatment of HF are included in this chapter. Diuretic use also is discussed in Chapter 13, Essential Hypertension. (See Chapter 11, Fluid and Electrolyte Disorders, for a thorough review of kidney physiology and the classification, mechanism of action, and side effects of diuretics.)

Diuretics are indicated in both systolic and diastolic HF for patients with circulatory congestion (pulmonary and peripheral edema) or cardiac distension (enlarged heart on chest radiograph). They produce symptomatic relief more rapidly than other drugs for HF. Monotherapy with diuretics is discouraged, however, even in patients with mild symptoms that respond well to diuretics. Because activation of the renin-angiotensin-aldosterone and sympathetic nervous systems contribute to the progression of HF, diuretics should be combined with an ACE inhibitor and a β -blocker unless contraindications exist. Conversely, continuous treatment with diuretics is not always necessary in patients with little or no evidence of fluid overload, and diuretics are relatively contraindicated in persons who are volume depleted or have compromised renal blood flow.^{6,7}

By enhancing renal excretion of sodium and water, diuretics diminish vascular volume, thus relieving ventricular and pulmonary congestion and decreasing peripheral edema. Initially, the goal of diuretic therapy is symptomatic relief of HF by decreasing excess volume without causing intravascular volume depletion. Once excess volume is removed, therapy is aimed at maintaining sodium balance and preventing reaccumulation of new fluid, while avoiding dehydration. The rate at which edema fluid can be removed is limited by its rate of mobilization from the interstitial to the intravascular fluid compartment. If diuresis is too vigorous, intravascular volume depletion, hypotension, and a paradoxical decrease in CO (caused by compromised venous return and inadequate ventricular filling) may result. Weight loss exceeding 1 kg/day is to be avoided except in patients with acute pulmonary edema.

The effectiveness of diuretics depends on the amount of sodium delivered to their site of action in the kidney and the patient's renal function.^{54,55} Proximal tubular reabsorption of sodium is increased in patients with severe HF when RBF is compromised, rendering thiazide and potassium sparing diuretics (which act primarily on the distal tubule) minimally effective. Thiazides increase the fractional excretion of sodium no more than 5% and lose their effectiveness when creatinine clearance (Cl_{Cr}) decreases to <30–50 mL/minute. The loop diuretics (furosemide, bumetanide, and torsemide) are more potent and retain their effectiveness until the creatinine clearance is <5 mL/minute. Metolazone has diuretic effects intermediate to that of the thiazide and loop diuretics and may maintain activity in patients with compromised renal function. In most patients with HF, loop diuretics are preferred. In addition to having activity in the ascending limb of the loop of Henle, furosemide has vasodilating properties that decrease renal vascular resistance. It also enhances sodium excretion by shifting RBF from the long juxtamedullary nephrons to shorter superficial nephrons. In pulmonary edema, the initial beneficial effects of furosemide may result more from dilation of venous capacitance vessels (decreasing preload) than from diuresis.^{54,55}

The onset of response after an IV injection of loop diuretics is ≤ 10 minutes, peaking within the first 30 minutes, and usually abating within 2 hours. Natriuresis usually begins 30 to 90 minutes after the oral administration of loop diuretics; it peaks within the first or second hour and lasts for 6 to 8 hours. The usual recommended doses for the loop diuretics are found in Table 18-4.⁵⁴

The concept of ceiling doses for loop diuretics should be understood.^{54,55} A key observation is that the effectiveness of diuretics depends on delivery (active secretion) of the drug into the proximal tubule in the kidney. Slow absorption (even if bioavailability is high) or protein binding impair tubular delivery and compromise diuretic response. Once the drug is in the tubule, however, further drug delivery produces no greater diuresis. Increasing single doses beyond the ceiling dose produces no additional diuretic response. As an alternative, improved diuresis may be obtained by giving the drug more frequently.

As discussed later in this chapter, combinations of diuretics with different mechanisms (e.g., a loop diuretic and metolazone) are used in patients whose conditions are refractory to high-dose loop diuretics.^{54,55} Because diuresis can lead to

Table 18-4 Loop Diuretic Dosing

| | <i>Furosemide</i> | <i>Bumetanide</i> | <i>Torsemide</i> |
|---------------------------------|-------------------|-------------------|------------------|
| Usual daily oral dose (mg) | 20–160 | 0.5–4 | 10–80 |
| Ceiling dose (mg) | | | |
| Normal renal function | 80–160 (PO/IV) | 1–2 (PO/IV) | 20–40 (PO/IV) |
| Cl _{Cr} : 20–50 mL/min | 160 mg (PO/IV) | 2 (PO/IV) | 40 mg (PO/IV) |
| Cl _{Cr} : <20 mL/min | 200 IV, 400 (PO) | 8–10 (PO/IV) | 100 (PO/IV) |

compensatory activation of the RAAS, combining a diuretic with an ACE inhibitor or using spironolactone has a theoretic basis (see Question 13).

Diuretics are indicated in diastolic HF, but pose a difficult challenge. This form of HF is highly volume dependent, becoming significantly worse in states of fluid overload, but responding with a rapid reduction in filling pressures and resolution of dyspnea following diuresis. Conversely, chronic diuretic use therapy runs the risk of restricting the end-diastolic volume, resulting in a significant reduction of CO. Thus, elevated filling pressure may be controlled at the expense of a greatly reduced SV such that the symptoms of dyspnea may be traded for those of fatigue and loss of exercise tolerance.⁵⁶

Aldosterone Antagonists

Despite their profound effects on reducing HF symptoms, no data substantiate that loop diuretics counteract the underlying cause of HF or modify mortality rates. The aldosterone antagonists (e.g., eplerenone and spironolactone) exert a mild diuretic effect by competitive binding of the aldosterone receptor site in the distal convoluted renal tubules. They are also referred to as potassium retaining or potassium sparing diuretics because sodium excretion at this level of the kidney is accompanied by an equimolar exchange for potassium. The Randomized Aldosterone Evaluation study investigators found that spironolactone substantially reduced both morbidity and mortality in a select group of patients with severe HF (NYHA class III and IV).⁵⁷ The authors speculated, however, that the protective effect of spironolactone was related more to a reduction in aldosterone-induced vascular damage and myocardial or vascular fibrosis than to its diuretic effect. Similarly, reduced mortality was observed in patients with left ventricular dysfunction following a recent MI treated with 25 to 50 mg of eplerenone (Inspra)⁵⁸ (see Question 14). No evidence indicates that the direct acting potassium sparing diuretics amiloride or triamterene exert a similar protective effect. The 2005 ACC/AHA guidelines recommend initiating aldosterone antagonists in patients with severe HF and in patients immediately post-MI who have LV dysfunction.⁷

Angiotensin-Converting Enzyme Inhibitors and Angiotensin Receptor Inhibitors^{59–62}

Drugs with vasodilating properties have become a primary treatment modality of HF. Arterial dilation provides symp-

tomatic relief of HF by decreasing arterial impedance (afterload) to left ventricular outflow. Venous dilation decreases left ventricular congestion (preload). The combination of these two properties provides additive benefits to alleviate the symptoms of HF and increase exercise tolerance. The first vasodilator drugs to be studied were hydralazine (essentially a pure arterial dilator) and nitrates (predominately venous dilators). By combining these two drugs, significant reductions in HF symptoms can be achieved along with a modest reduction in mortality rates. With the advent of ACE inhibitors, the use of hydralazine and nitrates has been relegated to a secondary role.

Angiotensin-converting enzyme inhibitors (e.g., benazepril [Lotensin], captopril [Capoten], enalapril [Vasotec], fosinopril [Monopril], lisinopril [Prinivil, Zestril], moexipril [Univasc], perindopril [Aceon], quinapril [Accupril], ramipril [Altace]), and trandolapril [Mavik]) possess both afterload and preload reducing properties (by blocking angiotensin II-mediated vasoconstriction) and volume-reducing potential (by inhibiting activation of aldosterone). They not only produce similar hemodynamic effects to the hydralazine-nitrate combination as a single agent, but they also favorably modify cardiac remodeling independent of vasodilation and have a more tolerable side effect profile. These advantages, coupled with evidence that ACE inhibitors slow the rate of mortality in HF more than the hydralazine-nitrate combination, led the authors of all the current guidelines to recommend unequivocally that ACE inhibitors are the drugs of choice for initial therapy, even in patients with relatively mild left ventricular systolic dysfunction.^{1–3,6}

The 2005 ACC/AHA guidelines state:

ACE inhibitors should be prescribed to all patients with HF due to left ventricular systolic dysfunction (LVEF) unless they have a contradiction to their use or have been shown to be unable to tolerate treatment with these drugs. Because of their favorable effects on survival, treatment with an ACE inhibitor should not be delayed until the patient is found to be resistant to treatment with other drugs. In general, ACE inhibitors are used together with β -blockers. ACE inhibitors should not be prescribed without diuretics in patients with current or recent history of fluid retention, because diuretics are needed to maintain sodium balance and prevent the development of peripheral and pulmonary edema. ACE inhibitors should be initiated at low doses, followed by gradual increments in dose if lower doses have been well tolerated. Fluid retention can blunt the

therapeutic effects and fluid depletion can potentiate the adverse effects of ACE, healthcare providers should ensure that the appropriate doses of diuretics are used before and during treatment with these drugs. Clinicians should attempt to use doses that have been shown to reduce CV events in clinical trials, but they should not delay the initiation of β -blockers in patients because of a failure to reach target ACE inhibitor doses.⁷

The pharmacologic actions of all the ACE inhibitors are essentially identical, but some of them have not been extensively studied or received FDA approval for use in HF. Their value in diastolic failure still is being investigated. Expanded discussion of ACE inhibitor use and side effects is found later in this chapter starting with Question 16.

A related class of drugs includes the angiotensin receptor blocker drugs candesartan [Atacand], eprosartan [Teveten], irbesartan [Avapro], losartan [Cozaar], olmesartan [Benicar], telmisartan [Micardis], and valsartan (Diovan).^{59,62} The receptor inhibitors offer theoretic advantages over ACE inhibitors by being more specific for angiotensin II blockade and having a lower risk of drug-induced cough. On the other hand, indirect block of bradykinin, NE, or prostaglandins by some or all of the ACE inhibitors may offer an advantage over receptor inhibitors. Before the Candesartan in the Treatment of Heart Failure—Assessment of Reduction in Mortality and Morbidity (CHARM) trial, no convincing evidence showed that angiotensin receptor blockers (ARB) were as effective as ACE inhibitors in reducing morbidity and mortality in patients with HF (see Question 20). According to the 2005 ACC/AHA guidelines, ARB are recommended in patients who are intolerant to ACE inhibitors (e.g., angioedema or intractable cough). Also, ARB can be considered as an add-on therapy in patients who continue to be symptomatic despite optimal conventional therapy. Currently, only candesartan and valsartan have FDA approved labeling for the treatment of HF.

β -Adrenergic Blocking Agents 21–26

Until the mid 1990s, some variation of the following statement could be found in any standard text on the treatment of HF: “ β -blockers and other negative inotropes are contraindicated.” This is a logical extension of previously held belief that sympathomimetic agonists and other positive inotropes are the logical choice to counteract the hemodynamic defects of systolic failure and that negative inotropes will exacerbate HF. A better understanding of the pathophysiology of HF led to a rethinking of this logic.^{20–25} As discussed, cardiac adrenergic drive initially supports the performance of the failing heart, but long-term activation of the sympathetic nervous system exerts deleterious effects that can be counteracted by the use of β -blockers. Nonetheless, initial trials with propranolol, pindolol, and labetalol in patients with systolic failure were disappointing. Much more favorable results have been achieved with metoprolol (Lopressor, Toprol XL) and bisoprolol, both of which are partially selective β_1 -blockers, and carvedilol (Coreg), a mixed α_1 - and nonselective β -blocking agent. Extended release metoprolol succinate (Toprol XL) and carvedilol are FDA approved for use in HF. Although some patients can initially have a temporary worsening of symptoms, continued use results in improved quality of life, fewer hospitalizations, and most importantly, longer survival. The

2005 ACC/AHA guidelines state that β -blockers should be prescribed to all patients with stable HF owing to reduced LVEF unless they have a contraindication to their use or have been shown to be unable to tolerate treatment with these drugs. β -Blocker treatment should be initiated as soon as LV dysfunction is diagnosed because of favorable effects that treatment can have on survival and disease progression. Intolerance or resistance to other HF therapies should not precede nor delay the initiation of β -blocker use in patients with HF.⁷ β -Blockers are discussed in greater detail in the case study portion of this chapter (see Questions 27–30 and 52).

Digitalis Glycosides (Digoxin)

Digitalis glycosides have several pharmacologic actions on the heart. Digoxin is the only drug from this family still marketed following the withdrawal of digitoxin in the late 1990s. It binds to and inhibits sodium-potassium ($\text{Na}^+ - \text{K}^+$) adenosine triphosphatase (ATPase) in cardiac cells, decreasing outward transport of sodium and increasing intracellular concentrations of calcium within the cells. Calcium binding to the sarcoplasmic reticulum causes an increase in the contractile state of the heart.

Until recently, the primary benefit of digoxin in systolic HF was assumed to be an increase in the force of contraction (positive inotropic effect) of the failing heart to increase EF and CO. Recent evidence suggests that even at serum concentrations below those associated with positive inotropism, digoxin has beneficial neurohumoral and autonomic effects by reducing sympathetic tone and stimulating parasympathetic (vagal) responses.^{6,63–66} Inhibition of ($\text{Na}^+ - \text{K}^+$) ATPase in vagal afferent fibers sensitizes cardiac baroreceptors to reduce sympathetic outflow from the CNS. Similarly, inhibition of ($\text{Na}^+ - \text{K}^+$) ATPase in renal cells reduces renal tubular reabsorption of sodium and indirectly suppresses renin secretion. This has led to the suggestion that the positive benefits of digoxin can be obtained with a lower risk of side effects by using smaller than traditional doses.⁶

In addition to effects on contractility, digoxin decreases the conduction velocity and prolongs the refractory period of the atrioventricular (AV) node. This AV node–blocking effect prolongs the PR interval and is the basis for use of digoxin in slowing the ventricular response rate in patients with AF and other supraventricular arrhythmias (see Chapter 19, Cardiac Arrhythmias). At higher serum concentrations, however, digoxin increases cardiac automaticity and irritability and decreases the refractory period of the atrial and ventricular myocardium, all of which predispose the patient to a multitude of unwanted heart rhythm disturbances.

Before the advent of ACE inhibitors, the emphasis of HF management was to stimulate the failing heart with inotropes. Digoxin was considered the obvious drug of choice, particularly for patients with coexistent HF and supraventricular arrhythmias. This was followed by a period when the role of digoxin was challenged, especially in patients with normal sinus rhythm, with critics proclaiming it as being minimally effective and having a high risk for toxicity. As evidence mounted that vasodilators could improve survival rates, no such data existed for digoxin. In the past few years, several studies have confirmed a clinical benefit for digoxin in reducing HF symptoms, independent of rhythm status, but survival data are still not convincing (see Question 15). As a result, the latest clinical guidelines state that digoxin therapy is unlikely to benefit

patients with stage A or stage B HF. In these patients, digoxin can be used for symptom management, only if they are treated with drug therapy shown to prolong survival (ACE inhibitors and β -blockers) or have not responded adequately to appropriate therapy. Patients in stage C or stage D HF who are symptomatic, with an enlarged heart and reduced LVEF, digoxin can be beneficial.⁷ Monotherapy with digoxin or in combination with only a diuretic is no longer recommended. Digoxin can also be considered in patients with HF who also have chronic AF, although β -blockers may be more effective than digoxin in controlling the ventricular response, especially during exercise. It is also important to document the patient's EF before considering the use of digoxin because the digitalis glycosides are not useful in diastolic HF and, in fact, may worsen this form of left ventricular dysfunction. Further discussions of the controversies surrounding digoxin use and detailed dosing guidelines are found in the case studies.

DIGOXIN PHARMACOKINETICS (TABLE 18-5)

Digoxin is a polar glycoside that is adequately but incompletely absorbed. Studies from the 1970s indicated that the absorption of oral tablets varied between manufacturers and from lot to lot of the same product.⁶⁷⁻⁷¹ (See the sixth edition of *Applied Therapeutics: The Clinical Use of Drugs* for the citations and abstracts of older articles.) In some instances, the differences were only in the *rate* of absorption but not necessarily in the *extent* of absorption (i.e., bioavailability) (Table 18-5). At least part of the variability correlated to differences *in vitro* dissolution. For this reason, most clinicians prefer to use the brand name product (Lanoxin), but published data regarding the lack of equivalence of current generic products are lacking. Four manufacturers (Bertek, Caraco, Stevens J, and Actavis Totowa) now market generic versions of digoxin that have been given an AB rating (one under the brand name of Digitek).

Bioavailability of digoxin also depends on the dosage form given. Again, most published information is from the 1970s and is subject to such limitations as differences in methodology between studies (single-dose versus multiple-dose studies) and use of nonspecific assays. The original studies appear to underestimate digoxin bioavailability.⁶⁷⁻⁷¹ As summarized by Reuning and others and based on studies using improved assay methods, the bioavailability of conventional tablets ranges from 70% to 80% (mean, 75%), whereas that of the commercially available elixir is slightly greater, ranging from 75% to 85%.⁷⁰ Nonetheless, considerable interpatient and inpatient variability exists. Higher bioavailability of solutions reported in some studies might be of little clinical relevance because the solutions used were prepared extemporaneously from solutions for injection.

Lanoxicaps are a liquid-filled soft gelatin capsule form of digoxin with improved bioavailability averaging 90% to 100%. The digoxin content of these capsules, however, is 80% of the corresponding tablet. Thus, a 0.2-mg Lanoxicaps is approximately equal to a 0.25-mg digoxin tablet. Because of high cost relative to conventional tablets, use of the capsules usually is reserved for those cases when the response achieved with the tablets has been erratic.

Digoxin's rapid onset of action (30–60 minutes) corresponds with peak plasma levels. Maximal effects from a single dose are observed 5 to 6 hours after drug administration, a time

Table 18-5 Digoxin Pharmacokinetics

| Parameter | Value |
|---|--|
| Bioavailability (F) | |
| Tablets | 0.75 (0.5–0.9) ^a |
| Elixir | 0.80 (0.65–0.9) |
| Liquid-filled capsules | 0.95 (0.8–1.0) |

| Premature maintenance | 0.001–0.009 mg/kg/day |
| Neonate maintenance | 0.01 mg/kg/day |
| Infant maintenance | 0.015–0.025 mg/kg/day |
| >2-year-old maintenance | 0.01–0.015 mg/kg/day |

^aMean value with range in parentheses.

^bVolume of distribution decreases in renal failure, possibly because of change in protein binding.

^cDigoxin serum concentration and effect are poorly correlated. Levels drawn <6 hours after a dose may be falsely elevated. Spironolactone and endogenous digoxin-like substances in the blood of neonates and renal failure patients can result in falsely elevated levels. Resting concentrations may be higher than those taken after exercise.

^dLoading doses not recommended except for patients in acute distress, but it takes several days (five half-lives) to reach steady-state with maintenance dose. A more specific loading dose can be calculated by multiplying the desired steady-state concentration by the volume of distribution.

^eThe dosage should be adjusted lower in the elderly or those with renal insufficiency by first estimating Cl_{Cr} to calculate an estimated digoxin clearance. The dosage is estimated by multiplying the target serum concentration times the estimated clearance. Cl_{Cr}, creatinine clearance; HF, heart failure; IV, intravenous; PO, by mouth.

at which drug distribution in the body is complete. Digoxin has a steady-state volume of distribution averaging 6.7 L/kg of lean body weight (range, 4–9 L/kg).^{67,70,71} Only 23% is protein bound, but the volume of distribution may be decreased significantly in renal failure (see Questions 46 and 47). A serum level of 0.8 to 2 ng/mL was recommended in older guidelines as being the therapeutic target, but new evidence indicates therapeutic benefit and greater safety by targeting serum

concentrations in the range of 0.5 to 1.2 ng/mL (see Questions 34 and 36).

Digoxin has a half-life ($t_{1/2}$) of 1.6 to 2 days (36–40 hours) and is characterized by first-order pharmacokinetics.^{67,69–71} With renal impairment, the half-life of digoxin is prolonged, reaching 4.4 days or more in total anuria.^{70–72} The renal clearance of digoxin (1.86 mL/minute/kg) is slightly greater than creatinine clearance, indicating a component of tubular secretion. Many have the erroneous impression that nonrenal excretion of digoxin is unimportant. In fact, anywhere from 20% to 40% of a given digoxin dose is excreted nonrenally, either as metabolites or in the feces,^{67,69–71} corresponding to a nonrenal clearance of 40 to 60 mL/minute (0.82 mL/minute/kg). In a few individuals, up to 55% of a dose is eliminated as metabolites, primarily as inactive dihydrodigoxin.^{70–72} Little digoxin (6.8%) enters the enterohepatic circulation, and its metabolism is unaltered in patients with cirrhosis.

Digoxin absorption, bioavailability, and elimination are partially mediated by P-glycoprotein (PGP), a multidrug transporter that acts as a drug efflux pump across cell membranes in epithelial and endothelial cells of the intestine, kidney, and liver.^{71,73} For drugs and toxins affected by PGP, the net effect is to reduce bioavailability (by transporting drugs from the blood back into the gut lumen) and promote clearance (e.g., by enhancing renal tubular secretion). For digoxin, this system comes into play when certain drugs that block the action of PGP are taken along with digoxin.^{73,74} For example, quinidine blocks intestinal and renal PGP, thus increasing digoxin bioavailability and reducing renal clearance. As a result, digoxin serum levels rise. This and other digoxin drug interactions are considered in greater detail in Questions 38–40.

In approximately 10% of patients given digoxin, a substantial portion of the drug can be metabolized by bacteria in the GI tract to cardioinactive reduced metabolites.^{71,72,75} In isolated cases, significantly increased requirements for digoxin dosage may be seen in patients who excrete large amounts of digoxin by this route. The resulting reduced bioavailability of digoxin is more of a problem when slowly absorbed generic tablets are used as opposed to rapidly absorbed solutions or Lanoxin brand tablets. In addition, concurrent use of certain oral antibiotics (e.g., erythromycin or clarithromycin) can lead to increased digoxin toxicity. This was initially ascribed to altered intestinal metabolism by the antibiotics, but with better understanding of the role of PGP in digoxin absorption and excretion, a probable explanation is that these antibiotics inhibit renal PGP, thus reducing enhanced digoxin renal clearance (See Question 40).

Jelliffe et al. present digoxin elimination in a slightly different context by describing the percent elimination in 24 hours.⁷⁶ By plotting creatinine clearance versus percent of drug eliminated per day (Fig. 18-5), they found a linear relationship between 24-hour drug excretion and renal function. As can be seen from the figure, the best-fit equation of the line ($y = b + mx$) is:

$$\% \text{ Digoxin eliminated/day} = 14 + \frac{Cl_{cr}}{5} \quad (18-1)$$

where the y intercept (b), representing nonrenal elimination, is 14%, and the slope of the line (m), representing that portion of daily elimination dependent on renal elimination, is one-fifth. At a creatinine clearance of 100 mL/minute, the percent

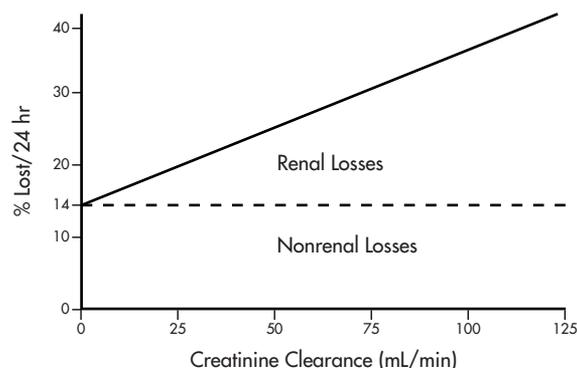

FIGURE 18-5 Relationship of digoxin elimination to renal function.

eliminated per day is 35%, whereas at a creatinine clearance of 0 (i.e., anuria), the percent eliminated per day is 14%, all via nonrenal clearance mechanisms.

Other Vasodilating Drugs: Hydralazine and Nitrates

Although ACE inhibitors have become the vasodilator drug of choice, the first vasodilators used in patients with HF were hydralazine and nitrates. Hydralazine (Apresoline) is a potent arterial dilating agent that provides symptomatic relief of HF by decreasing arterial impedance (afterload) to left ventricular outflow. Nitrates (e.g., nitroglycerin [NTG], isosorbide dinitrate, and isosorbide mononitrate) have venous dilating properties that decrease left ventricular congestion (preload). Used in combination, these two agents have additive benefits in alleviating the symptoms of HF and increasing exercise tolerance. Importantly, the hydralazine-isosorbide dinitrate combination was the first treatment regimen to show improved survival in severe HF compared with placebo (while patients continued their previous diuretic and/or digitalis therapy). In the *post hoc* analysis of the hydralazine-isosorbide dinitrate combination trial, there appeared to be greater efficacy in the cohort of black patients. The African American Heart Failure Trial (AHeFT)⁷⁷ has subsequently been performed and confirms the finding that the addition of hydralazine combined with isosorbide dinitrate to standard HF therapy with an ACE inhibitor and/or a β -blocker showed added benefit. Based on the results of AHeFT, the FDA has approved the combination product of hydralazine and isosorbide dinitrate (BiDiI) for the treatment of HF as an adjunct to standard HF therapy in black patients. The 2005 ACC/AHA guideline recommendations state that the combination of hydralazine and a nitrate might be reasonable in patients with current or prior HF symptoms and reduced LVEF who cannot tolerate ACE inhibitors or ARB. The guidelines go on to say that the addition of hydralazine and isosorbide dinitrate to patients with HF receiving ACE inhibitors and β -blockers, is reasonable and can be effective in blacks with NYHA functional class III or IV HF.⁷ The role of these vasodilators in diastolic failure is not well studied. IV NTG and nitroprusside (a mixed arterial and venous dilator) are also used in hospitalized patients with acute HF exacerbations (see Questions 47).

Other Inotropic Agents

Previous doubt about the clinical effectiveness of digitalis derivatives and concern over their potential for toxicity

prompted a search for alternative positive inotropic drugs. Dopamine and dobutamine, both of which are sympathomimetics, are commonly used in acute cardiac emergencies, but their use is limited by the need for IV administration. (See Chapter 21, Shock, for a more detailed discussion of these drugs.) Amrinone and milrinone, nonsympathomimetic inotropes (phosphodiesterase inhibitors), are associated with an unacceptably high incidence of side effects (thrombocytopenia and increased death rates) when given orally, but are available in parenteral form for short-term use (see Question 48).

Despite differing mechanisms of action to produce their cardiac stimulatory effect (primarily sympathomimetics or phosphodiesterase inhibitors), and whether or not the drug also has vasodilating properties (e.g., flosequinan), a disturbing trend emerged: Initial positive hemodynamic effects during the first few weeks to months of therapy with all of these drugs was followed by a trend toward increased mortality compared with placebo with continued therapy. The explanation for these unexpected findings are related to an overall undesirability of further enhancing sympathetic tone, overstimulation of an already fatigued heart, or proarrhythmic effects of some of the drugs. Whatever the mechanism, the enthusiasm for using inotropic therapy has waned. It is important, however, not to extrapolate these results to digoxin in light of the newer findings that digoxin also has neurohumoral modulating effects. All inotropes are relatively contraindicated in diastolic HF.

Calcium Channel Blockers

Amlodipine (Norvasc), felodipine (Plendil), isradipine (DynaCirc), nifedipine (Adalat, Procardia), and nifedipine (Cardene) are examples of calcium antagonists with arterial vasodilating and antispasmodic properties. They offer the theoretic advantage of being afterload-reducing agents in HF, but their applicability in systolic dysfunction is diminished by negative inotropic effects. Among these drugs, only amlodipine⁷⁸ and felodipine⁷⁹ have been documented to be safe in HF (i.e., do not make HF worse), but only a small subset of patients with nonischemic dilated cardiomyopathy actually had a positive beneficial effect with amlodipine.⁷⁸ Until more data are available, calcium channel blockers other than amlodipine and felodipine are contraindicated in patients with systolic dysfunction. On the other hand, the negative inotropic effects of some calcium antagonists, especially that of verapamil (Calan, Isoptin, Verelan), is an indication for use in diastolic HF.

PATIENT EVALUATION

Signs and Symptoms

1. A.J., a 58-year-old man, is admitted with a chief complaint of increasing shortness of breath (SOB) and an 8 kg weight gain. Two weeks before admission, he noted the onset of dyspnea on exertion (DOE) after one flight of stairs, orthopnea, and ankle edema. Since then, his symptoms have increased. He has also noted episodic bouts of paroxysmal nocturnal dyspnea (PND). Since then, he has been able to sleep only in a sitting position. A.J. notes a productive cough, nocturia (two to three times/night), and mild, dependent edema.

A.J.'s other medical problems include a long history of heartburn; a 10-year history of osteoarthritis, managed with various nonsteroidal anti-inflammatory drugs (NSAID); depression, and

hypertension, which has been poorly controlled with hydrodiuril (HCTZ). A strong family history of diabetes mellitus is also present.

Physical examination reveals dyspnea, cyanosis, and tachycardia. A.J. has the following vital signs: BP, 160/100 mm Hg; pulse, 90 beats/minute; and respiratory rate, 28 breaths/minute. He is 5 ft 11 in tall and weighs 78 kg. His neck veins are distended. On cardiac examination, an S₃ gallop is heard; point of maximal impulse (PMI) is at the sixth intercostal space (ICS), 12 cm from the midsternal line (MSL). His liver is enlarged and tender to palpation, and a positive hepatojugular reflux (HJR) is observed. He is noted to have 3+ pitting edema of the extremities and sacral edema. Chest examination reveals inspiratory rales and rhonchi bilaterally.

The medication history reveals the following current medications: HCTZ 25 mg QD; ibuprofen (Motrin) 600 mg QID; ranitidine (Zantac) 150 mg QHS; citalopram (Lexapro) 20 mg QD. He has no allergies and no dietary restrictions.

Admitting laboratory values include the following: hematocrit (Hct), 41.1% (normal, 40%–45%); white blood cell (WBC) count, 5,300/mm³ (normal, 5,000–10,000/mm³); Na, 132 mEq/L (normal, 136–144 mEq/L); potassium (K), 3.2 mEq/L (normal, 3.5–5.3 mEq/L); chloride (Cl), 100 mEq/L (normal, 96–106 mEq/L); bicarbonate, 30 mEq/L (normal, 22–28 mEq/L); magnesium (Mg), 1.5 mEq/L (normal, 1.7–2.7 mEq/L); fasting blood sugar (FBS), 100 mg/dL (normal, 65–110 mg/dL); uric acid, 8 mg/dL (normal, 3.5–7 mg/dL); blood urea nitrogen (BUN), 40 mg/dL (normal, 10–20 mg/dL); serum creatinine (SrCr), 0.8 mg/dL (normal, 0.5–1.2 mg/dL); alkaline phosphatase, 44 U (normal, 40–80 U/L); aspartate aminotransferase (AST), 30 U/L (normal, 8–42 U/L); BNP 364 pg/mL (normal <200 pg/mL); and thyroid-stimulating hormone (TSH) 2.0 μU/mL (0.5–5.0 μU/mL). The chest radiograph shows bilateral pleural effusions and cardiomegaly.

What signs, symptoms, and laboratory abnormalities of HF does A.J. exhibit? Relate these clinical findings to the pathogenesis of the disease and to left-sided or right-sided HF.

[SI units: Hct, 0.411 (normal, 0.4–0.45); WBC count, 5.3 10⁹/L (normal, 5.0–10.0); Na, 132 mmol/L (normal, 136–144); K, 3.2 mmol/L (normal, 3.5–5.3); Cl, 90 mmol/L (normal, 96–106); bicarbonate, 30 mmol/L (normal, 22–28); Mg, 0.1 mmol/L (normal, 0.85–1.35); FBS, 6.661 mmol/L (normal, 3.608–6.106); uric acid, 475.84 mmol/L (normal, 208.18–416.36); BUN, 14.28 mmol/L (normal, 3.57–7.14); SrCr, 70.72 mmol/L (normal, 44.2–106.08); alkaline phosphatase, 120 U (normal, 40–80); and AST, 100 U/L (normal, 8–42 U/L)(normal LFT, Na and Mg, chloride)]

The signs and symptoms of HF observed in A.J. are easily visualized when recalling that the work of the left ventricle is the major determinant of CO and that blood flows from the left ventricle into the arterial system, through capillaries into the venous system, and back into the right side of the heart. From the right side, the blood circulates through the pulmonary tree and back into the left ventricle. Thus, left-sided ventricular dysfunction primarily causes pulmonary symptoms because of back-up of blood into the lungs, whereas right-sided ventricular dysfunction causes mostly signs of systemic venous congestion. Although left ventricular failure usually develops first, most patients, including A.J., present with signs of combined left- and right-sided failure. The signs and symptoms of both left-sided and right-sided ventricular dysfunction are summarized in Table 18-6.

Table 18-6 Signs and Symptoms of Heart Failure

| | Left Ventricular Failure | Right Ventricular Failure ^a |
|-------------------|--|---|
| Subjective | DOE SOB Orthopnea (two to three pillows) PND, cough Weakness, fatigue, confusion | Peripheral edema Weakness, fatigue |
| Objective | LVH ↓BP EF <40% ^b Rales, S ₃ gallop rhythm Reflex tachycardia ↑BUN (poor renal perfusion) | Weight gain (fluid retention) Neck vein distention Hepatomegaly Hepatojugular reflux |

^aIsolated right-sided failure occurs with long-standing pulmonary disease (cor pulmonale) or after pulmonary hypertension.

^bEjection fraction normal in patients with diastolic dysfunction.

BP, Blood pressure; BUN, blood urea nitrogen; DOE, dyspnea on exertion; EF, ejection fraction; LVH, left ventricular hypertrophy; PND, paroxysmal nocturnal dyspnea; SOB, shortness of breath.

Left-Sided Heart Failure (Left Ventricular Dysfunction)

Weakness, fatigue, and cyanosis result from decreased CO and compromised tissue perfusion. If the left ventricle is not emptied completely, blood backs up into the pulmonary circulation. SOB, dyspnea (labored or uncomfortable breathing) on exertion (DOE), a productive cough, rales (crackles in the lung during auscultation), pleural effusions on chest radiograph, and cyanosis all result from pulmonary congestion. Pulmonary symptoms are aggravated in the reclining position, which minimizes the gravitational effects on excess fluids in the extremities and improves venous return to the heart and lungs. SOB in the prone position (orthopnea) is quantified by the number of pillows the patient must lie on to sleep comfortably. A.J., for example, could sleep only sitting upright. PND, also called *cardiac asthma*, is characterized by severe SOB that awakens the patient from sleep and is alleviated by an upright position. PND results from pulmonary vascular congestion that has advanced to pulmonary edema and bronchospasm while the patient sleeps.

Left ventricular hypertrophy (LVH) and cardiac dilation are caused by an increased end-diastolic volume (see section on Pathogenesis). These effects are observed on chest radiography as an enlarged heart silhouette. The PMI corresponds to the apex of the left ventricle and is visualized as an external pulsation on the left side of the chest. It is displaced laterally and downward from its normal location at the fifth intercostal space, <10 cm from the midsternal line. An S₃ gallop rhythm denotes a third heart sound often heard in close time proximity to the second heart sound (closing of the aortic and pulmonary valves) in HF. Rapid filling of the ventricles causes the S₃ sound and, in an adult, usually indicates decreased ventricular compliance. In patients with mitral valve regurgitation, an S₃ heart sound is common and denotes systolic dysfunction and elevated filling pressure. *Tachycardia* is caused by compensatory increases in sympathetic tone.

Weight gain and *edema* reflect sodium and water retention resulting from decreased renal perfusion (see section on

Pathogenesis). As RBF and GFR decrease, a disproportionate amount of BUN may be retained. This phenomenon is termed *prerenal azotemia* and may be detected by an elevated BUN-to-serum creatinine ratio of >20:1. A.J. has a ratio of >40:1. Prerenal azotemia also can be caused by dehydration and overuse of diuretics. Frequency of urination at night (*nocturia*) is because of improved perfusion of the kidney when the patient is lying down.

Right-Sided Heart Failure (Right Ventricular Dysfunction)

The signs and symptoms of right ventricular dysfunction are related either to hypervolemia or the back-up of blood from the right ventricle into the peripheral venous circulation. The overall effect is development of *systemic venous hypertension*.

Dependent pitting edema results from increased venous and capillary hydrostatic pressure, causing a redistribution of fluid from the intravascular to interstitial spaces. Ankle and pretibial edema are common findings after prolonged standing or sitting because fluid tends to localize in the dependent portions of the body secondary to gravitational forces. Sacral edema can be present in patients at bed rest. Edema is subjectively quantified on a 1+ (minimal) to 4+ (severe) scale. A.J. has 3+ pitting edema.

Hepatomegaly, hepatic tenderness, and ascites (fluid in the abdomen) arise from hepatic venous congestion and increased portal vein pressure. Metabolism of drugs highly dependent on the liver for body elimination can be notably impaired by both the backward venous congestion of the liver from right-sided heart failure and the decreased arterial perfusion of the liver from left-sided heart failure. Congestion of the GI tract makes the patient *anorectic*.

Neck vein distention, primarily seen as internal jugular venous distention (JVD), denotes an elevated jugular venous pressure (JVP). How high the neck veins are distended while the patient is lying down and how much the patient's head has to be raised before the JVD disappears give the clinician a rough estimate of the patient's central venous pressure (CVP). Jugular distension in centimeters is measured as the vertical distance from the top of the venous pulsation down to the sternal angle. Neck vein distension of <4 cm when the patient is lying with the head elevated at a 45 degree angle is considered normal for an average, healthy adult. Applying pressure to the liver can cause further distention of the neck veins if hepatic venous congestion is present. This phenomenon is termed *hepatojugular reflux*.

Ejection Fraction Measurement

2. Does A.J. have systolic or diastolic HF?

Shortness of breath, crackles on auscultation, neck vein distention, edema, and nearly all of A.J.'s other signs and symptoms are common between either form of left ventricular HF. An enlarged heart on a chest radiograph increases the suspicion of systolic failure, but this finding can be absent in some patients with systolic failure and present in others with diastolic failure.

The only correct way to differentiate systolic from diastolic failure is by measuring the LVEF. Thus, it is imperative that A.J., as with all patients with suspected HF, have an EF measured before beginning therapy because the treatment strategies between the two disorders differ. Two-dimensional

echocardiography coupled with Doppler flow studies (Doppler echocardiogram) is the diagnostic test of choice for measuring EF. This procedure uses sound waves, similar to sonar technology, to visualize and measure ventricular wall thickness, chamber size, valvular functioning, and pericardial thickness. EF is visually estimated based on changes in ventricular chamber size between diastole and systole. This method of EF measurement is not as technically accurate as that provided by ventriculography, but the procedure is more comfortable for the patient, and the correlation of the measured EF to that of the other methods is acceptable. The EF results from echocardiography are graded as normal, or mildly, moderately, or severely depressed.

Radionuclide left ventriculography (also called a multiple gated acquisition [MUGA] scan) uses radiolabeled technetium as a tracer to measure left ventricular hemodynamics. Although this method is the most accurate measurement of EF, it is moderately invasive because it requires venipuncture and radiation exposure. In addition, radionuclide scanning does not provide information on the architecture of the left ventricle. Magnetic resonance imaging and computed tomography are useful in evaluating ventricular mass but do not provide EF data.

Subsequently, A.J. underwent an echocardiogram. The results were reported as LVH with mild to moderate depression of EF, correlating approximately to an EF of 30% to 40%. This indicates mild systolic dysfunction. Because he has the combination of systolic dysfunction and classic congestive signs, he fits the criteria for having true CHF.

Stages of Heart Failure and New York Heart Association Classification

3. What stage of HF does A.J. exhibit according to the ACA/AHA criteria? How severe is A.J.'s disability according to the NYHA functional classification of HF?

The ACA/AHA staging scheme and the NYHA functional classification are described in the pathogenesis section of this chapter and are summarized in Table 18-3.^{6,22}

Because A.J. has active symptoms of HF and structural changes in cardiac architecture, he is in ACA/AHA stage C. On admission, A.J. is in NYHA functional class III_B or IV_A as evidenced by a need to sleep upright and an inability to undertake even minimal physical activity. Two years ago he would have been considered NYHA class II, but 3 weeks ago he was classified class III_A. Because he will not require inotropic support, he is not in ACA/AHA stage D.

Predisposing Factors

4. What factors contributed to the cause of A.J.'s HF?

Age and Hypertension

A.J.'s age of 58 puts him in a high-risk category for development of CV disease. He is especially vulnerable to HF because of his poorly controlled hypertension, which places an increased afterload on his left ventricle.

Nonsteroidal Anti-Inflammatory Drugs and Sodium Content

Ibuprofen used for A.J.'s arthritis could contribute to sodium overload. All NSAID (including COX-2 inhibitors) have well-documented, renally mediated sodium-retaining properties, in-

creasing the blood volume by up to 50% in some individuals (see Chapter 43, Rheumatoid Disorders).⁸⁰ Published epidemiologic studies have indicated that NSAID can exacerbate HF symptoms, resulting in hospitalizations for HF.^{81–83} This has been reported in patients with or without a previous diagnosis of HF.⁸⁴ NSAID exert their anti-inflammatory effects by inhibiting prostaglandins (PG) (prostacyclin and thromboxane). In the presence effective circulating volume depletion (HF or renal insufficiency), renal perfusion depends on prostaglandin synthesis. Blocking PG leads to sodium reabsorption, thus counteracting the beneficial effects of diuretics and ACE inhibitors. Without a compelling reason for their use, NSAID should be avoided in patients with HF.

Another potential source for sodium overload is in IV formulations. Sodium chloride is often used as a diluent for IV drug administration. Selected parenteral antibiotics, particularly nafcillin and ticarcillin, have high sodium content which should not be overlooked. Likewise, many over-the-counter (OTC) products, such as effervescent antacids and headache powders contain sodium bicarbonate (Alka-Seltzer, Bromo-Seltzer, Goody's Headache powder), making these drugs exceptionally high sources of sodium. Most prescription and non-prescription drug labels carry a disclosure of sodium content, however.

A.J.'s hypertension and HF are both poorly controlled and he has gained 8 kg. His clinical presentation (orthopnea, dyspnea, SOB, lower extremity edema, elevated JVP) clearly indicate fluid overload. This could be a result of high-dose ibuprofen use. His HCTZ should be replaced by a loop diuretic to enhance diuresis and resolve signs and symptoms of HF. Also, an ACE inhibitor should be added to the current regimen for BP control. Once he is euvolemic, consider adding a β -blocker before discharge. Lowering the dose or preferably discontinuing all NSAID might reduce sodium retention and edema and allow ACE inhibitor therapy to be more effective. Acetaminophen is an alternative for treating his osteoarthritis, although it lacks anti-inflammatory properties.

Diet

It is possible that A.J.'s diet contains a considerable excess of sodium from foods such as canned soups and vegetables, potato chips, or overuse of salt at mealtime. Dietary supplements (e.g., Ensure and Sustacal) and sports drinks (e.g., Gatorade) can also be rich sources of sodium. He should follow a controlled-sodium (e.g., 2–3 g/day) diet. If salt substitutes are used, he should be warned that they are high in potassium and could cause hyperkalemia if used concurrently with potassium supplements, an aldosterone inhibitor (spironolactone), or other potassium-sparing diuretics (amiloride, triamterene).

Drug-Induced Heart Failure

5. What are the basic mechanisms by which drugs can induce HF, and how can an understanding of these mechanisms be predictive of drugs to avoid in A.J.?

Drug-induced HF is mediated by three basic mechanisms: inhibition of myocardial contractility (negative inotropic agents), proarrhythmic effects, or expansion of plasma volume (Table 18-7). The latter category includes drugs that act primarily on the kidney (to either alter RBF or increase

Table 18-7 Drugs That May Induce Heart Failure**Negative Inotropic Agents**

| | |
|---------------------------------------|--|
| β -Blockers ^a | Most evident with propranolol or other nonselective agents Less with agents with intrinsic sympathomimetic activity (acebutolol, carteolol, pindolol); can also be caused by use of timolol eye drops |
| Calcium channel blockers ^a | Verapamil has most negative inotropic and AV-blocking effects; amlodipine has least |
| Antiarrhythmics | Most with disopyramide (Norpace); also quinidine Least with amiodarone |

Direct Cardiotoxins

| | |
|---|--|
| Cocaine, amphetamines | Overdoses and long-term myopathy |
| Anthracycline cancer chemotherapeutic drugs | Daunomycin and doxorubicin (Adriamycin); dose related; keep total cumulative dose <600 mg/m ² |

Proarrhythmic Effects

| | |
|--|---|
| Class IA, IB, Class III antiarrhythmic drugs | QT interval widening Probable torsade de pointe HF develops if disturbed rhythm compromises cardiac functioning |
| Non-antiarrhythmic drugs (See reference 87 for a complete list) | Same mechanism as above Often associated with drug interactions that inhibit metabolism of the offending drug leading to higher than desired plasma levels |

Expansion of Plasma Volume

| | |
|--|--|
| Antidiabetics | Metformin high dose may increase risk of lactic acidosis. Na retention with pioglitazone (Actos) and rosiglitazone (Avandia) |
| NSAID | Prostaglandin inhibition; Na retention |
| Glucocorticoids, androgens, estrogens | Mineralocorticoid effect; Na retention |
| Licorice | Aldosterone-like effect; Na retention |
| Antihypertensive vasodilators (hydralazine, methyldopa, prazosin, minoxidil) | ↓Renal blood flow, activation of renin-angiotensin system |
| Drugs high in Na ⁺ | Selected IV cephalosporins and penicillins Effervescent or bicarbonate containing antacids or analgesics Also liquid nutrition supplements |

Unknown Mechanism

| | |
|-----------------------------------|--|
| Tumor necrosis factor antagonists | Multiple case reports of new-onset HF or exacerbation of prior HF with etanercept and infliximab in patients with Crohns disease or rheumatoid arthritis |
|-----------------------------------|--|

^a β -Blockers and verapamil may be beneficial in diastolic HF. Carvedilol and metoprolol counteract autonomic hyperactivity in systolic dysfunction. AV, atrioventricular; HF, heart failure; IV, intravenous; Na, sodium; NSAID, nonsteroidal anti-inflammatory drugs.

sodium retention) or those that increase total body sodium and water because of their high sodium content.

The most recognized negative inotropic agents are the β -blockers. Nonselective β -adrenergic blockers (e.g., propranolol) decrease myocardial contractility and slow the HR. Both of these factors can compromise the heart's ability to empty effectively. Therefore, these drugs should not be used in systolic HF. Other well-documented negative inotropes include the calcium channel blockers (CCB), most notably verapamil (Calan, Isoptin); various antiarrhythmic agents, especially disopyramide (Norpace), quinidine, and other class IA drugs; and the anthracycline cancer chemotherapeutic agents (daunomycin and doxorubicin [Adriamycin]). The anthracyclines have a direct, dose-related cardiotoxicity that can be minimized by limiting total cumulative doses to 500 to 600 mg/m².^{85,86} For a more detailed description of anthracycline toxicity (see Chapter 89, Adverse Effects of Chemotherapy). In the final group of drugs gaining increased notoriety as cardiotoxins are the amphetamine-like drugs and cocaine when used chronically in large quantities or after an overdose.

Drugs that increase the QT interval induce proarrhythmic effects in some patients. Worsening of HF occurs if the dis-

turbed rhythm compromises cardiac functioning. Of particular concern is drug-induced torsade de pointes. Paradoxically, class IA (quinidine, disopyramide, and procainamide), class IC (encainide, flecainide, and propafenone), and class III (amiodarone, dofetilide, ibutilide, and sotalol) antiarrhythmics are among the best-documented proarrhythmic drugs. A multitude of noncardiac drugs, however, also are associated with QT interval prolongation and torsade de pointe (see Chapter 19, Cardiac Arrhythmias).⁸⁷

Examples of drugs that induce sodium and water retention are NSAID (via prostaglandin inhibition), certain antihypertensive drugs, glucocorticoids, androgens, estrogens, and licorice. Weight gain accompanied by peripheral and pulmonary edema has been observed in patients with stable HF given the thiazolidinedione antidiabetic drugs pioglitazone and rosiglitazone.⁸⁸ Worsening of HF appears to be dose dependent and is presumed to be at least partly caused by fluid retention. As a consequence, the FDA requires that the package insert for these two drugs recommend they not be administered to patients with NYHA class III or IV HF and that they be used cautiously in earlier stages of HF. Antihypertensive drugs either decrease RBF via direct vasodilation (e.g., hydralazine,

minoxidil, diazoxide) or via inhibition of the autonomic nervous system (e.g., guanethidine, methyldopa). Glucocorticoids and licorice (glycyrrhizic acid, carbenoxolone) have an aldosterone-like action.

TREATMENT

Therapeutic Objectives

6. What are the therapeutic goals in treating A.J.?

Cure is not a feasible therapeutic objective in patients with any form of HF. Exceptions include patients who are candidates for cardiac transplantation or in certain forms of idiopathic dilated cardiomyopathy (e.g., viral origin). The immediate objective for A.J. is to provide symptomatic relief as assessed by a reduction in his complaints of SOB and PND, improved sleep quality, and increased exercise tolerance. Over the next several days or weeks, the goal will be to get him back to his baseline status of NYHA class II or III HF. Parameters used to measure success in meeting this objective include reduced peripheral and sacral edema, weight loss, slowing of the HR to <90 beats/minute, normalization of BP, reduction of the BUN back to baseline, a smaller heart size on chest radiograph, decreased neck vein distention, loss of the S₃ heart sound, and an improved EF.

Long-range goals are to improve A.J.'s quality of life, including better tolerance of daily life activities, fewer future hospitalizations, avoidance of side effects of his therapy, and ultimately, an increased survival time. The achievement of these goals depends on the severity of A.J.'s disease, his understanding of his disease, and his adherence to prescribed interventions.

Diuretics

7. Bed rest and a 3-g sodium diet were ordered. Why should A.J. continue his diuretic therapy?

Excessive volume increases the workload of a compromised heart, and diuretics are an integral part of therapy. This is especially true if volume overload is symptomatic (e.g., pulmonary congestion) as it is in A.J. Diuretics produce symptomatic improvement more rapidly than any other drug for HF. They can relieve pulmonary and peripheral edema within hours or days, whereas the clinical effects of ACE inhibitors, β -blockers, and digoxin take weeks to months to be fully realized. Diuretics, however, should not be used alone in HF. Even when they are initially successful in controlling symptoms and reducing edema, they are ineffective in maintaining clinical stability for long periods without the addition of other drugs. More importantly, activation of the renin-angiotensin-aldosterone and sympathetic nervous systems in response to diuresis could possibly lead to HF progression.

Current guidelines all recommend diuretic therapy, both acutely and chronically, if clinical volume overload is evident, but further state that patients without peripheral or pulmonary edema can be treated either intermittently or without diuretics.^{1-3,6,7} Diuretics used on an intermittent (as-needed) basis are titrated based on changes in weight gain, neck vein distention, peripheral edema, or SOB. Patients with a good understanding of their disease can be instructed to weigh them-

selves daily and start taking their medicine if they gain more than 1 to 2 pounds in 1 day or 5 pounds over 1 week or have leg swelling. Doses can be withheld as long as patients are at their target weight. In other cases, diuretic-free intervals or weekends can be arranged. Even with these options, if the patient has experienced volume overload at some time during the course of his or her disease, either past or present, a diuretic should always be part of the regimen.^{6,7}

Despite their remarkable initial benefits, vigorous diuretic therapy carries the risk of volume depletion and diminished CO. Abrupt worsening of renal function (increased BUN or SrCr) or hypotension indicates the need to consider temporarily discontinuing diuretics.

Essentially, all patients with clinically evident HF require loop diuretics. A.J. has obvious signs of volume overload, indicating a need for more vigorous diuresis with a loop diuretic. His elevated BUN is worrisome and could worsen if he becomes dehydrated. The more likely outcome, however, is improved renal blood flow as his heart failure symptoms resolve, and subsequently improved renal function tests.

Furosemide and Other Loop Diuretics

8. It is decided to begin a combination regimen of furosemide and an ACE inhibitor for A.J. What route, dose, and dosing schedule of furosemide should be used?

ROUTE OF ADMINISTRATION

The pharmacology and dose comparison of loop diuretics is discussed in the Treatment Principles section of this chapter and in Table 18-4. Furosemide is the most commonly used loop diuretic for HF because of greater clinical experience and low cost. Bumetanide and torsemide are preferred in some settings because of more predictable absorption.^{54,55,89,90}

According to one group of investigators, patients with HF treated with torsemide fare better than those receiving furosemide.⁹⁰ During a 1-year open-label trial of 234 subjects, patients receiving torsemide were less likely to be admitted to the hospital for HF (17% with torsemide versus 32% for furosemide; $p = 0.01$). Admissions for all cardiovascular causes were also lower among patients taking torsemide (44%) than patients taking furosemide (59%). No differences were found in all cause hospital admission between the two groups (71% torsemide, 76% furosemide). Fatigue scores improved better in patients treated with torsemide, but no difference was found between groups in the rate of dyspnea score improvement. Because generic furosemide is much less costly to prescribe, routine switching to torsemide cannot be advocated until these results are verified by a double-blind, placebo-controlled trial.

Erratic responses to furosemide are more prevalent in persons with severe HF or diminished renal function. Some patients respond promptly and vigorously to small oral doses of furosemide, whereas others require large IV doses to achieve only minimal diuresis. Part of these differences can be explained by the drug's pharmacokinetics.^{54,91} Oral absorption of furosemide is incomplete, averaging 50% to 60% in healthy subjects and 43% to 46% in those with renal failure. When taken with a meal, absorption is delayed because of slowed gastric emptying, but the total amount absorbed does not differ significantly from that in fasting states. Claims are that

the absorption and, therefore, effectiveness of furosemide is further diminished in patients with HF attributable to edema of the bowel and decreased splanchnic blood flow. This has been partially refuted by one investigator, who noted an average furosemide bioavailability of 61% in patients with HF, the same as in normal patients.⁹² Total absorption in patients with HF varies widely (34%–80%), however, and both the rate of absorption and time to peak urinary excretion are delayed for furosemide and bumetanide.^{54,55,92}

When interpreting these bioavailability data, another important factor must be considered. The rate and extent of absorption are not only different among individuals (as illustrated by the examples already given), but intraindividual variability also exists. Ingestion of the same brand of furosemide by the same individual on multiple occasions can show up to a threefold difference in bioavailability. These differences are evident whether considering the innovator's brand (Lasix) or one of several generic brands.^{54,55,93,94} As with digoxin, these data on bioavailability differences are old and have not been verified or refuted by newer studies.

It might be inferred that IV therapy is the preferred route, giving a better response for any given dose. Surprisingly, this is not always the case. In both healthy volunteers and patients with HF, total daily fluid and electrolyte loss after oral therapy and parenteral therapy are comparable. The major difference is in the time course of response. During the first 2 hours, diuresis from the IV dose far exceeds that from the oral therapy, but by 4 to 6 hours, the total urinary output is equivalent.^{92,95,96} Therefore, considering the significant cost differential between oral and parenteral furosemide, the clinical advantage in using IV therapy is small. Exceptions to the rule are those patients with severe pulmonary edema who need acute symptomatic relief and those patients who have failed to respond to an adequate oral challenge.

DOSING

Typically, a patient's treatment is initiated with 20 to 40 mg of oral or IV furosemide given as a single dose and monitored for responsiveness (Table 18-4). If the desired diuresis is not obtained, the dose can be increased in 40- to 80-mg increments over the next several days to a total daily dose of 160 mg/day, usually divided into two doses. For torsemide, a usual starting dose is 10 to 20 mg/day, but a ceiling effect is noted in patients with HF at a dosage of 100 to 200 mg/day.^{54,97} Equivalent doses of bumetanide are 0.5 to 1.0 mg once or twice daily, titrated to a maximum of 10 mg daily. Because A.J. is not in acute distress, it could be argued that oral therapy would suffice. The decision, however, is to give a single 40 mg IV dose of furosemide for immediate symptom control, followed by 40 mg each morning.

Opinions differ to whether furosemide should be given once daily or in multiple doses. The drug's short half-life of 2 to 4 hours implies the need for multiple dosing. Nonetheless, equivalent daily diuresis has been observed following the same dose given in single or divided doses.⁹⁸ Another investigator found better effects from divided doses.⁹⁹ Because evening and nighttime doses of diuretics often disturb patients' sleep patterns (because of nocturnal diuresis), the total daily dose usually should be given as a single morning dose. For patients with symptomatic nocturnal dyspnea, two-thirds of the dose is given in the morning and one-third in the late afternoon or, if

necessary, at night. Torsemide (Demadex) has a slightly longer half-life and generally can be given once daily.

Adverse Effects

9. Examine A.J.'s laboratory values (see Question 1). Does A.J. have any of abnormal values? What is the significance of these abnormalities?

More thorough discussions of diuretic-induced side effects are found in Chapter 11, Fluid and Electrolyte Disorders and Chapter 13, Essential Hypertension. Those findings pertinent to A.J.'s case are discussed below.

AZOTEMIA

A.J. has an elevated BUN (40 mg/dL) but a normal SrCr (0.8 mg/dL). Normally, a BUN-to-creatinine ratio of 10 to 20:1 is seen. Progressive renal failure is characterized by an elevation of both BUN and creatinine. A disproportionately elevated BUN relative to creatinine is indicative of prerenal azotemia, the major cause of which is dehydration (e.g., overdiuresis) or poor renal perfusion (e.g., HF). SCr will also rise in some patients with prerenal azotemia, but will quickly return to normal with rehydration.

A.J.'s laboratory values reflect prerenal azotemia, but his edematous state and elevated BP point to a cause other than dehydration. The most probable cause of his azotemia is decreased RBF secondary to uncompensated HF. Diuretics should not be withheld and, in fact, judicious diuresis should improve his HF and help lower his BUN. Caution must be exercised because prolonged overdiuresis and dehydration can cause renal ischemia, leading to true renal damage. If this happens, the SCr also will begin to rise (see also Question 23).

HYPONATREMIA

A marginally low serum sodium of 132 mEq/L is noted. Low serum sodium, however, is *not* necessarily a sign of overdiuresis. Serum sodium reported by the laboratory is the *concentration* of sodium in the serum. A person may be significantly overdiuresed (dehydrated) with a large body deficit of sodium, but if that sodium is lost isotonicly, the serum sodium concentration will be normal. Conversely, a person such as A.J. can be volume overloaded (edema and hypertension), indicating excessive body sodium, but the serum sodium concentration may be normal or even low as explained below.

Hyponatremia (low serum sodium concentration) reflects the dilutional effect of extra free water in the plasma on sodium concentration. The most common causes of dilutional hyponatremia are excess ADH production or excessive water drinking (i.e., electrolyte-free fluids). Following a severely sodium-restricted diet, persons can develop hyponatremia. Likewise, patients given too much diuretic and who are then given salt-free fluids or who have compensatory ADH release by the body can become hyponatremic. Dilutional hyponatremia, resembling the syndrome of inappropriate antidiuretic hormone (SIADH) secretion, has been described following treatment with thiazide and loop diuretics. Patients with HF or hepatic cirrhosis are more likely to develop diuretic-induced dilutional hyponatremia because of preexisting defects in free water clearance. The exact cause of hyponatremia in A.J. is unknown, but his marginally low serum sodium does not contraindicate continued diuretic therapy.

HYPOKALEMIA

A.J. has a serum potassium of 3.2 mEq/L. Hypokalemia reflecting total body potassium depletion is a well-described, but often over emphasized, side effect of thiazide and loop diuretics. Using a definition of hypokalemia as a serum potassium <3.5 mEq/L, the incidence is 15% to 40% in patients receiving 50 to 100 mg/day of HCTZ.^{100,101} Lower doses of HCTZ (12.5–25 mg), however, can produce similar antihypertensive effect as higher doses, with little, or no change in plasma concentrations of potassium. Hypokalemia is associated with an increased incidence of ventricular arrhythmias. The development of arrhythmias may not be seen until the plasma concentration falls to 3.0 meq/L or lower.¹⁰² Some studies showed increased ectopic activity in persons with serum levels between 3.0 and 3.5 mEq/L.^{103–105} These latter studies have been criticized for including patients at high risk for complications. Mild hypokalemia can escalate into life-threatening hypokalemia, however. Also to be taken into account is the serum potassium concentration in patients before therapy, as well as the actual degree of fall in serum potassium. It is estimated that the risk of arrhythmias increases by 27% with each 0.5 meq/L reduction in the plasma potassium concentration below 3.0 mEq/L.¹⁰⁶

In chronic HF, potassium abnormalities are commonly seen, which is probably caused by the pathophysiologic alterations (renal dysfunction, activation of RAAS, and enhanced sympathetic tone) coupled with mandated aggressive diuresis. Several investigators have reported sudden cardiac death related to low serum potassium levels.^{107,108} Consensus guidelines for potassium replacement recommend that in patients with HF, instead of using higher doses of non-potassium-sparing diuretics it would be beneficial to use low doses in combination with potassium-sparing diuretics. This will prevent the risk of sudden cardiac death. Some experts recommend that the best strategy to avoid arrhythmias in patients with HF is to maintain serum potassium levels between 4.5 and 5.0 mEq/L.¹⁰⁹

A.J.'s serum potassium is 3.2 mEq/L. Although long-term potassium supplementation is not necessary with concomitant administration of ACE inhibitors, A.J. will be receiving increased doses of diuretics over the next several days and, therefore, may need additional potassium supplementation to prevent life-threatening hypokalemia. In addition, he could start digoxin in the future. Because low serum potassium levels predispose a patient to digitalis toxicity (see Questions 41–43), potassium replacement is warranted for A.J. (see Question 10).

HYPOMAGNESEMIA

A.J.'s serum magnesium level is 1.5 mEq/L. Severe hypomagnesemia can lead to somnolence, muscle spasms, a decreased seizure threshold, and cardiac arrhythmias, effects similar to those seen with hypocalcemia and hyperkalemia. Some investigators have claimed that many of the arrhythmias previously ascribed to diuretic-induced hypokalemia were actually caused by diuretic-induced hypomagnesemia.¹¹⁰ Concurrent hypokalemia and hypomagnesemia can be especially dangerous. A.J. should be given 1 g of MgSO₄ IV and observed for changes in his magnesium level. If needed, he could be given oral supplements of magnesium.

HYPERURICEMIA

Increases of 1 to 2 mg/dL in uric acid levels are common during thiazide administration. Rarely, 4- to 5-mg/dL eleva-

tions have been reported. A.J. shows an increase of 1 mg/dL. Most patients who develop elevated uric acid levels during treatment with diuretic agents remain asymptomatic and need not be treated. Only those with uric acid levels persistently >10 mg/dL, as well as those with a history of gout or a familial predisposition, should be considered for treatment with urate-lowering agents (see also Chapter 42, Gout and Hyperuricemia).

BNP

A.J.'s BNP is elevated (365 pg/mL). Various studies evaluating the diagnostic accuracy of BNP and N-terminal pro-B-type natriuretic peptide (NT-ProBNP) have used different cut-offs to define abnormal values. The most commonly used plasma concentration to define the upper limit of normal for BNP is 100 pg/mL, with concentrations >200 pg being considered an indicator of heart failure. Corresponding, concentrations for NT-proBNP are 125 pg/mL for patients <75 years of age and 450 pg/mL for patients >75 years of age. In patients with renal impairment, the clearance of these peptides is reduced; therefore, the reference range is 200 pg/mL for BNP and the corresponding value for NT-proBNP is 1200 pg/mL.¹¹¹ Moreover, concentration of these biomarkers is influenced by other factors such as age, sex, obesity, and other cardiac and noncardiac comorbidities. Asymptomatic patients with HF can also present with elevated BNP or NT-proBNP levels. This confounds the accurate interpretation of these markers and makes it challenging to integrate their usefulness into routine clinical practice. Elevated BNP and NT-ProBNP have an established utility in ruling out HF in patients who present to the emergency department with shortness of breath.¹¹² Measuring BNP levels for monitoring and guiding titration of drug therapy is still under investigation. According to the ACC/AHA guidelines, the value of serial BNP measurements in guiding therapy for patients with HF is not well established.⁷ A.J.'s elevated BNP levels, along with his clinical presentation, is indicative of HF exacerbation.

Potassium Supplementation

10. The physician gave A.J. one 1-g dose of magnesium sulfate and three 20-mEq doses of potassium chloride IV. This raised his serum magnesium to 2.0 and his potassium to 3.9 mEq/L. Should he receive prophylactic magnesium or potassium supplementation? What is the best drug and appropriate dose?

At this time A.J. does not need further magnesium replacement, but his serum magnesium level should be remeasured after he has received furosemide for a few days. If the level drops again, maintenance therapy with oral magnesium oxide tablets can be started.

A fall in serum potassium concentration can be seen within hours of the first dose of a diuretic, and the maximal fall usually is reached by the end of the first week of treatment. Potassium supplementation is not required in all patients receiving diuretics. They should be monitored frequently in the first few months of diuretic therapy to determine their potassium requirements. Similarly, when diuretics are stopped, it can take several weeks for serum potassium to return to normal. Therefore, it is possible that A.J.'s admitting potassium level of 3.2 mEq/L reflects the nadir of his response to HCTZ. His initial response to potassium supplementation shows that his hypokalemia will be

easily controlled. It might be argued that he should be observed for a few days and not given further supplements; however, because his diuresis is to be increased and digitalis therapy may later be considered, potassium supplementation is warranted.

DIETARY SUPPLEMENTS AND DOSAGE FORMS

Potassium replacement can be accomplished by one or more of the following: dietary supplementation with potassium-containing foods, pharmacologic replacement with various oral potassium salts, or use of potassium-sparing diuretics. Table 18-8 lists the potassium content of selected foods. In-

Table 18-8 Potassium Content of Selected Foods (400 mg Potassium is Approximately Equal to 10 mEq K⁺)^a

| Food | Quantity | Potassium Content (mg) (Approximate) |
|------------------------|-------------------------------------|--------------------------------------|
| Meats | | |
| Beef chuck | 3 oz | 200–400 |
| Beef round | 3 oz | 200–400 |
| Hamburger | 3 oz | 200–400 |
| Rib roast | 3 oz | 200–400 |
| Chicken fryer | 4 oz | >400 |
| Turkey | 4 oz | 200–400 |
| Vegetables | | |
| Artichoke | 1 medium | 200–400 |
| Avocado | ½ uncooked | 200–400 |
| Baked potato | 1 medium | >400 |
| Sweet corn | ½ cup | 200–400 |
| Dried beans | 8 oz (1 cup) cooked | >400 |
| Lima beans | ½ cup | 200–400 |
| Tomato | 1 medium raw or 4 oz (½ cup) cooked | 200–400 |
| Brussels sprouts | ½ cup | 200–400 |
| Broccoli | 4 oz (½ cup cooked) | 200–400 |
| Collard greens | 4 oz (½ cup cooked) | 200–400 |
| Spinach | 4 oz (½ cup cooked) | 200–400 |
| Winter squash | 4 oz (½ cup cooked) | >400 |
| Fruits | | |
| Banana | 1 medium | >400 |
| Orange | 1 medium | 200–400 |
| Grapefruit | 1 cup | 200–400 |
| Apricot | 3 medium | >400 |
| Peach | 1 medium | 200–400 |
| Nectarine | 1 large | >400 |
| Cantaloupe | 8 oz (1 cup) | >400 |
| Honeydew melon | 8 oz (1 cup) | >400 |
| Watermelon | 8 oz (1 cup) | 200–400 |
| Raisins | ½ cup | >400 |
| Prunes | 4 medium | 200–400 |
| Dates | 4 oz (½ cup) | >400 |
| Juices and milk | | |
| Orange | 8 oz (1 cup) | >400 |
| Grapefruit | 8 oz | 200–400 |
| Pineapple | 8 oz | 200–400 |
| Prune | 8 oz | >400 |
| Tomato | 8 oz | >400 |
| Milk | 8 oz (1 cup) | 200–400 |

^a39 mg K⁺ = 1 mEq.

clusion of these foods in the patient's diet may be all that is required to maintain potassium balance, especially in the 60% to 90% of people who are not susceptible to hypokalemia in the first place. The food products listed are expensive, however, and many are high in sodium, which makes them difficult to use for people following low-salt diets. Salt substitutes are another exogenous source of potassium. Patients using these products liberally may get adequate potassium replacement; in fact, they can contribute to hyperkalemia. Some patients object to the taste of salt substitutes.

If potassium replacement is prescribed, only *potassium chloride* (KCl) should be used because potassium-wasting diuretics can cause hypochloremic alkalosis; if the chloride ion is not replaced, alkalosis and hypokalemia will persist, even if large quantities of potassium are given.

Klor-Con and Kaon-Cl are slow-release, solid dosage forms of KCl crystals imbedded in a wax matrix. They are equal to KCl solution in bioavailability and are associated with less GI bleeding, ulceration, and stricture formation than enteric-coated potassium tablets. The major drawback to their use is high cost and the large number of tablets needed per day. Klor-Con has only 600 mg (8 mEq) or 750 mg (10 mEq) per tablet. Kaon-Cl contains 750 mg (10 mEq) per tablet. Slow-release potassium tablets should be avoided in patients with impaired GI motility, and enteric-coated potassium tablets should be avoided at all times.

A slow-release, microencapsulated form of KCl (Micro K, multiple generics) was originally postulated to produce fewer GI mucosal ulcerations than wax matrix slow-release tablets.¹¹³ Other investigators, however, could not detect any difference between the two formulations,^{114,115} and the Boston Collaborative Drug Surveillance Program could not find a positive association between wax matrix potassium use and significant upper GI bleeding.¹¹⁶

Another sustained-release potassium product, K-Dur, available as either 750 mg (10 mEq) or 1,500 mg (20 mEq) tablets, can either be swallowed whole or dissolved in water. It offers the advantage of being tasteless even when prepared as a solution. The only patient complaint is that the capsules dissolve in the mouth if not swallowed quickly.

DOSE REQUIREMENTS

It is difficult to predict the dose of KCl that will be required to maintain proper potassium balance. Many patients do well with 20 mEq/day, but it is questionable how many of these need any supplement at all. People with well-documented hypokalemia can require anywhere from 20 to 120 mEq of KCl/day.^{100,101,117} Those patients with disease states associated with high circulating aldosterone levels require doses of potassium in excess of 60 mEq/day.

POTASSIUM-SPARING DIURETICS

11. Would use of a potassium-sparing diuretic such as triamterene offer any advantage over a potassium supplement to prevent or treat hypokalemia? What dose should be used?

The direct-acting, potassium-sparing diuretics (amiloride and triamterene) may be more effective in preventing or correcting the fall in serum potassium than potassium supplements.^{118,119} These agents reduce urinary potassium losses, minimize alkalosis, and mobilize edema. Approximate

equivalent doses are amiloride 20 mg and triamterene 200 mg. At these doses, potassium-replenishing capacity is similar to that observed with a 10- to 20-mEq KCl supplement.¹¹⁸

Dyazide (or generic equivalent) and Maxzide are popular products that contain a combination of triamterene plus HCTZ. Although these products are effective in most cases, their cost is warranted only in a patient with documented hypokalemia with thiazide use alone. In one study, one full-strength Maxzide tablet (50 mg thiazide; 75 mg triamterene) was equivalent to 20 to 40 mEq of KCl.¹¹⁹ Moduretic (a combination of amiloride plus a thiazide) could also be used.

Hyperkalemia is the major toxicity from all the potassium-sparing diuretics and could occur even when they are used in combination with potassium-wasting diuretics. As a general rule, direct-acting, potassium-sparing diuretics should not be used together with either KCl, ACE inhibitors, ARB, or aldosterone inhibitors (spironolactone). Their combined use is warranted, however, in those patients requiring >50 mEq/day of KCl. Judicious monitoring is necessary to avoid hyperkalemia. (Also see Question 14 for additional considerations for using spironolactone in patients with severe HF.)

Monitoring

12. After a single 40-mg IV dose of furosemide, A.J. is begun on 40 mg of furosemide each morning and KCl tablets 20 mEq BID. How should his therapy be monitored?

A.J. needs to be monitored for both an improvement in his HF and for side effects (Tables 18-6 and 18-9). Subjectively, the clinician should monitor for decreased pulmonary distress and an increased exercise tolerance, demonstrating control of HF. Objective monitoring parameters for disease control include weight loss (ideal, 0.5–1 kg/day until ideal dry weight is achieved), a decrease in edema, flattening of neck veins, and disappearance of the S₃ gallop and rales. Because A.J. has hypertension, his BP also requires monitoring with a goal to reduce it to <120/80 mm Hg.

Table 18-9 Monitoring Parameters with Diuretics

| |
|---|
| ↓CHF symptoms (see Table 18-6) |
| Weight loss or gain; goal is 1–2 pound weight loss/day until “ideal weight” achieved ^a |
| Signs of volume depletion |
| Weakness |
| Hypotension, dizziness |
| Orthostatic changes in BP ^b |
| ↓Urine output |
| ↑BUN ^c |
| Serum potassium and magnesium (avoid hypokalemia and hypomagnesemia) |
| ↑Uric acid |
| ↑Glucose |

^aWeight loss may be greater during first few days when significant edema is present.

^bA ↓ in systolic BP of 10–15 mm Hg or a ↓ in diastolic BP of 5–10 mm Hg.

^cA rising BUN can be caused by either volume depletion from diuretics or poor renal flow from poorly controlled HF. Small boluses of 0.9% saline can be given cautiously to differentiate a rising BUN from volume depletion versus poor cardiac output. If volume depletion is present, saline will cause an ↑ in urine output and a ↓ in BUN. However, if the patient has severe HF, the saline could cause pulmonary edema. BP, blood pressure; BUN, blood urea nitrogen; HF, heart failure; K, potassium; Mg, magnesium.

Patients are sometimes instructed to record their weight each day and are allowed to adjust their diuretic dose based on changes observed. If they are at their ideal “dry weight,” they may reduce their dose of diuretic by 50% or even hold one or more doses. If weight increases more than 1 or 2 pounds in a day or 5 pounds per week, edema increases, or SOB returns, the dose of diuretic is temporarily increased.

Dizziness and weakness are subjective indices of volume depletion, hypotension, or potassium loss. Muscle cramps and abdominal pain could indicate rapid changes in electrolyte balance. Objectively, a lowering of BP, especially on standing, and a rising BUN (prerenal azotemia) signify overdiuresis. As discussed in Questions 9 and 10, serum sodium, potassium, and uric acid should be monitored routinely. Questioning the patient with regard to the onset of diuresis (relative to drug ingestion) and the duration of the diuretic effect helps develop the most convenient schedule for the patient.

Refractory Patients: Combination Therapy

13. Another patient presents with an initial history was similar to A.J.’s. After nearly 2 years of relatively good HF control on a regimen of 40 mg furosemide, 20 mg QD lisinopril, 200 mg QD metoprolol succinate, and 0.125 mg QD digoxin, urinary output diminished about 1 week ago and edema increased significantly. Nonadherence to drug therapy and salt restriction was ruled out. The dose of furosemide was increased to 80 mg QD two days ago without much effect. Should the dose of furosemide be increased further? Could another diuretic be added to the therapy?

As described in the discussion of the pharmacology of diuretics earlier in the chapter, all loop and thiazide diuretics must reach the tubular lumen to be effective. Because these drugs are highly bound to serum proteins and endogenous organic acids, they cannot enter the tubular lumen by glomerular filtration. For diuresis to begin, they must be transported into the proximal tubule by active secretion from the blood into the tubule. If this active transport is blocked, diuretics will not reach their site of action. This can lead to a diminished diuretic response in patients with either renal insufficiency or decreased RBF associated with uncompensated HF. In particular, patients with renal insufficiency or poor RBF often require large doses of diuretics to achieve a desired response. Endogenous organic acids also can accumulate during renal insufficiency, avidly binding the drug and preventing its access to the site of action.^{54,55}

Both the total amount of drug delivered to the tubule and the rate of delivery of the drug to the tubule determine the magnitude of diuretic response elicited.^{54,55} This explains why 80 mg of furosemide yields more diuresis than a 40-mg dose and why an IV injection provides a more rapid and vigorous diuresis than an oral dose. Once a threshold concentration (ceiling dose) is achieved within the tubule, higher concentrations produce no greater intensity of effect, but the duration of action may be prolonged. (See Question 8 for an expanded discussion about loop diuretic bioavailability and the concept of “gut wall edema.”)

In addition to these explainable causes, many patients develop a blunted diuretic response with continued therapy for unknown reasons. Generally, alternative treatment plans are pursued when the dose given approaches the ceiling doses for each drug listed in Table 18-4. Continuous infusions

of furosemide (2.5–3.3 mg/hour), bumetanide (1 mg/hour), or torsemide (3 mg/hour) can be more efficacious than intermittent bolus doses in patients with severe HF or renal insufficiency.^{54,55,120–124} Even higher doses are recommended by one clinician: 0.25 to 1 mg/kg/hour for furosemide, 0.1 mg/kg/hour for bumetanide, and 5 to 20 mg/hour for torsemide.¹²⁵ Another institution uses an aggressive protocol of a 100-mg IV bolus of furosemide followed by a continuous IV infusion at a rate of 20 to 40 mg/hr, which is doubled every 12 to 24 hours in nonresponding patients to a maximal infusion rate of 160 mg/hr to attain a diuresis rate of 100 mL/hr or higher.¹²⁶

In some instances, switching from one loop diuretic to another can overcome the problem.^{55,58,125} For example, torsemide might work when furosemide fails because of more reliable absorption with torsemide.^{89,90} If this maneuver fails, a combination of diuretics can be tried. The most effective regimens combine drugs that work at two different parts of the tubule.^{55,58} For example, a loop diuretic that works on the ascending limb of the loop of Henle is added to metolazone that blocks sodium reabsorption in the distal tubule. Various thiazide diuretics, including chlorthalidone (Hygroton), chlorothiazide (Diuril), and HCTZ, have been reported to effectively enhance diuresis when combined with a loop diuretic, but it is unclear if the responses are simply additive or truly synergistic. Rarely, triple therapy regimens of metolazone, loop, and potassium-sparing diuretics are used to optimize diuresis and electrolyte control.

Most clinicians choose a combination of metolazone plus furosemide or bumetanide based on demonstrated value in the literature and clinical experience. A small dose of metolazone (5 mg) is first added to the furosemide therapy, doubling the dose of metolazone every 24 hours until the desired diuretic response is achieved. If the synergism desired is seen with the first dose, the dose of the loop diuretic should be decreased. Metolazone's longer duration of action can cause a greater than predicted diuresis and electrolyte loss when combined with a loop diuretic. Thus, careful monitoring of weight, urine output, BP, and BUN is required. Because no parenteral form of metolazone exists, chlorothiazide, at a dose of 500 to 1,000 mg once or twice daily, is the only option for a non-loop diuretic that can be given intravenously.

Nondiuretic Effect of Spironolactone: Effect on Mortality

14. We return now to A.J. who was treated in Questions 1 to 12. It has been 2 days since he started furosemide, potassium supplements, and an ACE inhibitor. He complains of gastric cramping after each dose of potassium, even when taken with food. It is decided to discontinue the potassium supplement and start spironolactone at a dosage of 25 mg/day. Does this therapy offer any advantages other than diuresis and a source of potassium repletion?

Aldosterone contributes to HF through the increased retention of sodium and the depletion of potassium. Likewise, the diuretic and potassium-sparing actions of spironolactone are attributed to inhibition of aldosterone.¹¹⁸ Until recently, it was believed that optimal doses of ACE inhibitors fully suppressed the production of aldosterone because angiotensin II is a potent stimulus for aldosterone production. It is now recognized, however, that aldosterone levels can remain elevated through

a combination of nonadrenal production and reduced hepatic clearance. In addition, it has become clear that both angiotensin II and aldosterone have other negative effects on the CV system, including myocardial and vascular fibrosis, direct vascular damage, endothelial dysfunction, oxidative stress, and prevention of norepinephrine uptake by the myocardium.^{27,127} This led the Randomized Aldactone Evaluation Study (RALES) investigators to test the hypothesis that low doses of spironolactone might impart a cardioprotective effect in patients with severe HF independent of diuresis or potassium retention.⁵⁷ In this trial, 1,663 patients with a history of NYHA class IV HF within the previous 6 months (but in class III or IV on study entry), an EF of 35% or less, and continued treatment (unless contraindicated or not tolerated) with a loop diuretic (100%), an ACE inhibitor (94%), and digoxin (74%) were randomized to receive either spironolactone 25 mg (n = 822) or placebo (n = 841). The dose of spironolactone could be increased to 50 mg if HF worsened without evidence of hyperkalemia.

The study was discontinued prematurely after a mean follow-up of 24 months when a statistically significant reduction in mortality was observed. There were 386 deaths in the placebo group (46%) compared with 284 (35%) in the spironolactone group. These differences were first evident at 2 to 3 months after starting treatment. The greatest risk reduction was in CV deaths. In addition, more subjects had symptomatic improvement (as evidenced by moving to a lower NYHA class) and fewer had symptomatic worsening with the active drug. Hospitalization rates were lower in the patients treated with spironolactone. Serum creatinine and potassium concentrations were somewhat higher with active drug, but the changes were not considered clinically significant. Hyperkalemia developed in 2% of the patient on spironolactone and 1% of those on placebo. Gynecomastia was reported in 10% of men treated with spironolactone compared with only 1% of those receiving placebo.

It is important to emphasize that nearly all subjects had continuing HF symptoms despite maximal drug therapy with multiple drugs, including an ACE inhibitor. Although ACE inhibitors indirectly suppress aldosterone at therapeutic doses, the inhibition is not as complete as with spironolactone. Thus, this study provided the first clinical evidence that spironolactone protects against myocardial and vascular fibrosis and alters hemodynamic or hormonal mediators of HF.

Subsequently, the aldosterone receptor inhibitor eplerenone (Inspra) was studied in 6,632 patients with left ventricular dysfunction following MI. In the EPHEsus study, subjects were randomized to receive either eplerenone 25 mg QD initially, titrated to 50 mg QD, or placebo.⁵⁸ Concurrent therapy included diuretics (60%), ACE inhibitors (87%), β -blockers (75%), and aspirin (88%). During a mean follow-up of 16 months, there were 478 deaths (14.4%) in the active treatment group compared with 554 deaths (16.7%) with placebo (relative risk, 0.85; $p = 0.008$). Most deaths were from CV causes. Similar to spironolactone, more subjects experienced hyperkalemia with eplerenone than with placebo. Because eplerenone does not block progesterone and androgen receptors, gynecomastia and sexual dysfunction may be less.^{58,127} Eplerenone was initially approved by the FDA for hypertension, and gained labeling for patients after MI in late 2003.

Because A.J. had NYHA class III symptoms when first seen, he fits the profile of the subjects in the RALES study, although

he had not been taking his ACE inhibitor sufficiently long to obtain the full therapeutic benefit. Starting A.J. on spironolactone is appropriate because of his intolerance of potassium supplements and it might provide CV protection. The dose of 25 mg was chosen for A.J. This was the dose studied in RALES trial. This dose may or may not be sufficient to normalize his serum potassium. He will need to be followed to determine whether larger doses of spironolactone will be necessary or if a small dose of a potassium supplement might need to be restarted. If gynecomastia develops, eplerenone could replace spironolactone. (Also, see Question 21 regarding risk factors for hyperkalemia with spironolactone.)

Drugs of First Choice After Diuretics

Vasodilators and ACE Inhibitors: Comparison With Digoxin

15. The medical resident on your team asks you if it would be appropriate to add digoxin to A.J.'s medical treatment of HF. He has been told by a colleague that in clinical trials digoxin reduced both HF symptoms and hospitalizations for HF? What would you recommend?

Debates raged for years about whether digitalis glycosides or vasodilators should be the drug(s) of first choice for treating HF. By the time the AHCPR and first ACC/AHA guidelines were published in 1994 to 1995, a clear consensus was evident.^{1,2} Vasodilators are first-line therapy, with digoxin being added for patients with either supraventricular arrhythmias, failure to achieve symptomatic relief with vasodilators alone, or intolerable side effects from vasodilators. ACE inhibitors are preferred over other vasodilators because of proved efficacy, convenience of dosing, and fewer side effects. By 1999, experts also recommended starting β -blocker therapy earlier in the treatment plan.³ This latter point is discussed later. To understand the reason for the increased emphasis on ACE in-

hibitors and secondary role of digoxin requires an historical overview. A partial review is given here, but the citations and abstract of older articles are found in the sixth edition of *Applied Therapeutics: The Clinical Use of Drugs*.

CONTROVERSY OVER EFFICACY OF DIGOXIN

Correction of the underlying defect is a rational approach to the treatment of any disease. When considering HF solely as “pump failure” with a weakened myocardial muscle, then digitalis is the logical choice to improve cardiac contractility, CO, and renal perfusion. By focusing on symptom relief and increased exercise tolerance as markers of benefit, digoxin is effective. Critics, however, raised concerns that symptom relief was less in patients with normal sinus rhythm than in those with supraventricular arrhythmias. The most vocal critics claimed that the risk of digitalis toxicity did not warrant using this class of drugs in patients with normal sinus rhythm.

Using multivariate analysis, one group of investigators concluded that a third heart sound (S₃ gallop rhythm), an enlarged heart, and a low EF best predict those patients with normal sinus rhythm who will derive a beneficial response from digoxin.¹²⁸ Several other meta-analyses and critical reviews of the literature later concurred that many of the original trials were designed improperly or lacked proper controls and that digoxin therapy provides a beneficial effect, especially in patients with severe symptomatic ventricular systolic dysfunction.^{129,130}

VASODILATORS IMPROVE SURVIVAL (TABLE 18-10)

While these debates were ongoing, recognition of the contributions of the RAAS and the sympathetic nervous system in perpetuating the defects of HF brought initial interest in vasodilators. Again, the focus was on symptom relief. First hydralazine and nitrates, then their combination, and finally ACE inhibitors were all shown to be effective in reducing the symptoms of HF. Nonetheless, digitalis was usually used

Table 18-10 Clinical Trials of ACE Inhibitors in Left Ventricular Dysfunction⁶⁰

| Study | Patient Population | ACE Inhibitor | Time Started After MI | Treatment Duration | Outcome |
|---|---|---------------------------------------|-----------------------|--------------------|---|
| Studies in LV Dysfunction | | | | | |
| CONSENSUS ¹³² | NYHA IV (<i>n</i> = 253) | Enalapril vs. placebo | | 1 day–20 mos | Decreased mortality and HF |
| SOLVD-Treatment ¹³⁴ | NYHA II/III (<i>n</i> = 2,569) | Enalapril vs. placebo | | 22–55 mo | Decreased mortality and HF |
| V-HeFT II ¹³⁵ | NYHA II/III (<i>n</i> = 804) | Enalapril vs. hydralazine, isosorbide | | 0.5–5.7 yrs | Decreased mortality and sudden death |
| SOLVD-Prevention | Asymptomatic LV dysfunction (<i>n</i> = 4,228) | Enalapril vs. placebo | | 14.6–62 mos | Decreased mortality and HF hospitalizations |
| Studies in LV Dysfunction after MI | | | | | |
| SAVE ¹⁹³ | MI, decreased LV function (<i>n</i> = 2,331) | Captopril vs. placebo | 3–16 days | 24–60 mos | Decreased mortality |
| CONSENSUS II ¹⁹² | MI (<i>n</i> = 6,090) | Enalaprilat/enalapril vs. placebo | 24 hrs | 41–180 days | No change in survival; hypotension with enalaprilat |
| AIRE ¹⁹⁴ | MI and HF (<i>n</i> = 2,006) | Ramipril vs. placebo | 3–10 days | >6 mos | Decreased mortality |
| ISIS-4 ³³⁵ | MI (<i>n</i> = >50,000) | Captopril vs. placebo | 24 hrs | 28 days | Decreased mortality |
| GISSI-3 ³³⁷ | MI (<i>n</i> = 19,394) | Lisinopril vs. placebo | 24 hrs | 6 wks | Decreased mortality |
| TRACE ¹⁴⁸ | MI, decreased LV function (<i>n</i> = 1,749) | Trandolapril vs. placebo | 3–7 days | 24–50 mos | Decreased mortality |
| SMILE ³³⁶ | MI (<i>n</i> = 1,556) | Zofenopril vs. placebo | 24 hrs | 6 wks | Decreased mortality |

Adapted from Brown N, Vaughan D. Angiotensin-converting enzyme inhibitors. *Circulation* 1998;97:1411, with permission from reference.

first, especially in those patients with either supraventricular arrhythmias, an S₃ gallop rhythm, or both. Vasodilators were added to those patients failing a combined regimen of a diuretic and digoxin.

Finally, investigators began focusing on the more important issue of improving survival in patients with HF. The first evidence for decreased mortality came from the First Veteran's Administration Cooperative Study (V-HeFT I), which showed combined hydralazine–isosorbide dinitrate (hydralazine isosorbide dinitrate) treatment reduced mortality to a greater extent than placebo in patients with NYHA class III or IV HF.¹³¹ All subjects continued their previously prescribed diuretic and digitalis regimens. Active intervention consisted of combination hydralazine (300 mg/day) plus isosorbide dinitrate (160 mg/day). Cumulative mortality rates over an average of 2.3 years were significantly lower in the combination therapy group (38.7%) than with placebo (44%). Exercise tolerance and LVEF were improved with combination therapy at both the 8-week and 1-year follow-up, but not in the placebo group.

The Cooperative North Scandinavian Enalapril Survival (CONSENSUS) study was the first to show improved survival in patients with HF treated with an ACE inhibitor.^{132,133} A total of 253 men and women with severe HF (NYHA class IV) were treated with either enalapril or placebo. Digitalis, diuretics, and other vasodilators were continued. At the end of 6 months, 42% of patients in the enalapril group showed symptomatic improvement compared with 22% of those on placebo. The mortality rate was 26% in patients treated with enalapril compared with 44% in the placebo group, a 40% reduction. Follow-up at 2 years showed a sustained effect, with mortality being 47% with enalapril and 74% with placebo, a 37% reduction. Almost all deaths were cardiac in origin.

Although the results from both studies were encouraging, the high rate of mortality in the vasodilator groups (even when combined with diuretics and digoxin) is evidence of the poor outcome in patients with advanced HF. This is a sobering reminder of the poor prognosis associated with the later stages of HF despite aggressive therapy. In addition, both V-HeFT I and CONSENSUS I left several questions unanswered: Does vasodilator therapy work without digitalis? Would patients with less advanced HF (NYHA class I or II) show similar benefit? Which is the better treatment regimen, hydral-iso or an ACE inhibitor?

The SOLVD study addressed the issue of treating patients with less severe disease.¹³⁴ Subjects with NYHA class II or III HF and an EF <35% were treated with either enalapril at a dosage of 2.5 to 20 mg/day (n = 1,284) or placebo (n = 1,285) in addition to conventional therapy over an average of 41.4 months. Mortality rate was 35.2% in the enalapril group compared with 39.7% in the placebo group, with the greatest benefit being a reduction in deaths attributed to progressive HF. Two lessons can be gained from this trial: Patients with less severe disease also experience symptom improvement from vasodilator therapy, as well as experiencing lower mortality rates.

Next, the second Veteran's Administration Cooperative Study (V-HeFT II)^{135,136} sought to answer the question of relative benefit of hydral-iso versus enalapril. Patients receiving diuretics and digoxin for HF of varying degrees of severity (primarily functional class II or III) were randomized to either enalapril at a fixed dose of 20 mg/day or the hydralazine isosorbide dinitrate combination at a dosage of 300 mg hydralazine plus 160 mg of isosorbide. Mortality rates were lower in the

enalapril group (18%) than with combination therapy (28%), with the greatest benefit in both groups being for patients with less severe disease (functional class I or II). Although a placebo group was not included in this trial, the survival rate with hydralazine isosorbide dinitrate was the same as seen in V-HeFT I,¹³¹ inferring a beneficial effect with hydralazine isosorbide dinitrate in V-HeFT II as well. In addition, treatment with hydralazine isosorbide dinitrate was more effective than enalapril in improving patients' exercise tolerance and body oxygen consumption during peak exercise. EF also increased faster (but not necessarily to a greater extent) with hydralazine isosorbide dinitrate than with enalapril. In both V-HeFT I¹³¹ and V-HeFT II,¹³⁶ enalapril was better tolerated than hydralazine isosorbide dinitrate. In summary, a trend toward better symptom control occurred with hydralazine isosorbide dinitrate, but improved survival and fewer side effects were seen with enalapril. Although not specifically studied in this trial, these trends suggest a possible benefit to using all three drugs in combination together.

In all these trials, the investigators were careful to include only patients with systolic failure as evidenced by an EF <40%. Thus taken as a whole, they provide convincing evidence for the value of vasodilators in systolic failure.

DIGOXIN WITHDRAWAL TRIALS

In 1993, two digoxin withdrawal trials, PROVED¹³⁷ and RADIANCE,¹³⁸ were published. Both attempted to determine whether patients with HF who are already treated with digoxin will show deterioration of control or remain stable after discontinuation of digoxin. In both studies, patients had documented systolic failure (LVEF <35% by radionuclide ventriculography), mild to moderate symptoms (NYHA class II or III); and they were in normal sinus rhythm and were stable for at least 3 months with a treatment regimen of a diuretic and digoxin (baseline digoxin level 0.9–2.9 ng/mL). A significant difference was that patients in the RADIANCE trial were also stabilized on an ACE inhibitor in addition to the diuretic and digoxin.¹³⁷ A 12-week, double-blind, placebo-controlled treatment period followed initial stabilization in both studies. Patients in the active treatment groups continued digoxin at their previous dose. Those in the placebo groups were withdrawn from digoxin and given an identical looking placebo.

In PROVED,¹³⁷ 42 subjects continued digoxin and 46 were given placebo. There were 29% treatment failures in the withdrawal group compared with only 19% in those still taking digoxin. Treatment failure was defined as worsening HF symptoms requiring a therapeutic intervention (e.g., increased diuretic dosage or addition of a new drug), an emergency department (ED) visit or hospitalization for HF, or death. Exercise tolerance worsened in more patients taking placebo. Those taking digoxin tended to maintain lower body weight and HR as well as higher EF. In the RADIANCE study, 85 subjects continued digoxin therapy and 93 were switched to placebo.¹³⁸ Over the 12-week follow-up period, only 4 of the subjects taking digoxin (4.7%) developed worsening symptoms compared with 23 (24.7%) of the placebo-treated patients. More of the placebo-treated patients had worsening of the EF and lower quality of life scores. The finding that deterioration in symptoms after discontinuing digoxin often was delayed for several weeks offers a possible explanation why earlier clinical trials using shorter observation periods failed to establish a benefit from digoxin. When comparing the two trials directly, fewer

patients deteriorated in both arms in the RADIANCE study. Whether this is attributed to a greater benefit from combining an ACE inhibitor with a diuretic compared with using a diuretic alone cannot be established.

These studies establish a beneficial effect of digoxin, even in those patients receiving concurrent ACE inhibitors in RADIANCE. At least two factors, however, limit extrapolation to all patients with HF. First, the investigators only assessed the value of therapy indirectly by using a withdrawal design instead of initiating therapy in patients previously untreated with digoxin. Second, the patients had advanced disease as evidenced by NYHA class II or III symptoms despite triple drug therapy. Thus, the benefit of digoxin as initial monotherapy in early disease is still open to debate.

EFFECT OF DIGOXIN ON MORTALITY

An obvious missing link was whether treatment with digoxin improves survival rates. The seminal study to answer this question is the Digitalis Intervention Group (DIG) study.¹³⁹ In this study 6,800 patients with HF from 302 centers in the United States and Canada were randomized to receive either digoxin ($n = 3,397$) or placebo ($n = 3,403$). Eligibility requirements included an EF of 45% or less (mean, 28% in both treatment groups), normal sinus rhythm, and clinical evidence of HF. Most subjects were in NYHA class II or III HF, although a small number of both class I and class IV subjects were included. Concurrent therapies were diuretics (82%), ACE inhibitors (94%), and nitrates (42%). Of subjects in both groups, 44% were taking digoxin before randomization. The starting digoxin dose (or matching placebo) was based on age, weight, and renal function, with subsequent adjustments made according to plasma level measurements. Approximately 70% of subjects in both groups ended up taking 0.25 mg/day, compared with 17.5% taking 0.125 mg/day and 11% receiving dosages of 0.375 mg/day or higher. By 1 month, 88.3% of subjects on active drug had serum levels between 0.5 and 2.0 ng/mL, with a mean of 0.88 ng/mL. Patients were followed for an average of 37 months (range, 28 to 58 months).

For the primary outcome of total mortality from any cause, 34.8% of patients on digoxins and 35.1% of those on placebo patients died; corresponding CV deaths were 29.9% and 29.5%, respectively. Although neither of these differences is statistically different, a trend was seen toward fewer HF-associated deaths and statistically fewer hospitalizations (risk ratio, 0.72) with active treatment. As would be expected, cases of suspected digoxin toxicity were greater in the active treatment group (11.9% vs. 7.9%), but the incidence of true toxicity was low. These results can be interpreted either as disappointing in that overall mortality is not reduced, or as positive in that hospitalizations were fewer in the digoxin group and there is no increase in mortality as reported with nondigitalis inotropes.

This study improves on the PROVED and RADIANCE trials because it added digoxin to other therapy as opposed to being a withdrawal study and also because of the larger study population. Because nearly all patients were receiving concurrent vasodilator therapy, the value of digoxin as monotherapy on mortality rates remains unanswered.

DIRECT COMPARISON OF DIGOXIN TO VASODILATORS

Little data are available to directly compare digoxin with an ACE inhibitor.^{140–142} Two widely quoted studies are the Captopril-Digoxin Multicenter Research Group Study¹⁴¹ and

the Canadian Enalapril vs. Digoxin Study Group trial.¹⁴² Similarities between these two trials are inclusion of NYHA class II or III patients, all of whom had a reduced EF and were in normal sinus rhythm. All subjects continued to take diuretics, but other vasodilator therapy was discontinued. About half of the patients had an S₃ gallop rhythm, and about 60% were taking digoxin before entry into the studies. After an appropriate run-in period during which time diuretic doses were stabilized and previous digoxin therapy was discontinued, patients were randomized to receive either digoxin or an ACE inhibitor.

In the Captopril-Digoxin study, both drugs were superior to placebo as measured by symptom scores and treadmill exercise time.¹⁴¹ The trend toward a more favorable functional improvement with captopril (41% improving with captopril, 31% with digoxin, 22% with placebo) was nonsignificant. The increase in the EF in the digoxin group was greater. Six-month mortality was unchanged with either drug compared with placebo. More minor side effects were associated with captopril (44% vs. 30%), but more patients had to discontinue digoxin because of side effects (4.2% vs. 2.9%).

In the Enalapril-Digoxin study, more patients in the enalapril group showed functional improvement at 4 weeks (18% vs. 10%) and fewer showed functional deterioration (12.5% vs. 23%).¹⁴² By the end of 14 weeks, however, an equal number of patients had improved with both drugs (19%), but more patients continued to show deterioration with digoxin (30% vs. 12.5%). No differences in the more objective measurements of exercise time, left ventricular function, BP, pulse, and electrocardiographic (ECG) changes were noted between the two groups. More patients withdrew from the digoxin arm because of side effects.

Taken in the aggregate, these studies show no clear benefit of one class of drug vs. the other; ACE inhibitors may be slightly more rapid in onset of effect and associated with better tolerance of side effects, but digoxin may improve EF to a greater extent. Mortality differences were undetectable in the Captopril-Digoxin study because of the relatively mild disease in the patients at the outset resulting in mortality rates of only 6% to 8% in either study group. A larger sample size and longer duration of observation would be required to detect a significant difference in mortality.

To summarize, based on clinical outcomes (resolution of symptoms and improved cardiac function), both vasodilators and digitalis glycosides are effective in patients with documented systolic dysfunction. The documented improvement in survival rates with both hydralazine isosorbide dinitrate and ACE inhibitors, coupled with the neutral findings of the DIG study, tip the balance in favor of ACE inhibitors as initial therapy in all stages of HF. The use of both classes of drugs, plus diuretics, is indicated for severe HF.

The latest clinical ACC/AHA guidelines state that digoxin therapy is unlikely to benefit patients with stage A or stage B HF.⁷ In these patients, digoxin can be used for symptom management, only if they are treated with drug therapy shown to prolong survival (ACEI and β -blockers) or have not responded adequately to appropriate therapy. For patients in stage C or stage D HF who are symptomatic, with enlarged heart and reduced LVEF, digoxin can be beneficial. Monotherapy with digoxin or in combination with only a diuretic is no longer recommended.⁵

In the case of A.J., his physician should be discouraged from starting digoxin at this time. Instead, he should be counseled to

continue with the already prescribed ACE inhibitor in addition to continuing the furosemide. A strong argument can be made for starting a β -blocker such as metoprolol or carvedilol now or within the next few days. Based on your advice, A.J.'s doctor has decided to withhold digoxin and assess the response to just one drug (i.e., the ACE inhibitor) for now.

Angiotensin-Converting Enzyme Inhibitors

Agents of Choice

16. The formulary for A.J.'s insurance company only covers four ACE inhibitors: benazepril, captopril, enalapril, and lisinopril. Benazepril is being promoted because the current contract makes it the least expensive of the four drugs. Is there a preference for any specific agent to order for A.J.?

As a general rule, formulary decisions are first based on comparative pharmacologic activity, efficacy, and drug safety. Other factors to consider are labeled (FDA approved) indications, convenience of dosing schedule, and—all else being equal—the cost to the pharmacy (or institution) and the patient (or insurance carrier). A confounding factor is that hypertension is the primary labeled indication for all of the ACE inhibitors and was the initial basis for placing these drugs on formularies. The indication for HF was added after initial marketing and does not appear in the FDA-approved labeling for all of the drugs. Each of these factors is considered below.

The basic mechanism of action of all ACE inhibitors is the same and is described in the pathogenesis section of this chapter.^{59–61,143} They inhibit ACE (also called kinase II),

thereby reducing the activation of angiotensin II, a major contributor to the undesired hemodynamic responses to HF. Decreased circulating levels of norepinephrine, vasopressin, neurokinins, luteinizing hormone, prostacyclin, and NO also have been noted after administration of ACE inhibitors.

In addition, ACE is responsible for degradation of bradykinin, substance P, and possibly other vasodilatory substances unrelated to angiotensin II. Thus, part of the beneficial effects of ACE inhibitors is caused by the accumulation of bradykinin (Fig. 18-6). After attaching to bradykinin-2 (B_2) receptors, vasodilation is produced by stimulating the production of arachidonic acid metabolites, peroxidases, nitric oxide, and endothelium-derived hyperpolarizing factor in vascular endothelium. In the kidney, bradykinin causes natriuresis through direct tubular effects.

The net effect is that ACE inhibitors regulate the balance between the vasoconstrictive and salt-retentive properties of angiotensin II and the vasodilatory and natriuretic properties of bradykinin. The physiologic consequences of the pharmacologic effects of ACE inhibitors are reduced pulmonary capillary wedge pressure (preload) and lowered systemic vascular resistance and systolic wall stress (afterload). CO increases without an increase in HR. ACE inhibitors promote salt excretion by augmenting RBF and reducing the production of aldosterone and antidiuretic hormone. The beneficial effects on RBF, coupled with the drug's indirect inhibition of aldosterone, lead to a mild diuretic response, a distinct benefit over other vasodilator compounds such as hydralazine.

Vasodilation and diuresis are not the only value of ACE inhibitors in HF. Angiotensin II enhances vascular remodeling

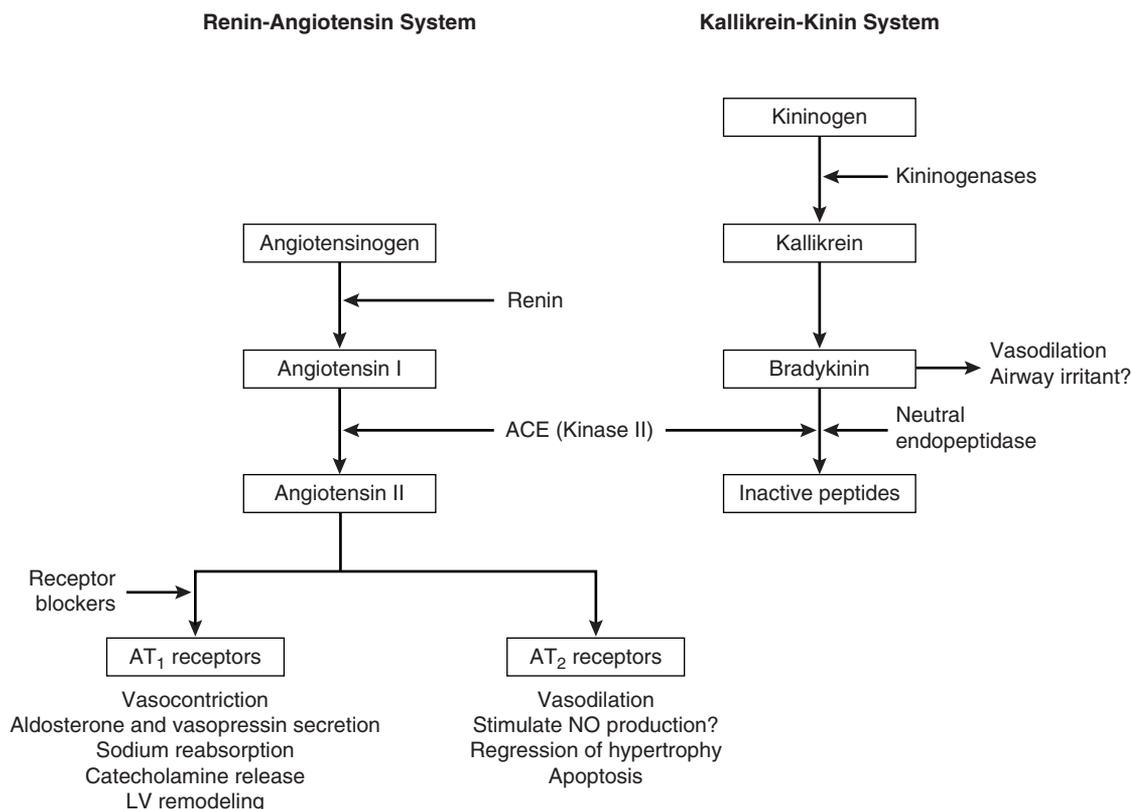

FIGURE 18-6 Angiotensin receptor blocker mechanism. ACE, angiotensin-converting enzyme; LV, left ventricular; NO, nitrous oxide.

(referred to as trophic effects on cardiac myocytes), whereas bradykinin impedes this process.^{59,144} In experimental models, ACE inhibitors impede ventricular remodeling by blocking the trophic effects of angiotensin II on cardiac myocytes. Evidence to whether preserving bradykinin levels effects remodeling is inconclusive, although it might attenuate the progressive deposition of collagen during the chronic phase of post-MI cardiac remodeling.

As of this writing, *captopril* (Capoten), *enalapril* (Vasotec), *fosinopril* (Monopril), *lisinopril* (Prinivil, Zestril), and *quinapril* (Accupril) have FDA-labeled approval for symptomatic relief of HF symptoms (Table 18-11). Evidence exists that other agents such as *benazepril* (Lotensin) also increase exercise capacity and quality of life in patients with chronic HF.¹⁴⁵ *Moexipril* (Univase), *ramipril* (Altace), and *trandolapril* (Mavik) have FDA-labeled approval for the treatment of left ventricular dysfunction after myocardial infarction. There does not seem to be a significant difference in side effects between agents. Based on these factors, no one drug is preferred over another.

Numerous placebo-controlled trials have documented the favorable effects of ACE inhibitor therapy on hemodynamic variables, clinical status, and symptoms of HF.^{143,146} Multiple studies demonstrate a consistent 20% to 30% relative reduction in HF mortality that is superior to other vasodilator regimens including the hydralazine–nitrate combination or angiotensin receptor inhibitors (see Question 15). The benefits of ACE inhibitors are independent of the etiology of HF (ischemic vs. nonischemic) or the severity of symptoms (NYHA class I through class IV).

Table 18-10 provides a brief summary of the results of the key ACE inhibitor HF trials.^{59–61,131–134,136,146,335–337} Many of these were reviewed previously in Question 15. Of the five approved agents, the most evidence for improved survival is available for enalapril in both chronically symptomatic patients (NYHA classes II–IV) and asymptomatic patients (NYHA class I) with evidence of an impaired EF after an MI.^{131–134,136} A 3-year follow-up to the Acute Infarction Ramipril Efficacy (AIRE) study reported mortality rates of 27.5% in ramipril-

treated subjects (target dose, 5 mg twice daily) compared with 38.9% with placebo, a 36% risk reduction.¹⁴⁷ Published data are also available for a positive effect on reducing short-term mortality with captopril, lisinopril, trandolapril, and zofenopril, primarily in relatively small populations of patients with chronic symptoms or in patients with new onset HF symptoms following an MI.^{60,148,149}

Direct comparison of different ACE inhibitors is limited to three trials. The first two comparing lisinopril (5 to 20 mg every day) to either captopril (12.5–50 mg daily in two divided doses)¹⁵⁰ or enalapril (5–20 mg daily)¹⁵¹ were only 12 weeks in duration. Exercise duration improved significantly with all three drugs at weeks 6 and 12. No statistically significant differences were found between drugs for NYHA class changes, HF symptoms, or side effects, although a trend was noted toward greater exercise duration at week 12 with lisinopril compared with enalapril. In the third study, fosinopril (5–20 mg) was compared with enalapril (5–20 mg) daily for 1 year.¹⁵² The fosinopril group had significantly fewer patients who were hospitalized for HF or who died (19.7%) than did the enalapril group (25%; $p = 0.028$). Nearly 60% of patients in the fosinopril group improved their NYHA class. The incidence of orthostatic hypotension was lower in the fosinopril group (1.6% vs. 7.6%, $p = 0.05$). No explanation was provided to why there might be a difference.

Based on the total body of data, it is difficult to designate an agent of choice. The 2005 ACC/AHA guidelines recommend selecting an ACE inhibitor that has shown reductions in both morbidity and mortality in clinical trials in either HF or in populations after MI. The following ACE inhibitors are considered first-line options based on clinical trials: captopril, enalapril, lisinopril, perindopril, ramipril, or trandolapril.⁷

Captopril and lisinopril (the lysine derivative of enalaprilat) are both active as the parent compound and do not have active metabolites. All other ACE inhibitors are inactive prodrugs that require enzymatic conversion by esterolytic enzymes to active metabolites (benazeprilat, enalaprilat, fosinoprilat, moexiprilat, perindoprilat, quinaprilat, ramiprilat, and trandolaprilat). The only clinical consequence of these differences is

Table 18-11 ACE Inhibitor Dosing in Systolic Dysfunction^a

| Drug | Dosage Form | Starting Dose ^b | Target Dose ^c | Maximum Dose |
|---|-------------------------------|----------------------------|--------------------------|--------------|
| Captopril ^d (Capoten, generic) | 12.5, 25, 50, 100 mg tablets | 6.25–12.5 mg TID | 50 mg TID | 100 mg TID |
| Enalapril (Vasotec) | 2.5, 5, 10, 20 mg tablets | 2.5–5 mg QD | 10 mg BID | 20 mg BID |
| Fosinopril (Monopril) | 10, 20, 40 mg tablets | 5–10 mg QD | 20 mg QD | 40 mg QD |
| Lisinopril (Prinivil, Zestril) | 2.5, 5, 10, 20, 40 mg tablets | 2.5–5 mg QD | 20–40 mg QD | 40 mg QD |
| Quinapril (Accupril) | 5, 10, 20, 40 mg tablets | 5–10 mg QD | 20 mg BID | 20 mg BID |
| Perindopril (Aceon) | 2, 4, 8 mg tablets | 2 mg QD | 8–16 mg QD | 16 mg QD |
| Ramipril (Altace) | 1.25, 2.5, 5, 10 mg capsules | 1.25–2.5 mg QD | 5 mg BID | 10 mg BID |
| Trandolapril (Mavik) | 1, 2, 4 mg tablets | 1 mg QD | 4 mg QD | 8 mg QD |

^aBenazepril, cilazapril, moexipril, perindopril, ramipril, trandolapril not labeled for use in heart failure.

^bStart with lowest dose to avoid bradycardia, hypotension, or renal dysfunction. All but captopril given QD in the morning at starting doses. Increase dose slowly at 2- to 4-week intervals to assess full effect and tolerance.

^cEnalapril, quinapril, ramipril could possibly be given QD instead of BID based on half-life.

^dCaptopril is short acting. Start with a 6.25- or 12.5-mg test dose, then 6.25 to 12.5 mg TID.

Adapted from ACC/AHA 2005 Guidelines update for the diagnosis and management of chronic heart failure in the adult: a report of American College of Cardiology, American Heart Association Task Force on Practice Guidelines (Writing Committee) to update the 2001 Guidelines for the Evaluation and Management of Heart Failure. *J Am Coll Cardiol* 2005;46E1; and American Society of Health-System Pharmacists. ASHP therapeutic guidelines on angiotensin-converting-enzyme inhibitors in patients with left ventricular dysfunction. *Am J Health Syst Pharm* 1997;54:2999, with permission.

a slightly delayed onset of effect with the first dose (2–6 hours for captopril, 4–12 hours for the others). Of greater distinction, captopril has a relatively short half-life and duration of action, necessitating three to four times daily administration in most patients. Although this characteristic may be advantageous when initiating therapy by allowing closer assessment of early side effects, for chronic maintenance it is preferred to use a drug that can be given either once or twice daily. All other ACE inhibitors meet this criterion, either as the parent drug (lisinopril) or as the active metabolite (all others). Based solely on half-life data, there would be no expected difference between any of the longer-acting agents. Theoretically, they could all be administered once daily. Package insert labeling and common standards of practice, however, have led to twice daily dosing, especially at higher doses, for enalapril, quinapril, and ramipril.

We can conclude that A.J. should start captopril for 1 to 2 days for initial dosage titration, but then quickly transferred to a longer-acting drug if he has a good response to the captopril. Because of the lack of demonstrated superiority of one agent over another, cost does become a factor in choosing a long-acting ACE inhibitor. Because costs are often site- or agency-specific, reflecting interplay between institutional or managed care purchasing contracts and insurance company or drug benefit manager policies, it is not possible to identify the single less expensive agent. A.J.'s doctor decides not to use benazepril, even though it is the least expensive drug, because it does not have FDA approval for HF. Instead, he chooses to start enalapril based on evidence for clinical efficacy, improved survival, and availability of a reduced-cost generic.

Dosage

17. A captopril dosage of 25 mg TID was ordered for A.J. How will this dosage be titrated in preparation for conversion to enalapril? How should he be monitored?

CAPTOPRIL DOSING

Continued experience with captopril has led to a better understanding of dose-response relationships and more rational therapy. Complete inhibition of ACE is achieved with 10 to 20 mg, but larger doses prolong the duration of action. Early single-dose studies suggested that large doses (25–150 mg) were needed for maximal reduction of HF symptoms. Thus, until a better understanding was gained on how to use the drug, patients often were started on 25 mg every 8 hours and quickly titrated to 150 to 300 mg/day. It is now recommended to start patients on doses as low as 6.25 to 12.5 mg every 8 hours for a few days and then titrate to the desired symptomatic and objective responses. This conservative dosing approach minimizes the bradycardia and hypotension associated with higher doses and also allows better assessment of changes that may occur in the patient's renal function. It is especially important to start with low doses in persons with renal insufficiency or a very low EF. Renal function and serum potassium should be assessed within 1 to 2 weeks of initiation of therapy and periodically thereafter, especially in patients with preexisting hypotension, hyponatremia, diabetes, or azotemia and in those taking potassium supplements or potassium-sparing diuretics.^{6,7}

Diuretic therapy must be monitored to prevent volume depletion or azotemia. ACE inhibitors are relatively contraindi-

cated in people who are volume depleted or who have severe renal impairment.

Although symptoms might abate in some patients within the first 48 hours of therapy with an ACE inhibitor, the clinical responses to these drugs are generally delayed and might require several weeks or months to become apparent. The lag period likely results from the time needed for the body to readjust various hormonal responses rather than a pharmacokinetic or pharmacologic phenomenon. Even if symptoms do not abate, long-term treatment with an ACE inhibitor should be maintained because these drugs can reduce the risk of hospitalization or death independent of their effect on symptoms. Abrupt withdrawal can lead to clinical deterioration and should be avoided unless life-threatening side effects (e.g., angioedema or renal failure) are evident.¹⁵³

Reviewing A.J.'s history (Question 1) and repeat vital signs and laboratory values (Question 15), we recall that he was hypertensive and had an elevated BUN at the time of his hospitalization. Both of these problems abated after starting furosemide, but his BUN is now still slightly above normal, although he is not hypotensive. We are, therefore, less concerned about the risk of hypotension, but we are unsure of how the ACE inhibitor will affect his renal function. If CO increases as desired, his renal function should improve; but if he becomes hypotensive, renal function may get worse. The 25-mg dose as currently ordered is probably safe in a stable patient such as A.J. It is prudent, however, to recommend lowering A.J.'s dosage of captopril to 12.5 mg as a single dose on the first morning. For less stable patients, a starting dose of 6.25 mg should be used. If A.J.'s BP and renal function remain stable after the test dose, he can get a total of three doses, approximately 8 hours apart, of 12.5 mg on the first day. On day 2, the dose can be raised to 25 mg three times daily. If he again remains stable on day 3, his regimen can be converted to enalapril, using a single daily dose.

CAPTOPRIL COMPARED WITH ENALAPRIL

18. After 2 days of taking captopril, A.J.'s exercise capacity has improved and his lower extremity edema has abated, but his HF is not optimally controlled. He is assessed to have between NYHA class II and III symptoms. BP values throughout the day have fluctuated in the range of 127–145/80–95 mm Hg and his weight is down to 70 kg. Repeat laboratory measurements include the following: Na, 139 mEq/L; K, 4.7 mEq/L; Cl, 98 mEq/L; CO₂, 27 mEq/L; BUN, 24 mg/dL; and SrCr, 0.6 mg/dL. An order is written to begin 5 mg/day of enalapril. Is this an appropriate choice of therapy? What is the target dose for him?

DOSE-RESPONSE RELATIONSHIPS

Cumulative evidence from all the clinical trials indicates a relationship between the degree of abatement in HF symptoms and the dose of drug given. Larger doses are more likely to improve the patient's quality of life and reduce the incidence of hospital stays, but the impact of larger doses when assessing mortality data is less clear. At the same time, higher doses are associated with a greater risk of side effects. Based on these principles, proposed recommended starting, target, and maximal doses for the ACE inhibitors are listed in Table 18-11.^{7,61}

In general, the guidelines conclude that ACE inhibitors should be initiated at low doses, but titrated to the maximal tolerated target dose. Supporting this principle are the results of

the ATLAS Trial.^{154,155} Lisinopril was given to 3,164 patients hospitalized during the previous 6 months and with NYHA class II–IV HF and an LVEF <30%. Open label lisinopril 2.5 to 5 mg was given for first 2 weeks, then 12.5 to 15 mg for an additional 2 weeks. If the initial doses were tolerated, subjects were randomized to daily therapy with lisinopril 2.5 to 5 mg (low dosage) or 32.5 to 35 mg (high dosage). All-cause mortality did not differ between the two groups (8% lower in the highest dose group compared with the lowest dose; $p = 0.128$). In the high dosage group, hospitalizations and the combined end point of death and hospitalization were reduced by 24% ($p = 0.003$) and 12% ($p = 0.002$), respectively. The higher dosage was tolerated by 90% of patients assigned this dose.

Despite these recommendations for using the highest tolerated doses, evidence also suggests that lower doses are beneficial. For example, the UK Heart Failure Network Study found that 10 mg twice daily enalapril was no more effective than 2.5 mg twice per day.¹⁵⁶ In this study, enalapril was given in low (2.5 mg BID), moderate (5 mg BID), and higher (10 mg BID) dosages to patients with NYHA class II–III HF. The primary combined end point (death, hospitalization from HF, and worsening HF incidence) occurred in 12.3%, 12.9%, and 14.7%, respectively, of patients receiving low, moderate, and higher enalapril dosages. None of the between group differences were statistically different. Mortality, evaluated separately, was 4.2%, 3.3%, and 2.9%, respectively, which were all not significant comparisons. Further information on dosing, pharmacologic, and pharmacokinetic information regarding the ACE inhibitors is found in Chapter 13, Essential Hypertension.

For enalapril, the recommended starting dosage is 2.5 to 5 mg/day. For older patients or those with other risk factors (i.e., systolic BP <100 mm Hg, those taking large doses of either loop diuretics or potassium-sparing diuretics, or those with preexisting hyponatremia, hyperkalemia, or renal insufficiency), the starting dosage of 2.5 mg/day would be more appropriate. This dosage, or an equivalent with one of the other drugs, should also be considered if the patient is being started directly on a long-acting drug without prior titration on captopril. For a patient such as A.J. who has already been treated with captopril for 2 days with no evidence of intolerance, a 5-mg dose is an appropriate recommendation.

The long-term target dosage of enalapril for A.J. is 10 to 20 mg BID. No clear formula exists for deciding how quickly to titrate to this dose. It depends on several factors, including the degree of reduction in his HF symptoms and side effects, and his motivation to take the medicine. Whenever dosage adjustments are made, it may take as few as 24 hours for the patient to perceive symptom reduction, but generally full hemodynamic steady state is not reached for 1 to 2 months. On the other hand, hypotension and other side effects are more immediate. A.J. should have his dose reassessed in 1 to 2 weeks to determine whether he can tolerate a dosage increase to 5 mg BID. Thereafter, an extra 5 mg/day could be added every 2 to 4 weeks. Thus, it could take 6 months or more to titrate upward to 20 mg BID. If the response to his symptoms is not positive and he has no side effects, the rate of titration could be made faster, either by shortening the assessment periods (e.g., every week) or by using larger dosage increments (e.g., 10-mg increase).

One study comparing long-term treatment with 50 mg TID of captopril vs. 20 BID of enalapril showed more hypotensive episodes and compromised cerebral and renal function in the patients treated with enalapril.¹⁵⁷ From this, it was postulated that the more sustained hypotensive effect of enalapril may actually be a disadvantage. A potential confounding variable, however, is that the 40-mg daily dose of enalapril may have been disproportionately high compared with the 150 mg/day dose of captopril.

ACE Inhibitor–Induced Cough

19. M.Y., presents to the outpatient HF clinic with an annoying productive cough after 6 weeks of lisinopril therapy. He has been titrated up to a dose of 20 mg QD. He is also taking 40 mg of furosemide OD, 50 mg metoprolol succinate OD, and 50 mg spironolactone OD. His HF symptoms are much improved. About 2 weeks ago, he developed an annoying nonproductive cough that persisted throughout the day and also made it difficult for him to fall asleep at night. After about 1 week, he went to see his primary care physician who told him that he had bronchitis and recommended that he use a guaifenesin and dextromethorphan containing cough syrup. During a routine clinic visit today, he still is bothered by his “bronchitis.” A chest examination reveals no evidence of wheezing, the S₃ heart sound has disappeared, and he still has a few crackles, but much less than when he was first admitted. His neck veins are only minimally elevated over normal, his ankle edema is 1+, and his weight is still 70 kg. BP today is 140/90 mm Hg. All laboratory values are normal except his potassium high at 5.0 mEq/L, BUN and creatinine are 19 mg/dL and 0.6 mEq/dL, respectively. Could the cough and “bronchitis” be a symptom of his HF? What are the recommendations for an ACE-induced cough?

Cough can be a sign of HF in patients with pulmonary congestion. In extreme cases, patients demonstrate “cardiac asthma” with severe air hunger, wheezing, and dyspnea. However, A.J.’s HF is much improved as evidenced by the objective data. The absence of wheezing and no prior history of asthma or smoking make an obstructive airways disease (asthma or COPD) unlikely. It is possible that he does have bronchitis, but he does not recall having a cold or other respiratory illness preceding the cough. Without other causes, a lisinopril-induced cough is suggested.

This side effect occurs with all ACE inhibitors.¹⁵⁸ Case reports indicate a possible lower incidence with fosinopril (Monopril), but this has not been confirmed under controlled conditions.¹⁵⁹ Cough is a well-established complication of lisinopril. ACE inhibitor-induced cough presents as a dry, nonproductive cough sometimes described as a “tickle in the back of the throat.” This complication can arise within hours of first dose, or it can present after weeks to months of starting an ACE inhibitor. Although, resolution of the cough can occur within 1 to 4 weeks, in some patients, it can persist up to 3 months after discontinuation of therapy.

Various case reports have found an incidence of cough in 5% to 35% of all patients. The incidence may be even lower, approximately about 3%, and is dose independent.¹⁶⁰ One investigator found a 5% to 10% incidence in white patients of European descent that rose to nearly 50% in Chinese patients.¹⁶¹ There may also be a higher incidence in women and black populations.¹⁵⁸

Bradykinin accumulation within the upper airway, decreased metabolism of proinflammatory mediators, such as substance P or prostaglandins, or both are proposed mechanisms of ACE inhibitor-induced cough. These chemicals then act as irritant substances in the airways to increase bronchial reactivity and induce coughing. Bradykinin stimulates unmyelinated afferent sensory C fibers by type J receptors involved in the cough reflex. Bradykinin is also a potent bronchoconstrictor, but pulmonary function remains unchanged, and persons with asthma are no more susceptible to the reaction than those who do not have asthma. Substance P, also degraded by ACE, has been implicated because it is a neurotransmitter for afferent sensory fibers, specifically C fibers. Because this is a pharmacologic effect rather than an allergic reaction, dosage reduction or switching from one ACE inhibitor to another is generally not helpful. Likewise, dosage reduction is often not helpful. The only way to definitively diagnose the drug-induced cough is to discontinue therapy. Even then, false-positive results can occur if the patient had a mild case of bronchitis that spontaneously resolved at about the same time that the ACE inhibitor was discontinued. If the cough persists after drug discontinuation, other causes should be investigated.

The AHA guidelines recommend continuing ACE inhibitors if the cough is not severe even when other causes of cough have been excluded. Arguing in favor of this action is the long-term survival benefits of ACE inhibitors. On the contrary, American College of Chest Physicians (ACCP) evidence-based practice guidelines recommend discontinuation of therapy if ACE inhibitor-induced cough is even suggested.¹⁶⁰ After cessation of therapy, resolution of cough confirms the diagnosis. For patients with persistent cough, ARB or hydralazine-isosorbide are safe alternatives. For now, M.Y. can continue taking lisinopril for another couple of weeks to determine if the cough will resolve on its own. His symptoms of HF have abated since the initiation of ACEI and the cough may be no more than an annoyance. He is not at risk for developing asthma or other airway problems. If his cough persists, an ARB is probably the best alternative.

The ACCP guidelines suggest that in patients for whom continuation of ACE therapy is determined to be medically necessary, either attempt rechallenge with an ACE inhibitor (although only a small subset of patients will tolerate the reintroduction of therapy with no reoccurrence of cough) or use a pharmacologic agent to suppress the cough (e.g., aspirin, amlodipine, ferrous sulfate).

Angiotensin Receptor Blockers

20. M.Y., is sufficiently disturbed by his cough and he has requested discontinuing lisinopril. Because he has had such good success with the ACE inhibitor, his physician wants to replace lisinopril with valsartan 40 mg BID. What evidence indicates that valsartan or other angiotensin-receptor blocking drugs are effective in treating HF? Are these drugs still associated with causing a cough?

Angiotensin II that is normally activated by the renin-angiotensin cascade interacts with several different membrane-bound receptors, two of which include angiotensin type 1 (AT₁) and type 2 (AT₂) receptors (Fig. 18-6).^{59,62,162} Attachment to AT₁ is responsible for most of the unwanted CV actions of angiotensin II, including vasoconstriction, activa-

tion of aldosterone, and stimulation of norepinephrine release. Angiotensin-receptor antagonists all preferentially bind to AT₁ to competitively inhibit attachment by endogenous angiotensin II, thus blocking angiotensin II activity.

As described above, ACE inhibition both affects angiotensin II production and also impairs the metabolism of bradykinin, substance P, and other vasoactive substances.^{59,62,162} These substances do not interact with either of the angiotensin receptors, but may independently be associated with production of the cough and first-dose hypotension seen with ACE inhibitors. By giving an AT₁ receptor antagonist, the positive benefits of blocking the CV effects of angiotensin II are achieved while sparing alteration of the kinin metabolism. Indeed, nearly all trials using various ARB to treat hypertension or HF have shown a reduced incidence of cough relative to the ACE inhibitors, with prevalence no greater than that of placebo. Of further interest is preliminary information that angiotensin II attachment to the AT₂ receptor might actually lead to beneficial effects, including vasodilation and protection of the vascular wall from proliferative atherosclerotic effects. These responses should remain intact with AT₁ receptor antagonists, but are at least partially blunted by ACE inhibitors.

Life-saving drugs (e.g., ACE inhibitors, β -blockers, and spironolactone) have an established role in the management of HF. Despite these therapies, many patients with HF remain at a high risk of CV death. Several clinical trials in HF have shown potential therapeutic benefit of the receptor antagonists in modifying HF symptoms (Table 18-12).¹⁶²⁻¹⁶⁹ A meta-analysis combined data on all-cause mortality and HF-related hospitalizations from 17 clinical trials that compared an ARB with either placebo or an ACE inhibitor in patients with HF.¹⁶³ Most of the trials also assessed short-term clinical end points such as exercise tolerance and EF. In total, 12,469 patients participated and 5 ARB (candesartan, eprosartan, irbesartan, losartan, and valsartan) were tested, assuming a class effect for all ARB. ARB favorably improved exercise tolerance and EF compared with placebo. They were not superior to ACE inhibitors in reducing all-cause mortality or hospitalizations for HF, however. The combination of an ARB and an ACE inhibitor was superior to ACE inhibitor monotherapy in reducing hospitalizations for HF but not in improving survival. In patients not receiving an ACE inhibitor (but receiving other HF drugs), a nonsignificant trend favored ARB over placebo for both reductions in all-cause mortality and hospitalizations for HF.

The first major clinical trial comparing an ARB with an ACE inhibitor in patients with HF was the Evaluation of Losartan in the Elderly (ELITE) study.¹⁶⁷ Among the strengths of this trial are (a) a relatively large population (722 subjects) who were all ACE inhibitor-naïve, (b) comparison of the receptor antagonist with an ACE inhibitor (captopril), and (c) an adequate duration (48 weeks) to allow a preliminary outcome evaluation of frequency of hospitalizations and incidence of death. All subjects were 65 years of age or older with NYHA class II-IV HF, had an EF of 40% or less (mean, 31%), and were not previously treated with either an ACE inhibitor or an ARB. Diuretics were used by 75% of the subjects, with 55% taking digoxin and 40% taking a non-ACE-inhibitor vasodilator. Losartan was started at 12.5 mg/day in 352 patients and titrated to a dose as high as 50 mg/day in 300 of them. The 370 subjects randomized to captopril began therapy at 6.25 mg three times daily and

Table 18-12 Clinical Trials of Angiotensin Receptor Blockers (ARB) in Heart Failure (HF)

| <i>Trial</i> | <i>Patient Population</i> | <i>ARB</i> | <i>Treatment Duration</i> | <i>Outcome</i> |
|-------------------------------------|--|---|---------------------------|---|
| ELITE ¹⁶⁷ | NYHA II-IV (<i>N</i> = 722) EF ≤40% | Losartan (50 mg QD) or Captopril (50 mg TID) | 48 wks | No significant difference observed for the primary endpoint (persistent renal dysfunction) or the secondary endpoint (composite of death/HF admissions) Losartan was associated with a lower mortality than Captopril |
| RESOLVD ¹⁶⁹ | NYHA II-IV (<i>N</i> = 768) EF ≤ 40% | Candesartan (4, 8 or 16 mg), or Candesartan (4 mg or 8 mg) + 20 mg Enalapril, or 20 mg Enalapril | 43 wks | Combination has greater benefits on LV remodeling. No difference in mortality No difference in NYHA class, QOL, 6 min walking distance |
| ELITEII ¹⁶⁸ | NYHA II-IV (<i>N</i> = 3,152) EF ≤40% | Losartan (50 mg QD) or Captopril (50 mg TID) | 48 wks | Losartan was not superior to Captopril in improving survival, but was significantly better tolerated. A subgroup analysis of ELITE II found a greater risk of death when Losartan was used in addition to β-blockers |
| Val-Heft ¹⁷⁰ | NYHA II-IV (<i>N</i> = 5,010) EF < 40% | Valsartan 160 mg bid or placebo bid | 23 mos | There was no difference in mortality between the two groups. In patients previously receiving both ACEI and a β-blocker (<i>N</i> = 1,610) the risk of death was increased with the addition of Valsartan |
| CHARM ¹⁷² Alternative | NYHA II-IV (<i>N</i> = 2,028) EF ≤40% | Candesartan (32 mg) vs. placebo. | 34 mos | 23% reduction in CV mortality or HF hospitalization favoring the Candesartan group. More side effects in the Candesartan group (hypotension, hyperkalemia, inc SCr vs placebo |
| CHARM ¹⁷³ Added | NYHA II-IV (<i>N</i> = 2,548) EF ≤40% | Candesartan (32 mg) + ACEI vs placebo | 41 mos | 15% risk reduction in CV mortality or HF admissions compared to placebo. However more side effects in the candesartan group (hypotension, hyperkalemia, increased SCr) vs placebo |
| CHARM ¹⁷⁴ Preserved | NYHA II-IV (<i>N</i> = 3,032) EF>40% | Candesartan (32 mg) vs placebo | 37 mos | Composite endpoint failed to reach significance. More side effects in the Candesartan group (hypotension, hyperkalemia, increased SCr) vs placebo |
| CHARM ¹⁷⁵ Overall | NYHA II-IV (<i>N</i> = 7,599) | Candesartan (32 mg) vs placebo | 38 mos | There was no overall difference in primary outcome of all cause death. |

ACEI, angiotensin converting enzyme inhibitor; EF, Ejection fraction; QOL, quality of life.

were titrated to a maximal dose of 50 mg three times daily (*n* = 310). For the primary study end point, a sustained increase in renal function decline, the two drugs performed identically with 10.5% of subjects in each group having a >0.3 mg/dL rise in SrCr. Similarly, functional ability increases were equal in both groups, and only 5.7% of both groups were hospitalized for worsening HF. An unexpected finding was a nonsignificant trend toward more deaths from all-causes in the captopril group (*n* = 32, 8.7%) compared with losartan (*n* = 17; 4.8%). Also, more subjects discontinued captopril than losartan because of adverse effects (20.8% vs. 12.2%). In particular, 3.8% of patients on captopril stopped the drug because of cough compared with none of those on losartan.

Several limitations of this study should be noted: (a) by design, the patients were all elderly; (b) 40% of the subjects were taking other vasodilators as a confounding variable; and (c) the primary end point was renal function changes, not hospitalization or death. Nonetheless, the study provided evidence that losartan is at least as effective as the reference ACE inhibitor (captopril) and that patients with HF have equal or fewer side effects with losartan, especially less cough.

The follow-up ELITE II Trial was specifically designed to test the hypothesis that losartan is superior to captopril in terms

of reduction in mortality and morbidity in patients 60 years of age or older.¹⁶⁸ Inclusion criteria and the dosages of losartan and captopril were identical to the first ELITE Trial. By enrolling a larger number of subjects (*N* = 3,162), it was powered to assess the primary endpoint of all-cause mortality. The intent was to continue the study until a combined total of 510 deaths occurred between the two treatment groups. After a mean follow-up of 1.5 years, no significance difference was seen in all-cause mortality (17.7% losartan vs. 15.9% captopril), sudden death (9% vs. 7.3%), or all-cause mortality plus hospitalization (47.7% vs. 44.9%) between the two treatment groups. Although ARB treatment was not clinically superior to ACE-inhibitor therapy, it was better tolerated with a withdrawal rate of 9.4%, as compared with 14.5% with ACE-inhibitor therapy (*p* = 0.001). Specifically, significantly fewer patients experienced cough with the ARB.

In the Randomized Evaluation of Strategies for Left Ventricular Dysfunction (RESOLVD)¹⁶⁹ study, 768 subjects were randomized to receive enalapril (up to 20 mg/day), candesartan (up to 16 mg/day), or a combination of both drugs added to diuretics, digoxin, or both for an average of 43 weeks. Inclusion criteria included NYHA class II–IV HF, LVEF <40%, and a 6-minute walking distance <500 meters. As in the ELITE trials,

all the subjects were ACE inhibitor-naïve. The combination of candesartan and enalapril was more beneficial for preventing left ventricular dilation and suppressing neurohormonal activation than either candesartan or enalapril alone. No differences were found among any of the three treatment groups in either hospitalization or mortality rates. Although not powered as a mortality trial, mortality rates were higher in the subjects receiving candesartan alone (6.1%) or candesartan combined with enalapril (8.7%) than in the group that received enalapril alone (3.7%).

The Val-HeFT trial was a double-blind, placebo-controlled study to measure the morbidity and mortality in NYHA class II–IV HF patients given valsartan.¹⁷⁰ In contrast to the ELITE and RESOLVD studies, 93% of subjects were already taking an ACE inhibitor at the time of randomization, 35% were taking a β -blocker, and 30% were taking both drugs. Patients were randomized to receive valsartan ($n = 2,511$) or placebo ($n = 2,499$) twice daily. The starting dose of valsartan was 40 mg BID, which was then titrated up to 160 mg BID by doubling the dose every 2 weeks. The target dose was achieved in 84% of patients taking the active drug. After a mean follow-up of 23 months (range, 0 to 38 months), no significant difference was observed in all-cause mortality between the valsartan group (19.7%) and the control group (19.4%). The combined end point of mortality and morbidity (including hospitalization from HF, cardiac arrest with resuscitation, and need for IV support) was significantly reduced among patients receiving valsartan (723 events, 28.8%) as compared to those receiving placebo (801 events, 32.1%), a 13% reduction ($p = 0.009$). Adverse events were low, leading to discontinuation of valsartan in 9.9% of subjects compared with 7.2% with placebo. Dizziness, hypotension, and renal impairment all occurred more frequently in those treated with valsartan.

Subgroup analysis of the VAL-HeFT study data raises interesting questions. For example, the observed reduction in the combined end point of morbidity and mortality was most pronounced in the small subgroup of only 226 patients (7% of the total study population) not receiving an ACE inhibitor compared with patients on the combination of an ACE inhibitor and valsartan. Further *post hoc* analysis found that within the 35% of subjects ($n = 1,610$) taking the combination of an ACE inhibitor and a β -blocker at baseline, the addition of valsartan as a third drug was associated with a trend toward increased morbidity and a statistically significant increase in the combined end point of mortality and morbidity. The clinical significance of these findings is unknown.

The overall study results suggest that a combination of valsartan and an ACE inhibitor reduces morbidity, but not mortality. Despite the intriguing results of the subgroup analysis, it is difficult to determine the independent effect of valsartan (i.e., when not combined with an ACE inhibitor or β -blocker) on morbidity or mortality. More worrisome is the implication that the three-drug combination of valsartan, an ACE inhibitor, and a β -blocker adversely affects morbidity and mortality.

Subsequent trials were designed to determine if a combination of neurohumoral agents provided additional benefits without causing harm in patients with HF. The Valsartan in Acute Myocardial Infarction Trial (VALIANT) of stable patients after MI with left-ventricular dysfunction was designed to test the hypothesis that valsartan alone and in combination with captopril (ACE inhibitors) will improve survival. In VALIANT,

70% of the patients were also receiving β -blockers. All-cause mortality, the primary endpoint, was identical in all groups. In addition, an increased rate of side effects was seen in the combination group. The failure to show a statistically significant difference in survival benefits could be owing to the trial design. The patients were simultaneously started on an ACE inhibitor and ARB, which is a variation from typical heart failure trials where patients are entered with an ACE inhibitor before the initiation of an ARB. Interestingly, among the subgroup of patients taking β -blockers, no evidence was found of harmful interaction with triple therapy.¹⁷¹ As a result of the VALIANT trial, the FDA approved the use of valsartan in patients at high risk following a heart attack and, in those with HF, the drug is no longer only reserved for ACE intolerant patients.

The most evidence addressing the efficacy and safety of ARB in HF comes from a series of three investigations known collectively as the Candesartan in Heart Failure Assessment of Reduction in Morbidity and Mortality (CHARM) trial. The individual components of the CHARM Program are (a) CHARM-Alternative, (b) CHARM-Added, and (c) CHARM-Preserved.^{172–174} All three investigations were randomized, double-blind, placebo-controlled trials that enrolled adult patients (>18 years of age) with at least a 4-week history of symptomatic (NYHA class II–IV) heart failure. Subjects randomized to candesartan were started on 4 mg and titrated to 32 mg once daily, as tolerated. Standard therapy (diuretics, β -blockers, digoxin, and spironolactone) was continued. For all three trials, the primary endpoint was the combined incidence of CV death, HF hospitalizations, or both. The differences in admission criteria and outcomes between the individual trials are discussed in the sections below.

CHARM-Alternative enrolled 2,028 subjects who met all of the inclusion criteria defined above plus two additional criteria: an EF of 40% or less (i.e., systolic dysfunction) and intolerance of ACE inhibitors (cough 72%, hypotension 13%, renal dysfunction 12%). Thus, subjects in this group received either an ARB alone ($n = 1,013$) or placebo ($n = 1,015$) without an ACE inhibitor, but this was not a head-to-head comparison of an ACE inhibitor with an ARB. After a median follow-up of 33.7 months, a 23% reduction was found in the primary outcome of CV death, hospital admission for HF, or both in the candesartan group (33%) compared with placebo (40%, $p = 0.004$). The overall incidence of drug discontinuations because of adverse events was not statistically different between candesartan (21%) and placebo (19%), but there were significantly more reports of symptomatic hypotension (3.7% vs. 0.9%), increased creatinine levels (6.1% vs. 2.7%), and hyperkalemia (1.9% vs. 0.3%) in those treated with candesartan. Of 39 patients who previously experienced angioedema on an ACE inhibitor, only 1 patient discontinued the study drug because of angioedema (Table 18-13). It is concluded that candesartan was generally well tolerated and reduced cardiovascular morbidity and mortality in patients with symptomatic chronic HF who were not receiving ACE inhibitors because of intolerance.

The CHARM-Added trial attempted to determine if the combination of an ACE-inhibitor plus an ARB offered any clinical advantages compared with an ACE inhibitor alone in patients with symptomatic HF with an ejection fraction of 40% or less (systolic dysfunction). Prior use of an ACE inhibitor was required for the 2,548 patients enrolled in this trial (96% were

Table 18-13 Adverse Events That Lead to Permanent Drug Discontinuation

| Trial | Outcomes | Candesartan | Placebo | P Value |

on an ACE inhibitor dose comparable to that used in previous mortality trials). At baseline, 55% of the patients were treated with β -blockers and 17% were on spironolactone. After a median follow-up of 41 months, 483 (38%) of patients in the combination ACE inhibitor-candesartan added group experienced the primary outcome of CV death, hospital admission for HF, or both compared with 538 (42%) in the placebo plus ACE inhibitor group (a 15% relative risk reduction, $p = 0.011$). Overall, the addition of candesartan to an ACE inhibitor and other usual HF treatments leads to a further clinically important reduction in CV events in patients with chronic systolic HF. It is interesting to compare the result of the CHARM-Added trial with those of the Val-HeFT trial. In Val-HeFT, 93% of the subjects receiving the ARB valsartan were concurrently receiving an ACE inhibitor. The combined end point of morbidity and mortality was significantly reduced with combination therapy in Val-HeFT, but not mortality alone. In that trial was also seen a trend toward more deaths in the small subgroup receiving the triple combination of a β -blocker with an ACE inhibitor and ARB. β -Blocker use had no adverse effect in CHARM-Added.

Limited information has been published regarding the role of ARB in patients with HF with preserved LV function (i.e., diastolic dysfunction). CHARM-Preserved enrolled 3,023 subjects who met the overall CHARM trial inclusion criteria defined previously plus one additional criterion: an EF of $>40\%$ (mean 54%). Thus, subjects would be classified as having symptomatic HF with normal (preserved) ejection fraction. They received either an ARB alone ($n = 1,514$) or placebo; only 20% of subjects in both groups were taking an ACE inhibitor at randomization, 56% were on a β -blocker, and 11%

were on spironolactone.¹⁷⁴ After a median follow-up of 36.6 months, a nonsignificant trend was noted toward reduction in the primary outcome of CV death or hospital admission for HF in the candesartan group (22%) compared with placebo (24.3%, $p = 0.118$). Cardiovascular deaths (170 vs. 170) and all cause mortality (244 vs. 237) were nearly identical in both groups, but the total number of hospitalizations for HF (402 vs. 566) was significantly reduced in the candesartan group ($p = 0.014$). Secondary outcomes consisting of composites of the primary outcomes plus MI, nonfatal stroke, and coronary revascularization also showed a nonsignificant trend in favor of candesartan. The most common side effects with candesartan were hypotension (2.4%), increase in creatinine (4.8%), and hyperkalemia (1.5%). Discontinuation because of an adverse event occurred in 17.8% of those treated with candesartan compared with 13.5% of placebo recipients ($p = 0.001$) (Table 18-13). Overall, the conclusion is that, in symptomatic patients with diastolic HF, no significant improvement in morbidity or mortality occurs with candesartan compared with placebo, other than a significant reduction in HF-related hospitalizations.

The combined results of all three CHARM components (CHARM-Added, CHARM-Alternative and CHARM-Preserved) were reported in the CHARM-Overall trial.¹⁷⁵ This composite analysis evaluates the benefits of candesartan in symptomatic patients with HF, regardless of left ventricular systolic function. Overall, 3,803 patients were assigned to candesartan and 3,796 to placebo. A different primary endpoint was chosen for the CHARM-Overall analysis: all-cause death. Although the combined results failed to detect a clinically significant reduction in all-cause death between candesartan and placebo (9% reduction; $p = 0.32$), significant reductions were seen in CV death (12%), hospital admission for HF (21%), and combined CV death or hospital admission for HF (the primary end point for the individual trials—16%).

The results of the CHARM trial further reinforce the conclusion that ARB can reduce morbidity and mortality in symptomatic patients with systolic HF, and they can be safely used in patients who are intolerant to ACE. Combination therapy (ACE inhibitor plus ARB) with concomitant use of β -blockers appears to be beneficial and safe, as long as patients are closely monitored for adverse effects. For symptomatic patients with HF with normal ejection fraction (diastolic dysfunction), addition of an ARB may be beneficial in reducing hospitalizations; however, the study did not show improved survival.

Based on this information, it is considered that the ARBs cause less cough than ACE-inhibitors and provide survival benefits in systolic HF. Because of his prior use of large doses of lisinopril with no evidence of hypotension, M.Y. should be able to tolerate valsartan (40 mg BID). He should be evaluated in 2 weeks for resolution of his cough. (See Chapter 13, Essential Hypertension, for further information on the mechanisms of action, metabolism, and dosing of ARB.)

Other ACE Inhibitor and Angiotensin Receptor Blocker Side Effects HYPERKALEMIA

21. Based on the data in Question 19, are there other side effects of M.Y.'s medications that need special monitoring? Will changing from lisinopril to valsartan reduce the risk of these side effects?

The ACE inhibitors, ARB, and β -blockers all have the potential to raise serum potassium concentrations via indirect aldosterone inhibition and other neurohormonal actions.^{176,177} For most patients, the magnitude of increase in serum potassium concentration from ACE inhibitors and ARB alone is relatively small, but the risk for developing hyperkalemia is greater if the patient has compromised renal function or advanced HF. Combination therapy of an ACE or ARB with potassium supplements, potassium-sparing diuretics, or β -blockers further accentuates the risk of hyperkalemia, regardless of the sequence of initiation of the individual drugs.

Of greater concern, several case reports and case series have reported hyperkalemia and hospitalizations induced by spironolactone in patients with HF. This became more evident as prescribing patterns for spironolactone dramatically changed after publication of the RALES study.¹⁷⁸ Not only was there a significant increase in the number of prescriptions for spironolactone for patients with HF, but doses higher than recommended by the clinical trials were often used, especially in patients with evidence of preexisting renal dysfunction. In addition, evidence indicated inadequate monitoring of serum potassium, renal function, and concomitant drug therapy (also see Question 14). Although concurrent use of a potassium-losing diuretic (e.g., a thiazide or loop diuretic) may counteract potassium retention from spironolactone or other drugs (ACE inhibitors, ARB, β -blockers), it is nearly impossible to predict who will develop hypo- or hyperkalemia or remain normokalemic.^{179,180} Thus, each patient must be assessed individually for personal response to various drug combinations and whether there is a need for potassium supplements or a reduction in their doses (Table 18-14).

M.Y. is concurrently receiving lisinopril and spironolactone. His potassium levels are elevated at 5.0 mEq/L. M.Y.'s dietary potassium intake should be assessed. He should be asked about the use of NSAID as well as herbal remedies, because herbs can be a hidden source of dietary potassium. He is on a combination of lisinopril and spironolactone. If M.Y. had to continue on lisinopril, his dose of lisinopril or spironolactone could be reduced. With the substitution of valsartan for lisinopril, the spironolactone dose will still most likely have to be lowered because ARB can also cause hyperkalemia by blocking the effects of aldosterone in the kidney identical to ACE inhibitors. On the other hand, if he were switched to a hydralazine–nitrate combination in place of the lisinopril, his spironolactone should be continued for its disease-modifying effects.

ANGIOEDEMA

22. R.S. is a 65-year-old black man who recently experienced new onset HF with presenting symptoms of shortness of breath while playing golf and persistent edema. Until then, he was healthy and taking no medications. He does not smoke, has no history of asthma or COPD, and no known allergies to food or drugs. R.S. has been taking furosemide 40 mg QD and lisinopril 10 mg QD for 3 weeks. He woke up this morning complaining of difficult breathing, neck swelling, and a “thick tongue.” Could this be an abnormal presentation of HF? What drug side effect may be occurring?

Angioedema (angioneurotic edema) is a severe, potentially life-threatening complication of ACE inhibitor

Table 18-14 Management of Hyperkalemia in Patients Treated With Aldosterone Antagonists

Guidelines for Minimizing the Risk of Hyperkalemia

1. Impaired renal function is a risk factor for hyperkalemia during treatment with aldosterone antagonists. The risk of hyperkalemia increases progressively when serum creatinine >1.6 mg/dL.* In elderly patients or others with low muscle mass in whom serum creatinine does not accurately reflect glomerular filtration rate, determination that glomerular filtration rate of creatinine clearance >30 mL per min is recommended.
2. Aldosterone antagonists should not be administered to patients with baseline serum potassium >5.0 mEq/L.
3. An initial dose of spironolactone 12.5 mg or eplerenone 25 mg is recommended, after which the dose may be increased to spironolactone 25 mg or eplerenone 50 mg if appropriate.
4. The risk of hyperkalemia is increased with concomitant use of higher doses of ACEI (captopril ≥ 75 mg daily; enalapril or lisinopril ≥ 10 mg daily).
5. Nonsteroidal anti-inflammatory drugs and cyclo-oxygenase-2 inhibitors should be avoided.
6. Potassium supplements should be discontinued or reduced.
7. Close monitoring of serum potassium is required; potassium levels and renal function should be checked in 3 days and at 1 week after initiation of therapy and at least monthly for the first 3 months.
8. Diarrhea or other causes of dehydration should be addressed emergently.

*Although the entry criteria for the trials of aldosterone antagonists included creatinine >2.5 mg/dL, most patients had creatinine much lower; in one trial, 95% of patients had creatinine of ≤ 1.7 mg/dL.

ACEI, angiotensin converting enzyme inhibitor.

treatment.^{181–183} Characterized by facial and neck swelling with obstruction to air flow by laryngeal and bronchial edema, this reaction resembles anaphylaxis. These symptoms are compatible with those being experienced by R.S. The mechanism of ACE inhibitor induction of angioedema is unknown, but is thought to be related to hypersensitivity to accumulated vasodilating kinins, similar to the cough reaction.

Some, but not all persons with drug-induced angioedema have a history of familial angioedema associated with a genetic defect in their complement system. ACE inhibitors are contraindicated in this population. In one series of case reports, 22% of the reported angioedema reactions occurred within 1 month of starting therapy, with the remaining 77% arising from several months to years later.¹⁸² Blacks and females may have a higher prevalence. The timing of when R.S. started lisinopril and his being black are consistent with the diagnosis of drug-induced angioedema.

Of concern is the observation that ACE inhibitor-induced angioedema is often misdiagnosed.¹⁸³ Several of the patients described in one series had been re-treated with the same or a different ACE inhibitor followed by a repeat episode of angioedema. It is prudent to avoid all ACE inhibitors in any patient with a history of angioedema from any cause.

Because the mechanism of ACE-induced angioedema is speculated to be caused by kinin accumulation, changing R.S.

to an ARB might be an option.¹⁸⁴ Several case reports, however, have implicated candesartan, losartan, and valsartan as possible causative agents of angioedema.^{181,185–188} In some cases, the subjects had previously experienced angioedema with an ACE inhibitor (indicating possible cross reactivity), whereas others were ACE inhibitor-naïve. One author claims that ARB-induced angioedema usually manifests after long-term administration (late onset) and with milder symptoms compared with relatively earlier onset with ACE inhibitors. Similar findings showing a low, but potential risk for ARB-induced angioedema in patients who are ACE inhibitor intolerant comes from the CHARM-Alternative trial.¹⁷² Of 39 patients with a history of angioedema while taking an ACE inhibitor, 3 developed angioedema on candesartan, although only 1 of the 3 actually discontinued taking candesartan. This and other conclusions regarding risk will require further observation. For now, it is prudent not to start an ARB in R.S. Options include starting a β -blocker or hydralazine-isosorbide. As discussed in Case 51, hydralazine-isosorbide might be a better choice for a black man.

EFFECTS OF ACE INHIBITORS AND ARB ON KIDNEY FUNCTION

23. B.N., a 62-year-old man, was admitted to the cardiac care unit (CCU) with a 2-day history of breathlessness causing him to sleep upright in a chair and preventing him from walking to the bathroom. Physical examination showed 4+ pitting edema of the legs, scrotal and sacral edema, and significantly distended neck veins. He had a CVP of 26 mm Hg (normal, 12). Laboratory values were: urine output, <20 mL/hour; BUN, 48 mg/dL; SCr, 2.0 mg/dL; and serum potassium, 3.2 mEq/L. Home medications, faithfully administered by his wife, included furosemide 240 mg/day, KCl 40 mEq/day, hydralazine 75 mg Q 6 hr, isosorbide dinitrate 20 mg Q 6 hr, metoprolol XL 200 mg QD, and digoxin 0.125 mg QD. He was not taking either an ACE inhibitor or an ARB because of a history of fluctuating SCr while taking both of these drugs.

A 100-mg IV bolus of furosemide in the ED resulted in a urine output of 600 mL over 2 hours, but with a subsequent rise of his BUN to 65 mg/dL. Finally, B.N. began captopril 12.5 mg TID. Within 2 days, B.N.'s breathing improved, his CVP was down to 16 mm Hg, and he was diuresing briskly. He was discharged 1 week later with mild SOB on exertion, 2+ ankle edema, and a reduction of his BUN to 28 mg/dL. Discharge medications included furosemide 120 mg/day, lisinopril 10 mg QD, metoprolol XL 200 mg QD, and digoxin 0.125 mg QD.

B.N. had a BUN of 48 mg/dL and a SCr of 2.0 mg/dL when he started captopril. The BUN first went up while he was in the hospital and later declined. Explain why these changes occurred. Are ACE inhibitors contraindicated in patients with renal insufficiency? Can they be used safely with diuretics in patients with renal insufficiency?

[SI units: BUN, 17.14, 23.21, and 9.99 mmol/L, respectively; SCr, 176.9 mmol/L; K, 3.2 mmol/L]

Note: The CVP measurement in this question refers to central venous pressure, an indicator of the right ventricular filling pressure or preload. (Refer to Chapter 21, Shock, and Question 48 in this chapter for a more thorough review of this and other cardiac hemodynamic monitoring parameters.) His initial CVP of 26 mm Hg was significantly elevated and the repeat value

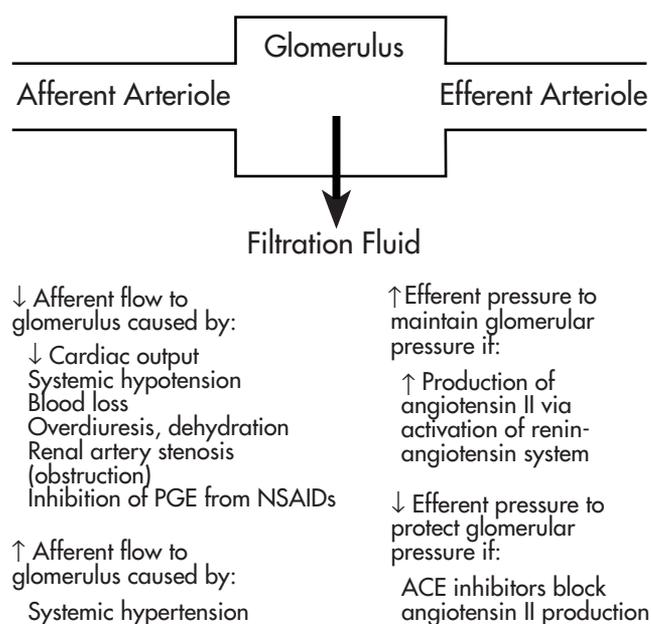

FIGURE 18-7 Factors affecting renal blood flow. Glomerular filtration is optimal when adequate hydrostatic pressure is maintained in the glomerulus. Governing factors include the blood flow rate to the glomerulus and the balance of afferent and efferent arteriole dilation/constriction. ACE, angiotensin-converting enzyme; NSAIDs, non-steroidal anti-inflammatory drugs; PGE, prostaglandin E.

of 16 mm Hg was returning toward the normal value of 12 mm Hg.

The effects of ACE inhibitors and ARB on RBF and renal function are complex. As seen in Figure 18-7, glomerular filtration is optimal when intraglomerular pressure is maintained at normal pressures. The balance between afferent flow into the glomerulus and efferent flow exiting the glomerulus determines the intraglomerular pressure. A drop in afferent flow or pressure occurring as a result of hypotension, volume loss (e.g., blood loss or overdiuresis), hypoalbuminemia, decreased CO (e.g., HF), or obstructive lesions such as renal artery stenosis all can significantly lower intraglomerular pressure and lead to impaired renal function. Similarly, long-standing hypertension can damage glomerular basement membrane capillaries and cause renal insufficiency.

In the case of low-pressure or low-flow states, the RAAS is activated to maintain intraglomerular pressure. A key factor in preserving glomerular pressure is *efferent vasoconstriction* mediated by angiotensin II. Increased efferent pressure helps to maintain intraglomerular pressure by impeding blood flow out of the glomerulus. When patients with low-pressure states are given ACE inhibitors or ARB, the protective mechanism of efferent vasoconstriction is inhibited and renal function can significantly and rapidly worsen. Conversely, in patients with hypertensive renal disease, glomerular function actually can improve because the ACE inhibitors lower afferent pressure and help protect the kidney. ACE inhibitors slow the progression of diabetic nephropathy and reduce proteinuria independent of their effect on BP (see Chapter 50, Diabetes Mellitus).

Patients with HF present with a complex picture. By decreasing afterload and preload, hope is that CO will improve after ACE inhibitor or ARB therapy, thus preserving or even enhancing RBF. If, however, starting ACE inhibitors or ARB

leads to a rapid decrease in systemic BP that is not followed by an increase in CO, worsening renal function may ensue. It is impossible to predict which event will occur. Therefore, ACE inhibitor or ARB therapy needs to be started with low doses and careful monitoring of the BP and renal function should occur as dosages are increased. Diuretics are not contraindicated, but the diuretic dosage may need to be reduced to avoid volume depletion and hypotension.

These events are illustrated in B.N. When he was first diuresed, the BUN increased. Addition of an ACE inhibitor in combination with furosemide led to significant clinical benefit, including improved renal function. For now, B.N. is tolerating captopril and is obtaining the desired effect. Because he has a history of fluctuating renal function with both ACE inhibitors and ARB, he will require frequent observation. NSAID also must be used with caution because inhibition of vasodilating renal prostaglandins in patients with low afferent flow can worsen renal function (see Question 26).

LESS COMMON SIDE EFFECTS

24. What side effects other than those experienced by M.Y., B.N., and R.J. have been associated with ACE inhibitors? Are any of these unique to a specific drug, or are they all a class effect?

Captopril initially was associated with significant side effects. Of subjects, 10% to 15% of those in early studies developed skin eruptions or fever. These effects were associated primarily with higher dosage (average, 683 mg/day) and are found less frequently when the drug is used in smaller doses (<225 mg/day). Skin reactions may be edematous, urticarial, erythematous, maculopapular, or morbilliform in nature. That the rashes disappear with continued therapy in some patients suggests that they may be caused by potentiation of kinin-mediated skin reactions. Transient loss of taste (ageusia), reflex tachycardia, and hypotension also are common at high doses. None of these have occurred in any of the patients in our cases.

Proteinuria, a transient rise in serum creatinine (independent of the mechanisms described in the previous question), agranulocytosis, neutropenia, and fatal pancytopenia¹⁸⁹ also have been attributed to captopril therapy. The marrow toxicity is minimized by keeping total daily doses below 75 mg and avoiding the use of captopril in patients with advanced renal failure.

A theoretic advantage of the newer ACE inhibitors over captopril is the lack of a sulfhydryl group as part of their clinical structures. The sulfhydryl group (also found in penicillamine) is associated with a high incidence of rashes, ageusia, proteinuria, and neutropenia. The clinical significance of this difference remains to be determined, especially because captopril side effects have declined since clinicians have begun to prescribe lower doses.

All ACE inhibitors are contraindicated in pregnancy.¹⁹⁰ Teratogenic effects, including kidney failure and skull and facial deformities, have been reported when taken during the second or third trimester of pregnancy. Risk of use during the first trimester is less clear.

One report described captopril-induced inhibition of digoxin renal clearance, resulting in increased serum digoxin levels.¹⁹¹ As with many of the other digoxin interactions described elsewhere in this chapter, the clinical significance of this interaction remains to be defined.

ACE Inhibitors in Asymptomatic Patients

25. W.N. is a 44-year-old white man diagnosed with an acute MI by ECG and cardiac enzyme changes 3 days ago following an episode of acute chest pain while driving his car. He was immediately treated with IV NTG and morphine and underwent thrombolytic therapy with streptokinase within 2 hours of the pain. He has no history of angina or hypertension, but was told that he had a high cholesterol level during a screening program 2 years ago. He was taking no medication before this event. Of note, W.N. has a strong family history of coronary artery disease and hyperlipidemia.

His hospital course has been unremarkable with only one episode of mild chest pain responding to sublingual NTG. BP is 130/83 mm Hg, pulse is 80 beats/minute with a regular rhythm. He has no ectopy, no complaints of SOB, and no evidence of edema. Lung sounds are normal as is his chest radiograph. All laboratory values have been normal except for an elevated creatine kinase (CK) and lactate dehydrogenase (LDH) on the day of admission, a total cholesterol of 245 mg/dL, and an LDL of 180 mg/dL. In preparation for discharge, he underwent repeat angiography and EF was measured by radionuclide ventriculography. His coronary arteries remain patent, but the EF is 35%. Discharge medications include aspirin 82 mg QD and simvastatin 5 mg OHS.

W.N. has evidence of left ventricular dysfunction based on his EF but is asymptomatic. How would his HF be staged in the ACC/AHA scheme and in the NYHA classification? Should he be started on a diuretic, an ACE inhibitor, or both?

This case exemplifies a patient with asymptomatic (NYHA symptom class I) left ventricular dysfunction. An EF <40% indicates systolic dysfunction following heart muscle damage from the MI. These abnormalities would place him in stage B by the ACC/AHA guidelines (Table 18-3). An absence of edema, SOB, or other clinical symptoms argues against the need for diuretics. The ACC/AHA guidelines, however, recommend starting patients such as W.N. on both an ACE inhibitor and a β -blocker.^{6,7}

Evidence supports the use of ACE inhibitors in asymptomatic patients with early left ventricular dysfunction to slow the progression of the disease, possibly by retarding the remodeling effects on the cardiac muscle that may otherwise occur. This is best exemplified by the results of the SOLVD prevention trial.¹⁹¹ Subjects enrolled in this study were actually a subset of the original SOLVD study,¹³⁴ with one important difference; although they had an EF of <35%, they were asymptomatic at the time of entry into the trial. Patients received either placebo (2,117 subjects) or enalapril titrated to a dose of 2.5 to 20 mg/day (2,111 subjects). Diuretics and all other active drugs were withheld unless the patient developed overt HF. Over the 37.4-month study period, 20% of the enalapril-treated patients developed symptoms of HF compared with 30% in the placebo group, a 37% reduction. The treatment group also had fewer hospitalizations for anginal symptoms and MI. As would be expected in this relatively low-risk population, mortality rates were low (14.9%–15.8%) and not statistically significant between the two groups. The death rates became more divergent in favor of enalapril late in the study as more patients developed overt HF. Because W.N. has no contraindications to using an ACE inhibitor, he should be started on 5 mg/day of enalapril and titrated to a target dose of 20 to 40 mg/day.

The reader also is referred to Chapter 17, Myocardial Infarction, for a related discussion on the early use of ACE inhibitors in symptomatic patients following infarction (CONSENSUS II, SAVE, and AIRE trials).^{192–194} Chapter 17 also thoroughly reviews the rationale for prescribing β -blockers in all patients following an MI unless contraindications exist. W.N.'s physician chose not to use propranolol because of his low LVEF. This is an acceptable choice, but metoprolol should be substituted for propranolol. Metoprolol reduces morbidity and mortality following MI and also slows the onset and progression of HF.

DRUG INTERACTION OF ACE INHIBITORS WITH ASPIRIN

26. Enalapril was started in B.N. for the reasons stated in Question 25. Aspirin, 82 mg QD, has also been prescribed. What are the potential benefits and risks of this combination of drugs?

Aspirin is recommended for all patients following MI (see Chapter 18, Myocardial Infarction). Several studies suggest that aspirin may attenuate the beneficial effects of ACE inhibitors when given together in patients with HF and other cardiovascular disorders. The proposed mechanism is inhibition of prostaglandin formation by aspirin, thus counteracting the clinical effects of ACE inhibitors that rely in part on prostaglandins to elicit their positive hemodynamic effects. The significance of this interaction is still being debated. Two comprehensive reviews of this interaction appear elsewhere.^{195,196} Both conclude that insufficient data exist to firmly establish or refute an adverse clinical outcome associated with the combination of aspirin and an ACE inhibitor in patients with HF.

The most widely quoted supporting evidence for a possible adverse effect comes from subgroup analysis of the SOLVD trial that compared enalapril with placebo in patients with HF.¹³⁴ Overall, patients taking aspirin and other antiplatelet drugs at the beginning of the trial had lower mortality rates. Antiplatelet drugs, however, were of benefit primarily only in patients taking placebo as opposed to those taking enalapril. The combination of enalapril with an antiplatelet agent was not associated with a mortality benefit, whereas combining placebo with aspirin was associated with reduced mortality (0.68 hazard ratio; 95% confidence interval [CI], 0.58 to 0.80). Similarly, the mortality benefit of enalapril was primarily in patients not taking antiplatelet agents (0.77 hazard ratio; 95% CI, 0.657–0.87) as opposed to those who were taking them (1.10 hazard ratio; 95% CI, 0.3 to 1.30). These observations are limited because it was a *post hoc*, retrospective analysis of the study data, and continuing use of antiplatelet drugs at the end of the trial was not assessed. Four other small published trials and two abstracts indicate a possible interaction with aspirin, all of which are limited by small sample sizes, short duration of assessment (single dose to several weeks), and reliance on hemodynamic measures, such as peripheral vascular resistance and pulmonary responses, instead of HF clinical outcomes.^{195,196} In these trials, the interaction appeared to be limited to aspirin and various ACE inhibitors, but was not observed between aspirin and losartan or between ticlopidine (which does not affect prostaglandins) and ACE inhibitors. Conversely, one published trial and two abstracts cited in the review articles suggest no interaction between aspirin or ifetroban (a thromboxane A₂ receptor antagonist) and an ACE inhibitor.^{195,196} In the largest of these trials (317 patients with ischemic cardiomyopathy and LVEF <35%) and with the longest follow-up (mean, 5.7 years),

use of aspirin was associated with lowered risk of mortality and hospital readmission, regardless of whether an ACE inhibitor was prescribed. Recently, a retrospective review of aspirin use in combination with ACE inhibitors in patients with HF resulted in no adverse effects seen in regard to the long-term survival.¹⁹⁷ Dosages of aspirin (100 mg/day or less) interact little with ACE inhibitors, whereas higher dosages may carry a greater risk. Some patients, for unknown reasons, are more susceptible to the interaction.

The 2005 ACC/AHA practice guidelines claim that many physicians believe that the data supporting the existence of an adverse interaction between aspirin and ACE inhibitors are not sufficiently compelling to justify altering the current practice of prescribing the two agents together.⁷ In contrast, other physicians would consider the withdrawal of aspirin (because no data indicate it can reduce the risk of ischemic events in patients with HF) or use of an alternative antiplatelet agent, such as clopidogrel, which does not interact with ACE inhibitors and which may have superior effects in preventing ischemic events.⁷

Use of β -Blockers in Systolic Heart Failure

27. Returning to the case of AJ: After 3 days of furosemide and an ACE inhibitor, A.J.'s PND has resolved, but he still has difficulty walking without SOB and fatigue. His lower extremity edema has significantly reduced. His current BP is 145/90 mm Hg, pulse 82 beats/minute and his weight has dropped to 73 kg after diuresis. Repeat laboratory measurements include the following: Na, 139 mEq/L; K, 4.3 mEq/L; Cl, 98 mEq/L; CO₂, 27 mEq/L; BUN, 27 mg/dL; and SrCr, 0.6 mg/dL. The medical team has decided to discharge the patient soon. You recommend that the patient should be initiated on a β -blocker before discharge. What is your rationale?

The physiologic basis for the use of β -blockers in HF and the changes observed in receptor sensitivity is described in greater detail in the pathophysiology section of this chapter.^{20–25} β -blockers have been evaluated during randomized clinical trials in more than 20,000 patients with varying degrees of systolic HF.^{20–25} Five meta-analyses have arrived at the same conclusions: the use of β -blockers is associated with a consistent 30% reduction in mortality and a 40% reduction in hospitalizations in patients with HF.^{198–202}

The 2005 ACC/AHA guidelines state that because bisoprolol, metoprolol succinate and carvedilol have been shown to reduce both HF symptoms and mortality, they should be prescribed to all patients with stable HF caused by left ventricular systolic dysfunction, unless there is a contraindication to their use or the patient is unable to tolerate treatment with a β -blocker.⁷ They should be a part of the primary treatment plan, usually in combination with a diuretic and an ACE inhibitor. Contrary to the practice of some clinicians, the use of β -blocker drugs should not be delayed until the patient is found to be resistant to treatment with other drugs. Another common misperception is that patients who have mild symptoms or who appear clinically stable on diuretics and ACE inhibitors (with or without digoxin) do not require additional treatment. Even these patients should receive a β -blocker to slow the rate of disease progression and reduce the risk of sudden death. Similarly, patients need not be taking high doses of ACE

inhibitors before being considered for treatment with a β -blocker. To the contrary, in patients taking a low dose of an ACE inhibitor, the addition of a β -blocker produces a greater reduction in symptoms and in the risk of death than an increase in the dose of an ACE inhibitor. Only those clinically unstable patients who are hospitalized in an intensive care unit, require IV positive inotropic support, have severe fluid overload or depletion, have symptomatic bradycardia or advanced heart block (unless treated with a pacemaker), or a history of poorly controlled reactive airways disease should not be given a β -blocker.⁵ Recent data, show that β -blockers can be initiated prior to discharge in patients hospitalized for HF, if they did not require IV inotropic support for their HF exacerbation.²⁰³

Based on all these factors, there is no question that A.J. should be started on a β -blocker. Treatment with a β -blocker should be initiated at low doses, followed by gradual increments in dose every 1 to 2 weeks as tolerated by the patient. Transient bradycardia, hypotension, and fatigue are not uncommon during the first 24 to 48 hours when β -blockers are first started or during subsequent incremental increases in dosage. Thus, patients should be monitored daily for changes in vital signs (pulse and blood pressure) and symptoms during this up-titration period. Bradycardia, heart block, and hypotension can be asymptomatic and require no intervention other than instructing the patient not to arise too quickly from a lying position to avoid postural changes. If either of these complications is accompanied by dizziness, lightheadedness, or blurred vision, it may be necessary to reduce the dose β -blocker, the ACE inhibitor, or both or to slow the up titration. The sense of lassitude generally resolves within several weeks without other intervention, but may be a reason to slow up-titration of the dose and rarely to reduce the dose or discontinue therapy. In patients where benefits are especially apparent, but bradycardia or heart block is a concern, insertion of a pacemaker should be considered.

Because initiation of β -blocker therapy can also cause fluid retention, patients should be instructed to weigh themselves daily and to adjust concomitantly administered diuretics as appropriate. Conversely, diuretic doses should be decreased temporarily when patients become hypotensive or their BUN begins to rise. Planned increments in the dose of a β -blocker should be delayed until any side effects observed with lower doses are tolerable or absent. In clinical trials, up to 85% of patients are able to tolerate short- and long-term treatment with these drugs and achieve the maximal planned dose.

Metoprolol and Bisoprolol

28. Metoprolol succinate (12.5 mg) is prescribed for A.J. Is this a good choice of agent and starting dose? What other similar drugs have been used to treat HF?

Several clinical trials substantiate the clinical benefits of metoprolol, a relatively selective β_1 -receptor blocker, in HF.^{204–207} By blocking β_1 receptors in the myocardium, HR, contractility, and CO are reduced at rest and during exercise, without a compensatory increase in peripheral vascular resistance. The relative sparing of β -receptors in the peripheral vasculature and lungs reduces vasoconstrictive and bronchospastic complications. In contrast to bucindolol and carvedilol, metoprolol has been shown to upregulate myocardial β_2 -receptors.²⁰

In the Metoprolol in Dilated Cardiomyopathy (MDC) study, 383 patients with nonischemic dilated cardiomyopathy and class II or III HF were randomized to immediate-release metoprolol tartrate (initiated at 5 mg BID and titrated to 100–150 mg/day in divided doses) or placebo.²⁰⁷ All were continued on standard therapy with diuretics, vasodilators, and digoxin as tolerated. In this trial was noted a nonstatistically significant trend toward both decreased mortality and listing for heart transplantation in the active treatment group.

Of greater interest is the Metoprolol CR/XL Randomized Intervention Trial in Heart Failure (MERIT HF) in which a 35% reduction in all-causes of mortality was observed with sustained-release metoprolol succinate.²⁰⁷ In this trial, 3,991 patients, most of whom had either NYHA class II or III HF, were randomized to metoprolol succinate controlled-release/extended-release (CR/XL) or placebo. The starting dose of metoprolol was 12.5 to 25 mg/day, which was gradually increased every 2 weeks to the target dose of 200 mg/day. Conventional therapy with diuretics, ACE inhibitors, and digoxin was continued. At the end of the trial, 64% of subjects assigned to active drug had reached the target dose. Planned follow-up was for 2 years, but the study was halted prematurely because of a statistically significant decrease in all-cause mortality in the metoprolol arm. Specifically, there was a 34% reduction in total mortality with a 38% decrease in cardiovascular mortality, a 41% reduction in sudden death, and a 49% reduction from death owing to worsening HF. All-cause hospitalization was also reduced by 18% and hospitalization for worsening HF was decreased by 35%. Although the number of subjects was too small to detect a statistical difference, patients with severe (class IV) HF seemed to benefit as well. Up to 15% of subjects had clinical worsening of HF, even at low metoprolol doses.

Encouraging results have also been seen with another relative β_1 -selective drug, bisoprolol fumarate (Zebeta).^{208,209} In the first Cardiac Insufficiency Bisoprolol Study (CIBIS I), 641 subjects with moderate to severe HF were randomized to placebo or bisoprolol (starting dose, 1.25 mg/day; maximal dose, 5 mg/day) added to conventional therapy for an average of 23 months.²⁰⁸ A statistically significant reduction in HF-associated hospitalization with the active drug and a nonsignificant trend toward reduced mortality were noted. In the larger Second Cardiac Insufficiency Bisoprolol Study (CIBIS II), reduction in both hospitalization and mortality in the bisoprolol-treated group was significant.²⁰⁹ A total of 2,647 patients were included in the second trial and doses were increased to as high as 10 mg/day. The study was stopped prematurely (average follow-up, 1.3 years) because of a 34% reduction in total mortality with bisoprolol. *Post hoc* analysis showed a 44% reduction in sudden death and a 26% reduction in death owing to worsening HF. As in the MERIT HF study, the number of patients with severe (class IV) HF was inadequate to determine the value of β -blocker therapy in this population.

Two dosage forms of metoprolol are marketed: metoprolol succinate extended release (Toprol XL) and metoprolol tartrate immediate release (Lopressor and generic). Only metoprolol succinate form is approved for HF in the United States, indicated for patients with mild to moderate (NYHA class II or III) HF of ischemic, hypertensive, or cardiomyopathic origin. The starting dose of 12.5 mg of metoprolol succinate prescribed for A.J. is consistent with the clinical trials and manufacturer's

package insert labeling. If the initial dose is tolerated, the dose can be doubled to 25 mg OD for an additional 2 to 4 weeks. The final target dose is 150 to 200 mg daily either as 100 mg BID or 200 mg QD.

An alternative is to use immediate release metoprolol tartrate (Lopressor) even though it is not approved for this indication in the United States. Following a test dose of 12.5 mg, the starting dose is 12.5 mg twice daily for 1 or 2 weeks. The smallest immediate release tablet size available is 25 mg tablets, therefore during the initial 1 to 2 weeks of treatment, the tablets will have to be split in half to achieve the appropriate dosing regimen. Since the only FDA-approved dosage form of metoprolol is the extended release succinate product, it is prescribed in most cases. Maintenance with a generic form of the immediate release product is less expensive, however, than the brand name extended release product.

When choosing among the various formulations of metoprolol, pharmacokinetic and bioavailability differences should be considered.^{204,205} Metoprolol succinate available as 25, 50, 100, and 200 mg tablets. Each tablet contains many tiny metoprolol succinate pellets, each individually coated with an ethylcellulose polymeric membrane. GI fluid penetrates the membrane of each pellet and slowly dissolves the drug. The saturated metoprolol solution is then released at a constant rate over 20 hours, consistent with zero-order kinetics, and provides β -blockade for 24 hours. The extended release formulation retains its release characteristics even if the scored tablet is divided in half, but it should not be crushed or chewed.

Absorption of metoprolol tartrate is approximately 95%, but the bioavailability metoprolol succinate is only 50% because of extensive first pass metabolism.^{204,205} Systemic bioavailability of the extended release product is even lower, averaging 70% of the immediate release preparation. This is likely because of the greater opportunity for first pass metabolism during slow absorption and less opportunity to saturate the metabolizing enzyme system. Because metoprolol succinate has consistently reduced bioavailability compared with immediate release metoprolol tartrate there is a concern that if a patient is receiving metoprolol tartrate and is switched to the same dosage of the succinate formulation, the patient, in effect, will receive approximately 25% less drug. Clinical studies, however, indicate that the β -blocking effects are similar, perhaps because of the prolonged action of the succinate product. The higher peak concentrations obtained with the metoprolol tartrate formulation is accompanied by a greater potential for hypotension compared with metoprolol succinate. Because the dosage has to be titrated to an individual patient, these differences may not be relevant unless the patient is being switched from one product to the other.

Metoprolol has several metabolic routes of elimination that can affect dosing and drug interactions. The major routes of elimination are via α -hydroxylation, O-demethylation, and N-dealkylation.^{204,205} A smaller portion is metabolized by cytochrome P450 2D6, and drugs that inhibit metabolism of that isoenzyme may affect the drug's plasma levels. Approximately 10% of patients are poor metabolizers, resulting in higher drug plasma concentrations in these patients.

A.J. should be advised that clinical response to metoprolol is usually delayed and may require 2 to 3 months to become apparent. Even if symptoms do not abate, long-term treatment

should be maintained to reduce the risk of major clinical events. Abrupt withdrawal of treatment with a β -blocker can lead to clinical deterioration and should be avoided.²¹⁰

Bisoprolol is FDA approved for treatment of HF. Dosage size limitations, however, restrict clinical use of this drug. For example, the starting dose of bisoprolol is 1.25 mg/day, whereas the smallest commercially available dose is a 5-mg scored tablet. Attempting to break the tablet into quarters is not practical.

Carvedilol

29. Might carvedilol be a better alternative than metoprolol for A.J.? What would be an appropriate dose and dosing schedule?

Carvedilol (Coreg), a mixed α - and β -blocker, was the first drug of this class to obtain FDA approval for management of HF.²¹¹ It might also have antioxidant effects to protect against loss of cardiac myocytes and to act as a scavenger of oxygen-free radicals that could potentiate myocardial necrosis. The correlation of these findings to clinical outcome is unknown.

Two pivotal studies support the use of carvedilol. The first was the U.S. Carvedilol Heart Failure Study.^{212–216} Subjects were almost equally divided between class II and III HF and all had an EF of 35% or less (mean, 22%) despite diuretics (95%), digoxin (90%), and an ACE inhibitor (95%). Subjects with a major myocardial event in the previous 3 months were excluded. After an initial open-label period when all patients received 6.25 mg twice daily of carvedilol, subjects were stratified based on severity of their HF and then randomized to either placebo ($n = 398$) or carvedilol ($n = 690$). The maximal dose given was 50 mg twice daily. Using an intention-to-treat analysis, 7.8% of deaths occurred in the placebo group over an average of 6.5 months compared with only 3.2% in the active treatment group, a statistically significant 65% risk reduction ($p = 0.001$). Most notably, death caused by progressive HF or sudden cardiac death was reduced. The patients treated with carvedilol also had fewer HF-related hospitalizations (19.6% vs. 14.1%). The most common side effect with carvedilol was dizziness, usually during the first few days of therapy, but more patients discontinued placebo for worsening HF or side effects than with carvedilol.

In the Australia/New Zealand Carvedilol Study, 415 patients with chronic, stable HF (NYHA class II or III, 85% taking concurrent ACE inhibitors, and average EF of 28%) were randomized to placebo ($n = 208$) or carvedilol ($n = 207$).²¹⁷ As in the U.S. study, those with severe symptoms were excluded, although 88% had a history of MI. Maintenance doses in subjects randomized to carvedilol ranged from 6.25 to 25 mg twice daily with an average follow-up of 19 months.

After 12 months, EF had increased by 5.3% and heart size was reduced in the carvedilol group compared with essentially no change in the placebo group. No differences between groups were found in treadmill exercise time, change in NYHA classification, or HF symptom scores, however. Only 26% of patients on carvedilol and 28% of those receiving placebo had improved NYHA symptom scores, with most (58% in both groups) having neither improvement nor worsening of symptoms.

At 19 months, the frequency of episodes of worsening HF was similar in the two groups. Total deaths in the carvedilol group ($n = 20$) were less than the placebo group ($n = 26$), but most of the difference in mortality was attributed to

noncardiovascular deaths. No difference was found in death from HF, MI, or total cardiac-related deaths. On a more positive note, there were 68% fewer hospital admissions for HF in the carvedilol group ($n = 23$) than for the placebo group ($n = 33$). Overall, these findings could be interpreted as being evidence for safety with either no overall benefit or a modest improvement with carvedilol.

The original FDA-approved indication for carvedilol was to reduce the progression of HF in patients with mild to moderate (NYHA class II or III) HF of ischemic or cardiomyopathic origin and whose conditions had been stabilized with other drugs (digitalis, diuretics, and ACE inhibitors). In keeping with the exclusion of patients with an unstable condition from the study protocols, carvedilol was not approved for use in NYHA class IV decompensated cardiac failure. As discussed in the next case, later studies confirmed the value of carvedilol in NYHA class IV HF. As with any β -blocker, carvedilol is not recommended for use in patients with asthma, COPD, or poorly controlled diabetes.

The starting dose of carvedilol is 3.125 mg twice daily, with a doubling of the dose every 2 weeks as needed or tolerated up to a maximum of 25 mg twice daily in patients weighing <85 kg and 50 mg twice daily in larger patients. Hypotension, bradycardia, fluid retention, and worsening HF symptoms can occur in the first few weeks of therapy, necessitating additional diuretics, a reduction of dose, or discontinuation of carvedilol. Taking carvedilol with food slows the rate of absorption and reduces the incidence of orthostatic hypotension, which occurs in up to 10% of patients taking the drug. Carvedilol phosphate (Coreg CR), a once-a-day extended release form of carvedilol, is market in the United States for hypertension treatment, but currently it has not been studied in patients with HF.

Because carvedilol is metabolized by the cytochrome P450 2D6 (CYP2D6) enzyme system, several potential drug interactions should be considered.^{211,218} The best documented are inhibition of metabolism by cimetidine and decreased carvedilol serum concentrations when taken with rifampin. Known inhibitors of CYP2D6 (e.g., quinidine, fluoxetine, paroxetine, and propafenone) can increase the risk of toxicity (especially hypotension), but substantiating data are lacking. Carvedilol has also been reported to increase serum digoxin levels by 15% by an unknown mechanism. Other sources of intrasubject variability in carvedilol response may be caused by differences in the extent or rate of absorption, stereospecific metabolism of the two isomers of the drug (carvedilol is a racemic mixture of S[-] and R[+] isomers), and impaired metabolism in the 10% of the population who lack CYP2D6 activity.²¹⁸

Choice of β -Blocker: Metoprolol vs. Carvedilol

No consensus exists regarding the relative superiority of one β -blocker over another. Although the additional properties of carvedilol (e.g., α_1 blockade and antioxidant properties) provide a theoretical basis for selecting carvedilol over metoprolol succinate or bisoprolol, the data from clinical trials provide conflicting conclusions. In one small head-to-head trial, carvedilol showed greater improvement in hemodynamic response during peak exercise and EF but no difference in symptom scores or exercise tolerance.²¹⁹ Another reported 30 patients with HF with persistent symptoms, despite at least 1 year of combined metoprolol and an ACE inhibitor.²²⁰ They were enrolled in an open-label, parallel trial and randomized either to

continue with metoprolol (mean dose, 142 ± 44 mg/day) or to cross over to maximal tolerated doses of carvedilol (mean dose, 74 ± 23 mg/day). At the end of 12 months, patients randomized to carvedilol showed a greater decrease in end-diastolic volume, more improvement in LVEF, and fewer ectopic beats on electrocardiogram. No significant difference was seen in symptoms or quality of life measures nor a negative effect of carvedilol on peak oxygen consumption.

One meta-analysis attempted a comparison of carvedilol with metoprolol using the surrogate end point of LVEF as a comparator.²²¹ Nineteen randomized, placebo or concurrent controlled trials involving a total of 2,184 patients with impaired LVEF were reviewed. Patients received a mean dose of 58 mg of carvedilol or the equivalent of 162 mg of extended release metoprolol. Combined results from the placebo controlled trials showed that both drugs significantly improved LVEF, with carvedilol found to be significantly better than metoprolol. Carvedilol increased LVEF 0.065% more than placebo compared with a 0.038% increase with metoprolol. These differences persisted when patients with ischemic HF were compared with those with nonischemic cardiomyopathy. In head-to-head comparative trials, carvedilol once again raised LVEF greater than metoprolol. No apparent difference, however, was noted between the two drugs based on improvements in symptom scores or exercise tolerance. The authors caution that EF is only one of several end points to be measured, and the question of superiority in clinical outcomes, such as mortality rates, remains unanswered.

Since publication of the meta-analysis, the results of the COMET trial became available.²²² In this multicenter, double-blind trial, 3,029 patients with NYHA class II–IV HF and EF $<35\%$ were randomized to either carvedilol (target dose, 25 mg BID) or metoprolol tartrate (target dose, 50 mg BID). Diuretics and ACE inhibitors were continued in all subjects if tolerated. All-cause mortality was 34% for carvedilol compared with 40% with metoprolol ($p = 0.0017$). The composite end point of mortality or all-cause hospital admissions was not statistically significant between groups (74% carvedilol and 76% metoprolol). One criticism of this study was use of metoprolol tartrate instead of the FDA-approved metoprolol succinate form. Comparable doses between the two study groups has been questioned because the target dose of carvedilol was 25 mg twice daily compared with the target dose of metoprolol tartrate being 50 mg twice daily. Also, the trial used resting HR to determine comparable β -blockade among study groups rather than HR response to exercise. Exercise-induced HR changes are considered a better indicator of β -blockade.

Side effects and patient tolerance is similar between β -blockers in most trials. One investigator observed that carvedilol caused more hypotension and dizziness than metoprolol or bisoprolol, possibly owing to α_1 blockade or more rapid absorption.²²³ Thus, metoprolol or bisoprolol may be preferred in patients with hypotension or with complaints of dizziness. Conversely, carvedilol may be preferred in patients with inadequately controlled hypertension.

Whether carvedilol is a better choice for A.J. cannot be definitely answered. A starting dosage of 3.125 mg twice daily of carvedilol could be used in place of metoprolol. Because of lower cost, it is decided to continue metoprolol and reserve use of carvedilol only if A.J. has difficulty tolerating metoprolol.

β -Blockers in Severe Heart Failure

30. The original clinical trials of β -blockers excluded patients with severe (NYHA class IV) HF at the time of randomization. For this reason the FDA limited the original approval of carvedilol for use in class II–III HF. Likewise, the ACC/AHA guidelines strongly support the use of β -blockers in class II–III HF, but are less definitive about severe HF. What evidence supports or refutes the use of β -blockers in class IV HF?

The COPERNICUS study demonstrated clear benefit of carvedilol without undue side effects in patients with severe HF.²²⁴ Conversely, the BEST Trial reported unimpressive results with another drug, bucindolol.²²⁵ Details of these two trials are provided below.

The COPERNICUS study was a double-blind, placebo-controlled trial assessing the clinical benefits and risks of carvedilol in 2,289 patients with advanced HF (NYHA class IIIB/IV).²²⁴ Subjects had symptoms of HF at rest or with minimal exertion and an EF of 25% or less despite diuretics (99%), ACE inhibitors (97%), and digoxin (67%). Excluded were subjects who required intensive care, had significant fluid retention, were hypotensive, had evidence of renal insufficiency, or were receiving IV vasodilators or positive inotrope drugs. The starting dose of carvedilol or matching placebo was 3.125 mg twice daily, which was increased every 2 weeks to a target dose of 25 mg twice daily. Of those in the carvedilol group, 65% achieved the target dose, with the mean dose being 37 mg at the end of the first 4 months of the trial. The trial was discontinued prematurely after an average patient follow-up of 10.4 months because of a significant survival benefit from carvedilol. There were 130 deaths in the carvedilol group and 190 deaths in the placebo group, with a 35% decrease in the risk of death with carvedilol (95% CI, 19% to 48%; $p = 0.0014$). For the secondary end point of all deaths and hospitalizations combined, there were 425 events with carvedilol compared with 507 in the placebo group, a 24% decrease (95% CI, 13% to 33%, $p = 0.001$). Fewer patients in the carvedilol group (14.8%) than in the placebo group (18.5%) withdrew because of adverse effects at 1 year ($p = 0.02$).

A concern over using β -blockers in patients with class IV HF is that they may be predisposed to more side effects during the initiation phase of therapy. One study retrospectively analyzed the outcomes of 63 patients who were NYHA class IV compared with 167 subjects ranging from class I through III.²²⁶ Adverse events occurred more frequently in the class IV patients (43%) than in the other subjects (24%; $p = 0.0001$) and more often resulted in permanent withdrawal of the drug (25% vs. 13%). Conversely, more class IV patients treated with carvedilol improved by more than one NYHA functional class than in the less symptomatic group (59% vs. 37%). A reanalysis of the COPERNICUS study data did not confirm a higher rate of intolerance over the first 8 to 12 weeks of carvedilol compared with placebo.²²⁷ No difference was found between carvedilol and placebo in terms of death, hospitalizations, or withdrawal because of adverse events during the first 8 weeks of therapy.

The BEST Investigators failed to demonstrate that bucindolol, a nonselective β -blocker with vasodilator properties, improved overall survival in patients with NYHA class III–IV HF.²²⁵ They randomized 2,708 patients to receive either bucindolol or placebo.

Although the active drug yielded a significant decrease in norepinephrine levels and improvement in left ventricular function, the study was stopped prematurely because of the low probability of showing any significant cardiovascular mortality benefit over placebo. A possible explanation is that bucindolol has intrinsic sympathomimetic activity (ISA) that may counteract some of the benefits of β -blockade. Moreover, subgroup analysis suggested that black patients might have fared worse with bucindolol, raising concerns that β -blockers may not be effective therapy for black patients with advanced HF (see Question 52 for further discussion of possible racial differences in drug response).

It can be concluded that β -blockers are safe and effective in class IV HF. The best data exist for carvedilol. Bucindolol should be avoided.

Digitalis Glycosides

Preparation for Treatment

31. Over the next 2 months, A.J.'s dose of extended release metoprolol was gradually increased to 200 mg/day. Other than some episodes of fatigue and lassitude during each dosage increment, he tolerated metoprolol well and, over time, he was more functional than he had been for several years. Over the ensuing 9 months, however, he again had several episodes of HF symptoms that necessitated a gradual increase of his furosemide dose to 120 mg in the morning and 40 mg in the mid afternoon. A potassium supplement was reinstated because his potassium levels were beginning to fluctuate as his furosemide was increased.

Today, his wife brought him to the ED because she could no longer care for him. His chief complaints are weakness, dizziness, extreme SOB, and inability to get out of bed. His weight has increased to 80 kg. His BP is considerably lower at 128/83 mm Hg, with a postural drop to 112/75 mm Hg. Abnormal laboratory values on admission are BUN, 31 mg/dL and serum creatinine, 1.4 mg/dL. His K is 4.3 mEq/dL. An ECG shows a HR of 98 beats/minute, normal sinus rhythm (NSR), and LVH, but no T-wave changes or ectopy. His valsartan is held for 24 hours while he is diuresed with several 40- and 80-mg boluses of IV furosemide and maintained on an NTG drip titrated to lower his pulmonary capillary wedge pressure (PCWP) below 15 and to keep his systolic BP >100 mm Hg. The plan is to reinstitute valsartan and to begin a digitalis glycoside. Is digitalis indicated for A.J.? What digitalis preparation should be prescribed?

Digoxin is the only digitalis glycoside marketed in the United States. The arguments for and against its use are presented in Question 15. Most of the recommendations stem from the Digoxin Intervention Group trial that found, in patients who had primarily class II or III symptoms, treatment with digoxin for 2 to 5 years had little effect on mortality, but modestly reduced the combined risk of death and hospitalization.¹³⁹

As presented earlier in this chapter, the ACC/AHA guidelines indicate that patients with HF are unlikely to benefit from the addition of digoxin in stage A or stage B HF. In these patients, digoxin can be used for symptom management, only if they are treated with drug therapy shown to prolong survival (ACE inhibitors and β -blockers) or have not responded adequately to appropriate therapy. In those patients who are stage C HF with current or prior symptoms of HF, despite receiving optimal doses of ACE inhibitors or β -blockers, digoxin can

be beneficial to reduce HF hospitalizations. A.J. fits the latter situation and, thus, is a logical candidate for adding digoxin as a fourth therapeutic intervention.

Digoxin is also prescribed routinely in patients with HF and concurrent chronic AF, but β -blockers may be more effective in controlling the ventricular response, especially during exercise. Digoxin should be avoided if the patient has significant sinus or atrioventricular block, unless the block is treated with a permanent pacemaker. It should be used cautiously in patients taking other drugs that can depress sinus or AV nodal function (e.g., amiodarone or β -blockers), although patients usually will tolerate this combination.

When A.J. entered the hospital today, he initially required IV furosemide and a NTG drip, but quickly stabilized. Digoxin is not indicated as primary therapy for stabilization of patients with acutely decompensated HF. Such patients should first receive appropriate treatment, including IV medications, as A.J. did. Thereafter, digoxin can be started as part of a long-term treatment strategy.

Gender Differences in Response to Digoxin

32. If A.J. had been a woman, would it have made any difference in the determination to prescribe digoxin?

Until recently, nothing indicated that gender-based differences existed relative to prognosis of HF or in response to drugs such as digoxin. Two interesting reports published in 2002 sparked interest in this topic. The first was an extension of the Framingham Heart Study.²²⁸ It was observed that over the past five decades the incidence of HF has been constant in men, but has declined by 31% to 40% in women during the interval of the last decade. During the last decade, survival rates for patients with HF have improved in both men and women, although the mortality rate is higher in men than in women. The more aggressive use of drugs, such as ACE inhibitors and β -blockers, are likely contributors to the improved outcomes. The authors speculate that the differences observed between men and women may reflect different causes of HF. For example, hypertension is a predominate cause of HF in women, whereas more men have prior MI as a contributor to HF.

The second report (a review article) more directly addresses the question of use of digoxin in men compared with women.²²⁹ As previously discussed, the DIG Trial reported approximately equal mortality rates (35%) in subjects with HF randomized to either placebo or digoxin, while continuing usual doses of diuretics and ACE inhibitors.¹³⁹ A 12% reduction was found in the rate of death from HF in the digoxin group, but a corresponding increase was noted in death presumed to be caused by arrhythmias. On retrospective *post hoc* analysis of the DIG study data, it was discovered that women overall had a lower death rate from any cause than men (31.0% vs. 36.1%, $p = 0.001$), an absolute difference of 5.8%.²²⁹ The death rate was also lower among women in the placebo group than among men taking placebo (28.9% vs. 36.9%; $p = <0.001$). Likewise, women taking digoxin had a lower death rate than men taking active drug (33.1% vs. 35.2%), but this difference was not statistically different ($p = 0.034$). A surprising finding was that women taking digoxin had a higher death rate than women taking placebo (33.1% vs. 28.9%), whereas death rates in men were essentially equal in both groups. The authors speculate that a possible mechanism for the increased

risk of death among women taking digoxin is an interaction between hormone-replacement therapy and digoxin. Progesterone might increase serum digoxin levels by inhibiting PGP, thus reducing digoxin renal tubular excretion. Consistent with this hypothesis, digoxin serum concentrations after 1 month of digoxin intervention were higher in women than in men. The study investigators, however, did not routinely gather data on estrogen and hormone replacement therapy or consistently measure serum digoxin levels later in the trial. Because these observations are a retrospective, it is difficult to establish the clinical significance of the data and it is premature to argue against the use of digoxin in women. Nonetheless, it is prudent to recommend keeping serum digoxin concentrations <1.0 to 1.2 ng/mL in all patients and avoid hormone replacement therapy in women with HF when taking digoxin.

Loading Dose

33. Can A.J. be started with a properly chosen digoxin maintenance dose, or is a loading (digitalizing) dose necessary?

Loading doses of digoxin are rarely necessary. Slow initiation of therapy with maintenance doses of digoxin in lieu of a loading dose is the method of choice for ambulatory or non-acutely ill patients with normal renal function. Even in the acute care setting, no indication exists for loading doses of digoxin for HF alone. The exception might be if the patient has AF and it is desired to control ventricular response as quickly as possible. Even then, alternative drugs are likely to be used (see Chapter 19, Cardiac Arrhythmias).

The main disadvantage to foregoing a loading dose is the delay in accumulating maximal body glycoside stores and achieving therapeutic effects. The time required to achieve 92% of plateau concentrations of a drug administered on a routine basis at maintenance doses is four half-lives. Thus, a patient with normal renal function ($t_{1/2} = 1.8$ days) given a daily dose of 0.125 mg of digoxin will reach peak serum concentration in approximately 7 days. If the same patient was anephric ($t_{1/2} = 4.4$ days), it would take 17 days to reach plateau, and the maximal concentration would be approximately 2.5 times that of a healthy subject receiving the same dose. Slow digitalization can delay the onset of toxic signs, which could go unrecognized if the patient is at home.

A further argument against using a loading dose is that no evidence indicates that achieving a steady-state serum concentration quicker has any demonstrable effect on the time to reduction of HF symptoms. In any case, the full benefit of digoxin can be delayed for several days or weeks. Thus, clinicians should avoid rapidly increasing doses. For example, it would be improper to increase a patient's maintenance dose after 3 days if no clinical improvement had been observed.

A.J. is in moderate to severe HF and in the hospital. It could be argued that a loading dose of digoxin would be safe in this environment and possibly could speed his therapeutic response. Nonetheless, the logical decision is to forgo a loading dose.

Serum Level Interpretation

34. What is the target serum digoxin concentration for A.J.?

The target therapeutic serum digoxin concentration is 0.5 to 1.2 ng/mL (mean, 0.75 ng/mL). Many older textbooks, review articles, and clinical trials contain the prior standard of

targeting serum digoxin concentrations in the range of 0.8 to 2 ng/mL, or a mean of 1.0 ng/mL. These older recommendations should be abandoned. Factors driving this change are information suggesting that the positive hemodynamic and neurohormonal effects of digoxin can be achieved at lower serum concentrations than those needed to induce a positive inotropic effect (see digoxin pharmacology discussion in the introduction to this chapter),^{63–66} use of digoxin as an adjunct to vasodilator therapy instead of as the primary intervention, and allowance for possible overestimation of the patient's renal function because of fluctuating control of HF. The correlation between serum digoxin concentrations and both therapeutic and toxic responses is considered in greater detail in Questions 36 and 41.

Maintenance Dose

35. As predicted, A.J.'s renal function improved with diuresis and IV NTG. The latest values are BUN 24 mg/dL and SrCr 0.8 mg/dL. Determine the appropriate maintenance dose of digoxin for A.J.

The usual maintenance doses of digoxin have traditionally ranged from 0.125 to 0.25 mg/day. With the increased emphasis on targeting lower serum concentrations, more patients are now empirically started at 0.125 mg/day. For example, because A.J. is of average body size, is relatively young, and has essentially normal kidney function, he empirically would have been started on a 0.25 mg/day maintenance dose in the past. A 0.125 mg dose, however, is recommended for him now. It is safest to start with a conservative dose and assess his needs after 1 to 2 weeks.

In all cases, smaller doses of digoxin are given to patients with impaired excretion rates (e.g., those with renal failure, older patients) or small-framed individuals. For example, a totally anuric patient may receive only 0.0625 mg/day. Because of the long half-life of digoxin, all patients are given a single daily dose.

Monitoring Parameters

36. Even after hearing the dosing principles from the prior question, A.J.'s physician decided to use a dose of 0.25 mg/day of digoxin because of his experience in using this size dose previously. How should A.J.'s digitalis therapy be monitored? How useful are digoxin serum levels in monitoring therapy?

No clear therapeutic end point exists for digitalis therapy. Nonspecific ECG changes (ST depression, T-wave abnormalities, and shortening of the QT interval) correlate poorly with both toxic and therapeutic effects of the drug.^{70,71} Although digoxin serum levels are readily available from most clinical laboratories, no "therapeutic level" and corresponding "toxic level" are clearly defined.

SERUM LEVEL INTERPRETATION

As stated in Question 34, a serum digoxin concentration of 0.5 to 1.2 ng/mL is now considered therapeutic because the beneficial parasympathomimetic and antiadrenergic effects of digoxin occur at lower concentrations than the inotropic effects. Interestingly, a recent *post hoc* analysis of the DIG trial, found that patients with serum digoxin concentrations in the range of 0.5 to 0.8 ng/mL had lower all-cause mor-

tality rates than patients with serum concentrations in either the 0.9 to 1.1 ng/mL range or >1.2 ng/mL.^{139,230} A few patients, especially if they are hypokalemic or hypomagnesemic, will manifest apparent signs of toxicity when serum digoxin concentrations are <1 ng/mL. At the other extreme, some patients tolerate concentrations >2 ng/mL with no signs of overt toxicity. Such overlap between therapeutic concentrations and toxic levels limits the absolute value of serum level monitoring. Serum levels can be used as a guide in confirming suspected toxicity or in explaining a poor therapeutic response, but clinical evaluation ultimately remains the best therapeutic guide. The correlation between serum digoxin concentrations and toxicity is considered in greater detail in Questions 40 and 41.

When interpreting serum digoxin concentrations, several procedural problems and patient characteristics must be taken into account. These include proper timing of sample collection, the effects of exercise, assay technique, and possible interfering substances in the patient's blood. A discussion of each of these factors follows.

Following an IV bolus dose or a single oral dose, equilibration of digoxin between the blood and tissues is slow. Because of this slow distribution phase, digoxin levels obtained <6 to 8 hours after the last dose may be falsely elevated and can lead to a misdiagnosis of toxicity. At steady-state, serum digoxin concentrations obtained after 24 hours (just before the next dose) are considered most reliable. If a sample is obtained randomly, the time of the last dose should be carefully noted.

Physical activity increases binding of digoxin to skeletal muscle; by redistributing the drug from the blood to the tissue, a lower serum digoxin concentration is observed clinically.^{231,232} The more strenuous the exertion, the greater the magnitude of effect, but even daily physical activity such as walking can decrease serum digoxin concentration by 20%.²³² About 2 hours of supine rest is required for digoxin levels to reach a new steady state. Clinical consequences of this effect might be the inappropriate increase of the digoxin dose or failure to identify a possible toxic level in a patient who has a serum digoxin concentration drawn soon after walking briskly.

Similarly, a patient's serum digoxin concentration while hospitalized might be higher than serum digoxin concentrations drawn as an outpatient even with no dose change. Conversely, other investigators concluded that the changes in concentration are not clinically relevant during everyday activity and may only be of consequence for patients with large differences in activity level in the time surrounding the blood draws.²³² Obviously, a standardized approach to obtaining blood samples is key to the appropriate interpretation of results.

INTERFERING SUBSTANCES

In addition to the poor correlation between serum digoxin concentration and clinical effect, both endogenous and exogenous substances can interfere with the digoxin assay.^{233–235} This is complicated further by the existence of a multitude of different assay methodologies, some of which are more susceptible to interference than others. All the tests are based on immunoassay methods, including several different fluorescence polarization immunoassays (FPIA) and numerous enzymatic immunoassays (e.g., CLIA, EMIT, TDx, ACA, Dimension,

Vitros). Among potential interfering substances are drugs and chemicals that are structurally similar to digoxin, most notably spironolactone (Aldactone) and possibly corticosteroids. Some assays also measure accumulated digoxin metabolites.

Other patient groups may have “endogenous digoxin-like substances” in their blood, imparting falsely elevated measurements. This has been noted in patients with liver and renal failure, pregnant women, and 2- to 6-day-old neonates. One theory is that excess bile acids in neonates or patients with liver or renal disease may be a source of endogenous digoxin-like immunoreactive factors (DLIF).²³⁴ In some of these patient groups, “digoxin levels” as high as 1.4 ng/mL may be measured without any drug in the body. It is essential that anyone monitoring serum digoxin levels be aware of which assay method is used in their laboratory and which substances can cause false-positive reactions. New turbidimetric digoxin immunoassays and enzyme-linked immunosorbent digoxin assays minimize or almost completely eliminate interference with DLIF, but enzymatic immunoassays are still the standard assay being utilized in United States laboratories.^{233,235,236}

CLINICAL EVALUATION

As with diuretic and vasodilator therapy, clinical monitoring is the key to evaluating adequacy of digitalis therapy. As A.J. begins to improve, he should have less dyspnea and complain less of orthopnea; venous distention and signs of pulmonary congestion will diminish or disappear; diuresis (monitored through urinary output and weight loss) may increase; and a lower HR may be observed.

The response of HR to digitalis can vary, depending on the patient’s underlying disease. Because bradycardia and other rhythm disturbances may herald digitalis toxicity, daily monitoring of A.J.’s pulse will be needed until his condition and serum levels have reached a steady state. Ankle edema does not mobilize immediately and is a poor therapeutic end point.

Factors That Alter Response

37. Two days after starting digoxin, A.J. was discharged from the hospital. After 10 days of taking a maintenance dose of 0.25 mg, a serum digoxin level drawn during a clinic visit was reported as 0.7 ng/mL. Examination in the outpatient clinic 2 weeks later revealed that he had become progressively dyspneic and edematous since his hospital discharge. A STAT serum digoxin level at 3:00 PM was 0.3 ng/mL. A.J. had taken his dose of digoxin at 8:00 AM. What are some possible explanations for these events?

As stated in Question 36, serum levels are not an absolute guide to monitoring digitalis therapy. A partial explanation could be that A.J. was not at rest when the level was drawn. In this case, however, the low serum levels are accompanied by deterioration in his symptoms of HF. We can be reasonably sure of the accuracy of the serum concentration measured because it was drawn at the appropriate time (i.e., at steady-state and at least 6 to 8 hours after the last dose); further, A.J.’s responses were compatible with the reported level. When doubt exists regarding the reliability of a reported serum level, the laboratory should be asked to repeat the measurement.

PATIENT ADHERENCE

Patient adherence must definitely be taken into consideration whenever unusually low serum concentrations are seen or a lack of response to any drug is observed. It is possible that A.J. is a poor complier because his BP was high on his first admission. He should be carefully counseled on the proper use of his medications.

DIGOXIN MALABSORPTION

Alteration of the absorption of digoxin following oral administration in patients with malabsorption syndromes has been studied.^{68,237} Finding was that poor and erratic absorption occurred in patients with malabsorption states, such as sprue, short-bowel syndrome, and rapid intestinal transit. Other investigators studied digoxin bioavailability in malabsorptive states, but could not demonstrate large differences in serum digoxin concentrations. They found, however, that use of more soluble forms, such as liquid-filled capsules, gave a better absorption than conventional tablets.⁶⁸

ALTERED DIGOXIN METABOLISM

Altered digoxin metabolism is rare, but should be considered. One patient has been described who required 1 to 2 mg digoxin daily to control AF.²³⁸ Although her half-life for digoxin was the same as control subjects, she metabolized a greater percentage of digoxin to cardioinactive products. Also, as previously stated, approximately 10% of persons given digoxin demonstrate bacterially mediated metabolism of the drug in the GI tract leading to a relative decrease in total amount of drug absorbed.⁷⁵

Concurrent metabolic abnormalities can decrease the responsiveness of digoxin. Hypocalcemia has been reported to cause a digitalis resistance, as has hyperthyroidism^{70,71} (see Chapter 49, Thyroid Disorders).

Drug Interactions QUINIDINE

38. As suspected, A.J. was found to have been taking his digoxin only sporadically. After being counseled on the importance of good adherence, he was restarted on 0.25 mg/day. He did well for the next 6 months until he noted the onset of palpitations, which were diagnosed by ECG as atrial fibrillation. A digoxin level drawn at that time was 1.2 ng/mL, but all other laboratory tests were normal. He began quinidine sulfate at a dosage of 200 mg QID with rapid resolution of the atrial fibrillation. Four days later, during a follow-up clinic visit, he was noted to have bradycardia with a pulse rate of 50 beats/minute. He also complained of nausea, dizziness, and weakness. His digoxin level was 2.0 ng/mL. What factors could be contributing to the apparent digitalis toxicity in A.J.?

In the past, quinidine and digoxin were frequently used adjunctively in the treatment of AF: digoxin to control ventricular response by decreasing AV node conduction, and quinidine to decrease atrial irritability. With the advent of newer drugs, this combination has largely fallen out of favor. Reports show that >90% of patients previously stabilized by digoxin who subsequently begin quinidine experience a 2- to 2.5-fold increase in serum digoxin levels.^{239–241} The actual magnitude of effect is highly variable and may depend on the dose of quinidine

administered. Little change is seen with quinidine doses of <500 mg/day. Serum digoxin concentrations usually begin to rise within 24 hours of starting quinidine and reach a new steady state in about 5 days. Conversely, when quinidine is discontinued, digoxin concentrations return to prequinidine levels in about 5 days.

Several conflicting effects of quinidine on digoxin pharmacokinetics have been observed.^{71,74} The most consistent finding is a 40% to 50% decrease in total body clearance of digoxin; much of this change is accounted for by decreased renal clearance.

The nonrenal clearance of digoxin also is affected by quinidine as evidenced by up to a doubling of digoxin plasma levels after addition of quinidine in patients with chronic renal failure.^{242,243} A reduced volume of distribution has been observed in some individuals, but this is not a consistent finding. Digoxin's half-life does not change, probably because the changes in distribution and clearance tend to counterbalance each other. A unifying mechanism to explain all of these observations is the ability of quinidine to inhibit PGP-mediated drug transport in the kidney, intestine, and possibly the liver.^{71,73,74} Under usual conditions, digoxin enters the renal tubule via both glomerular filtration and renal tubular secretion, the latter mechanism being under the influence of PGP-mediated transport. Inhibition of PGP by quinidine in the kidney partially blocks the tubular secretion step, thus decreasing renal clearance of the digoxin. In the intestines, PGP facilitates active transport of absorbed digoxin back into the intestinal tract. The net effect of inhibition of gut PGP by quinidine is increased bioavailability of digoxin.

Digoxin is found in only small concentrations in the plasma, with most of the drug being distributed to lean body tissues (e.g., skeletal and cardiac muscle). Despite clear evidence that serum digoxin levels are increased with quinidine, much less is known about the importance of this interaction on the heart and the clinical effects that ensue. Because both of these drugs can individually cause GI intolerance (e.g., nausea, vomiting, diarrhea), AV block, and bradycardia, it is difficult to differentiate simple additive effects from a true drug interaction without measuring serum level changes. One 9-month study of hospital admissions for suspected digitalis toxicity observed that 50% of patients treated with the quinidine–digoxin combination had ECG evidence of digoxin toxicity compared with 5% of patients taking digoxin alone or in combination with verapamil or amiodarone.²⁴⁴ Conversely, many patients tolerate the increased serum levels of digoxin with no apparent adverse consequences.

Faced with the complexity of this interaction, it is difficult for the clinician to plan a course of action when using these two drugs together. It has been suggested that the dose of digoxin be reduced by 50% when adding quinidine. Although this might minimize bradycardia, ventricular tachyarrhythmias, and GI effects, it also can lead to a loss of desired neurohormonal or positive inotropic effects. A more rational approach is to use smaller doses of digoxin in all patients, whether or not they are taking quinidine. Then, when adding quinidine, patients can maintain their previous digoxin dose with careful clinical monitoring for undesirable side effects. If necessary, a serum digoxin level can be obtained after 5 to 7 days of concurrent therapy. If it exceeds 1.2 ng/mL, the dose can be decreased. Concentrations in excess of 2.0 ng/mL are a definite

cause for concern. A.J. should have his digoxin dose reduced to 0.125 mg QD.

Treatment of Supraventricular Arrhythmias in Heart Failure DIGOXIN DRUG INTERACTION WITH AMIODARONE AND PROPAFENONE

39. Quinidine was started in A.J. because of atrial fibrillation. What alternatives to quinidine and digoxin could be recommended for A.J.? What other potential drug interactions does this present?

Supraventricular arrhythmias are frequently encountered in HF because volume or pressure overload can cause atrial distention and irritability. Specifically, atrial fibrillation is present in 25% to 50% of patients with advanced HF, contributing to reduced exercise capacity, increased risk of pulmonary or systemic emboli, and worse long-term prognosis.^{6,245} As in any patient with these arrhythmias, drug therapy should be aimed at controlling ventricular rate and preventing thromboembolic events. Cardioversion to normal sinus rhythm is unlikely to be successful. Left ventricular function and clinical status frequently improve after controlling atrial fibrillation, however, whether or not normal sinus rhythm is restored.

Digoxin slows the ventricular response associated with atrial fibrillation and, thus, is a logical choice in patients with concurrent HF. A potential limiting factor is that digoxin's AV blocking properties are most evident at rest, but are less consistent during exercise. Hence, digoxin may be ineffective at controlling exercise-induced tachycardia that limits the patient's functional capacity. β -Blockers are more effective than digoxin during exercise.^{246–248} Propranolol or atenolol are the β -blockers of choice in patients without HF, but metoprolol is a better choice in those with HF because of its proved role in HF management. If digoxin, β -blockers, or both are ineffective, amiodarone is another useful alternative. Verapamil and diltiazem are not appropriate choices for rate control in patients with HF because of their negative inotropic effects.

The benefits of restoring sinus rhythm remain unclear (see Chapter 19, Cardiac Arrhythmias.) Most patients who are electrically cardioverted revert to atrial fibrillation in a short time. The use of most other antiarrhythmic agents (e.g., quinidine, procainamide, propafenone, and other class II antiarrhythmics), except amiodarone, is associated with worse prognosis because of proarrhythmic effects and should be avoided. Warfarin is required for patients with AF, but not for other patients with HF. Finally, atrioventricular nodal ablation may be needed if tachycardia or bothersome symptoms persist despite aggressive pharmacologic intervention.

A.J. developed AF while already taking a relatively high dose of digoxin (0.25 mg/day) and metoprolol. As discussed above, quinidine is not the best choice because of its drug interaction potential and side effects, most notably the potential to cause other life-threatening arrhythmias. One alternative is to discontinue quinidine, keep the digoxin dose at 0.25 mg QD, and continue metoprolol. If his AF-associated palpitations persist, amiodarone should be started. (See Chapter 19, Cardiac Arrhythmias, for dosing of amiodarone in supraventricular tachyarrhythmias.) Because amiodarone is also a PGP inhibitor with a documented ability to reduce digoxin clearance in a manner similar to that described with quinidine, A.J.'s digoxin dose will need to be lowered to 0.125 mg.^{71,73} The onset of the interaction may not be apparent for a prolonged time

because of the long half-life of amiodarone. As serum concentrations of amiodarone slowly increase, digoxin clearance and bioavailability will be changing simultaneously. The net effect may be easily overlooked, but can result in increased serum concentrations of 30% to 60%. Similarly, propafenone increases digoxin steady-state concentrations by 30% to 60% in a dose-dependent fashion over the range of 450 to 900 mg/day of propafenone.^{71,249}

Other Digoxin Drug Interactions

40. What other potential drug interactions with digoxin might affect A.J.'s therapy?

Two comprehensive reviews of cardiac glycoside drug interactions have been compiled.^{239,250} Since publication of these earlier reviews, a greater understanding of PGP-mediated drug interactions has evolved.^{73,74} A brief summary of all digoxin interactions is found in Table 18-15. Two of the better-documented interactions (quinidine and amiodarone) were discussed in the previous cases. Others drugs recently recognized

as raising digoxin serum concentrations through PGP inhibition include atorvastatin (increased intestinal absorption),²⁵¹ CCB (especially verapamil and diltiazem),²⁵² erythromycin and clarithromycin (reduced renal digoxin clearance),^{253,254} and cyclosporine. Conversely, rifampin²⁵⁵ and St. John's Wort²⁵⁶ reduce oral digoxin bioavailability and serum concentrations via induction of intestinal PGP. Mylanta is the only drug listed in Table 18-15 that A.J. was taking. He should be counseled to avoid antacids within 1 or 2 hours before or 1 hour after a dose of digoxin or to use a nonprescription histamine₂ receptor blocker.

Digitalis Toxicity

SIGNS AND SYMPTOMS

41. Digoxin was prescribed for Z.T., a 70-year-old man with mild HF. The label on his prescription bottle instructed him to take one tablet (0.25 mg) BID for 3 days, then one tablet daily thereafter. Ten days later Z.T. returned to the clinic complaining of extreme fatigue, anorexia, nausea, and a "funny" heart beat.

Table 18-15 Digoxin Drug Interactions^a

| Drug ^b | Effect |
|---|--|
| Drugs Lowering Serum Digoxin Concentration | |
| Antacids | ↓Bioavailability via adsorption in gut |
| Cancer chemotherapy | Possible ↓bioavailability (especially combinations of cyclophosphamide and vincristine) |
| Cholestyramine (Questran) | ↓Bioavailability via adsorption in gut |
| Colestipol (Colestid) | ↓Bioavailability via adsorption in gut |
| Kaolin-pectin | ↓Bioavailability via adsorption in gut |
| Laxatives | ↓Bioavailability via gut hypermotility |
| Metoclopramide (Reglan) | ↓Bioavailability via enhanced gastric emptying (slow-release digoxin only) |
| Neomycin | Malabsorption of digoxin |
| Psyllium hydrophilic mucilloid (Metamucil) and dietary bran fiber | Possible ↓bioavailability via adsorption in gut |
| Rifampin ²⁵⁵ | Probable induction of intestinal P-glycoprotein causing ↓bioavailability. ↓Serum concentration after oral, but not IV digoxin. No change in digoxin renal clearance or half-life. |
| St. John's Wort ²⁵⁶ | Possible induction of P-glycoprotein |
| Sulfasalazine (Azulfidine) | Malabsorption of digoxin |
| Drugs Raising Serum Digoxin Concentration | |
| Alprazolam ³²⁹ | ↑Serum digoxin levels by unknown mechanism |
| Amiodarone (Cordarone) ^{71,73} | ↑Serum digoxin levels by unknown mechanism |
| Atorvastatin ²⁵¹ | 20% increase in serum digoxin concentration with 80 mg dose, minimal effect with 20 mg dose. Speculated to inhibit intestinal P-glycoprotein, but not proven |
| Calcium channel blockers ^{71,73,252} (See Question 56) | Inhibition of P-glycoprotein. Best documented with verapamil. |
| Captopril ¹⁹¹ | Inhibition of digoxin renal clearance by unknown mechanism |
| Clarithromycin ^{253,254} | Inhibition of P-glycoprotein, decreased digoxin renal clearance |
| Cyclosporine ^{71,73} | Inhibition of P-glycoprotein, decreased digoxin renal clearance |
| Erythromycin | ↑Bioavailability in persons who normally metabolize digoxin in intestinal tract. May also inhibit P-glycoprotein in gut. |
| Itraconazole ³³⁰ | ↑Serum digoxin levels by unknown mechanism |
| Omeprazole ^{331,332} | ↑Bioavailability (slight) due to altered gut metabolism |
| Propafenone ^{71,249} | Inhibition of P-glycoprotein |
| Quinidine (see Question 38) ^{71,73,74,239–244} | Inhibition of P-glycoprotein; decreased digoxin renal clearance and increased bioavailability. |
| Propranolol (Pro-Banthine) | ↑Bioavailability via slowed gastric emptying (slow-release digoxin only) |
| Telmisartan ³³³ | Unknown mechanism. Increased peak serum concentration 3–4 hr after dose, but only slight increase in 24 hr AUC or trough serum concentration |

^aReferences 71, 239, and 250 include a discussion of many of these interactions that do not include a specific reference citation.

^bReference numbers.

AUC, area under curve.

Close questioning and a “tablet count” disclosed that Z.T. failed to decrease his digoxin to 0.25 mg/day. An ECG revealed multiple premature ventricular contractions (PVC) and second degree AV block. A STAT serum digoxin level was 2.8 ng/mL. What signs and symptoms in Z.T. are consistent with digitalis toxicity? What are some other adverse effects of digitalis?

This case illustrates a risk of using digoxin loading doses and one of several ways that digitalis toxicity might present. The clinical presentation of digitalis toxicity is unpredictable. In some cases, a high serum digoxin level without any appreciable adverse effects is the only clue to possible digitalis toxicity. In other patients, such as Z.T., a multitude of symptoms can be present, including both noncardiac signs (e.g., GI complaints) and rhythm disturbances (e.g., palpitation, heart block, arrhythmias).

The most important adverse effects are those relating to the heart. A common misperception is that GI or other noncardiac signs will precede cardiac toxicity. To the contrary, cardiac symptoms precede noncardiac symptoms of digitalis toxicity in up to 47% of cases. Frequently (26%–66%), nonspecific arrhythmias are the only manifestation of toxicity, with estimates that rhythm disturbances occur in 80% to 90% of all patients with digitalis toxicity.²⁵⁷ On the other hand, rhythm disturbances in patients taking digitalis are not always related to toxicity. In one study of 100 consecutive patients with suspected digitalis-induced arrhythmias, only 24 were confirmed as being toxic as defined by resolution of cardiac irritability following drug withdrawal. In the other 76 patients, the dysrhythmia persisted long after drug removal.²⁵⁸

Most known arrhythmias can occur as a result of digoxin toxicity. Decreased conduction velocity through the AV node presents as a prolonged PR interval (first-degree AV block) and is seen in many patients with therapeutic levels of digitalis. As exemplified in Question 38, however, higher concentrations of digitalis can impair conduction and result in bradycardia or a variable block (second-degree AV block). With severe toxicity, complete (third-degree) AV block results in dissociation of the atrial and ventricular rates with a slow idioventricular rate predominating. AV block also may predispose patients to accelerated junctional rhythms. Increased automaticity of the atria can cause multifocal atrial tachycardia (MAT) with block, paroxysmal atrial tachycardia (PAT) with block, or atrial fibrillation.

Ventricular arrhythmias (as seen in Z.T.) are among the most common rhythm disturbances caused by digitalis toxicity and include unifocal and multifocal PVC, bigeminy (every other beat is a PVC), trigeminy, ventricular tachycardia, and ventricular fibrillation. Comprehensive reviews are available on the topic of digitalis-induced arrhythmias.^{257,258}

Hyperkalemia can develop as a consequence of massive digitalis poisoning.²⁵⁹ Toxic doses of digitalis severely poison the $\text{Na}^+ - \text{K}^+ - \text{ATPase}$ system, causing inhibition of the uptake of potassium by the myocardium, skeletal muscle, and liver cells. The shift of potassium from inside to outside the cell can result in significant hyperkalemia, especially in patients with underlying renal insufficiency. These same patients also are likely to accumulate digoxin in the body because of decreased clearance of the drug. Cardiac ectopy can be potentiated by the increase in serum potassium, especially when the potassium

concentration exceeds 5 mEq/L. Paradoxically, in patients with good renal function, hyperkalemia can enhance renal excretion of potassium, resulting in a deficit in total body potassium despite the continued high serum concentration of potassium.

Vague GI symptoms characteristic of digitalis toxicity are difficult to evaluate because anorexia and nausea are also part of H.F.’s clinical picture. During one prospective clinical study, an equal frequency of anorexia and nausea occurred in both toxic and nontoxic patients taking digoxin.²⁶⁰ Anorexia may be the earliest symptom, followed in 2 to 3 days by nausea. More than 25% of patients have GI symptoms for >3 weeks before diagnosis. Nonspecific abdominal pain and bloating caused by nonocclusive mesenteric ischemia secondary to digitalis-induced vasoconstriction also has occurred.

Central nervous symptoms of digitalis are common, possibly associated with potassium depletion in neural tissue. Chronic digitalis intoxication resulting from misformulation was observed in 179 patients.²⁶⁰ Acute extreme fatigue or visual disturbances were a complaint in 95% of these patients. Approximately 80% experienced weakness of the arms and legs, and 65% had psychic disturbances in the form of nightmares, agitation, listlessness, and hallucinations. Hazy vision and difficulties in both reading and red-green color perception frequently were present. Other complaints included glitterings, dark or moving spots, photophobia, and yellow-green vision. Disturbances in color vision returned to normal 2 or 3 weeks after discontinuation of digitalis.

Interestingly, six elderly patients had apparent digitalis-induced visual disturbances at serum concentrations below those considered to be toxic (all <1.5 ng/mL; range, 0.2 to 1.5 ng/mL).²⁶¹ Five of the reactions were described as photopsia (seeing lights not present in the environment) and one person had decreased visual acuity. Color vision disturbances or seeing color lights, both well-described with digitalis toxicity, were absent. The symptoms went away in all but one subject when digoxin was discontinued.

Some prospective studies showed a good correlation between serum digoxin levels and toxicity,^{260,262,263} whereas other investigators found a poor correlation.^{264,265} In one study, 87% of digitalis-toxic patients had levels >2 ng/mL and 90% of nontoxic patients had levels <2 ng/mL. Conversely, other investigators found that nearly 50% of subjects with a serum digoxin level >3 ng/mL were clinically stable without signs of digitalis toxicity.²⁶⁴ In the largest series studied to date, the average serum digoxin concentration in documented toxic patients (i.e., those with a suspected digitalis-induced arrhythmia that disappeared after drug withdrawal) was 2.9 ng/mL compared with 1.0 ng/mL in patients with suspected digitalis toxicity, but in whom the arrhythmia persisted after drug withdrawal.²⁵⁸ Approximately 38% of documented toxic patients, however, had serum digoxin concentrations <2 ng/mL (false-negative test results). Once levels exceed 6 ng/mL, the risk of mortality greatly increases.²⁶⁶

Because a significant overlap between toxic and therapeutic levels exists, serum level determinations are currently most useful as an aid in confirming suspected digitalis toxicity and in individualizing dosing regimens so that toxicity might be avoided. In particular, subjects with low serum potassium concentrations can demonstrate digitalis toxicity at lower serum digoxin concentrations.²⁶⁷

Allergic reactions to digitalis are rare. Unilateral or bilateral gynecomastia is observed during chronic digoxin administration and is reversible on withdrawal of the drug. This latter effect may occur in addition to the gynecomastia seen with spironolactone.

PREDISPOSING FACTORS

42. B.V., a 64-year-old alcoholic man, is admitted to the hospital with a 3-day history of epigastric pain radiating to the back and associated with nausea and vomiting. B.V. also has cirrhosis of the liver and mild HF that is well controlled with furosemide 80 mg/day, ramipril 2.5 mg BID, and digoxin 0.25 mg/day. He has a 3-year history of severe rheumatoid arthritis, which is moderately relieved with NSAID and prednisone 15 mg/day. Because the initial impression was acute pancreatitis, B.V. was placed on a nasogastric suction and 3 L of D51/4 NS daily. The next evening, the laboratory report disclosed the following: Na, 136 mEq/L (normal, 136–144 mEq/L); K, 2.3 mEq/L (normal, 3.5–5.3 mEq/L); Cl, 90 mEq/L (normal, 96–106 mEq/L); bicarbonate, 32 mEq/L (normal, 23–28 mEq/L); Mg, 1.3 mEq/L (normal, 1.7–2.7 mEq/L); creatinine, 0.8 mg/dL (normal, 0.5–1.2 mg/dL); AST, 80 U (normal, 40 U); alkaline phosphatase, 130 U (normal, 80 U); amylase, 1,200 U (normal, 4–25 U); digoxin, 1.8 ng/mL; and Cl_{Cr} , 100 mL/minute (normal, 100–125 mL/minute). An ECG showed a HR of 70 beats/minute with occasional PVC and runs of bigeminy. What factors predispose B.V. to digitalis toxicity?

[SI units: Na, 136 mmol/L (normal, 134–144); K, 2.3 mmol/L (normal, 3.5–5.3); Cl, 90 mmol/L (normal, 96–106); bicarbonate, 32 mmol/L (normal, 23–28); Mg, 0.65 mmol/L (normal, 0.85–1.35); creatinine, 70.72 mmol/L (normal, 44.2–106.08); AST, 80 U/L (normal, 40); alkaline phosphatase, 130 U/L (normal, 80); amylase, 1,200 U/L (normal, 4–25); and Cl_{Cr} , 1.67 mL/sec (normal, 1.67–2.08)]

This is an example of a subtle presentation of digitalis toxicity. The serum level is in the high end of the therapeutic range. Nevertheless, B.V. shows clinical signs of digitalis toxicity (e.g., PVC and bigeminy). His renal function is normal, so digoxin renal clearance should not be significantly altered. The major contribution to toxicity in B.V. is hypokalemia.

The association between digitalis toxicity and hypokalemia is well recognized. It has been observed that twice as much digitalis is required to produce toxicity in patients with serum potassium of 5 mEq/L than in those with a serum potassium of 3 mEq/L.²⁶⁷ A few patients will develop signs of toxicity with serum digitalis concentrations as low as 1.5 ng/mL if hypokalemia is present. Therefore, drugs, diseases, and medical maneuvers that induce hypokalemia or reduce the serum potassium from elevated to normal levels may unmask digitalis toxicity. A low serum potassium has been observed to increase the uptake of digitalis by the myocardial tissue.²⁶⁸

B.V. is taking furosemide. All diuretics, with the exception of potassium-sparing diuretics, can cause hypokalemia through kaliuresis. In addition, prednisone in high doses promotes potassium excretion in the distal portion of the renal tubule. B.V.'s prednisone dose should be tapered and eventually discontinued while one of the newer disease-modifying drugs is started (see Chapter 43, Rheumatic Disorders). Similarly, diseases in which mineralocorticoid activity is high (e.g., Cushing's disease, hyperaldosteronism) are associated with

low serum potassium levels. B.V.'s history of cirrhosis could lead to development of portal hypertension and ascites, both of which are associated with hyperaldosteronism.

Other causes of hypokalemia in B.V. include vomiting and nasogastric suction. Similarly, hypokalemia can result from diarrheal losses, including drug-induced diarrhea (e.g., amoxicillin, quinidine).

Although the relationship of hypokalemia to digitalis toxicity is stressed, hyperkalemia is also a risk factor.²⁵⁹ A bimodal effect of potassium on the AV node has been observed, whereby both hypokalemia and hyperkalemia may delay AV nodal conduction resulting in bradycardia and compensatory ventricular ectopy.

B.V. has metabolic alkalosis (HCO_3^- , 32 mEq/L) from the combined effects of diuretic therapy, vomiting, and nasogastric suctioning of hydrogen ion. Alkalosis results in the redistribution of potassium intracellularly and an increased renal excretion of potassium, thereby potentiating effects of hypokalemia (see Chapter 10, Acid-Base Disorders). In addition, alkalosis in and of itself has been associated with an increased incidence of digitalis toxicity. This is attributed to an intracellular depletion of potassium caused by increased urinary excretion and a relative increase in the ratio of extracellular to intracellular potassium.²⁶⁸ This has the same effect on the membrane potential as digoxin.

Another metabolic problem that could contribute to digitalis toxicity in B.V. is hypomagnesemia. The causes are the same as for hypokalemia, including diuretic therapy, nasogastric suction losses, and chronic alcoholism. The prevalence of hypomagnesemia is higher in digitalis-toxic patients; magnesium sulfate has been used successfully in the treatment of digitalis toxicity.²⁶⁹

Although not illustrated by B.V., hypercalcemia theoretically can predispose patients to digitalis toxicity. The electrical and contractile effects of calcium on the myocardium are similar to those of digitalis. For this reason, rapid IV infusions of calcium can facilitate the development of digitalis toxicity, and normal or low doses of digitalis can induce toxicity in patients with hypercalcemia (e.g., hyperparathyroidism or metastatic cancer). The clinical significance of calcium-induced digitalis toxicity is questionable; there have been no reports of digitalis toxicity secondary to oral administration of calcium-containing products.

Age may be an important predisposing factor in the production of digitalis toxicity in B.V. The same IV dose of digoxin administered to elderly and young patients produces higher serum concentrations of digoxin in the elderly. The higher levels and prolonged half-life observed in these patients are likely caused by diminished renal clearance of the drug and this population's smaller body size. It is important to emphasize that, although the serum creatinine of elderly patients may be within normal limits, the mean creatinine clearance is reduced.

The response to digitalis also can be altered in the very young (see Question 45). Lower doses are recommended in premature infants and neonates (<1 month) because of the decreased renal function normally observed in newborns.²⁷⁰ Although absorption, tissue distribution, and excretion of digoxin in infants are similar to those observed in adults, infants excrete a smaller percentage of digoxin metabolites than adults.

TREATMENT OF DIGITALIS TOXICITY

43. How should B.V.'s digitalis toxicity be treated?*Withholding Digitalis and Electrolyte Replacement*

For many patients without life-threatening arrhythmias or major electrolyte imbalances, simple withdrawal of digitalis is the only treatment required. Although it may take five half-lives for the drug to be totally eliminated from the body, the serum concentration will drop to a safe level after one to two half-lives (2 to 3 days for digoxin) in most individuals.

B.V. does not have significantly elevated digoxin levels, so his ectopy should disappear rapidly with drug withdrawal. His major problem is related to hypokalemia that must be corrected. As a general rule, potassium replacement should be considered in any patient with digitalis-induced ectopic beats who has low or normal serum potassium levels. Oral administration is acceptable unless the patient cannot take medication orally or has life-threatening ectopy. If digitalis-induced arrhythmias are sufficiently severe to warrant intravenously administered potassium, the maximal recommended rate of administration is 40 mEq/hour (preferably 10 mEq/hour) at a concentration not exceeding 80 to 100 mEq/L. A total of several hundred milliequivalents of potassium might be required to replete body stores. Potassium should be administered with caution in patients who have conduction disturbances characterized by second-degree or complete AV block because high doses can further depresses conduction velocity in the AV node.

B.V. has a significant potassium deficit with potentially dangerous arrhythmias but no contraindications to potassium therapy. He should receive 80 to 120 mEq of IV potassium over the next 24 hours and then be switched to an appropriate oral dose. He should be monitored for signs and symptoms of potassium toxicity with frequent ECG tracings (look for tall, peaked T waves; prolonged PR interval) and serum potassium determinations.

It is important to obtain a serum magnesium concentration when measuring potassium levels. Patients with a low serum magnesium level (<1.5 mEq/L) or whose condition fails to respond after potassium repletion should receive a 20 mg/kg (2 g in an adult) loading dose of magnesium sulfate administered as a 10% solution over 20 minutes, followed by a continuous infusion at a rate of 0.5 to 2 g/hour to maintain a serum magnesium level of at least 4 to 5 mEq/L. Magnesium is relatively contraindicated in patients with renal failure, hypermagnesemia, or a high-level AV block. The infusion should be discontinued if deep tendon reflexes are diminished or serum concentrations of magnesium exceed 7 mEq/L.

Antiarrhythmic Agents

Patients with bradycardia because of second- or third-degree AV block should be given IV atropine. The usual atropine dose is 0.5 to 1 mg over 1 to 2 minutes with a repeat in 15 to 30 minutes if the patient does not respond. Doses <0.5 mg can paradoxically worsen the AV block. Atropine should be used with caution in patients with prostatic hypertrophy because significant urinary retention and postrenal azotemia can occur. Alternatively, a temporary pacemaker can be placed. Because B.V.'s HR is 70 beats/minute, atropine is not indicated.

Virtually all of the antiarrhythmic agents have been used to treat digitalis-induced arrhythmias. Lidocaine and phenytoin have a theoretic advantage over quinidine-like agents be-

cause they do not further depress AV conduction. Phenytoin is particularly efficacious in the suppression of digitalis-induced tachyarrhythmias with or without first- or second-degree AV block. For B.V., potassium replacement will probably be all that is required. Because of his bigeminy, however, lidocaine could be administered for a few hours until he has been given sufficient potassium supplementation. (See Chapter 19, Cardiac Arrhythmias, for dosing guidelines for lidocaine and phenytoin.)

Peritoneal and hemodialysis are ineffective in removing digoxin from the body, but charcoal hemoperfusion is used for life-threatening overdoses in patients with renal failure.²⁷¹

*Digoxin Immune Fab***44.** All the treatments above are symptomatic. When is a specific antidote such as digoxin immune Fab indicated?

Most treatment regimens for digitalis toxicity are supportive only, either by counteracting the pharmacologic effects of digitalis or by interfering with further absorption of ingested tablets. A more definitive treatment consists of administration of digoxin-specific antibodies that bind digoxin molecules, rendering them unavailable for binding at receptors in the heart and other areas of the body.^{272–277} The antibodies bind intravascular digoxin and also diffuse into interstitial spaces to bind free digoxin. As the extracellular unbound (free) digoxin concentration decreases, intracellular digoxin diffuses into extracellular fluid and becomes available to be bound to the antidigoxin antibodies. A concentration gradient is thus created that promotes release of digoxin from binding sites. Ultimately, the digitalis-antibody complex is excreted in the urine. The official name of this product is digoxin immune Fab, ovine sold under the brand names of Digibind and DigiFab.

The use of digoxin Fab products is restricted to potentially life-threatening intoxications (severe arrhythmias or hyperkalemia) that are either refractory to more conservative therapy or associated with extremely high serum concentrations. The major reason for this approach is the high cost of digoxin Fab.

Digoxin immune Fab is supplied as a lyophilized powder (38 mg/vial of Digibind, 40 mg/vial of DigiFab) that, after reconstitution with 4 mL of sterile water for injection, yields a 10 mg/mL solution that should be used within 4 hours. One milligram of digoxin immune Fab binds 12.5 mcg of digoxin. Thus, the contents of one vial will bind approximately 0.5 mg of digoxin. The actual dose administered varies according to the estimated amount of digitalis glycoside in the body. For digoxin, the amount of drug in the body can be estimated by the formula:

$$\text{Body load in mg} = \frac{5.0(\text{SDC})(\text{Weight in kg})}{1,000} \quad (18-2)$$

where 5.0 is the volume of distribution of digoxin in liters per kilogram. An oral absorption of approximately 80% for digoxin is assumed. From this estimate, the total number of vials required for neutralization is calculated by dividing the total body load by 0.5 mg/vial. Patients with renal failure have a smaller volume of distribution of digoxin and thus have higher serum concentrations for any given dose.

In cases of extremely large single-dose ingestions for which the results of digoxin serum concentrations are not available, an empiric dose of 380 to 400 mg (10 vials) is given to an adult. An additional 380 to 400 mg can be given if needed.

For patients with toxicity during chronic therapy, 228 to 240 mg (6 vials) is adequate to treat most adults, whereas 38 to 40 mg (1 vial) is appropriate for children weighing <20 kg. The antibody usually is administered IV over 30 to 45 minutes, but it can be given more rapidly if the patient is in acute distress. It is recommended that the drug be infused through a 0.22-micron filter. Efficacy and safety is the same in children as in adults.²⁷³

Clinical improvement in the signs and symptoms of digitalis intoxication should occur within 30 minutes of antibody administration, with complete reversal of symptoms in 4 hours. If, after several hours, toxicity has not been adequately reversed or symptoms reappear, an additional dose can be given. In patients with renal insufficiency, the digitalis-antibody complex can be retained in the body for a prolonged time. If retained sufficiently long, Fab fragments could be degraded by the reticuloendothelial system, releasing active digitalis glycosides back into the circulation and necessitating re-treatment. For this reason, it has been proposed to give 50% of the calculated dose immediately over 15 minutes, then the remaining 50% as a continuous infusion over 7 hours.²⁷⁴

Immediately after treatment with digoxin-specific Fab, the active (free or unbound) digitalis concentration decreases to nearly undetectable levels, but the total (free plus antibody-bound) digoxin concentration increases. In <1 hour, the total concentration increases by 10- to 20-fold, peaking in about 10 hours at concentrations often exceeding several hundred nanometers per liter. The monitoring of serum digoxin levels following treatment with Digibind is of no value because most clinical laboratories measure only “total” serum concentrations of digitalis glycosides, a composite of both “free” and bound (to protein or Fab) drug.^{275,276}

The Fab fragment-digoxin complex is excreted via the kidneys. It takes several days before the entire complex is removed, allowing routine digoxin assays to once again become reliable. In one study of patients with varying degrees of renal function, the half-life of the initial phase of total digoxin decline was 11.6 hours and the half-life of the second, or terminal, elimination phase was 118 ± 57 hours.²⁷⁶ Unbound digoxin serum levels rebound to a mean maximal free digoxin concentration of 1.7 ± 1.3 mmol/L in 77 ± 46 hours, but are delayed to a greater extent in anephric patients.²⁷⁵ Paradoxical return of toxicity may be caused either by release of digoxin from the Fab-digoxin complex or late redistribution of digoxin from tissue stores into the plasma.^{274,276} As long as antibodies remain in the system, further therapy with digitalis preparations is compromised because of binding of any new doses. Thus, monitoring of unbound concentrations is necessary.

Side effects to digoxin-specific Fab antibodies are uncommon, but several cautions must be heeded.²⁷⁷ HF or AF can be precipitated by the removal of the pharmacologic effects of the digitalis glycoside. Similarly, as $\text{Na}^+ - \text{K}^+ - \text{ATPase}$ enzyme activity is restored, hypokalemia can develop. Serum potassium concentrations must be monitored frequently for the first several hours after Fab administration because potassium levels can drop precipitously as potassium shifts back into cells. This may require immediate potassium supplementation.

The incidence of hypersensitivity or other allergic reactions after Fab administration is rare, but the risk after repeated ingestions is unknown.²⁷⁷ Skin testing according to the directions in the digoxin immune Fab package insert should be followed in individuals at high risk, especially in patients with known aller-

gies to sheep serum or in whom digoxin-specific Fab has been administered previously. If an accelerated allergic reaction occurs, the drug infusion should be discontinued and appropriate therapy initiated, including antihistamines, corticosteroids, and airway management. Epinephrine should be used cautiously in patients with arrhythmias.

Pediatric Dosing

45. H.H., a 3-year-old girl with a congenital heart defect, is displaying increased symptoms of HF. She is awaiting surgery for repair of a ventricular septal defect and a damaged aortic valve. In the meantime, she is to receive digoxin therapy. All laboratory values, including renal function and electrolytes, are within normal limits. She weighs 28 lb (12.7 kg). Should digoxin dosing for H.H. be formulated using the same guidelines as for an adult? What loading dose and maintenance dose should H.H. be given?

Although many of the general principles that apply to use of digoxin in adults also apply to children, certain practical considerations and changes in pharmacokinetic parameters must be considered.²⁷⁰ Dosing in children is complicated by rapid changes in body size and tissue distribution, GI motility, and maturation of the liver and kidney.

Most children cannot swallow conventional tablets or capsules and must be given the liquid (elixir) dosage form. Although the pediatric population does not differ significantly from adults in their ability to absorb digoxin, large individual variability is noted and the elixir is generally more bioavailable than the tablets (Fig. 18-1).

An important difference is noted between children and adults in regard to tissue uptake and volume of distribution of digoxin. As noted previously, the average adult has a steady-state digoxin volume of distribution of 6.7 L/kg. Greater variability is seen in very young to older children with volume of distribution reported to be 7.5, 16.3, and 16.1 L/kg in neonates, 11-month-old infants, and children, respectively.²⁷⁰ Children have slightly higher digoxin protein-binding than adults, but neither group has a high enough percentage bound (i.e., <50%) to significantly affect tissue concentrations of the drug.

As in adults, clearance and half-life of digoxin in children are highly dependent on renal function and, to a lesser degree, on metabolism and biliary excretion. Elimination data in children are limited by the small number of available reports and the absence of studies in healthy pediatric subjects; nonetheless, a few generalizations can be made. Total body clearance is significantly impaired in premature and term neonates (with $t_{1/2}$ ranging from 61–170 hours). Older children and adolescents clear the drug at approximately the same rate as adults. These findings are consistent with poorly developed renal function in premature or young newborns, but the kidney becomes highly functional by 1 month of life and function approaches that of an adult by 1 year of age.

From these data, can be surmised that after the first year of life and through early childhood, children will need a *larger* dose on a per-kilogram basis than adults. This is based on a larger apparent volume of distribution, not altered drug clearance. Although no clear consensus is available on dosing of digoxin in children, the following guidelines have been published²⁷⁰: premature and term neonates should be digitalized with 0.01 to 0.03 mg/kg IV; infants should be given 0.04 to 0.05 mg/kg orally. For maintenance, the premature neonate can be given 0.001 to 0.009 mg/kg/day, neonates 0.010 mg/kg/day,

and infants (1 month to 2 years) 0.015 to 0.025 mg/kg/day. For children older than 2 years of age, the loading dose is 0.05 mg/kg orally followed by a daily maintenance dose of 0.01 to 0.015 mg/kg. As in adults, doses are adjusted based on clinical signs, renal function, and serum levels (Table 18-5).

For H.H., an argument can be made for starting a maintenance dose without a loading dose because she is not in acute distress. If a loading dose is required, an oral elixir could be used at 0.05 mg/kg (0.6–0.65 mg), split into two doses. Maintenance would be started at 0.01 mg/kg or approximately 0.125 mg/day. These doses are surprisingly large and reflect the large volume of distribution in children.

This IV loading dose is considerably smaller than what would be used in a person with normal renal function because of assuming a smaller volume of distribution. A corresponding oral loading dose would be approximately 0.3 mg after correcting for an average bioavailability of 75%. When using larger loading doses, the total dose is often divided into two portions, giving two-thirds of the dose to start and the remaining one-third 6 to 8 hours later. Because the dose for R.D. is small, the entire 0.2 mg can be given at once. If after 8 to 12 hours she is still in atrial fibrillation, an extra 0.1 mg could be given safely because the serum concentration was targeted at only 0.75 ng/mL.

Critical Care Management of Heart Failure

Non-ACE Inhibitor Vasodilator Therapy

46. L.M., a 50-year-old black man, was admitted several days ago with severe, progressive, and debilitating symptoms of HF. Family history is significant in that his father and two brothers died of heart attacks shortly after the age of 40. L.M. has a 12-year history of HF that is symptomatic despite treatment with full therapeutic doses of furosemide, enalapril, carvedilol, and digoxin. He has no history of hypertension, but previous studies suggested a diagnosis of cardiomyopathy with an EF of 18%. Over the previous 8 months, L.M.'s DOE became progressively worse, and for the month before admission he was confined to bed because of extreme fatigue. He awoke once or twice nightly with PND.

Physical examination on this admission revealed a dyspneic, cyanotic man in obvious distress but with no complaints of chest pain. His BP was 100/66 mm Hg and his pulse was 105 beats/minute. Significant JVD, bilateral rales, hepatomegaly, and 3+ peripheral edema also were observed. Chest radiograph revealed cardiomegaly and pulmonary congestion. L.M. was admitted to the CCU where a Swan-Ganz catheter was passed from an antecubital vein to the pulmonary artery.

Before therapy, L.M.'s PCWP was 27 mm Hg (normal, 5 to 12 mm Hg) and his cardiac index (CI) was 1.9 L/minute/m² (normal, 2.7 to 4.3 L/minute/m²). Several doses of IV furosemide were given, and IV nitroprusside was initiated at a dosage of 16 mcg/minute and eventually increased to 200 mcg/minute. At this dose, L.M.'s PCWP decreased to 15 mm Hg and his CI increased to 2.5 L/minute/m². He was eventually discharged home with furosemide 80 mg BID, spironolactone 50 mg QD, enalapril 20 mg BID, carvedilol 25 mg BID, digoxin 0.125 mg/day, hydralazine 75 mg QID, and isosorbide dinitrate 40 mg Q 6 hr. Categorize L.M.'s HF by NYHA class and ACC/AHA staging.

On admission L.M. was in NYHA class IV HF despite maximal doses of the recommend four-drug therapy with a loop

diuretic, ACE inhibitor, β -blocker, and digoxin. He was approaching ACC/AHA stage D as well. His PCWP was high and his CI was low, reflecting pulmonary vascular congestion (elevated preload) and poor CO, respectively. (See Chapter 21, Shock, for a more thorough review of principles of Swan-Ganz catheterization and hemodynamic monitoring. Also see the introduction to this chapter to review the concepts of afterload, preload, and the relative contributions of arterial and venous dilation to these hemodynamic changes). The immediate objective of therapy is to provide symptomatic relief by decreasing the PCWP and increasing the CO.

Most patients with acute HF can be classified into one of four hemodynamic profiles using relatively simple assessment techniques (Fig. 18-8).^{278–281} When using this scheme, patients are assessed for the presence or absence of elevated venous filling pressures (wet vs. dry patients) and adequacy of vital organ perfusion (warm vs. cold patients). Elevated filling pressure can be assessed at the patient's bedside by observing orthopnea, jugular venous distension, the presence of a third heart sound (S₃), peripheral edema, and ascites. Presence or absence of rales on auscultation is not considered a reliable indicator.²⁸¹ Hypotension, weak peripheral pulse, a narrow pulse pressure (<25%), cool forearms and legs, decreased mental alertness, and rising BUN and SrCr are indicators of decreased organ perfusion. In one series, 67% of patients admitted to the hospital with a low LVEF and class IV HF symptoms were classified as “wet and warm,” with 28% assessed as “cold and wet,” and only 5% as “cold and dry.”²⁷⁸ Few if any patients were in the “warm and dry category” because this is the status one is trying to achieve in well-compensated patients. Continuous blood pressure, ECG, urine flow, and pulse oximetry measurements are standard noninvasive monitoring for all patients. Invasive hemodynamic monitoring is used in critically ill patients when more precise measurements of filling pressure (e.g., right atrial or pulmonary artery pressure), systemic vascular resistance, and CO or cardiac index are desired. The goals are to achieve a right atrial pressure of <5 to 8 mm Hg, pulmonary artery pressure of <25/10 mm Hg, pulmonary artery wedge pressure of 12 to 16 mm Hg or less, a systemic vascular resistance of 900 to 1,400 dyn.s.m⁻⁵, and a cardiac index of 2.8 to 4.2 L/minute/m² (see Chapter 21, Shock, for more detailed discussion of hemodynamic monitoring).

For most patients presenting in the “wet and warm” category, the primary intervention is aggressive diuresis to reduce fluid overload rapidly. This is followed by optimization of the standard three-drug regimen of ACE inhibitors, β -blockers, and digoxin. In more severe cases (e.g., when pulmonary artery wedge pressure is > 18 mm Hg), initial use of an IV vasodilator, such as nitroglycerin or nesiritide, to reduce preload may be indicated. Nesiritide offers an advantage of having both natriuretic and vasodilatory properties and can add to the diuretic effect of furosemide in refractory patients.³⁴ Careful monitoring of pulmonary wedge pressure and cardiac index is necessary to avoid excessive reduction of pulmonary pressure that will then lead to deterioration of CO. In some cases, pulmonary artery pressure must be maintained somewhat above the normal range for optimal balance. Milrinone and other inotropes are not necessary for these patients, and may even cause deterioration of symptoms.^{282,283} (See also question 53 for further discussion of dobutamine and milrinone.)

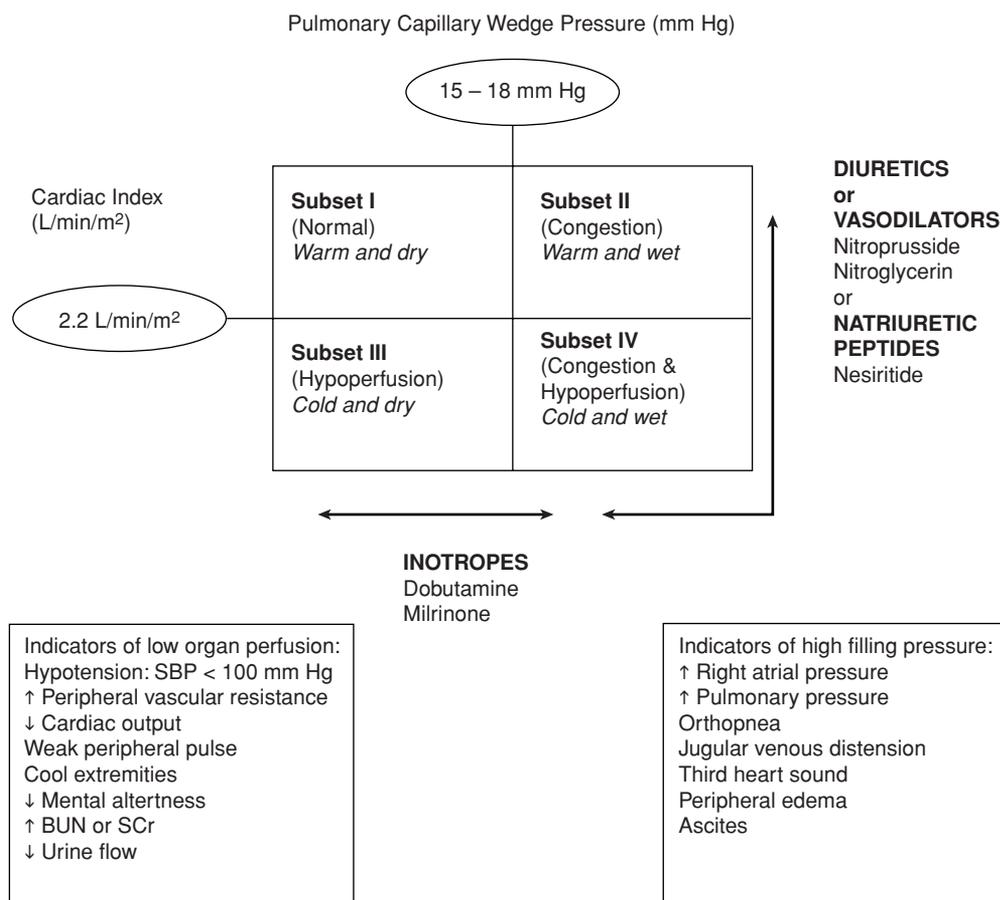

FIGURE 18-8 Hemodynamic profile of acute heart failure. BUN, blood urea nitrogen; SBP, systolic blood pressure; SrCr, serum creatinine. (Adapted with permission. Copyright © 2002 American Medical Association. All rights reserved.)

The “wet and cold” patients, such as L.M., who present with signs of both volume overload and hypoperfusion are more clinically challenging. Pulmonary artery wedge pressure is elevated and cardiac index is <2.2 L/minute/m². Immediate attention must be directed toward correcting hypoperfusion followed by aggressive diuretic therapy as in the “wet and warm” patients. β -Blockers and ACE inhibitors should be temporarily withdrawn if symptomatic hypotension is present. Because these patients often have both a low CO and high systemic vascular resistance, both vasodilators (e.g., nitroglycerin and nitroprusside) and an inotropic-vasodilator (e.g., dobutamine, low dose dopamine, or milrinone) might be considered; however, agreement is not unanimous regarding the agent of choice. The desired effect is reduced right-sided filling pressure (reduced preload via venous dilation) and reduced resistance to left ventricular outflow (reduced afterload via arterial dilation), both of which can increase CO and responsiveness to IV diuretics. These patients are generally monitored with pulmonary artery catheterization. The use of nesiritide in place of nitroprusside is possible, although it has not been well studied in this patient type. After stabilization, nitroprusside is slowly withdrawn and ACE inhibitors are reinstated, sometimes in combination with an oral nitrate, oral hydralazine, or both. Chronic discontinuation of ACE inhibitors with transition to a hydralazine–nitrate combination becomes necessary when

SrCr and BUN levels remain chronically elevated or worsen after ACE inhibitor dosage escalation. If inotropes are used, they can be started simultaneously with nitroprusside or reserved for patients not responding to vasodilators. Dobutamine may be preferred to milrinone because it causes less hypotension and is less expensive. Both milrinone and dobutamine are associated with undesirable tachyarrhythmias. Low dose dopamine is indicated if renal function is deteriorating.

The rare patient with low CO without evidence of volume overload (“cold and dry”) may be relatively stable and poses less need for immediate intervention. A short course of dobutamine or milrinone can be tried, but ultimately these patients should be placed on an outpatient regimen that includes an oral β -blocker if they are not already on this therapy.

Nitroprusside

47. What is the role of vasodilator therapy in L.M.?

On admission, L.M. had an elevated PCWP and a low CI. The presence of an elevated JVD and peripheral edema indicate volume overload. He is hypotensive, consistent with his low CI. Thus, he fits into the “wet and cold” category described in the previous question. Consistent with this diagnosis, he was given vigorous diuresis and nitroprusside. The HFSA guidelines⁴ recommend the addition of vasodilators in conjunction with

diuretics to reduce congestion in patients with fluid overload. In the presence of asymptomatic hypotension, IV nitroglycerin, nitroprusside, or nesiritide may be considered cautiously in combination with diuretics for rapid improvement of ADHF. In the presence of low systemic vascular resistance, arterial vasodilators (e.g., nitroprusside, high dose nitroglycerin, nesiritide) can further compromise perfusion, especially in patients who have preexisting hypotension.

Nitroprusside dilates both arterial and venous vessels; therefore, it has the theoretic advantage of decreasing both afterload and preload. Its major disadvantages include risk of hypotension that can cause a decrease in CO and reflex tachycardia; coronary steal (in ischemic patients); and accumulation of toxic metabolites, including thiocyanate toxicity (see Chapter 20, Hypertensive Emergencies). In addition, nitroprusside must be given by continuous IV infusion, which necessitates arterial line placement in most situations, and it is unstable if exposed to heat and light after reconstitution.

Intravenous Nitroglycerin

As the prototype of all nitrates, NTG primarily dilates the venous capacitance vessels with only a slight effect on the arterial bed. Intravenous NTG is indicated for patients with significant respiratory distress from pulmonary congestion despite large diuretic doses (see Question 31 for an example patient). It is hoped that the resulting reduction in left ventricular filling pressure (preload) will reduce PCWP to <18 mm Hg. Because nitrates have minimal or no effect on afterload, CO will likely remain unchanged or increase only slightly. NTG actually can decrease CO in some patients by reducing the left ventricular filling pressure to <15 mm Hg. Nitroprusside is a better choice for patients such as L.M. who have a low CI without evidence of myocardial ischemia. (See Chapter 17, Myocardial Infarction, and Chapter 21, Shock, for more information on dosing and side effects of IV NTG.)

Patients should be initiated on small doses of nitroprusside (6–20 mcg/minute) that are increased slowly to a maximum of 300 to 800 mcg/minute until a decrease in the PCWP or arterial pressure is observed. When stopping nitroprusside therapy, a slow taper is recommended because a rebound increase in HF has been observed 10 to 30 minutes after drug withdrawal. (For a more thorough discussion of nitroprusside use, see Chapters 20, Hypertensive Emergencies and 21, Shock.)

Nesiritide

Nesiritide (Natreco) is recombinantly produced human B-type natriuretic peptide (hBNP) containing the same 32 amino acids as native hBNP.^{33,34} (The pharmacologic activity of the natriuretic peptides was reviewed in the pathogenesis section of this chapter.) BNP binds to guanylate cyclase receptors on vascular smooth muscle (the BNP receptor) leading to expression of cyclic GMP and subsequent vasodilation. Other actions include inhibition of ACE, sympathetic outflow, and endothelin-1. Peripheral and coronary dilation coupled with improved renal blood flow and increased glomerular filtration all contribute to the beneficial effects of nesiritide. Metabolic clearance of nesiritide is by a combination of binding to cell surfaces with subsequent cellular internalization and lysosomal proteolysis as well as proteolytic cleavage by endopeptidase (e.g., neutral endopeptidase). It undergoes only minimal renal clearance.

The mean elimination half-life is 8 to 22 minutes (mean, 18 minutes), necessitating IV infusion therapy.

In clinical trials of hospitalized patients with severe HF, nesiritide produced hemodynamic effects and reduction in dyspnea scores comparable to NTG when used in combination with IV diuretics and either dopamine or dobutamine.^{33,34} Dose-dependent hypotension is the most common side effect with nesiritide, reported in 11% to 32% of patients. In some trials, nesiritide caused a higher incidence or longer duration of hypotension than NTG, whereas in other trials the incidence of hypotension was similar. The incidence of PVC and nonsustained ventricular tachycardia is less with nesiritide than with dopamine, dobutamine, or milrinone. Other side effects include headache, abdominal pain, nausea, anxiety, bradycardia, and leg cramps.

Because of high cost, the use of nesiritide is generally restricted to those patients with acute HF exacerbations who are fluid overloaded and have a PCWP >18 to 20 mm Hg despite high doses of diuretics and IV NTG. In contrast to NTG, nesiritide has natriuretic properties that are additive to those of the loop diuretics. It should be avoided in patients with a systolic blood pressure <90 to 100 mm Hg or in cases of cardiogenic shock. Dobutamine or milrinone should be added or substituted in hypotensive patients or those with a CI <2.2 L/minute/m².

The IV infusion of nesiritide is prepared by diluting the contents of a 1.5 mg vial to 6 mcg/mL in 250 mL of 5% dextrose or 0.9% NaCl. An initial loading dose of 2 mcg/kg is given intravenously over 60 seconds, followed by a continuous IV infusion at a rate of 0.01 mcg/kg/minute. The desired response is a reduction of PCWP of 5 to 10 mm Hg at 15 minutes. The dose can be increased in 0.005 mcg/kg/minute increments at 3-hour intervals to a maximum of 0.03 mcg/kg/minute. Dosage should be titrated to a PCWP <18 mm Hg and a systolic BP >90 mm Hg.

Although nesiritide is indicated in the treatment of ADHF, concerns have been raised about its safety. A meta-analysis of randomized, controlled trials of nesiritide in ADHF suggests that nesiritide use may be associated with worsening renal function and increased mortality.^{284,285} The conclusions of the meta-analysis have been criticized, however. For example, the Vasodilation in the Management of Acute congestive Heart Failure (VMAC) study that was included in the meta-analysis was not designed to evaluate renal endpoints and, therefore, the inclusion of the renal effects from this study may not be appropriate.²⁸⁶ Also, differences in baseline characteristics of the treatment groups may have contributed to an increased risk of 30-day mortality seen in those patients treated with nesiritide.

The efficacy and safety of nesiritide have also been evaluated in the outpatient setting. The Follow-up Serial Infusions of Nesiritide (FUSION I) trial²⁸⁷ was a pilot trial that included 202 patients with NYHA class III–IV who had been hospitalized for ADHF at least twice within the preceding year and once in the preceding month. Patients were randomized to receive usual care with or without open-label nesiritide. A subgroup of patients were identified as high risk if they had at least four of the following: serum creatinine >2.0 mg/dL during the preceding month, NYHA class IV for the preceding 2 months, >65 years of age, a history of sustained ventricular tachycardia, ischemic HF etiology, diabetes, or use of nesiritide or inotropic agents as outpatients within the preceding 6 months. These

patients at high risk experienced fewer HF exacerbations and renal adverse effects with nesiritide infusions.

This suggestion of potential benefit and safety in outpatients with severe HF was further explored in the Follow-Up Serial Infusions of Nesiritide for the Management of Patients With Heart Failure (FUSION II) trial.²⁸⁸ This was a randomized, placebo-controlled, double-blind prospective trial of 911 subjects with advanced HF or chronic decompensated HF. Subjects were randomized to receive a 2 mcg/kg nesiritide bolus followed by a 0.01 mcg/kg/minute infusion for 4 to 6 hours, or a matching placebo regimen, once or twice weekly for 12 weeks. Both groups also received optimal medical therapy and device therapy. Patients were entered only if their creatinine clearance was <60 mL/minute. No outpatient IV inotropic or vasodilator therapy was allowed during the 24-week study. After 24 weeks, no difference was noted in the primary end point of either death or hospitalization for cardiac or renal causes among patients in the nesiritide and placebo groups. Significantly more ($p = 0.79$) drug-related adverse events occurred in those in the nesiritide group (42.0%) compared with the placebo group (27.5%), mainly caused by hypotension. The incidence of worsening renal function, however, was significantly lower ($p = 0.046$) with nesiritide (32% in nesiritide group vs. 39% in the placebo group). There was no evidence that changes in SrCr were associated with renal harm.

The results of these studies alleviate some concerns regarding the safety of nesiritide. Additional data from the Acute Study of Clinical Effectiveness of Nesiritide in Decompensated Heart Failure (ASCEND-HF) study will shed more light on the safety and efficacy of nesiritide in ADHF.²⁸⁹

L.M. responded well to nitroprusside and needed no other therapy. However, IV nitroglycerin and IV nesiritide are alternatives to nitroprusside in patients with either “wet and warm” or “wet and cold” acute HF. Nitroglycerin or nesiritide can either be a substitute for nitroprusside or combined with nitroprusside.

Use of Inotropic Drugs

48. B.J. is a 60-year-old man who presents to the emergency department with worsening dyspnea on exertion. He reports increased SOB over the last week. His medical history includes HTN, CAD, hyperlipidemia, and HF (EF 25%). His medications include metoprolol XL 100 mg QD, enalapril 5 mg QD, furosemide 40 mg BID, aspirin 81 mg, and lovastatin 20 mg HS. His vital signs on admission included BP 92/70 mmHg, HR 92 beats/min RR 18 breaths/minute, O₂ saturation 94% on room air. Laboratory values were BUN 20 mg/dL, SrCr 1.4 mg/dL PCWP 21 mm Hg, CI 1.8 L/min/m², SVR 580 dyne sec/cm⁵. Physical examination reveals pulmonary and peripheral edema. He is given 80 mg IV furosemide and he does not respond adequately. The decision is to admit him to the CCU. His SrCr has increased to 1.8 mg/dL. Is B.J. a candidate for inotrope therapy? Why is milrinone preferred over amrinone?

Dopamine and Dobutamine

The hemodynamic profile of B.J. is category IV (cold and wet) because of hypoperfusion and congestion. According to the HFSA guidelines, IV inotropic agents (dobutamine, dopamine, milrinone, amrinone) are indicated in symptomatic patients

with reduced LVEF, low CO, or end-organ dysfunction (i.e., worsening renal function), and in patients who are intolerant to vasodilators.⁴ They are also recommended for patients with cardiogenic shock or refractory symptoms, and may be used in patients requiring perioperative support following cardiac and noncardiac surgery or for those awaiting transplantation. Dopamine is more effective as an arterial dilator, especially in the kidney, whereas dobutamine has more potent inotropic properties. (See Chapter 21, Shock, for further information on dopamine and dobutamine dosing.)

Phosphodiesterase Inhibitors: Amrinone and Milrinone

Although β -agonists, such as dobutamine, have been traditionally used in patients with ADHF, the phosphodiesterase inhibitors, amrinone (Inocor) and milrinone (Primacor), are alternatives to the catecholamines and vasodilators for the short-term parenteral treatment of severe congestive failure. These agents selectively inhibit phosphodiesterase F-III, the cyclic-adenosine monophosphate (AMP)-specific cardiac phosphodiesterase. They have direct cardiac-stimulating effects, but they are not sympathomimetics or inhibitors of Na⁺-K⁺-dependent ATP. Enzyme inhibition results in increased cyclic AMP levels in myocardial cells and, thus, enhances contractility. Their activity is not blocked by β -blockers. Because they are phosphodiesterase inhibitors, they also act as vasodilators. It has been suggested that at low doses they act more as unloading agents rather than inotropes; others refute this viewpoint. Their overall hemodynamic effect probably results from a combination of positive inotropic action plus preload and afterload reduction.

Amrinone initially was investigated for oral use, but it failed to gain FDA approval because of dose-dependent, reversible thrombocytopenia (up to 20% of patients), drug fever, liver function abnormalities, and possibly drug-induced ventricular arrhythmias. Amrinone remains available in an IV form for short-term use in severe HF. Therapy is initiated with a 0.75 mg/kg bolus over 2 to 3 minutes followed by a maintenance infusion of 5 to 10 mcg/kg/minute. Higher doses occasionally have been given, but doses exceeding 18 mcg/kg/day should be avoided. It has a half-life of approximately 2.5 to 3.5 hours in healthy individuals; this is prolonged to 6 to 12 hours in patients with HF. Lower doses are necessary in patients with renal insufficiency because amrinone is 50% excreted unchanged in the kidney. All dilutions should be made in saline (0.45%–0.9%) because amrinone is incompatible with dextrose-containing solutions.

With IV use, the major side effects to monitor are hypotension and precipitation of arrhythmias. The prevalence of thrombocytopenia is reduced to 2.4% with parenteral use. In summary, amrinone is effective in reducing SVR and PCWP and in increasing cardiac output, but as described below it appears to be less effective than dobutamine.

Milrinone is structurally and pharmacologically similar to amrinone.^{290–292} Besides inhibiting phosphodiesterase, it also may increase calcium availability to myocardial muscle. It has both inotropic and vasodilating properties. Heart rate increase and myocardial consumption may be less with milrinone than with dobutamine.^{282–283} The half-life of milrinone is short (1.5–2.5 hours) with renal clearance accounting for approximately 80% to 90% of total body elimination. Milrinone is about 15 to 20 times more potent than amrinone on

a weight basis. A typical loading dose is 50 mcg/kg administered over 10 minutes followed by a maintenance infusion of 0.5 mcg/kg/minute. The infusion is adjusted according to hemodynamic and clinical responses and should be lowered in patients with renal insufficiency. The primary concern with the use of milrinone is induction of ventricular arrhythmias, reported in up to 12% of patients. Supraventricular arrhythmias, hypotension, headache, and chest pain also have been reported. Thrombocytopenia is rare, a distinct advantage over amrinone. Overall, milrinone has become the drug of choice among the phosphodiesterase inhibitors.

The Outcomes of a Prospective Trial of Intravenous Milrinone for Chronic Heart Failure (OPTIME-CHF) trial assessed the in-hospital management of 951 patients with acute HF exacerbation (NYHA class III or IV, mean LVEF 23%), but not in cardiogenic shock.^{282,283} In addition to standard diuretic and ACE inhibitor therapy, subjects were randomized to receive either milrinone or placebo. The initial milrinone infusion rate was 0.5 mcg/kg/minute with no loading dose. For the primary end point of total numbers of days hospitalized for cardiovascular causes from the time of the start of study drug infusion to day 60, no difference was found between active drug and placebo (mean 12.3 days with milrinone and 12.5 days with placebo), nor was any difference seen in the mean number of days of hospitalization during the primary event. Death rates within 60 days were 10.3% with milrinone and 8.9% with placebo (NS, $p = 0.41$).²⁸² Follow-up analysis categorized subjects by etiology of HF (ischemic vs. nonischemic).²⁸³ Not unexpectedly, those with an ischemic cause did less well with hospital rates of 13.0 days for ischemic patients compared with 11.7 days for those without ischemia ($p = 0.2$). Corresponding death rates over 60 days were 11.6% and 7.5% ($p = 0.03$). Importantly, within the cohort of patients with ischemia ($n = 485$), milrinone-treated patients tended to have worse outcomes than those treated with placebo: 13.6 hospital days with milrinone vs. 12.4 days with placebo. Death occurred in 13.3% of patients on milrinone compared with 10.0% of those on placebo. For the composite of patients dying or being rehospitalized, 42% of milrinone subjects had events compared with 36% with placebo ($p = 0.01$). In contrast, nonischemic patients ($n = 464$) had a trend toward better outcomes with milrinone than with placebo: 10.9 hospital days for milrinone vs. 12.6 days with placebo, 7.3% deaths with milrinone compared with 7.7% with placebo, and the composite of death or hospitalization occurring in 28% of subjects with milrinone vs. 35% with placebo. From these data, the following conclusions can be drawn. The benefits of milrinone in patients with acute exacerbations of HF are minimal and more likely to be seen in patients with a nonischemic etiology of HF. Worse outcomes may be seen in patients with ischemic HF. Milrinone was not associated with excess mortality.

Few trials have yet compared dobutamine with milrinone in ADHF patients. One small retrospective analysis evaluated 329 patients admitted for ADHF with an EF of <20% who either received IV dobutamine or milrinone.²⁹³ Hemodynamic response, need for additional therapies, adverse effects, length of stay, and drug cost were evaluated. Patients in both groups were comparable in clinical presentation. Further, both groups had similar HR, BP, PCWP, and CO at baseline. The milrinone group, however, had higher mean pulmonary arterial pressure.

A greater percentage of patients received dobutamine therapy (269, 81.7%) vs. milrinone therapy (60, 18.3%). Only 19% of patients were taking β -blockers before admission. Clinical outcomes in both groups were similar. There was no significant difference in the in-hospital mortality rate, adverse effects, ventilator use, or length of stay. More patients in the dobutamine group required nitroprusside to achieve optimal hemodynamic response. A slightly better hemodynamic response occurred in the milrinone group, which did not translate into a more beneficial short-term clinical outcome. The study concluded that because both drugs have comparable efficacy, dobutamine may be a better choice than milrinone because it provided more drug cost savings during the hospital stay.

Other factors to consider when deciding which inotropic agent should be used in ADHF are renal function, BP, and concomitant β -blocker use. Milrinone has a longer half-life than dobutamine, and accumulates in cases of renal dysfunction. Milrinone is also a vasodilator, which can limit its use in patients with hypotension. The concomitant use of β -blockers can antagonize the action of dobutamine.

B.J. has responded poorly to IV furosemide, his renal function has deteriorated and his systolic BP is low. Patients with advanced HF, reduced blood pressure, and normal or low systemic vascular resistance often will not tolerate vasodilator therapy. Inotropic agents may be necessary to maintain circulatory function in these patients. According to HFSA guidelines, IV inotropes may be considered for patients who are unresponsive to diuretics or who have worsening renal function, especially if they have marginal systolic BP (<90 mm Hg). Phosphodiesterase inhibitors are preferred over dobutamine for patients who are receiving concomitant β -blockers. For the above-mentioned reasons, B.J. is a candidate for milrinone therapy. Patients must be on telemetry because milrinone has the potential to cause arrhythmias. Vital signs, SrCr, symptom relief, and urine output should be monitored. Once the patient's hemodynamic profile improves, milrinone should be discontinued and oral furosemide therapy can be resumed. At discharge, the outpatient HF medications should be optimized.

Outpatient Inotropic Infusions

49. Are there any indications for using repeated intermittent infusions of inotropes as part of a home care regimen?

It has been proposed to use regularly scheduled (e.g., weekly) intermittent infusions of dobutamine or milrinone in outpatient care centers or at home. The long-term safety and efficacy of inotropic therapy in general is regarded with skepticism, however. Nearly all the data on this therapeutic approach are from open-label and uncontrolled trials or studies that compare two inotropic agents without a placebo group.^{294–298} It is unclear if the benefit observed was the result of more intensive patient monitoring or an actual pharmacologic benefit. It also is speculated that long-term therapy actually may be cardiotoxic, as evidenced by an acute worsening of HF on withdrawal of the drug. The only placebo-controlled trial of intermittent infusion dobutamine was terminated because of excess mortality in the treatment group.²⁹⁵ Death occurred in 32% of 31 patients treated with dobutamine and only 14% of 29 treated with placebo. Whether this phenomenon is was

caused by progression of the underlying heart disease, continued drug therapy, or is a true cardiotoxic effect remains unknown. No corresponding data exist for milrinone, although as cited previously, a placebo-controlled trial with milrinone failed to support the routine use of IV milrinone as an adjunct to standard therapy in the treatment of patients hospitalized for an acute exacerbation of chronic HF.^{282,283} For this reason, the ACA/AHA guidelines explicitly indicate that intermittent infusions of dobutamine and milrinone in the long-term treatment of HF, even if advanced stages, should be avoided.⁶ Dobutamine is sometimes administered as long-term infusions (5–7.5 mcg/kg/minute continuously for 48–72 hours) in patients with refractory HF while awaiting transplant. The infusion is repeated as often as weekly.

Hydralazine

50. After L.M.'s condition was controlled with nitroprusside therapy, he was given his original medications plus spironolactone, hydralazine, and isosorbide dinitrate. Why were hydralazine and isosorbide used? What other forms of nitrates can be used in place of the isosorbide? Is combination therapy rational?

L.M. had already been treated with a loop diuretic, an ACE inhibitor (enalapril), a β -blocker, and digoxin. Despite this therapy, he was still doing poorly. Spironolactone was added for reasons discussed in Question 14. A possible next step in treating a patient with this advanced stage of HF is the addition of a non-ACE inhibitor vasodilator.

Hydralazine's predominate action is as an arteriolar dilator, making hydralazine the prototype afterload-reducing agent. Decreasing aortic impedance (afterload) is of little benefit in a normal or minimally diseased heart, but it may greatly improve severely compromised left ventricular function. SVR is decreased predictably and this, in turn, increases cardiac output (cardiac index).^{135,136,299} Hydralazine is also a direct-acting, smooth muscle relaxant with significant arteriolar dilating effects in the kidneys and limbs. It has essentially no effect on the venous system or on hepatic blood flow.

The reflex tachycardia and hypotension that frequently accompany hydralazine therapy when used in treating hypertension are minimal or absent, however, when it is used to treat HF. Increased CO overrides vasodilatory effects in the latter instance. In patients with end-stage cardiomyopathy, however, significant hypotension still can occur if the heart cannot respond appropriately. Another beneficial response to hydralazine is reduction of pulmonary vascular resistance in patients with severe pulmonary hypertension. This pulmonary arteriolar dilating effect of hydralazine is generally less beneficial than the venodilating effects of drugs such as nitrates and nitroprusside. Because hydralazine is devoid of venous dilating properties, CVP and PWCP are unchanged.^{136,299}

The effect of a single dose occurs in about 30 minutes and lasts up to 6 hours. Larger doses than typically used for the treatment of hypertension may be required for HF management. The average maintenance dose is 200 to 400 mg/day (50–100 mg every 6 hours). L.M. required 75 mg four times a day. Hydralazine used as monotherapy is not associated with long-term improvement in functional status, however.²⁹⁹ Combination therapy of hydralazine with either nitrates or ACE inhibitors is highly effective.

Although tachyphylaxis generally is not a significant problem with prolonged courses of hydralazine, some patients require increased diuretic doses to counteract hydralazine-induced fluid retention. This latter response reflects activation of the renin-angiotensin system following vasodilation of the renal vasculature. Other side effects accompanying hydralazine include transient nausea during the first few days of therapy; headache, flushing, or tachycardia; and a lupus syndrome associated with prolonged, high doses. (See Chapter 13, Essential Hypertension, for further discussion of hydralazine side effects and dosing.)

Oral and Topical Nitrates

Nitrates have complementary effects to those of hydralazine.^{135,136} They primarily dilate venous capacitance vessels, with minimal effects on selected arterial beds (coronary and pulmonary arteries). Venous dilation reduces preload, resulting in significant reductions in PCWP and right atrial pressure. They are especially effective in reducing the symptoms of pulmonary edema. The lack of significant arterial dilation accounts for the observations that SVR is minimally reduced and CO remains unchanged. Nitrate monotherapy is indicated for HF patients with valvular defects such as mitral or aortic regurgitation. In these patients, reduction of the ventricular filling pressure reduces left ventricular congestion.

ISOSORBIDE DINITRATE

Because sublingual NTG has a short duration of response, more attention has been focused on sublingual and oral isosorbide dinitrate. Sublingual isosorbide is well absorbed and does not undergo first-pass metabolism. Its onset is rapid (approximately 5 minutes), but its effects are relatively short (1–3 hours). The usual starting dosage is 5 mg every 4 to 6 hours, but dosages may be titrated to 20 mg or more every 4 to 6 hours. These larger doses are associated with longer beneficial effects (approximately 3 hours), but also a high frequency of intolerable headaches and hypotension.

Previous claims of a poor response to orally administered isosorbide because of a large first-pass metabolic effect have been refuted. Large oral doses overwhelm the metabolic capacity of the liver and produce beneficial effects. Oral isosorbide has a slow onset (15–30 minutes), but the duration of activity is slightly longer than that associated with sublingual administration (4–6 hours). Oral doses of 5 mg are probably ineffective; 10 mg is the smallest effective starting dose with further titration to dosages as high as 20 to 80 mg every 4 to 6 hours. The best dose for both sublingual and oral nitrates is that which provides the desired beneficial effect with the least side effects.

TRANSDERMAL NITROGLYCERIN

An innovative approach to NTG administration is transdermal patch systems (Minitran, Nitrek, Nitro-Dur). Topical application of these systems is said to provide 24 hours of continuous cutaneous absorption with more convenience and less mess than NTG ointment. Although most published data on these dose forms are in patients with angina, several reports are on their use in HF.

The initial enthusiasm for transdermal NTG has been tempered by the suggestion that tolerance develops quickly,

resulting in a benefit for much less than 24 hours following patch application. Considerable debate has arisen over this topic.^{300–302} Some reviewers suggest abandoning this form of therapy, whereas others argue that the studies showing negative benefit were flawed. Removal of the patch during the night might lead to restoration of response the following day. It has been suggested that while the antianginal effects of NTG are attenuated with chronic therapy, the beneficial preload-reducing properties for HF are sustained. Large doses (20–40 mg/24 hour), however, may be required, necessitating the use of several patches per day and resulting in significant expense to the patient. (See Chapter 16, Ischemic Heart Disease: Anginal Syndromes, for a more detailed discussion on the application and controversy surrounding NTG transdermal patches.)

Hydralazine–Nitrate Combination

Combined afterload and preload reduction is clearly of benefit both in improving symptoms and in enhancing long-term survival. Compared with ACE inhibitors, the hydralazine–isosorbide combination provides more significant improvement in exercise tolerance, but the side effect profile and survival statistics are better with ACE inhibitors.¹³¹ With combination therapy, CO is greater for any given level of ventricular filling pressure. Generally, the use of the two drugs together is not accompanied by reflex tachycardia or hypotension, but it is important to be careful not to compromise coronary blood flow in patients with coexistent angina.

The most compelling argument for the use of combination hydralazine and nitrate vasodilator therapy comes from the results of the two Veterans Administration Cooperative Studies (V-HeFT I and V-HeFT II).^{131,135,136} As discussed in more detail in Question 15, these two studies not only confirmed symptomatic relief and improved exercise tolerance with combination therapy, but they also showed improved survival. Also, see Question 51 for a discussion of the possible unique place in therapy of the hydralazine–nitrate combination in black patients.

In summary, nitrates alone are indicated for those patients with signs and symptoms of isolated pulmonary and venous congestion (i.e., dyspnea, increased pulmonary pressure, neck vein distention, edema). Conversely, use of an arterial dilator is more appropriate in a patient with high SVR, low CO, and normal PCWP. Most patients, such as L.M., exhibit symptoms of decreased CO and elevated venous pressure, making combination therapy the most attractive option. Although the hydralazine–isosorbide combination actually reduces symptoms slightly better than ACE inhibitors, the data on survival are more impressive with the ACE inhibitors. As illustrated by L.M.'s treatment regimen, a combination of an ACE inhibitor plus hydralazine, a nitrate, or both, is common in patients with far advanced disease.

Role of Race in the Pharmacotherapy of Heart Failure

51. Because L.M. is black, would he be expected to respond any differently to ACE inhibitors or hydralazine–isosorbide dinitrate than a patient who is not black?

In general, black patients develop HF at an earlier age and are more likely to have hypertension as a cause for HF. Conversely, the etiology of HF in non-black patients more often

results from ischemic heart disease. The rate of death caused by HF is higher for black patients than for non-black patients.

ACE Inhibitors and Hydralazine–Isosorbide

Racial differences in response to drug therapy have been proposed, although this issue is far from resolved.^{303–306} For example, a *post hoc* analysis of the V-HeFT trial data cited previously showed no difference in annual mortality between black (n = 180) and non-black patients (n = 450) in the placebo group (17.3% vs. 18.8%).^{131,273} Black patients in the hydralazine–nitrate group had a significantly lower annual mortality rate (9.7%), however, than did black subjects in the placebo group (17.3%), whereas non-black subjects had no survival benefit from the drug combination (16.9% vs. 18.8%). This implies that black patients, but not non-blacks, derive benefit from the treatment with hydralazine–isosorbide. These same investigators then reanalyzed the V-HeFT II trial results for possible racial differences between response to enalapril and the hydralazine–nitrate combination.^{136,304} The outcome is difficult to interpret because of the absence of a placebo group. The all-cause annual mortality rate for blacks (n = 215) was identical in the two drug groups (12.8% with enalapril and 12.9% with hydralazine–isosorbide.) In non-blacks (n = 574), the corresponding mortality rates were 11% with enalapril and 14.9% with hydral-iso. These data could be interpreted as either superior response to hydralazine–isosorbide in black subjects or inferior activity of ACE inhibitors in black patients. The latter interpretation is consistent with the hypothesis that ACE inhibitors might have a lesser BP-lowering effect in black patients with hypertension compared with non-blacks. A similar reanalysis of the SOLVD Prevention and Treatment¹³⁴ trials, both of which compared enalapril with placebo in patients with recent MI, concluded that enalapril therapy is associated with a significant reduction in the risk for hospitalization for HF among white patients (44% reduction) with left ventricular dysfunction, but not among similar black patients. Confounding variables contributing to all of the analyses presented include disproportionately low numbers of blacks in the trials, and possibly more underlying risk factors (e.g., hypertension) in the black subjects.

To further address the effect of race on response to ACE inhibitors, a meta-analysis of the seven major ACE inhibitor studies, representing a total of 14,752 patients was conducted.³⁰⁵ The conclusion was that that relative risk for mortality when taking an ACE inhibitor compared with placebo was identical (0.89) for both black and white patients. The authors of the meta-analysis urged that ACE inhibitors not be withheld from black patients. One other consideration with ACE inhibitors is an observed higher rate, although still rare, of angioedema in blacks than in whites. Until more data are available, ACE inhibitors should not be withheld from black patients, but careful monitoring is required to assess response.

The African American Heart Failure Trial (AHeFT) was designed to determine possible superiority of combination hydralazine plus isosorbide dinitrate in black patients.⁷⁷ AHeFT was a randomized comparison trial (n = 1050) of hydralazine–isosorbide dinitrate and placebo in black patients with NYHA class III or IV HF who were receiving standard HF therapy (94% diuretics, 87% β -blockers, 93% ACE inhibitors or ARB, 62% digoxin, and 39% aldosterone antagonists). The primary end point was a composite of all-cause death, first

hospitalization for HF, and quality of life scores at 6 months with secondary end points being individual components of the primary end point. Reduction in the composite primary end point events was statistically significant in favor of the active drug combination. Importantly, all-cause mortality declined 43% in the hydralazine–isosorbide dinitrate arm vs. placebo ($p = 0.012$). The study also reported a 39% reduction in first hospitalization for HF in the hydralazine–isosorbide dinitrate group vs. placebo ($p < 0.001$). As a result, the 2005 ACC/AHA guideline recommendations state that the addition of hydralazine and isosorbide dinitrate to HF patients receiving ACE inhibitors and β -blockers is effective in blacks with NYHA functional class III or IV HF.⁷ The results of AHeFT were also the primary factor leading the FDA to approve the combination product of hydralazine and isosorbide dinitrate (BiDil) for adjunctive treatment of heart failure in self-identified black patients already receiving standard therapy. Advantages of using BiDil in clinical practice include use of the same product studied in the clinical trial and potential improved compliance by using a combination tablet. Cost, however, may be lower when using generic hydralazine and isosorbide as separate drugs.

β -Blockers

A possible racial difference in response to β -blocker drugs has also been hypothesized based on differential effects observed in patients with hypertension.^{303,305,306} A *post hoc* analysis of the various U.S. Carvedilol Heart Failure trials^{212–216} concluded, however, that the benefit of carvedilol was apparently of similar magnitude in both black ($n = 217$) and non-black ($N = 877$) patients.³⁰⁶ Using the combined end point of the risk of death from any cause or hospitalization, the risk reduction of β -blockers compared with placebo was 48% in black patients and 30% in non-black patients. Because fewer black patients were studied, these differences did not reach statistical significance. Also seen were a significant improvement in NYHA functional class, EF, and patient global symptom assessment with carvedilol in both black and non-black patients.

Contradictory evidence comes from the β -Blocker Evaluation of Survival Trial (BEST).²²⁵ In this trial (also discussed in Question 30), 2,708 patients with NYHA class III (92%) or IV (8%) HF were randomly assigned to either bucindolol or placebo. Bucindolol is a nonselective β -blocker with partial agonist activity that imparts weak vasodilation. A unique characteristic of this study was that a subgroup analysis for racial differences was planned from the start. Although there was a trend toward reductions in cardiovascular mortality and hospitalization with the active drug, the trial was terminated after 2 years when it was determined that there was no mortality benefit of active drug compared to placebo (33% mortality in placebo group vs. 30% with bucindolol). A subgroup analysis showed a mortality benefit in non-black subjects, but none in black subjects. Subsequently, a meta-analysis of the five major β -blocker in HF studies was conducted, representing a total of 12,727 patients.³⁰⁵ When the BEST was included in the meta-analysis, the relative risk for mortality when taking an ACE inhibitor compared with placebo was 0.69 in white subjects, but only 0.97 for black patients. When this trial was excluded, the relative risks were reduced in both groups to 0.63 and 0.67 in whites and blacks, respectively. The difference between the two groups was not statistically significant, although the 95%

confidence interval for black patients was broader and included 1.0 (0.38–1.16). Based on all of these factors, it is likely that black patients will derive similar benefit from β -blockers as do whites when given carvedilol, metoprolol, or bisoprolol. Bucindolol should be avoided, most likely because of its partial agonist activity.

Left Ventricular Diastolic Dysfunction

52. D.F., a 58-year-old white woman, has a 5-year history of HF symptoms, including decreased exercise capacity, SOB, and distended neck veins. She has minimal peripheral edema. History is suggestive of rheumatic fever as a child, but she does not recall having any cardiac symptoms when she was younger, other than being told she had a murmur. Her symptoms are controlled with diuretics. She has history of hypertension. She has no other medical problems and all laboratory test findings are normal. Her BP is 155/85 and HR 90 beats/minute. Cardiac examination reveals a prominent S₄ heart sound and murmurs consistent with both significant mitral regurgitation and mild aortic regurgitation. Non-invasive echocardiography reveals a normal EF of 50%. Prior treatment included furosemide, most recently at 120 mg/day. The physician is considering adding a β -blocker or CCB to control the BP. Why might this consideration be appropriate?

This case exemplifies a patient with diastolic heart failure (DHF), also referred to as heart failure with preserved LV function. Risk factors for DHF include advanced age, female sex, hypertension, and coronary artery disease. This diagnosis can be made on the basis of LVH, clinical evidence of HF, a normal EF, and Doppler tissue echocardiography findings. The ideal treatment strategies for DHF have not been devised. Also, no drug selectively enhances myocardial relaxation without having associated effects on left ventricular contractility or on the peripheral vasculature.^{12–16}

Factors affecting HF control, such as dietary sodium intake, fluid intake, compliance, and NSAID and herbal remedy use, should be appropriately managed along with drug therapy. Symptomatic left ventricular diastolic HF is initially treated similarly to other forms of HF, by slow diuresis. Diuresis decreases preload and lessens passive congestion of the ventricles. Excessive lowering of venous and ventricular filling pressures, however, can worsen cardiac output and hypotension.

The most common cause of DHF is hypertension that leads to left ventricular hypertrophy and decreased cardiac compliance.³⁰⁷ Recent ACC/AHA guidelines recommend treating associated hypertension in accordance with the national guidelines and suggest considering lower blood pressure targets for patients with DHF ($< 130/80$ mm Hg).⁷ Drugs that cause regression of LV hypertrophy (e.g., ACE inhibitor, ARB, β -blockers) may also slow or reverse structural abnormalities associated with DHF.

Although ACE inhibitors have been used with success in some patients with DHF, the role of RAAS inhibition in HF with preserved LV function has not been rigorously studied. Several recent clinical trials have attempted to address this issue. In the Perindopril in Elderly patients with Chronic HF (PEP-CHF) trial,³⁰⁸ the ACE inhibitor perindopril failed to reduce the incidence of the primary endpoint (all-cause mortality or HF hospitalizations), but did reduce symptoms and

improved functional capacity over 2 years in patients with preserved LV function. The CHARM-preserved trial¹⁷⁴ also failed to show any difference in CV mortality, but fewer hospitalizations were seen in the candesartan group (see Question 21).

The Valsartan in Diastolic Dysfunction (VALIDD) trial,³⁰⁹ the first large-scale, randomized trial comparing the effects of valsartan or placebo added to standard antihypertensive therapy (which included diuretics, β -blockers, CCB or α -blockers) in patients with mild hypertension and diastolic HF. The hypothesis of this trial was that RASS inhibition with an ARB would be associated with greater improvement in diastolic dysfunction, possibly because of a greater regression of LVH or myocardial fibrosis. Patients with a history of stage 1 or 2 essential hypertension were randomized to receive either valsartan 160 mg, up-titrated to 320 mg, or matching placebo. Patients who did not achieve a target blood pressure goal of <135/80 mm Hg received additional therapy starting with a diuretic followed by a CCB or a β -blocker, then an α -blocker (excluding ARB, ACE, and aldosterone blockers). The primary endpoint was the change in diastolic myocardial relaxation velocity from baseline to 9 months with a secondary endpoint of change in LV mass. During the study, the placebo group received more concomitant antihypertensive therapy compared with the valsartan group. A small, but significant, increase was seen in diastolic relaxation velocity in both groups from baseline to follow-up ($p < 0.001$), but no significant difference between the treatment groups ($p = 0.29$). Blood pressure reduction at the end of the trial did not differ significantly between the two treatment groups (13 mm Hg reduction in valsartan vs. 10 mm Hg in placebo), which was associated with significant improvement in diastolic function. Thus, the authors concluded that aggressive BP control—even in mild hypertension—was associated with improvement in diastolic dysfunction, irrespective of whether BP reduction was achieved with a RAAS inhibitor or other antihypertensive agents. Several other trials are in progress that may provide further insight into the role of RAAS inhibitors in preserved LV function HF.

β -blockers or CCB are other classes of drugs of interest in DHF. Part of their value is to control hypertension, a risk factor for all forms of HF. More specific to DHF, β -blockers and CCB (especially verapamil) possess negative inotropic properties that may favorably influence the pathophysiology of diastolic dysfunction by (a) slowing the HR to allow more time for complete ventricular filling (via more complete left atrial emptying), particularly during exercise; (b) reducing myocardial oxygen demand; and (c) controlling BP. In addition, negative inotropic agents decrease myocardial contractility and can assist in overcoming the mechanical obstruction of the aortic and mitral valves during systole in patients with hypertrophic cardiomyopathy. Both agents also are beneficial in decreasing ischemia in patients with coronary artery disease.

Previous HF trials of β -blockers demonstrating decreased morbidity and mortality have mainly focused on patients with reduced LVEF. The Study of the Effects of Nebivolol Intervention on Outcomes and Rehospitalization in Seniors with Heart Failure (SENIORS) study³⁰⁹ is the first major trial to evaluate β -blocker use in elderly HF patients (70 years or older), irrespective of LV function. The trial randomized patients to Nebivolol ($n = 1,067$) or placebo ($n = 1,061$). Nebivolol is a selective β_1 -adrennergic receptor blocker with vasodilator properties that are mediated through nitric oxide release. This effect

may be beneficial in elderly patients, who tend to have low reserves of endothelial vasodilation.

The primary endpoint of the study was the combination of all-cause mortality and cardiovascular hospital admissions. The end point was significantly reduced by 14% in the Nebivolol group, regardless of the ejection fraction. Prospective subgroup analyses of the primary outcome by LVEF ($\leq 35\%$ or $> 35\%$), gender, age (≤ 75 years or > 75 years) showed benefits across all subgroups. Patients with EF $> 35\%$, however, appeared to benefit a little more than those with low EF%, and all-cause mortality was lower in patients aged > 75 years. The study reinforces the current recommendations that all HF patients with reduced EF should receive β -blockers. Only 35% of the patients had preserved LV function, however, and were mostly men. This is not typical of patients with HF, who are generally females and who tend to have greater incidence of diastolic HF.

Further studies are required to define the role of β -blockers in subject groups that are under-represented. On the other hand, no randomized controlled trials have demonstrated mortality benefits with CCB in patients with preserved LV function. CCB can be used in patients who have a contraindication to β -blockers to control BP and HR. Non-dihydropyridine CCB should not be used in patients with impaired LV dysfunction, however.

D.F. fulfills the criteria for having diastolic dysfunction, probably on the basis of mitral and aortic regurgitation as a result of childhood rheumatic fever. Her BP is not at goal and her HR is elevated. As already discussed, uncontrolled hypertension can promote left ventricle hypertrophy and myocardial remodeling, and can adversely affect the diastolic function. Therefore, an additional antihypertensive agent is warranted. Tachycardia alone can compromise the ventricle filling time and cause myocardial ischemia. So far, no data support use of one agent over the other. β -blockers and CCB can each reduce BP and HR. Because more experience has accrued with β -blockers and some mortality data on their use with DHF patients, D.F. can be started on a β -blocker such as metoprolol (25 mg BID).

53. A.F., a 48-year-old man, has a 5-year history of atrial fibrillation and mild HF stabilized with furosemide 40 mg/day and digoxin 0.25 mg/day. His previously well-controlled BP is now rising; the last pressure was 160/100 mm Hg despite good adherence with his diuretic therapy. All laboratory findings are normal. The digoxin level is 1.2 mg/mL. Is there evidence that calcium channel blockers may be helpful in controlling both hypertension and HF? If a calcium channel blocker is prescribed, will any interactions occur with his other drugs?

The arterial vasodilator properties of CCB form the basis for their use in hypertension. A logical extension would suggest a role in HF symptom management via afterload reduction. Use of these drugs, however, is limited by their negative inotropic effect, resulting from inhibition of calcium influx into heart muscle cells. This can result in a worsening of HF.^{310–312} Clinically, verapamil elicits the most negative inotropic effect and the dihydropyridine derivatives the least; diltiazem has intermediate effects. It is important not to develop a false sense of security that nifedipine or other dihydropyridines are clinically devoid of negative inotropic effects as demonstrated by the following randomized, crossover trial comparing IV

hydralazine (5–30 mg) with oral nifedipine (20–50 mg) in 15 patients.³¹¹ Both drugs were equally effective in reducing BP and SVR (a sign of afterload reduction), but hydralazine was more effective in increasing SV and CI. Four of the patients taking nifedipine experienced deterioration of their HF symptoms. The authors concluded that the vasodilatory properties of nifedipine are partially offset by its negative inotropic effect and that hydralazine is clinically superior.

A follow-up study using a randomized, crossover design challenged 28 patients with class II or III HF with nifedipine, isosorbide, and a combination of the two.³¹² Of patients, 24% on nifedipine and 26% on combined therapy had worsening of symptoms and required hospitalization compared with none in the isosorbide treatment arm.

The search for a more vascular selective CCB has focused on the newer agents amlodipine and felodipine. In the Prospective Randomized Amlodipine Survival Evaluation (PRAISE) trial, patients with dyspnea or fatigue at rest or minimal exertion (NYHA class III or IV) and an EF of 30% or less (mean 21%), were randomized to either placebo ($n = 582$) or amlodipine ($n = 571$) and followed for a median of 13.8 months (range, 6–33 months).⁷⁸ The starting dose of amlodipine (5 mg daily) was titrated to 10 mg daily if tolerated; the average dose at the end of the trial was 8.8 mg daily. Essentially all the patients were taking a combination of a diuretic, an ACE inhibitor, and digoxin. Nitrates were allowed for chest pain management, but hydralazine was excluded. For the combined primary end point of death from any cause, a cardiovascular-related hospitalization, or both, a nonstatistically different 9% risk reduction was noted in events with amlodipine compared with placebo (39% vs. 42%). For death rates alone, 33% of patients on amlodipine died compared with 38% in the placebo group. Again, these differences were not statistically significant ($p = 0.07$). Changes in EF, specific symptom scores, and quality of life measures were not reported, but the frequency of hospitalization for worsening HF was similar in both groups (36% amlodipine, 39% placebo.) Peripheral edema and pulmonary edema were more frequent in the amlodipine group, but hypertension and angina were more evident in the placebo group.

Stratification of the subjects into those with evidence of ischemic heart disease vs. those with nonischemic dilated cardiomyopathy showed a trend toward improved survival with amlodipine in the patients without ischemia. Overall, the results of this trial show a neutral effect of amlodipine, indicating that it could be used safely for concurrent hypertension or angina without making HF worse, but it does not appear to offer a significant advantage in actually treating the HF.

Similar findings have been reported with felodipine in the third report from the Vasodilator-Heart Failure Trial Study Group (V-HeFT III).⁷⁹ The primary objectives of this study were to evaluate the effects of extended-release (ER) felodipine ($n = 224$) compared with placebo ($n = 226$) on exercise tolerance, clinical symptoms, and clinical signs of HF for up to 39 months. Subjects were all men, with class II–III HF and an EF of <45% (mean, 30%). Before starting the study drug, subjects were optimized with an ACE inhibitor (97% with enalapril), diuretics (87%–90%), and digoxin (75%). The starting dose for felodipine was 2.5 mg twice daily, with a goal dose of 5 mg twice daily (mean dose, 8.6 mg/day after titration). At the 3-month evaluation point, EF increased slightly ($2.1 \pm 7.0\%$)

with amlodipine, compared with $-0.1\% \pm 6\%$ with placebo. At 12 months, no difference was seen between the two groups ($0.6 \pm 8.6\%$ with felodipine vs. $-0.6 \pm 8.6\%$ with placebo).

During the first 12 weeks of evaluation, neither felodipine nor placebo had either a positive or negative effect on time to dyspnea or fatigue on exercise testing; however, thereafter, a trend toward deterioration in exercise capacity was found with placebo, but not with felodipine. In the first 3 months, slightly more patients on felodipine were hospitalized than those on placebo (14.7% vs. 10.6%), but overall the rate of hospitalization was identical in the two groups (42% to 43%). The study was not powered to evaluate the effect of felodipine on mortality, but the observed mortality rates were 13.8% in the felodipine arm and 12.9% in the placebo arm.

In contrast to the PRAISE trial, treatment with felodipine had a more favorable effect in the subgroup of patients with a history of ischemia and CAD. The only adverse effect more common in the patients on felodipine was edema, which was reported at least once in 21% of felodipine subjects and 12.8% of those on placebo. The conclusions are almost identical to those with amlodipine: there does not seem to be any negative consequences to using felodipine, but it has little role in the management of HF. Both the amlodipine and felodipine trials leave unanswered the question of efficacy of CCB in patients not already taking an ACE inhibitor or digoxin.

Based on the previous discussion, nifedipine is not a good choice for A.F. In fact, nifedipine is contraindicated in any patient with systolic dysfunction. Likewise, verapamil is contraindicated even though it would otherwise lower his BP and control his atrial fibrillation by virtue of its AV nodal-blocking effect. Amlodipine and felodipine are safer alternatives for A.F.'s hypertension, but still not preferred. The more logical solution to A.F.'s problem is to add an ACE inhibitor and possibly a β -blocker to get a dual effect of controlling his BP and treating his HF. Digoxin can be continued for rate control of his atrial fibrillation, although as discussed in Question 40, adding a β -blocker can also help in rate control.

Interaction With Digoxin

In the absence of HF, a case could be made for the use of verapamil or diltiazem together with digoxin for additive benefit in the treatment of supraventricular arrhythmias; but, as with the use of digoxin and quinidine, a risk of increased digoxin serum levels exists. The most reproducible interaction is with verapamil.^{71,73,252} Steady-state concentrations of digoxin are consistently increased by 44% to 70% after the addition of verapamil. In some instances, the changes are only transient, with digoxin levels returning toward baseline concentrations (but not completely) after several weeks of continued combination therapy. The interaction is more pronounced in patients taking larger doses of verapamil (240–360 mg/day) and in patients taking quinidine as well. Verapamil's primary action is the reduction of nonrenal digoxin clearance, at least partially mediated by increased digoxin bioavailability via inhibition of intestinal PGP by verapamil.

Several investigators also have confirmed an interaction with diltiazem, but the magnitude of the rise in serum digoxin concentrations (20%–35%) is less than that seen with verapamil. One study reported a 45% increase in digoxin concentrations after nifedipine, whereas several other investigators could not detect a change in digoxin clearance. Although not

confirmed, the mechanism may involve inhibition of PGP by diltiazem, thus enhancing digoxin bioavailability. In summary, an interaction between CCB and digoxin definitely should be considered when using verapamil; it may be of some concern with diltiazem, and is probably insignificant with nifedipine.

Ventricular Arrhythmias Complicating Heart Failure

Amiodarone

54. B.J. (from Question 48) was stabilized over the next several days and discharged home with furosemide 40 mg QD, enalapril 5 mg QD, metoprolol XL 100 mg QD, aspirin 81 mg QD, and NTG 0.4 mg sublingual (SL) to be used as needed for chest pain. His EF after the infarction was 23%. Laboratory values were all normal. ECG monitoring during B.J.'s hospital stay showed normal sinus rhythm, but he was having 15 to 20 asymptomatic PVC/hour. At that time, it was decided not to treat his arrhythmia other than with metoprolol because he was asymptomatic. Over the next several months, he continued to have frequent PVC during follow-up examinations in the cardiology clinic.

It has now been 5 months since B.J.'s infarction and he is still having up to 12 to 15 PVC/minute. His exercise capacity is limited by SOB after walking about a block despite having his enalapril increased to 20 mg/day, metoprolol XL to 200 mg/day, and adding digoxin 0.25 mg QD. The furosemide is still at 40 mg/day because he has little edema. Is an antiarrhythmic agent indicated for B.J. at this time? What is the agent of choice and what dose should be given?

Premature ventricular contractions and other arrhythmias are a common complication of left ventricular dysfunction and may be present regardless of whether the patient has had an MI. Approximately 50% to 70% of patients with HF have episodes of nonsustained ventricular tachycardia on ambulatory monitoring.⁶ This myocardial irritability may be a result of autonomic hyperactivity or ventricular remodeling that can accompany HF. It is not clear, however, if these rhythm disturbances contribute to sudden death or simply reflect the underlying disease process. Recent studies suggest that sudden death in patients with HF is more likely caused by an acute ischemic event in patients with underlying CAD or to a bradyarrhythmia or electromechanical dissociation in patients with nonischemic cardiomyopathy. More importantly, suppression of ventricular ectopy in patients with HF has not been shown to lead to a reduction of sudden death in clinical trials. B.J.'s PVC were first noted after his MI. As discussed in detail in Chapters 17 (Myocardial Infarction) and 19 (Cardiac Arrhythmias), neither prophylactic antiarrhythmic therapy nor treatment of asymptomatic PVC following an MI has been proven to improve outcome or survival. In fact, because of concerns over proarrhythmic effects of most class IA (e.g., quinidine) and class IC (e.g., encainide, flecainide) drugs, as well as sotalol, treatment is considered contraindicated.

It has now been several months since B.J.'s infarct and he continues to have frequent PVC along with HF symptoms that place him in the NYHA class II–III category. It is suggested that amiodarone has value in patients with HF with arrhythmias because it has both antiarrhythmic properties as well as coronary vasodilating effects and α - and β -blocking properties. Thus, it may offer a dual benefit to reduce myocardial irritability and improve the hemodynamics of HF.

One meta-analysis reviewed 13 randomized, controlled trial of prophylactic amiodarone in patients with either recent MI ($n = 8$) or HF ($n = 5$).³¹³ None of the individual trials was powered to detect a mortality reduction of 20%. After loading doses of 400 to 800 mg/day for 2 weeks, maintenance doses ranged from 200 to 400 mg/day. This information taken as a whole, the authors concluded that prophylactic amiodarone reduces the rate of arrhythmic or sudden death in high-risk patients and this effect results in an overall 13% reduction in total mortality. Because this analysis combined trials of both MI and HF patients, it is helpful to look at two of the key HF trials.

In the Grupo de Estudio de la Sobrevida en la Insuficiencia Cardíaca en Argentina (GESICA) study,³¹⁴ 516 patients with class II to IV HF symptoms (79% class III or IV), an average EF of 20%, and frequent PVC on cardiac monitoring were randomized to receive either standard treatment (diuretics, vasodilators, digoxin) or a fixed dose of amiodarone plus standard treatment. The dose of amiodarone was 600 mg daily for the first 2 weeks, then 300 mg/day for at least 1 year. Of 260 patients on amiodarone, 87 (33.5%) died during follow-up compared with 106 of 256 (41.4%) receiving standard treatment, a statistically significant difference in favor of amiodarone ($p = 0.02$). Similarly, the number of HF-related hospitalizations was reduced with amiodarone. No data were presented on changes in EF, but a trend toward more patients in the amiodarone group being judged to have a decrease of at least one stage in NYHA class was noted.

Somewhat different outcomes were noted by the investigators in the Veteran's Administration Cooperative Survival Trial of Antiarrhythmic Therapy in Congestive Heart Failure (CHF-STAT) study.^{315,316} Entry criteria to this trial were similar to the GESICA study, with a primary indicator being >10 asymptomatic PVC per minute on 24-hour monitoring, but without sustained ventricular tachycardia. A higher dose of amiodarone was used, starting with 800 mg for the first 2 weeks, then 400 mg/day for 1 year. The dose was reduced to 300 mg/day after the first year, with the average follow-up being 45 months (4.5 years maximum). Disappointingly, no difference between groups for either all-cause mortality (39% amiodarone vs. 42% placebo) or sudden cardiac death (15% amiodarone vs. 17% placebo) was found. Similarly, 2-year survival was 69.4% with amiodarone and 70.8% with placebo. Higher survival in the amiodarone group after the first 2 years was a noted trend, but the number of subjects followed for longer periods was not sufficiently large to establish significance. An encouraging finding in this study was that EF improved more in the patients treated with amiodarone, rising from a baseline average of 24.9% to posttreatment values of 33.7%. Corresponding change in the standard treatment group was from a baseline of 25.8% to 29.2% at follow-up. Despite the increase in EF, symptom scores did not differ between the two groups.

Together, these two studies still leave unclear the role of amiodarone in patients with HF with asymptomatic arrhythmias. The encouraging finding is that amiodarone does not seem to have a negative effect on mortality as seen with other antiarrhythmic agents or with inotropic stimulants. On the other hand, the two studies cited have conflicting findings regarding value in improving survival and functional capacity of patients. In comparing the two studies, it has been noted that the patients in the GESICA study had more advanced

disease (79% class III or IV; average EF 20%; 55% 2-year placebo mortality) than those in the VA study (43% class III or IV; average EF 25%; 29% 2-year placebo mortality); more patients had nonischemic cardiomyopathy in GESICA (60%) compared with 29% in the VA study; 99% of the VA subjects were men, whereas 19% of GESICA subjects were women; and the dose of amiodarone was lower in GESICA.³¹⁷ Further subgroup analysis suggests that those with more advanced disease, nonischemic cardiomyopathy, and female sex have better outcomes. Contradicting this speculation was a trend toward better outcomes in the small number of patients with class II symptoms in GESICA.³¹⁴ Other factors to consider are the potential for significant side effects with amiodarone (see Chapter 19, Cardiac Arrhythmias) and the risk that digoxin levels might increase after the addition of amiodarone (see Question 39).

The ACC/AHA guidelines do not recommend routine ambulatory ECG monitoring in to detect asymptomatic ventricular arrhythmias in patients with HF, and also recommend against treatment if such arrhythmias are inadvertently detected.⁷ If symptomatic ventricular arrhythmias should arise, or there is determined to be a high risk for sudden death, one of the following should be considered: a β -blocking drug, amiodarone, and/or an implantable cardioverter-defibrillator (ICD). As discussed extensively throughout this chapter, nearly all patients with HF should have a β -blocker as part of their regimen because these drugs reduce all cause mortality, not just sudden death. B.J. was started on metoprolol after his MI, but continued to have ectopy despite continued use of a β -blocker. Nonetheless, it is decided not to use amiodarone because he has ischemic cardiomyopathy and is not bothered by his arrhythmia.

IMPLANTABLE CARDIOVERTER-DEFIBRILLATOR

55. Is B.J. a candidate for an implantable cardioverter-defibrillator implantation?

Although amiodarone is the preferred antiarrhythmic agent in patients with HF with reduced EF to prevent reoccurrent atrial fibrillation and symptomatic ventricular arrhythmias, it has not shown survival benefits. Ventricular arrhythmias are associated with high frequency of sudden cardiac death (SCD) in patients with HF. Numerous trials have established the role of ICD in primary and secondary prevention of sudden cardiac death. The most recent trial, the Sudden Cardiac Death in Heart Failure trial (SCD-HeFT) evaluated the efficacy of amiodarone in patients with LV dysfunction.³¹⁷ The patients (NYHA class II–III) were randomized to conventional therapy or placebo, conventional therapy plus amiodarone, or conventional therapy plus ICD. Amiodarone was no better than placebo, whereas, ICD decreased mortality by 23%. A subgroup analysis showed that patients with class II HF had a greater drop in mortality with ICD use than class III patients. Also, amiodarone decreased survival in class III HF. The role of amiodarone in patients with NYHA class III needs to be further evaluated before it is routinely used in patients with LV dysfunction.

The 2005 ACC/AHA guidelines recommend the use of ICD in patients after MI with reduced LVEF and who have a history of ventricular arrhythmias. ICD is also recommended for primary prevention in patients with nonischemic cardiomyopathy and ischemic heart disease who have a LVEF \leq 30%,

with NYHA functional class II or III symptoms while on optimal standard oral therapy, and in patients who have reasonable expected survival with a good functional status of 1 or more years.⁷ Patients with ischemic heart disease should be at least 40 days post MI to receive an ICD. B.J. is currently on optimal HF drug regimen. Based on the results of SCD-HeFT trial, he would benefit from ICD implantation.

CARDIA-RESYNCHRONIZATION THERAPY

56. C.M., a 49-year-old woman with a history of cardiomyopathy (EF 25%), presents to the HF clinic with NYHA class III symptoms. She reports increased SOB, chest pain, and fatigue. She has been optimized on drug therapy for 3 months. Her medications include metoprolol 200 mg QD, furosemide 40 mg BID, lisinopril 20 mg QD, spironolactone 25 mg QD, and KCl 40 mEq. An ECG showed sinus rhythm at a rate of 72 beats/minute, QRS duration of 144 millisecond. Is she a candidate for CRT?

Approximately one-third of the patients with advanced systolic HF exhibit intra- or interventricular conduction delays that cause the ventricles to beat asynchronously.³¹⁸ This ventricular dyssynchrony, which is often seen on the ECG as a wide QRS complex with a left bundle branch block, can lead to deleterious effects on cardiac function. Patients may present with reduced EF, decreased CO, and presence of NYHA class III–IV HF symptoms. These are all associated with increased mortality.

Cardiac resynchronizathion therapy (CRT) is the use of cardiac pacing to coordinate the contraction of the left and right ventricles.³¹⁹ Initial randomized trials of CRT show reduced HF symptoms, and improved exercise tolerance and quality of life; but they have not demonstrated conclusive mortality benefits. The Comparison of Medical Therapy, Pacing, and Defibrillator in Heart Failure (COMPANION) trial³¹⁹ enrolled 1,520 patients with NYHA class II or IV (ischemic or non-ischemic cardiomyopathies, QRS interval of at least 120 milliseconds, and LVEF \leq 35%) who were treated with optimal drug therapy (ACE, diuretics, β -blockers, and spironolactone). Patients were randomized to receive optimal drug therapy (OPT) alone, OPT and CRT with a pacemaker, or OPT and CRT with ICD (CRT-D). The primary endpoint was a composite of all-cause mortality and hospitalization. Both CRT and CRT-D groups were associated with a decreased risk of primary endpoint, respectively ($p = 0.014$, $p = 0.01$) compared with OPT alone. All-cause mortality at 1 year was decreased by 24% in the CRT group and 43% in the CRT-D group however was not significantly reduced in the CRT group.

The results of the Cardiac Resynchronization in Heart Failure study (CARE-HF)³²⁰ extended the landmark findings of the COMPANION trial. CARE-HF demonstrated a significant all-cause mortality reduction for CRT pacing without defibrillator backup (CRT-P) in patients with HF medically treated similarly. This study was conducted in a total of 813 patients. The inclusion criteria were NYHA class III–IV, EF \leq 35%, and QRS duration of \geq 120 milliseconds (MS). Approximately 35% of patients had ischemic heart disease. The primary endpoint of all-cause deaths and hospitalizations for a major cardiovascular reason occurred in fewer patients in the CRT group compared with the OPT group (39% vs. 55%; $p < 0.001$). Death or hospitalization for worsening HF was also significantly reduced in the CRT group.

Thus, the combined results of CARE-HF and COMPANION confirm the importance of CRT and CRT-D in improving ventricular function, HF symptoms, and exercise tolerance, while also reducing frequency of HF hospitalizations by 37% and death by 22%.³²¹ The role of CRT in patients with mild HF symptoms, narrow QRS, chronic atrial fibrillation, and right bundle branch block need to be explored.

According to the 2005 ACC/AHA guidelines,⁷ patients with NYHA class III and ambulatory patients with class IV HF should receive CRT (unless contraindicated) if they meet the following criteria: LVEF $\leq 35\%$, presence of electric asynchrony as shown by a wide QRS (>120 milliseconds), and receiving optimal HF standard medical therapy. Despite optimal doses of HF medications, C.M. continues to have HF symptoms. CRT could provide incremental benefits beyond what is provided with neurohormonal therapy.

Herbal Products and Nutritional Supplements

57. W.L., a 60-year-old man with HF recently diagnosed by his naturopath, is concerned by his decreasing exercise capacity and increasing SOB during his morning walks in the local mall. His blood pressure is 170/85 mm Hg and he has 1 to 2+ ankle edema. He distrusts medical doctors and wants to treat his HF naturally. One time in the past he was given hydrochlorothiazide for BP reduction, but stopped taking it after a few days because he did not tolerate the urinary urgency it caused. The naturopath has prescribed 200 mg/day of Hawthorn leaf and 50 mg/day of coenzyme Q. How effective is this treatment plan likely to be?

Hawthorn

Hawthorn extracts from the leaves and flowers of *Crataegus monogyna* and *C. oxyacantha* have been reported to have beneficial effects in mild HF.^{322,323} Oligomeric procyanidins and flavanoids are considered the key active ingredients. Hawthorn extracts have shown positive inotropic action, weak ACE inhibition, vasodilating properties, and increased coronary blood flow *in vitro* and in animal models. In short-term (8 weeks or less), placebo-controlled trials in patients with the equivalent of NYHA class II HF, modest improvements were noted in exercise tolerance and subjective symptoms as well as decreases in HR and BP. Patients with more advanced HF were excluded. A systematic review by Pittler et al. also concluded that hawthorn extract was efficacious in the treatment of HF on top of standard HF therapy.³²⁴ Conversely, the results of the Hawthorne Extract Randomized Blinded Chronic Heart Failure (HERB-CHF) trial failed to provide any evidence that hawthorn was beneficial in patients with HF who were already receiving standard medical therapy.³²⁵ The Commission E monograph lists no side effects or contraindications. In clinical trials, side effects of hawthorn include nausea, vomiting, diarrhea, palpitations, chest pain, and vertigo. These side effects are more common when doses exceed 900 mg/day, but in some trials have not occurred more often than placebo. The risks and benefits of using hawthorn and digoxin together, both of which have positive inotropic effects, is not known.

To further investigate the longer-term benefits of hawthorn, additive effects to conventional therapy, and effect on mortality were tested in the Survival and Prognosis: Investigation of Crataegus Extract WS 1442 in Congestive Heart Failure

(SPICE) trial.³²⁶ The trial enrolled 2,681 patients with NYHA class II–III, LVEF $\leq 35\%$, who were randomized to hawthorn or placebo for 2 years. Although the study failed to show any clear cardioprotective benefits in the treatment of chronic HF, hawthorn was well tolerated and can be safely added to standard therapy.

Coenzyme Q

Coenzyme Q, also known as ubiquinone and ubidecarenone, is an endogenously synthesized provitamin that is structurally similar to vitamin E and serves as a lipid-soluble electron transport carrier in mitochondria and aids in the synthesis of adenosine triphosphate.^{327,328} It might also have membrane-stabilizing properties, enhance the antioxidant effects of vitamin E, and stabilize calcium-dependent slow channels. In animal models, it has positive inotropic effects, although weaker than from digoxin. As has been reviewed, more than 18 open-label and double-blind, randomized clinical trials have been conducted of coenzyme Q in patients with HF ranging from NYHA classes II to IV.³²⁷ Doses varied from 50 to 200 mg/day. In contrast to Hawthorn, the patients in many of these trials were also taking diuretics, ACE inhibitors, and digoxin. Different trials used different end point measurements. Positive effects on subjective symptoms, NYHA class improvement, EF, quality of life and hospitalization rates have all been observed. Two trials, however, failed to demonstrate significant changes in EF, vascular resistance, or exercise tolerance. None of the trials had sufficiently large samples sizes or adequate duration of assessment to detect reduction in mortality. Side effects were consistently minimal, but included nausea, epigastric pain, diarrhea, heartburn, and appetite suppression. Mild increases in lactate dehydrogenase and hepatic enzymes have been rarely reported with coenzyme Q doses in excess of 300 mg/day.

It can be concluded that hawthorn and coenzyme Q are both safe in the treatment of HF and might provide symptomatic improvement, especially in patients with mild HF (NYHA class II). Only coenzyme Q has been shown to be of benefit as an adjunct to conventional therapies. It is unknown if using hawthorn and coenzyme Q together, as prescribed for W.L., will have an additive effect. No conclusion can be drawn about their effects on mortality rates.

W.L. has poorly controlled systolic hypertension and HF that is beginning to interfere with his activities of daily life. Although evidence indicates that patients with NYHA class II HF obtain symptomatic improvement with hawthorn and coenzyme Q, this does not address W.L.'s hypertension. (As reviewed by Tran et al.,³²⁷ conflicting data exist on the value of coenzyme Q in lowering blood pressure.) Also the results of the SPICE trial did not demonstrate any mortality benefits. Also, no incremental benefits were seen when combined with standard therapy. Even if W.L. and his naturopath are both satisfied with his responses to hawthorn and coenzyme Q, significant concern still exists of what will happen when and if his disease progresses. Uncontrolled hypertension in patients with HF can further lead to cardiac remodeling resulting in worsening HF. Currently he is presenting with symptomatic HF, therefore he should be started on a diuretic to alleviate his symptoms. Starting with a 20-mg dose of furosemide and titrating slowly may be one approach. For all of the reasons cited throughout this chapter, one must also argue strongly

for starting an ACE inhibitor to control his hypertension. He should be counseled that the urinary frequency he experienced previously should diminish after a few days.

He is being started on both hawthorn and coenzyme Q simultaneously. If he does improve, it will be difficult to assess

whether it is because of only one of the agents or the combination. With this in mind, it might be more logical to continue hawthorn alone at a dose of 450 mg BID. If no benefit is derived after 1 month, hawthorn should be stopped and coenzyme Q started at 100 mg/day.

Adequate blood pumping depends on a continuous, well-coordinated electrical activity within the heart. This chapter reviews and discusses cardiac electrophysiology, arrhythmogenesis, common arrhythmias, and antiarrhythmic treatment.

Electrophysiology

Cellular Electrophysiology

An electrical potential exists across the cell membrane that changes in a cyclic manner related to the flux of ions across the cell membrane, principally K^+ , Na^+ , and Ca^{2+} . If the change in the membrane potential is plotted against time in a given cycle of a His-Purkinje fiber, a typical action potential results (Fig. 19-1).

The action potential can be described in five phases. Phase 0 is related to ventricular depolarization resulting from sodium

entry into the cell through fast sodium channels. On a surface electrocardiogram (ECG), phase 0 is represented by the QRS complex. Phase 1 is the overshoot phase where calcium enters the cell and contraction occurs. During phase 2, the plateau phase, inward depolarizing currents through slow sodium and calcium channels are counterbalanced by outward repolarizing potassium currents. Phase 3 constitutes repolarization, which on an ECG is represented by the T wave. During phase 4, sodium moves out of the cell and potassium moves into the cell via an active pumping mechanism. During this phase, the action potential remains flat in some cells (e.g., ventricular muscle) and does not change until it receives an impulse from above. In other cells (e.g., sinoatrial [SA] node), the cell slowly depolarizes until it reaches the threshold potential and again spontaneously depolarizes (phase 0). The shape of the action potential depends on the location of the cell (Fig. 19-1). In both

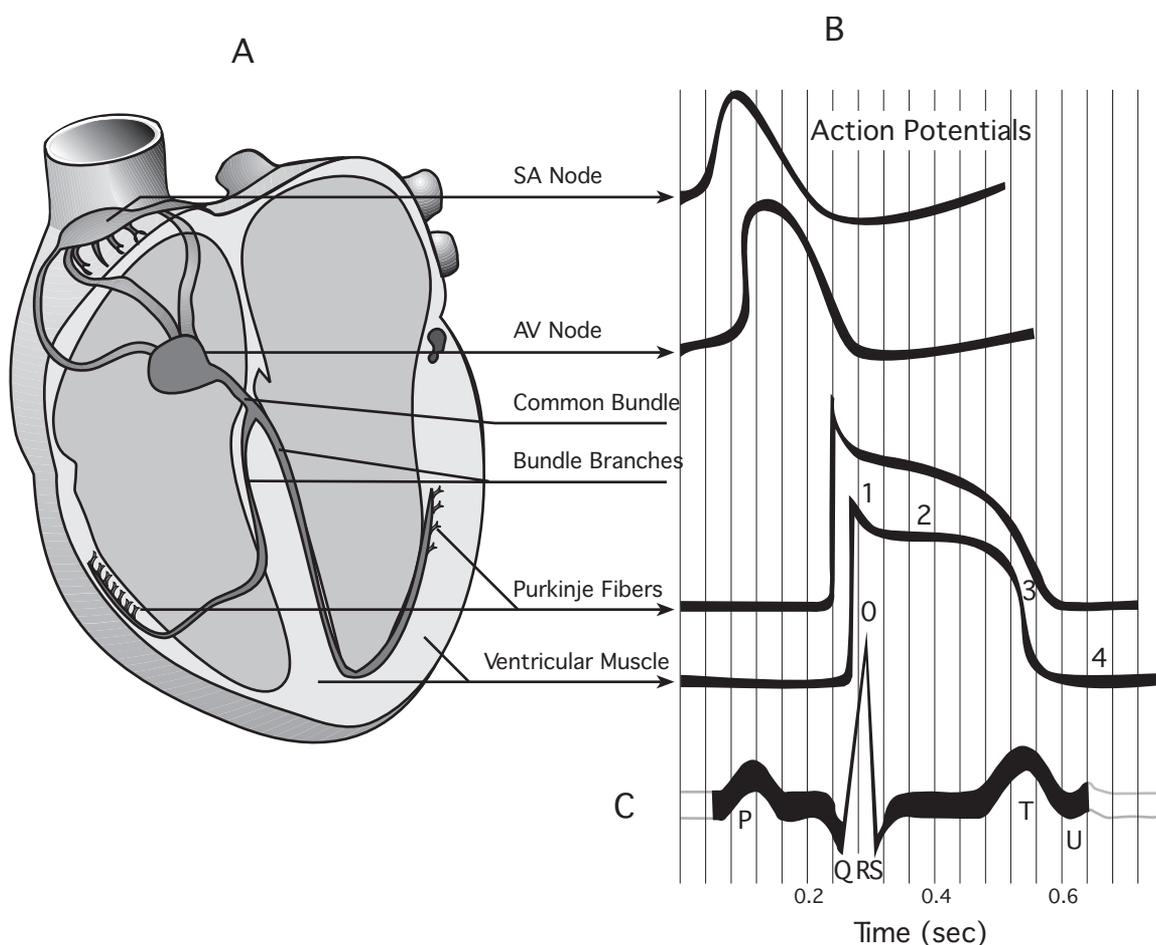

FIGURE 19-1 The cardiac conduction system. **A:** Cardiac conduction system anatomy. **B:** Action potentials of specific cardiac cells. **C:** Relationship of surface electrocardiogram to the action potential. SA, sinoatrial; AV, atrioventricular.

the SA and atrioventricular (AV) nodes, the cells are more dependent on calcium influx than sodium influx, resulting in a less negative resting membrane potential, a slow rise of phase 0, and the capability of spontaneous (automatic) phase 4 depolarization (Fig. 19-1).

The upward slope of phase 0, referred to as V_{max} , is related to the conduction velocity. The steeper the slope, the more rapid is the rate of depolarization. Another influence on V_{max} is the point at which depolarization occurs. The less negative the threshold potential, the slower V_{max} will be, and hence conduction velocity is slowed. Drugs can affect V_{max} and conduction velocity by blocking the fast sodium channels or by making the resting membrane potential less negative (e.g., class I agents).

The action potential duration is the length of time from phase 0 to the end of phase 3. The effective refractory period is the length of time that the cell is refractory and will not propagate another impulse. Both measurements can be obtained from intracardiac recordings of the action potential. Class IA and III agents prolong the refractoriness of the heart.

Normal Cardiac Electrophysiology

Normal cardiac electrical activity begins with automatic impulse generation (automaticity) at the SA node and then normal impulse conduction through the heart.

AUTOMATICITY

Automaticity is the ability of cells (often referred to as pacemaker cells) to depolarize spontaneously. These cells are located in the SA and AV nodes and the His-Purkinje system. The SA node is normally the dominant pacemaker because it reaches the threshold faster than other nodes in a normal heart, resulting in 60 to 100 depolarizations per minute. The innate AV node and Purkinje rate of depolarization is 40 to 60 and 40 depolarizations per minute, respectively. In the healthy heart, the AV node and Purkinje fibers are prevented from spontaneous depolarization (overridden) by the more frequent impulses from the SA node. If the normal conduction system is disrupted (e.g., after a myocardial infarction [MI]), the AV node or Purkinje fibers may temporarily become the dominant pacemaker.

CONDUCTION

An impulse normally originates in the SA node and travels down the specialized intranodal pathways to activate the atrial muscle and the AV node. The AV node holds the impulse briefly before releasing it to the bundle of His. It then travels to the right and left bundle branches and out to the ventricular myocardium via the Purkinje fibers. The ECG tracing consists of a series of complexes that correspond to electrical activity

Table 19-1 Normal Electrophysiological Intervals

| Interval | Normal Indices (milliseconds) | Electrical Activity | Measured by |
|------------------|-------------------------------|----------------------------|-------------------|
| P-R | 120–200 | Atrial depolarization | Surface ECG |
| QRS | <140 | Ventricular depolarization | Surface ECG |
| QTc ^a | <400 | Ventricular repolarization | Surface ECG |
| J-T ^b | — | Ventricular repolarization | Surface ECG |
| A-H ^c | <140 | — | Intracardiac lead |
| H-V ^d | <55 | — | Intracardiac lead |

^aQTc interval is the Q-T interval corrected for heart rate. A common method for calculating QTc is the Q-T interval/(R-R interval)^{1/2} (Bazett formula).

^bJ-T interval is obtained by subtracting the QRS interval from the Q-T interval.

^cA-H interval is the time it takes for an impulse to travel from the sinoatrial node to the bundle of His.

^dH-V interval is the time it takes for an impulse to travel from the bundle of His to the Purkinje fibers.

ECG, electrocardiogram.

in a specific location or anatomic site. By convention, these electrical deflections have been labeled the P wave, QRS complex, and T wave. The P wave represents depolarization of the atria, whereas the QRS complex reflects ventricular depolarization. The T wave reflects repolarization of the ventricles. To evaluate the intact conduction system, conduction intervals at different sites can be obtained. The normal intervals as measured by ECG or intracardiac electrodes are shown in Table 19-1. Drugs and ischemia can alter the conduction and hence the ECG intervals. The effects of antiarrhythmic agents on the ECG are described in Table 19-2.

An Approach to Reading Electrocardiograms

Electrocardiographic Paper

Calculation of the various intervals and widths is facilitated by recording the ECG waveforms on graph paper consisting of large squares defined by heavier lines, which in turn are composed of smaller squares. Each small square is 1 mm long and represents 0.04 seconds. The larger squares are composed of five small squares (5 mm in length) and represent 0.20 seconds (Fig. 19-2).

Table 19-2 Pharmacologic Properties of Antiarrhythmics

| Type | Surface ECG | | | Conduction Velocity | Refractory Period |
|------|----------------|--------------|--------------|---------------------|-------------------|
| | P-R Interval | QRS Interval | Q-T Interval | | |
| IA | 0/↑ | ↑ | ↑↑ | ↑↓ ^a | ↑ |
| IB | 0 | 0 | 0 | 0/↓ | ↓ |
| IC | ↑ | ↑↑ | ↑ | ↑ | 0 |
| II | ↑↑ | 0 | 0 | ↓ ^b | ↑ ^b |
| III | 0 ^c | 0 | ↑↑ | 0 | ↑ |
| IV | ↑↑ | 0 | 0 | ↓ ^b | ↑ ^b |

^aConduction increases at low dosages and decreases at higher dosages.

^bOn atrial and atrioventricular nodal tissue.

^cMay cause P-R prolongation independent of class III antiarrhythmic activity.

ECG, electrocardiogram.

Rhythm Interpretation

ECG tracings are evaluated through a systematic review as described:

1. Is the rate fast or slow? A simple method to determine the rate is to count the number of complexes occurring within 6 seconds and multiply by 10. Most ECG recording paper places vertical lines at the top of the grid, 3 seconds apart. Therefore, if eight complexes appear within a 6-second length of strip, the rate is 80 beats/minute.
2. Are there P waves before each QRS complex, and is their configuration normal? Are the P wave-to-P wave and R wave-to-R wave intervals regular or irregular? If the rhythm is irregular, is the pattern of irregularity consistent (regularly irregular) or totally random (irregularly irregular)? P waves appearing before the QRS complex usually indicate that the impulse originated in the SA node and was subsequently conducted to the ventricle. Abnormal-appearing P waves indicate that an atrial site other than the SA node is initiating the beat. Irregular rhythms may be due to an impulse originating from a site other than the SA node before the normal pacemaker can fire (premature beat); they also may result from failure to conduct impulses from the atria.
3. Are the P-R and QRS complexes within normal limits? Is the QRS complex normal in its configuration? Impulses originating above the ventricles with normal conduction through the bundle branches and myocardium produce a normal-appearing, narrow QRS complex. Impulses originating in the ventricle give rise to wide, bizarre-appearing QRS complexes.

Pathophysiology

Abnormal Impulse Formation

Abnormal impulse formation can arise from abnormal automaticity or triggered activity originating from the SA node (e.g., sinus bradycardia) or other sites (e.g., junctional or idioventricular tachycardia). Causes of abnormal automaticity include hypoxia, ischemia, or excess catecholamine activity.

Triggered activity occurs when there is an attempted depolarization before or after the cell is fully repolarized, but not by a pacemaker cell (Fig. 19-3). These after-depolarizations may occur in phase 2 or 3 (early) or phase 4 (delayed) of the action potential. Early after-depolarizations (EADs) arise from a reduced level of membrane potential and may require a bradycardic state. Torsades de pointes (TdP), a form of polymorphic ventricular tachycardia (VT), is believed to be initiated by EADs. Delayed after-depolarizations, often seen with digoxin toxicity, are believed to be secondary to an overload of intracellular free calcium.

Abnormal Impulse Conduction

RE-ENTRY

The most common abnormal conduction leading to arrhythmogenesis is re-entry. A re-entrant circuit is formed as normal conduction occurs down a pathway that bifurcates into two pathways (e.g., AV node or left and right bundle branches). The impulse travels along one pathway (Fig. 19-4, pathway 1) but encounters unidirectional antegrade (forward movement) block in the other pathway (Fig. 19-4, pathway 2). The impulse that passed through the unblocked pathway propagates in a

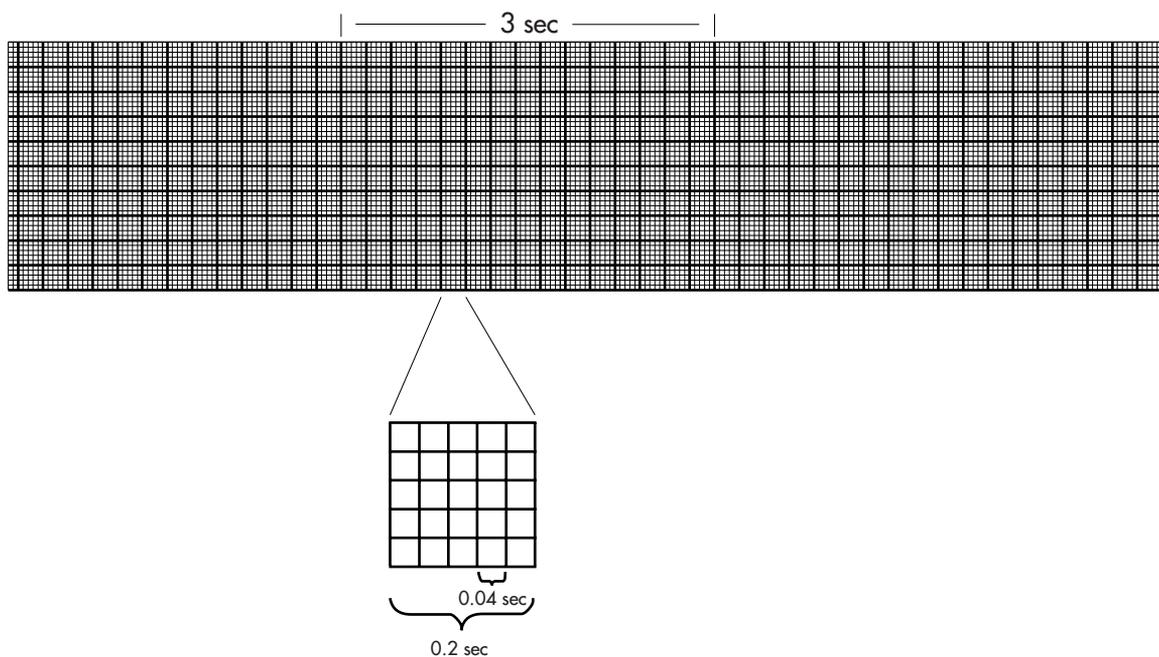

FIGURE 19-2 Electrocardiogram recording paper.

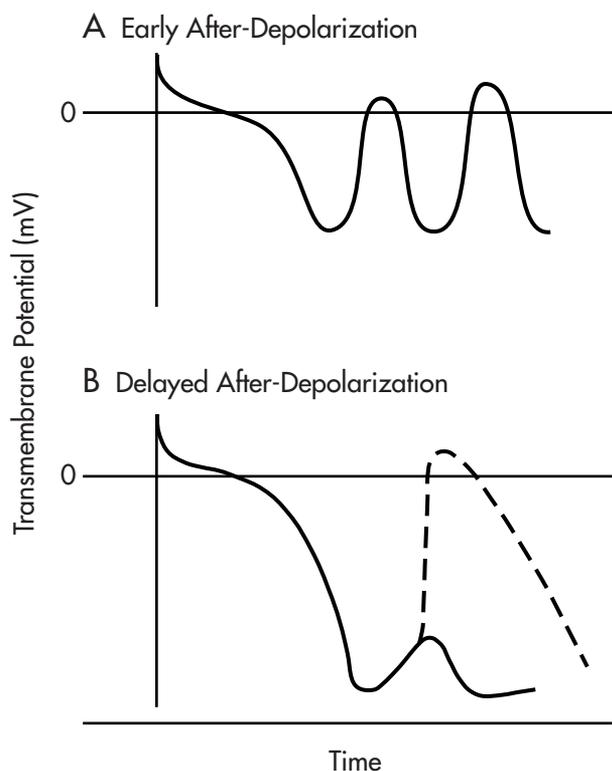

FIGURE 19-3 Triggers of triggered activity. **A:** Early after-depolarizations; repolarization is interrupted by secondary depolarization. Such responses may excite neighboring fibers and be propagated. **B:** Delayed after-depolarizations; after full repolarization is achieved, the cell transiently depolarizes. If the delayed after-depolarization reaches threshold, a propagating response can be seen (---). *Source:* Reproduced with permission from Bigger JT, Hoffman BF. *Antiarrhythmic drugs.* In: Goodman AG et al, eds. *Goodman and Gilman's The Pharmacologic Basis of Therapeutics.* New York: McGraw Hill; 1991:853.

retrograde manner (i.e., moves backward) through the previously blocked pathway. This abnormal impulse can travel down the first pathway again when it is not refractory. Supraventricular and monomorphic VT are both examples of re-entrant arrhythmias (see question 20).

BLOCK

Another form of abnormal impulse conduction occurs when the normal conducting pathway is blocked and the impulse is forced to travel through nonpathway tissues to cause depolarization. Common examples are left bundle branch blocks

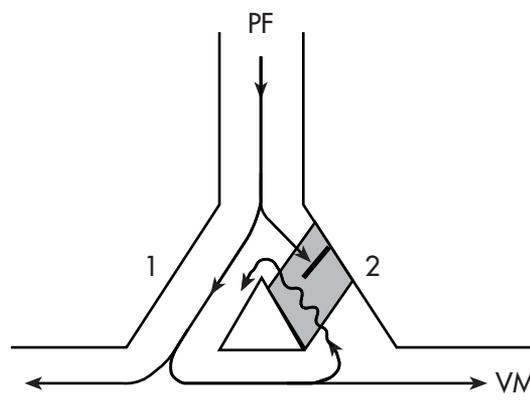

FIGURE 19-4 Re-entrant circuit of the ventricle. A branched Purkinje fiber (PF) terminates on a strip of ventricular muscle (VM). The shaded area in branch 2 represents a depolarized area that is the site of a one-way block; thus, the sinus impulses are blocked in this area, but retrograde impulses are propagated. Retrograde conduction in branch 2 is slow enough for the cells in branch 1 to recover and respond to the re-entry impulse. *Source:* Reproduced with permission from Bigger JT, Hoffman BF. *Antiarrhythmic drugs.* In: Goodman AG et al, eds. *Goodman and Gilman's The Pharmacologic Basis of Therapeutics.* New York: McGraw Hill; 1991:853.

(LBBBs) and right bundle branch blocks (RBBBs) in the ventricles. A block in one path necessitates retrograde conduction through the opposite bundle to stimulate both ventricles. Typically, the nonpathway tissue conducts the electrical impulse more slowly than normal conduction tissues.

Classification of Arrhythmias

All arrhythmias originating above the bundle of His are referred to as supraventricular arrhythmias. These may include sinus bradycardia, sinus tachycardia, paroxysmal supraventricular tachycardia, atrial flutter, atrial fibrillation (AF), Wolff-Parkinson-White (WPW) syndrome, and premature atrial contractions (PACs). These arrhythmias are characterized by normal QRS complexes (i.e., normal ventricular depolarization) unless there is a bundle branch block. Not all of these rhythm changes are necessarily a sign of pathology. For example, athletes with a well-conditioned heart and large stroke volume commonly have slow heart rates (sinus bradycardia). Vigorous exercise is commonly accompanied by transient sinus tachycardia.

Arrhythmias originating below the bundle of His are referred to as ventricular arrhythmias. These include premature ventricular contractions (PVCs), VT, and ventricular fibrillation (VF).

Conduction blocks often are categorized separately based on their level or location, which can be a supraventricular site (e.g., first-, second-, or third-degree AV block, see Question 27) or in the ventricle (e.g., RBBB or LBBB). An alternative method of classifying arrhythmias is based on the rate: bradyarrhythmia (<60 beats/minute) or tachyarrhythmia (>100 beats/minute).

Antiarrhythmic Drugs

Based on their electrophysiologic and pharmacologic effects, there are four Vaughn-Williams antiarrhythmic drug classes. Class I drugs, sodium channel blockers, are subdivided further, depending on the duration of channel blockade (class IA is intermediate, IB is quick, and IC is long). Class II drugs are β -adrenergic blockers, class III drugs are potassium channel blockers, and class IV drugs are calcium channel blockers. The classification, pharmacokinetics, and adverse effects of these agents are summarized in Table 19-3.

Class IA and class III antiarrhythmics increase repolarization time, the QTc interval, and the risk of TdP. Class II and IV antiarrhythmics can decrease the heart rate (may cause bradycardia), decrease the force of ventricular contractility (may decrease stroke volume), and prolong the PR interval (may cause second- or third-degree AV block). Class IB antiarrhythmics work only in ventricular tissue, so they cannot be used in AF or atrial flutter. Class IC antiarrhythmic agents are useful, but should never be used after an MI or with heart failure (HF) or severe left ventricular hypertrophy (classified as structural heart diseases) because increased mortality can result. These drugs are discussed in greater detail later.

SUPRAVENTRICULAR ARRHYTHMIAS

The specific arrhythmias include (a) those primarily atrial in origin, such as AF, atrial flutter, paroxysmal sinus tachycardia,

ectopic atrial tachycardia, and multifocal atrial tachycardia; and (b) atrioventricular nodal re-entrant tachycardia (AVNRT) and atrioventricular re-entrant tachycardia (AVRT) involving accessory pathways within the atria and/or ventricle. AVNRT and AVRT often self-terminate and are paroxysmal (episodic) in nature; thus, they are commonly referred to as paroxysmal supraventricular tachycardias (PSVTs). The most common supraventricular arrhythmias are AF, atrial flutter, and PSVT.

Atrial Fibrillation/Flutter

AF is characterized by rapid, ineffective writhing of the atrial muscle with a classic “irregularly irregular” ventricular rate. The source of the arrhythmia is one or more ectopic areas (foci) that act as independent pacemakers and fire at such a rate as to suppress normal impulse generation from the SA node. On the ECG, no identifiable P waves are present (Fig. 19-5). In contrast, atrial flutter (Fig. 19-6) is characterized by typical sawtooth atrial waves, at a rate of 280 to 320 beats/minute and a variable ventricular rate, depending on the nature of the AV block present (e.g., 2:1, 3:1, or 4:1 block). In most cases, the ventricular rate is approximately 150 beats/minute. Patients with atrial flutter often progress to AF. The underlying diseases and treatments of atrial flutter and AF are similar. The arrhythmogenic mechanism of AF may be due to multiple re-entrant wavelets, occurring in a paroxysmal, chronic, or acute pattern. The most common presentation is paroxysmal atrial fibrillation (PAF), which can progress to chronic AF; thus, the two overlap. An example of PAF is presented in the following section.

Clinical Manifestation and Underlying Causes

1. J.K., a 66-year-old man, presents with complaints of mild shortness of breath (SOB) and palpitations for the last 2 weeks. He experienced palpitations of shorter duration three times in the last year, but these were not associated with SOB. His medical history includes type II diabetes mellitus for the past 5 years, hypertension, and gout. There is no history of rheumatic heart disease, MI, HF, pulmonary embolism, or thyroid disease. Medications include glyburide (DiaBeta) 5 mg twice a day (BID), hydrochlorothiazide 25 mg/day, and allopurinol (Zyloprim) 300 mg/day. J.K. does not smoke or drink alcohol. Physical examination reveals a blood pressure (BP) of 136/84 mmHg, pulse of 154 beats/minute with an irregularly irregular pattern, respiratory rate (RR) of 16 breaths/minute, and temperature of 98.2°F. He has bilateral rales on chest auscultation. Cardiac examination reveals an irregularly irregular rhythm without murmurs, gallops, or rubs. His jugular vein is distended 4 cm, but no organomegaly is found. His extremities have 1+ pitting edema. The ECG shows AF (Fig. 19-5), and the chest radiograph is compatible with mild HF. A cardiac echocardiogram reveals the atrial size to be <5 cm (normal) and a previously unknown ejection fraction (EF) of 35% (low). In view of his history and previous episodes, J.K. is diagnosed with PAF. Which of J.K.’s other medical problems may predispose him to AF development? What other conditions commonly are associated with AF?

AF is commonly associated with or a manifestation of other diseases or disorders (Table 19-4).¹ When treatable underlying causes are present, they should be corrected because this may resolve the AF. This episode of AF in J.K. could be due to

Table 19-3 Vaughn-Williams Classification of Antiarrhythmic Agents

| <i>Drug and Classification</i> | <i>Pharmacokinetics</i> | <i>Indications</i> | <i>Side Effects</i> |
|---|--|--|---|
| Class IA (can cause torsade de pointes similar to class III agents) | | | |
| Quinidine sulfate (83% quinidine; SR: Quinidex) Quinidine gluconate (62% quinidine; SR: Quinaglute) | $t_{1/2} = 6.2 \pm 1.8$ hr (affected by age, cirrhosis); Vd = 2.7 L/kg (\downarrow in HF); liver metabolism, 80%; renal clearance, 20%; Cp = 2–6 mcg/mL, CYP3A4 substrate, CYP2D6 inhibitor, P-glycoprotein inhibitor | AF (conversion or prophylaxis), WPW, PVCs, VT | Diarrhea, hypotension, N/V, cinchonism, fever, thrombocytopenia, proarrhythmia |

a previously undiagnosed cardiomyopathy (EF = 35%). In a small percentage of patients who do not have underlying heart disease, AF is called “lone” AF, which usually has a more benign course.

Consequences of Atrial Fibrillation

2. What clinical findings demonstrated by J.K. are typically associated with AF? What are the likely consequences of his AF?

The most common complaint in AF, as illustrated by J.K.’s history, is chest palpitations (the sensation of the heart beating rapidly or unusually in the chest). This is a result of the rapid ventricular contraction rate, which typically ranges from 100 to 160 beats/minute. The H-R and R-R interval (time from the R wave in one QRS complex to the R wave in the next complex) is irregularly irregular (random irregularity). During AF, the atrial kick, or the atria’s contribution to stroke volume (via the Frank-Starling mechanism), is lost. Because the atrial kick may account for 20% to 30% of the total stroke volume, symptoms of inadequate blood flow such as lightheadedness, dizziness, or reduced exercise tolerance may occur during AF. However, some patients are asymptomatic except for palpitations. Depending on the underlying ventricular function, signs of HF, such as SOB and peripheral edema, may develop, as experienced by J.K. Conversely, AF could have been precipitated by his previously undiagnosed underlying HF.

Patients with AF are at risk for thrombotic stroke.² With the chaotic movement of the atria, normal blood flow is disrupted and atrial mural thrombi may form. The risk of stroke

increases following restoration of normal sinus rhythm, which allows more efficient cardiac contractility and expulsion of the thrombus. Patients with nonvalvular AF have a fivefold increase in the risk of stroke; this risk increases as patients have an increased number of associated risk factors. Other concurrent diseases that may increase the risk of stroke are HF, cardiomyopathy, thyrotoxicosis, congenital heart disease, and valvular heart disease.

Treatment of Atrial Fibrillation

GOALS OF THERAPY

3. What are the initial therapeutic goals and general approaches used to treat AF in patients like J.K.?

The two initial goals of treatment are to relieve symptoms and reduce the risk of stroke. Slowing the ventricular rate during AF can help accomplish the first goal in most patients; anticoagulation can help achieve the second goal if it is indicated. Cardioversion to normal sinus rhythm can be delayed unless the patient is hemodynamically compromised due to the AF.

VENTRICULAR RATE CONTROL

4. J.K. is given a 1-mg loading dose of digoxin, followed by a 0.25-mg every day (QD) maintenance dose. What is the purpose of administering digoxin? What are the relative advantages and disadvantages of digoxin compared with other agents to control ventricular rate?

Digoxin

The first treatment goal is to slow the ventricular response rate, which allows better ventricular filling with blood. Table 19-5 displays the agents commonly used to control the ventricular response and provides the loading and maintenance doses. Because of its direct AV node blocking effects and vagomimetic properties, digoxin prolongs the effective refractory period of the AV node and reduces the number of impulses conducted through the AV node (negative dromotropy). Cardioversion to normal sinus rhythm can be delayed unless the patient is hemodynamically compromised due to the AF.

Digoxin should not be regarded as first-line therapy for control of ventricular response rate in AF, except in patients with

impaired left ventricular function or HF.³ First, this is because there are several limitations associated with digoxin use. After an intravenous (IV) dose, it will take more than 2 hours for the onset of effect and 6 to 8 hours for the maximal effect, which is markedly slower than other negative dromotropes.⁴ Second, digoxin therapy may prolong AF episodes. In one study of 72 patients with PAF, the relative risk of longer AF episodes associated with digoxin was 4.3 compared with other negative dromotropic agents ($p = 0.01$). This may be because digoxin shortens the refractory period of atrial muscle, which increases AF susceptibility. Third, digoxin is less effective than β -blockers and nondihydropyridine calcium channel blockers during states of heightened sympathetic tone (e.g., exercise or emotional stress), a common precipitant of PAF.^{3–6} Finally, digoxin serum concentrations may be increased when combined with P-glycoprotein inhibitors such as verapamil, quinidine, propafenone, flecainide, and amiodarone.^{7–10} Normally, P-glycoprotein in the brush border membrane of intestinal enterocytes pumps digoxin into the lumen of the gut and reduces its bioavailability. When digoxin is given with inhibitors, more complete absorption occurs. (See Chapter 18 for further discussion of digoxin and digoxin drug interactions.)

5. What other drugs can be used for ventricular rate control, and what are their relative advantages and disadvantages compared with digoxin?

β -Adrenergic Blocking Agents

β -adrenergic blocking agents are another class of negative dromotropes used in AF. Propranolol, metoprolol, and esmolol are available for IV administration. Each agent rapidly controls the ventricular rate both at rest and during exercise. β -blockers are the first choice in high catecholamine states

Table 19-5 Agents Used for Controlling Ventricular Rate in Supraventricular Tachycardias^a

| Drug | Loading Dose | Usual Maintenance Dose | Comments |
|----------------------------|---|---|---|
| Digoxin (Lanoxin) | 10–15 mcg/kg LBW up to 1–1.5 mg IV or PO over 24 hr (e.g., 0.5 mg initially, then 0.25 mg Q 6 hr) | PO: 0.125–0.5 mg/day; adjust for renal failure (see Chapter 19) | Maximum response may take several hours; use with caution in patients with renal impairment |
| Esmolol (Brevibloc) | 0.5 mg/kg IV over 1 min | 50–300 mcg/kg/min continuous infusion with bolus between increases | Hypotension common; effects additive with digoxin and calcium channel blockers |
| Propranolol (Inderal) | 0.5–1.0 mg IV repeated Q 2 min (up to 0.1–0.15 mg/kg) | IV infusion: 0.04 mg/kg/min PO: 10–120 mg TID | Use with caution in patients with HF or asthma; additive effects seen with digoxin and calcium channel blockers |
| Metoprolol (Lopressor) | 5 mg IV at 1 mg/min | PO: 25–100 mg BID | Use with caution in patients with HF or asthma; additive effects seen with digoxin and calcium channel blockers |
| Verapamil (Isoptin, Calan) | 5–10 mg (0.075–0.15 mg/kg) IV over 2 min; if response inadequate after 15–30 min, repeat 10 mg (up to 0.15 mg/kg) | IV infusion: 5–10 mg/hr PO: 40–120 mg TID or 120–480 mg in sustained-release form daily | Hypotension with IV route; AV blocking effects are additive with digoxin and β -blockers; may increase digoxin levels |
| Diltiazem (Cardizem) | 0.25 mg/kg IV over 2 min; if response inadequate after 15 min, repeat 0.35 mg/kg over 2 min | IV infusion: 5–15 mg/hr PO: 60–90 mg TID or QID or 180–360 mg in extended-release form daily | Response to IV therapy occurs in 4–5 min; hypotension; effects additive with digoxin and β -blockers |

^a AV nodal ablation is a nonpharmacologic alternative to control the ventricular response, but the effect is permanent and requires chronic ventricular pacing afterward. AV, atrioventricular; BID, twice a day; HF, heart failure; LBW, lean body weight; PO, orally; IV, intravenously; Q, every; QID, four times a day; TID, three times a day.

such as thyrotoxicosis and postcardiac surgery. However, given their negative inotropic effects, β -blockers should not be used to acutely control the ventricular response in patients with HF. Even though β -blockers are used to treat HF (e.g., bisoprolol, carvedilol, metoprolol), they need to be started at low doses and titrated prudently over several weeks to therapeutic doses^{11,12} (see Chapter 18). When trying to achieve rate control, more aggressive dosing may be needed. β -blockers should also be avoided in patients with asthma because of their β_2 -blocking properties, and blood sugar levels should be monitored more closely in patients with diabetes mellitus because the signs and symptoms of hypoglycemia (except sweating) can be masked.

Calcium Channel Blockers

Calcium channel blockers are also effective in slowing ventricular rate at rest and during exercise. Both verapamil and diltiazem can be administered IV for a rapid (4–5 minutes) reduction in heart rate.¹³ They work through their effect on slow calcium channels within the AV node. Although the duration of action produced by bolus dosing is short, both agents can be administered either as a continuous drip or orally. Given the ability of calcium channel blockers to cause arteriolar dilation, a transient decrease in blood pressure can be expected. IV calcium pretreatment can be used to attenuate the blood pressure decrease among patients with hypotension, near hypotensive blood pressure, or left ventricular dysfunction. Calcium pretreatment does not appear to diminish the negative dromotropic effects of nondihydropyridine calcium channel blockers.^{14–16} Verapamil and diltiazem should be used with caution in HF, and verapamil can increase the concentrations of other cardiovascular drugs such as digoxin, dofetilide, simvastatin, and lovastatin.¹⁷ Verapamil and diltiazem are good alternatives to β -blockers in asthmatics.³

For chronic therapy, oral negative dromotropes are recommended. A recent study suggests that β -blockers are the most effective rate controlling agents but that many patients require changes from initial therapy before adequate rate control is achieved.¹⁸ If higher-dose monotherapy with one of the negative dromotropes is needed to control symptoms but is associated with intolerable side effects, combining lower-dose digoxin with a β -blocker or calcium channel blocker might be effective.^{5,19–21}

J.K. has signs of HF, so digoxin is a reasonable choice. IV verapamil and β -blockers may worsen the signs and symptoms of HF and the β -blockers may mask signs of hypoglycemia in J.K. The goal of rate control should be a resting and an exercising heart rate of <90 and 140 beats/minute, respectively.²¹

LONG-TERM MANAGEMENT STRATEGY

Rate versus Rhythm Control

6. Despite adequate rate control with digoxin (resting heart rate = 75 beats/minute), J.K. still complains of SOB. Would a rhythm or rate control strategy be most appropriate for J.K. at this point?

Several trials have compared rate control to rhythm control as long-term management strategies in AF. The North American Atrial Fibrillation Follow-up Investigation of Rhythm Management (AFFIRM) study was the largest of these. AFFIRM was a randomized, multicenter comparison of rate

control and rhythm control, and it enrolled 4,060 patients with AF and a high risk of stroke.²² The primary end point was all-cause mortality. Antiarrhythmic drugs were chosen at the discretion of the treating physician, but more than 60% of the patients received amiodarone or sotalol as the initial antiarrhythmic agent. Rate control agents included digoxin, β -blockers, and nondihydropyridine calcium channel blockers. After a mean follow-up of 3.5 years, there was a trend toward lower overall mortality ($p = 0.08$), with significant reductions in hospitalizations (10% lower, $p = 0.001$) and TdP (300% lower, $p = 0.007$) in the rate control group. The results of three smaller studies of rate versus rhythm control in AF echo those of AFFIRM.^{23–25} Rate control has also been shown to be more favorable from a cost-effectiveness standpoint, and quality of life appears to be the same, regardless of whether a long-term rate or rhythm control strategy is chosen.^{26–28}

In conclusion, using rhythm control in patients with AF rather than rate control does not improve outcomes and increases the risk of hospitalizations and TdP. This suggests that a majority of patients can simply be managed with rate control and, if indicated, anticoagulation. However, it should be noted that studies in this area generally included older, less symptomatic patients, and it is unclear whether a rhythm control strategy could be beneficial in younger, highly symptomatic patients.³

Conversion to Normal Sinus Rhythm

7. Due to continued bothersome symptoms, J.K. is scheduled for elective cardioversion in 3 weeks. Warfarin treatment is begun, and J.K.'s prothrombin time is to be maintained at an international normalized ratio (INR) of 2 to 3. Why is warfarin therapy being used?

J.K. is to be maintained on warfarin for 3 weeks before cardioversion to prevent the embolization of any atrial clots. These atrial clots form most often in small side pouches on the atria called appendages.^{3,29} Because the frequency of right atrial appendage thrombosis is half that of left atrial appendage thrombosis in AF patients, the risk of stroke is enhanced much more than the risk of pulmonary embolism.²⁹ Studies in patients with AF showed that those who were anticoagulated before cardioversion had a lower incidence (0.8%) of emboli than those who were not anticoagulated (5.3%).³⁰ Warfarin is recommended during the 3-week period before cardioversion for patients who have been in AF for more than 2 days.³¹ The dose should be titrated to produce an INR of 2 to 3. If cardioversion is successful, patients should remain on warfarin for 4 weeks because normal atrial activity/function may not return for up to 3 weeks, and patients may be at risk of late embolization.³² J.K. has had AF for a minimum of 2 weeks; thus, he should be maintained on warfarin for 3 weeks before he is scheduled for cardioversion.

Cardioversion can be accomplished pharmacologically or with electrical or direct current (DC) cardioversion. DC cardioversion quickly and effectively restores 85% to 90% of patients with AF to normal sinus rhythm.³² If DC conversion alone is ineffective, it can be repeated in combination with antiarrhythmic drugs.³³ In one study, the success rate of electrical cardioversion was significantly higher in AF patients (duration of AF averaged 119 days) with ibutilide pretreatment (1 mg) compared to those without pretreatment (100% vs. 72%,

$p = 0.001$).^{33,34} Other studies have found promising results with class IA antiarrhythmic agents and contradictory data with flecainide. Amiodarone is effective for this purpose, but it may be inconvenient to load patients with amiodarone several days before DC cardioversion.³

Although DC cardioversion is highly effective, its use is limited to some degree by the need for general anesthesia (short-acting benzodiazepine, barbiturate, or propofol). Pharmacologic conversion could be used in order to avoid the use of general anesthesia or if a patient wants to avoid DC cardioversion; however, success rates are generally lower with pharmacologic cardioversion than with DC cardioversion. One study suggests that attempting chemical conversion first with ibutilide, with all failures subsequently receiving electrical cardioversion, is more cost effective (saving \$138/patient) than using DC cardioversion in all patients.³⁴ Therefore, many factors must be considered when selecting the optimal method for cardioversion of atrial fibrillation in an individual patient.

Chemical Conversion—*Ibutilide, Propafenone, and Flecainide*

8. The decision is made to attempt chemical cardioversion with ibutilide. If therapy fails, J.K. will undergo DC cardioversion later in the day. How does ibutilide therapy compare with the other therapeutic choices for chemical cardioversion? What type of patient is likely to remain free of AF recurrence following cardioversion?

Many class I and III antiarrhythmic agents have been evaluated for efficacy in placebo-controlled trials for conversion of AF or atrial flutter to normal sinus rhythm. The best-studied agents include IV ibutilide, oral propafenone, IV or oral flecainide, oral quinidine, oral sotalol, oral and IV amiodarone, and oral dofetilide. This section focuses on ibutilide, propafenone, and flecainide.

IV ibutilide, a class III antiarrhythmic agent with potassium channel-blocking and slow sodium channel-enhancing effects, was the first agent that the U.S. Food and Drug Administration (FDA) approved for the termination of recent onset AF/atrial flutter. Ibutilide is administered as a 1-mg infusion over 10 minutes, followed by another 1-mg infusion over 10 minutes if conversion has not occurred by 10 minutes after the infusion. The conversion rate for recent onset AF is 35% to 50%; the conversion rate is 65% to 80% in atrial flutter. Coadministration of magnesium (1–2.2 g) with ibutilide produced a 20% relative increase in rate of successful conversion.³⁵

As is the case with most class III antiarrhythmic agents, the main adverse effect is TdP, which occurred in approximately 4% of patients. Coadministration of ibutilide with magnesium may also reduce the risk for TdP; however, more study is needed in this area.³¹ A recent study suggests that the use of ibutilide for acute conversion in patients already taking amiodarone or propafenone does not increase proarrhythmia risk.³⁶ Aside from the risk of TdP, therapy is well tolerated.^{37,38}

Propafenone is a class IC agent with β -blocking properties. When given in doses of 450 to 750 mg orally (600 mg was the most used dose), the initial conversion rate in patients with AF ranged from 41% to 57%. In contrast to ibutilide, no patients experienced ventricular arrhythmias (including TdP), but a risk of hypotension, bradycardia, and QRS prolongation was noted.^{39–41}

Oral flecainide is another class IC antiarrhythmic agent. In one study, 300 mg oral flecainide converted 68% of pa-

tients to sinus rhythm within 3 hours and 91% of patients by 8 hours. Another study using 2 mg/kg IV flecainide over 10 minutes followed by 200 to 300 mg orally demonstrated a 71% conversion rate. The efficacy in atrial flutter has yet to be established. Sinus node dysfunction; prolongation of intraventricular rhythm; dizziness, weakness, and gastrointestinal (GI) disturbances have been reported.^{42,43}

Conversion to and maintenance of normal sinus rhythm is determined by the duration of the arrhythmia, underlying disease processes, and left atrial size. Duration of AF for more than 1 year significantly reduces the chances of maintaining a normal sinus rhythm.⁴⁴ When the atrial size exceeds 5 cm, there is a <10% chance of maintaining normal sinus rhythm at 6 months.

J.K.'s chance of being maintained in normal sinus rhythm is good because the duration of his AF is short and the echocardiogram revealed only slight enlargement of his left atrium. Ibutilide is chosen because it has good efficacy and safety, does not interact with digoxin like propafenone can, and is not contraindicated like the class IC agents in patients with heart failure or left ventricular hypertrophy (structural heart disease) like J.K.

Quinidine

9. If an agent like quinidine is used, instead of ibutilide, to convert the patient to normal sinus rhythm, why would it be especially important to attempt ventricular rate control first?

The effects of quinidine and other type IA antiarrhythmic agents on the AV node are bimodal. At low concentrations, AV node conduction may be enhanced by the drug's antivagal properties. If this occurs before normal sinus rhythm is achieved by quinidine, the ventricular rate may actually increase. At higher concentrations, the type IA agents slow AV node conduction. Because it is difficult to predict which effect on the AV node will predominate in a given patient, it is prudent to initiate a rate controlling agent first.

Dofetilide

10. After failing cardioversion with ibutilide, J.K. is converted to normal sinus rhythm using a single 200-J electric shock. He is discharged from the hospital on digoxin and warfarin and advised to follow up with a cardiologist 4 weeks later. Within 2 weeks, J.K. experiences several episodes of brief, symptomatic, and self-terminating palpitations. His physician prescribes oral dofetilide and informs J.K. that he will be admitted to the hospital for the first 3 days of treatment to determine a safe and effective dose. Why is dofetilide unique among the antiarrhythmic drugs used in AF and atrial flutter? What drug interactions limit its use?

Oral dofetilide is a class III antiarrhythmic agent that inhibits the delayed rectifier potassium current (IKr).^{45,46} It is the only class III agent indicated for both acute cardioversion of AF/atrial flutter and maintenance of normal sinus rhythm. However, the risk of TdP has prompted its manufacturer to mandate a minimum of 3 days of ECG monitoring in a properly equipped facility during therapy initiation. Two clinical trials, EMERALD (European and Australian Multicenter Evaluative Research on Atrial Fibrillation Dofetilide)⁴⁷ and SAFIRE-D (Symptomatic Atrial Fibrillation Investigation and Randomized Evaluation of Dofetilide),⁴⁸ have shown AF/atrial flutter

patients to have conversion rates of 30% on higher doses of dofetilide. Patients failing chemical conversion received electrical conversion. If this conversion succeeded, they were continued on dofetilide for 1 year. At 1 year, 60% of those converted with the 500-mcg dose were still in sinus rhythm. Also, dofetilide appears to exert neutral effects on mortality rates in HF and post-MI patients.^{49,50}

The dofetilide dose is based on the patient's creatinine clearance (Cl_{cr}); the doses are 500, 250, and 125 mcg twice daily with Cl_{cr} above 60 mL/minute, 40 to 60 mL/minute, and 20 to 39 mL/minute, respectively. The QTc interval must be measured (using a 12-lead ECG) 2 to 3 hours after the first dose. If the QTc interval does not increase by >15% or if it does not surpass 500 milliseconds (550 milliseconds in patients with ventricular conduction abnormalities), the QTc interval still needs to be measured 2 to 3 hours after each subsequent dose, but not with a 12-lead ECG. If the QTc interval exceeds the above parameters, the subsequent dose should be reduced by 50%. If the QTc interval measured 2 to 3 hours after the first adjusted dose (using a 12-lead ECG) is still above the acceptable range, dofetilide should be discontinued. If the QTc interval is within an acceptable range following the first adjusted dose, all subsequent postdose QTc intervals do not need to be measured with a 12-lead ECG. All patients must be ECG monitored by at least a single lead for 3 days.⁵¹

Drug interactions pose a significant problem with dofetilide. Cimetidine, ketoconazole, megestrol, prochlorperazine, and trimethoprim (including in combination with sulfamethoxazole) inhibit active tubular secretion of dofetilide and can elevate dofetilide plasma concentrations.^{46,51} Because the incidence of TdP is directly related to dofetilide plasma concentrations, concomitant use with these agents is contraindicated.⁵¹ Concomitant administration of dofetilide with verapamil or hydrochlorothiazide increases the incidence of TdP by an unknown mechanism and is contraindicated as well.⁴⁶ Concurrent use of agents that can prolong the QTc interval is not recommended with dofetilide.⁵¹ Dofetilide also undergoes metabolism by the CYP3A4 isoenzyme to a minor extent. Therefore, inhibitors of this isoenzyme (e.g., amiodarone, azole antifungal agents, diltiazem, nefazodone, protease inhibitors, quinine, serotonin reuptake inhibitors, zafirlukast) should be coadministered with caution with dofetilide. Other agents that can potentially increase dofetilide levels (through inhibition of tubular secretion) include amiloride, metformin, and triamterene. Hence, these agents should be cautiously coadministered with dofetilide.⁵¹

Maintenance Antiarrhythmic Therapy

11. Evaluate the value of using an antiarrhythmic agent to maintain J.K. in normal sinus rhythm. What are the risks and benefits of the different antiarrhythmic agents used for this purpose?

Whether J.K. should be placed on an antiarrhythmic is a judgment of benefit versus risk. There is no doubt that various antiarrhythmics can prevent episodes of AF. However, J.K.'s need for antiarrhythmic therapy should be weighed against the potential for adverse effects. Overall, both rate and rhythm control strategies lead to similar rates of overall mortality, but the risk of hospitalization and TdP and cost is likely higher with

rhythm control. Hence, if adequate rate control can eliminate J.K.'s symptoms, that is the preferred strategy. If symptoms are limiting his quality of life or adequate rate control cannot be achieved, rhythm control is a valuable option. In this case, the physician has chosen rhythm control, and there are no compelling reasons to try to persuade him otherwise given the symptomatic nature of the AF episodes. The question now becomes how to choose the best antiarrhythmic agent for J.K. To do this, the efficacy and adverse effect profiles for each agent should be reviewed.

Class IA, IC, and III antiarrhythmics (see Table 19-2 for electrophysiologic and ECG effects and Table 19-3 for pharmacokinetics and side effects) prevent the recurrence of AF. Quinidine, flecainide, sotalol (Betapace AF), and dofetilide are approved by the FDA for maintenance of sinus rhythm; propafenone and amiodarone are commonly used as well.

Quinidine

If quinidine is used, sustained-release (SR) formulations such as quinidine sulfate (Quinidex) or quinidine gluconate (Quinaglute) are preferred because they produce smaller peak-to-trough fluctuations than rapid-release products and can be administered twice daily to enhance compliance. Nausea, vomiting, and diarrhea occurring early in therapy are reported in up to 30% of patients receiving quinidine, requiring 10% to discontinue therapy. A unique symptom complex referred to as cinchonism occurs when quinidine blood levels exceed 5 mcg/mL. This disorder is characterized by disturbed hearing (tinnitus, decreased auditory acuity), visual abnormalities (blurred vision, altered color perception, diplopia), and central nervous system (CNS) alterations (headache, confusion, delirium). Quinidine raises digoxin serum concentrations, which is important in J.K., but it is also a potent inhibitor of the CYP2D6 isoenzyme, which affects the metabolism of carvedilol, codeine, desipramine, and propafenone. HF and older age are additional risk factors that can raise quinidine concentrations, which would be a confounder for J.K. Use of quinidine is limited to third-line therapy for this indication based on a meta-analysis showing improved maintenance of sinus rhythm but nonsignificant increases in mortality (3.2% mortality vs. 0.8%).⁵²

Flecainide and Propafenone

The class IC agents flecainide and propafenone are effective in suppressing AF.^{53–55} The efficacy rate may be as high as 61% to 92% for flecainide.⁵⁶ Flecainide and possibly other class IC agents may cause other arrhythmias, especially in patients with structural heart disease, and they should be avoided in such patients. Propafenone, a class IC agent with β -blocking properties, is as efficacious as flecainide and is relatively safe in patients without ischemic heart disease and an EF above 35%; it may be preferred in patients who require additional AV blockade.^{57,58} In comparison with quinidine (average dose 1,067 mg), propafenone (average dose 615 mg) was significantly better at reducing the occurrence of AF and at reducing the ventricular rate when AF occurred. A 75% reduction in symptomatic arrhythmic attacks occurred in 75% of the propafenone group versus 46% of the quinidine group. Both therapies were well tolerated, with 4% of patients in both groups withdrawing. Dizziness was the most common reason for discontinuation in the propafenone group, whereas

GI disturbances were most common in the quinidine group.⁵⁹ Propafenone was superior to placebo and sotalol in a study of 254 patients with paroxysmal or persistent AF.⁶⁰ In this study, the monthly rate of developing either AF recurrence or an adverse effect was 5.26% with sotalol, 3.13% with propafenone, and 9.19% with placebo. Propafenone was also shown to be superior to amiodarone when both efficacy and adverse effects were considered in another study.⁵⁵ Monthly progression to AF recurrence or adverse effects in this study was 3.18% for amiodarone and 3.96% for propafenone.

A novel approach to maintaining sinus rhythm with flecainide and propafenone has been recently reported.⁶¹ In this study, patients with AF and no significant cardiovascular disease self-administered oral propafenone or flecainide on experiencing symptoms of AF recurrence. AF recurrence was experienced on 618 occasions in 165 patients. Patient-initiated therapy was successful in converting 84% of these patients and 7% experienced adverse effects. Use of this strategy (single dose of propafenone or flecainide when AF recurs instead of chronic suppression) also reduced the number of emergency room visits and hospitalizations.

Sotalol, Amiodarone, and Dofetilide

Class III agents (sotalol, dofetilide, and amiodarone) prolong refractoriness in the atria, ventricle, AV node, and accessory pathway tissue, and can prevent recurrence of AF. The efficacy of sotalol in delaying the recurrence of AF was evaluated in a double-blind, placebo-controlled, multicenter, randomized trial that enrolled 253 patients with AF or atrial flutter.⁶² The median times to recurrence were 27, 106, 229, and 175 days with placebo, sotalol 160 mg/day (divided in two doses), sotalol 240 mg/day (divided in two doses), and sotalol 320 mg/day (divided in two doses), respectively. In one comparative study, sotalol was as effective as quinidine in maintaining sinus rhythm after cardioversion.⁶³ The risk of developing TdP with sotalol has prompted its manufacturer to mandate a minimum of 3 days of ECG monitoring in a properly equipped facility during therapy initiation. Furthermore, during initiation and titration, QTc intervals should be monitored 2 to 4 hours after each dose, and sotalol is contraindicated in patients with a Cl_{cr} of less than 40 mL/minute. Bradycardia, dizziness, and GI disturbances are common intolerable side effects of sotalol.⁶⁴

Amiodarone is more effective than quinidine, sotalol, and propafenone.^{65–69} The Canadian Trial of Atrial Fibrillation (CTAF) compared the ability of low-dose amiodarone (200 mg/day) versus propafenone (450–600 mg/day) and sotalol (160–320 mg/day) to prevent recurrence of atrial fibrillation in 403 patients with a recent episode of AF (within the preceding 6 months).⁶⁷ After a mean follow-up of 16 months, 35% of the amiodarone-treated patients had a recurrence of AF versus 63% in the combined group with sotalol and propafenone ($p = 0.001$). Another more recent study supports the CTAF study results by demonstrating superior efficacy with amiodarone as compared to sotalol and placebo.⁶⁸ Low doses of amiodarone (200–400 mg/day) have a high rate of efficacy and a reduced incidence of the serious adverse effects often associated with high doses of this drug.⁶⁶ In view of its unusual pharmacokinetics and potential serious adverse effects, however (see Table 19-3 and Questions 30, 36, and 37), amiodarone should be reserved for patients with HF, where it has specific safety data, or when other agents such as sotalol, propafenone, or dofetilide have failed.³

Dofetilide is another class III agent that has been shown to be effective for the maintenance of sinus rhythm after conversion and safe in heart failure patients (see question 10 for dosing in renal impairment, critical drug interactions, and monitoring).

In view of J.K.'s new onset of HF and frequent uncomfortable episodes of AF, dofetilide, and amiodarone are logical first choices with proven efficacy and studies in HF patients showing relative safety. Propafenone and flecainide are contraindicated in patients like JK with structural heart disease (heart failure and possible left ventricular hypertrophy due to hypertension).

12. Do any medications without direct effects on cardiac ion channels have a role in maintaining sinus rhythm?

Angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), and statins may have a potential role in the management of atrial fibrillation. A recent meta-analysis reported that ACE inhibitors or ARBs prevent the development of atrial fibrillation (odds ratio [95% confidence interval (CI)] = 0.51 [0.36–0.72]), prevented failure of DC cardioversion (0.47 [0.24–0.92]), and prevented recurrence of atrial fibrillation after DC cardioversion (0.39 [0.20–0.75]).⁷⁰ These agents likely prevent structural remodeling of the atria in patients with or at risk for atrial fibrillation. Therefore, these medications probably prevent the formation of the substrate necessary for atrial fibrillation. Preliminary data suggest that statins may also prevent AF recurrence after DC cardioversion of persistent AF.⁷¹ In this study, 3-month recurrence rate in the control group was 45.8% compared to 12.5% in the statin (atorvastatin) group ($p = 0.02$). The anti-inflammatory properties of atorvastatin were proposed as the reason for less recurrence with statin therapy because C-reactive protein was reduced in the atorvastatin group but not the control group.

13. If J.K. fails trials of multiple antiarrhythmic agents, what nonpharmacologic treatments are available to him for maintenance of sinus rhythm?

A premature stimulus originating from the pulmonary veins is often responsible for initiating atrial fibrillation. As such, a technique in which ablation is used to isolate the pulmonary veins has been developed. At 1 year, this technique prevented AF recurrence in 86% of patients, while antiarrhythmic drugs prevented recurrence in 22% of patients ($p < 0.001$).⁷²

Stroke Prevention

ASPIRIN AND WARFARIN

14. J.K. is discharged from the hospital on dofetilide 500 mcg BID, which is appropriate given his Cl_{cr} of 92 mL/minute. He has been doing fine for 2 weeks after discharge. Should J.K. remain on warfarin therapy? Should aspirin be added or substituted?

Patients with nonvalvular and valvular AF have a 5- and 17-fold increased risk for stroke compared with patients without AF, respectively.² Stroke can lead to death or significant neurologic disability in up to 71% of patients, with an annual recurrence rate as high as 10%.⁷³ In large, randomized trials, patients with nonvalvular atrial fibrillation benefited from antithrombotic therapy. In the Stroke Prevention in Atrial Fibrillation (SPAF) study, both aspirin 325 mg/day and warfarin (titrated to an INR 2.0–4.5) reduced the risk of stroke significantly with an acceptable level of hemorrhagic complications.⁷⁴ In this

trial, patients younger than 60 years of age without hypertension, recent heart failure, or prior thromboembolism had a low risk of thromboembolism and did not benefit from warfarin therapy.⁷⁴ The results of SPAF II and Copenhagen Atrial Fibrillation, Aspirin and Anticoagulation Trials, both of which were direct comparisons of warfarin and aspirin, indicate that warfarin is more effective than aspirin in preventing stroke.^{75,76} Although greater efficacy was derived from warfarin therapy in the SPAF II study, a higher incidence of bleeding complications was noted with warfarin in patients older than 75 years of age, especially those with risk factors for bleeding (previous thromboembolism, GI, or genitourinary bleeding).⁷⁵

Patients younger than 60 years who have “lone” AF should be maintained on aspirin alone because the bleeding risk with warfarin is maintained, but the benefits are reduced in this population. Older patients and those with thromboembolic risk factors should receive warfarin because the benefits of therapy far outweigh the risks, and the patient should maintain an INR of 2.0 to 3.0.^{77,78}

A common issue with warfarin therapy is the variability in dosing requirements from patient to patient. Intensive participation in anticoagulation monitoring is necessary to ensure that patients reach a therapeutic range and stay within that range. Recently, a simple blood test has been developed for commercial use called the PGx Predict warfarin test. This test could be used to help predict maintenance warfarin dose requirements by assessment of CYP2C9 genotype and VKORC1 genotype.⁷⁹ Certain polymorphisms in CYP2C9 genotype translates into variability in activity of the CYP2C9 enzyme, a principal enzyme in warfarin metabolism. The VKORC1 gene encodes for part of the vitamin K epoxide reductase complex, the target for warfarin therapy. Therefore, VKORC1 genotype polymorphisms lead to variability in sensitivity to the effects of warfarin. Use of this test may become more common in the future and could help simplify the dosing of warfarin in patients with atrial fibrillation.

Because J.K. has a low bleeding risk (no history of thromboembolism, diastolic hypertension, or GI/genitourinary bleeding) and an increased risk of stroke due to his age (66 years), he should continue to receive warfarin therapy without concomitant aspirin. Even though J.K. is in normal sinus rhythm on dofetilide at this time, in the AFFIRM trial, only 73% and 63% of patients remained in sinus rhythm at 3 and 5 years, respectively.²² These patients did not necessarily know when they went back into AF.

15. M.P. is a 38-year-old woman who has had chronic atrial flutter for the past 2 years. She has no other medical history and is taking metoprolol 50 mg BID. She does not want to take the drug any longer because it reduces her exercise tolerance. Is there a nonpharmacologic therapy for atrial flutter? Does the treatment of atrial flutter differ from the treatment of AF? Is radiofrequency catheter ablation an acceptable nonpharmacologic option for M.P.?

As mentioned previously, atrial flutter is an unstable rhythm that often reverts to sinus rhythm or progresses to AF. If atrial flutter is episodic, its underlying cause should be identified and treated if possible. If a patient remains in atrial flutter, the treatment goals (control of ventricular rate, return to normal sinus rhythm) are the same as those for AF. Similar agents and doses can be used to control the ventricular response. Chemical conversion, low-energy (<50 J) DC cardioversion or rapid atrial

pacings may acutely convert atrial flutter back to sinus rhythm, but the recurrence of atrial flutter is high.

Radiofrequency catheter ablation therapy is a nonpharmacologic treatment of atrial flutter. Electrophysiologic studies are performed initially to determine the optimal site for ablation. Various sections of the atria and pulmonary veins (where they intersect with the atria) are probed with a catheter that delivers cardiac pacing. Once an area is stimulated with pacing and an atrial ectopic/re-entrant focus is recognized, the area is ablated. Ablation destroys atrial or pulmonary vein tissue integral to the initiation or maintenance of the atrial flutter by delivering electrical energy over electrodes on the catheter. This procedure is successful in 75% to 90% of cases and can be recommended for patients with atrial flutter who are drug resistant or drug intolerant, or who do not desire long-term therapy.

Radiofrequency ablation therapy may be suitable for M.P. However, if exercise intolerance is her primary complaint, this can be relieved by switching M.P. to another drug such as verapamil.

Atrial Fibrillation After Bypass Surgery

β-BLOCKERS AND AMIODARONE

16. H.L., a 55-year-old woman with triple vessel disease, is scheduled for coronary artery bypass surgery (CABG) in 3 days. Her medical history includes exercise-induced angina treated with nitrates, metoprolol, and diltiazem. What is the incidence of AF after CABG surgery? Should H.L. be treated with a drug to prevent the postoperative occurrence of AF?

More than 750,000 CABG or heart valve surgeries (cardiothoracic surgery) are performed annually in the United States.⁸⁰ Without prophylaxis, AF develops in up to 65% of patients, and two-thirds of the cases occur on postoperative day 2 or 3.⁸¹ The underlying mechanism is unknown, but it may be related to sympathetic activation, pericarditis, or atrial dilation from volume overload.^{82,83} The arrhythmia usually converts spontaneously but can result in temporary symptomatology (lightheadedness), a higher risk of cerebrovascular accident, and a longer hospital stay.⁸³

β-blockers, amiodarone, and sotalol are proven prophylactic strategies to reduce the incidence of postcardiothoracic surgery AF.^{83–85} Of these, β-blockers and amiodarone have been shown to reduce other clinical events and shorten length of stay.^{80,83–85} In addition, both β-blockers and amiodarone can be used together in the same patient as a prophylactic strategy.^{84,85} If a patient is receiving a β-blocker before surgery and cannot receive it after surgery, the risk of postcardiothoracic surgery AF is even higher than if they were never on the β-blocker (due to β-blocker withdrawal). Therefore diligence in trying to assure continued β-blockade in these patients is important.⁸⁵

Although many studies evaluating the use of amiodarone prophylaxis have been conducted, the Atrial Fibrillation Suppression Trial II (AFIST II) had a regimen that allowed for dosing patients with elective and emergent surgery and the beneficial results were in addition to a high baseline utilization of β-blockers.⁸⁵ In AFIST II, a hybrid IV and oral amiodarone regimen was evaluated versus placebo. In this study, IV amiodarone (1,050 mg) was given over 24 hours after surgery and then oral drug (400 mg three times daily) was given for 4 postoperative days (equal to 7 g oral drug given over 5 days). In

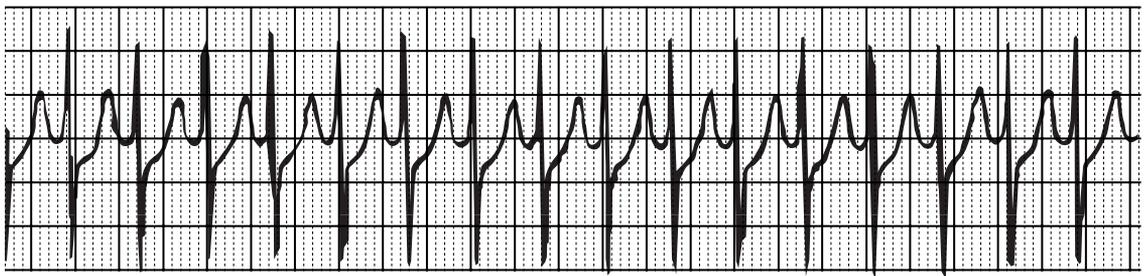

FIGURE 19-7 Supraventricular tachycardia. Source: Reproduced with permission from Stein E. *Rapid Analysis of Arrhythmias: A Self-Study Program*. 2nd ed. Philadelphia: Lea & Febiger; 1992.

this study, amiodarone reduced the 30-day risk of AF by 42.7% and symptomatic AF by 68.3%. Amiodarone regimens using all oral dosing have also been studied and showed similar benefits with similar delivered amiodarone doses.^{83,84}

17. H.L.'s metoprolol therapy was discontinued prior to surgery and she was not treated prophylactically. There were no immediate postsurgery complications. On postoperative day 2, she develops AF with a ventricular response rate of 142 beats/minute and a BP of 126/75 mmHg. How should H.L. be managed?

β -blocker withdrawal after surgery is one of the most potent risk factors for developing postcardiac surgery AF. Now that she has AF, the decision to treat H.L.'s AF depends on her heart rate and how well she tolerates the arrhythmia; antiarrhythmics are often not needed in the short-term management of this disorder. For many years, digoxin has been used to control the ventricular response. However, following surgery, patients have a high sympathetic tone, and digoxin is often ineffective. β -blockers are effective and preferred if there are no other contraindications.⁸⁶ They are especially preferred in patients such as H.L., who have been taking β -blockers preoperatively because withdrawal of β -blockers can increase the occurrence of postoperative AF.^{86,87}

H.L.'s rapid ventricular rate should be controlled. Propranolol 1 mg IV every 5 minutes (up to 0.1 mg/kg), metoprolol 5 mg IV repeated at 2-minute intervals (up to a total dose of 15 mg), esmolol 0.5 mg/kg bolus followed by a continuous infusion at a rate of 50 to 300 mcg/kg/minute, or verapamil 5 to 10 mg IV every 1 to 4 hours are all options for H.L., who appears to be hemodynamically stable. If one of these therapy choices is ineffective, a loading dose of digoxin can be administered IV as adjunctive therapy with a β -blocker or verapamil.

18. Metoprolol is started and ventricular rate control is achieved 4 minutes after administering the second 5-mg dose. The patient receives 50 mg oral metoprolol therapy an hour later, converts to normal sinus rhythm spontaneously the next day, and is prepared for discharge. The metoprolol therapy is discontinued. Should an antiarrhythmic agent be initiated for H.L. to prevent recurrence of AF?

Using prophylactic antiarrhythmic agents after discharge in patients with AF within a few days of CABG surgery does not seem to protect against recurrent AF. In one trial, all patients with AF after CABG surgery were given verapamil, quinidine, amiodarone, or placebo at discharge and were then followed with Holter monitoring for 90 days. There was no difference in the occurrence of AF between the placebo group (3.3% in-

cidence) and the other groups (6.7% incidence for each treatment group).⁸⁸ Because H.L. was treated with metoprolol for angina pectoris before the surgery, therapy can be reinitiated if the anginal pain resumes with exercise.

Paroxysmal Supraventricular Tachycardia

Clinical Presentation

19. B.J., a 32-year-old woman, presents to the emergency department (ED) complaining of fatigue and palpitations. She has had similar episodes approximately twice a year for the past 2 years but has not sought medical attention. She is in no apparent distress and has a temperature of 98°F, heart rate of 180–190 beats/minute, BP of 95/60 mmHg, and RR of 12 breaths/minute. Her ECG (Fig. 19-7) shows a heart rate of 185 beats/minute; the P waves cannot be found, and the QRS complex is 110 milliseconds (normal <120). The diagnosis is PSVT. What is the clinical presentation of PSVT, and what are the consequences of this arrhythmia?

PSVT often has a sudden onset and termination. At the time of PSVT, the heart rate is usually 180 to 200 beats/minute. As illustrated by B.J., patients experience palpitations as well as nervousness and anxiety. In patients with a rapid ventricular rate, dizziness and presyncope (near-fainting) can occur, and the rhythm may degenerate to other serious arrhythmias. Depending on the underlying heart function, angina, HF, or shock may be precipitated. It has not been demonstrated that patients with episodes of PSVT are at an increased risk of stroke.

Arrhythmogenesis—Re-entry

20. What is the arrhythmogenic mechanism of PSVT?

AV nodal re-entry is the most common mechanism of paroxysmal supraventricular arrhythmias (Fig. 19-4). Under certain conditions, such as following an acute MI, atrial impulses will be blocked in one of the two AV nodal pathways in a unidirectional manner (antegrade block). After the impulse reaches the distal end of one pathway, it will conduct in a retrograde fashion through the other pathway, setting up a circular movement causing tachycardia.

Reciprocating tachycardias occur when there is an accessory pathway. Orthodromic AV reciprocating tachycardia is a re-entry tachycardia involving antegrade conduction through the AV node and retrograde conduction through a bypass tract. Antidromic AV reciprocating tachycardia is a re-entry tachycardia involving antegrade conduction through an accessory pathway and retrograde conduction via the AV node or

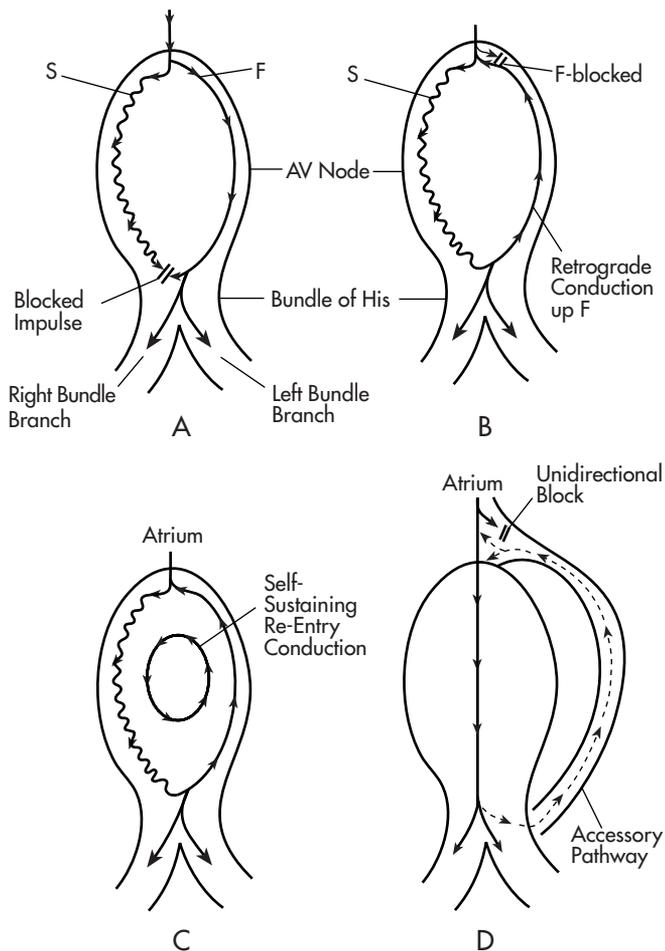

FIGURE 19-8 The atrioventricular (AV) node in paroxysmal supraventricular tachycardia and Wolff-Parkinson-White syndrome. A. A bifurcation of an impulse, one propagated fast and another slow. B. The slow impulse in Figure 19-8A can send impulses in a retrograde fashion. C. The re-entry from Figure 19-8A to Figure 19-8B can be self-sustaining. D. Normal impulse conduction through the AV node, but abnormal retrograde conduction up an accessory pathway, as would be seen in a patient with Wolff-Parkinson-White syndrome.

another accessory pathway (e.g., WPW syndrome) (Fig. 19-8). Antidromic reciprocating tachycardias manifest as wide QRS complexes resembling ventricular arrhythmias.

Treatment

21. B.J. tries the Valsalva maneuver, and her ventricular rate is reduced to 175 beats/minute; the other parameters are unchanged. She is given adenosine 6 mg as an IV bolus, administered over 1 minute, with no effect on the PSVT rate. Another dose of adenosine 12 mg has no effect. No side effects are noted from therapy. What treatment options can be used if B.J. is hemodynamically unstable? What is the Valsalva maneuver? What is a probable reason for B.J.'s unresponsiveness to adenosine? Are there any drug interactions that might diminish adenosine's effect?

NONDRUG TREATMENT

Valsalva Maneuver

Although her BP is low at 95/60 mmHg, B.J. is maintaining an adequate perfusion pressure, so nondrug treatment or va-

gal maneuvers should be attempted first. Two common vagal techniques are pressure over the bifurcation of the internal and external carotid arteries and the Valsalva maneuver (forcible exhalation against a closed glottis, similar to bearing down to have a bowel movement). The increase in pressure induced by these maneuvers is sensed by the baroreceptors, causing a reflex decrease in sympathetic tone and an increase in vagal tone. The increase in vagal tone will increase refractoriness and slow conduction in the AV node, thereby slowing the heart rate; the arrhythmia will terminate in 10% to 30% of cases.⁸⁹ If B.J. is hemodynamically unstable or becomes hemodynamically unstable at any time, she should receive synchronous DC cardioversion.

DRUG THERAPY

Adenosine

Drug therapy involves blocking the AV node because most PSVT rhythms involve a re-entry circuit within this area. Adenosine, a purine nucleoside that exerts a transient negative chronotropic and dromotropic effect on cardiac pacemaker tissue, is considered the drug of choice for the acute treatment of PSVT because of its rapid and brief effect.⁹⁰ An initial 6-mg IV bolus is given; if this is unsuccessful within 2 minutes, it can be followed by one or two additional 12-mg IV boluses, up to a maximum of 30 mg. Because of its short half-life (9 seconds), adenosine should be administered as a rapid bolus (over 1–3 seconds), followed immediately by a saline flush. Thus, B.J.'s failure to respond is likely attributed to the prolonged (1-minute) infusion time.

Theoretically, adenosine may be ineffective or higher doses may be required in patients who are receiving theophylline because theophylline is an effective adenosine receptor blocker. Larger doses of other methylxanthines (caffeine or theobromine) may also theoretically interact like theophylline. Conversely, concomitant use of dipyridamole may accentuate adenosine's effects because dipyridamole blocks the adenosine uptake (and subsequent clearance).

22. B.J. is given 12 mg adenosine IV over 2 seconds, followed by a 20-mL normal saline flush. Thirty seconds later, she complains of chest tightness and pressure. Is B.J. experiencing a heart attack? Is this response a result of a drug interaction between adenosine and another medication?

B.J. is experiencing a common side effect of adenosine. Patients receiving adenosine should be warned that they may experience transient chest heaviness, flushing, or feelings of anxiety. SOB and wheezing may be observed in patients with asthma. Lower doses are usually required in heart transplant patients, and caution should be observed when administering adenosine to these patients.

Calcium Channel Blockers

23. B.J. is still in PSVT. What other acute therapeutic options should be considered at this time?

Nondihydropyridine calcium channel blockers, verapamil and diltiazem, can be used in patients with PSVT. Verapamil (2.5–5 mg IV given over 2 minutes) achieves peak therapeutic effects in 3 to 5 minutes after dosing and can be repeated at 10- to 15-minute intervals to a maximum dose of 20 mg if needed. The elderly should receive the verapamil infusion

over 3 minutes. Patients ages 8 to 15 years should receive 0.1 to 0.3 mg/kg as an IV bolus over 1 minute. A repeat dose of 0.1 to 0.2 mg/kg can be administered 15 to 30 minutes later if the effect was inadequate. Diltiazem is given as a 0.25-mg/kg IV bolus over 2 minutes, and a second bolus of 0.35 mg/kg can be given 15 minutes later if the effect is inadequate. Both calcium channel blockers have an 85% conversion rate.⁹¹ However, verapamil should not be used in patients with wide complex tachycardia of unknown origin because it may lead to hemodynamic compromise and, potentially, VF.

β -blockers and digoxin can be used if calcium channel blockers or adenosine fail.

24. B.J. is given 5 mg IV verapamil over 1 minute, followed by an additional 5 mg 10 minutes later. She converts to normal sinus rhythm 3 minutes after the second dose. Because she has experienced symptoms that could be attributed to PSVT in the past, she may be a candidate for chronic therapy to slow conduction and increase refractoriness at the AV node. Which agents have been evaluated for this indication? Is there a role for radiofrequency catheter ablation therapy for PSVT like there is for atrial flutter?

On a long-term basis, PSVT is managed with agents that slow conduction and increase refractoriness in the AV node, thereby preventing a rapid ventricular response. These include oral verapamil, diltiazem, β -blockers, or digoxin. Class IA, IC, and III agents are used occasionally to slow conduction and increase refractoriness of the fast bypass tract to prevent triggering impulses such as premature atrial and ventricular contractions. Radiofrequency catheter ablation is indicated if drug therapy cannot be administered safely (e.g., in a pregnant woman), managed conveniently (e.g., in noncompliant patient), or tolerated (because of side effects).

Electrophysiologic testing is used to determine the location of the re-entrant tract, which then can be abolished, thereby interrupting accessory pathways. This treatment approach potentially is curative and is used increasingly in medical centers under the direction of a specially trained electrophysiologist.

B.J. has had a few episodes of PSVT in the past but has not been on any suppressive therapy. This history suggests that chronic suppressive therapy should be tried first. Because she responded to IV verapamil, oral SR verapamil (Isoptin SR) was prescribed at a dosage of 240 mg/day.

Wolff-Parkinson-White Syndrome

25. M.B., a 35-year-old man, presents to the ED with a chief complaint of chest palpitations for 4 hours. He relates a history of many similar self-terminating episodes since he was a teenager. He took an unknown medication 5 years ago that decreased the occurrence of the palpitations, but he stopped taking it due to side effects. M.B.'s vital signs are BP 96/68 mmHg; pulse 226 beats/minute, irregular; RR 15 breaths/minute; and temperature 98.7°F. A rhythm strip confirms AF, with a QRS width varying from 0.08 to 0.14 seconds. To control the ventricular rate, 10 mg IV verapamil is administered over 2 minutes. Within 2 minutes, VF is noted on the monitor. M.B. is defibrillated to normal sinus rhythm. A subsequent ECG demonstrates a P-R interval of 100 milliseconds (normal 120–200) and delta waves compatible with WPW. What is WPW syndrome?

WPW is a pre-excitation syndrome in which there is an accessory bypass tract (known as a Kent bundle) connecting

the atria to the ventricle (Fig. 19-8). An impulse can travel down this pathway and excite the ventricle before the expected regular impulse through the AV node arrives (hence the term pre-excitation). If there is antegrade conduction over the bypass tract while the patient is in normal sinus rhythm, the ECG will demonstrate a short P-R interval (<100 milliseconds), a delta wave that represents a fused complex from pre-excitation, and the regular QRS complex following AV conduction. WPW can occur in children and adults without overt cardiac disease. Paroxysmal AV reciprocating tachycardias and AF occurs in these patients at a higher incidence than in the general population of the same age.⁹² Similar to M.B., the rapid heart rate experienced during the tachycardia may cause palpitations, lightheadedness, and fatigue. When patients with WPW develop AF, there is a danger that impulses will be conducted directly to the ventricle, causing a rapid ventricular rate that may evolve into VF.

26. Why did verapamil cause VF in M.B.? What drug or drugs would be appropriate for M.B., and what drugs should be avoided?

Verapamil can block AV conduction by increasing the effective refractory period, allowing all impulses from the atrial area to conduct down the bypass (Kent) tract. Because M.B. had AF, the rapid atrial impulses were conducted directly down the bypass tract to the ventricle, causing VF. In addition, verapamil may enhance conduction over the accessory pathway by shortening its effective refractory period. Also, peripheral vasodilation can induce a reflex sympathetic discharge that can, in turn, decrease the effective refractory period of the accessory pathway.^{93,94}

The most common presentation of WPW syndrome involves normal antegrade conduction down the AV node and retrograde conduction back up through the accessory pathway. This will manifest as orthodromic reciprocating re-entrant tachycardia. Thus, drugs that inhibit antegrade impulse conduction through the AV node (e.g., verapamil, digoxin) will terminate the re-entrant tachycardia and can be suitable in the absence of AF. The less common variety of WPW is antegrade conduction through the accessory pathway with retrograde transmission up through the AV node, resulting in an antidromic re-entrant tachycardia. Similarly, AV nodal blocking agents will terminate this type of re-entrant tachycardia. In some situations, such as experienced by M.B., rapid AF with an accessory pathway occurs, which can lead to VF and cardiac arrest.

The antiarrhythmic drugs used to treat patients with AF who have an accessory pathway, such as M.B., include those that depress conduction and increase the effective refractory period of the fast sodium channel-dependent tissue of the accessory pathway. This includes most class I antiarrhythmics, with the class IB agents being least effective. Procainamide, an FDA-approved drug for this indication, is a reasonable first choice.⁹⁵ Propafenone and flecainide are also effective and may be preferred over procainamide.^{96–99} Amiodarone and sotalol may also be effective, but clinical experience is limited.^{100–102} Radiofrequency ablation of the bypass tract is used more frequently for these patients to prevent VF.

Further therapy for M.B. may not be useful at this time. However, if he has recurrent AF or other symptomatology associated with WPW, radiofrequency catheter ablation or drug therapy as outlined previously could be indicated.

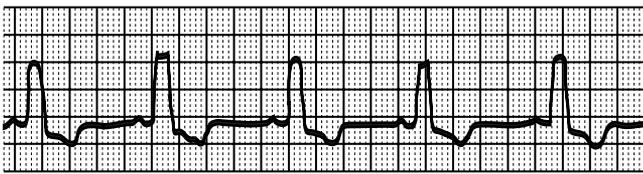

FIGURE 19-9 Bundle branch block. Note that the QRS interval is prolonged. A 12-lead electrocardiogram is required to make the diagnosis of left bundle branch block. *Source:* Reproduced with permission from Stein E. *Rapid Analysis of Arrhythmias: A Self-Study Program*. 2nd ed. Philadelphia: Lea & Febiger; 1992.

CONDUCTION BLOCKS

Various arrhythmias can result from blockage of impulse conduction. These can occur above the ventricle, such as first-, second-, and third-degree (complete) AV block. Others, such as RBBB or LBBB and trifascicular block, originate below the bifurcation of the His bundle. Although conduction blocks can be classified as either supraventricular or ventricular arrhythmias, they are discussed as a separate group because their mechanism of arrhythmogenesis is similar and their treatment is different from other arrhythmias.

27. H.T., a 63-year-old man, was admitted to the coronary care unit (CCU) 12 hours ago with an acute inferior wall MI. He has remained stable. On admission, he had the rhythm strip shown in Figure 19-9 (LBBB). Twelve hours later, it has changed to the rhythm strip shown in Figure 19-10 (Wenckebach or type I, second-degree AV block). Are these rhythms potentially hazardous to H.T.? How is second-degree AV block different from first- or third-degree AV block?

H.T.'s rhythm strip revealed a diagnosis of LBBB. Bundle branch block occurs when the electrical impulse cannot be conducted along the left or right fascicle of the His-Purkinje system (Fig. 19-1). In H.T., the impulse travels down the right bundle normally, and the right ventricle contracts at the normal time. The left bundle is blocked and, therefore, the left side is depolarized from an impulse conducted from the right ventricle. This impulse must travel through atypical conduction tissues (with slower conduction), and hence the left side depolarizes later. This is revealed on the ECG by a widened QRS complex. Bundle branch blocks, particularly in the left fascicle, are associated with coronary artery disease, systemic hypertension, aortic valve stenosis, and cardiomyopathy.¹⁰³ Typically, they

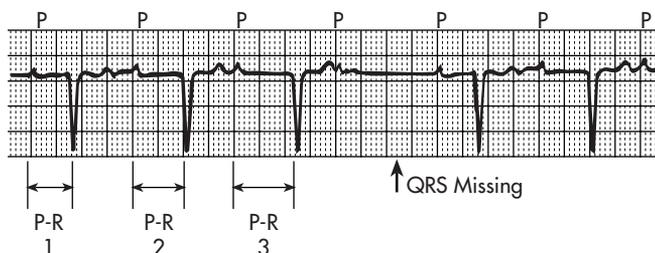

FIGURE 19-10 Second-degree atrioventricular block type I (Wenckebach). The P-R interval progressively prolongs until, after the third complex, a QRS complex is not conducted. *Source:* Reproduced with permission from Stein E. *Rapid Analysis of Arrhythmias: A Self-Study Program*. 2nd ed. Philadelphia: Lea & Febiger; 1992.

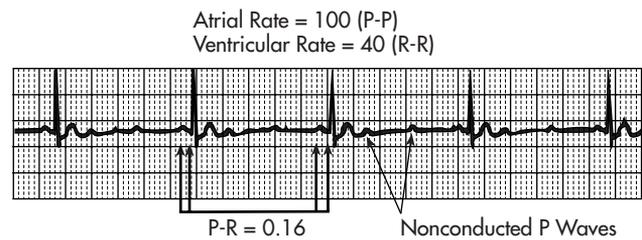

FIGURE 19-11 Second-degree atrioventricular block type II (3:1 fixed block).

do not lead to clinical cardiac dysfunction on their own. Because H.T. has LBBB, he can develop complete heart block (third-degree block) if for any reason his right fascicle is damaged.

First-degree AV block is usually asymptomatic. The ECG will show P waves with a prolonged P-R interval (normal >200 milliseconds), but each wave is followed by a normal QRS complex. First-degree AV block is a common finding in patients taking digoxin, verapamil, or other drugs that slow AV conduction.

Second-degree heart block consists of two types. Mobitz type I (Wenckebach) is characterized by progressive lengthening of the P-R interval with each beat and a corresponding shortening of the R-R interval until finally an impulse is not conducted; the cycle then starts over again. Mobitz type II (Fig. 19-11) impulse conduction is blocked in a fixed, regular pattern (e.g., 3:1 block, where for every three P waves, only one is conducted).

Third-degree heart block (complete heart block) occurs when none of the impulses from the SA node are conducted to the ventricles. During third-degree block, the ventricle must develop its own pacemaker (escape rhythm), which may be too slow to provide adequate cardiac output, causing the patient to become symptomatic. A mechanical pacemaker is needed for treatment of third-degree AV block. AV blocks can be caused by drugs, acute MI, amyloidosis, and congenital abnormalities.¹⁰⁴

Atropine

28. How should H.T.'s heart block be treated?

H.T. is experiencing a Wenckebach rhythm, which is often transient following an inferior wall MI. As long as he is hemodynamically stable, he should be monitored closely. If his heart rate and BP drop, atropine 0.5 mg IV bolus (maximum 2 mg) can increase the heart rate. This is only a short-term therapy; if the hemodynamic compromise persists, a pacemaker must be inserted to initiate the impulse to control the heart rate.

VENTRICULAR ARRHYTHMIAS

Recognition and Definition

Ventricular arrhythmias arise from irritable ectopic foci within the ventricular myocardium. Impulses from these ectopic foci generate wide, bizarre-looking QRS complexes leading to PVCs (Fig. 19-12). PVCs can arise from the same ectopic site (unifocal) or can be multifocal in origin. They can be simple (e.g., isolated or infrequent) or complex (e.g., R on T, in which

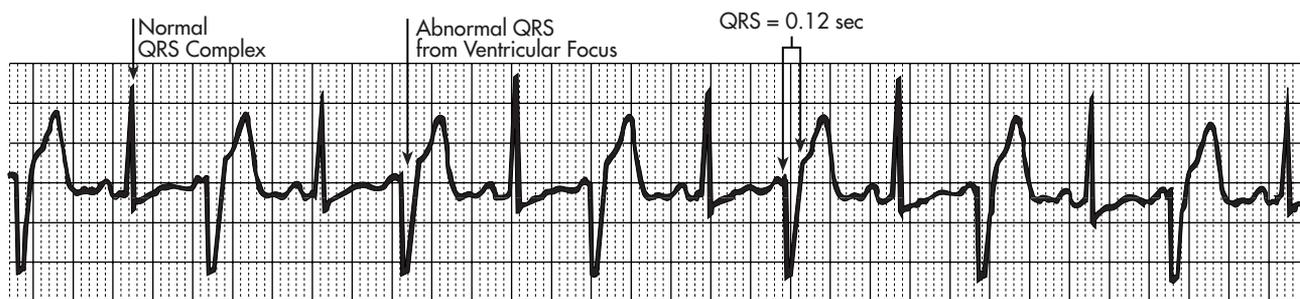

FIGURE 19-12 Premature ventricular contraction. Every other beat is a premature ventricular (ectopic) contraction.

the R wave of a PVC falls on top of a normal T wave). Other presentations include runs of two or more beats, bigeminy (every other beat is a PVC), or trigeminy (every third beat is a PVC). Three consecutive PVCs are usually defined as VT, which can be nonsustained or sustained. Ventricular flutter, VF, and TdP are other serious forms of ventricular arrhythmias (Figs. 19-13 to 19-16). The presentation, etiology, treatment, and ion channels associated with TdP are discussed separately.

Nonsustained ventricular tachycardia (NSVT) (Fig. 19-13) commonly is defined as three or more consecutive PVCs lasting <30 seconds and terminating spontaneously. Sustained VT (SuVT) is defined as consecutive PVCs lasting >30 seconds, with a rate usually in the range of 150 to 200 beats/minute. P waves are lost in the QRS complex and are indiscernible. SuVT (Fig. 19-15) is a serious development because it can degenerate into VF. Ventricular flutter is characterized by sustained, rapid, regular ventricular beats (normal >250/minute) and usually degenerates into VF. VF (Fig. 19-14) is characterized by irregular, disorganized, rapid beats with no identifiable P waves or QRS complexes. It is believed to be triggered by multiple re-entrant wavelets in the ventricle. There is no effective cardiac output in patients with VF.^{103,104}

Etiology

Common factors that cause ventricular arrhythmias are ischemia, the presence of organic heart disease, exercise, metabolic or electrolyte imbalance (e.g., acidosis, hypokalemia or hyperkalemia, hypomagnesemia), or drugs (digitalis, sympathomimetic amines, antiarrhythmics). It is essential to identify and remove any treatable cause (e.g., metabolic or electrolyte imbalance and proarrhythmic drugs) before initiating antiarrhythmic drug therapy.

Evaluation of Life-Threatening Ventricular Arrhythmias

An episode of life-threatening ventricular arrhythmia (i.e., SuVT, TdP, VF) carries a significant risk of morbidity and mortality. Adequate documentation of the arrhythmia and its suppression by either drugs or a mechanical device are essential. Patients suspected of having or documented to have symptoms of a life-threatening arrhythmia (e.g., syncope, out-of-hospital cardiac arrest) should be admitted to the hospital and evaluated. At present, two approaches are used to evaluate the arrhythmia and the effectiveness of therapy: ambulatory (Holter) monitoring and electrophysiologic studies.^{103,104}

Holter Monitoring

Holter monitoring is continuous ECG monitoring, usually for 24 to 48 hours, with or without exercise (e.g., treadmill exercise). The patient wears a portable ECG monitoring device in a purselike carrier and maintains a written log of daily activities and possible arrhythmia symptoms. The ECG is then played back in the laboratory, correlating the presence of arrhythmias with patient activity and symptoms. Monitoring should be implemented before and after drug intervention. One criterion clinically used in judging efficacy is that a drug is considered effective if it suppresses 100% of runs of VT longer than 15 beats, 90% of shorter runs, 80% of paired PVCs, or 70% of all PVCs, and there is an absence of exercise-induced VT.¹⁰⁵

Electrophysiologic Studies

Electrophysiologic studies are the second approach in evaluating the efficacy of antiarrhythmic drugs. This approach is especially useful in patients with sporadic ventricular arrhythmias that may be missed by short-term monitoring. This procedure involves right ventricular catheterization and introduction

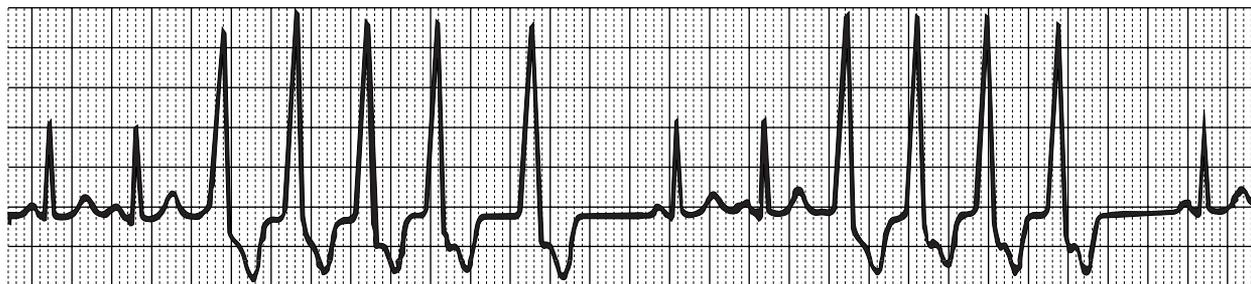

FIGURE 19-13 Nonsustained ventricular tachycardia. Source: Reproduced with permission from Goldberger AJ, Goldberger E. *Clinical Electrocardiology: A Simplified Approach*. 4th ed. St. Louis, MO: Mosby-Year Book; 1990.

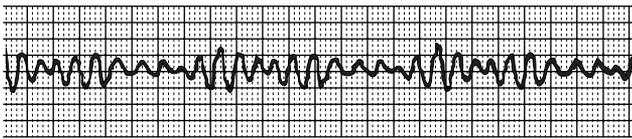

FIGURE 19-14 Ventricular fibrillation.

of up to three electrical stimuli at the right ventricular apex of the heart to induce baseline VT.¹⁰⁶ If the arrhythmia is not reproducibly induced, repeated stimulation with up to three extra stimuli is usually performed at the right ventricular outflow tract. Once VT is reproducibly induced at baseline, drug therapy is started. The drug is considered effective if the SuVT is rendered noninducible or occurs in runs of less than six beats. A partial response to drug therapy is obtained if the drug converts SuVT to NSVT or decreases the VT rate (e.g., increases VT cycle length by 100 milliseconds), with elimination of symptoms.¹⁰⁷

Drugs that achieve satisfactory response by Holter technique or complete suppression by the electrophysiologic technique have been shown to improve long-term survival in uncontrolled trials.^{108–110} Similarly, a partial response by the electrophysiologic method has also improved long-term outcome.¹¹¹ In a randomized, comparative study of Holter monitoring versus electrophysiologic study, Holter monitoring led to a prediction of efficacy more often than electrophysiologic study, although there was no difference in the success of drug therapy as selected by either method.¹¹⁰

Premature Ventricular Contractions

29. A.S., a 56-year-old woman, is admitted to the CCU with a diagnosis of acute anterior wall MI. Her vital signs are BP 115/75 mmHg, pulse 85 beats/minute, and RR 15 breaths/minute. Auscultation of the heart reveals an S₃ gallop. Her electrolytes include potassium (K) 3.8 mEq/L (normal 3.5–5.0) and magnesium (Mg) 1.4 mEq/L (normal 1.6–2.4). Otherwise, her examination is within normal limits. Two days later, an echocardiogram estimates her EF to be 35% (normal >50%). During her stay in the CCU and in the step-down unit, multiple PVCs (15/minute) were noted on the bedside monitor. No antiarrhythmic agent was ordered. Should A.S.'s multiple PVCs be treated with a class I antiarrhythmic drug?

[SI units: K, 3.8 mmol/L (normal 3.5–5.0); Mg, 0.72mmol/L (normal 0.8–1.2)]

Occasional PVCs are a benign, natural occurrence, even in a healthy heart, and are not an indication for drug therapy. Similarly, asymptomatic simple forms of PVCs, even in patients with other cardiac disease, are usually not an indication for treatment. However, the presence of frequent PVCs is a

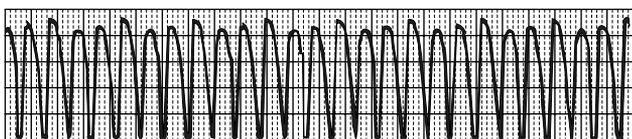

FIGURE 19-15 Sustained ventricular tachycardia.

well-described risk factor for sudden cardiac death (SCD).¹¹² In patients with a low EF induced by the PVCs or NSVT, the risk for sudden cardiac death can increase 13-fold. Suppressing PVCs under these conditions may reduce the risk of SCD.

Type IC Antiarrhythmic Agents

Because PVCs are a risk factor for SCD, the National Institutes of Health launched the Cardiac Arrhythmia Suppression Trial (CAST)^{113,114} to assess the benefit of PVC suppression in survivors of MI. CAST was a prospective, randomized, placebo-controlled trial that evaluated three antiarrhythmic agents: flecainide, encainide, and moricizine (all class IC agents). The choice of these drugs was based on results of a pilot study of 1,498 patients that showed adequate suppression of arrhythmia (PVCs) in the target population. Ten months after initiation of the study, CAST was discontinued because of excess total mortality and cardiac arrests in patients receiving flecainide and encainide. Forty-three of 755 patients in the flecainide/encainide group died of arrhythmia or cardiac arrest versus 16 of the 743 patients taking placebo. Furthermore, total mortality in the flecainide/encainide group was 8.3% (63/755) compared with 3.5% (26/743) in the placebo group.¹¹³ In the moricizine group, which was reported separately in CAST II, 16 of 660 patients in the drug group died compared with 3 of 668 patients in the placebo group in the initial 2 weeks. Subsequent long-term follow-up did not show a difference between moricizine and placebo.¹¹⁴ It is generally believed that the excessive death rate in the drug-treated groups was due to the proarrhythmic effect of the drugs. Because the patients enrolled in CAST were asymptomatic and at low risk for the development of arrhythmias, they were at greater risk for drug toxicity (relative to benefit). Although many issues have been raised concerning CAST, one conclusion is that patients with a recent MI and the presence of asymptomatic PVCs should not be treated with encainide, flecainide, or moricizine. Whether other class I antiarrhythmics will produce similar results is unknown. Thus, the decision not to treat A.S.'s PVCs with class I antiarrhythmic medications was a sound one. The proarrhythmic effects of the drug may outweigh the potential danger of PVCs at this time.

30. What alternatives to class I antiarrhythmics should be considered for A.S.?

β -Blocking Agents

A β -blocker should be considered in this patient and in all patients with an acute MI unless specific contraindications exist. β -blocking drugs have been shown to reduce the risk of reinfarction and cardiac arrest when started early in the course of an MI and continued for more than 7 to 14 days. In pooled analyses from 28 clinical trials on β -blockers, the mortality rate was decreased by 28% at 1 week, with most of the benefit obtained within the first 48 hours. An 18% reduction in reinfarction and a 15% reduction in cardiac arrest were also documented.^{115–117} A recent substudy looking specifically at patients with new signs of mild to moderate HF and acute MI determined that IV metoprolol (5-mg bolus every 5 minutes repeated three times to deliver 15 mg over 15 minutes) followed by 200 mg/day of oral metoprolol reduced overall mortality significantly at 3 months and 1 year.¹¹⁸ This suggests that a

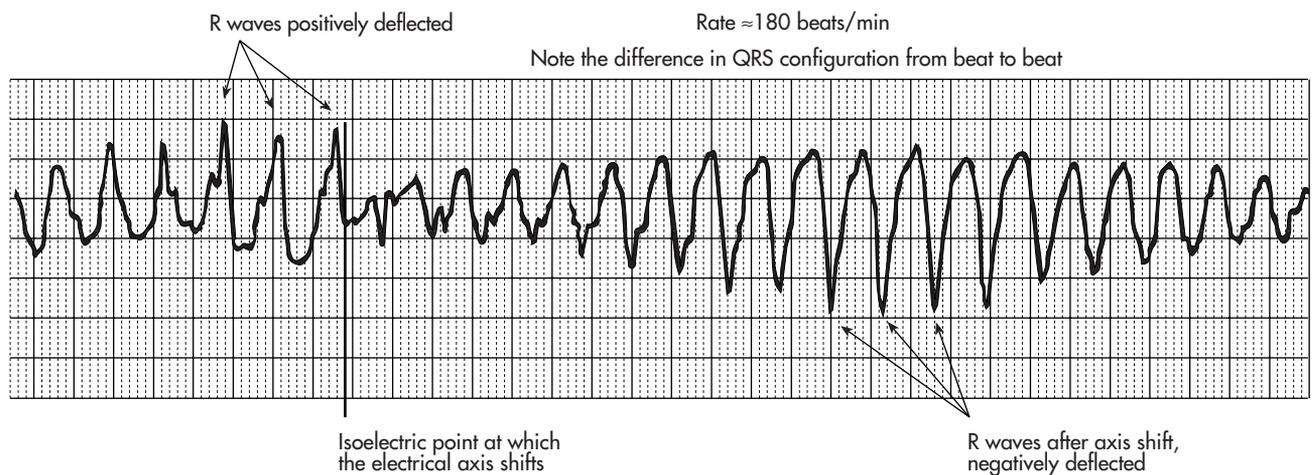

FIGURE 19-16 Torsades de pointes.

reduced EF after MI (as in A.S.) or a large MI is not a contraindication to β -blocker therapy.

The importance of the β -blocking effect after MI is further illustrated by the results of two MI sotalol trials. The first trial of sotalol, a class III antiarrhythmic agent with β -blocking properties, showed an 18% reduction in overall mortality, which was similar to that seen in other β -blocking trials.¹¹⁹ The second trial, the Survival With Oral D-Sotalol (SWORD) trial, evaluated the d-isomer of sotalol only. This isomer does not have β -blocking properties, and this trial was stopped early because the mortality rate was significantly increased.¹²⁰ The American Heart Association and the American College of Cardiology recommend the routine use of IV β -blockers (followed by oral therapy) to prevent the early occurrence of VF¹²¹ (see Chapter 17).

Amiodarone

In high-risk patients with MI who are not candidates for β -blockade, alternative antiarrhythmic therapy with amiodarone can be considered. Amiodarone is a class III antiarrhythmic agent but also has antiadrenergic, class I, and class IV activity. The first trial evaluating the use of amiodarone in patients who had specific contraindications for β -blockade was conducted in Poland. Treatment with amiodarone (800 mg/day for 7 days followed by 400 mg/day for 6 days of the week for 1 year) was associated with a significant reduction in cardiac mortality and significant ventricular arrhythmias. Overall mortality showed a trend toward benefit, but statistical significance was not achieved.¹²² An evaluation of amiodarone in post-MI patients with frequent PVCs (>10/hour) or at least one run of VT was conducted in the Canadian Amiodarone Myocardial Infarction Arrhythmia Trial (CAMIAT).¹²³ In this trial, amiodarone (10 mg/kg/day for 14 days, then 300–400 mg/day for 16 months) significantly reduced the incidence of VF or arrhythmic death by 48.5% compared with placebo. Arrhythmic death alone was reduced by 32.6%, and all-cause mortality was reduced by 21.2%, but statistical significance was not achieved for these end points. Patients with heart failure or a previous MI had a majority of the benefit from amiodarone therapy.

A complementary study, the European Myocardial Infarct Amiodarone Trial (EMIAT), evaluated MI survivors with a re-

duced EF (<40%).¹²⁴ Based on the results of this study, amiodarone (800 mg for 14 days, then 400 mg for 14 weeks, and then 200 mg for the rest of the study) significantly reduced arrhythmic deaths by 35% compared with placebo. However, this study did not demonstrate any trend toward reduced mortality (mortality was 13.86% with amiodarone vs. 13.72% with placebo). This suggests that amiodarone should not be used in all patients with a reduced EF after an MI, but that it could benefit patients in whom antiarrhythmic therapy is indicated. Hence, if A.S. reports problematic symptoms associated with the PVCs or develops additional risk factors for arrhythmia while on β -blockade, antiarrhythmic therapy with amiodarone can be given without an increased risk of overall mortality^{122–124} (see Chapter 17).

Nonsustained Ventricular Tachycardia

31. D.S., a 62-year-old man, was admitted recently for an inferior wall MI. Following the infarction, he has been free of further pain and does not exhibit signs of HF. An echocardiogram shows an EF of 48%, but D.S. does experience runs of VT (Fig. 19-13) lasting from three beats to 20 seconds in length. D.S. states that he feels his heart racing during the longer episodes. Should D.S.'s VT be treated? If so, what are the treatment options?

D.S. is experiencing NSVT, which can occur in patients with underlying heart disease, both ischemic and nonischemic (idiopathic dilated cardiomyopathy, hypertrophic cardiomyopathy). It is not clear which of these patients is at highest risk for SCD. The Multicenter Unsustained Tachycardia Trial (MUSTT) used electrophysiologic testing to see if laboratory inducibility of sustained monomorphic VT could predict the duration or frequency of NSVT in patients with NSVT, coronary artery disease, and a reduced EF. No significant difference in the frequency or duration of spontaneous NSVT was noted, and no clinically important differences were noted between the groups with or without laboratory inducibility.¹²⁵

The present treatment guidelines are based on the underlying left ventricular function.¹²⁶ If a patient has an EF higher than 40% and no symptoms, therapy is not indicated. If symptoms are present (e.g., palpitations, lightheadedness), a β -blocker is preferred unless it is contraindicated by the

presence of uncompensated HF or asthma/chronic obstructive pulmonary disease. In addition to controlling symptoms, β -blockers reduce the incidence of cardiac death in post-MI patients with and without PVCs.¹²⁷ If the patient has a reduced EF (<40%), it is uncertain what the best treatment should be. However, oral β -blocker therapy, with careful titration of dosage, may be considered because β -blockade is now an approved therapeutic approach in HF patients.

Because D.S. is symptomatic but has preserved ventricular function, he should certainly be started on a β -blocker. Pindolol or any other β -blocker with intrinsic sympathomimetic activity should be avoided because they have not been shown to be “cardioprotective” following an MI. The results from the CAMIAT study suggest a role for amiodarone in this patient if β -blockers are contraindicated or inadequate.¹²³

Sustained Ventricular Tachycardia

Treatment

32. S.L., a 64-year-old woman, presents to the ED with a chief complaint of palpitations. Her medical history includes hypertension controlled with a diuretic and an inferior wall MI 6 months ago. She is pale and diaphoretic but able to respond to commands. Her vital signs are BP 95/70 mmHg, pulse 145 beats/minute, and RR 10 breaths/minute. When telemetry monitoring is established, S.L. is found to be in SuVT (Fig. 19-15). S.L. states that she has a history of allergy to Novocain. How should she be treated?

The acute treatment of patients with SuVT depends on their hemodynamic stability. If unstable, patients should receive synchronous cardioversion, which will decrease the chance of triggering VF. If the patient is conscious, a short-acting benzodiazepine (e.g., midazolam) should be administered before the procedure.

LIDOCAINE

In patients with stable BP, IV agents such as lidocaine or procainamide are used to abolish the tachycardia. Lidocaine can be administered as a 1-mg/kg bolus, no faster than 50 mg/minute. More rapid rates can cause hypotension and asystole. If the initial bolus does not “break” the tachycardia, additional boluses of 0.5 mg/kg are administered 8 to 10 minutes apart until a total dose of 3 mg/kg is given. The need for a supplemental bolus dose at 8 to 10 minutes is based on the rapid distribution half-life (8 minutes) of lidocaine. At one distribution half-life, the plasma concentration is reduced by 50%, and the concentration at the effective site (the central compartment) is also reduced by 50%.¹²⁸

PROCAINAMIDE

Procainamide is an alternative agent if lidocaine is ineffective or is not tolerated. The efficacy of lidocaine is low (11%–25% success) if it is being used to convert VT not arising during ischemia or within 72 hours of an MI, while the efficacy of procainamide is similar, regardless of the presence of baseline ischemia or infarction.¹²⁹ A loading dose of 12 mg/kg is administered at a rate of 50 mg/minute. Hypotension is often the rate-limiting factor and can be minimized by administering the drug at a slower rate (20–35 mg/minute). Once the patient has converted to normal sinus rhythm, a continuous infusion (dosage, 1–4 mg/minute) can be started. The infusion should be reduced in renal failure because the parent drug and

the active metabolite, *N*-acetyl procainamide (NAPA), can accumulate. NAPA itself has class III antiarrhythmic activity and is eliminated entirely by the kidneys.

S.L. is hemodynamically stable at this time, so lidocaine should be given in an attempt to abolish the tachycardia. Lidocaine can be used even though S.L. reports an allergy to procaine (Novocain). Procaine is an ester-type local anesthetic, whereas lidocaine and procainamide are amide-type local anesthetics; thus, there is no cross-reactivity between the two types.

33. A 1-mg/kg lidocaine bolus is given at 50 mg/minute, and two additional boluses of 0.5 mg/kg are given at 10-minute intervals before normal sinus rhythm is restored. A continuous infusion of lidocaine is started at 4 mg/minute and continued for 48 hours. How should lidocaine concentrations be monitored over the next 12 to 24 hours?

Once converted to normal sinus rhythm, S.L. can be maintained on a continuous lidocaine infusion at a rate based on the estimated clearance of the drug (1–4 mg/minute). Lidocaine clearance can be reduced by HF, acute MI, advanced age, significant liver disease, and drugs such as propranolol or cimetidine.^{128,130,131} Under these conditions, a lower infusion rate should be used and the plasma lidocaine concentration determined in 12 to 24 hours (see average therapeutic concentration in Table 19-3). The lidocaine concentration also should be obtained after 24 hours if a prolonged infusion is anticipated because lidocaine clearance decreases in this situation. Phenobarbital and phenytoin may increase lidocaine clearance, thereby lowering the plasma concentration.¹³²

34. After 17 hours of the lidocaine infusion, S.L. is having difficulty manipulating a spoon to eat her Jell-O. She is becoming increasingly agitated and is inaccurately saying that people keep coming into her room and taking her things. Could these side effects be a result of lidocaine toxicity?

S.L. is probably exhibiting CNS side effects from lidocaine. If longer-term antiarrhythmic therapy is needed, it should be with another agent that is administered orally.

Lidocaine toxicity typically presents as alterations in the CNS such as dizziness, drowsiness, paresthesias, visual disturbances, tinnitus, slurred speech, trembling, loss of coordination, confusion, somnolence, hallucinations, unresponsiveness, seizures, or agitation. Cardiovascular toxicity (conduction disturbances, bradyarrhythmias, and hypotension) is rare and usually occurs when serum concentrations exceed 9 mcg/mL. Lidocaine also possesses weak negative inotropic activity, which is clinically most evident during prolonged infusions or in patients with a pre-existing depressed myocardium (e.g., acute MI).¹³³ In those at-risk individuals, negative inotropy could reduce cardiac output and cause or worsen HF symptoms. It is likely that S.L. is experiencing lidocaine toxicity, and her infusion should be reduced to 2 mg/minute or lidocaine therapy discontinued.

SOTALOL

35. S.L.’s attending physician believes that she should undergo further testing, and an electrophysiologist is consulted. It is determined that electrophysiologic testing is necessary because S.L. has a history of SuVT. On baseline testing, SuVT at a rate of 220 beats/minute was induced twice with the catheter placed at the

right ventricular apex. Sotalol 80 mg BID is prescribed. Describe the properties of sotalol and its adverse effects. How effective is sotalol in this situation? Is it the right choice for S.L.?

Sotalol is a unique agent that possesses nonselective β -blocking activity (class II) and prolongs repolarization (class III activity).¹³⁴ The immediate effect of sotalol in suppression of inducible VT or fibrillation is modest, generally averaging response rates of 30% to 35% using Holter monitoring, but as high as 56% in one report.¹¹⁰ However, a randomized, comparative trial called the Electrophysiologic Study Versus Electrocardiographic Monitoring (ESVEM) study, using both Holter monitoring and electrophysiologic testing, demonstrated that sotalol treatment produced a significantly lower probability of recurrence of arrhythmia, death from any cause, death from a cardiac cause, and death from arrhythmia compared with other drugs.¹¹⁰ Thus, the initial or acute efficacy of sotalol, although not impressive, can lead to better long-term results than many other drugs. The adverse effects associated with sotalol (e.g., fatigue, bradycardia, hypotension, TdP) are covered in the AF and TdP sections, respectively.

Because S.L. has no contraindications and had an MI 6 months ago, sotalol is a suitable initial choice. Sotalol can be initiated at 80 mg twice daily and advanced to a maximum recommended dose of 640 mg/day. The half-life of sotalol is 8 to 18 hours. Because it is cleared by the kidneys, its clearance is reduced and its half-life prolonged in patients with renal dysfunction. S.L.'s BP, heart rate, and ECG should be monitored. If her rate-related ("corrected") Q-T (QTc) interval becomes prolonged (see section on TdP), the dose should be reduced or the drug discontinued.

AMIODARONE

36. Sotalol is discontinued because S.L. developed a QTc interval above 500 milliseconds. What is the role of amiodarone for S.L.'s arrhythmia based on its efficacy and safety? If S.L. is to be treated with amiodarone, how should it be initiated and monitored?

Amiodarone exhibits properties of classes I, II, III, and IV antiarrhythmic agents. Although it has class II effects on the heart, amiodarone is virtually devoid of antiadrenergic effects outside the heart and is not contraindicated in patients with asthma. The antiadrenergic effects arise from inhibition of adenylate cyclase, the enzyme that catalyzes production of the second-messenger product cyclic adenosine monophosphate. Amiodarone can also cause a reduction in β -1 receptor density.^{129,135}

This drug has unique pharmacokinetic properties. Its apparent volume of distribution is 5,000 L. Because it is extensively bound to tissue and is lipophilic, its half-life after long-term administration is 14 to 53 days. The main metabolite of amiodarone is desethylamiodarone. Although this metabolite is active, its contribution to the overall antiarrhythmic activity is not clearly delineated.

Because of the extremely long half-life of amiodarone, loading doses are used to accelerate the onset of drug effect. One to 2 g/day (200–500 mg four times daily) is given over a 1-week period; after that time, a maintenance dose can be established. Typically, for treating ventricular arrhythmias, 300 to 400 mg/day is used for maintenance, but doses may range from 100 to 800 mg/day. Although a concentration–effect

relationship is hard to determine for amiodarone, levels above 2.5 mg/L are associated with an increased incidence of adverse effects.¹³⁵

Amiodarone has many serious adverse effects involving a variety of organ systems, the most serious and life-threatening of which is pulmonary fibrosis. This historically occurred in 5% to 10% of the population given chronic doses of 600 to 1,200 mg QD for amiodarone, with a 5% to 10% mortality rate for those who developed it.¹³⁶ Large-scale, multicenter, double-blind, placebo-controlled clinical trials in HF and after MI have provided much information on the safety of amiodarone using new and lower dosages (e.g., maintenance doses of 300–400 mg QD). From these trials, comprising 2,250 patients who received amiodarone for 1 or 2 years, there were three deaths from pulmonary fibrosis in the EMIAT study (0.4% incidence in this study), and no deaths were reported in the other studies.^{67,122–124,129,137} Severe pulmonary fibrosis was reported in 0.3% of patients in a Polish study and in 1.2% of patients in the CHF STAT trial (compared with 0.9% in the placebo group).^{67,122} Unspecified pulmonary disorders were reported in 5.2% of patients in the EMIAT study (compared with 4% in the placebo group) and in 3.8% of patients in the CAMIAT study (compared with 1.2% in the placebo group). The dosage regimens and beneficial effects of therapy from the Polish, EMIAT, and CAMIAT studies were reported in the section on the treatment of PVCs. Briefly, the dosage for all studies ranged from 600 to 800 mg/day for 7 to 14 days as a loading dose followed by maintenance regimens of 300 to 400 mg/day.

Despite the lower incidence of adverse pulmonary events observed in these studies, it is still necessary to monitor for the development of pulmonary fibrosis. A baseline chest radiograph and pulmonary function tests (diffusion capacity in particular) are recommended. The chest radiograph should be repeated at 6- to 12-month intervals, but pulmonary function tests need be repeated only if symptoms (dyspnea, nonproductive cough, weight loss) occur. Patients should be specifically questioned about these symptoms because early detection can decrease the extent of lung damage^{67,122–124,138} (see Chapter 25).

Liver toxicity can range from an asymptomatic elevation of transaminases (two to four times normal) to fulminant hepatitis. Thus, liver enzymes should be monitored at baseline and every 6 months (see Chapter 29). The most common GI complaints are nausea, anorexia, and constipation.

Both hypothyroidism and hyperthyroidism have been reported, although hypothyroidism is more common. The thyroid complications are a consequence of amiodarone's large iodine content and its ability to block the peripheral conversion of thyroxine (T_4) to triiodothyronine (T_3).

Other bothersome side effects are corneal deposits (usually asymptomatic); blue-gray skin discoloration in sun-exposed areas; photosensitivity; exacerbation of HF; and CNS effects that include ataxia, tremor, dizziness, and peripheral neuropathy. Other than an eye examination and pulmonary function tests, which should be repeated when the patient is symptomatic, all other blood tests should be repeated every 6 months for routine monitoring.¹³⁶

37. S.L. is placed on amiodarone 400 mg BID for 7 days. On day 2 of amiodarone therapy, her INR is 2.5. On day 8, she is switched

to 400 mg/day of amiodarone for maintenance therapy. Her INR on day 16 of amiodarone therapy is 4.2, and warfarin is held. Why is her INR above normal?

Amiodarone is a potent enzyme inhibitor of the cytochrome P450 enzyme system. Two of the most significant interactions associated with amiodarone are with warfarin and digoxin. Warfarin is composed of two isomers, R and S. The R-isomer is eliminated through the cytochrome P450 1A2 system, whereas the S-isomer is eliminated through the cytochrome P450 2C9 system. The S-isomer is five times more potent than the R-isomer. Amiodarone inhibits the elimination of warfarin's isomers through both enzyme sites. However, the time course of the interaction is somewhat different than other enzyme inhibitors due to amiodarone's long half-life. When amiodarone is added to stable warfarin therapy, close monitoring (at least weekly) is needed for up to 4 weeks.¹³⁹ Usually, dosages of warfarin are reduced by 30% to 50% after amiodarone is instituted.¹³⁹

Amiodarone inhibits the elimination of digoxin as well. Digoxin levels increase approximately 50% by day 5 and 100% by day 14¹⁴⁰ (see Chapter 18). Close monitoring is required for 2 weeks after digoxin initiation.¹⁴⁰ Even if amiodarone is discontinued, it can continue to interact with other drugs for more than a month (depending on the dose delivered) due to its long half-life.⁹ Amiodarone may substantially increase the levels of quinidine, whereas ritonavir (Norvir) may potently inhibit the elimination of amiodarone.¹³⁹

Implantable Cardiac Defibrillators

38. After 2 weeks on amiodarone, S.L. develops a run of VT lasting about 2 minutes. She is admitted for placement of an implantable cardioverter-defibrillator (ICD). What is an ICD, and how does it work?

ICDs are devices implanted under the skin with wires or patches that are advanced or attached so they are in direct contact with the ventricular myocardium. The ICD has sensing, pacing, and defibrillation capabilities. When an arrhythmia is sensed, the ICD will first try to pace the heart out of the arrhythmia. This is most effective (80% successful) when the VT rate before pacing is below 180 beats/minute. If pacing fails to terminate the arrhythmia, a generator will turn on and create a certain number of joules (J) of energy. Unlike external paddle defibrillators, which deliver 100 to 360 J of energy, the energy delivered by an ICD to defibrillate the heart is usually 5 to 30 J. This is adequate for two main reasons. The ICD delivers energy directly to the heart rather than having to pass the energy through skin, bone, and other organs. The use of a biphasic waveform in an ICD rather than a monophasic waveform also reduces the energy needed to defibrillate.

As the energy needed to defibrillate the heart with an ICD is increased, the amount of time the generator needs to create the energy is also increased. This is problematic because long charge times leave the patient in the arrhythmia for a longer period of time and may cause syncope. As such, the lowest energy needed to defibrillate the patient (the defibrillation threshold) is determined experimentally. To do this, the patient has an arrhythmia started by the electrophysiologist, and the device is set to shock at different energies to determine the lowest successful defibrillation energy. The electrophysiologist then sets

the energy output at 10 J above that level (a safety margin).¹⁴¹ Using the "DFT 10-J" rule prolongs battery life and reduces syncopal episodes associated with arrhythmia recurrence versus always using the ICD's maximal energy output.

However, the impact of drugs, herbals, and endogenous substances on the DFT are not well described. If a drug significantly increases the DFT, then it may reduce the effectiveness of a 10-J safety margin.

The first major results from a randomized trial came in 1996 with the publication of the MADIT (Multicenter Automatic Defibrillator Implantation Trial) study.¹⁴² This study enrolled 196 patients with prior MI; left ventricular EF 35% or below; documented asymptomatic NSVT; and inducible, nonsuppressible, ventricular tachyarrhythmia on electrophysiologic testing. The effect of ICDs versus conventional medical therapy (the majority of patients received amiodarone) on the primary end point, all-cause mortality, was followed for an average of 27 months. There were 39 deaths in the conventional medical therapy group and 15 deaths in the ICD group (hazard ratio for the ICD was 0.46; 95% CI, 0.26–0.82; $p = 0.009$).

A few years later, the results from the MUSTT extended the evidence that ICD therapy may have beneficial effects on mortality in patients at high risk for sudden death.¹⁴³ This larger study ($n = 704$) had similar inclusion criteria to the MADIT trial with the exception of a slightly higher EF cut-off (>40%). The primary end point was cardiac arrest or death due to arrhythmia. Patients were randomized to electrophysiologically guided therapy or no antiarrhythmic therapy. Of the patients who received electrophysiologically guided therapy, nearly half received antiarrhythmic drugs (mostly class I agents), and the remainder were given ICDs. The primary end point was achieved in 25% of patients receiving electrophysiologically guided therapy and in 32% of patients who did not receive antiarrhythmic therapy (relative risk, 0.73; 95% CI, 0.53–0.99).

The Antiarrhythmics Versus Implantable Defibrillators (AVID) study compared ICDs to therapy with amiodarone or sotalol. This study investigated a population at high risk (they had already experienced VF and been cardioverted previously, or they had documented VT with syncope or another serious complication and an EF <40%). Overall, 1,016 patients were randomly assigned to either antiarrhythmics or ICDs. This study was stopped early (after 18 months) because the incidence of overall mortality was significantly lower in the ICD group (15.8%) than in the antiarrhythmic group (24.0%).¹⁴⁴

Patients with ICDs who have frequent bouts of ventricular arrhythmogenesis are at high risk of developing ICD anxiety (known as ICD psychosis). They live in fear of their ICD going off again because it causes pain and they are forced to think of their own mortality. Use of antiarrhythmic agents to reduce the number of times the ICD goes off per month usually helps alleviate this anxiety.

Whether ICDs could be used in patients at high risk of arrhythmia (post-MI with a left ventricular EF <30%) but without past ventricular arrhythmic events was investigated in the Multicenter Automatic Defibrillator Implantation Trial II (MADIT II). ICD implantation plus conventional therapy was compared with conventional therapy alone. Conventional therapy consisted of β -blockers, ACE inhibitors, lipid-lowering drugs, diuretics, and digoxin in approximately 60% to 80% of patients in both groups. The ICD group had a 31% lower

overall mortality rate than the conventional therapy group. If this therapy becomes standard of care for this population, approximately 3 to 4 million patients will be eligible, and 400,000 new patients will be eligible each year.¹⁴⁵

Clearly, S.L. should have the device placed: It is her best chance for prolonging long-term survival. Depending on the number of times the machine discharges per month and the patient's response, adjunctive antiarrhythmics may be needed.

Torsades de Pointes

Proarrhythmic Effects of Antiarrhythmic Drugs and Clinical Presentation

39. G.G. is a 71-year-old woman who is taking sotalol 80 mg BID for a previous episode of SuVT. At baseline, her QTc interval was 445 milliseconds, and her Cl_{cr} was 52 mL/minute. Four weeks after therapy was initiated, she complained of bouts of dizziness. She went to her cardiologist's office earlier today, and an ECG was performed by the ECG technician. She was released and told that the cardiologist would call her later in the day after she read the ECG. While driving home 10 minutes ago, she passed out and hit a parked car. When the paramedics arrived, the ECG strip showed TdP with a ventricular rate of 110 beats/minute. She is now awake and alert. The ECG taken in the physician's office shows a QTc interval prolonged at 540 milliseconds. What is QTc interval prolongation? Why does QTc interval prolongation indicate an increased risk of TdP? Could an antiarrhythmic agent such as sotalol cause this arrhythmia? How does Cl_{cr} factor into this?

The QT interval denotes ventricular depolarization (the QRS complex in the cardiac cycle) and repolarization (from the end of the QRS complex to the end of the T wave). Certain ion channels in phases 2 and 3 of the action potential are vital in determining the QT interval (Fig. 19-1). An abnormal increase in ventricular repolarization increases the risk of TdP. TdP is defined as a rapid polymorphic VT preceded by QTc interval prolongation. TdP can degenerate into VF and as such can be life threatening (Fig. 19-16).¹⁴⁶

Because there is tremendous variability in the QT interval resulting from changes in heart rate, the QT is frequently corrected for heart rate (QTc interval). Several correction formulas for the QT interval exist and give similar results at most heart rates. The most common correction formula uses QT and RR intervals measured in seconds as follows: $[QTc = QT/(RR^{0.5})]$.

The Committee for Proprietary Medicinal Products suggests that a QTc interval over 500 milliseconds or a level that has increased as a result of medications by more than 60 milliseconds from baseline is a cause for concern of enhanced risk of TdP. Increases of 30 to 60 milliseconds from baseline are a potential concern.¹⁴⁶ The American College of Cardiology, American Heart Association, and European Society of Cardiology produced combined guidelines that address this issue as well. They suggest that agents prolonging the QTc interval through potassium channel blockade, with the possible exception of amiodarone, should be dosed to keep the QTc in sinus rhythm below 520 milliseconds.³ As an aside, amiodarone is unique among class III antiarrhythmic agents in that it blocks both IKr and the slow IK channel (IKs). This provides less heterogeneity in ventricular repolarization and reduces the risk of

TdP over agents that prolong the QTc interval solely by IKr blockade.

G.G. was in excess of the acceptable QTc interval of 500 milliseconds shortly before the time when TdP occurred. This QTc interval is much higher than would be expected in a subject without drug therapy or other risks of TdP. In a 150-subject trial, the average QTc interval of patients without comorbid diseases or concurrent medications was 403 ± 28 milliseconds. The QTc interval was 13 milliseconds lower in men than women (397 ± 27 and 410 ± 28 milliseconds, respectively). This is backed up by epidemiologic studies where 70% of TdP was found to occur in women. The QTc interval also increases with aging. Within the age categories of 20 to 40 years, 41 to 69 years, and >69 years, the QTc intervals were 397 ± 27 , 401 ± 28 , and 412 ± 28 milliseconds, respectively.¹⁴⁷ Hence, G.G.'s increased age and female gender probably contributed to her higher baseline QTc interval of 445 milliseconds, but this is still below the baseline 450 milliseconds cut-off for using sotalol.

Sotalol is known to cause QTc interval prolongation in a dose-dependent manner. Total daily doses of 160, 320, 480, and >640 mg gave patients a steady-state QTc interval of 463, 467, 483, and 512 milliseconds, and the incidence of TdP was 0.5%, 1.6%, 4.4%, and 5.8%, respectively.

It is likely that G.G.'s reduced renal function put her at high risk for sotalol accumulation and accentuated QTc interval prolongation. In patients with a Cl_{cr} above 60 mL/minute, the sotalol dose of 80 mg BID is appropriate, but in patients like G.G. with a Cl_{cr} <40 to 60 mL/minute, the starting dose should be 80 mg daily owing to sotalol's predominant renal clearance.

40. What transient conditions or other disorders can increase the risk of TdP in patients on class IA or III antiarrhythmics?

Hypokalemia, hypomagnesemia, and hypocalcemia are important transient causes of QTc interval prolongation. Follow-up ECG monitoring is advised if a patient on a class IA or III antiarrhythmic has a disorder that radically alters electrolytes, such as severe diarrhea, metabolic acidosis, or ketoacidosis. Also, patients with renal failure have dramatic electrolyte shifts occurring during dialysis that may cause QTc interval changes. As such, avoidance of these antiarrhythmics or close ECG monitoring is warranted.

All class III and class IA antiarrhythmic agents except amiodarone and ibutilide exhibit IKr potassium channel reverse use dependence: This means that they block IKr potassium channels when the channels are in their inactive state. As such, the QTc interval will tend to shorten at faster heart rates and lengthen at slower heart rates. Hence, patients with an acceptable QTc interval while in AF may have an elevated QTc interval after they convert back to sinus rhythm if the ventricular rate markedly slows. A second ECG should be taken once sinus rhythm is restored to avoid this complication. Proper ventricular rate control with class II or IV antiarrhythmics before using chemical cardioversion can reduce the chances of dramatic heart rate reductions after conversion to sinus rhythm. In addition, patients who develop a bradycardic disorder should be monitored very closely. Finally, patients with vasovagal syncope usually experience transient vagally mediated bradycardia during a syncopal episode. This can increase the QTc interval and may make therapy more dangerous.

Investigators have discovered gene mutations responsible for hereditary long QTc interval syndrome,¹⁴⁸ an inherited cardiac disorder that predisposes patients to syncope, seizures, and sudden death. Sudden death in long QTc interval syndrome is usually secondary to TdP, which degenerates into VF.^{148,167} Drug therapy with QTc-prolonging agents would be risky in this population.

Because G.G. did not have a family history of hereditary long QT syndrome, but was being treated with sotalol (an agent known to be associated with TdP) in renal dysfunction, it can be assumed that sotalol therapy was responsible for her arrhythmia.

Proarrhythmic Effects of Nonantiarrhythmic Drugs

41. Which nonantiarrhythmic drugs cause TdP? What is the mechanism of TdP initiation in this situation?

Nonantiarrhythmic agents can also exhibit potassium channel inhibition and can prolong the QTc interval. Most of these drugs, including erythromycin, fluoroquinolones, and antipsychotics cause QTc interval prolongation by inhibiting the IKr ion channel, just like quinidine and sotalol.^{146,149–151} Ranolazine, however, inhibits IKr, IKs, calcium, and sodium channels, and given its unique pharmacologic profile, the relationship between QTc interval prolongation and TdP is not established.¹⁵²

In general, nonantiarrhythmic agents increase the QTc interval in relation to the dosage administered and the blood concentration attained.^{150,151} However, antipsychotics such as ziprasidone seems to have a plateau effect for QTc prolongation. The placebo group had a 2.6-millisecond reduction in the QTc interval, compared to increases of 0.6 to 9.7 milliseconds over the range of approved doses of ziprasidone (<80–160 mg/day). When doses >200 mg/day were given, the QTc interval increases were 6.4 milliseconds on average, suggesting a plateau effect. This is underscored by the experience with the drug to date, where 10 cases of overdose (>300 mg single dose) were reported, with no QTc interval exceeding 500 milliseconds.¹⁵³

In most subjects, the QTc interval prolongation for nonantiarrhythmic agents is less than the 30-millisecond increase from baseline that consensus groups have defined as being a potential concern for TdP. The lack of concern for a general population receiving normal doses of antiarrhythmics is underscored by data on terfenadine that led to its eventual removal from the market. It increased random ECG QTc intervals by 4 to 18 milliseconds in most studies. In addition, when its metabolism is blocked via CYP3A4 enzyme inhibitors such as itraconazole and ketoconazole, QTc interval increases of 41 and 82 milliseconds resulted, respectively.¹⁴⁶ Terfenadine underwent the largest evaluation of the risk of life-threatening ventricular arrhythmias to date in the COMPASS study. This cohort trial compared the incidence of life-threatening arrhythmic events in 597,189 patients from four Medicaid databases. Terfenadine was compared to two other over-the-counter (OTC) antihistamines (diphenhydramine and clemastine—the active ingredient in Tavist) and ibuprofen. In this trial, terfenadine was shown to have significantly fewer life-threatening arrhythmic events (0.037%) than the other OTC antihistamines (0.085%, $p = 0.05$) and ibuprofen (0.057%, $p = 0.05$), and similar events to clemastine

(0.021%). However, when the subgroup of patients receiving ketoconazole with terfenadine was evaluated, the adjusted relative risk was 23.55 times that of terfenadine alone ($p = 0.001$), a substantial risk.¹⁵⁴ Hence, the risk of arrhythmogenesis was not realized before taking into account the pharmacokinetic drug interaction, which in previous studies had been shown to increase the QTc interval into the zone for concern. Patient with renal failure (including those on dialysis), severe electrolyte disturbances, or hereditary long QTc interval syndrome were not rigorously studied but would theoretically also be at greater baseline risk.

Drug interactions accentuating the blood concentrations and subsequently the risk of TdP led to the withdrawal of terfenadine, astemizole, and cisapride from the U.S. market.^{155,156}

Interestingly, erythromycin is not only metabolized through the cytochrome P450 3A4 system, but its active metabolite can also inhibit the cytochrome P450 3A4 system. Because the metabolite of erythromycin must be enzymatically activated and accumulate in the plasma before inhibiting the 3A4 system, it does not usually affect its own elimination (autoinhibition), but it can affect other drugs eliminated through this metabolic route.¹⁵⁶

The antipsychotics are unique in that inhibitors of their metabolism do not result in appreciable increase in the QTc interval. This is likely because of the aforementioned QTc interval plateau effect. This was clearly demonstrated in Study 054, where several atypical antipsychotics (ziprasidone, risperidone, olanzapine, and quetiapine) and two typical antipsychotics (thioridazine and haloperidol) were evaluated. Therapy was given for more than 21 days to allow steady state to occur, and maximal doses in the package inserts were used for all drugs except thioridazine, for which half the maximum dose was given. In the second phase of the study, a CYP metabolic inhibitor was added to assess the impact of drug interactions on the QTc interval. In phase I of the trial, only thioridazine had QTc interval increases above 30 milliseconds (average 35.6 milliseconds; 95% CI, 30.5–40.7 milliseconds). None of the other agents had an average or an upper limit of the 95% CI for the QTc interval change exceeding 30 milliseconds. In phase II, the use of a specific CYP enzyme inhibitor did not cause a significant increase in the QTc interval for any agent compared to phase I.¹⁵⁷

A list of nonantiarrhythmic agents implicated in causing QTc interval prolongation and known pharmacokinetic drug interaction increasing the blood concentrations of these drugs is given in Table 19-6.

Because G.G. was not taking nonantiarrhythmic agents that are associated with TdP, sotalol is still the most likely culprit.

Treatment

42. How should TdP be treated? What treatments should be considered for L.S.?

If the patient is significantly hemodynamically compromised (frequently associated with a ventricular rate >150 beats/minute and unconsciousness) while in TdP, electrical cardioversion is the therapy of choice and should be given immediately. Stepwise increasing shocks of 100 to 200, 300, and 360 J (monophasic energy) can be tried if earlier shocks are unsuccessful.

Table 19-6 Nonantiarrhythmic Agents Implicated in QTc Interval Prolongation or Torsades de Pointes^a

| Drug Class | Agent | Drugs That Increase Blood Concentrations of These QTc Interval Prolonging Drugs |
|-------------------------------|--|---|
| Antianginal | Ranolazine | CYP3A4 inhibitors |
| Antibiotics: macrolides | Erythromycin (lactobionate and base) | CYP3A4 inhibitors |
| Antibiotics: fluoroquinolones | Gatifloxacin, grepafloxacin, lomefloxacin, moxifloxacin, sparfloxacin | |
| Antibiotics: other | Trimethoprim-sulfamethoxazole, pentamidine isethionate | |
| Antidepressants | Tricyclics, maprotiline | CYP1A2, 2D6, or 2C9 inhibitors |
| Antiemetics | Dolasetron | |
| Antimalarials | Mefloquine, quinine | Sodium bicarbonate, acetazolamide, cimetidine |
| Antipsychotics | Atypicals, butyrophenones, typicals | CYP1A2, 2D6, 2C9, 3A4 inhibitors |
| Calcium channel blockers | Bepridil | |
| Dopaminergics | Amantadine | Hydrochlorothiazide, quinidine, quinine, trimethoprim-sulfamethoxazole |
| Narcotics | Methadone | CYP3A4 and 1A2 inhibitors |
| Sympathomimetics | Albuterol, ephedra, epinephrine, metaproterenol, terbutaline, salmeterol | Monoamine oxidase inhibitors |
| Other | Arsenic, organophosphates | |

^aAn up-to-date list can be found at www.torsade.org.

MAGNESIUM

In a hemodynamically stable patient, magnesium is frequently considered the drug of choice to restore normal sinus rhythm. It benefits patients whether they have hypomagnesemia or normal serum magnesium levels. However, magnesium is not effective for patients with polymorphic VT without TdP and with normal QT intervals. A common magnesium regimen is 1 to 2 g given over 5 to 10 minutes (in 50 mL D5W) as a loading dose and then 1 g/hour for up to 24 hours. However, loading doses of 1 to 6 g given over several minutes followed by an IV infusion for 5 to 48 hours at a rate of 3 to 20 mg/minute have also been used. The exact mechanism of action for magnesium in TdP is not known, but it reduces the occurrence of triggered activity such as early after-depolarizations and has L-type calcium channel and IK1 blockade during phase 3 of the action potential.

CLASS IB ANTIARRHYTHMICS

The second class of drugs commonly used to abolish TdP is the class IB antiarrhythmic agents (e.g., mexiletine, lidocaine, tocainide). Unlike quinidine and the class III antiarrhythmic agents, the class IB agents do not inhibit potassium outflow during phases 2 and 3.^{150,158} In addition, blockade of inward sodium channels causes a shortening of the QT interval in some patients. Preliminary data suggest that class IB antiarrhythmic agents have considerable benefit in patients with sodium channel-activated QT prolongation, but virtually no effect on patients with potassium channel blockade-induced QT prolongation.^{159,160} In a landmark trial, mexiletine was given to patients who had hereditary long QT syndrome,¹⁵⁹ and the patients were analyzed by their genetic etiology of long QT. The group with a deficient gene for the potassium channel had no QT shortening, whereas those with a defective sodium gene had significant shortening of the QT interval. These divergent responses were confirmed in an in vitro study using mexiletine with either clofilium, a potassium channel blocker, or almokalant, a pure sodium channel activator.¹⁶⁰

Cardioacceleration with isoproterenol (1–4 mcg/minute) or cardiac pacing has also been shown to be beneficial.^{161,162}

As previously described, sotalol, quinidine, and *N*-acetyl procainamide's ability to prolong the action potential duration is diminished at faster heart rates (reverse use dependence).¹⁶³ The more the IKr potassium channels are activated, the less susceptible the channels are to inhibition by potassium channel-blocking drugs.

Because G.G. has regained consciousness and is hemodynamically stable, a bolus injection of 2 g magnesium should be administered over 10 minutes. If it is successful, a continuous infusion of magnesium (1 g/hour for up to 24 hours) should be given, and the serum potassium level should be determined. If hypokalemia is present, it should be corrected. If the arrhythmia recurs, cardiac pacing should be used. If the patient becomes hemodynamically unstable again, electrical cardioversion with 200 J is warranted. Future drug therapy with appropriately dosed sotalol, amiodarone, or ICD therapy will need to be determined subsequently.

Naturopathic Therapy for Arrhythmias

43. D.B. is interested in natural products to replace his antiarrhythmic therapy, which he says is too expensive. Are there any herbal or natural agents that can prevent or treat arrhythmias?

Herbal Therapies

Many herbal remedies have been touted as beneficial in “normalizing heart rhythm,” but in vivo supportive data are lacking for most agents. Avoid using herbal products that contain cardiac glycosides such as lily of the valley, oleander, strophantus, hispidus seeds, squill, dogbane, *Adonis vernalis*, ouabain, and *Thevetia peruviana*. Although the effects can mimic those of digoxin, there is no way to monitor blood concentrations so they cannot be used safely.

Food Supplements and Minerals

Omega-3 fatty acids and magnesium are the best-studied alternative and complementary therapies for arrhythmias and are described as follows. In addition, dietary deficiencies of taurine

Table 19-7 Commonly Used Drugs in Cardiac Arrest

| Drug | Formulation | Dosage/Administration ^a | Rationale/Indications | Comments |
|------------------|---|---|---|--|
| Amiodarone | 50 mg/mL Vials: 3, 9, 18 mL | 300 mg diluted in 20–30 mL D5W or NS; additional 150 mg (diluted solution) can be given for recurrent or refractory VT or VF. | Exhibits antiadrenergic properties and blocks sodium, potassium, and calcium channels. First-line antiarrhythmic pulseless VT and VF. | Excipients (polysorbate 80 and benzyl alcohol) can induce hypotension. Failing to dilute can induce phlebitis. |
| Atropine Sulfate | 0.05, 0.1, 0.4, 0.5, and 1 mg/mL | 1 mg IV, repeated every 3–5 minutes (maximum of 3 mg) for persistent asystole. | Blocks parasympathetic activity due to excessive vagal activity. Indicated in asystole, or slow PEA. | Must be given rapidly to avoid paradoxical vagal activity. |
| Epinephrine | 0.1 mg/mL (1:10,000) or 1 mg/mL (1:1,000) | 10 mL of a 1:10,000 solution of epinephrine (1 mg; dilute 1:1,000 solution in 0.9% sodium chloride) every 3–5 minutes. | Increases coronary sinus perfusion pressure through α -1 stimulation. Indicated in pulseless VT, VF, asystole, and PEA. | Epinephrine or vasopressin can be used for these indications. |

PEA, pulseless electrical activity; VF, ventricular fibrillation; VT, ventricular tachycardia.

and selenium may predispose to arrhythmias. If deficiencies are found, supplementation seems promising.^{164,165}

The largest prospective randomized controlled trial to test the efficacy of omega-3 fatty acids for secondary prevention of coronary heart disease was the Grupo Italiano per lo Studio della Spravvivenza nell'Infarto Miocardico (GISSI) prevention study.¹⁶⁶ In this trial, 11,324 patients with coronary heart disease were randomized to 300 mg vitamin E, 850 mg omega-3 fatty acids (given as eicosapentaenoic acid [EPA] and docosahexanoic acid [DHA] ethyl esters), both, or neither. After 3.5 years, the group given omega-3 fatty acids had a 20% reduction in overall mortality and a 45% reduction in sudden death. Vitamin E was ineffective. Limitations to this study were that it was not placebo controlled, and the dropout rate was 25%. However, a prospective cohort study, a case-control study, and four prospective dietary intervention trials also demonstrated a reduction in sudden cardiac death from increases in sources high in omega-3 fatty acids (e.g., fatty fish). A nested case-control study showed that patients with MI and subsequent sudden death had lower levels of both EPA and DHA in their blood than MI patients without sudden death.¹⁶⁷

Animal and in vitro studies suggest that omega-3 fatty acids may prevent arrhythmias by reducing the amount of scar tissue formation after an MI, and prevent calcium overload by maintaining the activity of L-type calcium channels and by inhibiting voltage-gated sodium channels.¹⁶⁸

In addition to its beneficial effects in AF and TdP chemical conversion, magnesium has been evaluated as a ventricular rate controller in AF. In a small study, IV magnesium ($MgSO_4$, 2 g over 1 minute then 1 g/hour for 4 hours) reduced the heart rate by 16% within 5 minutes and then maintained the heart rate. No heart rate change occurred in the placebo group.¹⁶⁹ In a direct comparative trial versus verapamil (5 mg plus 5 mg IV followed by an infusion of 0.1 mg/minute), verapamil was significantly better as a rate controller (28% of patients had a heart rate <100 beats/minute with magnesium vs. 48% for verapamil). However, the magnesium group had significantly better conversion to normal sinus rhythm (58% in the magnesium group vs. 23% in the verapamil group).¹⁷⁰ Combination therapy with digoxin and magnesium versus digoxin alone was investigated in a small study. Digoxin use alone resulted in 50% of patients achieving a ventricular rate of <90 beats/

minute at 24 hours. However, combination therapy with $MgSO_4$ (2 g over 15 minutes, then 8 g $MgSO_4$ over 6 hours) and digoxin resulted in 100% of patients achieving the ventricular rate goal.¹⁷¹ There is some indication that magnesium can also benefit patients on digoxin chronically for AF who have frequent PVCs. Magnesium glycerophosphate 570 mg daily (23.4 mmol elemental magnesium) or placebo was given over the course of 4 weeks. The use of magnesium reduced the incidence of PVCs by 56%. No difference was noted for the patients randomized to placebo over the 4 weeks.¹⁷² Future studies should be conducted to further evaluate this potentially cost-effective therapy.

In summary, omega-3 fatty acids may provide protection against ventricular arrhythmias in patients with ischemic heart disease. How it interacts with other antiarrhythmic agents is not well studied. In AF, magnesium can improve the rate-controlling effects of digoxin, but it should be used only when digoxin alone cannot adequately control the ventricular response. Magnesium does not seem to inhibit spontaneous cardioversion and may have some efficacy in chemical cardioversion.

CARDIOPULMONARY ARREST

Cardiopulmonary Resuscitation

Cardiac arrest from VF, pulseless VT, pulseless electrical activity (PEA), and asystole are life-threatening emergencies. Table 19-7¹⁷³ reviews commonly used drugs for these indications, and Figure 19-17 highlights key features of the management of pulseless arrest. This section reviews important aspects of therapy and provides clinical pearls, but the reader should also review the national consensus source document for these disorders, which includes more detail than can be given here.¹⁷³

Treatment

44. M.N., a 52-year-old man, is visiting his wife, who is hospitalized for pneumonia. He goes into the bathroom and 2 minutes later his wife hears a dull thud. She calls out for her husband, but he does not respond. After an additional 2 minutes, health care

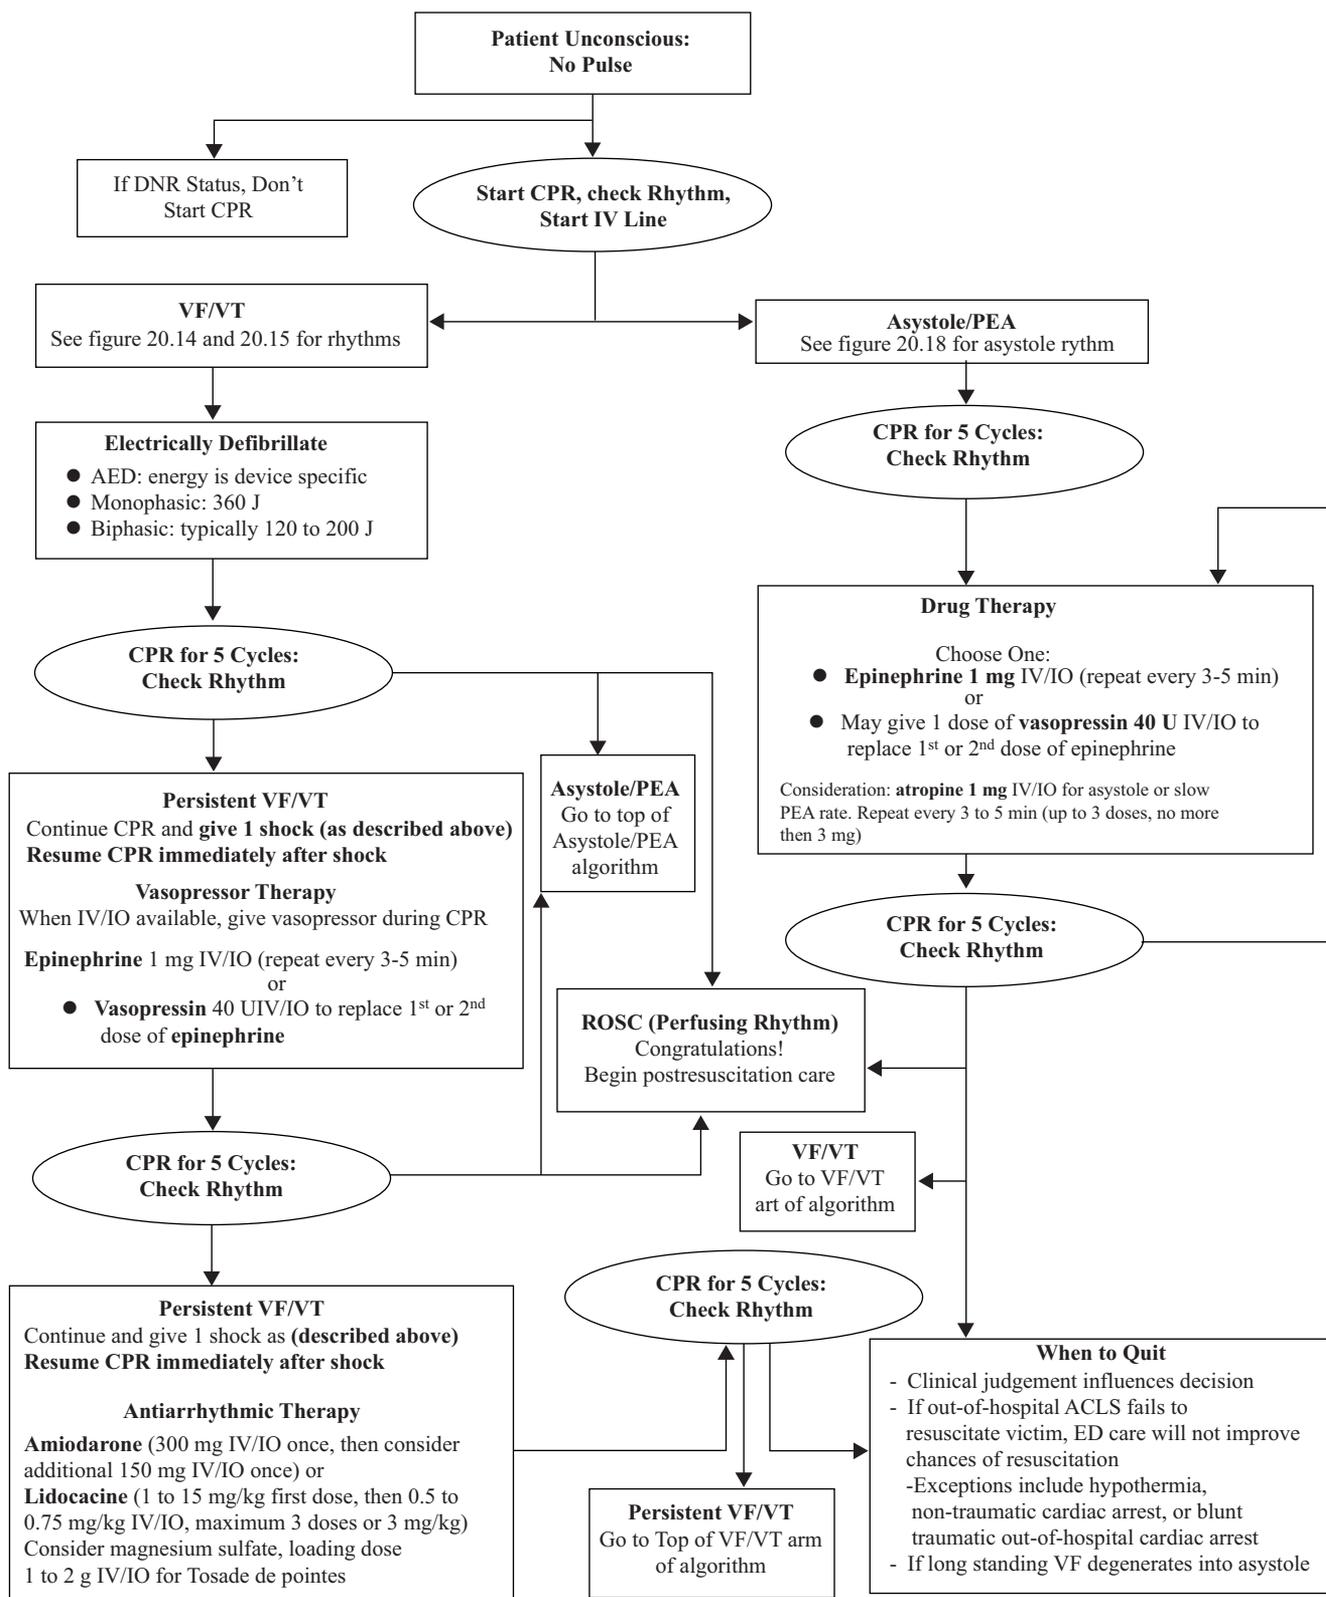

FIGURE 19-17 Cardiac arrest treatment algorithm. AED, automated external defibrillator; CPR, cardiopulmonary resuscitation; DNR, do not resuscitate; ED, emergency department. IO, intraosseous; IV, intravenous; PEA, pulseless electrical activity; ROSC, restoration of spontaneous circulation; VF, ventricular fibrillation; VT, ventricular tachycardia. Source: Adapted from reference 173.

workers open the bathroom door and find M.N. unresponsive and pulseless. Cardiopulmonary resuscitation (CPR) is initiated and a Code Blue is called. The ECG shows VF (Fig. 19-14), and there is no BP. In addition to CPR, what initial therapy is available?

Determining the underlying rhythm disturbance is important because it directs health care workers to follow the advanced cardiac life support (ACLS) algorithm for pulseless VT or VF (Fig. 20.17). This algorithm calls for electrical defibrillation first, but other clinicians should work to establish IV access in case defibrillation fails.¹⁷³

External Defibrillation

Although commercially available manual defibrillators provide monophasic or biphasic waveform shocks, the biphasic defibrillator has become the preferred device due to its high first-shock efficacy (>90% termination of VF at 5 seconds post-shock). Biphasic defibrillators deliver one of two waveforms, a truncated exponential waveform or a rectilinear waveform. Most commercially available biphasic defibrillators display the device-specific energy dose range that should be used. Respective initial selected energies of 150 to 200 J and 120 J are reasonable choices for initial shocks delivered by truncated exponential waveform and rectilinear waveform defibrillators, respectively. However, if a health care provider operating a manual biphasic defibrillator is uncertain of the effective energy dose to terminate VF, an initial 200 J shock can be employed. For second and subsequent shocks delivered by manual biphasic defibrillators, the same or higher energies should be used. For first and subsequent shocks, a shock of 360 J should be delivered if a monophasic defibrillator is used to terminate VF.¹⁷³

45. The initial shock fails to cause a return of spontaneous circulation in M.N. An IV line is established in a peripheral arm vein. The algorithm now calls for epinephrine or vasopressin, but which one should be used?

Epinephrine/Vasopressin

Although epinephrine stimulates β -1, β -2, and α -1 adrenoceptors, it is the α -1 adrenoceptor effects that are most closely associated with efficacy in VF or pulseless VT.¹⁷³ Applying α -1 adrenoceptor stimulation increases systemic vascular resistance (via vasoconstriction), which elevates coronary perfusion pressure. This increase in coronary perfusion pressure is most likely the key to enhancing the return of spontaneous circulation after subsequent electrical defibrillation. Epinephrine may convert fine VF to a coarse variety that may be more amenable to defibrillation.

The recommended dose of epinephrine is 1 mg (10 mL of a 1:10,000 dilution; refer to Table 19-7) given by IV push. The dosage can be repeated at 3- to 5-minute intervals during resuscitation. If the drug is given IV via a peripheral line, which in this case includes a peripherally inserted central catheter, then a 20-mL flush with normal saline is recommended to ensure delivery into the central compartment. Only chest compressions cause blood circulation in VF or pulseless VT, so movement of drugs from the periphery to the heart (where the benefit will occur) is severely impaired.

If intravenous access is unavailable, health care providers may attempt to establish intraosseous (IO) access in the patient. For IO injection of drugs, a cannula should be placed in

a noncollapsible venous plexus; the onset and systemic drug concentrations achieved with IO administration are similar to that achieved by central venous access. Typical sites of IO needle insertion include the anterior tibial bone marrow, distal femur, medial malleolus, or anterior superior iliac spine.

Vasopressin is an exogenously administered antidiuretic hormone. In supraphysiological doses, vasopressin stimulates V1 receptors and causes peripheral vasoconstriction. Vasopressin use during CPR causes intense vasoconstriction to the skin, skeletal muscle, intestine, and fat, with much less constriction of coronary vascular beds. Cerebral and renal vasodilation occurs as well.¹⁷³

The results of a prospective, randomized, controlled, multicenter study ($n = 1,186$) that enrolled out-of-hospital cardiac arrest patients who presented with VF, PEA, or asystole, showed that administration of vasopressin as adjunctive therapy resulted in similar survival to hospital admission rates compared with adjunctive epinephrine therapy.¹⁷⁴ Patients were randomized to receive two ampules of 40 IU vasopressin or two ampules of 1 mg epinephrine. The second dose of vasopressin was injected if spontaneous restoration of circulation did not occur within 3 minutes after the first injection of the drug. If the absence of spontaneous circulation persisted, the physician administering CPR had the option of injecting epinephrine. The primary outcome measure of the study was overall survival to hospital admission. The reported survival rates were similar between the two treatment groups for both patients with PEA and those with VF. Of note, a post-hoc analysis showed that survival to hospital admission rates were 29% and 20%, respectively, for vasopressin- and epinephrine-treated patients who presented with asystole requiring CPR ($p = 0.02$).

An in-hospital study of 200 cardiac arrest patients (initial rhythm: 16%–20% VF, 3% VT, 41%–54% PEA, 27%–34% asystole) showed no difference in 1-hour or hospital discharge survival for vasopressin 40 IU versus epinephrine 1 mg.¹⁷⁵ Similarly, a recent meta-analysis of five randomized trials showed no survival advantage of vasopressin treatment over epinephrine treatment at the times of hospital discharge or 24 hours posttreatment.¹⁷⁶

Based on these trials, it would be reasonable to use a single dose of vasopressin 40 IU as an alternative to either the first or second dose of epinephrine 1 mg in the treatment of VF (or pulseless VT).

ENDOTRACHEAL ADMINISTRATION

If IV access is not available, endotracheal administration of epinephrine is acceptable. Many agents (lidocaine, epinephrine, atropine, or naloxone [LEAN]) can be delivered via this route.^{173,177} The patient should be horizontal rather than in the Trendelenburg position. A catheter should be passed beyond the tip of the endotracheal tube, at which point chest compressions should be stopped. The drug solution should be sprayed quickly down the endotracheal tube, followed by 5 to 10 rapid ventilations with a respirator bag. Medications should be diluted in 10 mL of normal saline or distilled water. Endotracheal absorption is greater with distilled water than with normal saline, but distilled water has a more negative effect on P_{aO_2} . In general, the total bioavailability by the endotracheal route is reduced compared with the direct IV route; therefore, 2 to 2.5 times the usual dose should be given.

If IV or endotracheal routes are not available, then intracardiac injection could be used. Potential problems with the intracardiac route include pneumothorax, inability to perform chest compressions while the intracardiac drugs are being given, and coronary artery laceration. Intramuscular or subcutaneous administration is not appropriate because poor peripheral perfusion leads to unpredictable absorption.

46. Because M.N. has an IV site and the time from cardiac arrest to ACLS was brief, epinephrine was chosen and a 1-mg bolus was given, followed with a 20-mL normal saline flush. The arm was elevated for 20 seconds to ensure adequate delivery. Thirty seconds after administration, a 200-J shock is given (via biphasic manual defibrillator), but it fails to convert VF. What can be done now?

The most recently updated ACLS guideline calls for the use of amiodarone in cases of VF or pulseless VT that do not respond to CPR, a minimum of two shocks, and a vasopressor.¹⁷³

Intravenous Amiodarone/Lidocaine

The effect of amiodarone in VF or pulseless VT was studied in the ARREST (Amiodarone for Resuscitation of Refractory Sustained Ventricular Tachyarrhythmias) trial.¹⁷⁸ This study was conducted in patients who experienced cardiac arrest in an out-of-hospital situation with therapy given by paramedics in the field. Patients who failed three stacked shocks and one dose of epinephrine with an electrical countershock were randomized to amiodarone 300 mg IV bolus or placebo. This was followed by other antiarrhythmics used in ACLS (2000 guidelines; lidocaine, procainamide, or bretylium) if the clinicians desired. Amiodarone significantly increased the chance of survival to hospital admission (44% vs. 34% of placebo group, $p = 0.03$), but survival to hospital discharge was not changed. Of note, 66% of patients received antiarrhythmic drug treatment for pulseless VT or VF after amiodarone administration. In addition, recipients of amiodarone were more likely to experience hypotension (59% vs. 48% of placebo, $p = 0.04$) or bradycardia (41% vs. 25% of placebo group, $p = 0.004$).

The occurrence of hypotension among amiodarone recipients has been attributed to the presence of two excipients, polysorbate 80 and benzyl alcohol. Of interest, a recent study conducted by Somberg et al.¹⁷⁹ showed that a new formulation of amiodarone (Amio-Aqueous; Academic Pharmaceuticals, Lake Bluff, IL) had a similar risk of hypotension as lidocaine after VT termination (1% in both groups).

The ALIVE (Amiodarone Versus Lidocaine in Ventricular Ectopy, $n = 347$) trial directly compared IV amiodarone 300 mg to lidocaine 1- to 1.5-mg/kg bolus.¹⁸⁰ In this trial, patients needed to fail three stacked shocks and epinephrine plus an additional shock to be eligible for randomization to either amiodarone or lidocaine. Amiodarone was given as an initial dose of 5 mg/kg followed by a shock. If unsuccessful, a dose of 2.5 mg/kg was given followed by a subsequent shock. Lidocaine was given as a 1.5-mg/kg bolus followed by a shock. If therapy failed, then a second bolus of 1.5 mg/kg was used with a subsequent shock. If the first antiarrhythmic drug failed, other routine antiarrhythmic drugs for cardiac arrest (per 2000 ACLS guidelines; e.g., procainamide, bretylium) could be tried. Patients given amiodarone were 90% more likely to experience the primary outcome, survival to hospital admis-

sion, than those given lidocaine ($p = 0.009$). Unfortunately, no significant advantage to hospital discharge occurred (5% vs. 3%).

On the basis of these findings, amiodarone is the only antiarrhythmic agent with proven ability to improve return of spontaneous circulation and short-term survival versus other antiarrhythmic therapy. However, it has not yet been shown to improve survival to hospital discharge.^{178,180} Lidocaine should be considered as an alternative to amiodarone for VF or pulseless VT patients who remain unresponsive to multiple shocks, epinephrine/vasopressin, and CPR. The dosing regimens of amiodarone and lidocaine for the treatment of VT or pulseless VF are highlighted in Table 19-7.

47. Amiodarone 300 mg followed by electrical defibrillation fails to cause a return of spontaneous circulation in M.N. A subsequent 150-mg dose also fails. However, M.N. did convert to normal sinus rhythm for 9 seconds before going back into VF. Should resuscitation be discontinued?

M.N. is at serious risk of death due to VF. However, as long as M.N. remains in VF, it is appropriate to continue active therapy. If M.N. degenerates into asystole after this long period of VF, then resuscitation efforts should be discontinued. However, if a patient only had a brief period of VF before having asystole, it is prudent to use the asystole algorithm and apply active therapy.

48. Because the patient is still in VF and had a brief period in sinus rhythm, a 1.5-mg/kg bolus of lidocaine is given. Is it necessary to give additional bolus doses or start a lidocaine infusion at this time?

In cardiac arrest, the movement of lidocaine from the initial volume of distribution to the total body volume of distribution is attenuated, and with a cardiac output of only 15% of normal with chest compressions, there is not enough liver perfusion to clear the lidocaine, making supplemental boluses or continuous infusion unnecessary while cardiac arrest continues. M.N. converts to sinus rhythm, and the rhythm holds. He is unconscious and has three broken ribs, and his mental functioning or long-term survival is not known at this time. M.N. is a candidate for two supplemental bolus doses (0.75 mg/kg) at 10-minute intervals now and for a continuous infusion of lidocaine at 30 to 50 mcg/kg/minute.

Pulseless Electrical Activity

49. J.D. is an 80-year-old woman who experiences cardiac arrest in the hospital. A rhythm is noted on the monitor, but no femoral pulse is felt. M.N. is in PEA. How should she be treated?

PEA is the clinical situation in which there is organized electrical activity on the monitor without a palpable pulse. Although electrical activity is present, it fails to stimulate the

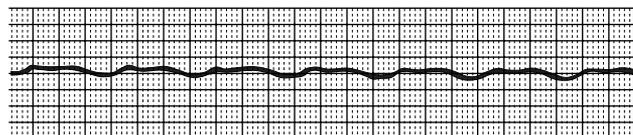

FIGURE 19-18 Asystole.

contractile process. Virtually all patients in true PEA die. However, not all patients who present with a rhythm and no pulse are in true PEA. Therefore, it is important to rule out treatable causes in patients who appear to be in PEA. The major treatable causes are hypovolemia, hypoxia, acidosis, hyperkalemia, hypokalemia, hypothermia, cardiac tamponade, pulmonary embolism, acute coronary syndrome, trauma, and drug overdose. In the absence of an identifiable cause, the focus of resuscitation is to administer high-quality CPR, and after the initial rhythm check, resume CPR during the establishment of IV/IO access.¹⁷³

Once IV/IO access becomes available, administer epinephrine 1 mg every 3 to 5 minutes or give one dose of vasopressin 40 U in place of the first or second dose of epinephrine, because published studies have failed to demonstrate a survival advantage of either vasopressor for patients experiencing PEA.^{173,175,176} In addition, although its efficacy has not been validated by prospective controlled studies, the current ACLS guidelines recommend the consideration of atropine as an adjunct to vasopressor treatment for patients in PEA. Atropine 1 g can be given every 3 to 5 minutes up to a maximum dose of 3 mg for persistent PEA. Figure 19-17 summarizes the sequence of interventions in PEA.

In establishing the diagnosis of PEA, two points should be made. First, the carotid artery is the preferred site to check for a pulse. A systolic pressure of 80 mmHg is required to generate a radial pulse, 70 mmHg for a femoral pulse, and 60 mmHg for a carotid pulse. A Doppler ultrasound can be used to more accurately determine if blood flow is present. Second, it may be useful to interrupt CPR and listen for heart sounds. The presence of sounds indicates that the heart valves are opening and closing and that contraction is occurring. Thus, one should intensify the search for a treatable cause. The absence of heart sounds does not confirm a lack of contraction.

Asystole

50. K.K. is a 73-year-old man who experiences cardiac arrest. The ECG shows a flat line, and the patient is determined to be in asystole (Fig. 19-18). Is this rhythm treatable?

Lack of electrical activity or asystole, such as PEA, carries a grave prognosis. Its development usually indicates a prolonged arrest, which may explain its poor response to treatment. However, a few patients will go directly from a sinus rhythm into asystole and may be resuscitated. Enhanced parasympathetic tone, possibly due to a vagal reaction, manipulation of the airway from intubation, suctioning or insertion of an oral airway, or chest compression, may play a role in inhibiting supraventricular and ventricular pacemakers. Therefore, anticholinergic or parasympathetic drugs that block vagal activity may be beneficial.

As described in case 45, a post-hoc analysis performed by Wenzel et al.²⁰⁵ demonstrated superior survival rates at the time of hospital admission in vasopressin-treated patients, compared to epinephrine-treated patients. However, no difference in intact neurologic survival was noted between the two vasopressor treatment groups. Consequently providers may choose to administer vasopressin 40 IU IV (in place of a first or second dose of epinephrine) or epinephrine 1 mg IV every 3 to 5 minutes. Because of its vagolytic effects, atropine 1 mg IV may be repeated every 3 to 5 minutes or until a total of 3 mg has been administered. Figure 19-17 summarizes the sequence of interventions in patients with asystole.

The patient should be evaluated for adequate oxygenation and ventilation or the presence of severe metabolic imbalances. Electrical defibrillation to rule out fine VF may be attempted, but defibrillation of asystole is of no benefit. When VF and asystole are terminated, it is common for the patient to become hypotensive. Fluids and inotropic and vasopressor support are then warranted.

The term *hypertensive crisis* is arbitrarily defined as a severe elevation in blood pressure (BP), generally considered to be a diastolic pressure > 120 mmHg.¹ If these disorders are not treated promptly, a high rate of morbidity and mortality will ensue.² These disorders are divided into two general categories: *hypertensive emergencies* and *hypertensive urgencies* (Table 20-1).^{3,4} Signs and symptoms of these disorders are nonspecific and may overlap. The distinction usually depends on the clinical assessment of the life-threatening nature of each episode. The term *hypertensive emergency* describes a clinical situation in which the elevated BP is immediately life threatening and needs to be lowered to a safe level (not necessarily to normal) within a matter of minutes to hours.^{1,3} The level to which the BP is elevated does not in itself represent a true emergency. A *hypertensive urgency* is less acute and can be accelerated or even malignant. It is not immediately life threatening, and a reduction of BP to a safe level can occur more slowly over 24 to 48 hours.^{1,5}

Hypertensive crises are usually characterized by an acute and marked elevation of arterial pressure, arteriolar spasm, necrotizing arteriolitis (necrosis in the media of the arterioles), and secondary organ damage. Hypertensive emergencies generally occur in patients with catecholamine producing adrenal tumors (pheochromocytoma), renal vascular disease, or accelerated essential hypertension. Acute life-threatening elevations of BP can also occur in previously normotensive individuals with acute glomerulonephritis, head injury, or severe

burns; during pregnancy (eclampsia); and with use of recreational drugs such as cocaine, as well as from abrupt drug withdrawal, drug–drug interactions (including herbal medications), erythropoietin administration, or drug–food interactions (i.e., patients receiving monoamine oxidase inhibitors who ingest foods rich in tyramine).^{6–8}

Rapid, severe BP elevation is not always the hallmark of a hypertensive emergency. Indeed, even moderate elevations of arterial pressure in the context of multiple disease states demand prompt treatment. Examples include acute left ventricular failure, intracranial hemorrhage, eclampsia, dissecting aortic aneurysm, and postoperative bleeding at suture sites.

Hypertensive emergencies rarely develop in previously normotensive patients.⁹ Most commonly, they complicate the accelerated phase of poorly controlled, chronic hypertension.¹ In several studies of patients with hypertensive emergency, a history of hypertension was previously diagnosed in >90% of the patients, suggesting that hypertensive emergencies are almost entirely preventable.^{9,10} Effective management of chronic hypertension has lowered the number of patients who present with hypertensive emergencies to <1%.¹¹ In a study on the prevalence of end organ complications in hypertensive crisis, central nervous system (CNS) abnormalities were the most frequently reported. Cerebral infarctions were noted in 24%, encephalopathy in 16%, and intracranial or subarachnoid hemorrhage in 4% of patients. CNS abnormalities were followed in incidence by cardiovascular complications, such as acute heart

Table 20-1 Hypertensive Emergencies Versus Urgencies

| Emergencies | Urgencies |
|--|---|
| Severely elevated blood pressure (diastolic > 120 mmHg) ^a | Severely elevated blood pressure (diastolic > 120 mmHg) ^a |
| Potentially life threatening | Not life threatening |
| End organ damage present or high risk: | Minimal end-organ damage with no pending complications |
| CNS (dizziness, N/V, encephalopathy, confusion, weakness, intracranial or subarachnoid hemorrhage, stroke) | Accelerated malignant hypertension |
| Eyes (ocular hemorrhage or funduscopic changes, blurred vision, loss of sight) | Optic disc edema |
| Heart (left ventricular failure, pulmonary edema, MI, angina, aortic dissection) | Coronary artery disease |
| Renal failure/insufficiency | Post- or perioperative hypertension Pre- or post-kidney transplant |
| Pheochromocytoma crisis | |
| Drug-induced hypertensive crisis | |
| MAOI–tyramine interactions | |
| Overdose with PCP, cocaine, or LSD | |
| Drug interaction–induced hypertension | |
| Clonidine withdrawal | |
| Cocaine use | |
| Eclampsia (complicated pregnancy) | |
| Requires immediate pressure reduction | Treated over several h to d |
| Requires IV therapy (Table 20-2) | Oral therapy or slower-acting parenteral drugs preferred (Table 20-3) |

^a Degree of blood pressure elevation less diagnostic than rate of pressure rise and presence of concurrent diseases or end organ damage. See Chapter 13 for staging of hypertension.

CNS, central nervous system; IV, intravenous; LSD, lysergic acid diethylamide; MAOI, monoamine oxidase inhibitor; MI, myocardial infarction; N/V, nausea and vomiting; PCP, phencyclidine.

failure and pulmonary edema, which were seen in 36% of patients and acute myocardial infarction and unstable angina in 12% of patients. Acute dissection was noted in 2% and eclampsia in 4.5% of patients.⁹

However, even with effective therapy, the mortality for patients with a history of hypertensive crisis continues to be significant. Hypertensive emergencies occur more often in African Americans than in Caucasians, among patients who have no primary care physician, and among those who do not adhere to their treatment regimens.^{9,12} In addition, systolic blood pressure control has been identified as an independent risk factor for the development of hypertensive crisis.¹³

ACCELERATED AND MALIGNANT HYPERTENSION

The terms *accelerated* and *malignant hypertension* have been used to describe severe hypertension accompanied by specific funduscopic changes.^{4,14} Accelerated hypertension is characterized by the presence of retinal hemorrhages, exudates (yellow deposits within the retina due to leaks from capillaries and microaneurysms), and arteriolar narrowing and spasm. The incidence of accelerated hypertension among ambulatory patients is diminishing, and mortality from it is declining.¹⁵ Ma-

lignant hypertension, an extension of the accelerated form, is remarkable for the presence of papilledema (edema of the optic nerve).¹¹ It occurs more commonly in middle-age hypertensive patients, with peak prevalence in the 40- to 60-year age range. If malignant hypertension occurs with no previous history of hypertension or in a patient who is younger than 30 or older than 60, a secondary cause should be suspected. Despite the funduscopic changes, the terms *accelerated* and *malignant* are often used synonymously. It is now also known that the clinical outcomes do not differ on the basis of funduscopic findings, suggesting that they are part of the same process.¹⁵ Currently, these terms as “hypertensive crisis,” “hypertensive emergency,” and “hypertensive urgency.”¹⁶ Although hypertensive emergencies are much less common than hypertensive urgencies, without a thorough patient history it is often difficult to know whether end organ dysfunction is new or has progressed.

Signs and Symptoms

Symptoms associated with hypertensive crisis are highly variable and reflect the degree of damage to specific organ systems. The primary sites of damage are the CNS, heart, kidneys, and eyes.

Central Nervous System

CNS damage can present solely as a severe headache or may be accompanied by dizziness, nausea, vomiting, and anorexia. Headache (42%) and dizziness (30%) were the most frequently reported symptoms for emergency room patients diagnosed with hypertensive urgency.¹⁷ Mental confusion with apprehension indicates more severe disease, as does nystagmus, localized weakness, or a positive Babinski sign (i.e., upward extension of the great toe and spreading of the smaller toes when moderate pressure is applied along a curve from the sole to the ball of the foot). CNS damage may be rapidly progressive, resulting in coma or death. If a cerebrovascular accident has occurred, slurred speech or motor paralysis may be present.

Other Complications

Cardiac complications of hypertensive crisis include heart failure (HF), acute pulmonary edema, angina pectoris, and acute coronary syndrome. Myocardial infarction (MI) can also be precipitated. Ocular symptoms of hypertensive crisis usually are related to changes in visual acuity. Complaints of blurred vision or loss of eyesight are often associated with funduscopic findings of hemorrhages, exudates, and occasionally papilledema. Renal complications include hematuria, proteinuria, pyelonephritis, and elevated serum blood urea nitrogen (BUN) and creatinine levels.

Principles of Treatment

Oral Versus Parenteral Therapy

An elevated BP in the absence of life-threatening signs or symptoms is not an indication for parenteral treatment. Oral antihypertensive regimens are more appropriate for the management of these urgent cases. Practitioners should exercise caution in the treatment of patients with elevated blood pressures in the absence of target organ damage. Aggressive dosing with oral medications to rapidly lower blood pressure is not without

risk and can lead to hypotension and subsequent morbidity. Some have suggested that the term “hypertensive urgency” leads to overly aggressive treatment and should be discarded in favor of a less ominous term such as “uncontrolled” blood pressure.⁵ In contrast, hypertensive emergencies require immediate hospitalization, generally in an intensive care unit, and the administration of parenteral antihypertensive medications to reduce arterial pressure.¹⁸ Effective therapy greatly improves the prognosis, reverses symptoms, and arrests the progression of end organ damage. Treatment reverses the vascular changes in the eyes and slows or arrests the progressive deterioration in renal function. Treatment of malignant hypertension can transiently worsen renal function. However, after 2 to 3 months of adequate medical therapy, renal function may gradually improve to the premalignant level of renal insufficiency or to a new, slightly deteriorated level. The time required for recovery of renal function ranges from 2 weeks to 2 years. A low serum creatinine level, in the absence of marked cardiomegaly or renal shrinkage, has been associated with a good chance for recovery of renal function.¹⁹ In patients with mild encephalopathy, neurologic symptoms resolve within 24 hours after treatment.²⁰ Resolution of papilledema occurs in 2 to 3 weeks, whereas funduscopic exudates can require up to 12 weeks for complete resolution.²¹ Whether treatment can completely reverse end organ damage is related to two factors: how soon treatment is begun, and the extent of damage at the initiation of therapy.

There are two fundamental concepts in the management of hypertensive emergencies. First, immediate and intensive therapy is required and takes precedence over time-consuming diagnostic procedures. Second, the choice of drugs will depend on how their time course of action and hemodynamic and metabolic effects meet the needs of a crisis situation. If encephalopathy, acute left ventricular failure, dissecting aortic aneurysm, eclampsia, or other serious conditions are present, the BP should be lowered promptly with rapid-acting, parenteral antihypertensive medications such as diazoxide (Hyperstat), esmolol (Brevibloc), enalaprilat (Vasotec IV), fenoldopam (Corlopam), hydralazine (Apresoline), labetalol (Normodyne, Trandate), nicardipine (Cardene IV), nitroglycerin (Tridil, Nitrostat IV, Nitro-Bid IV), nitroprusside (Nipride), or trimethaphan (Arfonad)^{1,3,4,11,22–24} (Table 20-2). If a slower BP reduction over several hours or days is acceptable, rapid-acting oral therapy using captopril (Capoten), clonidine (Catapres), prazosin (Minipress), labetalol, or minoxidil (Loniten) may be used^{4,11,24–26} (Table 20-3). A summary of treatment recommendations for acutely lowering blood pressure for selected indications are listed in Table 20.4.

Goals of Therapy

The rate of BP lowering must be individualized because ischemic damage to the heart and brain can be provoked by a precipitous fall in BP.^{26–30} Antihypertensive drugs should be used cautiously in patient groups at high risk for developing hypotensive complications, such as the elderly and patients with severely defective autoregulatory mechanisms. The latter group includes those with autonomic dysfunction or fixed sclerotic stenosis of cerebral or neck arteries.³¹ In addition, patients who have chronically elevated BP are less likely to tolerate abrupt reductions in their BP, and the amount of reduction appropriate for those patients is somewhat less than

for those whose BP is acutely elevated. In patients with hypertensive encephalopathy, cerebral hypoperfusion may occur if the mean BP is reduced by >40%.³² Thus, it has been suggested that the mean pressure be lowered by no more than 20% to 30%.^{32,33} For hypertensive emergencies, it is recommended that the mean arterial pressure be reduced initially by no more than 25% (within minutes to 1 hour), then if stable, this should be followed by further reduction toward a goal of 160/100 mmHg within 2 to 6 hours and gradual reduction to normal over the next 8 to 24 hours.³ A diastolic pressure of 100 to 110 mmHg is an appropriate initial therapeutic goal.¹ Lower pressures may be indicated for patients with aortic dissection. Another exception to this rule applies in patients with acute cerebrovascular accidents. Cerebral autoregulation is disrupted in this setting and the use of antihypertensives may cause a reduction in cerebral blood flow and increasing morbidity. Current guidelines recommend lowering blood pressure following acute ischemic stroke in the presence of end organ damage if the blood pressure is >220/120 mmHg in patients ineligible for thrombolytic therapy or >185/110 mmHg in those who are candidates for thrombolytics.^{34,35} Lower blood pressure in patients undergoing thrombolytic therapy reduces the risk of intracerebral bleeding.

HYPERTENSIVE URGENCIES

Patient Assessment

1. M.M. is a 60-year-old African American male with a long history of heart failure, poorly controlled hypertension believed to be due to nonadherence, and a history of MI. He was referred from a community health center this morning for a thorough evaluation of his elevated BP. He has not taken his captopril (Capoten), amlodipine (Norvasc), or hydrochlorothiazide for the past 7 days. M.M. is completely asymptomatic. Physical examination reveals a BP of 180/120 mmHg and a pulse of 92 beats/minute. Funduscopic examination is pertinent for mild arteriolar narrowing, without hemorrhages or exudates. The discs are flat. His lungs are clear, and the cardiac examination is unremarkable. The electrocardiogram (ECG) indicates normal sinus rhythm (NSR) at a rate of 90 beats/minute with first-degree atrioventricular (AV) block. The chest radiograph is interpreted as mild cardiomegaly. Serum electrolytes, BUN, and serum creatinine (SrCr) are within normal limits. A urinalysis (UA) is significant for 2+ proteinuria. What is the therapeutic objective in treating M.M.? How quickly should his BP be lowered, and what therapeutic options are available?

M.M. has stage II hypertension with a BP of 180/120 mmHg.³ However, the absolute magnitude of BP elevation does not in itself constitute a medical emergency requiring an acute reduction in BP. There is no evidence of encephalopathy, cardiac decompensation, chest pain, or rapid change in renal function. Therefore, no evidence exists to indicate a rapid deterioration in the function of target organs.

As is often the case, M.M.'s lack of BP control is related to medication nonadherence. M.M.'s clinical presentation requires that his BP be lowered over the next several hours, while being careful not to induce hypotension. Rapid-acting oral agents can be used for this purpose; parenteral therapy is not warranted. A number of different oral regimens using clonidine, captopril, labetalol, prazosin, or minoxidil are available.

Table 20-2 Parenteral Drugs Commonly Used in the Treatment of Hypertensive Emergencies

| Drug (Brand Name) | Dose/Route | Onset of Action | Duration of Action |
|--|---|-------------------------|------------------------------|
| Nitroprusside ^a (Nitropress) 50 mg/2 mL (most commonly used) | IV infusion ^a Start: 0.5 mcg/kg/min Usual: 2–5 mcg/kg/min Max: 8 mcg/kg/min | Sec | 3–5 min after D/C infusion |
| Diazoxide (Hyperstat IV) 300 mg/20 mL | 50–150 mg IV Q 5 min or as infusion of 7.5–30 mg/min ^d | 1–5 min | 4–12 hr |
| Enalaprilat ^e (Vasotec IV) 1.25 mg/mL 2.5 mg/2 mL | 0.625–1.25 mg IV Q 6 hr | 15 min (max, 1–4 hr) | 6–12 hr |
| Esmolol ^f (Brevibloc) 100 mg/10 mL 2,500 mg/10 mL concentrate | 250–500 mcg/kg over 1 minute then 50–300 mcg/kg/min | 1–2 min | 10–20 min |
| Fenoldopam (Corlopam) 10 mg/mL 20 mg/2 mL 50 mg/5 mL | 0.1–0.3 mcg/kg/min | <5 min | 30 min |
| Hydralazine ^g (generic) 20 mg/mL | 10–20 mg IV | 5–20 min | 2–6 hr |
| Labetalol ^h (Normodyne) 20 mg/4 mL 40 mg/8 mL 100 mg/20 mL 200 mg/20 mL | 2 mg/min IV or 20–80 mg Q 10 min up to 300 mg total dose | 2–5 min | 3–6 hr |
| Nicardipine ⁱ (Cardene IV) 25 mg/10 mL | IV loading dose 5 mg/hr increased by 2.5 mg/hr Q 5 min to desired BP or a max of 15 mg/hr Q 15 min, followed by maintenance infusion of 3 mg/hr | 2–10 min (max, 8–12 hr) | 40–60 min after D/C infusion |
| Nitroglycerin ^j (Tridil, Nitro-Bid IV, Nitro-Stat IV) 5 mg/mL 5 mg/10 mL 25 mg/5 mL 50 mg/10 mL 100 mg/20 mL | IV infusion pump 5–100 mcg/min | 2–5 min | 5–10 min after D/C infusion |
| Trimethaphan (Arfonad) 500 mg/10 mL | IV infusion pump 0.5–5 mg/min | 1–5 min | 10 min after D/C infusion |
| Phentolamine (Regitine) | 1–5 mg IV initially, repeat as needed | Immediate | 10–15 min |

^aNitroprusside is the drug of choice for acute hypertensive emergencies. It is supplied as 50 mg of lyophilized powder that is reconstituted with 2–3 mL of 5% dextrose in water (D₅W), yielding a red-brown solution. The contents of the vial are added to 250, 500, or 1,000 mL of D₅W to produce a solution for IV administration at a concentration of 200, 100, or 50 mcg/mL, respectively. The container should be wrapped with metal foil to prevent light-induced decomposition. Under these conditions, the solution is stable for 4 to 24 hr. A rising BP may indicate loss of potency. A change in color to yellow does not indicate effectiveness. The appearance of a dark brown, green, or blue color indicates loss in activity. The drug is more effective if the head of the bed is slightly raised. When changing to a new bag, the administration rate may require adjustment.

^bThiocyanate levels rise gradually in proportion to the dose and duration of administration. The $t_{1/2}$ of thiocyanate is 2.7 days with normal renal function and 9 days in patients with renal failure. Toxicity occurs after 7–14 days in patients with normal renal function and 3–6 days in renal failure patients. Thiocyanate serum levels should be measured after 3–4 days of therapy, and the drug should be discontinued if levels exceed 10–12 mg/dL. Thiocyanate toxicity causes a neurotoxic syndrome of toxic psychosis, hyperreflexia, confusion, weakness, tinnitus, seizures, and coma.

^cSigns of cyanide toxicity include lactic acidosis, hypoxemia, tachycardia, altered consciousness, seizures, and the smell of almonds on the breath. Concurrent administration of sodium thiosulfate or hydroxocobalamin may reduce the risk of cyanide toxicity in high-risk patients.

^dDiazoxide is administered as a bolus dose (13 mg/kg Q 5 min to a max of 150 mg/injection) or as a slow infusion (15–20 mg/min) until a diastolic pressure of 100 mmHg is reached. Significant fluid retention following diazoxide can cause HF and pulmonary edema. Concurrent loop diuretics are recommended (e.g., furosemide 40 mg IV) if diazoxide is given by rapid IV bolus. Reflex in heart rate and stroke volume are potentially dangerous in patients with angina or MI. Concurrent β -blockers may be protective.

^eNot approved by the U.S. Food and Drug Administration for treatment of acute hypertension.

^fApproved for intraoperative and postoperative treatment of hypertension.

^gParenteral hydralazine is an intermediate treatment between oral agents and more aggressive therapies such as nitroprusside or diazoxide. It can be given IV or intramuscularly, but there is no appreciable difference in onset of action (20–40 min) between the two routes. This slow onset minimizes hypotension.

^hLabetalol is contraindicated in acute decompensated HF due to its β -blocking properties. A solution for continuous infusion is prepared by adding two 100-mg ampules to 160 mL of IV fluid to give a final concentration of 1 mg/mL. Infusions start at 2 mg/min and are titrated until a satisfactory response or a cumulative dose of 300 mg is achieved.

ⁱIndicated for short-term treatment of hypertension when the oral route is not feasible or desirable.

^jRequires special delivery system due to drug binding to PVC tubing. Also see Chapters 16 and 17 for further information regarding nitroglycerin.

|---|--|--|
| Nausea, vomiting, diaphoresis, weakness, thiocyanate toxicity, ^b cyanide toxicity (rare) ^c | Arterial and venous vasodilator | Renal failure (thiocyanate accumulation), pregnancy, increased intracranial pressure |
| Hyperglycemia, Na retention, ^d tachycardia, painful extravasation | Arterial vasodilator | Angina pectoris, MI, aortic dissection, pulmonary edema, intracranial hemorrhage |
| Hyperkalemia | ACE inhibitor | Hyperkalemia, renal failure in patients with dehydration or bilateral renal artery stenosis, pregnancy (teratogenic) |
| Nausea, thrombophlebitis, painful extravasation | β -adrenergic blocker | Asthma, bradycardia, decompensated HF, advanced heart block |
| Tachycardia, headache, nausea, flushing | Dopamine-1 agonist | Glaucoma |
| Tachycardia, headache, angina | Arterial vasodilator | Angina pectoris, MI, aortic dissection |
| Abdominal pain, nausea, vomiting, diarrhea | α - and β -adrenergic blocker | Asthma, bradycardia, decompensated HF |
| Headache, flushing, nausea, vomiting, dizziness, tachycardia; local thrombophlebitis change infusion site after 12 hr | Arterial vasodilator (Ca channel blocker) | Angina, decompensated HF, increased intracranial pressure |
| Methemoglobinemia, headache, tachycardia, nausea, vomiting, flushing, tolerance with prolonged use | Arterial and venous vasodilator | Pericardial tamponade, constrictive pericarditis, or increased intracranial pressure |
| Tachyphylaxis, ileus, constipation, urinary retention, pupillary dilation | Ganglionic blocker | Postoperative glaucoma |
| Chest pain, nausea, vomiting, dizziness, headache, nasal congestion, arrhythmia | α -adrenergic blocker | Angina, coronary insufficiency, MI or history of MI, hypersensitivity to mannitol |

In M.M., restarting his medications in a controlled manner so as not to drop his BP too rapidly may also be a reasonable option for treatment. Later, he can be converted to a regimen designed to enhance outpatient compliance by selecting medications with once-daily dosing. For example, lisinopril or another long-acting angiotensin-converting enzyme (ACE) inhibitor would be preferred for outpatient maintenance instead of the captopril previously prescribed. Good patient counseling will help M.M. better understand the severity of his disease and the need to take his medications. Timely follow-up within several days following treatment of hypertensive urgency is of paramount importance for the appropriate management of these patients.

Oral Drug Therapy

Rapidly Acting Calcium Channel Blockers

2. M.M.'s physician has ordered nifedipine to be given 10 mg sublingually. Is this appropriate therapy to acutely lower his BP?

Clonidine, labetalol, prazosin, minoxidil, and captopril have all been used to lower BP acutely. These oral agents take several hours to adequately lower pressure and are therefore useful in treating hypertensive urgencies but not emergencies. Oral ACE inhibitors, other than captopril, are not useful for acutely lowering BP because their onset of action is too slow. The immediate-release calcium channel blockers, including diltiazem, verapamil, and nicardipine, can rapidly lower BP; however, the most extensive experience is with nifedipine. Nifedipine, when given orally or by the “bite and swallow” method, was previously recommended as a rapid-acting alternative to parenteral therapy in the acute management of hypertension. However, its use has been associated with life-threatening adverse events due to ischemia, MI, and stroke.^{26–30} The prompt absorption of rapidly acting calcium channel blockers is followed by a sudden and precipitous decrease in BP as a result of peripheral vasodilation. This reduces coronary perfusion, induces a reflex tachycardia, and increases myocardial oxygen consumption.^{28,36} Decreased cerebral blood flow with sublingual nifedipine has also been reported.³⁷ Elderly patients with underlying coronary or

Table 20-3 Oral Drugs Commonly Used in the Treatment of Hypertensive Urgencies

| <i>Drug (Brand Name)</i> | <i>Dose/Route</i> | <i>Onset of Action</i> | <i>Duration of Action</i> | <i>Major Side Effects^a</i> | <i>Mechanism of Action</i> | <i>Avoid or Use Cautiously in Patients With These Conditions</i> |
|---|---|--|---------------------------|--|---|---|
| Captopril ^b (Capoten) 12.5-, 25-, 50-, 100-mg tablets | 6.5–50 mg PO | 15 min | 4–6 hr | Hyperkalemia, angioedema, BUN if dehydrated, rash, pruritus, proteinuria, loss of taste | ACE inhibitor | Renal artery stenosis, hyperkalemia, dehydration, renal failure, pregnancy |
| Clonidine (Catapres) 0.1-, 0.2-, 0.3-mg tablets | 0.1–0.2 mg PO initially, then 0.1 mg/hr up to 0.8 mg total | 0.5–2 hr | 6–8 hr | Sedation, dry mouth, constipation | Central α -2-agonist | Altered mental status, severe carotid artery stenosis |
| Labetalol (Normodyne, Trandate) 100-, 200-, 300-mg tablets | 200–400 mg PO repeated Q 2–3 hr | 30 min–2 hr | 4 hr | Orthostatic hypotension, nausea, vomiting | α - and β - adrenergic blocker | Heart failure, asthma, bradycardia |
| Minoxidil (Loniten) 2.5-, 10-mg tablets | 5–20 mg PO | 30–60 min; maximum response in 2–4 hr | 12–16 hr | Tachycardia, fluid retention | Arterial and venous vasodilator | Angina, heart failure |

^aAll may cause hypotension, dizziness, and flushing.
^bOther oral ACE inhibitors too slow in onset to be useful but can be used for maintenance.
ACE, angiotensin-converting enzyme; \uparrow BUN, blood urea nitrogen; PO, orally.

cerebrovascular disease, volume depletion, or concurrent use of other antihypertensive drugs are at increased risk for significant adverse events. In addition, no outcome data are currently available to critically assess the efficacy of this therapeutic intervention. Therefore, until more data become available, administration of immediate-release nifedipine capsules or other rapidly acting calcium channel blockers sublingually, by the

“bite and chew” method, or by swallowing intact is not recommended.

The cavalier use of rapid-release nifedipine to acutely lower BP is potentially dangerous and should be discouraged in M.M. His age, history of MI, absence of symptoms, and lack of new or progressive target organ damage do not warrant the acute and potentially dangerous drop in BP. M.M.’s BP can be managed

Table 20-4 Treatment Recommendations for Hypertensive Crises

| <i>Clinical Presentation</i> | <i>Recommendation</i> | <i>Rationale</i> |
|--|---|--|
| Aortic dissection | Nitroprusside, nicardipine, or fenoldopam plus esmolol or IV metoprolol; labetalol; trimethaphan. Avoid inotropic therapy. | Vasodilator will decrease pulsatile stress in aortic vessel to prevent further dissection expansion. β -blockers will prevent vasodilator-induced reflex tachycardia. |
| Angina, myocardial infarction | Nitroglycerin plus esmolol or metoprolol; labetalol. Avoid nitroprusside. | Coronary vasodilation, decreased cardiac output, myocardial workload, and oxygen demand. Nitroprusside may cause coronary steal. |
| Acute pulmonary edema, left ventricular failure | Nitroprusside, nicardipine, or fenoldopam plus nitroglycerin and a loop diuretic. Alternative: enalaprilat. Avoid nondihydropyridines, β -blockers. | Promotion of diuresis with venous dilatation to decrease preload. Nitroprusside, enalaprilat decrease afterload. Nicardipine may increase stroke volume. |
| Acute renal failure | Nicardipine or fenoldopam. Avoid nitroprusside, enalaprilat. | Peripheral vasodilation without renal clearance. Fenoldopam shown to increase renal blood flow. |
| Cocaine overdose | Nicardipine, fenoldopam, verapamil, or nitroglycerin. Alternative: labetalol. Avoid β -selective blockers. | Vasodilation effects without potential unopposed α -adrenergic receptor stimulation. CCBs control overdose-induced vasospasm. |
| Pheochromocytoma | Nicardipine, fenoldopam, or verapamil. Alternatives: phentolamine, labetalol. Avoid β -selective blockers. | Vasodilation effects without potential unopposed α -adrenergic receptor stimulation. |
| Hypertensive encephalopathy, intracranial hemorrhage, subarachnoid hemorrhage, thrombotic stroke | Nicardipine, fenoldopam, or labetalol. Avoid nitroprusside, nitroglycerin, enalaprilat, hydralazine. | Vasodilation effects without compromised CBF induced by nitroprusside and nitroglycerin. Enalaprilat and hydralazine may lead to unpredictable BP changes when carefully controlled BP management is required. |

BP, blood pressure; CBF, cerebral blood flow; CCB, calcium channel blocker; IV, intravenous.

safely using other oral medications. Captopril, labetalol, or clonidine can be used to lower his BP, and he can be restarted on his oral maintenance regimen with appropriate follow-up care.

Clonidine

3. A decision is made not to use nifedipine, but rather to give M.M. oral clonidine. What is an appropriate starting dose? What is the correlation between the loading dose and the maintenance dose?

Clonidine is considered a safe, effective first-line therapy for hypertensive urgency. It is a centrally acting, α_2 -adrenergic agonist that inhibits sympathetic outflow from the CNS. After acute administration, clonidine reduces mean arterial pressure, cardiac output, stroke volume, and cardiac rate. There is little change in the total peripheral resistance or renal plasma flow. The initial reduction in cardiac output is caused by decreased venous return to the right side of the heart secondary to venodilation and bradycardia, not secondary to decreased contractility. Guanabenz (Wyntensin) has a similar mechanism of action, but documented efficacy in the acute treatment of hypertension is lacking.

BP can be lowered gradually over several hours using oral clonidine. Traditional dosing regimens have included an initial oral loading dose (0.1–0.2 mg) followed by repeated doses of 0.1 mg/hour until the desired response is achieved or until a cumulative dose of 0.5 to 0.8 mg is reached.³⁸ A significant reduction in BP is first seen within 1 hour, and the mean arterial pressure decreases by 25% in most patients after several hours. Anderson et al. reported a 94% response rate to an oral loading dose.³⁸ Patients required a mean total dose of 0.45 mg, and the maximum response occurred 5 to 6 hours after the start of therapy. Some authors, however, have cautioned against the use of sequential loading doses, citing lack of benefit over placebo and the potential for unpredictable adverse effects, particularly abrupt occurrences of hypotension.³⁹ If loading doses are to be used, it is especially important to reduce doses in patients with volume depletion, those who have recently used other antihypertensive drugs, and the elderly.^{1,23,40}

The acute response to oral clonidine loading is not predictive of the daily dose required to maintain acceptable BP control. Maintenance oral therapy with clonidine is somewhat empiric; however, total daily doses should be spread between twice and three times daily dosing due to the drug's short half-life. The major portion of the total daily dose can be given at bedtime to minimize daytime sedation.

ADVERSE EFFECTS AND PRECAUTIONS

4. What precautions should be exercised when using the oral clonidine loading regimen?

Oral clonidine is generally well tolerated. Adverse effects include orthostatic hypotension, bradycardia, sedation, dry mouth, and dizziness. Sedation is a particularly troublesome side effect, and because of this, clonidine should not be used in patients in whom mental status is an important monitoring parameter. Because clonidine can decrease cerebral blood flow by up to 28%, it should not be used in patients with severe cerebrovascular disease.^{22,41} Clonidine also should be avoided in patients with HF, bradycardia, sick sinus syndrome, or cardiac

conduction defects,²³ as well as patients at risk for medication nonadherence because of the rapid rise in BP that can occur with sudden drug withdrawal.^{42,43}

Other Oral Drugs

CAPTOPRIL

5. M.M. has a history of heart failure and normal renal function on admission. Based on these findings, would captopril be a reasonable choice for initial treatment? How should it be given? What if his BUN or SrCr were elevated?

Captopril, an orally active ACE inhibitor, has been used both orally and sublingually to acutely lower BP.^{44,45} Captopril decreases both afterload and preload, increases regional blood flow, and lowers total peripheral vascular resistance.²³ For this reason, captopril and other ACE inhibitors are often considered the drugs of choice in patients with heart failure. (See Chapter 18 for a discussion of the use of ACE inhibitors in heart failure.) Given that M.M. appeared to be well controlled on his ACE inhibitor prior to arbitrarily stopping his medications, it is reasonable to restart an ACE inhibitor and reinforce medication adherence issues.

After oral administration, the onset of action of captopril occurs within minutes and peaks 30 to 90 minutes after ingestion. Sublingual captopril (25 mg) significantly reduces angiotensin II levels within 24 hours.⁴⁶ Sublingual captopril also has been recently reported to increase cerebral blood flow to a greater extent in patients with BP >180/120 mmHg compared to nifedipine.³⁷ Clinically, it reduces BP within 10 to 15 minutes, with effects persisting for 2 to 6 hours. Sublingual captopril is as effective as nifedipine in acutely reducing mean arterial pressure in both urgent and emergent conditions.^{45,47,48}

Despite these beneficial effects, captopril, as well as all other ACE inhibitors, must be used with caution in patients with renal insufficiency or volume depletion. In most cases, an elevated BUN or SrCr will provide a clue to the existence of these conditions; however, captopril can also induce severe renal failure in patients with bilateral renal artery stenosis or renal artery stenosis in a solitary kidney. Such conditions may not be easy to detect in the context of an acute hypertensive emergency. Therefore, in patients in whom these conditions can be excluded, captopril can be considered for therapy. First-dose hypotension is a common limiting factor with captopril use. This complication is most likely to occur in patients with high renin levels, such as those who are volume depleted or those receiving diuretics. Under these circumstances, initial doses should not exceed 12.5 mg, with repeat doses an hour or more later if necessary. Although he was not taking his diuretic, M.M. is still likely to have high renin levels due to his history of HF. Therefore, captopril would be a reasonable choice as initial therapy in M.M., which can later be replaced by a longer-acting ACE inhibitor.

MINOXIDIL, PRAZOSIN, AND LABETALOL

6. What other oral agents are used to acutely lower BP?

Minoxidil, a potent oral vasodilator, has been used successfully in the treatment of severe hypertension.^{49,50} An oral loading dose of 10 to 20 mg produces a maximal BP response in 2 to 4 hours and can be followed by a dose of 5 to 20 mg every 4 hours if necessary. Unfortunately, its onset of action is

slower than that of clonidine or captopril. Another complicating factor is that β -blockers and loop diuretics generally must be used concomitantly to counteract minoxidil-induced reflex tachycardia and fluid retention.⁵⁰ Therefore, minoxidil should be used only in patients who are refractory to other forms of therapy or who have previously been taking this agent.

Prazosin has been used to a limited degree to treat hypertensive urgencies. An oral loading dose of 5 mg maximally reduced BP within 60 to 120 minutes.⁵¹ However, hypotension can be a significant limiting factor. More controlled studies are required before this drug can be recommended.

Oral labetalol, a combined α - and β -receptor antagonist, is an alternative to oral clonidine or captopril for the treatment of severe hypertension, but the most appropriate dosing regimen remains to be determined.^{52–55} Initial doses of 100 to 300 mg may provide a sustained response for up to 4 hours.⁵³ Labetalol (200 mg given at hourly intervals to a maximum dose of 1,200 mg) was comparable to oral clonidine in reducing mean arterial pressure.⁵⁵ An alternative regimen using 300 mg initially followed by 100 mg at 2-hour intervals to a maximum of 500 mg was also successful in acutely lowering BP.⁵⁴ However, Wright et al.⁵⁶ were unable to achieve an adequate BP response in a small series of patients using a single loading dose of 200 to 400 mg. Because labetalol can cause profound orthostatic hypotension, patients should remain in the supine position and should be checked for orthostasis before ambulation. In addition, labetalol should be avoided in patients with asthma, bradycardia, or advanced heart block.

Following initial treatment with oral captopril, M.M.'s BP was reduced to 150/100 mmHg. His oral medications were then restarted, captopril was switched to lisinopril, and he was scheduled for follow-up in 1 week.

HYPERTENSIVE EMERGENCIES

Patient Assessment

7. M.R., a 55-year-old African American male, presents to the emergency department (ED) with a 3-day history of progressively increasing shortness of breath (SOB). Over the past 2 days, he developed a severe headache unrelieved by ibuprofen (Advil), as well as substernal chest pain, anorexia, and nausea. His medical history includes asthma and a 5-year history of angina, which resulted in hospitalization for an acute inferior MI 2 months before admission. He has been taking albuterol via metered-dose inhaler (MDI; Proventil, Ventolin), furosemide (Lasix), isosorbide dinitrate (Isordil Titradose, Sorbitrate), felodipine (Plendil), and lisinopril (Prinivil, Zestril), but discontinued these medications on his own 3 weeks ago.

Physical examination reveals an anxious-appearing man who is alert, oriented, and in moderate respiratory distress. His vital signs include a pulse of 125 beats/minute, respiratory rate of 36 breaths/minute, BP of 220/145 mmHg without orthostasis, and a normal body temperature. Funduscopic examination shows arteriolar narrowing and AV nicking without hemorrhages, exudates, or papilledema. There is no jugular venous distention, but bilateral carotid bruits are present. Chest examination reveals decreased breath sounds with bilateral rales extending to the tip of the scapula. M.R.'s heart is displaced 2 cm left of the midclavicular line with no thrills or heaves. The rhythm is regular with

an S₃ and an S₄ gallop; no murmurs are noted. The remainder of M.R.'s examination is within normal limits.

Significant laboratory values include sodium (Na), 142 mEq/L (normal 136–144); potassium (K), 4.9 mEq/L (normal 3.5–5.5); chloride (Cl), 101 mEq/L (normal 96–106); bicarbonate, 23 mEq/L (normal 23–28); BUN, 30 mg/dL (normal 10–20); creatinine, 1.2 mg/dL (normal 0.5–1.2); hematocrit (Hct), 38% (normal 40%–45%); hemoglobin (Hgb), 13 g/dL (normal 14–18); and white blood cell (WBC) count and differential, within normal limits. UA shows 1+ hemoglobin and 1+ protein. Microscopic examination of the urine reveals 5 to 10 red blood cells (RBCs) per high-power field (HPF) and no casts. Pulse oximetry reveals an oxygen saturation of 88%. An ECG demonstrates sinus tachycardia and left ventricular hypertrophy. The chest radiograph shows moderate cardiomegaly and bilateral fluffy infiltrates.

What aspects of M.R.'s history and physical examination are characteristic of an emergent need to immediately lower his BP?

[SI units: Na, 142 mmol/L (normal 136–144); K, 4.9 mmol/L (normal 3.5–5.5); Cl, 101 mmol/L (normal 96–106); bicarbonate, 23 mmol/L (normal 23–28); BUN, 10.71 mmol/L urea (normal 3.57–7.14); creatinine, 106 mmol/L (normal 44.2–106.08); Hct, 0.38 (normal 0.40–0.45); Hgb, 130 g/L (normal 140–180)]

As discussed previously, hypertensive crisis occurs most often in African American men and individuals between the ages of 40 and 60. M.R. meets all characteristics of this population. Furthermore, many patients who present with hypertensive emergencies have a recent history of discontinuing the use of their antihypertensives,^{9,12} as is the case with M.R. and M.M. in case 1.

Recent-onset severe headache, nausea, and vomiting are consistent with CNS signs of severe hypertension, as are the acute onset of angina (substernal pain) and HF (SOB, increased pulse and respiratory rate, cardiomegaly, S₃, and chest x-ray findings of pulmonary edema). The absence of signs of right-sided HF such as jugular venous distention or hepatomegaly suggests an acute onset of HF caused by hypertension as opposed to a gradual worsening of chronic HF. M.R.'s urinary sediment is relatively unimpressive at this time, especially in light of his history, and his ocular complications are minimal.

Parenteral Drug Therapy

Nitroprusside

8. M.R. is to be started on nitroprusside. Is this an appropriate choice of drug? What alternatives to nitroprusside are available?

M.R.'s arterial pressure should be lowered with parenteral medications, which have a rapid onset of action. Nitroprusside, fenoldopam, intravenous (IV) nitroglycerin, and trimethaphan all decrease total peripheral resistance rapidly with minimal effect on myocardial oxygen consumption and heart rate. Of these agents, either nitroprusside or fenoldopam would be preferred in patients with hypertension accompanied by acute left ventricular failure in the absence of MI. Parenteral nitroglycerin is similar to nitroprusside except that it has relatively greater effect on venous circulation and less effect on arterioles. It is most useful in patients with coronary insufficiency, ischemic heart disease, MI, or hypertension following coronary bypass surgery (also see question 24). In addition, nitroprusside and IV nitroglycerin may both improve elevated

left ventricular diastolic pressures in patients presenting with hypertensive urgency. Trimethaphan is not an acceptable choice because rapid tolerance develops to its hypotensive action and its use is associated with many side effects (see Question 29). Fenoldopam and nitroprusside are equally efficacious in acutely lowering BP.^{57–60} Both drugs have an immediate onset, are easily titratable, have a short duration of action, and are relatively well tolerated. Fenoldopam may also increase renal blood flow, thereby reducing the risk for worsening renal function.^{61–64} Unlike nitroprusside, fenoldopam does not cause cyanide or thiocyanate toxicity, but it is considerably more expensive than nitroprusside.

Therefore, in the absence of any significant renal or liver disease, nitroprusside is the preferred treatment for M.R.

HEMODYNAMIC EFFECTS

Nitroprusside has many pharmacologic effects that should improve M.R.'s condition. It dilates both venous and arterial vessels, thereby increasing venous capacitance and decreasing the venous return or preload on the heart (see Chapters 18 and 21). A decrease in the pulmonary capillary wedge pressure and ventricular filling pressure will ultimately improve M.R.'s pulmonary edema. Afterload is also decreased as a result of arterial dilation. This action increases cardiac output, reduces arterial pressure, and increases tissue perfusion.

CONCURRENT USE OF DIURETICS

9. Should M.R. be given a diuretic before nitroprusside therapy is begun?

Administration of potent IV diuretics is relatively ineffective in the acute treatment of hypertension except in patients with concomitant volume overload or HF. Many patients with hypertensive emergencies are vasoconstricted and have normal or reduced plasma volumes; therefore, diuretics have little effect and may actually aggravate renal failure or cause other adverse effects.^{19,65} Furthermore, when diuretics are given acutely in combination with other antihypertensive agents, profound hypotension can occur.

The immediate value of diuretics in acute HF is related more to their hemodynamic effects (venodilation) than to diuresis. Venodilation following IV diuretic administration decreases right-sided cardiac filling pressures, decreases pulmonary artery and wedge pressures, and increases cardiac output before diuresis occurs.⁶⁶ The presence of HF and severely elevated BP in M.R. warrants the IV administration of either furosemide 20 to 40 mg or bumetanide (Bumex) 1 mg.

DOSING AND ADMINISTRATION

10. How should nitroprusside be prepared and administered? What dose should be used initially?

Because of its extreme potency, sodium nitroprusside must be prepared in exact concentrations and administered at precisely calculated rates using a controlled infusion device, and BP must be closely monitored. Sodium nitroprusside is supplied in units of 50 mg of lyophilized powder. The powder is reconstituted with 2 to 3 mL of 5% dextrose in water (D₅W), shaking gently to dissolve.⁶⁷ The contents of the vial are then added to 250, 500, or 1,000 mL of D₅W to produce a solution for IV administration with a drug concentration containing

200, 100, or 50 mcg/mL. This solution should have a slight brownish tint.

Nitroprusside decomposes on exposure to light, so the solution should be shielded with an opaque sleeve. It is not necessary to protect the tubing from light. Reconstituted solutions are stable for 24 hours at room temperature. A change in the solution's color from light brown to dark brown, green, orange, or blue indicates a loss in activity, and the solution should be discarded.

Effective infusion rates range from 0.25 to 10 mcg/kg/minute. Cyanide toxicity may occur with prolonged administration or with infusion rates >2 to 3 mcg/kg/minute.^{68,69} For M.R., an infusion of nitroprusside should be initiated at a rate of 0.25 mcg/kg/minute, using a microdrip regulator or an infusion pump. The dose should be increased slowly by 0.25 mcg/kg/minute every 5 minutes until the desired pressure is achieved. A maximum infusion rate of 10 mcg/kg/minute has been recommended. If adequate BP reduction is not achieved within 10 minutes following maximum dose infusion, nitroprusside should be discontinued.³ The dosage must be individualized according to patient response using continuous intra-arterial BP recording and observing for signs or symptoms of toxicity.

THERAPEUTIC END POINT

11. A nitroprusside infusion of 0.25 mcg/kg/minute is started. What is the goal of therapy?

M.R.'s arterial pressure should be reduced to near-normal levels; however, because he has cerebral occlusive disease (carotid bruits), excessive reduction of his BP should be avoided. Overly aggressive reduction of BP in the presence of major cerebral vessel stenosis may decrease cerebral blood flow and produce strokes or other neurologic complications.

Normal cerebral blood flow remains relatively constant over a wide range of systemic BP measurements through autoregulatory mechanisms.^{41,70} The autoregulatory effects can prevent gross alterations in cerebral blood flow from either slow or rapid changes in systemic arterial pressures. In addition, the BP required to maintain cerebral perfusion is higher in hypertensive patients than in normotensive individuals. If M.R.'s BP is reduced excessively, cerebral blood flow may decrease sharply. Therefore, a diastolic BP of 100 to 105 mmHg would be a reasonable initial therapeutic goal for him. If hypotension occurs, nitroprusside should be discontinued and M.R. should be placed in the Trendelenburg position, where the head is kept lower than the trunk.

CYANIDE TOXICITY

12. M.R. is being treated with nitroprusside. However, over the last 36 hours, dose titration to 7 mcg/kg/minute has been necessary to control his BP. Is he at risk for developing cyanide toxicity? What indices of toxicity should be monitored? Should thiosulfate or hydroxocobalamin be given to prevent toxicity?

A major concern when using sodium nitroprusside is toxicity secondary to the accumulation of its metabolic byproducts, cyanide and thiocyanate. Sodium nitroprusside decomposes within a few minutes after IV infusion. Free cyanide, which represents 44% of nitroprusside by weight, is released into the bloodstream, producing prussic acid (hydrogen cyanide),

which is responsible for the acute toxicity.⁷¹ The amount of hydrogen cyanide released is directly proportional to the size of the dose.⁷² Endogenous detoxification of cyanide occurs through a mitochondrial rhodanese system, which, in the presence of a sulfur donor such as thiosulfate, converts cyanide to thiocyanate.⁷¹ This enzymatic detoxification of cyanide exhibits zero-order pharmacokinetics and is dependent on the enzyme rhodanese and an adequate supply of thiosulfate. A healthy person can eliminate cyanide hepatically at a rate equivalent to the cyanide production during a nitroprusside infusion of up to approximately 2 mcg/kg/minute.⁷³ Theoretically, cyanide can be expected to accumulate in the body when the rate of the sodium nitroprusside infusion exceeds 2 mcg/kg/minute for a prolonged period. This rise can be prevented by administering sodium thiosulfate simultaneously.^{74,75} A mixture of 0.1% sodium nitroprusside plus 1% sodium thiosulfate is as effective as sodium nitroprusside alone and is substantially less toxic.⁷⁴ For this reason, some clinicians have recommended that all patients receiving nitroprusside receive concomitant thiosulfate infusions.^{76,77} IV boluses of thiosulfate may be effective, but they require frequent dosing. Rindone and Sloane⁷² noted that 10 mg of sodium thiosulfate for every 1 mg of nitroprusside should be considered in high-risk patients (e.g., those with malnutrition) or when large doses of nitroprusside are administered (>3 mcg/kg/minute). The presence of hepatic or renal failure may also predispose the patient to cyanide toxicity.^{73,78} However, no studies have assessed the chemical compatibility of nitroprusside and sodium thiosulfate.

It is generally stated that symptomatic cyanide toxicity occurs infrequently, although several deaths have been reported after the use of sodium nitroprusside.⁷⁷ Cyanide toxicity occurs most commonly when large doses (total dose 1.5 mg/kg) of nitroprusside are administered rapidly to patients undergoing a surgical procedure that requires induction of hypotension. However, cyanide toxicity and mortality associated with nitroprusside exceed 3,000 and 1,000 cases per year, respectively, according to two sources.^{77,79} The increasing concern about cyanide toxicity has resulted in a revision of the product label, which warns that sodium nitroprusside administration increases the body's concentration of cyanide ion to toxic and potentially fatal levels, even when given within the range of recommended doses. The revised labeling further states that infusions at the maximum recommended dose can overwhelm the body's ability to buffer the cyanide within 1 hour.

Although concurrent sodium thiosulfate administration has been recommended in high-risk patients, no clinical data are available to indicate that it reduces overall mortality. Furthermore, this intervention may result in the accumulation of thiocyanate, particularly if sodium thiosulfate is given at high infusion rates or to patients with renal insufficiency. A 1-year retrospective review at a tertiary care teaching hospital with a level 1 trauma center found that none of the patients receiving nitroprusside at infusion rates >2 mcg/kg/minute were concurrently treated with sodium thiosulfate.⁸⁰

Hydroxocobalamin has also been used to reduce cyanide toxicity secondary to nitroprusside infusions.⁷⁸ The concurrent administration of a continuous infusion of hydroxocobalamin (25 mg/hour) lowers RBC and plasma cyanide concentrations.⁸¹ Hydroxocobalamin combines with cyanide to form cyanocobalamin, which is nontoxic and excreted in the urine. Approximately 2.4 g of hydroxocobalamin is required to neutralize the cyanide released from 100 mg of

nitroprusside. Therefore, its use is limited due to poor availability and cost considerations. Importantly, unlike hydroxocobalamin, cyanocobalamin is not effective in reducing or preventing cyanide toxicity.

To summarize, the use of hydroxocobalamin or sodium thiosulfate is likely to be of greatest value in patients receiving large doses of sodium nitroprusside acutely or in patients receiving high infusion rates for an extended period. However, with the availability of safer alternatives (e.g., fenoldopam, IV labetalol, IV nicardipine) for use in high-risk patients, the use of hydroxocobalamin or thiosulfate is rarely required.

Cyanide toxicity can be detected early by monitoring M.R.'s metabolic status. Lactic acidosis is an early indicator of toxicity because the progressive inactivation of cytochrome oxidase by cyanide results in increased anaerobic glycolysis.⁸¹ A low plasma bicarbonate concentration and low pH, accompanied by an increase in the blood lactate or lactate-to-pyruvate ratio, and an increase in the mixed venous blood oxygen tension could indicate cyanide toxicity.⁸² Additional signs of cyanide intoxication include tachycardia, altered consciousness, coma, convulsions, and the occasional smell of almonds on the breath.^{72,82} Hypoxemia resulting from pulmonary arterial shunting has also been reported during nitroprusside therapy. Measuring serum thiocyanate levels is of no value in detecting the onset of cyanide toxicity. If toxicity develops, the infusion should be stopped and appropriate therapy for cyanide intoxication instituted. The need for such a high-dose infusion of nitroprusside to maintain M.R.'s pressure may increase his risk for cyanide toxicity, warranting close monitoring of his acid-base balance.

THIOCYANATE TOXICITY

13. Explain the difference between cyanide toxicity and thiocyanate toxicity. What is M.R.'s risk for thiocyanate toxicity if he is continued on a dose of 7 mcg/kg/minute? Is monitoring of serum thiocyanate concentrations necessary?

Sodium nitroprusside is more likely to produce thiocyanate toxicity. Although this complication is also rare, patients with renal failure who receive prolonged infusions are particularly susceptible. The cyanide released from nitroprusside is normally metabolized by thiosulfate in the liver to thiocyanate via sulfation. This conversion of cyanide to thiocyanate proceeds relatively slowly, and thiocyanate levels rise gradually in proportion to the dose and duration of sodium nitroprusside administration. The half-life of thiocyanate is 2.7 days with normal renal function and 9 days in patients with renal failure.⁷⁶ When sodium nitroprusside is infused for several days at moderate dosages (2–5 mcg/kg/minute), toxic levels of thiocyanate can occur within 7 to 14 days in patients with normal renal function and 3 to 6 days in patients with severe renal disease.⁷¹ A total daily dose of up to 125 mg is nontoxic in patients with normal renal function, whereas 1,000 mg/day may produce toxicity within 24 to 48 hours. Unfortunately, infusion of sodium thiosulfate, which helps reduce cyanide toxicity, can cause accumulation of thiocyanate, resulting in clinical toxicity, especially in patients with renal failure.⁷⁸

Thiocyanate causes a neurotoxic syndrome manifested by psychosis, hyperreflexia, confusion, weakness, tinnitus, seizures, and coma.^{73,76} Prolonged exposure to thiocyanate can suppress thyroid function through inhibition of iodine uptake and binding by the thyroid.⁷⁶ Routine measurement of blood

levels of thiocyanate is unnecessary and is recommended only in patients with renal disease or when the duration of the nitroprusside infusion exceeds 3 or 4 days. Nitroprusside should be discontinued if serum thiocyanate levels exceed 10 to 12 mg/dL.^{83,84} Life-threatening toxicity is of concern when blood thiocyanate levels exceed 20 mg/dL. In emergency cases, thiocyanate can be readily removed by hemodialysis.⁷⁶

For M.R., the potential for thiocyanate toxicity is low because his renal function is normal and the anticipated infusion duration is relatively short. Therefore, measurement of thiocyanate levels is not indicated at this time.

Other side effects associated with nitroprusside therapy include nausea, vomiting, diaphoresis, nasal stuffiness, muscular twitching, dizziness, and weakness. These effects are usually acute and occur when nitroprusside is administered too rapidly. They can be reversed by decreasing the infusion rate.

14. M.R.'s serum chemistries and arterial blood gas values indicate a metabolic acidosis. Should the nitroprusside infusion be continued at 7 mcg/kg/minute? What alternative is available?

Although the duration of M.R.'s nitroprusside therapy has been short, tolerance to the antihypertensive effect requires the use of a high-dose infusion to maintain BP control. Thus, acidosis may represent toxicity as a result of cyanide accumulation. The nitroprusside infusion should be discontinued at this time, and another rapidly acting, easily titratable parenteral antihypertensive such as fenoldopam or IV nicardipine should be initiated.

Fenoldopam

15. What are the advantages and disadvantages of fenoldopam compared with sodium nitroprusside?

HEMODYNAMIC EFFECTS

Fenoldopam is a parenteral, rapidly acting, peripheral dopamine-1 agonist used to manage severe hypertension when a rapid reduction of BP is required.⁸⁵⁻⁸⁸ Stimulation of the dopamine-1 receptors vasodilates coronary, renal, mesenteric, and peripheral arteries.⁸⁹ Vasodilation of the renal vasculature increases renal blood flow in hypertensive patients,^{61,62,64} a property that may be particularly advantageous in patients with impaired renal function.^{63,90} However, no outcome data are available to document that this effect reduces morbidity and mortality in patients with severe hypertension. Fenoldopam has also been used to control perioperative hypertension in patients undergoing cardiac bypass surgery because, relative to nitroprusside, it either maintains or increases urinary output.^{91,92} Fenoldopam is as effective as sodium nitroprusside for the acute treatment of hypertension and does not cause either cyanide or thiocyanate toxicity.⁵⁸⁻⁶⁰ Fenoldopam is as efficacious as, but considerably more expensive than, sodium nitroprusside.⁵⁷ Outcome studies will be required to assess the impact of fenoldopam on increasing renal blood flow and urine output in the management of patients with hypertensive emergencies. Until such time, it should be used only as an alternative to nitroprusside in patients such as M.R., who are at high risk for cyanide or thiocyanate toxicity.

DOSING AND ADMINISTRATION

16. How should fenoldopam be administered?

Fenoldopam is administered as a continuous infusion (without a bolus dose) beginning at a rate of 0.1 mcg/kg/minute. It is then titrated upward, according to BP control, in increments of 0.05 to 0.1 mcg/kg/minute at 15-minute intervals. The maximum dose is 1.6 mcg/kg/minute, and its use has been studied for up to 48 hours of therapy. Clearance of fenoldopam is not altered by renal or liver disease. Like nitroprusside, fenoldopam also has a short duration of action, with an elimination half-life of approximately 5 minutes, thus allowing for easy titration. Once the target blood pressure is achieved, fenoldopam can be gradually tapered as oral therapy is initiated, if rebound hypertension has not occurred.^{87,93}

ADVERSE EFFECTS

17. M.R. is converted to a continuous infusion of fenoldopam, and his BP is well controlled on 0.3 mcg/kg/minute. What monitoring parameters should be followed?

Fenoldopam is well tolerated and relatively free of side effects. BP and heart rate should be followed closely to avoid hypotension and dose-related tachycardia. The vasodilating effect may also cause flushing, dizziness, and headache. Serum electrolytes should be monitored, and in some cases, potassium supplementation is required. Fenoldopam should be used cautiously in patients with glaucoma or intraocular hypertension due to a dose-dependent increase in intraocular pressure.^{94,95}

18. Which antihypertensive agents should be avoided in M.R.? Why?

Labetalol, a potent, rapidly acting antihypertensive with both α - and β -blocking activity, is very effective in the treatment of various hypertensive emergencies,⁹⁶⁻¹⁰² but it should not be used in M.R. (see Question 19). Hemodynamically, labetalol reduces peripheral vascular resistance (afterload), BP, and heart rate, with almost no change in the resting cardiac output or stroke volume.¹⁰³

M.R. is experiencing chest pain, and he is tachycardic; these signs and symptoms are most likely caused by his severely uncontrolled hypertension and the presence of acute left ventricular failure. Even though labetalol might improve M.R.'s angina, the negative inotropic action could acutely compromise his left ventricular dysfunction, an effect that outweighs the potential benefit of afterload reduction. In addition, even though labetalol is one of the safest β -blocking drugs when used in patients with asthma,¹⁰⁴ no β -blocker should be used as initial treatment in patients with asthma. Labetalol should be used only if alternative methods of reducing M.R.'s pressure fail.

Diazoxide, a potent, rapidly acting hypotensive agent closely related to the thiazide group of drugs, should also be avoided in M.R. for several reasons (see Question 25). The hypotensive action is caused by a reduction in peripheral vascular resistance through direct relaxation of arterioles. As arterial pressure is lowered, baroreceptor reflexes are activated, leading to cardiac stimulation with increased heart rate, stroke volume, and cardiac output. The cardiostimulating effect of diazoxide could be potentially dangerous in patients such as M.R., who have ischemic heart disease and a recent history of MI.¹⁰⁵ Neurologic and cardiovascular symptoms may occur with rapid administration of diazoxide.

There are other reasons why diazoxide should be avoided or used cautiously in M.R. Although diazoxide has a thiazide-like structure, it causes significant sodium and water retention, which could be deleterious in a patient such as M.R. with severe HF and pulmonary edema.^{106,107} The exact mechanism for this effect is unknown, but it may be through an activation of the renin system or a direct antinatriuretic effect on the renal tubules.

Labetalol

19. C.M., a 52-year-old Caucasian male, is admitted to the hospital with a 3-day history of increasing exertional substernal chest pain (without SOB), diaphoresis, nausea, and vomiting. His history is significant for poorly controlled hypertension, glaucoma, and angina pectoris. Prior medications include dorzolamide ophthalmic drops (Trusopt), atenolol (Tenormin), hydrochlorothiazide, and oral nitrates. Physical examination reveals an anxious man who is alert and oriented. He has a BP of 210/146 mmHg without orthostasis and a regular pulse of 115 beats/minute. Bilateral hemorrhages and exudates are present on funduscopic examination. The lungs are clear and the heart is enlarged, but there are no murmurs or gallops. Examination of the abdomen is unremarkable, and there is no peripheral edema. The neurologic examination is normal.

Significant laboratory values include the following: Na, 140 mEq/L (normal 136–144); Cl, 109 mEq/L (normal 96–106); bicarbonate, 18 mEq/L (normal 23–28); BUN, 49 mg/dL (normal 10–20); and creatinine, 2.8 mg/dL (renal function previously noted to be within normal limits). UA shows proteinuria and hematuria. The ECG demonstrates sinus tachycardia with left axis deviation, left ventricular hypertrophy, and nonspecific ST-T wave changes. The chest radiograph reveals mild cardiomegaly.

C.M. is given nitroglycerin sublingually (Nitrostat), and 1 inch of nitroglycerin ointment (Nitrol Paste) is applied topically. He is started on IV labetalol. Is this choice of treatment reasonable, considering C.M.'s angina and acute renal failure?

[SI units: Na, 140 mmol/L (normal 136–144); Cl, 109 mmol/L (normal 96–106); bicarbonate, 18 mmol/L (normal 23–28); BUN, 17.493 mmol/L urea (normal 3.57–7.14); creatinine, 247.52 mmol/L (normal 44.2–106.08)]

The presence of chest pain, retinopathy, and new onset renal disease, as well as the magnitude of the BP elevation in C.M., warrant a prompt reduction in BP. The combination of sublingual and topical nitroglycerin may help in acutely lowering his BP and relieving his chest pain while waiting for more definitive treatment to be implemented.

IV labetalol is a potent antihypertensive drug that has been used successfully in various hypertensive emergencies.^{96–102} Labetalol blocks both β - and α -adrenergic receptors and also may exert a direct vasodilator effect. The β -blockade is nonselective with α to β potency of 3:1 for oral and 7:1 for IV labetalol. Labetalol is particularly advantageous in C.M. because the immediate onset of action will reduce peripheral vascular resistance without causing reflex tachycardia. Myocardial oxygen demand will be reduced and coronary hemodynamics will be improved, making this agent an excellent choice for patients such as C.M., who have coronary artery disease or MI. In addition, IV labetalol does not significantly reduce cerebral blood flow; therefore, it may be useful in patients with cerebrovascular disease.^{1,23}

Fenoldopam or nitroprusside could also be used to treat C.M. Fenoldopam could potentially benefit renal function by increasing renal blood flow, but C.M.'s history of glaucoma would preclude its use. In addition, equally effective but less costly alternatives are available. Treatment with nitroprusside would expose C.M. to the potential risk of cyanide and thiocyanate toxicity with his new onset renal failure. In contrast, labetalol has been used successfully in patients with renal disease without deleterious side effects.^{108,109} Labetalol is eliminated by glucuronidation in the liver, with <5% of the dose being excreted unchanged in the urine. Therefore, labetalol may be better tolerated than nitroprusside by patients with hepatic failure because toxic nitroprusside metabolites also accumulate in this situation. The presence of renal disease in C.M. will not necessitate an alteration in the dose of labetalol.

CONTRAINDICATIONS

20. What cautions should be exercised when using labetalol in C.M.?

Labetalol's disadvantages are primarily related to its β -blocking effects, which predominate over its α -blocking effects. Therefore, it should not be used in patients with asthma, heart block greater than first degree, or sinus bradycardia, and it should be used with caution in patients with severe uncontrolled HF^{97,101,110} (see Question 18). None of these is present in C.M. Like other β -blockers, labetalol may mask the symptoms of hypoglycemia in insulin-dependent diabetic patients; it should also be used with caution in patients with Raynaud's syndrome.¹¹⁰ Labetalol has been effective in the treatment of hypertension associated with pheochromocytoma and excess catecholamine states.¹¹¹ However, because labetalol is primarily a β -blocker, paradoxical hypertension may occur in patients with pheochromocytoma. These individuals have adrenal tumors that excrete high amounts of norepinephrine, which results in relatively unopposed α -receptor stimulation.¹¹² More clinical experience is required before labetalol can be recommended in patients with pheochromocytoma.^{5,96} Labetalol may also be particularly useful for the treatment of antihypertensive withdrawal syndromes.¹¹

21. Will C.M.'s age or prior use of antihypertensives affect his response to labetalol?

There appears to be a positive correlation between age and response to labetalol. Older patients achieve a greater reduction in BP and, therefore, require smaller doses.^{113,114} Failure to lower BP has also been observed.^{115–117} This phenomenon was believed to be related to single-bolus administration or prior treatment with α - and β -blocking drugs.¹¹⁰ However, subsequent studies have confirmed the effectiveness of labetalol in patients pretreated with antihypertensives, including β -blockers.¹¹⁸

22. How should parenteral labetalol be given to C.M.?

For acute BP reduction, C.M. should be placed in the supine position. IV labetalol can be given by pulse administration or continuous infusion.^{96–101} Small incremental bolus injections are administered, beginning with 20 mg given over 2 minutes, followed by 40 to 80 mg every 10 to 15 minutes until the desired response is achieved or a cumulative dose of 300 mg is reached. The desired response is usually achieved with a mean

dose of 200 mg in 90% of patients.⁹⁷ Following IV injection, the maximal effect occurs within 5 to 10 minutes,⁹⁹ and the antihypertensive response may persist for >6 hours.¹¹⁸ Because the rate of BP reduction is accelerated with an increase in infusion rate,⁹⁹ a controlled continuous infusion may provide a more gradual reduction in arterial pressure with less frequent adverse effects.^{101,119} A solution for continuous infusion (0.5–2.0 mg/minute) is prepared by adding two ampules (200 mg total) to 160 mL of IV fluid to give a final concentration of 1 mg/mL. The infusion can then be started at a rate of 2 mg/minute and titrated until a satisfactory response is achieved or until a cumulative dose of 300 mg is reached.

PARENTERAL/ORAL CONVERSION

23. C.M. was treated with a labetalol infusion and required a cumulative dose of 180 mg to achieve a diastolic pressure of 100 mmHg. His anginal symptoms resolved almost immediately, but 3 hours after the infusion, C.M. became faint and dizzy while ambulating. Should oral labetalol be withheld? When oral labetalol is given, what adverse effects can be expected?

Postural hypotension and dizziness are dose related and more commonly associated with the IV route of administration.^{103,110} C.M. should remain in a supine position following the IV administration of labetalol, and his ability to tolerate an upright position should be established before permitting ambulation. Oral labetalol can be given to C.M. when his supine diastolic BP increases by 10 mmHg. There is no correlation between the oral maintenance dose and the total initial IV dose. C.M. should be started on an empirical dose of 100 to 200 mg oral labetalol twice daily, and this should be titrated as necessary. Other side effects commonly associated with labetalol include nausea, vomiting, abdominal pain, and diarrhea in up to 15% of the patients.¹¹⁰ Scalp tingling is an unusual side effect that has been reported in a few patients after IV administration; it tends to disappear with continued treatment. Other side effects include tiredness, weakness, muscle cramps, headache, ejaculation failure, and various skin rashes.

Nitroglycerin

24. Would parenteral nitroglycerin be an acceptable alternative to labetalol for C.M.?

Severe, uncontrolled hypertension in the setting of unstable angina or MI requires an immediate reduction in BP. Nitroprusside has been used successfully, but IV nitroglycerin can have more favorable effects on collateral coronary flow in patients with ischemic heart disease.¹²⁰ By diminishing preload, nitroglycerin decreases left ventricular diastolic volume, diastolic pressure, and myocardial wall tension, thus reducing myocardial oxygen consumption.¹²¹ These changes favor redistribution of coronary blood flow to the subendocardium, which is more vulnerable to ischemia. At high dosages, nitroglycerin dilates arteriolar smooth muscles, and this reduction in afterload also decreases myocardial wall tension and oxygen consumption.¹²²

IV nitroglycerin has a rapid onset of action and a short duration, and is easily titratable. It is generally appropriate to begin IV nitroglycerin at dosages in the range of 5 to 10 mcg/minute, increased as needed to control pressure and symptoms. The usual dose is in the range of 40 to 100 mcg/minute. The ma-

ior limiting side effects are headache and the development of tolerance. In general, IV nitroglycerin is well suited for use in patients such as C.M. who have unstable angina or in patients who have hypertension associated with MI or coronary bypass surgery.

Diazoxide

25. R.N., a 32-year-old African American female, is admitted to the hospital with a 2-day history of nausea, blurred vision, confusion, and an intractable generalized headache. Her medical history is remarkable for asthma and diet-controlled diabetes mellitus. Physical examination reveals an alert but disoriented woman with a BP of 220/160 mmHg (without orthostasis) and a pulse of 110 beats/minute. There is no evidence of heart failure, but the neurologic examination reveals an altered mental status. Serum electrolytes, BUN, creatinine, UA, chest x-ray, and ECG are within normal limits. R.N.'s plasma glucose level is 275 mg/dL. The assessment at this time is hypertensive encephalopathy. Diazoxide is ordered. How should diazoxide be administered to R.N. to achieve an optimal hypotensive response? Under what circumstances is diazoxide preferred over other agents?

Diazoxide should be administered as a small bolus or by slow infusion because larger doses cause cerebral and cardiovascular hypoperfusion due to an abrupt decline in blood pressure. Studies confirm that diazoxide can be administered safely and effectively as a minibolus (1–3 mg/kg every 5–15 minutes to a maximum of 150 mg in a single injection) or by slow infusion (15–30 mg/minute)^{123,124} until a diastolic BP of 100 mmHg is achieved. Single-dose injections of >150 mg should not be used. Diazoxide can also be given by repetitive infusions according to the following schedule: loading dose of 7.5 mg/kg IV over 1.5 hours (which usually decreases mean arterial pressure by 25%), followed by 10% of the loading dose every 6 hours for maintenance.¹²⁵ In general, diazoxide should be used only in patients who (a) cannot tolerate labetalol (e.g., asthma or advanced heart block), (b) require a more gradual lowering of BP than that produced by nitroprusside, and (c) require a more rapid and certain drop in BP than that which can be produced by oral antihypertensive agents.¹²⁶

Diazoxide should be used with caution in patients with diabetes mellitus because it can increase blood glucose. Blood glucose needs to be monitored during therapy and treated accordingly.¹²⁷

The hypotensive effects of diazoxide begin within 1 minute, and maximum effects occur within 2 to 5 minutes. The patient should remain recumbent for 15 to 30 minutes after the injection of each dose of diazoxide, and the BP should be monitored every 5 minutes for the first 30 minutes. The duration of action is variable in that the BP gradually increases to the pretreatment level in 3 to 15 hours. Diazoxide, when given by slow infusion, produces a maximum reduction in mean arterial pressure of 25% in 25 to 30 minutes, which lasts up to 8 hours.^{124,126} If R.N. fails to respond to the first dose, repeated doses should be given at 10-minute intervals until a cumulative dose of 600 mg is reached.

A major disadvantage of diazoxide is the occurrence of reflex tachycardia, which can precipitate or worsen angina in patients with coronary artery disease. Small IV doses of propranolol (0.2 mg/kg) can be used in situations in which tachycardia is dangerous.¹²⁶

Hydralazine

26. T.M., a 30-year-old Caucasian male with a history of chronic glomerulonephritis and poorly controlled hypertension, came to the ED complaining of early morning occipital headaches during the past week. He has no other complaints. He has not taken any BP medication in a month. Physical examination revealed an afebrile male in no acute distress with a BP of 160/120 mmHg without orthostasis and a regular pulse of 90 beats/minute. Fundoscopic examination revealed bilateral exudates without hemorrhages or papilledema. The lungs were clear. Cardiac examination was pertinent for cardiomegaly and an S₄ gallop. The remainder of the physical workup was normal.

Laboratory results include Hct, 32%; BUN, 40 mg/dL; creatinine, 2.5 mg/dL; and bicarbonate, 18 mEq/L. UA reveals 2+ protein, 2+ hemoglobin with 4 to 10 RBCs/HPF. The ECG demonstrates NSR with left ventricular hypertrophy. The chest radiograph is unremarkable.

T.M. was given 20 mg hydralazine IV, and a repeat BP after 1 hour was 150/100 mmHg. What are the advantages and disadvantages of parenteral hydralazine, and when should it be used to acutely lower BP?

[SI units: Hct, 0.32; BUN, 14.28 mmol/L urea; creatinine, 221 mmol/L; bicarbonate, 18 mmol/L]

Hydralazine is a direct vasodilator that reduces total peripheral resistance through relaxation of arterial smooth muscle. It is rarely used to treat hypertensive emergencies, excluding eclampsia, because its antihypertensive response is less predictable than that of other parenteral agents. It is not consistently effective in controlling crises associated with essential hypertension.

Contraindications

Hydralazine should not be used in patients with coronary heart disease because the reflex tachycardia causes an increase in myocardial oxygen demand, which may result in the development or worsening of ischemic symptoms. In addition, hydralazine should be avoided in patients with aortic dissection because of its reflex cardiostimulating effect. In contrast, hydralazine can be useful in patients such as T.M., who have chronic renal failure because the reflex increase in cardiac output is accompanied by an increase in organ perfusion. In addition, there is considerable experience with the use of hydralazine in patients with eclampsia who are less likely to have underlying coronary artery disease (see Chapter 47).

DOSING AND ADMINISTRATION

Parenteral hydralazine should be considered an intermediate treatment between oral agents and more aggressive therapy with such agents as fenoldopam or nitroprusside. It can be given IV or intramuscularly. The onset of action develops slowly over 20 to 40 minutes, thus minimizing the risk of acute hypotension. Parenteral doses are considerably lower than oral doses because of increased bioavailability.

Other Parenteral Drugs

27. Are there alternatives to hydralazine for parenteral treatment of hypertensive urgencies?

INTRAVENOUS ENALAPRILAT

Enalaprilat, the active metabolite of the oral prodrug enalapril (Vasotec), is approved by the U.S. Food and Drug Administration for the treatment of hypertension when oral therapy is not feasible. Although not approved for the treatment of hypertensive crisis, enalaprilat has been used to treat severe hypertension.^{128–133} The initial dose is 0.625 to 1.25 mg IV and can be repeated every 6 hours, if necessary. Initial doses should not exceed 0.625 mg in patients receiving diuretics or in patients with clinical evidence of hypovolemia. The onset of action is within 15 minutes, but the maximum effect may take several hours. Because only 60% of the patients respond to BP reduction within 30 minutes, it cannot be reliably used to acutely lower pressure in emergent cases.¹³¹ Although higher initial doses have been successfully used to achieve BP control,¹³² some evidence indicates that doses >0.625 mg do not significantly alter the magnitude of enalaprilat's antihypertensive effect.¹³⁰ Because ACE inhibitors do not impair cerebral blood flow, enalaprilat may be useful for the hypertensive patient at risk for cerebral hypoperfusion. Enalaprilat also is beneficial in patients with HF. Precautions for the use of enalaprilat are similar to those of captopril (see question 5). Because of the prolonged time required to achieve an adequate response, limited clinical experience, and variable response rates (especially in African Americans), enalaprilat cannot be recommended for the routine treatment of patients with hypertensive emergencies.^{131,133}

INTRAVENOUS ESMOLOL

Esmolol is a parenteral cardioselective β_1 -blocker with a rapid onset and short duration of action. It has been used primarily in perioperative settings to control tachycardia induced by various surgical stimuli, including endotracheal intubation.¹³⁴ Esmolol has also been used to manage supraventricular tachyarrhythmias.^{135,136} It has been particularly useful in treating postoperative hypertension, especially if associated with tachycardia. In a small series of patients undergoing cardiac bypass surgery, the antihypertensive effect of esmolol was comparable to that of nitroprusside.¹³⁷

Hypotension is the most commonly reported adverse event and is directly related to the duration of esmolol administration.¹³⁸ However, because of the short half-life, resolution of hypotension occurs within 30 minutes of discontinuing the infusion. Like other β -blockers, esmolol is contraindicated in patients with asthma, advanced heart block, or severe HF.

For the management of hypertension, esmolol should be given as a loading dose of 250 to 500 mcg/kg over 1 minute, followed by a maintenance infusion of 50 to 300 mcg/kg/minute. Irritation, inflammation, and induration at the infusion site occur in 5% to 10% of patients.

INTRAVENOUS CALCIUM CHANNEL BLOCKERS

Parenteral verapamil (Isoptin) and diltiazem (Cardizem), although clinically effective for prompt lowering of blood pressure, have not been extensively studied in patients with hypertensive emergencies. In addition, they should be used with extreme caution when acutely treating any hypertensive patient with concomitant systolic HF due to their negative inotropic effects. Nicardipine (Cardene IV), in contrast, has been proven effective in multiple studies of populations with hypertensive

emergencies, and, as a dihydropyridine, has less negative inotropic activity compared to nondihydropyridines.

Intravenous Verapamil

IV verapamil (5–10 mg) produces a significant reduction in BP, which occurs within 15 minutes and persists for 6 to 8 hours. As a cardiovascular drug, it is primarily used as a rate-controlling agent in the treatment of supraventricular tachycardias.

Intravenous Diltiazem

IV diltiazem is approved for temporary control of the ventricular rate in atrial fibrillation or atrial flutter and for rapid conversion of paroxysmal supraventricular tachycardia.^{139–141}

Parenteral diltiazem has also been used to control hypertension that occurs intraoperatively and postoperatively^{142,143} and in patients with acute coronary artery disease.^{144,145} However, published experience with the use of IV diltiazem for the treatment of severe hypertension is limited. Onoyama et al.¹⁴⁶ administered a continuous infusion of diltiazem at a dosage of 5 to 40 mcg/kg/minute to a small group of patients with hypertensive crisis. A normotensive level was achieved within 6 hours without any signs of organ ischemia. In a follow-up study,¹⁴⁷ a continuous infusion of diltiazem averaging 11 mcg/kg/minute resulted in a 25% reduction in both systolic and diastolic BP measurements within 30 minutes. The magnitude of the decrease was directly correlated with the pretreatment BP level. Atrioventricular nodal conduction abnormalities were noted in both studies during drug infusion. Patients receiving IV diltiazem require continuous monitoring by ECG and frequent BP checks. This form of therapy should be avoided in patients with sick sinus syndrome or advanced degrees of heart block. Until additional information is available, caution should be exercised in using parenteral diltiazem to lower BP acutely.

Intravenous Nicardipine

Nicardipine is a potent cerebral and systemic vasodilator and a useful therapeutic option in the management of severe hypertension. Unlike other dihydropyridines, nicardipine is photo resistant, water soluble, and available intravenously. Its onset of action is within 1 to 2 minutes, and its elimination half-life is 40 minutes.¹⁴⁸ Hemodynamic evaluations demonstrated that IV nicardipine significantly decreased mean arterial pressure and systemic vascular resistance and significantly increased cardiac index with little or no change in heart rate.¹⁴⁹ Titratable IV nicardipine has been studied extensively for use in controlling postoperative hypertension,^{149–153} severe hypertension,^{154,155} and acute hypertension in patients with hemorrhagic or ischemic stroke.^{156,157}

In the treatment of postoperative hypertension,¹⁴⁹ IV nicardipine was administered as an infusion titrated in the following manner: 10 mg/hour for 5 minutes, 12.5 mg/hour for 5 minutes, and 15 mg/hour for 15 minutes, followed by a maintenance infusion of 3 mg/hour thereafter. The mean response time and infusion rate were 11.5 minutes and 12.8 mg/hour, respectively. Ninety-four percent of the patients responded, and adverse effects included hypotension (4.5%), tachycardia (2.7%), and nausea and vomiting (4.5%).

The efficacy and safety of IV nicardipine for the treatment of severe hypertension were documented in a double-blind, placebo-controlled multicenter trial of 123 patients.¹⁵⁴ Therapy of IV nicardipine was begun with dosages of 5 mg/hour

and titrated up to 15 mg/hour as indicated until the therapeutic end point was achieved. The mean dosage of IV nicardipine at the end of maintenance therapy was 8.7 mg/hour. Ninety-one percent of patients on nicardipine achieved the prespecified BP target within a mean administration time of 77 minutes. In an open-label trial,¹⁵⁵ patients receiving nicardipine required significantly fewer dose adjustments per hour than patients receiving nitroprusside (1.7 vs. 3.3, respectively). Serious adverse effects reported in these trials were uncommon. The most commonly reported adverse effects included headache, hypotension, tachycardia, dizziness, and nausea.

When compared with sodium nitroprusside for patients with severe hypertension, IV nicardipine was as effective with fewer adverse effects.¹⁵⁵ In studies of patients receiving nicardipine versus nitroprusside for postoperative hypertension following cardiac endarterectomy and coronary artery bypass grafting, breakthrough BP was controlled more rapidly with nicardipine and required fewer overall dose titrations. In addition, nicardipine was well tolerated and did not lead to an increased risk of complications.^{158,159}

In summary, IV nicardipine is an alternative to sodium nitroprusside for the immediate treatment of severe and postoperative hypertension.^{40,160} It has a rapid onset of action, with sustained BP control over the infusion period. It is easily titratable, with a predictable response, and is relatively free of severe adverse effects. It may be useful in patients with cerebral insufficiency or peripheral vascular disease. Because of the potential for reflex tachycardia, it should be used with caution in patients with coronary ischemia.

INTRAVENOUS PHENTOLAMINE (REGITINE)

IV phentolamine is primarily used in the management of hypertensive emergencies induced by catecholamine excess, as seen in pheochromocytoma. The mechanism of action is through nonselective competitive antagonist at α -adrenergic receptors. Phentolamine is dosed in 1- to 5-mg boluses and should be given cautiously due to the risk of causing hypotension. The onset of action is almost immediate and the duration of action is short (<15 minutes). IV infusions are not recommended due to unpredictable drops in BP. As BP control is achieved, an oral α -adrenergic blocking agent such as phenoxybenzamine (Dibenzylin) can be given if needed. β_1 - and β_2 -selective antagonists are not recommended for BP control in cases of pheochromocytoma.¹⁶¹

Aortic Dissection

Treatment

28. B.S., a 68-year-old Caucasian male with a long history of hypertension, asthma, and noncompliance, presents to the local ED complaining of the sudden onset of severe, sharp, diffuse chest pain that radiates to his back between his shoulder blades. Significant findings on physical examination include a pulse of 100 beats/minute, BP of 200/120 mmHg, clear lungs, and an S₄ without murmurs. The laboratory data are unremarkable. The ECG results are interpreted as sinus tachycardia with left ventricular hypertrophy, but no acute changes are noted. The chest radiograph is significant for widening of the mediastinum. An emergency chest computed tomography scan reveals a dissection

at the arch of the aorta. What antihypertensive medication would be most appropriate for B.S., and why?

Dissection of the aorta occurs when the innermost layer of the aorta (the intima) is torn such that blood enters and separates its layers. The ultimate treatment for dissection of the aorta depends on its location and severity; however, the first principle of therapy is to control any existing hypertension with agents that do not increase the force of cardiac contraction. This lessens the force that the cardiac impulse transmits to the dissecting aneurysm.

THERAPEUTIC CONSIDERATIONS

The aim of antihypertensive therapy in aortic dissection is to lessen the pulsatile load or aortic stress by lowering the BP. Reducing the force of left ventricular contractions, and consequently the rate of rise of aortic pressure, retards the propagation of the dissection and aortic rupture.¹⁶² The treatment of choice for aortic dissection has classically been a vasodilatory agent such as sodium nitroprusside, fenoldopam, or nicardipine in combination with a β -blocker titrated to a heart rate of 55 to 65 beats/minute.^{162,164} Labetalol monotherapy has been used as an alternative.¹⁶⁵ These drugs decrease BP, venous return, and cardiac contractility.

One common regimen is a combination of IV sodium nitroprusside (0.5–2 mcg/kg/minute) plus IV esmolol (25–200 mcg/kg/minute).¹⁶⁰ The concurrent administration of a β -blocking agent with a vasodilator is desirable because the latter may induce reflex tachycardia in response to vasodilation.

Trimethaphan can also be used in aortic dissection. Its advantage over sodium nitroprusside is that it reduces both arterial pressure and its rate of increase; therefore, it does not require concurrent administration of β -blockers. However, the major disadvantages are tachyphylaxis, urinary retention, and ileus. Direct vasodilators such as diazoxide and hydralazine should be avoided because they increase stroke volume and left ventricular ejection rate. These effects augment the pulsatile flow and accentuate the sharpness of the pulse wave. This increases mechanical stress on the aortic wall and may lead to further dissection.¹⁶¹

Depending on the location of the dissection, surgical intervention may be required.^{164,166} However, until a definitive diagnosis is made, the primary goal is to reduce the BP and myocardial contractility to the lowest level compatible with the maintenance of adequate renal, cerebral, and cardiac perfusion.¹⁶¹ In aortic dissection, the systolic BP should be lowered to 100 to 120 mmHg or a mean arterial pressure <80 mmHg.¹⁶⁶

The first choice of drug for B.S. is trimethaphan. Although labetalol or a combination of nitroprusside with esmolol has been used successfully in the antihypertensive treatment of dissecting aortic aneurysms, B.S.'s medical history of asthma precludes the use of β -blockers.

TRIMETHAPHAN

29. How should trimethaphan be administered, and what indices of toxicity should be monitored?

Trimethaphan is a ganglionic blocking drug that inhibits sympathetic nervous effects on the arterioles, veins, and heart. Its hypotensive effect is immediate. Severe hypotension after administration of trimethaphan may last for 10 to 15 min-

utes. The hypotensive effect is most pronounced when the patient is upright, and it is often necessary to elevate the head of the bed to achieve an optimal effect. To correct hypotension, trimethaphan should be discontinued and the patient should be placed in the Trendelenburg position.

The drug is usually prepared in a concentration of 500 mg/L of D₅W. The infusion is initiated at 0.5 to 1 mg/minute, and the rate is increased every 3 to 5 minutes until the desired response is obtained. Because minor changes in the infusion rate can produce dramatic changes in BP, the rate must be carefully regulated (preferably by a constant infusion pump), and the BP must be monitored continuously. Therapy with oral antihypertensive agents should begin simultaneously, and an attempt should be made to discontinue the ganglionic blocker within 48 hours before significant tolerance renders the patient resistant to its action.

The prolonged use of trimethaphan is limited by its important sympathoplegic side effects and the rapid development of tachyphylaxis. Urinary retention often occurs with prolonged therapy, necessitating insertion of an indwelling catheter. Constipation and paralytic ileus may occur, as well as paralysis of visual accommodation.

Cocaine-induced Hypertension

Treatment

30. B.K. is a 54-year-old Caucasian male who presents to the ED complaining of 8/10 chest pain associated with diaphoresis and nausea that began 2 hours ago. BK reports using cocaine about 1 hour before his chest pain began. His medical and social histories include hypertension for which he takes hydrochlorothiazide 25 mg daily. He also admits to using cocaine five to seven times per week for the past 21 years and smoking one and a half packs per day for the past 35 years. An ECG reveals ST segment elevations <1 mm in leads V₂ and V₃ and sinus tachycardia. Cardiac enzymes are drawn, and the first set is negative. His cardiac exam was unremarkable. His vital signs include a blood pressure of 205/162 mmHg; heart rate of 132 beats/minute, regular rate and rhythm; and respiratory rate of 24 breaths/minute, and he is afebrile. All laboratory values are within normal limits. Chest x-ray is unremarkable. What agents should be used to manage cocaine-induced hypertension? What agents should be avoided?

Cocaine, a sympathomimetic, can induce severe hypertension by inhibiting the reuptake of norepinephrine and dopamine and thereby increasing neurotransmitter concentrations in the synaptic cleft. This leads to pronounced vasoconstriction and tachycardia. This increase in heart rate and/or BP increases cardiac oxygen demand leading to coronary vasospasm. Cocaine exerts its onset of action within seconds to minutes and has a serum half-life of 30 to 90 minutes.^{167,168}

Management of cocaine-associated hypertensive crisis should be controlled with nicardipine, verapamil, or nitroglycerin. Calcium channels blockers and IV nitroglycerin are preferred in patients with active myocardial ischemia because they have both been shown to reverse cocaine-induced hypertension and vasoconstriction.^{169,170} Benzodiazepines can also be used because they can attenuate the effect of cocaine on the cardiac system, decrease chest pain, and reduce heart

rate.^{167,171} Fenoldopam and nitroprusside can be used as alternative agents.^{172,173}

The use of β -blockers should be avoided in patients who present with hypertension or myocardial ischemia/MI with recent cocaine use. β -blockers will result in unopposed α -adrenergic vasoconstriction, leading to further elevation in BP and heart rate.^{172,173} Labetalol possesses both α - and β -blockade, and its use has been reported in cocaine-

intoxicated patients.¹⁷⁴ Labetalol has been shown to increase seizure activity and mortality in animals with cocaine intoxication and does not alleviate cocaine-induced coronary vasoconstriction.^{175,176} Labetalol has also been shown to worsen BP when α -stimulation has been left unopposed in patients with pheochromocytoma.^{112,177} Therefore, caution should be used if labetalol is used in patients with recent cocaine use.

INTRODUCTION

Shock is defined in simple terms as a syndrome of impaired tissue perfusion usually, but not always, accompanied by hypotension. This impairment of tissue perfusion eventually leads to cellular dysfunction, followed by organ damage and death if untreated. The most common causes of shock are situations that result in a reduction of intravascular volume (hypovolemic shock), myocardial pump failure (cardiogenic shock), or

increased vascular capacitance (distributive shock, sepsis). The type of treatment required depends on the etiology.

In recent years, medical support of patients with shock has improved because of better technologies for hemodynamic monitoring, recognition of the value of vigorous volume replacement, appropriate use of inotropic and vasoconstrictive agents, and the development of better ways to treat the underlying cause of the shock syndrome. Understanding the principles of shock should further enhance prompt recognition

Table 21-1 Classification of Shock and Precipitating Events**Hypovolemic Shock****Hemorrhagic**

- Gastrointestinal bleeding
- Trauma
- Internal bleeding: ruptured aortic aneurysm, retroperitoneal bleeding

Nonhemorrhagic

- Dehydration: vomiting, diarrhea, diabetes mellitus, diabetes insipidus, overuse of diuretics
- Sequestration: ascites, third-space accumulation
- Cutaneous: burns, nonreplaced perspiration and insensible water losses

Cardiogenic Shock**Nonmechanical Causes**

- Acute myocardial infarction
- Low cardiac output syndrome
- Right ventricular infarction
- End-stage cardiomyopathy

Mechanical Causes

- Rupture of septum or free wall
- Mitral or aortic insufficiency
- Papillary muscle rupture or dysfunction
- Critical aortic stenosis
- Pericardial tamponade

Distributive Shock**Septic Shock**

- Anaphylaxis

Neurogenic

- Spinal injury, cerebral damage, severe dysautonomia

Drug-Induced

- Anesthesia, ganglionic and adrenergic blockers, and over-doses of barbiturates, narcotics

Acute Adrenal Insufficiency

inflammatory cytokine release, and the generation of oxygen radicals. When cells are subjected to a prolonged period of ischemia, anaerobic metabolism begins. This inefficient process results in a decrease of adenosine triphosphate (ATP) stores and causes the buildup of lactic acid and other toxic substances that can alter the cellular machinery and eventually result in cell death. In the advanced stages of shock, irreversible cellular damage leads to multiple organ system failure (MOSF), also known as multiple organ dysfunction syndrome (MODS).

Inflammatory cytokines are produced by the body in response to ischemia, injury, or infection. The phrase *systemic inflammatory response syndrome* (SIRS) is the recommended umbrella term to describe any acute, overwhelming inflammatory response, independent of the cause.² This syndrome can occur after a wide variety of insults, including hemorrhagic shock, infection (septic shock), pancreatitis, ischemia, multi-trauma and tissue injury, and immune-mediated organ injury. SIRS is usually a late manifestation of hypovolemic forms of shock. It is uncommon in cardiogenic shock, but is the hallmark of septic shock. SIRS is clinically characterized by profound vasodilation, which impairs perfusion, and increased capillary permeability, which can lead to reduced intravascular volume.

The following mediators have been identified as possible causes of the proinflammatory reaction underlying sepsis and multiple organ failure³:

- Macrophages and their products
- Cytokines: tumor necrosis factor (TNF), interleukin-1 (IL-1), interleukin-6 (IL-6), and interleukin-8 (IL-8)
- Neutrophils and products of degranulation
- Platelets and the coagulation factors formed on their surfaces
- Derivatives of arachidonic acid
- T and B lymphocytes and their products

of patients at risk, rapid initiation of corrective measures, and development of innovative treatment regimens.

CAUSES

Table 21-1 outlines the classification of shock and precipitating events.¹ Recognition of the etiology and underlying pathology of the various forms of shock is essential for managing this condition. The distinctions among subtypes of shock only apply, however, in the relatively early stages. As the syndrome evolves and compensatory mechanisms are overwhelmed, it becomes increasingly difficult to determine the subtypes because the clinical and pathophysiologic features of advanced shock are the same for all. Also, different types of shock can occur at the same time (e.g., a patient with septic shock who is also hypovolemic).

PATHOPHYSIOLOGY

Tissue perfusion is a complex process of oxygen and nutrient delivery as well as waste removal. When perfusion is impaired, it sets up a cascade of events that can eventually end in death. Although the etiology of shock is varied, the eventual progression (if untreated) to cell death and subsequent organ dysfunction results from a common pathway of ischemia, endogenous

CLINICAL PRESENTATION

Independent of the pathophysiologic cause, the clinical syndrome of shock progresses through several stages. During each step, the body uses and exhausts various compensatory mechanisms to balance oxygen delivery (DO₂) and oxygen consumption (VO₂) in an effort to maintain perfusion of vital organs. A major determinant of tissue perfusion is the systemic or mean arterial pressure. Mean arterial pressure (MAP) is a function of the product of blood flow (cardiac output [CO]) and systemic vascular resistance (SVR). Cardiac output is the product of heart rate (HR) and stroke volume (SV) (Fig. 21-1). Vascular resistance is determined primarily by vascular smooth muscle tone, modulated by the sympathoadrenal system and by circulating humoral and local metabolic factors. These interacting factors are what contribute to the clinical syndrome seen in patients with shock.

The classic findings observed with shock include the following:

- Systolic blood pressure (SBP) <90 mmHg (or >60 mmHg decrease from baseline in a hypertensive patient)
- Tachycardia (HR >90 beats/minute)
- Tachypnea (respiratory rate [RR] >20 breaths/minute)
- Cutaneous vasoconstriction: cold, clammy, mottled skin (although not typical of distributive shock)

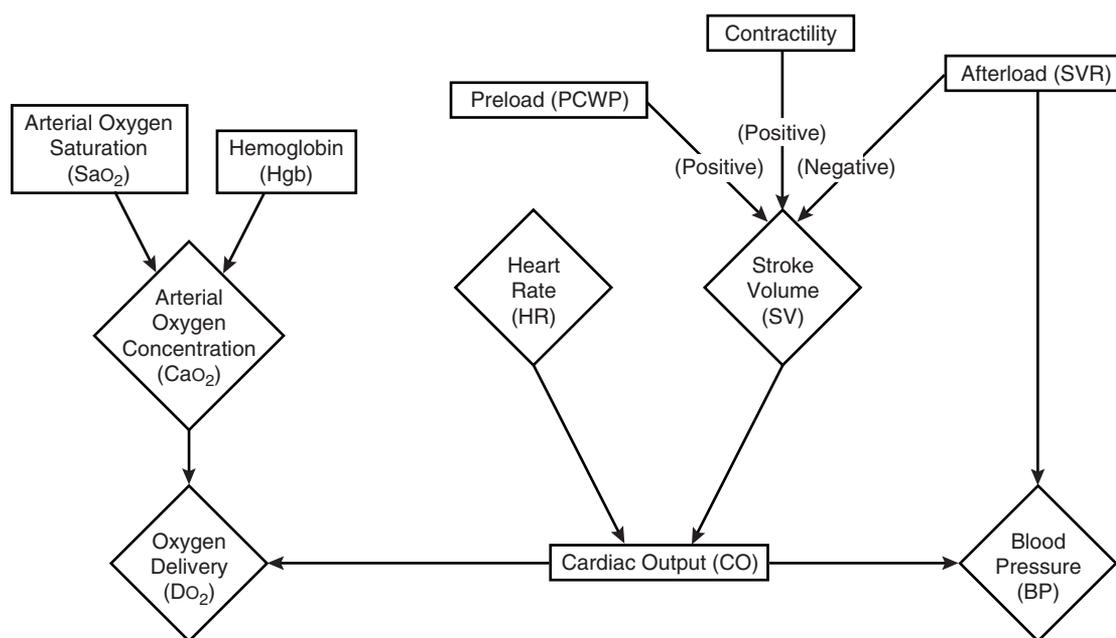

FIGURE 21-1 Determinants of blood pressure, cardiac output, and oxygen delivery.

- Mental confusion (agitation, stupor, or coma)
- Oliguria: urine output <20 mL/hour
- Metabolic acidosis (lactic acidosis secondary to anaerobic glycolysis)

Not all these described findings are encountered in every patient with shock, and considerable variability exists in both the rapidity and sequence of onset. This depends on the severity of the initiating event, the underlying mechanism, and the baseline condition of the patient, including medications that may alter the clinical presentation. Therefore, it is important to consider the patient's medical and pharmacologic history while closely monitoring for subtle clinical changes that may signal impending deterioration and necessitate immediate intervention.

HEMODYNAMIC MONITORING

Hemodynamic monitoring in the critically ill patient is mandatory to properly assess and manage various shock states. Both noninvasive and invasive monitoring techniques can be used to measure cardiovascular performance in patients and to differentiate the causes of various conditions that result in hypoperfusion and organ dysfunction. The values obtained with hemodynamic monitoring should always be used in conjunction with clinical judgment.

Noninvasive Monitoring

An important part of hemodynamic monitoring in the critically ill patient involves noninvasive measures. Clinical examination and vital signs (temperature, HR, BP, RR) provide valuable information regarding the cardiovascular system and organ perfusion. Other well-established noninvasive techniques for monitoring the hemodynamic status of patients include pulse

oximetry (for measuring arterial oxygen saturation [SaO_2]) and transthoracic echocardiography, which can estimate the functional status of the heart and heart valves.

New noninvasive technologies are being developed. End tidal carbon dioxide (EtCO_2) monitors are used to determine oxygen consumption and help guide therapies designed to improve oxygen delivery and consumption. New devices that can measure CO and tissue perfusion noninvasively (or minimally invasively), such as gastric tonometry, esophageal Doppler monitoring, thoracic bioimpedance, and others have been developed,^{4,5} but are not used routinely in most intensive care units (ICU). Although important, noninvasive measures have limitations, and certain hemodynamic values must be measured invasively at the present time.

Invasive Monitoring

The evaluation of critically ill patients is a complicated matter, and data that can be important in the diagnosis and assessment of illness as well as the patient's response to therapy must occasionally be obtained by invasive techniques.

Arterial Pressure Line

The arterial line is a common tool in the ICU. It consists of a small catheter placed into an artery (usually the radial or femoral artery) and attached to a pressure transducer. This allows for continuous measurement of BP and also provides for easy access for arterial blood gas (ABG) samples to be drawn and analyzed. Arterial lines should never be used for medication administration.

Central Venous Catheter

Common in the ICU, the central venous catheter consists of a large-bore catheter usually inserted into either a subclavian or jugular vein. It can be used for infusion of fluid and

medications; when attached to a pressure transducer, it can be used to measure the central venous pressure (CVP), a reflection of right atrial pressure and the volume status of the patient.

Pulmonary Artery Catheter

The introduction of flow-directed, balloon flotation pulmonary artery (PA) catheters by Swan and colleagues⁶ (Swan-Ganz catheter) in the 1970s represented a major advance in invasive bedside hemodynamic monitoring. The PA catheter enables clinicians to assess both right and left intracardiac pressures, determine CO, and obtain mixed venous blood samples. These capabilities allow one to evaluate volume status and ventricular performance, derive hemodynamic indices, and determine systemic oxygen delivery and consumption. There are several versions of the PA catheter. Some include additional lumens for intravenous (IV) infusions, temporary transvenous pacing, and continuous monitoring of mixed venous oxygen saturation. Newer catheters can measure CO on a continuous basis. The essential components for hemodynamic monitoring are incorporated in the standard quadruple lumen catheter pictured in Figure 21-2. This catheter is composed of multiple lumens, each terminating at different points along the catheter. When properly positioned, the proximal port (C) terminates in the right atrium is used to measure right atrial pressure, to inject fluid for CO determination, and to administer IV fluids. The distal port (B), which terminates at the tip of the catheter (E), is positioned in the pulmonary artery beyond the pulmonary valve and is used to measure pulmonary artery and pulmonary capillary wedge pressure (PCWP; described below) and to obtain mixed venous blood samples. Intermittent inflation of the balloon is accomplished by inserting 1.5 mL of air into the balloon inflation valve (D). The thermistor (A) contains a temperature probe and electrical leads that connect to a computer, which calculates CO by the thermodilution technique.

Although the pulmonary artery catheter is confined to the pulmonary vasculature, left ventricular (LV) pressure can be ascertained from the PCWP. When the balloon is inflated, the PA catheter advances to a pulmonary artery branch of equal diameter and becomes lodged or “wedged” in this position. Because forward flow from the right ventricle ceases beyond the wedged PA segment, a static fluid column exists between the LV and PA catheter tip during diastole when the mitral valve is open. If no pressure gradients are in the pulmonary vasculature beyond the balloon and if mitral valve function is normal, the PCWP then equilibrates with all distal pressures and thus indi-

rectly reflects left ventricular end-diastolic pressure (LVEDP). Based on the relationship between pressure and volume, the LVEDP is equivalent to the left ventricular end-diastolic volume (LVEDV) which is also known as *preload*.

The use of PA catheters is not without potential complications. Arrhythmias, thrombotic events, infections, and, very rarely, PA rupture have been reported. Several recent trials have called into question the routine use of pulmonary artery catheters. A meta-analysis of 13 randomized, controlled trials involving 5,051 patients was recently published.⁷ The authors found that the use of the PA catheter did not have a significant effect on mortality or number of days in the hospital. The use of the catheter was associated with a higher use of inotropic agents and IV vasodilators. The trials included in the analysis excluded patients in whom the catheter was thought to be required for treatment. An international consensus conference recommends against the routine placement of the pulmonary artery catheter in patients with shock.⁸ More studies are needed to determine the value of PA catheter data-driven treatment protocols. Because hypotension alone is not required to define shock, the presence of inadequate tissue perfusion on physical examination is more important than the numbers obtained by invasive monitoring.⁸

DETERMINANTS OF CARDIAC FUNCTION AND HEMODYNAMIC INDICES

The effective interpretation and management of hemodynamic parameters requires a thorough understanding of the physiologic determinants of CO and arterial pressure. Assuming oxygen content of blood is adequate, CO and SVR are the ultimate determinants of oxygen delivery and adequate arterial pressure, and thus overall tissue perfusion. As outlined in Figure 21-1, cardiac output may be quantified as the product of SV and HR. SV is determined by preload, afterload, and contractility. The effects of these factors on hemodynamic parameters are interrelated and complex and must be assessed carefully when selecting therapeutic interventions that will produce the desired response. A good review of the determinants of cardiac performance is found in Chapter 18, Heart Failure. Table 21-2 and the Glossary provide definitions of terms and normal hemodynamic indices, which are discussed in the following section.

Measured Hemodynamic Indices

Right Atrial Pressure and Central Venous Pressure

The right atrial pressure (RAP), as measured by a PA catheter, reflects the filling pressure or end-diastolic pressure of the right ventricle (RV) and is used as an index of RV preload. Central venous pressure, as determined by a catheter advanced to the superior vena cava or right atrium, is another means of measuring RV filling pressure and is considered equivalent to the RAP. Vascular capacitance, circulating blood volume, and myocardial contractility maintain RAP. A low RAP usually reflects hypovolemia or vasodilation. An elevated RAP can signify increased intravascular volume, right ventricular heart failure, tricuspid regurgitation, pulmonary embolus, pulmonary hypertension, obstructive airway disease with cor pulmonale, or pericardial tamponade. In tamponade, the LV filling pressure also is elevated to the same degree as the RAP.

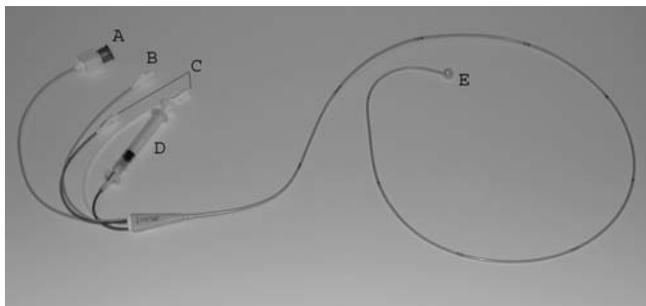

FIGURE 21-2 Pulmonary artery catheter. (See text for definitions of A, B, C, D, and E.)

Table 21-2 Normal Hemodynamic Values and Derived Indices

| | <i>Equation</i> | <i>Normal Value</i> | <i>Units</i> |
|---|---|---------------------|---|
| Directly Measured | | | |
| Blood pressure (BP) (systolic/diastolic) | | 120–140/80–90 | mmHg |
| Cardiac output (CO) | $CO = SV \times HR$ | 4–7 | L/min |
| Central venous pressure (CVP) ^a | | 2–6 | mmHg ^b |
| Heart rate (HR) (pulse) | | 60–80 | beats/min |
| Mean pulmonary artery pressure (MPAP) | | 12–15 | mmHg |
| Pulmonary artery pressure (PAP) (systolic/diastolic) | | 20–30/8–12 | mmHg |
| Pulmonary capillary wedge pressure (PCWP) | | 5–12 ^c | mmHg |
| Derived Indices | | | |
| Cardiac index (CI) | $CI = \frac{CO}{BSA^d}$ | 2.5–4.2 | L/min/m ² |
| Left ventricular stroke work index (LVSWI) | $LVSWI = (MAP - PCWP) (SVI)(0.0136)$ | 35–85 | g/m ² /beat |
| Mean arterial pressure (MAP) | $MAP = \frac{2(\text{Diastolic BP}) + \text{Systolic BP}}{3}$ | 80–100 | mmHg |
| Perfusion pressure (PP) | $PP = MAP - PCWP$ | 50 | mmHg |
| Pulmonary vascular resistance (PVR) | $PVR = \frac{(MPAP - PCWP)}{CO} (74)$ | 20–120 | dynes.sec.cm ⁻⁵ |
| Stroke volume (SV) | $SV = \frac{CO}{HR}$ | 60–130 | mL/beat |
| Stroke volume index (SVI) | $SVI = \frac{SV}{BSA}$ | 30–75 | mL/beat/m ² |
| Systemic vascular resistance (SVR) ^e | $SVR = \frac{(MAP - CVP)}{CO} (74)$ | 800–1,440 | dyne.sec.cm ⁻⁵ |
| Systemic vascular resistance index (SVRI) | $SVRI = SVR \times BSA$ | 1,680–2,580 | dyne.sec.cm ⁻⁵ .m ² |
| Oxygen delivery (Do ₂) | $Do_2 = CO - CaO_2 [CaO_2 = (Hgb - SaO_2 - 13.9)]$ | 700–1,200 | mL/min |
| Oxygen consumption (Vo ₂) | $Vo_2 = Co - Hgb - 13.9 - (SaO_2 - Svo_2)$ | 200–400 | mL/min |

^aCVP is essentially synonymous with RAP.

^b2–6 mmHg = 3–6 cm H₂O (conversion: 1 mm = 1.34 cm H₂O).

^cMay optimally ↑ PCWP to 16–18 mmHg in critically ill patients.

^dBSA, body surface area = 1.7 m² (average male).

^eSVR is synonymous with total peripheral resistance (TPR).

Right-sided heart pressures are unreliable indicators of concurrent LV function.⁹ In patients with cardiac or pulmonary disease or on mechanical ventilation, RAP or CVP measurements actually may vary inversely with the PCWP. Therefore, reliance on right-sided heart pressures from CVP catheters alone is adequate only in select patients.

Pulmonary Artery Systolic Pressure

Pulmonary artery systolic (PAS) pressure is obtained during systole after the opening of the pulmonic valve when blood is ejected from the right ventricle into the pulmonary artery. It measures the pressure generated by the RV during contraction. Elevations in PAS pressure occur when pulmonary vascular resistance is increased. This occurs in patients with acute or

chronic parenchymal pulmonary disease, pulmonary embolus, hypoxemia, or acidosis, as well as in those receiving vasoactive drugs. A low PAS pressure usually results from a reduced circulating blood volume.

Pulmonary Artery Diastolic Pressure

Pulmonary artery diastolic (PAD) pressure is measured during diastole after the closure of the pulmonic valve when the blood moves from the pulmonary artery into the pulmonary capillaries. As previously described with respect to the PCWP, the PAD pressure also may reflect LVEDP. Under normal circumstances, the PAD pressure is approximately equal (within 1–3 mmHg) to the PCWP and can be used in place of the latter as an indication of LVEDP. Because the catheter is more

proximally located and is not in a “wedged” position, the PAD pressure may not correlate as well as the PCWP with the LVEDP. In conditions that increase pulmonary vascular resistance, such as those mentioned for pulmonary artery systolic pressure, the PAD may be substantially greater than the PCWP. Also, when heart rates are >120 beats/minute, PAD pressure exceeds PCWP. This is because diastole is shortened and reduces the time necessary for equilibrium of blood flow.

Pulmonary Capillary Wedge Pressure

Pulmonary capillary wedge pressure is the most reliable reflection of LVEDP measured with the pulmonary artery catheter. LVEDP, in turn, provides the closest approximation of preload, the initial end-diastolic fiber length, which is determined clinically by LVEDV. Because neither LVEDV nor LVEDP are readily measurable, PCWP is used as an indicator of preload.

Preload is an important determinant of stroke volume. The relationship between preload and stroke volume is illustrated in Figure 21-3, the Frank-Starling curve. According to this mechanism, the degree of myocardial fiber shortening, and hence SV, is proportional to the initial myocardial fiber length, or ventricular volume, at the onset of contraction. As shown in Figure 21-1, if HR remains the same, SV is proportional to cardiac output. Initially, for any given state of contractility, an increase in preload generates a contraction that results in a corresponding increase in SV. Once an optimal preload is attained, as indicated by the flat portion of the curve, further elevations in ventricular filling pressure will not enhance SV and, in fact, can result in a decline in contractility and a decrease in SV. Significant increases or decreases in the level of ventricular contractility (inotropy), independent of alterations in preload or afterload, result in shifts in the ventricular function curve, with corresponding changes in SV. As shown in Figure 21-3, enhanced myocardial contractility caused by such

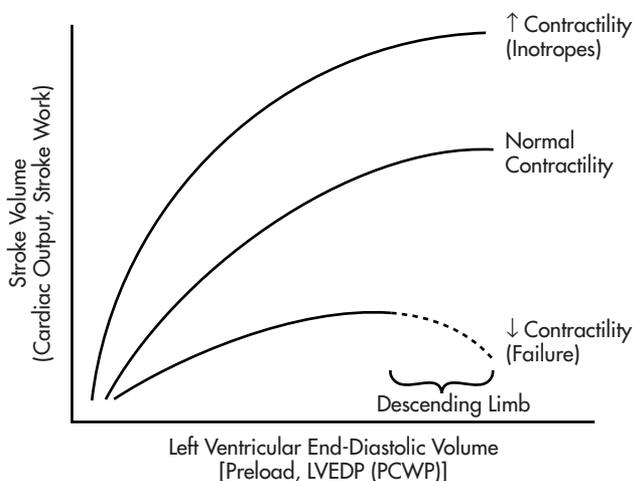

FIGURE 21-3 Ventricular function (Frank-Starling) curve. In the normal heart, as preload (LVEDP), measured clinically by PCWP, increases, stroke volume (cardiac output, stroke work) increases, until the contractile fibers reach their capacity, at which point the curve flattens. A change in contractility causes the heart to perform on a different curve. If the contractile fibers exceed their capacity, as with severe heart failure, the heart will operate on the descending limb of the curve.

factors as increased sympathetic nerve activity, endogenous catecholamines, or exogenous inotropic agents, shifts the ventricular function curve upward and to the left, thus augmenting SV for a given preload. Conditions that reduce contractility, such as loss of contractile mass, use of pharmacologic depressants, systemic hypoxia, local ischemia, or acidosis, shift the curve downward and to the right, thereby diminishing SV.

Although LVEDP or PCWP can generally be substituted for LVEDV when evaluating cardiac function, the use of PCWP as a reflection of LVEDV has limitations. In patients with mitral stenosis, pulmonary veno-occlusive disease, or high levels of positive end-expiratory pressure (PEEP) with mechanical ventilation, PCWP will exceed LVEDV and inaccurately reflect LVEDV.

The relationship between LVEDP and LVEDV is curvilinear and is determined by compliance. In conditions in which ventricular compliance is abnormal, the correlation between LVEDP and LVEDV is altered, and PCWP cannot be assumed to accurately reflect preload. Therefore, it is important to be aware that certain conditions or interventions can result in potential alterations in ventricular compliance and PCWP and interpret measurements accordingly.

The PCWP also is a useful measure of pulmonary capillary hydrostatic pressure, the major driving force for the development of pulmonary congestion. Thus, the PCWP helps the clinician determine whether pulmonary edema is cardiogenic or noncardiogenic in origin. PCWP is higher than pulmonary hydrostatic pressure with adult respiratory distress syndrome (ARDS) or elevated pulmonary vascular resistance.

Cardiac Output

Cardiac output determination involves injecting a 10-mL bolus of cold crystalloid solution through the PA catheter and measuring the temperature at the tip of the catheter via the thermistor. The relationship between the temperature change over time and blood flow allows calculation of the CO.¹⁰ PA catheters are available that use a small heat generator and a heat sink in the catheter itself, which allows the continuous determination of CO with the same concept of thermodilution. Some conditions may make measurement of CO less reliable. Tricuspid valve regurgitation and intracardiac shunts, such as ventricular septal defects, affect the way blood flows past the tip of the thermistor and, thus, may give erroneous values.

Mixed Venous Oxygen Saturation

Mixed venous oxygen saturation (SV_{O_2}) can be measured with fiberoptic sensors in newer versions of the PA catheter, or it can be measured directly from blood drawn from the catheter before oxygenation in the lungs. It can be used as an indicator of the global adequacy of perfusion and can be used to calculate the body's consumption of oxygen (VO_2 , see later section). The SV_{O_2} may be particularly useful in situations in which CO measurements are unreliable (e.g., tricuspid valve regurgitation) or in clinical situations in which oxygen consumption is increased despite normal oxygen delivery (e.g., septic shock).

Derived Hemodynamic Indices

Parameters that reflect cardiovascular function can be derived from the hemodynamic measurements obtained from the Swan-Ganz catheter (Table 21-2 and Glossary).

Stroke Volume

Stroke volume is the amount of blood ejected by the ventricle with each systolic contraction, and it is directly proportional to the contractile state of the myocardium. When CO is increased by therapeutic maneuvers, it is important to know whether the increase is caused by an inotropic (SV) or a chronotropic response (HR).

Cardiac Index

Cardiac index is the CO adjusted for body surface area (BSA). Because CO is a relative measure based on size, cardiac index provides a more meaningful assessment of a person's output.

Pulmonary Vascular Resistance and Systemic Vascular Resistance

Pulmonary vascular resistance (PVR) and systemic vascular resistance (SVR, afterload) are determined by dividing the change in pressure by the flow (pressure change/cardiac output = resistance). Therapeutic maneuvers that alter SVR do not indicate a change in any specific vascular bed, such as the renal or splanchnic vascular beds; changes in SVR reflect the overall change. The systemic vascular resistance index (SVRI) is a normalized SVR for body surface area.

Left Ventricular Stroke Work Index

Left ventricular stroke work index (LVSWI) is an indication of LV contractility that takes into account preload, afterload, and CO. The constant 0.0136 is the conversion factor that changes millimeters of mercury per liter (mmHg/mL) into gram-meters. Elevation in LVSWI can be achieved by changing preload, afterload, or contractility.

Oxygen Transport Variables

Hypoperfusion associated with shock is not as readily detectable as hypotension. An imbalance between oxygen supply and demand may not be recognized until irreversible organ dysfunction has begun. Thus, it can be valuable in some patients to monitor oxygen transport variables and use these values to guide therapy.

Oxygen Delivery

Oxygen delivery (DO_2) can be calculated as the product of CO and the arterial concentration of oxygen (CaO_2). Hemoglobin concentration (Hgb) and arterial oxygen saturation (SaO_2) are the primary determinants of CaO_2 . A smaller contribution to the equation is the amount of oxygen dissolved in the blood, determined by the arterial pressure of oxygen (PaO_2), which can be left out to simplify calculations:

$$DO_2 = (CO)(CaO_2)$$

where

$$CaO_2 = (Hgb)(SaO_2)(13.9)$$

Oxygen Consumption

Oxygen consumption (VO_2) estimates the oxygen demand of the body and can be calculated as the product of CO and the difference between the arterial and venous concentrations of oxygen ($CaO_2 - CVO_2$). Rearranged and simplified, the equation can be represented as follows:

$$VO_2 = (CO)(Hgb)(13.9)(SaO_2 - SvO_2)$$

Normally, consumption is independent of supply, except at low rates of DO_2 . In some critically ill patients, however, consumption can depend on supply even in what would be considered "normal" DO_2 ranges. In these patients, it may be appropriate to increase the delivery of oxygen until the increase in consumption has reached a plateau.¹¹ This may help to "repay" some of the oxygen debt induced by hypoperfusion. Further increases in DO_2 to supranormal ranges with inotropic drugs, such as dobutamine, have not been conclusively shown to benefit patients and may have a detrimental effect.^{12,13} A factor to consider in evaluating these values and the studies that use them is the potential for mathematic coupling of data. CO, hemoglobin, and arterial oxygen saturation are common components of both equations. Errors in the measurement of these parameters lead to errors in the calculation of both delivery and consumption of oxygen.

ETIOLOGIC CLASSIFICATION OF SHOCK AND COMMON MECHANISMS

The most common clinical conditions associated with the major forms of shock are reviewed in the following sections and detailed in Table 21-1. The pathogenesis, epidemiology, clinical, and hemodynamic manifestations for each classification are briefly discussed and further illustrated in case studies throughout the chapter. Table 21-3 describes the common hemodynamic findings for the various forms of shock.

Hypovolemic Shock

Shock secondary to a reduction in intravascular volume is referred to as *hypovolemic shock*. Whether the primary insult is the external loss of fluid volume (e.g., blood, plasma, or free water) or the internal sequestration of these fluids into body cavities (third spacing), the overall result is reduced venous return (decreases in CVP and PCWP) and decreased CO (Table 21-3). The severity of hypovolemic shock depends on the amount and rate of intravascular volume loss and each person's capacity for compensation. Although responses vary,

Table 21-3 Hemodynamic Findings in Various Shock States

| | Hypovolemic | Cardiogenic | Distributive (Septic) |
|-----------------------------|-------------|-------------|-----------------------|
| Heart Rate | ↑ | ↑ | ↑ |
| Blood Pressure ^a | ↓ | ↑/↓ | ↓ |
| Cardiac Output | ↓ | ↓ | ↓ ^b |
| Preload (PCWP) | ↓ | ↑ | ↑/↓ |
| Afterload (SVR) | ↑ | ↑ | ↓ |

^aPatients may be in a state of compensated shock in which BP is normal but clinical signs of hypoperfusion are evident.

^bCardiac output is increased early in sepsis but can be decreased in late, severe.

a healthy person may tolerate an acute loss of as much as 30% of his or her intravascular volume with minimal clinical signs and symptoms.¹⁴ Compensatory mechanisms such as increases in HR, myocardial contractility, and SVR, are sufficiently effective for this loss in volume such that measurable falls in systolic BP are not detected. Losses in excess of 80% generally overwhelm compensatory mechanisms and the patient's condition can deteriorate to overt shock with hypotension and signs of hypoperfusion. If restorative measures are not taken immediately, irreversible shock and death may result. The most common and dramatic cause of hypovolemic shock is hemorrhagic shock in which intravascular volume depletion occurs as a result of bleeding. Trauma is responsible for most cases of acute hemorrhagic shock; other significant causes are rupture of vascular aneurysms, acute gastrointestinal bleeding, ruptured ectopic pregnancy, and postoperative bleeding. Other mechanisms for hypovolemic shock are conditions associated with either (a) excess fluid losses from gastrointestinal or renal sources or (b) plasma loss caused by burns or sequestration (also known as *third-space accumulation*).

Cardiogenic Shock

A shock state arising primarily from an abnormality of cardiac function constitutes cardiogenic shock. The causes of cardiogenic shock can be separated largely into mechanical and nonmechanical (Table 21-1), although occasionally, patients may have a combination of causes. Regardless of the source, the underlying problem in cardiogenic shock is a decrease in CO that is not caused by a reduction in circulating blood volume. This decrease in CO results in the syndrome of shock: hypotension with a decrease in arterial BP, and hypoperfusion as the delivery of oxygenated blood to the tissues is reduced. Eventually, organ dysfunction and death result if measures to restore perfusion are not successful.

The most common cause of cardiogenic shock is LV dysfunction and necrosis as a result of acute myocardial infarction (AMI) (see Chapter 17, Myocardial Infarction). Necrosis of the left ventricle can be the result of a single massive myocardial infarction (MI), or it may follow numerous smaller events. Increases in sympathetic tone—seen clinically as increased HR and peripheral vasoconstriction—initially serve to increase CO and maintain central arterial pressure. When LV necrosis exceeds approximately 40% of the contractile mass of the heart, normal compensatory responses can no longer maintain CO, and hypotension and hypoperfusion result. In addition to decreased perfusion to vital tissues and organs, the decrease in CO leads to a reduction in the flow of blood through the coronary arteries, which can lead to infarct extension and a further worsening of cardiac performance.

The incidence of cardiogenic shock after AMI has remained relatively stable over the past 20 years. A recent study found an average incidence of 7.1% from 1975 to 1997.¹⁵ The in-hospital mortality for those patients developing shock has decreased somewhat over this time frame, most likely because of coronary reperfusion strategies. The overall mortality rate, however, has remained high, with most series reporting an average of 60% to 80%.^{15,16}

Cardiogenic shock caused by mechanical problems occurs relatively infrequently. In this setting, the systolic function (contractile ability) of the heart may be normal, but other

defects render the heart unable to eject a normal volume of blood. Pericardial tamponade (bleeding into the pericardial sac) and tension pneumothorax (air leakage from the lung into the chest) cause cardiogenic shock by compressing the heart and decreasing the diastolic filling. Acute valvular insufficiency or stenosis prevents the normal ejection of blood. Ventricular septal or free wall rupture can occur, often in the setting of AMI, with the reduction in CO related to the inability of the LV to eject a normal volume of blood during systole.

Nonmechanical origins of cardiogenic shock involve a decrease in the function of the heart muscle itself. Myocardial infarction involving the RV can cause cardiogenic shock, even with normal LV systolic function. In this situation, the volume of blood reaching the LV (preload) is reduced because of the right ventricle's inability to move blood to the left side of the heart. In most patients with cardiogenic shock and RV infarction, significant LV dysfunction is present as well.

Patients with chronic heart failure (HF) (see Chapter 18, Heart Failure) usually can compensate for their poor cardiac function, but acute exacerbations can cause cardiogenic shock with hypotension, hypoperfusion, and organ dysfunction. Cardiac dysfunction occasionally can be seen with severe sepsis because of increases in the production of inflammatory cytokines that have a depressant effect on the myocardium. A similar picture also can be seen following cardiopulmonary bypass during heart surgery, which activates the inflammatory cascade.

The symptoms of cardiogenic shock are largely the same as for other types of shock. Hypotension and signs of inadequate tissue perfusion, such as confusion, oliguria, tachycardia, and cutaneous vasoconstriction, are present in many patients. Differentiating cardiogenic shock from distributive or hypovolemic shock requires further examination. A history of coronary artery disease or symptoms of MI are important findings. Hypovolemia occurs in up to 20% of patients in cardiogenic shock, but patients frequently have signs of volume overload because the heart cannot move blood through the circulation. Peripheral edema can be seen in the extremities; lung sounds are diminished and rales may be present as pulmonary edema develops. These findings are particularly evident in patients with severe HF.

Because the distinction between cardiogenic and other forms of shock can be difficult to make based on physical examination alone, further testing with invasive hemodynamic monitoring may be required to establish the diagnosis and guide therapy. Table 21-4 lists the common laboratory, electrocardiogram (ECG), chest radiograph findings, and Table 21-3 lists the common hemodynamic findings in cardiogenic shock.

Distributive Shock

Distributive shock is characterized by an overt loss of vascular tone, causing acute tissue hypoperfusion. Although numerous events can initiate distributive shock, most cases are readily reversed by supportive measures and treatment or elimination of the underlying cause.

Septic Shock

Distributive shock secondary to sepsis, or septic shock, is associated with a high mortality rate, reflecting the limited therapeutic options available at this time. Approximately

Table 21-4 Typical Findings of Early Cardiogenic Shock

- Arterial blood gas (ABG)
 - Hypoxemia secondary to pulmonary congestion with ventilation-perfusion abnormalities
 - Metabolic acidosis with a compensatory respiratory alkalosis
- Elevated blood lactate levels (which contributes to the acidosis)
- Complete blood count (CBC)
 - Leukocytosis
 - Thrombocytopenia (if disseminated intravascular coagulation is present)
- Elevated cardiac enzymes if myocardial infarction is present
- Electrocardiogram (ECG)—one or more of the following
 - T-wave changes indicating infarction
 - Left bundle-branch block
 - Sinus tachycardia
 - Arrhythmia
- Chest radiograph
 - Pulmonary edema or evidence of adult respiratory distress syndrome (ARDS)
- Echocardiography
 - Valvular or mechanical problems if present
 - Normal or decreased ejection fraction
- Hemodynamic monitoring—one or more of the following
 - Reduced cardiac output
 - Arterial hypotension
 - Elevated pulmonary capillary wedge pressure (PCWP) and pulmonary artery pressure (PAP)
 - Elevated systemic vascular resistance (SVR)

500,000 cases of sepsis syndrome are seen annually, with mortality rates ranging from about 30% at 1 month to 50% at 5 months. Epidemiology studies show that approximately 25% of cases of sepsis syndrome eventually result in septic shock. Septic shock is the number one cause of death in the noncoronary ICU and the 13th most common cause of death in the United States. It has been projected that the incidence of sepsis will increase 1.5% per year mainly because of the disproportionate growth of the elderly in the U.S. population.^{17–20}

The consensus conference of the American College of Chest Physicians (ACCP) and the Society of Critical Care Medicine (SCCM) defines sepsis syndrome as a systemic inflammatory response resulting from infection.² When associated organ dysfunction, hypoperfusion, or hypotension is present, it is termed *severe sepsis*; when hypotension persists despite adequate fluid resuscitation and requires inotropic or vasopressor support, it is termed *septic shock* (see Table 21-5 for definitions). More than half the cases of septic syndrome occur in the ICU, one-third occur in other currently hospitalized patients, and 10% to 15% of cases are present on admission to the emergency department (ED).¹⁹ Progression to septic shock occurs in about half of patients who have septic syndrome within 1 month of onset, as defined by hypotension. Persons most at risk for septic shock are those who are immunocompromised or have underlying conditions that render them susceptible to bloodstream invasion. Groups at risk include neonates, the elderly, patients with acquired immune deficiency syndrome (AIDS),

alcoholics, childbearing women, and those undergoing surgery or who have experienced trauma. Other predisposing factors include coexisting diseases such as diabetes mellitus, malignancies, chronic hepatic or renal failure, and hyposplenism; exposure to immunosuppressant drugs and cancer chemotherapy; and procedures such as insertion of urinary catheters, endotracheal tubes, and IV lines.

Septic shock is characterized initially by a normal or high cardiac output and a low systemic vascular resistance (Table 21-3). Hypotension is caused by the low SVR as well as alterations in macrovascular and microvascular tone, which result in maldistribution of blood flow and volume. Changes in the microvasculature can lead to loss of normal microvascular autoregulatory mechanisms resulting in constriction of capillaries, changes in cellular rheology, fibrin deposition, and neutrophil adherence. This causes vascular “sludging” and, in some cases, arteriovenous shunts that bypass capillary beds. Loss of intravascular fluid caused by increased vascular permeability and third spacing of fluid further adds to hypovolemia. In an effort to compensate for the changes in volume and SVR, the body goes into a hyperdynamic state and increases CO. Most patients develop myocardial dysfunction as manifested by decreased myocardial compliance, reduced contractility, and ventricular dilation, but maintain a normal CO because of tachycardia and cardiac dilatation. Although the cause of, and mechanism for, this abnormality are not fully understood, it is not believed to be caused by myocardial ischemia. Rather, it is thought to be caused by one or more circulating inflammatory mediators, such as cytokines, tumor necrosis factor- α (TNF- α), platelet activating factor (PAF), arachidonic acid, nitric oxide (NO), and reactive oxygen species. In late septic shock, the body is no longer able to compensate because of the cardiac effects of the inflammatory mediators and myocardial edema, therefore resulting in a decreased CO. The end product of this complicated pathway is cellular ischemia, dysfunction, and eventually cellular death unless the chain of events is interrupted.

The pathogenesis of sepsis is more fully understood now, but the exact mechanisms are still not completely clear. It is known that the changes that take place during sepsis are caused by the immunologic host response to infection which involves inflammatory and immunodepressive (anti-inflammatory) phases. It is unknown, however, whether these phases are sequential (inflammatory then immunodepressive) or whether immunosuppression is a primary response to sepsis rather than a compensatory response.

The inflammatory stage of sepsis is initiated by an infection with a microorganism, most commonly bacterial. Organisms can either enter the bloodstream directly (producing positive blood cultures) or may indirectly elicit a systemic inflammatory response by locally releasing their toxins or structural components at the site of infection. The lipopolysaccharide endotoxin of gram-negative bacteria is the most potent soluble product of bacteria that can initiate a response and is the most studied, but other bacterial products can initiate the response, including exotoxins, enterotoxins, peptidoglycans, and lipoteichoic acid from gram-positive organisms. The binding of these toxins to cell receptors promotes proinflammatory cytokine production, primarily TNF- α and IL-1. These toxins stimulate the production and release of numerous endogenous mediators that are responsible for the inflammatory consequences of sepsis.

Table 21-5 ACCP/SCCM Consensus Conference Definitions

| | |
|--|---|
| Infection | Microbial phenomenon characterized by an inflammatory response to the presence of microorganisms or the invasion of normally sterile host tissue by those organisms. |
| Bacteremia | The presence of viable bacteria in the blood. |
| Systemic inflammatory response syndrome (SIRS) | The systemic inflammatory response to a variety of severe clinical insults. The response is manifested by two or more of the following conditions: Temperature >38°C or <36°C Heart rate >90 beats/min Respiratory rate >20 breaths/min or PaCO ₂ <32 mmHg (<4.3 kPa) WBC >12,000 cells/mm ³ , <4,000 cell/mm ³ , or >10% immature (bands) forms |
| Sepsis | The systemic response to infection. The systemic response is manifested by two or more of the following conditions as a result of infection: Temperature >38°C or <36°C Heart rate >90 beats/min Respiratory rate >20 breaths/min or PaCO ₂ <32 mmHg (<4.3 kPa) WBC >12,000 cells/mm ³ , <4,000 cell/mm ³ , or >10% immature (band) forms |
| Severe sepsis | Sepsis associated with organ dysfunction, hypoperfusion, or hypotension. Hypoperfusion and perfusion abnormalities may include, but are not limited to, lactic acidosis, oliguria, or an acute alteration in mental status. |
| Septic shock | Sepsis with hypotension, despite adequate fluid resuscitation, along with perfusion abnormalities that may include, but are not limited to, lactic acidosis, oliguria, or an acute alteration in mental status. Patients who are on inotropic or vasopressor agents may not be hypotensive at the time that perfusion abnormalities are measured. |
| Hypotension | A systolic BP of <90 mmHg or a reduction of >40 mmHg from baseline in the absence of other causes for hypotension. |
| Multiple organ dysfunction syndrome | Presence of altered organ function in an acutely ill patient such that homeostasis cannot be maintained without intervention. |

The cytokines act synergistically to directly affect organ function and stimulate the release of other proinflammatory cytokines, such as IL-6, IL-8, PAF, complement, thromboxanes, leukotrienes, prostaglandins, NO, and others.

The presence of these cytokines promotes inflammation and vascular endothelial injury, but also causes an overwhelming activation in coagulation. Thrombin has potent proinflammatory and procoagulant activities and its production is increased in sepsis. The human body normally counteracts these effects by increasing fibrinolysis, but the homeostatic mechanisms in the septic patient are dysfunctional. There are decreases in the levels of protein C, plasminogen, and antithrombin III as well as increased activity of plasminogen activator inhibitor-1 (PAI-1) and thrombin activatable fibrinolysis inhibitor (TAFI), endogenous agents that inhibit fibrinolysis.²¹ The patient is in a coagulopathic state, which promotes formation of microvascular thrombi leading to hypoperfusion, ischemia, and ultimately, organ failure. Multiple organ failure is responsible for about half the deaths caused by septic shock.²²

The clinical features of septic shock are fever, chills, nausea, vomiting, and diarrhea. Characteristic laboratory findings include leukocytosis or leukopenia; thrombocytopenia with or without coagulation abnormalities; and often, hyperbilirubinemia. These features are usually readily detectable and occur within 24 hours after bacteremia develops, particularly if the bacteremia is caused by gram-negative organisms. In the ex-

trêmes of age (very young or very old) or in debilitated patients, hypothermia can be present, however, and positive findings may be limited to unexplained hypotension, mental confusion, and hyperventilation.

In contrast to the classic progression of shock, persons dying from septic shock often have a normal or elevated CO. Death within the first week after the onset of sepsis occurs as a result of intractable arterial hypotension that is secondary to a significantly depressed SVR. This causes extensive maldistribution of blood flow in the microvasculature, with subsequent tissue hypoxia and the development of lactic acidosis. Death occurring beyond the first week usually is caused by multiple organ failure that began during the acute circulatory failure. Severe, unresponsive hypotension as a result of a decreased CO does occur in a subpopulation of patients with septic shock; cardiogenic shock becomes superimposed on the distributive shock of sepsis, but this is not the most common cause of death.²³

HYPOVOLEMIC SHOCK

Acute Hemorrhagic Shock

1. B.A. is a 55-year-old man brought to the ED after being stabbed in the abdomen; he had significant blood loss at the

scene. On arrival, he is confused and oriented only to person. His skin is pale and cool, with vital signs showing a HR of 125 beats/minute, SBP of 85 mmHg, and a RR of 30 breaths/minute. Describe the physiologic changes in B.A. in response to his injury. What are the goals of resuscitation in patients with hemorrhagic shock?

B.A. has lost a significant amount of intravascular fluid directly from his stab wound and also from traumatic tissue edema. He is hypotensive with a compensatory increase in both HR and respiratory rate (RR). His pale, cool skin indicates shunting of blood from the periphery to maintain perfusion of vital organs. Based on his clinical presentation, B.A. is in decompensated shock.

The major hemodynamic abnormality in hypovolemic shock is decreased venous return (preload) to the heart, resulting in a decrease in CO. Oxygen delivery to the tissues is reduced from this and from the loss of oxygen-carrying hemoglobin. The physiologic response of the body to a sudden decrease in volume (preload) is a release of catecholamines (epinephrine, norepinephrine). The subsequent increase in HR and contractility help maintain CO. The peripheral vasoconstriction caused by the sympathomimetic response serves to maintain arterial pressure. In addition, fluid shifts from the interstitial spaces into the vasculature to increase preload. These responses are effective at maintaining BP in patients with a loss of up to approximately 30% of the total blood volume. B.A.'s increased HR and signs of peripheral vasoconstriction are consistent with these compensatory changes. His SBP is still low, however, and he has signs of decreased perfusion to his brain, manifested by confusion and disorientation. Given the severity of his condition, if intravascular losses are not rapidly replaced, myocardial dysfunction may ensue and lead to irreversible shock.

The goals of resuscitation of patients in hypovolemic shock are the correction of inadequate tissue perfusion and oxygenation, and limiting secondary insults, such as reperfusion injury or compartment syndrome. HR, BP, and urine output have been traditional markers for the adequacy of resuscitation, but reliance on these end points alone is acceptable only in the initial management of hemorrhagic shock. One concern is that patients may persist in a state of compensated shock even after these parameters are normalized.^{24,25} Ongoing deficiencies in oxygen delivery to vital organs may progress and, if left untreated, organ dysfunction and death may result. Measurement of base (bicarbonate) deficit and lactate levels can be used to assess the global adequacy of perfusion. Metabolic acidosis can signal that resuscitation is incomplete despite normal vital signs.

Treatment

CHOICE OF FLUID IN HYPOVOLEMIC SHOCK

2. Is an IV saline solution adequate to compensate for BA's blood loss? What other type of fluid might be better to resuscitate this patient?

Once an adequate airway is established and initial vital signs are obtained, the most important therapeutic intervention in hypovolemic shock is the infusion of IV fluids. Initially, crystalloids or colloids are used to restore blood volume as blood products may not be immediately available and are frequently unnecessary to manage mild shock (10%–20% blood loss).¹⁴

CRYSTALLOIDS VERSUS COLLOIDS

Crystalloids are isotonic solutions that contain either saline (0.9% sodium chloride; "normal saline") or a saline equivalent (lactated Ringer's [LR] solution). *Colloidal solutions* contain large oncologically active molecules that are derived from natural products such as proteins (albumin), carbohydrates (dextran, starches), and animal collagen (gelatin) (Table 21-6).

The choice of a crystalloid versus a colloid solution to restore blood volume in hemorrhagic shock is controversial. The controversy primarily involves the ultimate distribution of these fluids in the extracellular compartment, which, in turn, depends on their composition. Isotonic solutions (normal saline or RL solution) freely distribute within the extracellular fluid compartment, which is divided between the interstitial and intravascular spaces at a ratio of 3:1. This distribution is determined by the net forces of colloid oncotic pressure (COP) and hydrostatic pressure, both inside and outside the capillary vascular space. Consequently, large volumes of crystalloid fluid are required to expand the intravascular space during resuscitation. In contrast, intact capillary membranes are relatively impermeable to colloids and, therefore, colloids effectively expand the intravascular space with little loss into the interstitium. Comparatively smaller volumes of colloids than of crystalloids are thus required for resuscitation, and because these large molecules persist intravascularly, their duration of action is longer. It is often thought that three to four times as much volume of crystalloid is necessary to provide the same degree of volume expansion as obtained from a colloid. Many of the colloidal agents, however, can cause allergic or hypersensitivity reactions as well as coagulopathic effects and colloids are much more expensive than crystalloids.

Proponents of crystalloids argue that both intravascular and interstitial fluids are depleted in hypovolemic shock because of the rapid shifts between the extracellular compartments. Volume replacement of both fluid spaces is best accomplished

Table 21-6 Composition and Properties of Crystalloids

| Solution | Sodium (mEq/L) | Chloride (mEq/L) | Potassium (mEq/L) | Calcium (mEq/L) | Magnesium (mEq/L) | Lactate (mEq/L) | Tonicity Relative to Plasma | Osmolarity (mosm/l) |
|----------------------|----------------|------------------|-------------------|-----------------|-------------------|-----------------|-----------------------------|---------------------|
| 5% Dextrose | 0 | 0 | 0 | 0 | 0 | 0 | Isotonic | 253 |
| 0.9% Sodium Chloride | 154 | 154 | 0 | 0 | 0 | 0 | Isotonic | 308 |
| Plasma-Lyte (Baxter) | 140 | 103 | 10 | 5 | 3 | 8 | Isotonic | 312 |
| Lactated Ringer's | 130 | 109 | 4 | 3 | 0 | 28 | Isotonic | 273 |
| 7.5% Sodium Chloride | 1,283 | 1,283 | 0 | 0 | 0 | 0 | Hypertonic | 2,567 |

by using crystalloids. In addition, loss of capillary integrity in shock can cause the leak of larger molecules (e.g., the colloidal proteins) into the interstitium. This increase in the oncotic pressure in the interstitium would favor fluid movement out of the vascular space into the tissues, with resultant edema.

Proponents of colloids contend that resuscitation with these solutions more rapidly and effectively restores intravascular volume following acute hemorrhage. For a given infusion volume, colloidal solutions (e.g., albumin) will expand the intravascular space two to four times more than crystalloids. Because a larger volume of crystalloid would have to be infused to restore the vascular space, the risk of developing pulmonary edema may be higher. It is also argued that large volumes of crystalloids will further dilute the plasma proteins, resulting in a decrease in the COP, which can also promote the development of pulmonary edema. This concept is based on Starling's law of capillary forces governing fluid movement, which in the pulmonary vessel wall is determined by the COP-PCWP gradient (i.e., the net force generated by the colloid oncotic pressure minus the pulmonary hydrostatic pressure [PCWP]). The normal colloid oncotic pressure is 25 mmHg and an average PCWP is 12 mmHg; thus, a net intravascular force of 13 mmHg favors fluid retention in the vascular space. In critically ill patients, a COP-PCWP gradient <6 mmHg is thought to be associated with a higher incidence of pulmonary edema. Despite these theoretic differences, clinical studies comparing colloids with crystalloids have failed to show any differences in the development of pulmonary edema. Research suggests that certain subgroups may be at greater risk for the development of pulmonary edema, but considerable variance remains because of differences in physiologic end points, criteria for assessing pulmonary edema, and the extent of shock.

In an effort to find a consensus among the results of divergent clinical trials, numerous meta-analyses have been performed comparing resuscitation with crystalloids or colloids. Two earlier meta-analyses concluded that resuscitation of burn and trauma patients with colloids results in increased mortality.^{26,27} The explanation offered for the detrimental effect of colloids is that trauma and burns cause an increase in pulmonary capillary and vascular permeability resulting in extravasation of the colloid into the interstitium, which further worsens the effective vascular volume and pulmonary edema. The Cochrane Database analysis found that albumin was associated with an overall higher risk of death, whereas the most recent meta-analysis funded by the Plasma Protein Therapeutics Association did not find an increase in mortality in any patient groups including trauma.^{28,29} It is important to recognize that several limitations to these meta-analyses exist because of differences in study inclusion criteria (heterogeneity), differences in fluid management, and dosages of albumin used. What is known is the difference in cost per therapy. One study determined the secondary cost-effectiveness analysis per therapy, which revealed that the cost of using crystalloids was \$43.13 per life saved, as opposed to \$1,493.60 per life saved with colloid.²⁸ These estimates were based on an average per-patient intake of 6.57 L of fluid for the crystalloid group, at a cost of \$5.95/L, and an average of 230 g of albumin in the colloid group, at a cost of \$5.00/g.

Recent evidence supports the idea that albumin may not be as detrimental as once thought. The SAFE trial is the largest randomized, prospective trial to evaluate albumin versus nor-

mal saline (NS) resuscitation in the critically ill.³⁰ The primary end point was 28-day mortality, which was not statistically different for albumin compared with NS. Also no statistical differences were identified in any of the predefined subgroups (trauma, ARDS, severe sepsis), although a trend was seen toward increased mortality in the trauma patients who received albumin, most specifically in patients with head trauma. Because resuscitation with albumin was not found to be better than saline, this landmark trial will most likely alter perceptions of albumin; whether or not this trial will have an impact on albumin prescribing practices remains to be determined.

Given the lack of evidence for a significant clinical difference between crystalloids and colloids and the greater expense of using albumin, the guidelines for the use of resuscitation fluids developed by the University Hospital Consortium (UHC), a nonprofit alliance of U.S. academic medical centers, remain unchanged.³¹ For the resuscitation of hemorrhagic shock, crystalloids should be the initial fluid of choice. The American College of Surgeons Advanced Trauma Life Support course¹⁴ also recommends the rapid infusion of isotonic crystalloids for the initial fluid resuscitation of trauma patients. Thus, use of either normal saline or LR solution would be appropriate for B.A. Albumin and blood are not needed.

CRYSTALLOIDS

3. A large-bore IV catheter is inserted into B.A.'s arm and STAT blood samples are sent for type and crossmatch, complete blood count (CBC), prothrombin time (PT), partial thromboplastin time (PTT), and serum chemistry (BUN, creatinine, Na, K, Cl, and bicarbonate). Warmed LR solution (2 L) is infused rapidly, and the operating room is notified. B.A.'s systolic BP has increased to 90 mmHg, but the bleeding has not stopped. A Foley catheter is inserted to measure urine output. LR is continued, with 500 to 1,000 mL boluses ordered to be given to maintain hemodynamic stability while waiting for fully crossmatched blood. Are the doses of LR given to B.A. appropriate? What clinical and objective parameters should be monitored to determine the success of fluid replacement?

Volume Requirements

Isotonic crystalloids equilibrate rapidly between the interstitial and intravascular spaces at a ratio of 3:1. For every liter of fluid infused, approximately 750 mL will pass into the interstitium, whereas 250 mL will remain in the plasma. Based on estimated blood loss, the "three-to-one rule" may be applied as a general guideline: for each 1 mL of blood loss, 3 mL of crystalloid is infused. Because this determination of blood loss is based solely on clinical assessment and not on quantitative measurements, treatment is best directed by the response to initial therapy rather than the initial classification. Close observation of hemodynamic status with consideration of the patient's age, particular injury, and prehospital fluid therapy is essential to avoid inadequate or excessive fluid administration.

A safe and effective approach for using crystalloids in the resuscitation of patients in hemorrhagic shock is to give 1 to 2 L of fluid as an initial bolus as rapidly as possible for an adult or 20 mL/kg for a pediatric patient.¹⁴ Additional fluid boluses may be necessary, depending on the patient's response. Between boluses, fluids are slowed to maintenance rates

(150–200 mL/hour), with ongoing evaluation of the patient's physiologic response for signs of continued blood loss or inadequate perfusion that would indicate the need for additional volume replacement.

Indications that circulation is improving include normalization of BP, pulse pressure, and HR. Signs that actual organ perfusion is normalizing and that fluid resuscitation is adequate include improvements in mental status, warmth and color of skin, improved acid-base balance, and increased urinary output. The minimal acceptable urine output for a patient is 0.5 mL/kg. Persistent metabolic acidosis in a normothermic shock patient usually indicates the need for additional fluid resuscitation; sodium bicarbonate is not recommended unless the pH is <7.2.¹⁴ The serum lactate and base deficit are important values to track to determine that the patient is receiving adequate resuscitation. It is important to note that resuscitation is not defined by just one value or number, such as BP, but the constellation of indicators of overall perfusion.

LACTATED RINGER'S VERSUS NORMAL SALINE

4. Is there an advantage to using LR solution over normal saline?

The American College of Surgeons Committee on Trauma recommends lactated Ringer's solution as the fluid of choice for the initial resuscitation of trauma patients and normal saline as the second choice.¹⁴ Because normal saline has a high chloride content (45 mEq more than LR), it can cause hyperchloremic acidosis, thereby worsening the tissue acidosis that occurs in the setting of hypovolemic shock. This likelihood is increased with impaired renal function. LR, in contrast, is a buffered solution designed to simulate the intravascular plasma electrolyte concentration. It contains 28 mEq/L of lactate, which is metabolized to bicarbonate in patients with normal circulation and intact liver function.³² In situations in which hepatic perfusion is reduced (20% of normal) or hepatocellular damage is present, lactate clearance may be significantly decreased, particularly in combination with hypoxia (O₂ saturation 50% of normal).³³ In patients with shock and those having cardiopulmonary bypass during surgery, the half-life of lactate, normally 20 minutes, increases to 4 to 6 hours and 8 hours, respectively. Because unmetabolized lactate can be converted to lactic acid, prolonged infusion of LR could cause tissue acidosis in predisposed patients. In actuality, however, no differences in serum pH, electrolytes, lactate, or survival have been found in patients with hemorrhagic trauma who have received either LR or normal saline. In practice, normal saline and LR typically are used interchangeably because neither solution appears to be superior to the other.

HYPERTONIC SALINE

5. What is the role of hypertonic saline (HS) in the setting of hemorrhagic shock?

The use of HS (with and without dextran) for resuscitation in hemorrhagic shock has been studied extensively in animal models,^{34–36} and more recently has been the focus of clinical research.^{37–39} The advantage of HS as a resuscitative fluid is the smaller volume of fluid required to expand the intravascular compartment as compared with isotonic solutions. This could be a particular advantage in the prehospital setting (e.g.,

field rescue by emergency medical technicians) given the large volumes of fluids necessary to keep up with ongoing blood loss.

With a high concentration of sodium, HS exerts an osmotic effect, translocating fluid from the interstitial and cellular compartments to the intravascular space. Consequently, plasma volume is rapidly expanded to a greater extent than similar volumes of crystalloid solutions, and systemic BP, CO, and oxygen transport are readily increased. HS also improves myocardial contractility, causes peripheral vasodilation, and redistributes blood flow preferentially to the splanchnic and renal circulation. In addition, intracranial pressure is reduced, which may be a potential advantage in trauma patients with concomitant head injury.^{34–39}

Hypertonic saline-dextran (7.5% sodium chloride in 6% dextran 70 [HSD]) was compared with isotonic crystalloid solution for prehospital resuscitation in a multicenter trial of hypotensive trauma patients.³⁸ Patients were randomly assigned to receive 250 mL of either HSD or a standard isotonic solution, after which fluids were given as necessary to achieve stabilization. No differences in overall survival were noted; however, a significant survival advantage was seen in the HSD group requiring surgery. Fewer complications occurred in the HSD group, including a lower incidence of ARDS, renal failure, and coagulopathy. Although serum sodium levels were significantly higher in the HSD group, no adverse clinical symptoms of hypernatremia were seen.

In a similar trial, the effects of resuscitation with 250-mL volumes of HS (7.5%), HSD, or normal saline were compared in trauma patients admitted to the ED in hypovolemic shock.³⁹ Differences in overall mortality or complication rates in the three groups were not significant. In comparison to isotonic saline, however, the hypertonic solutions significantly improved MAP and significantly decreased the volume of fluid required to restore systolic pressure.

Recent studies with HS suggest that it may help to reduce multiple organ system failure and infections following traumatic injury. The mechanism has yet to be fully elucidated, but in animal models, HS reduces neutrophil margination,⁴⁰ which may play a role in the development of lung injury, ARDS, and reperfusion injury. In another study the use of HS resulted in a decreased susceptibility to sepsis and improved survival in a murine model of hemorrhagic shock.⁴¹

These clinical trials suggest that HS may be safe and effective for the initial resuscitation of hemorrhagic shock and may help prevent the development of posttraumatic multiple organ system failure and sepsis. Despite these positive findings, hypertonic saline solutions are not widely used.

BLOOD REPLACEMENT

6. B.A. has received 3 L of LR solution to maintain hemodynamic stability. His current vital signs are BP, 92/60 mmHg; HR, 115 breaths/minute; and RR, 28 breaths/minute. He is still confused and is becoming more agitated and combative. Urine output has been only 10 mL in the past 30 minutes. Laboratory results include the following: hematocrit, 23% down from 27% (normal, 40%–54%); hemoglobin, 7.6 g/dL down from 9 g/dL (normal, 14–18 g/dL); ABG pH, 7.18 (normal, 7.35–7.45); Pco₂, 35 mmHg (normal, 35–45 mmHg); Po₂, 110 mmHg (normal, 75–100 mmHg); and HCO₃⁻, 17 mEq/L (normal, 23–29 mEq/L). Two

units of packed red blood cells (PRBC) are now available, and B.A. is being prepared for the operating room. Describe the current status of B.A.'s resuscitation and the need for blood products.

[SI units: Hct, 0.23 (normal, 0.40–0.54); hemoglobin, 1.18 mmol/L (normal, 2.17–2.79 mmol/L); HCO_3^- , 17 mmol/L (normal, 23–29 mmol/L)]

B.A. is still exhibiting signs of inadequate tissue perfusion. Although his BP has improved and his HR has decreased, his mental status has declined, urine output has been negligible, and his blood gas indicates metabolic acidosis. B.A. has not been adequately resuscitated from his hemorrhage, is still actively bleeding, and should receive the available blood at this point.

The prior conventional approach to the transfusion of critically ill patients was to maintain the hemoglobin above 10 g/dL or the hematocrit above 30%. This transfusion trigger was found to be detrimental in a population of mixed medical-surgical ICU patients compared with a group of patients who were maintained at a lower hemoglobin of 7 g/dL and therefore received fewer transfusions. This lower hemoglobin level may be appropriate for critically ill patients who are in an ICU and have decreased hematocrit values because of fluid resuscitation and daily blood draws, but not for a patient who is actively bleeding as evidenced by the falling hemoglobin and hematocrit and signs of underperfusion. In acute hemorrhage, the actual degree of blood loss is not accurately reflected by the hemoglobin and hematocrit values, and it also does not take into account the body's ability to compensate for the loss of oxygen-carrying capacity. Because it takes at least 24 hours for all fluid compartments to come to equilibrium, a normal hematocrit (or Hgb concentration) in the setting of hemorrhagic shock does not rule out significant blood loss or indicate adequacy of transfusion. Only when equilibrium has been reached can these measures be used reliably to gauge blood loss. On the other hand, if cardiopulmonary function is normal and if volume status is maintained, an increase in CO can compensate for a reduction in hemoglobin (O_2 content) to a certain degree (Fig. 21-1).

Because inadequacy of tissue perfusion, and hence oxygen delivery, is the primary abnormality in shock, the need for transfusion therapy is more accurately determined by the patient's oxygen demand, rather than an arbitrary hematocrit or hemoglobin value. Calculation of DO_2 and VO_2 can be used to determine the adequacy of perfusion. Although these values can be determined by use of a pulmonary artery catheter and arterial and venous blood samples, for practical purposes, the patient's response to initial fluid resuscitation and clinical signs of inadequate tissue perfusion are the primary determinants for blood transfusion. Patients who are not acutely bleeding and who do not respond to initial volume resuscitation or who transiently respond but remain tachycardic, tachypneic, and oliguric, clearly are underperfused and will likely require blood transfusion. Trauma patients who have acute bleeding issues or who demonstrate signs of underperfusion should be considered for transfusion much sooner, thus B.A. should receive a transfusion.

ADVERSE EFFECTS OF TRANSFUSION

7. After the transfusion, B.A. has a serum potassium concentration of 4.8 mEq/L (normal, 3.7–5.2 mEq/L) compared with

4.5 mEq/L before the transfusion. Could this be a result of the blood product? Is B.A. also at risk for contracting human immunodeficiency virus (HIV) or viral hepatitis from his transfusion of PRBC? Would whole blood be a better choice than packed cells?

Possible risks of blood transfusions include electrolyte abnormalities, hemolytic reactions, transmission of infectious disease, coagulopathies, and immunosuppression. Banked blood is stored with citrate anticoagulant additive. With multiple transfusions, the large amount of citrate can cause hypocalcemia and acid-base abnormalities. Hyperkalemia also can occur because transfusion of stored blood causes the release of potassium from hemolyzed (ruptured) red blood cells (RBC). Hemolytic transfusion reactions are the most common cause of acute fatalities from blood transfusions. Astute recognition of the signs and symptoms of a transfusion reaction, such as anxiety, pain at infusion site, fever, hypotension, tachycardia, hemolysis, and hemoglobinuria, can prevent unnecessary morbidity and mortality. Transfusions can also cause acute lung injury owing to recipient neutrophil priming by reactive lipid products from the red blood cell membrane, which causes capillary endothelial damage in the lungs. The increase in serum potassium observed in B.A. may be from the blood product or it may simply reflect hemolysis of blood cells in the test tube after the blood draw. In either case, the measured serum concentration of 4.8 mEq/L is not sufficiently high to be of concern. It is unlikely that a true hemolytic reaction is occurring.

Blood products and donors are screened for disease, thus transmission of viral illness is a small risk. It is estimated that the transmission of hepatitis B is 1 case for every 63,000 units transfused, hepatitis C is 1:103,000, and HIV is 1:676,000.⁴²

Hemostatic abnormalities, specifically coagulopathies and thrombocytopenia, may be transiently related to dilution from administration of large volumes of crystalloids, colloids, or banked blood, but are more likely caused by the extent of injury and the development of disseminated intravascular coagulopathy. Banked whole blood contains sufficient coagulation factors (including labile factors V and VIII) to maintain hemostasis during the life span of the unit; however, it does not contain platelets because they do not survive the temperatures required for RBC storage.

Immunosuppression has also been associated with blood transfusions as evidenced by enhanced graft survival in renal transplant recipients, tumor recurrence in patients with colorectal carcinoma, and in postoperative infections. The immunosuppression from transfusion is multifactorial, but it is most likely caused by the infusion of donor white cells, which create a competition between the donor and recipient leukocytes. This mechanism is not, however, the only cause because immunosuppression is associated with autologous blood transfusions as well as the infusion of plasma alone.

Whole blood offers no significant advantage over packed red cells as long as other less-expensive fluids (crystalloids) are used for volume expansion. After extracting the red cells to provide oxygen-carrying capacity, other blood elements (e.g., fresh frozen plasma and platelets, clotting factors) can be used for other patients with specialty needs. Thus, packed RBC are an appropriate blood replacement product for B.A. His PT, PTT, platelets, electrolytes, and mixed venous blood gases, if available, should be monitored frequently. These tests enable correction of any coagulopathy or electrolyte abnormality and

assist in the assessment of the adequacy of tissue oxygenation. This information, in addition to the aforementioned factors, can be used to gauge his response to therapy and his need for supplemental blood products such as platelets and frozen fresh plasma.

Because of the limited supply and potential adverse effects associated with blood, research is under way to develop blood substitutes. The ideal agent would have a longer shelf life, a reduced risk of disease transmission, and less risk of transfusion reactions. The agents in various stages of clinical research include the modified hemoglobins and the perfluorocarbons. The exact role the blood substitutes would play in transfusions is unclear, and problems have occurred, such as short half-life and vasoconstriction associated with some of the products thus far. No agents have yet been approved, but research is continuing.

Postoperative Hypovolemia

Hypovolemia versus Pump Failure

8. B.A. goes to the operating room and they find several colonic tears that require a colon resection. He has been admitted to the ICU following surgery, intubated and receiving 60% oxygen. His ABG are adequate and he is receiving 150 mL/hour of LR solution intravenously. His initial post-operative and 2-hour postoperative hemodynamic profiles are as follows (initial parameters in parentheses): BP (S/D/M), 90/50/63 (110/70/68) mmHg; pulse, 90 beats/min (84); CO, 3 L/min (4.5); CVP, 6 (10); PCWP, 8 mmHg (12); SVR, 1,200 dyne.sec.cm⁻⁵ (950); urine output, 25 mL/hour (70); temperature, 37.9°C (35); Hct, 32% (30%). Based on the hemodynamic profile, determine whether B.A. is hypovolemic or experiencing pump failure following his surgery.

[SI unit: Hct, 0.32 (normal, 0.40–0.54)]

Most of B.A.'s hemodynamic changes are consistent with hypovolemia. These include a drop in BP, CVP, CO, PCWP, and urine output. The decrease in PCWP suggests that preload is reduced, resulting in a lower CO. Urine output has declined and probably reflects a compensatory drop in renal perfusion to preserve intravascular volume. The pulse pressure is narrowed, suggesting blood flow has decreased. (Changes in pulse pressure correlate with changes in SV in individual patients; that is, as pulse pressure narrows, SV decreases.) B.A.'s HR did not increase by that much, but it is unclear if he was taking any medications before his injury, such as a β -blocker. As the body temperature rises postoperatively, vasodilation decreases SVR and increases the intravascular space. If intravascular volume is inadequate and increased sympathetic tone cannot generate a sufficient CO, mean BP falls. The most likely explanation for the hemodynamic change in B.A. is hypovolemia, although he also should be evaluated for the occurrence of a perioperative cardiac event. His ABG should be checked to assess oxygen requirements.

Causes

9. What are the most likely causes of hypovolemia in B.A.?

Common causes of hypovolemia in surgical patients are postoperative bleeding, third spacing, and temperature-related vasodilation. Postoperative bleeding can produce hypovolemia; however, B.A.'s initial and 2-hour postoperative he-

matocrit of 30% and 32%, respectively, do not support bleeding as a cause.

Following major vascular or bowel surgery, it is not unusual for patients to "third space" significant amounts of intravascular volume. The bowel walls and interstitial space can sequester large amounts of fluids, and this can produce a state of relative hypovolemia as is occurring with B.A. This is especially apparent for the first 12 to 24 hours after the surgical procedure. B.A. is receiving 150 mL/hour of LR solution, but this is apparently not sufficient to maintain his intravascular volume.

Mild hypothermia is common during operative procedures. As patients warm up postoperatively, vasodilation occurs, expanding the intravascular space. If the amounts of IV fluids administered are insufficient to compensate for the increased venous capacitance, BP and CO will decline during the re-warming phase, which can range from 1 to 6 hours. B.A. has rewarmed from 34°C to 37°C in 2 hours, which is not unusual after a major operative procedure. His temperature could conceivably rise to as high as 38°C to 38.5°C during the first 12 to 24 hours after surgery.

Other considerations include inadequate fluid administration during the operative procedure and the effects of drugs given in the operating room or in the immediate postoperative period (e.g., morphine sulfate and other narcotics) that have systemic vasodilatory properties.

Volume Replacement and Ventricular Function

10. How will volume replacement improve B.A.'s CO and perfusion pressure?

Starling's mechanism indicates that the volume of blood returned to the heart is the main determinant of volume pumped by the heart. Therefore, as venous return is increased, the CO also will increase within physiologic limits (Fig. 21-1). The PCWP, which approximates LV end-diastolic volume, can be used to assess venous return or preload to the left ventricle.

A ventricular function curve can be constructed by plotting a measure of cardiac pumping action (CO, SV, or LVWSI) against a measure of preload (PCWP). A change in preload moves the ventricular output upward or downward along a given curve (Fig. 21-3). Two hours after surgery, B.A.'s PCWP has fallen from 12 to 8 mmHg and his CO has fallen from 4.5 to 3 L/minute. Therefore, additional volume replacement is warranted.

11. B.A. is given a 500-mL bolus of NS over 10 minutes and this results in the following hemodynamic profile: BP (S/D/M), 96/60/71 mmHg; pulse, 84 beats/minute; CO, 3.5 L/minute; PCWP, 10 mmHg; SVR, 1,170 dyne.sec.cm⁻⁵. Assess B.A.'s response to the fluid challenge (see Table 21-2 for normal values).

According to the Starling curve, a small change in PCWP in response to a volume challenge with a minimal change in CO, represents a ventricle on the flat portion of the ventricular function curve (Fig. 21-3). Additional fluid therapy given to these patients can increase their risk for pulmonary edema without improving CO. In contrast, a large change in PCWP in response to a fluid challenge with a significant increase in CO represents a ventricle on the steep portion of the curve. In B.A., the change in PCWP from 8 to 10 mmHg and the increase in CO show that he is still responsive to fluid; thus, it is reasonable to administer more fluid to enhance CO and renal perfusion.

Fluid Challenge

12. One hour after the 500-mL NS bolus, B.A.'s hemodynamic profile returns to his postoperative state. ABG are acceptable and LR solution is infusing at 200 mL/hour. B.A. is continuing to "third-space" intravascular volume. Based on this information, develop guidelines for additional fluid challenges in B.A.

Acceptable guidelines for administering additional fluid challenges to hypovolemic patients are based on the direction and degree of change in the various hemodynamic parameters in response to a fluid load rather than to their absolute values. These include the right atrial pressure, PCWP, CO, and BP. Using the PCWP as a guide, an increase in the PCWP of 5 mmHg after a 250- to 500-mL fluid challenge over 10 minutes implies the LV is still functioning on the steep portion of the volume-pressure curve. If the PCWP rises abruptly as fluid is given, with a small change in CO, the flat portion of the ventricular function curve has been reached and the IV infusion rate should be slowed. If signs and symptoms of inadequate tissue perfusion fail to improve or worsen and if the PCWP remains > 16 to 18 mmHg, fluid challenges should be stopped and inotropic therapy initiated.

Generally, most critically ill patients require a CI > 2.5 L/minute/m² and a PCWP of 10 to 18 mmHg to maintain acceptable MAP of 65 to 75 mmHg. A downward trend in the lactate and base deficit, the change in hemodynamic parameters as well as vital signs and urine output should serve as appropriate indicators for additional fluid.

13. B.A. has received a total of 3.5 L normal saline in boluses over the past 6 hours and remains hemodynamically unchanged. His urine output has averaged 25 mL/hour for the past 4 hours, indicating volume replacement is inadequate. Given his age and the lack of response to initial crystalloid administration, the decision is made to infuse 500 mL of 6% hetastarch over the next 30 minutes. How does hetastarch compare with human serum albumin as a volume expander for B.A.?

Albumin and Hetastarch

Albumin, the predominant protein in the plasma, accounts for approximately 80% of the colloid oncotic pressure,⁴³ the force that maintains fluid in the intravascular space. Human serum albumin is the colloidal agent against which all others are compared for volume-expanding properties. It is prepared commercially from pooled donor plasma that is heat-treated to eliminate the potential for disease transmission. On infusion, 5% albumin increases plasma volume by approximately half the volume infused, or 18 mL/g, with an initial duration of action of 16 hours.⁴³ Substantial side effects primarily involve transient clotting abnormalities and anaphylactic reactions (0.5%), both of which are rare.³⁵ The anaphylactoid reaction is caused by the pasteurization process, causing albumin to polymerize, which produces an antigenic macromolecule. Albumin solutions also contain citrate, which can lower serum calcium concentrations, and which in turn could theoretically lead to decreased LV function.³² It is now generally believed that the effects on coagulation and serum calcium are related to the volume of fluid infused rather than albumin administration.⁴³ Albumin is available as a 5% solution that is isotonic with the plasma and a 25% solution that is hypertonic. The 5% solution is generally preferred for routine volume expansion, whereas

the 25% solution is most useful in correcting hypoproteinemia or intravascular hypovolemia in patients with excess interstitial water.

Hetastarch or hydroxyethyl starch (HES) is a synthetic colloid made from amylopectin, which closely resembles human serum albumin, but is considerably less expensive. Available as a 6% solution in normal saline, HES expands the plasma volume by an amount greater than the volume infused because the high oncotic pressure draws water from the interstitial spaces. HES solutions are composed of a wide range of molecular weights which explains its complex pharmacokinetics. It has an average molecular weight of 69,000 units with a range of 10,000 units to greater than 1 million units. Smaller molecular weights are excreted more quickly in the urine, whereas larger particles remain in the circulation longer and are slowly taken up by tissues or the reticuloendothelial system. The clinical effects of HES last up to 24 hours. Hetastarch generally is well tolerated with a low incidence of side effects and allergic reactions. Dose-related reductions in platelet count and transient increases in PT and PTT have been reported with moderate infusions of HES (<1,500 mL/day) and are significant with larger volumes.⁴⁴ HES causes factor VIII levels to be lowered beyond that which can be attributed to hemodilution and also increases fibrinolysis. This places patients with von Willebrand's disease at greater risk of bleeding. There have not been any direct accounts of HES causing bleeding, but it is recommended that a maximum of 20 mL/kg/day (or 1,500 mL) be used to prevent alterations in coagulation parameters. Most patients respond to 500 to 1,000 mL so this limit does not usually impede treatment. HES can also cause elevation in serum amylase levels up to three times the normal level. This is because hetastarch binds to amylase and thus delays its excretion. HES does not actually interfere with pancreatic function.

Numerous clinical studies have compared albumin and hetastarch for fluid resuscitation in patients with and without shock. One study reported that HES was as effective as albumin in restoring hemodynamic stability and improving oxygen delivery in patients who were given comparable amounts of either fluid over 24 hours.⁴⁵ Other studies in hypovolemic patients have reported no difference in hemodynamic parameters when similar volumes of either HES or albumin were given as serial boluses to maintain CO and ventricular filling pressures.^{46,47} In postoperative cardiac surgery patients, HES and albumin were found to be equally efficacious in restoring volume status and maintaining hemodynamic stability.^{48,49}

In summary, resuscitation with moderate volumes of hetastarch is safe and hemodynamically equivalent to albumin. Either 5% albumin or 6% HES would be acceptable for intravascular volume expansion in B.A.

CARDIOGENIC SHOCK

Postoperative Cardiac Failure

Assessment by Hemodynamic Profile

14. R.G. is a 68-year-old man who is admitted to the ICU following coronary artery bypass grafting. He has a long history of ischemic heart disease with two previous myocardial infarctions. His preoperative ejection fraction was 45%. He also has a history of hypertension and hypercholesterolemia. His home medications

are aspirin, lisinopril, metoprolol, and simvastatin. He is sedated, intubated, and on mechanical ventilation with 60% inspired oxygen. One hour after admission to the ICU, his blood pressure and urine output have fallen. Urine output has dropped from 80 mL/hour initially to 15 mL/hour. Chest tube output has been stable at 40 mL/hour. His ECG shows no signs of ischemia. Laboratory values show pH 7.32 (normal, 7.36–7.44); PaCO₂ 28 mmHg (normal, 35–45); PaO₂ 110 mmHg (normal, 80–100); HCO₃⁻ 20 mEq/L (normal, 23–29); Hct 34% (normal, 39%–49%). His current hemodynamic profile shows: BP (S/D/M) 92/45/61; pulse 105 beats/min; CO 2.8 L/minute (normal, 4–7) CI 1.4 L/minute/m² (normal, 2.5–4.2); CVP 12 mmHg (normal, 2–6); PA pressure (S/D) 35/22 mmHg (normal, 20–30/8–12); PCWP 22 mmHg (normal, 5–12) SVR 1400 dyne·sec·cm⁻⁵ (normal, 800–1,440). What is your assessment of R.G.'s clinical status and hemodynamics?

[SI units: HCO₃⁻, 20 mmol/L (normal, 23–29 mmol/L); Hct, 0.34 (normal, 0.39–0.49)]

Clinically, R.G. has signs of hypoperfusion manifested by low urine output and metabolic acidosis. Evaluation of his hemodynamics will help determine a potential cause for his hypoperfusion and decide on appropriate therapeutic interventions to prevent his condition to worsen to serious organ dysfunction and death.

Possible causes of hypoproliferative shock or shock in cardiac surgery patients include hypovolemia from operative and postoperative bleeding; excessive vasodilation from medications; the effects of cardiopulmonary bypass on the inflammatory cascade; tamponade; or perioperative MI. Another concern is “stunning” of the myocardium caused by surgical trauma, which can take from hours to days to resolve.

Hypovolemia should always be evaluated first when assessing hemodynamic profiles. Using pressor or inotropic agents in the setting of hypovolemia is rarely effective and can lead to serious adverse effects (e.g., cardiac arrhythmias). Also, correction of hypovolemia is relatively straightforward and can be accomplished rapidly. R.G.'s tachycardia, low urine output, low blood pressure, and low cardiac output could indicate volume depletion. His hematocrit is adequate, however, and the data from his PA catheter show an elevated CVP and PCWP, suggesting that preload is not the problem.

Excessive vasodilation is also unlikely in R.G., given that his calculated SVR (afterload) is in the high normal range. Cardiac tamponade should always be considered after cardiac surgery, and is usually manifested by very high CVP, PCWP and PA pressures, with significant decreases in CO and BP. R.G.'s CVP and PCWP are not as high as would be expected in pericardial tamponade, and his chest tube output has remained consistent, suggesting that blood is not accumulating.

Based on this hemodynamic profile, it appears that R.G. is in shock because of acute heart failure, most likely from postoperative myocardial dysfunction, although he should also be evaluated for myocardial ischemia or infarction and to rule out early cardiac tamponade. This evaluation should not delay the initiation of therapy. His severely depressed CO should be treated immediately to prevent further decompensation.

Therapeutic Interventions

15. The chest radiograph shows mild pulmonary edema, and fine rales were heard throughout the lower half of lung fields on

auscultation. Tamponade is not evident on the radiograph. The ECG shows ST-T wave changes, but no indication is seen of an acute MI. Cardiac enzymes are pending. BP and CO need to be improved to increase perfusion to vital organs. Three therapeutic interventions are available: fluid challenge, vasodilators, and inotropic agents. How would these choices affect R.G.'s ventricular function?

FLUID CHALLENGE (PRELOAD INCREASE)

Augmentation of preload with a fluid challenge to improve CO is the first option. However, R.G.'s PCWP is already 22 mmHg and increasing this value above 18 to 20 mmHg usually does not result in further benefit.⁵⁰ Furthermore, R.G. has signs of pulmonary edema on chest radiograph and his PaO₂ is 110 mmHg on 60% inspired oxygen (FiO₂). Therefore, elevation of intravascular volume might increase the pulmonary vascular hydrostatic pressure and worsen his pulmonary edema. If a fluid challenge is attempted to enhance preload, no more than 100 mL of normal saline should be given without repeating the hemodynamic measurements. If the PCWP rises, but the CO does not improve, fluid challenges should be discontinued. Elevating the preload without appreciably improving CO also can increase LV wall tension, which is a major determinant of myocardial oxygen consumption; consequently, myocardial ischemia could develop. Although R.G. has signs of pulmonary edema, diuretics to reduce his volume overload can be detrimental to his cardiac output and should not be used until R.G.'s hemodynamics and signs of hypoperfusion have improved.

VASODILATORS (AFTERLOAD REDUCTION)

A peripheral vasodilator also could be used. This will decrease pulmonary venous congestion by reducing preload (PCWP), and thus pulmonary vascular hydrostatic pressure. It will improve CO by decreasing the resistance to ventricular ejection (afterload) as well. With myocardial ischemia, a reduction of the LV filling pressure may improve subendocardial blood flow, reduce the myocardial wall tension, and reduce the LV radius. The resultant decrease in myocardial oxygen consumption will help prevent further depression of cardiac function. In patients with LV failure, arterial resistance is elevated because of a reflex increase in sympathetic tone in response to a fall in systemic arterial pressure. In LV failure, CO becomes increasingly dependent on resistance to outflow from the left ventricle. Lowering the SVR will shift the ventricular function curve up and to the left, depending on whether an arterial, venous, or mixed vasodilator is used, thereby improving cardiac performance at a lower filling pressure (Fig. 21-4).

R.G. appears to have LV failure with elevations in PCWP and SVR. Vasodilator therapy in this setting will likely improve his CO and, therefore, increase the delivery of oxygen to the tissues and prevent organ dysfunction. The major risk of vasodilator therapy in R.G., however, is further reduction of an already low MAP. Although the reduction in BP may be offset by an increase in CO, a significant drop in arterial BP could occur, which could reduce coronary pressure and thereby exacerbate or produce myocardial ischemia in addition to decreasing perfusion to other vital organ systems. Vasodilator therapy should be reserved for situations in which hemodynamic monitoring shows the patient to have LV failure with elevations in PCWP, SVR, and a systolic BP >90 mmHg.

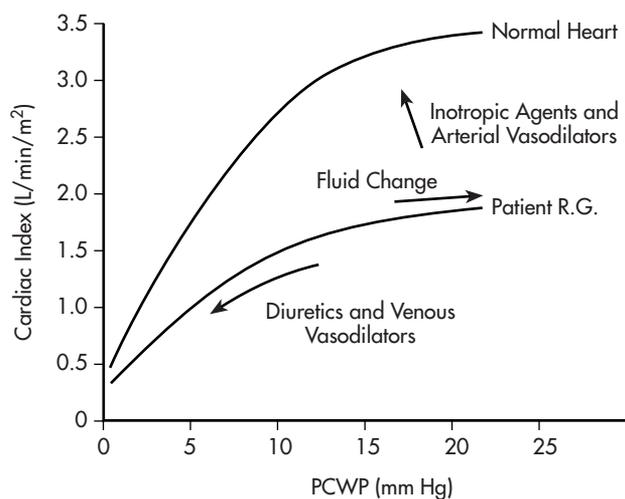

FIGURE 21-4 Ventricular function curve for R.G. PCWP, pulmonary capillary wedge pressure.

INOTROPIC SUPPORT

A rapid-acting inotropic agent (e.g., dopamine, dobutamine, epinephrine) also can be used to increase myocardial contractility and CO. This intervention shifts the ventricular function curve upward and slightly to the left (Fig. 21-4). The disadvantage of this intervention is that improved CO is accompanied by an increased myocardial oxygen demand. Depending on the agent selected, three of the determinants of myocardial oxygen consumption could be elevated: HR, contractility, and ventric-

ular wall tension. Therefore, inotropic support is directed at establishing or maintaining a reasonable arterial pressure and ensuring adequate tissue perfusion by improving the CO.

In summary, the most appropriate therapeutic intervention for R.G. at this time would be inotropic support. The PCWP is elevated, suggesting that the preload has been maximized; therefore, fluid boluses may worsen R.G.'s pulmonary edema. Although R.G.'s SVR is slightly elevated (1,400 dyne.sec.cm⁻⁵), his BP is low; therefore, initial use of a peripheral vasodilator could jeopardize perfusion. Thus, an acceptable initial therapeutic intervention to improve CO and tissue perfusion is inotropic support. After a reasonable BP has been established, addition of a peripheral vasodilator could be considered to further enhance CO if needed, and diuretics added to reduce his pulmonary edema.

Inotropic Agents

16. Which inotropic agent is the best choice for R.G.?

DOPAMINE

Dopamine, a precursor of norepinephrine, has inotropic, chronotropic, and vasoactive properties, all of which are dose dependent (Table 21-7). At 0.5 to 2 mcg/kg/minute, dopamine stimulates dopaminergic receptors primarily in the splanchnic, renal, and coronary vascular beds, which may produce vasodilation, improve renal blood flow (controversial), and maintain natriuresis. The effect on dopaminergic receptors is not blocked by β -blockers, but is antagonized by dopaminergic-blocking agents such as the butyrophenones and phenothiazines.

Table 21-7 Inotropic Agents and Vasopressors

| Drug | Usual Dose | Receptor Sensitivity | | | Pharmacologic Effect | | | |
|--------------------------|--|----------------------|-----------|-----------|----------------------|-----|------------------|-----|
| | | α | β_1 | β_2 | VD | VC | INT | CHT |
| Dobutamine | 2.5–15 mcg/kg/min | + | +++ | ++ | ++ | -- | +++ ^a | + |
| Dopamine | 0.5–2 mcg/kg/min ^b (renal) | -- | -- | -- | -- ^b | + | + | + |
| | 2–5 mcg/kg/min | -- | + | -- | -- ^b | + | + | + |
| | 5–10 mcg/kg/min | + | ++ | -- | ++ | ++ | ++ | ++ |
| | 15–20 mcg/kg/min | +++ | ++ | -- | -- ^b | +++ | ++ | ++ |
| Epinephrine ^c | 0.01–0.1 mcg/kg/min | + | +++ | ++ | + | -- | +++ | ++ |
| | 0.1 mcg/kg/min | +++ | ++ | ++ | -- | +++ | ++ | ++ |
| Isoproterenol | 0.01–0.1 mcg/kg/min | -- | ++++ | +++ | +++ | -- | +++ | +++ |
| Milrinone | 50 mcg/kg bolus, then 0.375–0.75 mcg/kg/min | -- | -- | -- | +++ | -- | ++ | -- |
| Norepinephrine | 0.05–0.5 mcg/kg/min Highly variable, titrate to desired MAP | ++++ | ++ | -- | -- | +++ | + ^d | + |
| Phenylephrine | 0.5–5 mcg/kg/min Highly variable, titrate to desired MAP | +++ | -- | -- | -- | +++ | -- | -- |
| Vasopressin ^e | 0.04 units/min ^f | -- | -- | -- | -- | +++ | -- | -- |

^aDobutamine, amrinone, and milrinone have more inotropic effect than dopamine.

^bDopamine at 0.5–2 mcg/kg/min stimulates dopaminergic receptors, causing vasodilation in the splanchnic and renal vasculature.

^cEpinephrine has predominant inotropic effects; norepinephrine has predominant vasoconstrictive effect. Epinephrine may vasodilate at low dosages, vasoconstrict at high dosages.

^dCardiac output unchanged or may decline because of vagal reflex responses that slow the heart.

^eVasopressin stimulates V₁ receptors to cause vasoconstriction in the periphery.

^fDosing for sepsis; in other vasodilatory conditions, may be titrated from 0.01 to 0.1 U/min.

CHT, chronotropic; INT, inotropic; MAP, mean arterial pressure; SBP, systolic blood pressure; VC, peripheral vascular vasoconstriction; VD, peripheral vascular vasodilation.

Depending on the clinical state of the patient, low dosages of dopamine may slightly increase myocardial contractility, but usually will not alter HR or SVR significantly.

At 2 to 5 mcg/kg/minute, the improved cardiac performance produced by dopamine is through direct stimulation of β_1 -adrenergic receptors and indirectly through release of norepinephrine from nerve terminals. Increased β_1 -adrenergic receptor stimulation increases stroke volume (inotropic effect), HR (chronotropic effect), and consequently CO. These cardiac effects can be blocked by β -blockers.

At infusion rates of 5 to 10 mcg/kg/minute, the α -adrenergic receptors are activated. At this dosage, the vasoactive effects on peripheral blood vessels are unpredictable and depend on the net effect of β_1 -adrenergic stimulation, α -adrenergic stimulation, and reflex mechanisms. MAP and PCWP usually will rise.

At doses >15 to 20 mcg/kg/minute, dopamine primarily stimulates peripheral α -adrenergic receptors. SVR increases, splanchnic and renal blood flow decreases, and LV filling pressure is raised. Cardiac irritability is a potential complication and the overall myocardial oxygen consumption is increased. The increase in SVR limits CO; thus, infusion rates should be limited to <10 to 15 mcg/kg/minute in patients with cardiac failure.

DOBUTAMINE

Dobutamine, a synthetic catecholamine, is a potent positive inotropic agent with predominant direct β_1 -agonist effects and weak β_2 - and α_1 -effects. With greater β_2 -vasodilatory than α_1 -vasoconstrictive actions, dobutamine can produce reductions in systemic and pulmonary vascular resistance. The reduction in SVR also may be caused by a reflex decrease in vasoconstriction secondary to enhanced CO. Phenoxybenzamine blocks the α -adrenergic response and propranolol blocks the β -adrenergic response. Unlike dopamine, dobutamine does not release endogenous norepinephrine or stimulate renal dopaminergic receptors.⁵¹

Studies assessing dobutamine in cardiac failure demonstrate consistent increases in CO and stroke volume, with reductions in PCWP and SVR. The reduction in filling pressures, as indicated by a lowered PCWP, results in a decrease in LV wall tension and oxygen consumption. Consequently, coronary perfusion pressure, a major determinant of coronary blood flow, improves and, thus, the oxygen supply to the heart is improved (see Glossary for the definition of perfusion pressure). In comparison to dopamine, dobutamine tends to induce less tachycardia. This feature, combined with the reductions in PCWP and systemic vascular pressure, in addition to the increased perfusion pressure, tends to reduce overall myocardial oxygen consumption.

Compared with dopamine, dobutamine has equal or greater inotropic action. Dobutamine lowers PCWP and SVR with increasing doses, whereas dopamine may increase PCWP and SVR with increasing doses.⁵² The effect on HR is variable; however, evidence suggests that dobutamine is less chronotropic than dopamine at lower infusion rates. In the clinical setting, dobutamine may be preferred in patients with depressed CO, elevated PCWP, and increased SVR with mild hypotension. The increase in CO may not be sufficient to raise the BP in a patient who initially is moderately to severely hypotensive. Thus, dopamine may be preferred in patients with

depressed CO, normal or moderately elevated PCWP, and moderate or severe hypotension.

EPINEPHRINE

Similar to dopamine, epinephrine has dose-dependent hemodynamic effects (Table 21-7). At lower infusion ranges (0.01–0.1 mcg/kg/minute) epinephrine stimulates β_1 -adrenergic receptors, causing increases in HR and contractility. As the dose increases, more α_1 -receptor stimulation occurs, resulting in vasoconstriction and corresponding increases in SVR.

Epinephrine is frequently used in the cardiac surgery setting, despite a lack of comparative evidence. A survey from Germany found that epinephrine was the first agent chosen for low cardiac output by 41.8% of physicians, compared with dobutamine by 30.9%.⁵³ The favorable hemodynamic effects (increased CO and BP) make it an attractive option for R.G.; however, epinephrine can induce hyperglycemia through gluconeogenesis and has been shown to increase lactate levels compared with other pressors and inotropes.⁵⁴ R.G. already has signs of acidosis (pH 7.32, HCO_3^- 20 mEq/L) and increased lactic acid production by epinephrine could be detrimental to his organ function. Epinephrine should be reserved for patients with a markedly depressed cardiac output in conjunction with severe hypotension.

In summary, very few comparable studies of inotropic agents in this setting have been conducted and, thus, the selection of agent is often based on the expected clinical benefit as well as individual experience with the drugs. R.G. would benefit from an increase in his CO, as well as in his MAP. The clinician elects to start R.G. on a dopamine infusion.

Selection and Initiation of Therapy

17. Based on the hemodynamic dose effects described in the previous question, at what dose would you initiate a dopamine infusion in R.G.? What therapeutic outcomes are anticipated at this dose and over what time? What adverse effects may be encountered with this dose of dopamine?

R.G. has a MAP of 61 mmHg, a CI of 1.4 L/minute/m², a PCWP of 22 mmHg, and an HR of 105 beats/minute. The goal of therapy is to increase the CI to at least 2.5 L/minute/m², maintain a MAP of at least 70 mmHg (preferably closer to 80 mmHg, depending on clinical signs of hypoperfusion), reduce the PCWP, and maintain a HR <125 beats/minute. A urine output of at least 0.5 mL/kg/hour (37 mL/hour in R.G.) is desirable. A reasonable initial infusion rate would be 3 mcg/kg/minute. This dose should increase cardiac contraction and CO, resulting in an increase in renal blood flow. Because the onset of action is within minutes, the patient can be re-evaluated and the infusion rate can be titrated upward by 1 to 2 mcg/kg/minute every 10 minutes, depending on the hemodynamic data obtained. The hemodynamic response to dopamine is highly variable among patients; thus, careful titration to lowest effective infusion rate is advised.

Adverse effects encountered with dopamine infusion include increased HR, anginal pain, arrhythmias, headache, hypertension, vasoconstriction, nausea, and vomiting. Extravasation of large amounts of dopamine during infusion can cause ischemic necrosis and sloughing. At higher dosages, α_1 -adrenergic effects are more prominent, causing peripheral arterial vasoconstriction and an increase in venous pressure that

leads to increases in afterload, preload, and myocardial oxygen demand as well as ischemia.

18. Dopamine is initiated at 3 mcg/kg/minute in R.G. and titrated to 8 mcg/kg/minute over the next 2 hours. A repeat chest radiograph shows slight worsening of pulmonary edema. The following hemodynamic profile is obtained (previous values are in parentheses): BP (S/D/M), 115/62/80 mmHg (92/45/61); pulse, 140 beats/minute (105); CO, 3.8 L/minute (2.8); CI, 2.2 L/minute/m² (1.4); RAP, 10 mmHg (12); PCWP, 20 mmHg (22); SVR, 1,473 dyne.sec.cm⁻⁵ (1,400); urine output, 30 mL/hour (15); and Hct, 36% (34). Do these data indicate a favorable or adverse hemodynamic effect from dopamine in R.G.?

Dopamine at 8 mcg/kg/minute has established a trend in the desired direction for CI; however, the HR has increased significantly. The SVR and PCWP have not changed appreciably, and the urine flow has increased. Further analysis reveals that the stroke volume (CO/HR) has only increased from 25 mL/beat to 27 mL/beat; thus, the major increase in CO has resulted from the chronotropic rather than the inotropic effect of dopamine. As a net response, the dopamine has most likely affected the myocardial oxygen supply-to-demand ratio adversely; however, this cannot be established definitively. R.G. should be monitored closely for signs of myocardial ischemia.

Changing Therapy

19. The clinician decides that a HR of 140 beats/minute is unacceptable in R.G., who has a history of MI. Subsequent attempts to taper the dopamine to lessen the induced tachycardia without dropping the CI and perfusion pressure are unsuccessful. Dobutamine is suggested as an alternative to dopamine. What hemodynamic changes would you expect with dobutamine in R.G.? Does dobutamine offer any advantages over dopamine?

As mentioned above, dobutamine has equivalent or greater inotropic action than dopamine and can cause less tachycardia. The major difference between the two agents is the effect of dopamine on α_1 -receptors. With dobutamine's absence of clinical effect on α_1 , patients may experience a decrease in the SVR resulting from the unopposed β_2 -receptor effects. In R.G., we should see an increase in CI from the inotropic effect and perhaps a decrease in SVR which would further improve his CI. We will have to monitor R.G. carefully as his MAP is still relatively low, and any major reduction in vascular resistance could adversely affect this.

20. How would you initiate therapy with dobutamine and reduce the dopamine?

Dobutamine should be started at a low dosage (i.e., 2.5 mcg/kg/minute). The onset of effect is rapid and the half-life short (approximately 2 minutes), with steady-state conditions generally achieved within 10 minutes of initiation of therapy. This allows dose titration every 10 minutes based on patient tolerance. The rate of infusion required to increase CO typically is between 2.5 and 10 mcg/kg/minute, although higher infusion rates are sometimes rarely required (up to 20 mcg/kg/minute). Once the dobutamine has been started, a reduction in the dose of dopamine should be attempted. A decrease of 20% of the current infusion rate every 10 to 15 minutes is reasonable.

21. What are the adverse effects associated with dobutamine?

Adverse effects that can occur during dobutamine administration are arrhythmias, nausea, anxiety, and tremors. The increases in contractility and HR caused by dobutamine can cause an increase in myocardial oxygen consumption and can lead to ischemia in patients with coronary artery disease. Another limiting factor to dobutamine is tolerance to its hemodynamic effects with long-term continuous use. A decline in CO and HR has been seen after prolonged infusion and is most likely caused by downregulation of β_1 -receptors. Of concern, evidence suggests that inotropic agents can be associated with an increased risk of mortality in patients with heart failure despite the improvement of symptoms and hemodynamic indices.⁵⁵

EFFECTS ON HEMODYNAMICS

22. Dobutamine is initiated and titrated up to 7.5 mcg/kg/minute. Concurrently, the dopamine is tapered down to 2.0 mcg/kg/minute, resulting in the following hemodynamic profile (previous values in parentheses): BP (S/D/M), 122/60/80 mmHg (115/62/80); pulse, 115 beats/minute (140); CO, 4.2 L/minute (3.8); CI, 2.5 L/minute (2.2); RAP, 10 mmHg (10); PCWP, 16 mmHg (20); SVR, 1,333 dyne.sec.cm⁻⁵ (1,473); PaO₂, 115 (110) mmHg; PaCO₂, 38 (28) mmHg; pH, 7.41 (7.32); HCO₃⁻, 24 mEq/L (20); and urine output, 60 mL/hour (30). Assess the improvement in hemodynamic change and urine output with the addition of dobutamine and decreased infusion rate of dopamine.

The CI has continued to increase and the PCWP and SVR have fallen. The increase in perfusion pressure in conjunction with the fall in afterload, preload, and HR will favorably affect the myocardial oxygen supply:demand ratio. The fall in HR with the increase in CO indicates that the stroke volume has increased significantly from 27 to 36 mL/beat. Other signs of improved systemic perfusion include the reversal of the acidosis observed initially and improved urine output.

The improved urine output can be attributed to the combined effects of dobutamine on the CO and subsequent improvement in the perfusion to the kidney and perhaps to the renal effects of dopamine, although the latter effects are controversial and have been debated vigorously. Traditionally, it was thought that the effects of low-dose dopamine on the dopaminergic receptors in the renal vasculature improves kidney blood flow and, consequently, renal function. Randomized, controlled trials have demonstrated increases in urine output with low-dose dopamine,⁵⁶ but have not been able to show a reduction in incidence or degree of renal dysfunction.^{57,58} Despite the lack of convincing evidence for benefit, low-dose dopamine is widely used in critical care units. The use of low-dose dopamine often does not produce any hemodynamic changes, and adverse effects are rare.⁵⁹ Thus, its use can be considered in patients with oliguria, with the understanding that it may only have a diuretic action.

Tapering Inotropic Support

23. R.G. has remained stable with dobutamine 7.5 mcg/kg/minute and dopamine 2.0 mcg/kg/minute for the past 4 hours. Urine output continues to be adequate. How would you taper the inotropic agents and what parameters would you monitor?

An acceptable method is to taper dobutamine by 2 mcg/kg/minute every 30 to 60 minutes and discontinue the dopamine. At such a low infusion rate, the effect of dopamine on R.G.'s hemodynamics is probably negligible and there is no need to titrate down at this level. Dobutamine has an elimination half-life of approximately 2.5 minutes; thus, steady-state plasma levels will occur in a short period. When tapering vasoactive agents, it is prudent, however, to let the patient stabilize hemodynamically at new infusion rates for a period that exceeds the time to achieve a new steady-state plasma concentration. After each reduction in the infusion rate, hemodynamic data can be assessed. Reasonable guidelines would be to keep the mean arterial pressure at 75 to 80 mmHg, HR at <110 beats/minute, PCWP at 12 to 18 mmHg, and CI at >2.5 L/minute/m². After the dobutamine is discontinued, the dopamine can be discontinued as well. R.G. should be evaluated for reinstatement of the medications he was receiving before surgery.

Severe Heart Failure

Assessment by Hemodynamic Profile

24. A.R. is a 65-year-old woman admitted to the ICU in acute respiratory distress. She has a medical history of coronary artery disease, an MI 4 years ago, hypertension, HF, and renal insufficiency. A.R. has a history of poor compliance with her medications and admits to discontinuing her usual medications (furosemide, enalapril, metoprolol, and digoxin) 5 days ago.

A.R. is confused, in obvious distress, and cannot catch her breath. Her extremities are pale and slightly cool. Her vital signs are as follows: temperature, 36.8°C; HR, 124 beats/minute; RR, 35 breaths/minute; BP, 104/65; and SaO₂, 85% on 6 L/minute of O₂ via a face mask. Her admission weight is 95 kg (stated home weight, 87 kg). A Foley catheter and peripheral IV are placed, and samples are sent to the laboratory for analysis. ABG values include the following: pH, 7.33 (normal, 7.35–7.45); PaCO₂, 28 mmHg (normal, 35–45 mmHg); PaO₂, 57 mmHg (normal, 75–100 mmHg); and HCO₃⁻, 20 mEq/L (normal, 23–29 mEq/L). Other laboratory results are sodium, 130 mEq/L (normal, 136–145 mEq/L); potassium, 5.2 mEq/L (normal, 3.5–5.0 mEq/L); and creatinine, 1.9 mg/dL (normal, 0.2–0.8 mg/dL). A pulmonary artery catheter is placed and initial hemodynamic values are RAP, 15 mmHg (normal, 2–6 mmHg); PCWP, 30 mmHg (normal, 5–12 mmHg); pulmonary artery pressure (PAP), 45/28 mmHg (S/D); CO, 3.5 L/minute (normal, 4–7 L/minute); CI, 1.6 L/minute (2.5–4.2 L/min) (BSA, 2.2 m²); and SVR, 1,440 dyne.sec.m⁻⁵ (normal, 800–1,440 dyne.sec.m⁻⁵). Chest radiograph shows pulmonary edema with no signs of pneumonia. ECG shows sinus tachycardia with nonspecific T-wave changes and LV hypertrophy.

Describe A.R.'s clinical situation and assess her hemodynamic variables. What initial therapies should be instituted? (Also see Chapter 19, Heart Failure.)

[SI units: sodium, 130 mmol/L (normal, 136–145); potassium, 5.2 mmol/L (normal, 3.5–5); creatinine, 168 μmol/L (normal, 18–71 μmol/L)]

A.R. is in respiratory distress because of pulmonary edema and acute heart failure. Her vital signs show a decreased BP and poor oxygenation. Her CO is low with high preload (PCWP, 30 mmHg) and she has increased SVR. She has some signs of inadequate perfusion manifested by her confusion and cool skin. As described in Chapter 18, patients can be classified

into four different hemodynamic categories based on volume status (wet versus dry) and organ perfusion status (cold vs. warm) with subsequent treatment strategies based on which category the patients fits.^{60,61} A.R. would best be described as wet and warm, although she does have some early evidence of inadequate perfusion as well.

A.R.'s laboratory values (potassium, 5.2 mEq/L; creatinine, 1.9 mg/dL) show renal insufficiency, and the low serum sodium (130 mEq/L) most likely represents volume overload and hemodilution because total body sodium load in patients with HF is usually high. A.R.'s high RAP and PCWP are consistent with volume overload as well and probable cardiogenic pulmonary edema. In many patients, the onset of pulmonary congestion occurs when the PCWP is 18 to 20 mmHg, and overt pulmonary edema can occur when the PCWP exceeds 30 mmHg. Filling pressures are elevated secondary to activation of the renin-angiotensin system with subsequent sodium and water retention by the kidney in response to the low CO. Patients with chronic HF often can tolerate higher filling pressures (PCWP) than patients who acutely develop HF because the change is gradual. It is, therefore, important to follow the clinical signs, rather than treat a specific number for patients in pulmonary edema.

Improvement of A.R.'s respiratory status is the initial priority, and she should be intubated if attempts to provide supplemental oxygen via face mask are not successful in elevating her PO₂. An MI should be ruled out, although the probable precipitating event is the noncompliance with her medication regimen. In the “wet and warm” patient, diuretics should be given to reduce volume overload and pulmonary edema. (See Chapter 18, Heart failure for a discussion of diuretic use in patients with heart failure.)

Therapeutic Interventions

VASODILATORS

25. Sixty minutes after a 40-mg IV furosemide dose, A.R. is now more confused, and her urine output has declined after an initial good response to the furosemide. A.R.'s vital signs are HR, 110 beats/minute; BP, 110/50 mmHg; RR 20 breaths/minute; and SaO₂ 93% on 100% face mask O₂. The PA catheter shows a RAP of 16 mmHg; PAP, 38/24 mmHg; PCWP, 24 mmHg; CO, 4.2 L/min; CI, 1.9 L/min/m²; and SVR, 1,028 dyne.sec.m⁻⁵. Laboratory results show the following: PO₂, 79; Hct, 34%; Hgb, 11.2; and SVO₂, 54%. What other therapeutic options are available for treatment of A.R.'s acute HF and pulmonary edema given the current hemodynamic values and clinical situation?

A.R.'s condition has deteriorated clinically; her calculated oxygen delivery is low (DO₂ 608 mL/minute) and her mixed venous oxygen saturation (Svo₂) is decreased, suggesting hypoperfusion. Improvement in A.R.'s CO is needed to increase perfusion and prevent organ dysfunction. A.R. is now best classified as “wet and cold.” Vasodilators have become an accepted part of treatment for HF based on the following underlying pathophysiology (also see Chapter 18, Heart Failure). As CO falls, the sympathetic nervous system and renin-angiotensin system are activated to maintain circulatory stability. Arterial pressure is maintained by the excessive increase in SVR (afterload), which increases the resistance to ejection of blood from the LV. Venoconstriction shifts some of the blood volume from the peripheral veins to the central circulation, which

contributes to an elevation of right and left atrial pressures (preload). A normal heart responds to the increase in preload and afterload by increasing contractility, but in HF, the heart's intrinsic capacity to increase contractility has been lost. As a result, the neurohormonal compensatory mechanism activated to maintain arterial pressure increases the work load on the heart and this leads to a further decrease in CO. Patients tend to spiral down this vicious cycle until the CO is lower and the SVR is higher than optimal to maintain perfusion pressure. Vasodilators disrupt the compensatory mechanisms that elevate preload and afterload and shift the ventricular function curve upward, which allows a greater CO at a lower LV filling pressure.

Three categories of vasodilators are available. Arterial vasodilators (e.g., hydralazine) decrease afterload, thus reducing impedance to LV outflow. Venous vasodilators (e.g., nitroglycerin [NTG]) primarily decrease venous return (preload), thus improving ventricular compliance, subendocardial coronary perfusion, and pulmonary hydrostatic pressure. Finally, mixed arterial and venous vasodilators have balanced effects on both preload and afterload reduction (e.g., nitroprusside, nesiritide, angiotensin-converting enzyme inhibitors). The fall in SVR from arterial vasodilation can potentially cause hypotension and a reflex increase in HR; however, this is infrequently seen in patients with HF because the decrease in SVR is counterbalanced by an increase in CO, which tends to maintain arterial pressure. Excessive preload reduction can cause deficient ventricular filling, thereby reducing the CO. The overall response in any given patient depends on that patient's baseline hemodynamic and volume status. At this time, A.R.'s BP has normalized, but she still has signs of inadequate perfusion. A trial of a vasodilator therapy for afterload and preload reduction may improve A.R.'s clinical status.

Nitroprusside

26. The clinician decides to begin an infusion of nitroprusside for afterload and preload reduction in A.R. How should therapy be initiated? What are the end points of therapy? What adverse effects are associated with nitroprusside infusion?

The initial infusion rate of nitroprusside should be no greater than 0.5 mcg/kg/minute. The infusion rate can be titrated upward by 0.25 mcg/kg/minute every 5 minutes until the mean arterial pressure falls 5 to 10 mmHg. Nitroprusside will lower SVR through arterial vasodilation and will decrease PCWP through venodilation. Cardiac output will increase as the afterload is reduced. Reasonable goals of therapy in A.R. are a cardiac index of >2.5 L/minute. A mean arterial pressure above 70 mmHg will ensure adequate organ perfusion, but BP should be kept as low as A.R. tolerates clinically, because this will reflect maximal afterload reduction. A reduction in PCWP to a level that maintains CO without causing pulmonary edema is also desirable. In A.R., a goal PCWP of 16 to 18 mmHg is reasonable.

Adverse effects associated with nitroprusside administration include excessive hypotension, reflex tachycardia, potential worsening of myocardial ischemia, thiocyanate toxicity (especially with renal dysfunction, prolonged infusions, and high infusion rates), accumulation of cyanide with subsequent cyanide toxicity, worsening arterial hypoxemia from increases in ventilation-perfusion mismatch, and, rarely, methemoglo-

binemia and hypothyroidism. (Also see Chapter 20, Hypertensive Emergencies, for a discussion of nitroprusside.)

27. Over the next 2 hours, A.R. received two doses of IV furosemide (40 mg). Nitroprusside was titrated to 1.2 g/kg/minute resulting in the following hemodynamic profile (previous values in parentheses): BP (S/D/M), 100/50/66 mmHg (110/50/70); pulse, 94 beats/minute (110); CI, 2.8 L/minute/m² (1.9); PCWP, 22 mmHg (24); SVR, 906 dyne.sec.cm⁻⁵ (1,028); urine output, 50 mL/hour (10); PaO₂, 80 mmHg (70); PaCO₂, 46 mmHg (46); pH, 7.32 (7.26); and HCO₃⁻, 24 mEq/L (21). Cardiopulmonary examination reveals an S₃ gallop and bibasilar rales are present, but diminished from previous examination. The ECG shows a sinus rhythm. Evaluate the effect that nitroprusside and furosemide have had on A.R.'s hemodynamic profile and clinical status.

The CI has improved significantly (1.9 to 2.8 L/minute/m²) and the stroke volume has increased from 27 to 48 mL/beat. The improved stroke volume has decreased endogenous catecholamine levels, which, in turn, has decreased the HR (110–94 beats/minute) and SVR. A.R. has improved clinically and her ABG indicate improvement of the metabolic acidosis. The increased urine output can be attributed to the combined effects of the diuretic and increased CO. Overall, A.R. has improved substantially. Supplemental oxygen still is required, but the oxygen concentration needed to maintain an adequate arterial oxygen content has been lowered.

At this point, a further reduction in preload may benefit A.R.'s respiratory function because the PCWP still is elevated at 22 mmHg. The mean arterial pressure is slightly lower than acceptable, however, and a further increase in the nitroprusside dose to reduce preload further may lower the MAP to a level that would compromise coronary and cerebral perfusion, as well as perfusion to other vital organs.

CHOICE OF ADDITIONAL THERAPY

28. What therapeutic interventions are available to further reduce A.R.'s preload and improve her status?

Four options are available. The first is to continue current therapy (nitroprusside and furosemide) and wait for the diuresis to continue to reduce preload. However, because her MAP is slightly lower than desired, signs of inadequate systemic perfusion must be monitored closely as a guide to additional or reduced diuretic therapy. The goal is to find the filling pressure (PCWP) that maximizes SV without causing pulmonary edema.

The second option to reduce preload would be the addition of IV NTG. An initial dose of 0.25 mcg/kg/minute is reasonable. Initial titration should be in 0.25 mcg/kg/minute increments at intervals of 3 to 5 minutes guided by patient's clinical response. If no response is seen at 1 mcg/kg/minute, titration increments of 0.5 to 1 mcg/kg/minute may be used. (See Chapter 17, Myocardial Infarction, and Chapter 18, Heart Failure, for additional discussion of intravenous nitroglycerin.)

The third option is to continue the nitroprusside and add dobutamine to improve CO through inotropic support. A dobutamine infusion of 3 mcg/kg/minute is a reasonable initial dose. Either choice is acceptable as long as A.R. is monitored closely.

A fourth option would be the use of an agent, such as nesiritide (see below), to reduce preload and potentially augment

diuresis, although A.R.'s blood pressure may not tolerate the hemodynamic effects of this agent.

Transition to Oral Vasodilators

29. After 48 hours of nitroprusside, intermittent furosemide, and low-dose dobutamine, A.R. has remained hemodynamically stable. The decision is made to reinstitute A.R.'s previous medications (furosemide, enalapril, metoprolol, and digoxin). No evidence supports a new MI. How would you reinstitute the enalapril (10 mg BID) and taper the nitroprusside in A.R.?

Guidelines for tapering short-acting vasodilators when substituting long-acting oral agents are not strict. In this case, a reasonable approach would be to give the enalapril (Vasotec) at a lower dosage than A.R. was taking previously (e.g., 5 mg BID) and reduce the nitroprusside infusion rate by 25%. Then, obtain a CO and PCWP every 2 to 4 hours to assess the contribution of the enalapril to the afterload and preload reduction. If the MAP declines excessively after the addition of enalapril, the nitroprusside dose will have to be reduced further. A smooth transition from IV therapy to oral therapy often depends on the skill of the nursing staff and their familiarity with the hemodynamic effects of the drugs. In addition, A.R. will have to be monitored for signs of renal insufficiency, a potential adverse effect of angiotensin-converting enzyme (ACE) inhibitors. If she develops worsening renal function, an alternative vasodilator strategy, such as hydralazine and nitrate therapy, may be necessary (see Chapter 18, Heart Failure).

Other Therapies

PHOSPHODIESTERASE INHIBITORS

30. Milrinone is a noncatecholamine inotropic agent with vasodilator activity. If A.R.'s condition had failed to respond to nitroprusside and furosemide, this drug would have been a potential therapeutic option for treatment of her acute cardiac failure. What are the considerations in choosing which agent to use? How would you dose milrinone and what adverse effects would you expect with its administration? Does milrinone offer any advantage over catecholamine inotropic agents (e.g., dobutamine, dopamine) or a pure vasodilator such as nitroprusside?

The phosphodiesterase (PDE) inhibitors (also referred to as inodilators) are a class of drugs that have combined inotropic and vasodilator effects. All agents in this class have basically the same mechanism of action: they inhibit intracellular phosphodiesterase, the enzyme responsible for metabolic inactivation of cyclic adenosine monophosphate (cAMP). The resulting increased concentration of cAMP enhances sympathetic nervous system activity that produces positive inotropic effects. Increased cAMP also causes relaxation of vascular smooth muscle and, therefore, decreases SVR.

The hemodynamic effects seen with PDE inhibitors include increased inotropy, reduced SVR, and improved LV diastolic compliance. These changes result in an increase in CI and a decrease in LV afterload and filling pressures. Almost all the phosphodiesterase inhibitors have been shown to elevate CI and stroke volume index. Myocardial oxygen demand is increased by the increase in myocardial contractility and HR. On the other hand, LV filling pressures and SVR are decreased,

leading to a decrease in myocardial oxygen demand. The net effect depends on the balance of the opposing forces.

Milrinone

Milrinone is the phosphodiesterase inhibitor most often used in clinical practice. It is primarily cleared by the kidneys, and has an elimination half-life from 1 to 3 hours in patients with normal renal function. In patients with severe heart failure, or in patients with renal failure, an increase in the elimination half-life can be seen. The onset of action occurs within minutes following a loading dose.

The long half-life of milrinone compared with the catecholamine agents makes a loading dose necessary before an infusion can be started. IV milrinone usually is initiated with a 50 mcg/kg loading dose administered over 10 minutes, followed by a maintenance infusion of 0.25 to 0.75 mcg/kg/minute. The loading dose is frequently skipped in patients at risk for hypotension. Patients with HF or renal insufficiency will have a reduced elimination rate and require dose adjustment.

Intravenous administration of milrinone in patients with severe heart failure results in a significant increase in CO, while decreasing PVR and SVR through vasodilation. HR usually remains unaltered, although hypotension can occur when vasodilation exceeds the increase in CO and in hypovolemic patients. Theoretically, the effect of milrinone on myocardial oxygen consumption should be favorable because it does not substantially alter HR while lowering LV filling pressure. A recent placebo-controlled study of the short-term use (48-hour infusion) of milrinone in patients with acute exacerbations of heart failure found no significant differences in mortality, length of hospitalization, or readmission, and found significant increases in arrhythmias and hypotension in the milrinone group.⁶² Although patients were excluded from this trial if their treating physician felt that inotropic therapy was essential, it is important to recognize that the improvement of hemodynamic variables does not necessarily imply improved outcome.

Milrinone therapy has few serious side effects, the most significant being hypotension and arrhythmias. Because milrinone may increase arrhythmia frequency and cause sudden death, it should be used cautiously in patients with severe ventricular arrhythmias. Thrombocytopenia has also been reported with milrinone use.

Compared with pure vasodilators such as nitroprusside, milrinone offers the advantage of positive inotropic action, which can increase CO to a greater degree. The increased inotropy comes at a cost of increased myocardial work, or oxygen consumption, which is a potential disadvantage of PDE inhibitors.

Comparisons of the hemodynamic effects of milrinone, dobutamine, and dopamine show that milrinone is more similar to dobutamine than to dopamine. Therefore, the advantage of milrinone over dopamine would be the same as that of dobutamine over dopamine (see Question 19). In contrast to dobutamine, milrinone is a less potent inotropic agent and a more potent vasodilator. In a comparison of these agents, patients receiving dobutamine had a higher BP and PCWP compared with those on milrinone, reflecting the increased vasodilation with milrinone.⁶³ The longer duration of action poses a problem if an undesirable effect occurs, although the lack of a chronotropic effect with a resultant increase in myocardial oxygen consumption may be beneficial in A.R., who has a history of MI. Trials

evaluating milrinone-based versus dobutamine-based therapy have found similar outcomes in patients with decompensated heart failure and in patients awaiting heart transplantation, with increased cost associated with milrinone.^{64,65} The current cost of milrinone has decreased with the arrival of a generic product.

Because the inotropic mechanism of milrinone is independent of β -receptors, it may be of value in patients who do not respond to catecholamine inotropic agents because of β -receptor blockade or downregulation of β -receptors.⁶⁶ This may be an important consideration, as β -blocker therapy is becoming standard in the treatment of heart failure as evidenced by the use of metoprolol in A.R. In addition, milrinone has a different mechanism of action and, therefore, it may have synergistic inotropic effects with catecholamines.

NESIRITIDE

31. Nesiritide is a new agent approved for the treatment of decompensated heart failure. What are the hemodynamic effects of nesiritide and how does it compare with other agents used in the treatment of advanced heart failure?

Human brain, or B-type, natriuretic peptide (BNP) is produced by the ventricle in response to increased filling pressures. The endogenous protein has several important actions on hemodynamics as described in Chapter 18, Heart Failure. Nesiritide is a recombinant form that is identical to endogenous BNP. The actions of nesiritide include mixed arterial and venous dilation, increased sodium excretion, and suppression of the deleterious effects of the renin-angiotensin-aldosterone and sympathetic nervous system.^{67–69} Compared with placebo, the effects on hemodynamics are a decrease in PCWP, PA pressures, and SVR, and an increase in CO.⁶⁹ Nesiritide does not possess direct inotropic activity; the increase in CO is a result of the decrease in afterload.

The Vasodilation in the Management of Acute CHF (VMAC) study evaluated nesiritide compared with nitroglycerin in the treatment of heart failure.⁷⁰ The investigators found that nesiritide improved PCWP better than nitroglycerin, and was more effective at reducing the symptoms of dyspnea with fewer adverse effects. Compared with dobutamine in a randomized, open-label trial, nesiritide caused less tachyarrhythmias and more hypotension, with similar effects on the signs and symptoms of CHF.⁷⁰ Nesiritide is dosed as a 2 mcg/kg load, followed by an infusion of 0.01 mcg/kg/minute. The infusion may be titrated up to a maximum of 0.03 mcg/kg/minute. Few data are available concerning infusions of nesiritide for longer than 48 hours. The balanced vasodilation and increased sodium excretion with nesiritide makes it an attractive option in the treatment of advanced heart failure, particularly in diuretic-resistant patients with elevated filling pressures and dyspnea. Hypotension is the most common adverse effect, occurring in up to 35% of patients.⁷⁰

The use of nesiritide has generated controversy. A meta-analysis of three randomized, controlled trials suggested that nesiritide use may be associated with worsening renal function and an increased risk of short-term mortality.⁷¹ These findings have been debated considerably with other analyses failing to confirm the increased mortality risk.⁷² Until more conclusive outcome data are available, the use of nesiritide should be reserved for those patients with acutely decompensated heart failure who are not responding to more conventional strategies,

and should be limited to no more than 48 hours of therapy. (See Chapter 18, Heart Failure, for additional information about the clinical use of nesiritide.)

Acute Myocardial Infarction

Immediate Goals of Therapy and General Considerations

32. M.J., a 57-year-old man, is brought to the ED complaining of severe chest pain and difficulty breathing. On physical examination, M.J. has a BP of 80/40 mmHg (normal, 120/80 mmHg) (by cuff) with a weak pulse of 115 beats/minute (normal, 60–80 beats/minute). His RR is 24 breaths/minute (normal, 18 breaths/minute) and his breathing is shallow. Heart sounds include S₃/S₄ gallops, but no murmurs are heard. The jugular venous pulse is normal. He has diffuse rales over the lower lung fields with moderate wheezing. M.J. is cold and clammy to touch; however, his temperature is normal. He is restless, anxious, and confused about time and date. Arterial blood gas (ABG) measurements on 2 L/minute oxygen via nasal prongs are PaO₂, 65 mmHg (normal, 75–100 mmHg); PaCO₂, 44 mmHg (normal, 35–45 mmHg); pH, 7.22 (normal, 7.35–7.45); and HCO₃⁻, 18 mEq/L (normal, 23–29 mEq/L). The ECG shows ST segment elevation in the anterior lateral leads and 6 to 10 premature ventricular contractions (PVC) per minute. Serum potassium is normal. A Foley catheter is inserted to monitor urine output. Cardiac enzymes are pending. M.J. has no known history of cardiac disease and takes no medication. What immediate goals of therapy are necessary to stabilize and treat M.J.?

[SI unit: HCO₃⁻, 18 mmol/L (normal, 23–29)]

M.J. has signs of cardiogenic shock with decreased systemic perfusion. His BP is low, his HR is elevated, and his respiratory status is compromised. M.J. is restless, anxious, and confused, indicating poor cerebral perfusion. His ABG results indicate a component of metabolic acidosis secondary to poor systemic perfusion. The ST elevation on the ECG is consistent with an acute anterior MI.

As discussed in Chapter 17, Myocardial Infarction, most patients presenting with MI are routinely treated with aspirin, a β -blocker, and a thrombolytic (unless contraindicated) or immediate percutaneous coronary intervention (PCI). The presence of cardiogenic shock can alter the interventional strategy, however. Patients presenting in cardiogenic shock after MI may progress rapidly to irreversible organ system dysfunction as the compensatory mechanisms fail to maintain tissue perfusion. Treatment of these critically ill patients involves two components: (a) stabilization and (b) definitive treatment. Initial stabilization of the patient must be attained before further evaluation and treatment of the cause of cardiogenic shock can proceed. The goals are to maintain adequate oxygen delivery to the tissues and to prevent further hemodynamic compromise. Stabilization includes (a) establishing ventilation and oxygenation (arterial PO₂ should be >70 mmHg); (b) restoring central arterial BP and CO with vasopressors and inotropic agents, if needed; (c) infusing fluids, if hypovolemic; and (d) treating pain, arrhythmias, and acid-base abnormalities, if present.

Administration of oxygen by mechanical ventilation enhances the myocardial oxygen supply and may contribute to improved ventricular performance. Mechanical ventilation is indicated when arterial oxygen saturation cannot be maintained above 85% to 90% despite 100% oxygen per face mask. Once

the patient is intubated, maximal sedation should be provided to alleviate anxiety and discomfort.

The arterial pressure must be increased to provide adequate coronary and systemic perfusion to meet oxygen requirements. Some areas of ischemia in the infarct zone may be depressed but viable, provided myocardial oxygen supply exceeds demand. If the myocardial oxygen demands are not met, however, myocardial tissue necrosis will expand into the area of ischemia. This results in further hemodynamic impairment and initiates a vicious feedback cycle that can lead to intractable pump failure and irreversible shock. To be effective, treatment of cardiogenic shock should favorably influence the balance between oxygen supply and demand in the ischemic zone.

Optimizing preload to improve CO and systemic perfusion is crucial, especially in patients with RV infarction. In patients with severe LV impairment caused by cardiogenic shock, increasing intravascular volume can worsen pulmonary congestion. M.J. currently has signs of pulmonary congestion and RV infarction is not immediately evident; thus, a fluid challenge must be administered cautiously or withheld until hemodynamic monitoring can be established.

Inotropic agents or vasopressors should be used to increase systemic BP and re-establish coronary perfusion in patients with cardiogenic shock and hypotension. The use of vasoactive agents is not without risk, however, because they can exacerbate ventricular arrhythmias and increase oxygen consumption in ischemic myocardium. Therefore, the minimal dose that will provide adequate perfusion pressure should be used. Achieving a MAP of 65 to 70 mmHg is the immediate goal of therapy. Elevation of the MAP above 80 mmHg is unnecessary because at this level, coronary blood flow is not significantly changed, but energy expenditure is high.

Correction of metabolic acidosis is best accomplished by treating the underlying cause. Improving tissue perfusion by optimizing oxygen content and increasing CO can eventually restore aerobic metabolism and eliminate lactic acid production. The use of sodium bicarbonate to correct lactic acidosis in cardiogenic shock and other critically ill patients is controversial. Sodium bicarbonate can have numerous adverse effects, such as hypernatremia, paradoxical intracellular acidosis, and hypercapnia; conclusive data on its efficacy are lacking. Bicarbonate therapy, therefore, warrants caution and is recommended only, if at all, when severe acidemia (pH <7.2 or $\text{HCO}_3^- < 10$ to 12 mEq/L) is present.

Because inotropic agents and vasoconstrictors can increase myocardial oxygen consumption and potentially extend the area of necrosis in patients with infarct-induced cardiogenic shock, the careful selection and titration of agents that will best preserve myocardium while sustaining systemic arterial pressure and tissue perfusion is essential. Although correction of volume deficits and early pharmacologic support may prevent the extension of myocardial damage, it must be emphasized that exclusive use of these measures does not improve survival. Therefore, drug therapy must be considered only an interim maneuver to preserve myocardial and systemic integrity while further therapeutic interventions and definitive therapy are being considered.

As mentioned, cardiogenic shock following AMI occurs in only a small percentage of patients, but carries a high mortality rate. Reperfusion of the occluded artery is of paramount importance in these patients. Two options are available for restoring

patency of the artery. Thrombolytic therapy and percutaneous transluminal coronary angioplasty, with or without stenting (see Chapter 17, Myocardial Infarction).

Thrombolytic therapy in acute MI may reduce the incidence of subsequent cardiogenic shock, but its value may be limited in patients who have already developed shock.⁷³ The effectiveness of thrombolytics is reduced in this setting, possibly because of reduced delivery of the agent to the coronary artery thrombus as a result of hypotension.⁷⁴ The use of an intra-aortic balloon pump (IABP) to augment coronary artery blood flow may improve the efficacy of thrombolytics.⁷⁵ In settings when interventional cardiac procedures such as percutaneous transluminal coronary angioplasty (PTCA) or stenting are not readily available, insertion of an IABP and thrombolytics should not be delayed if indicated.

Early PTCA may be of more benefit than thrombolytics in patients with cardiogenic shock complicating acute MI. In a subset of patients with cardiogenic shock in the GUSTO-1 trial, angioplasty resulted in a reduction in 30-day mortality rate from 61% to 43%.⁷⁶ Numerous other trials have demonstrated improved outcomes with PTCA in patients with shock compared with historical controls. However, problems with subgroup analysis and nonrandomized trials include the potential for selection bias. Operator skill also is a consideration in this setting, and larger centers with greater experience may have better outcomes than smaller centers.

An early revascularization strategy with angioplasty or bypass surgery was recently compared with medical management of these patients, including thrombolytics and intra-aortic balloon counterpulsation.⁷⁷ No significant difference was found in mortality rate at 30 days; however, at 6 months, the mortality rate in the revascularization group was 50.3% versus 63.1% for the medical therapy group. Follow-up at 1 year also demonstrated a significant increase in survival.⁷⁸

Assessment by Hemodynamic Profile

33. M.J. has a history of cerebrovascular disease and is thus ineligible for thrombolytic therapy. Therefore, he will require revascularization in the form of balloon angioplasty or coronary artery bypass surgery to improve his chances of survival. Meanwhile, he is given dopamine at 5 mcg/kg/minute to stabilize him hemodynamically before revascularization procedures are initiated. Lidocaine (100-mg IV bolus plus a 2-mg/minute infusion) also is instituted to correct the PVCs. Oxygen administration is changed to 100% via face mask. Morphine sulfate, 2 mg IV, is given for chest pain. IV NTG was initiated at 0.25 mc/kg/minute for myocardial ischemia, but had to be discontinued because intolerable hypotension developed. M.J. is admitted to the ICU where an arterial line and pulmonary artery line are placed, revealing the following hemodynamic profile (previous values in parentheses): BP (S/D/M), 92/46/61 mmHg (80/40 by cuff); pulse, 122 beats/min (115); CO, 2.8 L/minute; CI, 1.5 L/minute/m²; RAP, 16 mmHg; PCWP, 26 mmHg; SVR, 1,314 dyne.sec.cm⁻⁵; PaO₂, 70 mmHg (65); PaCO₂, 48 mmHg (44); pH, 7.24 (7.22); HCO₃⁻, 21 mEq/L (18); and urine output, 10 mL/hour. (M.J. weighs 82 kg and has a BSA of 1.9 m².) The chest radiograph shows evidence of pulmonary edema. Assess M.J.'s hemodynamic profile and response to dopamine therapy.

M.J.'s clinical and hemodynamic parameters confirm the diagnosis of cardiogenic shock. He is clearly not hypovolemic,

as manifested by an elevated RAP and PCWP. Although his SBP is slightly improved, his CI (<1.8 L/minute/ m^2), PCWP (>18 mmHg), and low urine output (<25 mL/hour) are all characteristic findings with this form of shock. Patients with cardiogenic shock from an acute event (such as an MI) are usually in a much more critical clinical situation than patients who have an acute exacerbation of chronic heart failure. Patients with HF have compensated over time for the increases in preload and reduced CO, but patients such as M.J. have not had time to develop compensatory mechanisms.

Dopamine, at an infusion rate of 5 to 10 mcg/kg/minute, has made M.J. more tachycardic, has not substantially enhanced CO, and the MAP is less than optimal for coronary perfusion. M.J. has signs of pulmonary edema that are consistent with the elevated pulmonary wedge pressure. The PaO_2 of 70 mmHg is marginally acceptable considering he is on 100% oxygen per face mask.

Therapeutic Interventions

FLUID THERAPY VERSUS INOTROPIC SUPPORT

34. The decision is made to intubate M.J. Would a fluid challenge or additional doses of dopamine improve M.J.'s status?

In M.J., a fluid challenge could exacerbate the pulmonary edema because after an AMI, ventricular compliance is decreased and a small change in LVEDV could result in a disproportionately large increase in PCWP. Thus, in patients with an AMI, the benefits of a fluid challenge must be balanced against the risk of aggravating pulmonary edema. M.J. has an elevated RAP and PCWP, indicating that he has at least adequate, if not excessive, preload. If a fluid challenge is going to be administered, no >100 mL of normal saline should be infused without further evaluation of hemodynamic and clinical data.

Increasing the dopamine infusion rate might improve CO and perfusion pressure, but at the expense of increasing the HR even further. The increased HR, along with the elevated PCWP, could adversely affect the myocardial oxygen supply-to-demand ratio. However, the increase in coronary blood flow (caused by the rise in arterial pressure) and the decrease in LV chamber size (associated with the increase in contractility), it is hoped would tend to offset the increase in myocardial oxygen requirements.

It is not entirely clear which patients in cardiogenic shock will respond to dopamine. One trial of 24 patients in cardiogenic shock found that a mean infusion rate of 9.1 mcg/kg/minute was required to produce beneficial effects on CO, urine output, HR, and PCWP in survivors.⁷⁹ Nonsurvivors had no change in MAP, PCWP, or HR at an average infusion rate of 17.1 mcg/kg/minute.

COMBINATION INOTROPIC THERAPY

35. Occasionally, a patient's hemodynamic status improves with the combined use of inotropic agents. Would the addition of dobutamine or a phosphodiesterase inhibitor to treat M.J.'s cardiogenic shock be beneficial?

The combination of dobutamine and dopamine was studied in eight cardiogenic shock patients requiring mechanical ventilation.⁸⁰ None of the patients had experienced an MI within the preceding 7 days. Each patient received three infusions in a randomly assigned order: dopamine at

15 mcg/kg/minute; dobutamine at 15 mcg/kg/minute; and a combination of dopamine and dobutamine each at 7.5 mcg/kg/minute. All three regimens increased CI, stroke index, LVSWI, and HR similarly. MAP increased with the dopamine and the dobutamine-dopamine combination, but did not change with dobutamine alone. SVR was significantly lower with dobutamine alone compared with the other two regimens. PCWP was elevated most with the dopamine infusion alone as was myocardial oxygen consumption. The combination regimen offered hemodynamic superiority over either agent alone in this group of patients.

Given M.J.'s significantly low arterial BP, the addition of a PDE inhibitor, such as milrinone, could be problematic. These agents tend to have more vasodilating properties than dobutamine, and their long-half lives can present difficulties in management if hypotension does develop. Until M.J.'s BP is improved, PDE inhibitors should be avoided.

In summary, further inotropic support with dopamine or the addition of dobutamine would be indicated in M.J. at this time. The dopamine could be increased to 12.5 mcg/kg/minute or dobutamine could be initiated at 5 mcg/kg/minute. Neither maneuver is without risk. Dobutamine could lower the MAP, adversely affecting coronary perfusion pressure. Dopamine might elevate the PCWP. The addition of dobutamine or an increase in dopamine dose could increase HR even more. Any of these would adversely affect the myocardial oxygen supply-to-demand ratio and could further extend the area of ischemia or necrosis.

36. Despite the addition of dobutamine at a rate of 5 to 7.5 mcg/kg/minute and initiation of ventilatory support via tracheal intubation, M.J. continues to show signs of deterioration, with progressive obtundation and loss of bowel sounds. His systemic arterial pressure has continued to decline, and his dopamine is now up to 18 mcg/kg/minute. Preload reduction was attempted previously with NTG; however, the drop in BP was intolerable. A repeat hemodynamic profile shows the following (previous values in parentheses): BP (S/D/M), 86/40/55 (92/46/61); pulse, 132 beats/minute (122); CO, 3.0 L/minute (2.8); CI, 1.6 L/minute/ m^2 (1.5); RAP, 18 mmHg (16); PCWP, 24 mmHg (26); SVR, 986 dyne. $sec.cm^{-5}$ (1,314); urine output, 8 mL/hour (10); PaO_2 , 75 mmHg (70); $Paco_2$, 42 mmHg (48); pH, 7.26 (7.24); and HCO_3^- , 19 mEq/L (21). The ECG shows atrial tachycardia with occasional PVC. What therapeutic alternatives can be considered at this time?

M.J. is still in severe cardiogenic shock and his tissue perfusion continues to deteriorate as evidenced by a further reduction in urine output, a loss in bowel sounds, continuing acidosis, and central nervous system (CNS) obtundation. Because his systemic arterial pressure and tissue perfusion have declined despite the addition of dobutamine and maximal doses of dopamine, additional support with a potent vasopressor and the insertion of an IABP are indicated.

NOREPINEPHRINE

Norepinephrine is a potent α -adrenergic agonist that vasoconstricts arterioles at all infusion rates, thereby increasing SVR. Thus, systemic arterial and coronary perfusion pressures both rise. Norepinephrine also stimulates β_1 -adrenergic receptors to a lesser extent, resulting in increased contractility and stroke volume. However, HR and CO usually remain constant,

or may even decrease secondary to the increased afterload and reflex baroreceptor activation. Although coronary perfusion pressure is enhanced as a result of the elevation in diastolic pressure, myocardial oxygen consumption also is increased. Consequently, myocardial ischemia and arrhythmias may be exacerbated and LV function further compromised.

Infusions of norepinephrine are begun at 0.01 to 0.05 mcg/kg/minute and titrated upward to achieve a SBP of 90 to 100 mmHg. Administration should be through a central IV line because local subcutaneous necrosis can result from peripheral IV extravasation. Prolonged infusion of larger doses will transiently exert a beneficial effect by diverting blood flow from the peripheral and splanchnic vasculature to the heart and brain; however, this ultimately can compromise capillary perfusion to the extent that end-organ failure, particularly renal failure, ensues.

To reduce the potential risk of end-organ damage, a reasonable approach is to add norepinephrine to the infusion of dobutamine, and reduce the dopamine infusion rate to 0.5 to 2 mcg/kg/minute. This will theoretically support renal and splanchnic perfusion, although this effect is controversial, as discussed above. In addition, any deficits in plasma volume should be corrected when identified by hemodynamic monitoring.

Adverse effects of norepinephrine are related mostly to excessive vasoconstriction and compromise of organ perfusion. Worsening of ventricular function can occur because of increased afterload and tissue necrosis and sloughing can develop if extravasation occurs. Cardiac arrhythmias can emerge and HR can increase; however, in some cases the HR may slow secondary to baroreceptor-mediated reflex increases in vagal tone.

Again, it must be emphasized that pharmacologic support for M.J., particularly the use of norepinephrine, is only an interim maneuver to temporarily maintain hemodynamic function while revascularization procedures are being considered. Patients who cannot be stabilized with pharmacologic intervention, and in whom systemic or myocardial perfusion is becoming compromised, may require further support through insertion of a mechanical circulatory assist device (e.g., intra-aortic balloon pump).

INTRA-AORTIC BALLOON PUMP

When drug therapy is ineffective at stabilizing patients in cardiogenic shock, mechanical intervention should be considered. Mechanical interventions such as intra-aortic balloon counterpulsation can rapidly stabilize patients with cardiogenic shock, especially those with global myocardial ischemia or infarction complicated by mechanical defects, such as papillary muscle rupture or ventricular septal rupture. Intra-aortic balloon counterpulsation augments coronary arterial perfusion pressure during diastole and reduces LV impedance during systole. Sometimes combined inotropic support and intra-aortic balloon counterpulsation are required to maintain an acceptable BP (SBP >90 mmHg) and CI (>2.2 L/minute/m²).

The IABP or intra-aortic counterpulsation has been in use for more than 15 years and remains the most commonly used mechanical assist device. It is designed to improve coronary perfusion and reduce afterload, thus providing short-term reperfusion of the ischemic myocardium. A 30- to 40-mL balloon catheter is inserted into an artery (usually femoral) and advanced to just below the arch of the aorta. Balloon inflation

and deflation are synchronized with the ECG to inflate during diastole (after the aortic valve closes) and deflate at the onset of systole. The inflated balloon in diastole increases coronary perfusion by elevating the mean aortic pressure. The rapid deflation of the balloon at the onset of systole decreases SBP, thus reducing afterload and improving cardiac ejection. The enhanced myocardial perfusion provided by IABP may reduce vasopressor requirements, thereby further decreasing myocardial oxygen consumption. Occasionally, IABP augmentation is sufficient to allow the institution of vasodilators (e.g., nitroprusside) or inodilators (e.g., milrinone). Complications of IABP include thrombocytopenia from the mechanical destruction of platelets and the potential for limb ischemia because of reduced blood flow in the artery into which the IABP catheter is inserted. Heparin anticoagulation is usually used with IABP because the device has a large surface area that can be thrombogenic.

Recently, more advanced circulatory-assist devices (HeartMate, Novacor, Abiomed) have been developed. Mechanical assistance with these devices is used for patients with cardiogenic shock who need support while awaiting definitive, corrective therapy or as a bridging mechanism before cardiac transplantation.⁸¹ Long-term use of some of these devices has been investigated in patients with severe cardiac failure who are not transplant candidates.⁸² Implantation of a left ventricular assist device (LVAD) was compared with medical management in patients with severe heart failure. Survival at 1 year was 52% in the LVAD group, compared with 25% in the medical management group. The high cost of these devices will undoubtedly limit their use to only the most severely ill patients.

In summary, M.J.'s condition has continued to deteriorate since his admission to the ICU. Attempts at stabilizing his hemodynamic parameters with dopamine, dobutamine, and norepinephrine have failed. This is evidenced by inadequate tissue perfusion, which is reflected clinically by his continued lactic acidosis, decreased urine output, reduced bowel sounds, and CNS obtundation. M.J.'s best chance of survival is to have early revascularization of his ischemic myocardium with either coronary bypass surgery or PTCA. Meanwhile, the addition of norepinephrine and intra-aortic counterpulsation can provide temporary support for M.J. before his procedure.

SEPTIC SHOCK

Clinical and Hemodynamic Features

37. M.K., a 56-year-old man, was admitted 5 days ago with a chief complaint of acute abdominal pain of 3 days' duration associated with bloody diarrhea, fever, tachypnea, and hypotension. A diagnosis was superior mesenteric artery occlusion with necrotic bowel, leading to surgery for removal of necrotic bowel tissue. During postoperative days 1 through 4, his serum creatinine (SrCr) increased to 1.5, and he could not be completely weaned from ventilatory support. Vital signs were stable. Antibiotic therapy included clindamycin and gentamicin in appropriate doses.

M.K. has a history of coronary artery disease with stable angina pectoris that has been treated with lisinopril, simvastatin and NTG. He had no other medical problems before admission.

On the morning of postoperative day 5, M.K. complains of chills and has a spiking fever to 39.4°C. Physical findings include a BP of 98/60 mmHg, pulse 128 beats/minute, and a RR of

28 breaths/minute. His urine output has dropped to 25 mL/hour and bowel sounds are absent. The chest radiograph shows an enlarged heart with bilateral pulmonary infiltrates and right lower lobe atelectasis. M.K. has become confused and disoriented. ABG on an inspiratory oxygen concentration (FIO₂) of 40% are as follows: PaO₂, 76 mmHg (normal, 75–100 mmHg); PaCO₂, 34 mmHg (normal, 35–45 mmHg); HCO₃⁻, 15 mEq/L (normal, 23–29 mEq/L); and pH, 7.31 (normal, 7.35–7.45). M.K. has had increased bronchial secretions over the past 2 days. Pertinent laboratory values are SrCr, 1.8 mg/dL (normal, 0.2–0.8 mg/dL); BUN, 32 mg/dL (normal, 10–20 mg/dL); and WBC count, 18,000 cells/mm³ (normal, 4,500–11,000 cells/mm³).

Urine, sputum, and blood samples are sent for culture and sensitivity. A fluid bolus of 1,000 mL normal saline is given. Arterial and pulmonary artery catheters are inserted revealing the following hemodynamic profile. M.K. weighs 70 kg and has a BSA of 1.7 m²: BP (S/D/M), 90/50/63 mmHg; pulse, 122 beats/minute; CO, 6 L/minute (normal, 4–7 L/min); CI, 3.5 L/minute/m² (normal, 2.5–4.2 L/minute/m²); PCWP, 12 mmHg (normal, 5–12 mmHg); SVR, 720 dyne.sec.cm⁻⁵ (normal, 800–1,440 dyne.sec.cm⁻⁵). What hemodynamic and clinical features of M.K. are consistent with septic shock?

[SI units: SrCr, 135 μmol/L (normal, 15–61); BUN, 22.72 mmol/L (normal, 7.1 to 14.3); WBC count, 18 10⁹/L (normal, 4.5–11); HCO₃⁻, 15 mmol/L (normal, 23–29)]

Hemodynamic signs consistent with septic shock include hypotension, tachycardia, elevated CO, low SVR, and a low PCWP. Although the absolute value for CO is high or at the upper limits of the normal range in septic shock, it is inadequate to maintain a BP that will perfuse the essential organs in the face of a decreased SVR, evidenced by the low oxygen delivery and consumption. M.K. has a metabolic acidosis (pH 7.31 with a PaCO₂ 30 mmHg, HCO₃⁻ 15 mEq/L), indicating anaerobic metabolism most likely caused by decreased perfusion causing lactic acidosis, and a CO that is inadequate to meet the oxygen requirements of the tissues.

Other features consistent with septic shock in M.K. include worsening pulmonary function as indicated by his ABG measurement; declining urine output and altered sensorium, indicating decreased renal and cerebral perfusion; a rising WBC count; and a spiking fever.

Therapeutic Approach

The management of septic shock is directed toward three primary areas: (a) eradication of the source of infection, (b) hemodynamic support and control of tissue hypoxia, and (c) inhibition or attenuation of the initiators and mediators of sepsis.

Eradicating the Source of Infection

38. What factors should be considered in determining antimicrobial therapy in septic shock? What are the potential sources of infection in M.K.?

Systemic infection caused by either aerobic or anaerobic bacteria is the leading cause of septic shock. Fungal, mycobacterial, rickettsial, protozoal, or viral infections can also be encountered. Among sepsis syndromes caused by aerobic bacteria, gram-negative organisms (e.g., *Enterobacteriaceae*, *Pseudomonas*, and *Haemophilus*, in decreasing order of frequency) are implicated slightly more often than gram-positive

bacteria (e.g., *Staphylococcus aureus*, *Staphylococcus coagulase negative*, *Streptococcus*, and *Enterococcus*, from highest to lowest frequency). Even these trends vary, however, depending on the infection site. For example, when an organism can actually be cultured in the blood, slightly more gram-positive infections (35%–40%) than gram-negative infections (30%–35%) are found. In non-bloodstream infections (e.g., respiratory tract, genitourinary system, and the abdomen, in descending order of frequency) 40% to 45% can be attributed to gram-negative organisms and 20% to 25% are caused by gram-positive organisms.¹⁹ Polymicrobial infections make up the next largest group, followed by fungi, anaerobes, and others. In 10% to 30% of sepsis syndrome cases, no organisms can be isolated. Careful consideration of the patient's history and clinical presentation often reveals the most likely cause.

Eradicating the source of infection involves the early administration of antimicrobial therapy, and, if indicated, surgical drainage. The use of an appropriate antibiotic regimen is associated with a significant increase in survival. In one large retrospective study, shock and mortality rates were reduced by 50%.⁸³ The selection of antibiotics should take into account the presumed site of infection; whether the infection is community- or hospital-acquired; recent invasive procedures, manipulations, or surgery; any predisposing conditions; and the likelihood of drug resistance. Ideally, the primary source of the infection can be determined and therapy specifically tailored to the most likely organisms. If the source of infection is unclear, however, early institution of broad-spectrum antibiotics is generally recommended while awaiting culture results. Empiric therapy is indicated, given a >50% mortality rate caused by gram-negative sepsis within the first 2 days of illness and the increasing frequency of polymicrobial infections.⁸³ Recommended empiric regimens typically include an aminoglycoside plus a third-generation cephalosporin or a similar broad-spectrum agent to cover for gram-positive cocci, aerobic gram-negative bacilli, and anaerobes (Also see Chapter 56, Principles of Infectious Diseases.)

M.K. has several potential sources of sepsis. The first is hospital-acquired pneumonia. M.K. has been intubated for 5 days, infiltrates appear on chest radiograph, and sputum production has increased over the past 2 days. Abdominal abscess or recurrent bowel ischemia also should be considered because bowel sounds are absent. Although no complaints of abdominal tenderness have been elicited, surgical exploration may be necessary. Other potential sources for infection include the urinary tract because M.K. has had an indwelling Foley catheter in place since admission. All IV catheters should be changed if possible.

Clindamycin is discontinued and imipenem and vancomycin are added to broaden M.K.'s antibiotic coverage. Imipenem should adequately cover nosocomial gram-negative pathogens such as *Pseudomonas aeruginosa* and *Acinetobacter baumannii* as well as abdominal anaerobic organisms. Vancomycin will cover *S. aureus* from possible IV contamination as well as potential staphylococcal pneumonia. Antimicrobial therapy is adjusted once cultures are finalized.

Initial Stabilization

39. What are the immediate goals of therapy in M.K.? How can they be achieved and assessed?

The goals in treating septic shock, in addition to eradicating the precipitating infection, are to optimize the delivery of oxygen to the tissues and to control abnormal use of oxygen and anaerobic metabolism by reducing the tissue oxygen demand. Tissue injury is widespread during sepsis, most likely because of vascular endothelial injury with fluid extravasation and microthromboses, which decrease oxygen and substrate utilization by the affected tissues. The mainstay of therapy is volume expansion to increase intravascular volume, enhance CO, and ultimately delay associated development of refractory tissue hypoxia. The therapeutic goals used for hemodynamic resuscitation are controversial. The issue is whether therapy should be directed to physiologic end points of tissue perfusion or clinical end points, such as BP and urine output. The physiologic end points include clearance of blood lactate concentrations, base deficit, mixed venous oxygen saturation (SvO₂), and increased CO. Although definitive evidence is lacking, a combination of these physiologic and clinical end points should be used to guide therapy.

Fluids are the mainstay of treatment because increasing CO will improve capillary circulation and tissue oxygenation by maintaining sufficient intravascular volume. If fluids do not correct the hypoxia or if filling pressures are increased, the sequential addition of inotropes and vasopressors is indicated. Blood transfusions should be used if the hematocrit is below 21% unless there is an active source of bleeding or a history of cardiac disease, in which case the hematocrit value would be maintained at a higher value. Crystalloids (with electrolytes to correct imbalances) should be initiated to maintain the CI goal as well as a MAP of 65 mmHg or a SBP of 90 mmHg. The MAP is a better reflection of systemic arterial pressure because it considers the diastolic pressure, which is an essential component of blood flow. Although MAP and BP are not absolute measures of blood flow to all vital organs, these pressures are considered the therapeutic end points that will sustain myocardial and cerebral perfusion. After optimization with fluid therapy, inotropic and vasopressor agents are indicated if the patient remains hypotensive with a low CI and if signs of inadequate tissue perfusion persist.

One study has shown that early goal-directed therapy in the treatment of severe sepsis and septic shock leads to improved survival.⁸⁴ This approach to patient care integrates both physiologic and clinical end points of resuscitation as early as possible to maintain perfusion during the early stages of sepsis. This study randomized patients admitted to an ED to standard therapy versus goal-directed therapy, which consisted of at least 6 hours of continuous care in the ED where they received a central venous catheter capable of measuring central venous oxygen saturation (ScvO₂). The treatment group maintained a CVP of 8 to 12 mmHg with continued fluid boluses and a MAP >65 mmHg with vasopressor treatment initiated if necessary. If the ScvO₂ was <70%, red cells were transfused to achieve a hematocrit of at least 30%. If the CVP, MAP, and HCT were optimized and the ScvO₂ was still <70%, dobutamine was administered to improve the delivery of oxygen to the tissues. The primary efficacy end point was in-hospital mortality, which was statistically significantly lower in the early goal-directed group. The results of this study have prompted many institutions to develop sepsis bundles that incorporate the same variables and end points of therapy as early as possible in the treatment of sepsis. Sepsis bundles often incorporate the many issues addressed in the Surviving Sepsis Campaign Guidelines, such as

ventilatory support, initial choice of antibiotics, glucose control, and stress ulcer prophylaxis.⁸⁵

M.K. should receive fluid boluses to maintain perfusion with a MAP >65 mmHg and a CVP in the 8 to 12 mmHg region, and ideally receive a central line to monitor his mixed venous oxygen saturation. Continued, excessive fluid challenges to increase preload in M.K. must be approached cautiously, however, because he has a history of ischemic heart disease and ongoing evidence suggestive of pneumonia, both of which could be made worse by overly aggressive fluid boluses. In addition, patients in septic shock are susceptible to developing noncardiogenic pulmonary edema or ARDS, which can cause severe deterioration in pulmonary function. Therefore, fluid boluses should be given with ongoing monitoring to determine the CVP and PCWP at which CO is maximal. This approach will avoid excessive CVP and PCWP beyond which CO is no longer increased, thereby reducing the potential formation of pulmonary edema.

In summary, the immediate goal of therapy is to maximize oxygen delivery to the tissues. Fluid resuscitation is the mainstay of therapy and improves oxygen delivery by increasing CO; however, inotropic and vasopressor agents are often required for additional cardiovascular support. A favorable response to immediate resuscitative efforts will be reflected by a reversal or halt in the progression of the metabolic acidosis, improved sensorium, and increased urine output. In M.K., surgical evaluation for an ongoing or new abdominal process and selection of appropriate antibiotics while maintaining hemodynamic support are the clinical goals of therapy.

Hemodynamic Management

FLUID THERAPY VERSUS INOTROPIC SUPPORT

40. M.K. is given two 1,000-mL fluid boluses, and norepinephrine is begun at a rate of 0.02 mcg/kg/minute. Over the next 2 hours, he receives 3 L of fluid in boluses and the norepinephrine is increased to 0.15 mcg/kg/minute to maintain his BP. Signs of pulmonary edema have become more prominent. M.K. has the following hemodynamic profile (previous values in parentheses): BP (S/D/M), 94/46/62 mmHg (90/50/63); pulse, 124 beats/minute (122); CO, 7.0 L/minute (6); CI, 3.2 L/minute/m² (3.5); RAP, 13 mmHg (8); PCWP, 18 mmHg (12); SVR, 560 dyne.sec.cm⁻⁵ (733); urine output, 15 mL/hour; PaO₂, 62 mmHg (76); Paco₂, 38 mmHg (34); HCO₃⁻, 19 mEq/L (15); pH, 7.30 (7.31); Do₂, 445 mL/minute (438); Vo₂, 118 mL/minute (114); and PEEP, 5 cm H₂O. Which of the following therapeutic considerations would be reasonable for M.K. at this time: additional fluid boluses, an increase in the norepinephrine infusion rate, or initiation of a different vasopressor?

M.K. continues to be hypotensive despite a PCWP of 18 mmHg and a norepinephrine infusion rate of 0.15 mcg/kg/minute. The goals of therapy remain the same (i.e., maximize arterial oxygen content and oxygen delivery to reverse cellular anaerobic metabolism).

M.K.'s PaO₂ of 62 mmHg correlates with an oxygen-hemoglobin saturation of approximately 90%, which should provide an adequate arterial oxygen content. However, oxygen delivery still may be inadequate because the CI is <3.5 L/minute/m², and Do₂ and Vo₂ have not reached normal levels. In addition, decreased oxygen use can contribute to the continued acidosis. Thus, further attempts to enhance the CI and hence, oxygen delivery, are appropriate. However, M.K. has worsening signs of pulmonary edema and a history

of cardiovascular disease that will influence the choice of therapeutic options.

Although fluid administration is the mainstay of therapy in septic shock, the elevation of M.K.'s PCWP to 18 mmHg without a significant increase in CO suggests that an optimal PCWP has been reached. Therefore, additional fluid therapy to maintain his BP may worsen his pulmonary edema and further compromise his pulmonary gas exchange. A plot of CO versus the PCWP (ventricular function curve) would provide a more accurate assessment of the PCWP at which CO is maximal. Additional fluid boluses at this time should be used only to maintain the current level of intravascular volume status.

Vasopressors

NOREPINEPHRINE

When fluid therapy fails to maintain a satisfactory MAP despite an elevated CO, the use of a vasopressor should be considered. Norepinephrine is predominantly an α -adrenergic agonist (Table 21-7) and is frequently used as an adjunct to therapy when inotropic agents alone are unsuccessful. Because concern exists that excessive vasoconstriction might cause reflex decreases in CO and hypoperfusion of vital organs, the use of norepinephrine has often been limited to end-stage shock. However, studies indicate that norepinephrine alone, or in combination with inotropic agents can be beneficial in the management of septic shock.⁸⁶

Martin et al. compared the ability of dopamine and norepinephrine to reverse hemodynamic and metabolic abnormalities of hyperdynamic shock.⁸⁷ They prospectively randomized 32 volume-resuscitated patients with hyperdynamic sepsis to receive either dopamine or norepinephrine with the goal of achieving and maintaining normal hemodynamic and oxygen transport parameters for at least 6 hours. If goals were not achieved with one agent, the other agent was added. With the use of dopamine, 31% of patients met the predefined therapeutic goals. In contrast, 93% of patients treated with norepinephrine met the predefined goals. Of the patients who did not respond to dopamine, 91% achieved the goals with the addition of norepinephrine. In this study, norepinephrine was found to be superior to dopamine, with improvement in arterial BP, urine flow, oxygen delivery and consumption, and lactate levels.

In a similar study of patients in whom previous therapy with plasma volume expansion and dopamine or dobutamine had failed, norepinephrine reversed hypotension and significantly increased MAP, SVR, and urine output.⁸⁶ The CI was increased, albeit insignificantly, in 7 of 10 patients, presumably because of stimulation of cardiac β -receptors. By limiting the SVRI to 700 dyne.sec.cm⁻⁵/m², the investigators were able to prevent excessive vasoconstriction and promote an increased perfusion pressure to vital organs as reflected by an improved urine flow. Oxygen delivery and consumption were measured in 6 of 10 patients with variable results. Although no patient died of refractory hypotension, 4 of 10 patients died of progressive hypoxia, leading the authors to conclude that regardless of the catecholamines used, the ultimate goal of therapy should be to maximize oxygen delivery and consumption.

PHENYLEPHRINE

Occasionally, patients will respond to epinephrine or phenylephrine when other catecholamines have failed, al-

though neither of these agents is considered to be first-line therapy. Epinephrine stimulates α -, β_1 -, and β_2 -adrenergic receptors (Table 21-7). CO is augmented via increased contractility and HR, with the contribution of each being highly variable. Blood vessels in the kidney, skin, and mucosa constrict in response to α -adrenergic stimulation, while vessels in the skeletal muscle vasodilate because of β_2 effects. A biphasic response in SVR is observed with increasing doses as β_2 -receptors are activated at the lower range, while α_1 -receptors are stimulated at higher levels. The improvement in CO, therefore, may be negated by an increase in afterload at higher dosages.

Phenylephrine is a pure α -adrenergic agonist (Table 21-7) and, thus, increases systolic, diastolic, and mean arterial pressures through vasoconstriction. Reflex bradycardia can occur secondarily because of the absence of β -adrenergic effects. The increase in afterload, while increasing myocardial oxygen consumption, correspondingly increases coronary blood flow because of increased perfusion pressure and autoregulation. Therefore, in patients with myocardial hypoxia, or in those experiencing atrial or ventricular arrhythmias, phenylephrine can be beneficial because it has minimal direct cardiac effects. In situations in which the CO is decreased, however, phenylephrine can be detrimental. This occurs because preload is reduced from interstitial fluid losses as a result of increased capillary hydrostatic pressure effects. This response, in addition to the reflex bradycardia may significantly impair CO (Table 21-7).

VASOPRESSIN

Catecholamines have been the mainstay of treatment to support BP in septic patients once adequate fluid resuscitation has been achieved. Sepsis, however, can cause a decrease in responsiveness to catecholamines resulting in refractory hypotension, possibly because of downregulation of adrenergic receptors. Thus, other avenues of supportive treatment have been researched. Septic patients exhibit an increased sensitivity to vasopressin. Vasopressin is an endogenous hormone that has very little effect on BP under normal conditions, but becomes very important in maintaining BP when the baroreflex is impaired, such as in shock states. Vasopressin's direct vasoconstricting actions are mediated by the vascular V₁-receptors coupled to phospholipase C.^{88,89} When these receptors are activated, calcium is released from the sarcoplasmic reticulum in smooth muscle cells leading to vasoconstriction. One study found that vasopressin levels were very low in septic patients, whereas patients in cardiogenic shock displayed an appropriate increase in vasopressin release for the degree of hypotension.⁹⁰ The same investigators showed that a low-dose, continuous IV infusion of vasopressin at 0.04 U/minute in 19 patients with septic shock caused a statistically significant increase in vasopressin levels, systolic arterial pressure, and systemic vascular resistance when added to pre-existing catecholamine treatment. Six of ten patients were able to maintain BP on vasopressin alone. Stopping the vasopressin infusion resulted in decreases of BP to pretreatment levels, and reinstatement of the infusion increased BP within minutes. It is presumed that vasopressin secretion is impaired as opposed to enhanced vasopressin metabolism, but it is not entirely clear why this occurs. Most likely it is a combination of a deficient baroreflex-mediated secretion of vasopressin, impaired sympathetic function, and potentially depletion of the secretory stores of vasopressin.

Other studies support the vasopressor effects of vasopressin in septic patients already on catecholamines with persistent hypotension and also show a vasopressor-sparing effect on catecholamines. The most recent double-blind, randomized trial showed that norepinephrine infusion could be decreased by the addition of vasopressin administration.⁹¹ Another statistically significant finding from this study was that urine output and creatinine clearance both increased more in the vasopressin group than in the norepinephrine group. It seems reasonable at this point to use vasopressin in patients with septic shock who are on high doses of catecholamines or those who need further vasopressor support. Further studies are needed to determine if treatment with vasopressin confers a mortality benefit.

M.K. has decreased MAP despite the addition and increased titration of norepinephrine. Because it has been found that patients in septic shock have decreased endogenous levels of vasopressin, it would be reasonable to add vasopressin at 0.04 U/minute to the prior norepinephrine infusion to increase the MAP and renal perfusion.

Inotropic Agents

Although the use of inotropic agents is well established, controlled comparative studies have not clearly determined which agent, or combination of agents, is most useful in the management of septic shock. Because differences among the inotropic agents are significant, however, selection of the most appropriate drug should be guided by careful consideration of the patient's hemodynamic status.

DOPAMINE

Dopamine has frequently been the initial pharmacologic agent chosen for the treatment of septic shock. If the MAP is low with a depressed CO and a low SVR, dopamine is an appropriate choice because its combined α -adrenergic vasoconstrictive actions and β -adrenergic inotropic effects will increase SVR and CO, thereby effectively raising it. In situations in which the PCWP is elevated or in patients with decreased ventricular compliance, the use of dopamine may be limited because it significantly increases venous return and ventricular filling pressure. In addition, dopamine increases shunting of pulmonary blood flow, leading to a decline in PaO₂. This effect may worsen hypoxemia in patients with pneumonia or ARDS.

DOBUTAMINE

Dobutamine is often advocated as the secondary inotropic agent in the management of septic shock, particularly in patients with low CO and high filling pressures. Dobutamine produces a greater increase in CO than dopamine, but also lowers SVR. In contrast to dopamine, dobutamine lowers PCWP, decreases myocardial oxygen consumption, and causes less pulmonary shunting. Because dobutamine can lower ventricular filling pressure, volume status must be monitored closely to avoid the development of hypotension and reduced MAP. Fluids should be administered as needed to maintain the PCWP at maximal tolerated levels of 16 to 18 mmHg. With the administration of greater amounts of fluid, CO, oxygen delivery, and systemic oxygen consumption are significantly increased. Dobutamine does increase Do₂ and CI when given concurrently with or after volume resuscitation. Decreases in PaO₂ and increases in venous PO₂, as well as adverse

effects on myocardium, may be evident at higher dosages (>6 mcg/kg/minute).⁹²

Combinations of vasopressors and inotropes can also be used to achieve desired hemodynamic parameters. Because gastrointestinal perfusion can be compromised owing to the vasoconstricting effects of catecholamines and may play a role in the pathogenesis of multiple organ dysfunction, the combination of norepinephrine and dobutamine has been studied to determine if an advantage exists to using norepinephrine alone, epinephrine alone, or a combination.^{54,93} One prospective study randomized patients with a MAP <60 mmHg despite adequate fluid resuscitation and treatment with high dose dopamine to either dobutamine plus norepinephrine or epinephrine monotherapy titrated to a MAP >80 mmHg.⁵⁴ The variables were the MAP, metabolic effects as evidenced by lactate and pyruvate concentrations, and splanchnic perfusion measured by gastric pH (pH_i) and partial pressure of carbon dioxide (PCO₂) gap. This study showed that both therapies, norepinephrine plus dobutamine and epinephrine monotherapy, were equally effective at achieving hemodynamic goals, but that treatment with epinephrine alone could worsen splanchnic oxygen utilization and potentially lead to ischemic injury. Currently, it is unknown whether a specific catecholamine regimen provides a significant benefit over others. There is conflicting data about which vasopressor can increase gastric perfusion and whether this increase can alter progression to organ dysfunction.

41. Given M.K.'s history of cardiovascular disease, what considerations must be accounted for before initiating a vasopressor agent? Outline an overall approach to maintaining adequate hemodynamic status.

M.K. has a history of coronary artery disease and is susceptible to myocardial ischemia. Therefore, a careful balance must be achieved between myocardial oxygen consumption and coronary perfusion pressure. Further attempts to optimize MAP and CI with norepinephrine alone could increase myocardial oxygen consumption and precipitate ischemia. Evidence suggests that the goal of therapy in treating patients with septic shock, or any form of shock for that matter, is not to simply normalize BP, but to optimize oxygen delivery and consumption. Once anemia and hypoxia have been corrected, CO becomes the remaining parameter that can be adjusted to increase oxygen supply, but raising arterial BP and CO with inotropic agents or vasopressors before restoring adequate blood volume actually can worsen tissue perfusion. Therefore, the selection of an inotropic agent must take into consideration the patient's current hemodynamic status and the individual properties of those agents that will most effectively maintain or increase the MAP and CO. In many instances, because of individual variability and response, more than one inotropic agent or addition of a vasopressor is required to achieve these end points. These interventions must be made with strict follow up of the patients' response to the interventions to prevent any adverse consequences, especially in those patients who are predisposed to an adverse event such as M.K.

It is important to realize that the response to exogenous catecholamines in patients with septic shock is highly variable and a successful regimen in one patient may be unsuccessful in another. In addition, septic patients often require infusion rates in the moderate-to-high range. Therefore, the goal is to

use one or more agents at the dosages necessary to achieve the desired end points without unduly compromising the patient's status. The use of catecholamines, however, is only a stabilizing measure. Strict attention to all other physiologic parameters—as well as nutritional support, antibiotic modification, and ongoing surgical intervention—cannot be overemphasized.

Other Therapies

Therapies directed against the initiators and mediators of sepsis are currently the focus of intense investigation. As previously discussed, numerous exogenous and endogenous substances are involved in the pathogenesis of sepsis. Strategies under development include antioxidants and free radical scavengers, antiendotoxin therapy, inhibition of leukocytes, secondary mediators (i.e., TNF- α , IL-1, cytokine pathway), coagulation and arachidonic acid metabolites, complement, and NO. Although several experimental therapies hold considerable promise for the future, controlled human data are still lacking.

CORTICOSTEROIDS

42. What is the rationale for the use of glucocorticosteroids in the treatment of septic shock, and is there evidence to support their use for this indication?

The use of corticosteroids in sepsis and septic shock has been a controversial topic for many years. Corticosteroids were originally proposed as a treatment option because of their anti-inflammatory properties with the hope of attenuating the body's response to infection. More recently it has been shown that critically ill patients exhibit impaired cortisol secretion because of a relative adrenocortical insufficiency, and it is suspected that these patients display a glucocorticoid peripheral resistance syndrome. Almost 50% of patients with septic shock exhibit relative adrenal insufficiency defined as a maximal change in cortisol level of <9 mcg/dL after a 250 mcg IV dose of corticotropin.⁹⁴

Several clinical trials have been performed over the past few decades with varying results and meta-analyses have recommended discontinuation of high-dose corticosteroid therapy because of detrimental outcomes.^{95,96} End points that have been studied include time to reversal of septic shock (defined by cessation of vasopressor support) and mortality. Older trials used different definitions of septic shock, however, and the timing and dosing of steroids were highly variable. Most recently, the randomized, double-blind, placebo-controlled trial by Annane et al.⁹⁷ showed a mortality benefit after 28 days associated with the use of low doses of hydrocortisone and fludrocortisone in patients with relative adrenocortical insufficiency (nonresponders to corticotropin) and septic shock. All patients received a corticotropin stimulation test and relative adrenocortical insufficiency was defined as a response of 9 mcg/dL or less (nonresponders). It was found that in nonresponders, 63% of the placebo group died, whereas 53% of the corticosteroid group died ($p = 0.02$). Time to cessation of vasopressor support was also shortened by the use of steroids in the treatment group compared with placebo in the nonresponders. Responders did not show any benefit from the use of corticosteroids, and actually had slightly worse outcomes when they did receive steroids. This study suggests the use of corticosteroids in vasopressor-dependent septic shock *only* in those patients who exhibit relative adrenal insufficiency. The outcomes of this trial are controversial and some evidence that

is not yet published indicates that steroids may not be as beneficial in every patient with septic shock, but possibly only for those with severe sepsis with refractory hypotension.

Because M.K. is refractory to increasing doses of norepinephrine and is in severe sepsis, a corticotropin stimulation test should be administered and hydrocortisone 50 mg IV every 6 hours plus fludrocortisone 50 mcg/feeding tube every 24 hours should be started after the stimulation test. Treatment can be discontinued if the results of the stimulation test show that M.K. is not adrenally insufficient.

STATINS

43. Is there any significance to the fact that M.K. was on statin therapy before his episode of sepsis? Should his statin therapy be continued?

Aside from their well-described lipid-lowering effects, statins appear to have immunomodulatory and anti-inflammatory effects. Statin therapy lowers C-reactive protein levels, inhibits endothelial cell dysfunction, causes upregulation of endothelial NO synthase, and blocks immune cell receptors.⁹⁸ A growing body of evidence shows that patients who are on a statin before the inciting septic event may have a decreased likelihood of developing sepsis, and a mortality benefit may exist for those with sepsis or multiple organ dysfunction. All studies in humans thus far have been retrospective and in patients who were previously on a statin. One trial showed a significant survival benefit associated with continuing statin therapy in patients who were bacteremic compared with those who were never on statin therapy.⁹⁹ Potentially more important is that the highest mortality was seen in those patients who had been on statin therapy, but had been discontinued (result not statistically significant). These results may lend credence to the idea of a rebound phenomenon that could be detrimental if statins are not continued. Statins are often discontinued in septic patients because of concern for adverse effects and further organ dysfunction. Presently, it is not clear whether statins should always be continued in septic patients, and it is unknown whether statins should be initiated in patients who develop sepsis. Further evidence by means of prospective, randomized trials is needed to further define the role of statins in sepsis.

DROTECOGIN ALFA

44. Is M.K. a candidate for recombinant activated protein C? Is there any evidence to support its use in septic shock, and what are the major risks associated with its use?

Activated protein C (APC) is an endogenous protein that acts as one of the regulators of the coagulation cascade and also interrupts the amplification cycle of inflammation.²¹ Protein C is the inactive precursor to APC, and conversion to the active form requires thrombin to complex with thrombomodulin. APC enhances fibrinolysis and has potent inhibitory effects on thrombin, which possesses thrombotic as well as inflammatory effects. Other anti-inflammatory effects of APC stem from suppression of TNF- α , IL-6, and IL-1 production.

Patients in septic shock develop microvascular thrombosis, which leads to organ hypoperfusion, cell dysfunction, multiple organ dysfunction, and death. The systemic response to infection activates the coagulation pathway leading to the generation of thrombin and deposition of fibrin as well as initiating an inflammatory reaction via activation of cytokines.

Adult and pediatric septic patients have low levels of protein C and a poor outcome is expected for those patients with the lowest levels.¹⁰⁰ The deficiency in protein C is probably due to enhanced degradation as well as impaired synthesis of protein C. It is also apparent that patients in septic shock exhibit lower levels of thrombomodulin, the protein necessary for the conversion of protein C to activated protein C. Thus, the use of APC would counter the anticoagulant deficiency as well as suppress the inflammatory reaction that would normally take place due to the infection.

The Protein C Worldwide Evaluation in Severe Sepsis (PROWESS)¹⁰¹ trial is the only published phase III clinical trial reporting the safety and efficacy of drotrecogin- α (recombinant APC). It was a randomized, double-blind, placebo-controlled, multicenter trial that was stopped early because of the statistically significant difference in the primary end point, 28-day all-cause mortality, before enrollment was complete. Included in the study were patients with a known or suspected infection plus three or more signs of systemic inflammation and at least one organ system dysfunction caused by sepsis. Patients also had to begin treatment of drotrecogin- α at 24 mcg/kg/hour for 96 hours within 24 hours of meeting inclusion criteria. The list of exclusion criteria was extensive to ensure that patients who were at higher risk for bleeding did not participate in the trial. No standardized protocol was established for the critical care provided to the patient (e.g., antibiotics, vasopressors, inotropes). Treatment with APC reduced D-dimer and IL-6 levels, indicating attenuation of the procoagulant and inflammatory effects of sepsis. Treatment with drotrecogin- α was associated with a 6.1% absolute reduction in mortality at 28 days after the start of infusion. The incidence of serious bleeding was higher in the APC group, almost reaching statistical significance ($p = 0.06$). A subgroup analysis showed that patients with higher Acute Physiology and Chronic Health Evaluation (APACHE) II scores (>25) benefited the most from treatment with APC. A follow-up study mandated by the U.S. Food and Drug Administration (FDA) showed that APC use in septic patients with single organ failure or an APACHE II score <25 was not effective in achieving a decrease in mortality at 28 days and was actually associated with an increase in bleeding complications.¹⁰² Based on the results of these studies, APC should be used only in patients with sepsis with an APACHE II score >25 or with two or more organ systems in failure.

M.K. meets the criteria for severe sepsis because he meets three of the requirements for SIRS (white blood cell count [WBC] = 18,000 cells/mm³; use of mechanical ventilation; HR >90 beats/minute) and has three dysfunctional organ systems. He requires vasopressor support, is on a ventilator, and has an increase in his SrCr. He also has several potential sources of infection with pulmonary infiltrates and increased secretions, and the formation of an abdominal abscess is a possibility. His surgery was 5 days before his decompensation, so his bleeding risk should be minimal; however, the patient should be closely monitored. The cost of APC is substantial: approximately \$7,000 for a 70-kg person for 96 hours. M.K. is a candidate for APC use; however, the risks of bleeding need to be carefully assessed because the use of APC could lead to devastating adverse events. Because of this, the formation of institutional guidelines to determine the patient population in which this drug can be more safely administered is highly recommended.

45. What other treatment options are under research for septic shock?

Because endotoxin is the initiator of the inflammatory cascade of gram-negative sepsis, extensive research has been devoted to development and study of antibodies against the core lipid-A portion of endotoxin, which possesses most of the biologic activity. To date no antiendotoxin therapies have shown any benefit.

Monoclonal antibodies to TNF- α (anti-TNF-Mab) confer significant protection in various animal models of septic shock induced by endotoxin, gram-negative, or gram-positive bacteremia. Investigations into anti-TNF antibodies prompted a large controlled clinical trial, by the INTERSEPT study group.¹⁰³ The results showed no difference in 28-day mortality rates between groups, and patients in the nonshock group derived no benefit. One recent study testing anti-TNF antibody fragments was terminated early because of funding issues; however, a trend was noted toward more shock-free and ventilator-free days.¹⁰⁴ More interesting is the observation that patients without a detectable baseline TNF- α level did worse than those with an elevated baseline level. Some evidence supports a biphasic immunologic pattern with an initial hyperinflammatory phase that is counterbalanced by an anti-inflammatory response, which may lead to a hypoinflammatory state (immunoparalysis). It is possible that tailoring therapy by providing anticytokine therapy to only those patients who are in the proinflammatory state may be beneficial versus providing it to all patients who are in septic shock. More studies are in progress.

Another approach to blocking the effects of TNF involves the use of soluble TNF receptors, which bind to, and inactivate, TNF before it interacts with its cellular receptor. Although effective in primate models of sepsis, a clinical trial examining escalating doses of soluble TNF receptor in patients with sepsis syndrome revealed an increase in mortality in patients receiving higher dosages of the receptor as compared with lower-dose therapy and placebo.¹⁰⁵

Ethyl pyruvate has recently been identified as an experimental anti-inflammatory agent that also has anticoagulant effects.¹⁰⁶ This is currently the only other agent with a dual immunomodulatory and anticoagulant effect such as drotrecogin- α . Clinical studies are needed to determine whether this therapy will have beneficial effects in the treatment of sepsis.

Continuous hemofiltration is a technique that removes proinflammatory mediators, and has potential for treatment of septic patients. The use of adsorbents in hemoperfusion columns aids in the removal of toxic compounds from the circulatory system. Experimental data show that TNF- α , IL-1, IL-6, IL-8, and endotoxin can be removed from the circulation of septic patients by continuous hemofiltration.^{107,108} Many animal studies show that hemofiltration improves hemodynamic indices and human data are promising. No controlled, randomized clinical trials have evaluated continuous hemofiltration, however.

GLOSSARY

Afterload: Ventricular wall tension developed during contraction. Determined by the resistance or impedance the ventricle must overcome to eject end-diastolic volume. Left

- ventricular afterload is determined primarily by systemic vascular resistance; right ventricular afterload is determined primarily by pulmonary vascular resistance.
- Arterial pressure (AP):** Pressure in the central arterial bed; determined by cardiac output and systemic vascular resistance.
- Body surface area (BSA):** Average = 1.7 m^2 .
- Cardiac index (CI):** Cardiac output per square meter of body surface area (BSA).
- Cardiac output (CO):** Amount of blood ejected from the left ventricle per minute; determined by stroke volume and heart rate. $\text{CO} = \text{SV} \times \text{HR}$.
- Central venous pressure (CVP)**—also called right atrial pressure (RAP): Measures mean pressure in right atrium and reflects right ventricular filling pressure. Primarily determined by venous return to the heart.
- Compliance:** Distensibility of the relaxed ventricle or stiffness of the myocardial wall.
- Contractility:** The inotropic state of the myocardium; affects stroke volume and cardiac output independently of preload and afterload.
- Heart rate (HR):** Number of myocardial contractions per minute; regulated by autonomic nervous system. An increase or decrease alters cardiac output in same direction.
- Left ventricular stroke work index (LVSWI):** Amount of work the left ventricle exerts during systole; adjusted for body surface area (BSA).
- Oxygen consumption (VO_2):** The amount of oxygen consumed by the body per unit time. The product of cardiac output and the difference between the arterial and venous concentrations of oxygen.
- Oxygen delivery (DO_2):** The amount of oxygen delivered by the body per unit time, the product of cardiac output and arterial oxygen concentration.
- Perfusion pressure:** The pressure gradient between the coronary arteries and the pressure in either the right atrium or left ventricle during diastole. A major determinant of coronary blood flow and oxygen supply to the heart.
- Preload:** End-diastolic fiber length before contraction; represented by left ventricular end-diastolic volume (LVEDV); approximated by left ventricular end-diastolic pressure (LVEDP) and pulmonary capillary wedge pressure (PCWP). Right ventricular preload is reflected by central venous pressure (CVP) or right arterial pressure (RAP).
- Positive end-expiratory pressure (PEEP):** The application of positive pressure at the end of the expiratory phase of respiration to improve oxygenation.
- Pulmonary artery pressure (PAP):** *Systolic (PAS):* Measures pulmonary artery pressure during systole; reflects pressure generated by the contraction of the right ventricle. *Pulmonary artery diastolic (PAD):* Measures pulmonary artery pressure during diastole; reflects diastolic filling pressure in the left ventricle. May approximate pulmonary capillary wedge pressure (PCWP); normal gradient $<5 \text{ mmHg}$ between PAD and PCWP.
- Pulmonary capillary wedge pressure (PCWP):** Measures pressure distal to the pulmonary artery; reflects left ventricular filling pressures. May optimally increase to 16 to 18 mmHg in critically ill patients. Usually lower than or within 5 mmHg of *pulmonary artery diastolic (PAD)*.
- Pulmonary vascular resistance (PVR):** Measure of impedance or resistance within the pulmonary vasculature that the right ventricle must overcome during contraction; determines right ventricular afterload.
- Stroke volume (SV):** Amount of blood ejected from the ventricle with each systolic contraction. $\text{SV} = \text{CO}/\text{HR}$.
- Stroke volume index (SVI):** Stroke volume per square meter of body surface area (BSA).
- Systemic vascular resistance (SVR):** Measure of impedance applied by systemic vascular system to systolic effort of left ventricle; determined by autonomic nervous system and condition of vessels. Determinant of left ventricular afterload.
- Systemic vascular resistance index (SVRI):** Systemic vascular resistance adjusted for body surface area (BSA).

According to the National Institutes of Health (NIH) Expert Panel Report 3 (EPR-3): Guidelines for the Diagnosis and Management of Asthma,¹ *asthma* is defined as a chronic inflammatory disorder of the airways in which many cells and cellular elements play a role, in particular, mast cells, eosinophils, T lymphocytes, neutrophils, and epithelial cells. In susceptible persons, this inflammation causes recurrent episodes of wheezing, breathlessness, chest tightness, and cough, particularly at night and in the early morning. These episodes are usually associated with widespread but variable airflow obstruction that is often reversible either spontaneously or with treatment. The inflammation also causes an increase in

the existing bronchial hyperresponsiveness to a variety of stimuli.² This definition of asthma is the same as the 1997 NIH guidelines² and has evolved from earlier national/international guidelines.^{3–6}

At least 22 million Americans have asthma.¹ It is an underdiagnosed and undertreated condition that is estimated to have overall costs exceeding \$12 billion annually in the United States.⁷ Asthma is the leading cause of lost school days in children and is a common cause of lost workdays among adults.

Mortality from asthma has decreased in the 21st century, from 4,657 deaths in 1999 to 3,816 deaths in 2004 in the United States according to the Centers for Disease Control and Prevention,^{8,9} but morbidity and mortality are still

unacceptably high, especially in inner-city minority populations. This chapter emphasizes the 2007 NIH EPR-3 guidelines.¹ Application of the principles of these recent guidelines by clinicians and patients is vital to further reducing asthma morbidity and mortality.

Etiology

Childhood-onset asthma is usually associated with atopy, which is the genetic predisposition for the development of immunoglobulin E (IgE)-mediated response to common aeroallergens. Atopy is the strongest predisposing factor in the development of asthma.¹ A very common presentation of asthma is a child with a positive family history of asthma and allergy to tree and grass pollen, house dust mites, household pets, and molds.

Adult-onset asthma may also be associated with atopy, but many adults with asthma have a negative family history and negative skin tests to common aeroallergens. Some of these patients may have nasal polyps, aspirin sensitivity, and sinusitis. In the British 1958 birth cohort study, participants were monitored for wheezing and asthma at periodic intervals from birth into their mid-forties.¹⁰ In the subset of patients who were seemingly asymptomatic during late adolescence and early adulthood, the presence of asthma at 42 years of age was significantly higher in those patients who had a history of wheezing in childhood. Exposure to factors (e.g., wood dusts, chemicals) at the workplace that may cause airway inflammation is also important in many adults. Inflammatory mechanisms are similar, but not the same, as in atopic asthma. Some clinicians may still refer to *intrinsic asthma* when referring to these patients and *extrinsic asthma* when discussing atopic asthma.

In addition to atopy and exposure to occupational chemical sensitizers being major risk factors for the development of asthma, several contributing factors may increase the susceptibility to the development of the disease in predisposed individuals.^{1,5} These factors include viral infections, small size at birth, diet, exposure to tobacco smoke, and environmental pollutants.^{1,5}

Recent literature has focused on the “hygiene hypothesis,” an imbalance of TH2- and TH1-type T lymphocytes, to explain the marked increase in asthma in westernized countries.^{1,5,8} Infants who have older siblings, early exposure to day care, and typical childhood infections are more likely to activate TH1 responses (protective immunity), resulting in an appropriate balance of TH1/TH2 cells and the cytokines that they produce. On the other hand, if the immune response is predominately from TH2 cells (which produce cytokines that mediate allergic inflammation), development of diseases such as asthma is more likely. Examples of factors favoring this imbalance include the common use of antimicrobial agents, urban environment, and Western lifestyle. Further insights into the pathogenesis of asthma continue to be discovered.^{1,7,11,12}

Pathophysiology

Asthma is caused by a complex interaction between inflammatory cells and mediators. As noted in the definition of asthma, mast cells, eosinophils, T lymphocytes, neutrophils, and epithelial cells are of central importance. The bronchial epithelium in asthmatics has been described as fragile, with various

abnormalities including destruction of ciliated cells and overexpression of epidermal growth factors.¹³ Figure 22-1 depicts the complex interaction of cells and mediators associated with airway inflammation.

After exposure to an asthma-precipitating factor (e.g., aeroallergen), inflammatory mediators are released from bronchial mast cells, macrophages, T lymphocytes, and epithelial cells. These mediators direct the migration and activation of other inflammatory cells, most notably eosinophils, to the airways.^{1,11,12} Eosinophils release biochemicals (e.g., major basic protein and eosinophil cationic protein) that cause airway injury, including epithelial damage, mucus hypersecretion, and increased reactivity of smooth muscle.^{1,7,11}

Research continues to determine the role of a subpopulation of T lymphocytes (TH2) in asthmatic airway inflammation.^{1,11} TH2 lymphocytes release cytokines (e.g., interleukin [IL]-4 and IL-5) that at least partially control the activation and enhanced survival of eosinophils.^{1,4,11} The complexity of airway inflammation is indicated by the fact that at least 27 cytokines may have a role in the pathophysiology of asthma.¹¹ In addition, at least 18 chemokines (e.g., eotaxins) have been identified that are important in delivery of eosinophils to the airways.¹¹ One biomarker of airway inflammation is exhaled nitric oxide (NO), which has been used as a treatment guide in chronic asthma.¹ Bronchial NO has been found to be elevated during periods of exacerbations and is measurably decreased with administration of inhaled steroids but not β_2 -agonists.^{14,15} Failure to adequately minimize severe and long-term airway inflammation in asthma may result in airway remodeling in some patients. Airway remodeling refers to structural changes, including an alteration in the amount and composition of the extracellular matrix in the airway wall leading to airflow obstruction that eventually may become only partially reversible.^{1,16}

Hyperreactivity (defined as an exaggerated response of bronchial smooth muscles to trigger stimuli) of the airways to physical, chemical, immunologic, and pharmacologic stimuli is pathognomonic of asthma.² Examples of these stimuli include inhaled allergens, respiratory viral infection, cold, dry air, smoke, other pollutants, and methacholine. Endogenous stimuli that can worsen asthma include poorly controlled rhinitis, sinusitis, and gastroesophageal reflux disease.¹ In addition, premenstrual asthma has been reported, but the exact hormonal mechanism is not known.¹⁷

Although patients with allergic rhinitis, chronic bronchitis, and cystic fibrosis also experience bronchial hyperreactivity, these patients do not experience bronchiolar constriction as severely as do patients with asthma. The degree of bronchial hyperreactivity of asthmatics correlates with the clinical course of their disease, which is characterized by periods of remissions and exacerbations. During times of remission, a more intense stimulus is required to produce bronchospasm than during times of increased symptoms. Numerous theories have been proposed to explain the bronchial hyperreactivity found in asthma, yet none fully explains the phenomenon. Inflammation appears to be the primary process in the pathogenesis of bronchial hyperreactivity; however, neurogenic imbalances in the airways also may play a significant role.⁵ Inflamed airways are hyperreactive (i.e., irritable). Hyperreactivity can be measured in the physician's office by having the patient inhale small concentrations of nebulized methacholine or histamine or by exercise (e.g., treadmill). The concentration of aerosolized

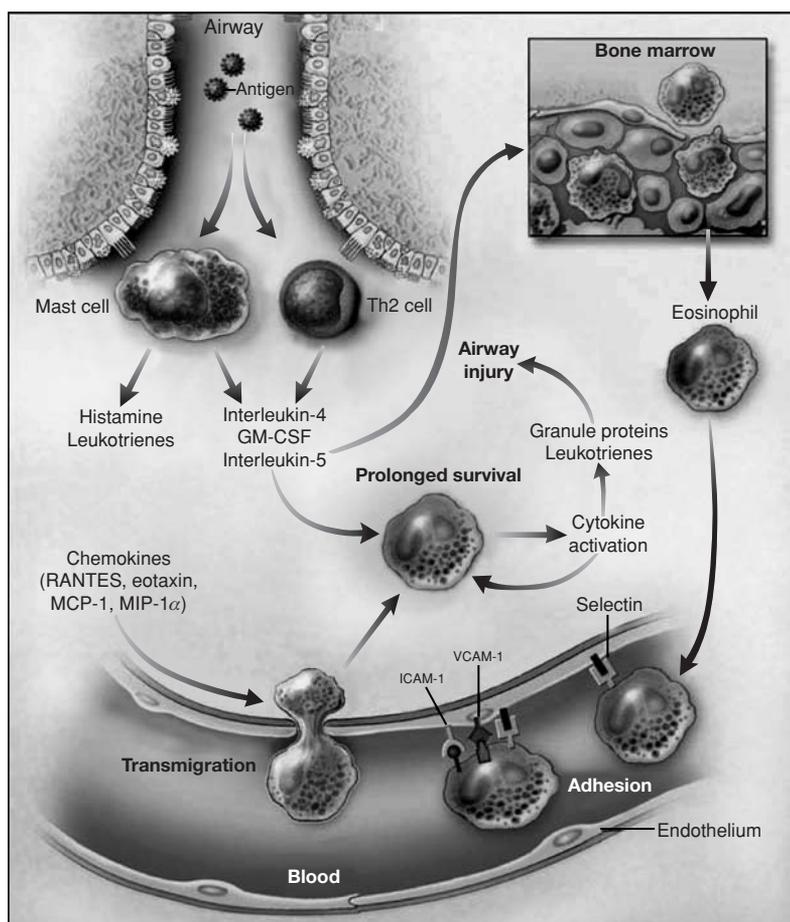

FIGURE 22-1 Airway inflammation. Inhaled antigen activates mast cells and Th2 cells in the airway. They in turn induce the production of mediators of inflammation (such as histamine and leukotrienes) and cytokines including interleukin-4 and interleukin-5. Interleukin-5 travels to the bone marrow and causes terminal differentiation of eosinophils. Circulating eosinophils enter the area of allergic inflammation and begin migrating to the lung by rolling, through interactions with selectins, and eventually adhering to endothelium through the binding of integrins to members of the immunoglobulin superfamily of adhesion proteins: vascular-cell adhesion molecule 1 (VCAM-1) and intercellular adhesion molecule 1 (ICAM-1). As the eosinophils enter the matrix of the airway through the influence of various chemokines and cytokines, their survival is prolonged by interleukin-4 and granulocyte-macrophage colony-stimulating factor (GM-CSF). On activation, the eosinophil releases inflammatory mediators, such as leukotrienes and granule proteins, to injure airway tissues. In addition, eosinophils can generate GM-CSF to prolong and potentiate their survival and contribution to persistent airway inflammation. MCP-1, monocyte chemoattractant protein; and MIP-1 α , macrophage inflammatory protein. methacholine or histamine that decreases the forced expiratory volume in 1 second (FEV_1) by 20% is referred to as the PD_{20} or the PC_{20} (provocative dose or concentration that decreases the FEV_1 by 20%).² An indicator of optimal anti-inflammatory therapy is an increase in the PD_{20} over time as the airways become less inflamed and therefore less hyperreactive.

Another concept related to inflammation is “late-phase” versus “early-phase” asthma (Fig. 22-2). The inhalation of specific allergens in atopic asthmatics produces immediate bronchoconstriction (measured by a drop in peak expiratory flow [PEF] or FEV_1) that spontaneously improves over an hour or is reversed easily by inhalation of a β_2 -agonist. Although this early asthmatic response (EAR) is blocked by the preadministration of β_2 -agonists, cromolyn, or theophylline, a second bronchoconstrictive response often occurs 4 to 12 hours later. This late asthmatic response (LAR) often is more severe, more prolonged, and more difficult to reverse with bronchodilators than is the EAR. The LAR is associated with the influx of inflammatory cells and mediators as described previously. Bronchodilators do not block the LAR to allergen challenge; corticosteroids block the LAR but do not affect the EAR; and cromolyn blocks both.²

Pathologic changes in asthmatics found at autopsy include (a) marked hypertrophy and hyperplasia of the bronchial smooth muscle, (b) mucous gland hypertrophy and excessive mucous secretion, and (c) denuded epithelium and mucosal edema due to an exudative inflammatory reaction and inflam-

matory cell infiltration.¹ Hyperinflation of the lungs from air trapping with extensive mucous plugging is found at autopsy in patients who have died from acute asthma attacks, but these changes also are seen at autopsy in asthmatics dying from other causes. The bronchial smooth muscle hypertrophy and mucus hypersecretion are secondary to the chronic inflammatory response.

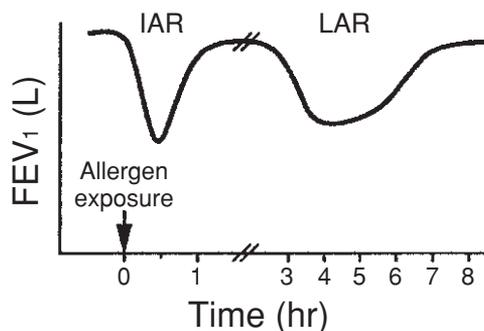

FIGURE 22-2 Typical immediate and late asthmatic responses seen after exposure to relevant allergen. Immediate asthmatic response (IAR) occurs within minutes, whereas late asthmatic response (LAR) occurs several hours after exposure. Patients may demonstrate isolated IAR, isolated LAR, or dual responses. (Reproduced with permission from Herfindal ET, Gourley DR. *Textbook of Therapeutics Drug and Disease Management*. 7th ed. Baltimore: Williams & Wilkins, 1996.)

Symptoms

The heterogeneity of asthma is reflected best in its clinical presentation. Classically, patients with asthma present with intermittent episodes of expiratory wheezing, coughing, and dyspnea. Some patients, however, experience chest tightness or a chronic cough that is not associated with wheezing. There is a wide spectrum of disease severity, ranging from patients with occasional, mild bouts of breathlessness to patients who wheeze daily despite continuous high dosages of medication. In addition, the severity of asthma may be influenced by environmental factors (e.g., specific seasonal allergens). Symptoms often are associated with exercise and sleep (refer to Questions 43 and 48).

Classification of asthma severity is of major importance in defining initial long-term treatment. Based on three age groups, EPR-3 uses the classifications of intermittent, mild persistent, moderate persistent, and severe persistent asthma (Tables 22-1–22-3). The frequency of symptoms is a key component of asthma classification.¹ For example, mild persistent asthma is defined as symptoms more than two times per week or nocturnal symptoms (including early morning chest tightness) more

than two times per month. Many clinicians are unaware that this level of symptoms is defined as persistent asthma. This classification is of major significance when selecting long-term drug therapy in that daily use of anti-inflammatory agents is an essential part of management for persistent asthma.¹

Diagnosis and Monitoring

History

The diagnosis of asthma is based primarily on a detailed history of intermittent symptoms of wheezing, chest tightness, shortness of breath, and coughing. These episodes may be worse seasonally (e.g., springtime or late summer and early fall) or in association with exercise. History of nocturnal symptoms with awakening in the early morning is a critical component to assess. In addition, history of symptoms after exposure to other common triggers (e.g., cats, perfume, second-hand tobacco smoke) is typical (Table 22-4). A positive family history and the presence of rhinitis or atopic dermatitis also are significant. After a careful history is obtained, skin testing may

Table 22-1 Classifying Asthma Severity in Children 0 to 4 Years of Age

Classifying severity in children who are not currently taking long-term control medication.^a

| Components of Severity | | Classification of Asthma Severity (Children 0–4 Years of Age) | | | |
|------------------------|---|--|--|-----------------|-----------------------|
| | | Intermittent | Mild | Persistent | |
| | | | | Moderate | Severe |
| Impairment | Symptoms | ≤2 days/week | >2 days/week but not daily | Daily | Throughout the day |
| | Nighttime awakenings | 0 | 1–2x/mo | 3–4x/month | >1x/week |
| | SABA use for symptom control (not prevention of EIB) | ≤2 days/week | >2 days/week but not daily | Daily | Several times per day |
| | Interference with normal activity | None | Minor limitation | Some limitation | Extremely limited |
| Risk | Exacerbations requiring oral systemic corticosteroids | 0–1/yr | ≥2 exacerbation in 6 months requiring oral corticosteroids or ≥4 wheezing episodes in 1 year lasting >1 day AND risk factors for persistent asthma | | |
| | | ← Consider severity and interval since last exacerbation. Frequency and severity may fluctuate over time. → Exacerbations of any severity may occur in patients in any severity category. | | | |
