Foreword

The invitation to present *Dermatology in Public Health Environments* is certainly among the most honorable in the almost 30 years I devoted to public health dermatology. Having known the organizers for long time, I am sure that, in addition to the search for updated knowledge, high scientific rigor, and careful selection of experienced practicing professionals for writing the chapters, it was a work of love for my fellow beings.

Dermatologic conditions are among the most frequent reasons for the seeking health care. They produce suffering, low quality of life, and overburden of services. They also generate direct and indirect high costs. Access to health services is difficult in middle- and low-income countries, but even in industrialized countries access is far from ideal. A less than optimal approach, which is common especially in primary care services, increases costs and complications.

I am certain that this fully illustrated textbook will be very useful for doctors, nurses, psychologists, and physiotherapists, whether they are in training or full professional activity. The multidisciplinary approach reveals the concern for comprehensive care in outpatient clinics, aiming at improving care and reducing costs. Public health concepts that are not always available to clinically active professionals are innovatively presented in part I. Parts II to VI include in-depth information on different dermatologic conditions, and part VII on systemic diseases with frequent dermatologic manifestations. Practical and helpful is the section on signs and symptoms (part IX). Also innovative is part VIII, which covers emerging issues related with environmental problems and those arising from various human activities.

I reiterate my confidence in the importance of *Dermatology in Public Health Environments* (*Bonamigo RR and Dornelles SIT – editors*), and I am sure that both professionals and patients will be grateful for this great endeavor carried out with excellence.

Mauro Cunha Ramos, MSc, PhD, Dermatologist

"If you can look, see. If you can see, repair"

José Saramago (book: Ensaio Sobre a Cegueira)

Preface by Renan Rangel Bonamigo

Publishing a Dermatology book with an emphasis on public health has a great meaning: it demonstrates that the health of a population is intrinsically related to the social conditions into which it is inserted.

Dermatology is a specialty of daily human suffering, and we consider that each professional involved in care can act to minimize this. Furthermore, it is essential that managers of health systems acquire knowledge of the epidemiologic characteristics of the main dermatologic diseases.

We hope that this book will be useful to students and professionals who are interested in understanding patients with a dermatologic problem and, within academic, scientific, and ethical high precepts, seek to help; and that it is also useful for understanding the multiple relationships that exist between public health and the environment, socioeconomic conditions, and priorities determined by governments and nations.

Acknowledgements

Dedication

This book is for all those who dedicate their professional lives to Public Health and, to represent them, I dedicate it especially to Yuçara T. Rangel Bonamigo, a Brazilian nurse who worked in Public Health for many years, as an actual humanistic reference.

Porto Alegre, Brazil   Renan Rangel Bonamigo, MD, PhD

Preface by Sergio Ivan Torres Dornelles

Public health are words that elicit the art and science of preventing disease, prolonging life, enabling health and physical and mental efficiency through the community's organized endeavor. This book results from one idea and the opportunity to make available to health care teams an enriching material to help increase the knowledge of dermatologic diseases affecting the population, by aiming higher than the characteristics that help diagnosis, prevention, and treatment. Some chapters in this book address a series of appropriate measures to develop a social structure that possibly provides all social individuals with necessary health care. This team work by Springer, the editors, and authors certifies health accomplishments that enable an outstanding level of knowledge in Dermatology.

It is already known that the scientific research is traditionally based on reliability. In order to keep such virtue intact and unsuspicious in the scientific environment, a reliable work has to allow for the validation of the reported results by accepting what is made known by the specialized literature as a source of new knowledge. Therefore, the so-called scientific community has to follow behavioral standards not only in the research itself but also in the disclosure of the acquired information and knowledge. These standards were strictly followed in this book because the invited authors have undisputedly followed them. For this reason we are extremely grateful for their extensive contribution to this project and commitment to science.

As editors we expect this book to provide easy access to knowledge for all professionals related to public health, and the provision of improved health and comfort to the population.

Acknowledgements

Life provides many moments to say "thank you". This is one of these moments. Teachers, colleagues, students, patients, they all had significantly motivated us to write this book and that is why we must thank them all. We now say "Thank you" and want you to feel honored.

But I send my special thanks to my family, always central when opportunities must be sought. Therefore, the major foundation which guided my steps toward this goal is my family. My parents provided me a wonderful experience during a first phase; three extremely significant people were the highlights during the second phase, my wife Susana, and my sons Lúcio and Marcel. Thank you so much!

Dedication

For this work to have a long reach in time we must dedicate it to those who somehow helped us to write it. So this book is for all my colleagues from the Outpatient Clinic of Sanitary Dermatology (Ambulatório de Dermatologia Sanitária), where I had worked for three decades, a place that taught me how to give comfort to the less favored. But I have to mention that it was a sought after and cultivated idea which enabled us to collect all of this information, whose progenitor was Professor Renan Rangel Bonamigo, well known for his scientific capacity and ethics. To Prof. Bonamigo, the main editor of this book and a scientific partner for over a decade, we should give full credit.

Another name has to be mentioned, that of Professor Roberto Lopes Gervini, since he was one of my most outstanding masters to whom I owe the most considerate thanks in the fields of science and life.

There is also room to honor all patients who trusted us with their faith and hope in our procedures, people who gave us the opportunity to learn all those details that do not belong in the medical literature.

Part I

Dermatology in Public Health

Concepts of Relevants Diseases in Public Health

João Luiz Bastos, Rodrigo Pereira Duquia,
and Jeovany Martínez-Mesa

Key Points Summary

- A public health approach to health and disease emphasizes health problems that are frequent, produce severe impacts on individuals/societies, and are amenable to change
- "Magnitude" refers to the frequency of health problems in the context of populations or some of their specific segments
- The impact of health problems on individuals and societies is frequently known as "transcendence"
- The extent to which knowledge and resources (be they human, material, financial, etc.) are available to tackle health problems corresponds to "vulnerability"

- Taken together, magnitude, transcendence, and vulnerability should be used to build a list of public health priorities, along with other relevant criteria
- Defining public health problems according to these and other concepts is key to offering high-quality care to all patients

Introduction

A public health approach to disease processes and health issues is often seen as fundamentally important whenever health policy development or health service planning is among the main activities to be carried out in the context of any health care system. However, such an approach is not commonly regarded as of utmost importance when clinical care is to be provided to patients or individuals in need. In fact, the clinical and population perspectives to health and disease are often taught in medical schools by distinct faculties of physicians or surgeons whose scopes of action do not seem to show a high degree of overlap. The end result is that these perspectives seem to be disconnected from each other for the majority of health professionals, even though they are complementary and, if mastered, greatly contribute to the provision of quality care to all health care users.

Our primary goal in this chapter is to give salience to the intersections between the population and clinical perspectives, taking the concept of "public health problem" as a point of departure. By giving meaning to the conceptions of public health and epidemiology, we aim to present a set of technical criteria on which to base the definition of priorities in the health field: "magnitude," "transcendence," and "vulnerability." While we recognize that these are not exhaustive criteria on their own—that is, social, political, economic, and historical concerns should also be taken into account in the process of setting priorities—we do believe that they have sound potential to reconcile population and clinical perspectives, and to help bring the patient (as opposed to mere pathologic entities) back to the center of clinical care.

The chapter goes on to discuss causes of health and disease in populations and individuals, drawing from widely known publications and authors in the field of public health. An underlying assumption is that what causes diseases in population groups is different from what causes diseases in individuals. Such a distinction is needed, because the extent to which a health issue may be tackled by population or individual measures also helps to define a public health problem. Next, some dermatologic problems are presented and discussed in light of the aforementioned criteria in order to clarify that some health problems may be important from a population perspective, while also being clinically less serious (i.e., easily treated). Thus, both clinical and population approaches are depicted as complementary, even though they may not come to the same conclusions or point to similar needs when planning or effectively providing care to patients.

The text that follows is divided into four distinct subsections. The first, "Defining Priorities," reviews the following subjects: public health, epidemiology, public health problems, and causes of health/disease in populations and individuals. A subsection named "Practical Applications" brings examples of disease processes and health conditions that illustrate the application of the population and clinical perspectives; a list of terms or jargon is included under the heading "Glossary." Finally, interested readers are presented with three supplementary bibliographic references that offer additional thoughts and opportunity for further learning.

Defining Priorities

Public health has been defined in multiple ways in the past 100 years. It is mostly concerned with the application of knowledge to the organization of health care systems and health care services, as well as to factors that drive population patterns of health to control disease occurrence through continued surveillance and governmental interventions. One of the most famous definitions of public health dates back to the 1920s and was set forth by Charles-Edward Amory Winslow, a North American bacteriologist, public health expert, and professor at Yale University.

According to Winslow [1], "public health is the science and the art of preventing disease, prolonging life, and promoting physical health and efficiency through organized community efforts for the sanitation of the environment, the control of community infections, the education of the individual in principles of personal hygiene, the organization of medical and nursing service for the early diagnosis and preventive treatment of disease, and the development of the social machinery which will ensure to every individual in the community a standard of living adequate for the maintenance of health."

On the other hand, epidemiology is often regarded as a scientific discipline whose primary aim is to help public health achieve its own goals. Whether epidemiology has lost momentum in serving public health is a matter of controversy, and interested readers are referred to two specific publications for further discussions on this topic [2, 3]. Nevertheless, epidemiology is thought to be the cornerstone of public health, literally meaning "the study of what is upon the people," given that its etymology derives from the three Greek word roots "epi" (upon or among, in English), "demos" (people or population), and "logos" (study or scrutiny), clearly suggesting that epidemiology encompasses a population-based approach, not an individual one.

According to Gordis [4], a renowned North American epidemiologist, epidemiology "is the study of how disease is distributed in populations and the factors that influence or determine this distribution." Other definitions of epidemiology exist elsewhere [5, 6].

Indeed, we argue that most public health activists and epidemiologists would easily agree with our view that epidemiology is about frequency, distribution, and causes of health problems in a given population. By frequency, we mean the extent to which a specific population segment is affected by a certain health condition. For example, if 20 out of 1,000 city residents have diabetes, the frequency of this health condition would equal to $^{20}/_{1,000}$ or 2.0%. While the overall frequency of diabetes would be 2.0%, some groups within this population could present higher rates of such a chronic condition. Suppose that there were 600 women in this city and that 15 of them had diabetes; the frequency of diabetes among women would then amount to 2.5% ($^{15}/_{600}$), whereas the frequency of diabetes among men would equal to $^{5}/_{400}$ or 1.3%. When we compare the frequency of diabetes among different subgroups, we are, in fact, studying its distribution within the same population. Similarly, when we study factors that potentially underlie or are responsible for the frequency of diabetes, as well as its (often unequal) distribution in relation to any other social characteristic (e.g., gender), we are investigating the causes or determinants of the health problem in question.

Hence, it should be clear to the reader that what public health and epidemiology have in common is that both aim at addressing health problems in the context of populations: they either base their actions on "community efforts," as Winslow accurately acknowledged, or take "population" as the reference to study health profiles, following Gordis's conceptualization. However, not all health problems are accorded the same level of priority, and therefore do not warrant similar efforts toward their control, treatment, and/or prevention. When it comes to prioritizing health issues, the concept of "public health problem" becomes particularly relevant, and it is to this concept that we now turn.

What becomes a priority and is effectively addressed in the public health field is dependent upon several factors and their complex interrelationships. Of note, political, social, economic, and historical concerns play an important part in this process, and should never be thought of as irrelevant criteria upon which a list of the most important diseases is built. For instance, the concept of "neglected tropical diseases" was primarily coined to increase public awareness of a group of infectious diseases that are frequent in low-income populations in poor regions of the Americas, Asia, and Africa, but do not receive adequate treatment and sufficient research funding [7], i.e., they are not prioritized. Paradoxically, these are diseases for which reliable and efficient public health and individual measures are usually available, but which lack timely and adequate treatment or prevention due, in part, to a widespread disregard for the developing world on the part of powerful countries and international/national health agencies. In other words, neglected tropical diseases technically fit the criteria of a public health problem (whose concept is discussed in detail below), even though political, economic, and power relations among and within countries contribute to their long-standing persistence in the poorest and most vulnerable populations of the world.

What, then, should we take into consideration to classify a health condition as a public health problem? As argued in the previous paragraph, this question is far from settled, although we believe that the three following concepts are particularly useful in setting public health agendas and defining public health priorities. "Magnitude," which is commonly referred to by scholars in the public health field, pertains to the frequency of health problems in populations and their subgroups. According to this concept, the higher the frequency of a health condition, the higher the likelihood that it will be classified as a public health problem. Hypertension, for instance, is a widespread disease whose prevalence rates reach up to 40–50% in many populations worldwide. In contrast, the frequency of all types of cancer tends to be very low, especially in the general population, and not among patients admitted to

specialized oncology services. Therefore, if we considered only magnitude, we would conclude that hypertension is a public health problem, while all types of cancer are not. Nevertheless, "high magnitude" is not a mandatory attribute in classifying a health condition as a public health problem. An interesting example is the recent microcephaly epidemic associated with Zika virus infection described in Brazil and some other countries [8]. In absolute numbers, microcephaly cases attributed to Zika infection are perhaps insignificant, but ethically unacceptable. This example leads us to the discussion of a second criterion to define a public health problem: "transcendence."

Along with magnitude, "transcendence" must also be a criterion on which to build a list of public health priorities. Transcendence includes the impact of each health condition on individuals and societies as a whole. In the previous example of microcephaly and Zika virus infection, the impact of this condition on individuals, families, and the whole society explains why it could be considered a public health problem. In addition, take, for example, the case of dental caries. As well as causing pain, discomfort, and negatively influencing social interactions, dental caries is associated with absence from work and school, in addition to posing a great burden on dental health services because of treatment demands. Cancers are also burdensome, in that the quality of life is severely diminished and the associated costs of treatment are expressively high. Following this criterion, microcephaly, cancers, and dental caries would be public health problems, whereas mild health conditions with low impact on individuals/societies, such as sunburn, would not.

The third concept commonly used to define a public health problem is "vulnerability." Such a term is somewhat misleading to most readers, because vulnerability is more often than not attributed to individuals or specific population groups subjected to processes of marginalization and social exclusion. In this chapter, however, vulnerability refers to the existence of knowledge and availability of resources to efficiently tackle a specific health issue: literally, vulnerability is the extent to which a health condition is

"vulnerable" to changes through the application of existing knowledge and available resources. This means that only those problems for which effective measures of control, treatment, or prevention exist should be prioritized in terms of public health. Returning to the topic of microcephaly and Zika virus infection, the control of the vector, the *Aedes aegypti* mosquito, is key to combating disease transmission. However, this would only be achieved through the implementation of strategies at multiple levels: governments, communities, and individuals should all be engaged in actions to reduce mosquito breeding and disease transmission, including measures related to improved sanitation, early detection of cases, and adequate treatment of affected mothers and newborns. Another simple example is iron deficiency, which is controllable through community and individual actions based on the available knowledge and resources in most societies. Thus, according to the concept of vulnerability, iron deficiency and Zika virus infection should be regarded as public health problems.

Rothstein [9] contends that any health condition should be treated as a public health problem "when government action is more efficient or more likely to produce an effective intervention," as compared to individual measures, to address the problem. The distinction between problems that may be dealt with at the governmental/population level and those issues that are amenable to individual action brings us to one final clarification: causes of health and disease in populations are different from causes of health and disease in individuals.

As Rose [10] rightfully pointed out in 1985, the potential causes of diseases among individual cases will likely differ from the causes of diseases among populations. To fully understand this idea, let us consider a brief example. Suppose an epidemiologist carries out an investigation to ascertain whether fluoridation of public water supplies is associated with fewer dental caries lesions in children and adolescents. If the whole population under study is homogeneously exposed to water fluoridation, the investigator will not be able to demonstrate that caries levels vary according to access to fluoridated water, i.e.,

regardless of varying caries levels among groups of children and adolescents, the entire population is exposed to fluoridated water. Rather, the study of this specific population will easily point out that dental caries may, in fact, be linked to individual characteristics (sugar consumption, tooth brushing, use of dental floss, etc.) owing to the fact that these health-related behaviors vary a lot from individual to individual within the population. However, if the same investigator decides to compare this highly exposed population with another one, whose levels of fluoride exposure are lower, fluoridation of drinking water could be identified as a protective factor for dental caries. Therefore, depending on the groups being compared and the level of analysis (populations or individuals), investigators may identify different sets of causes for sick individuals or sick populations. In the case under consideration, sugar consumption, tooth brushing, and use of dental floss would be individual determinants of caries. On the other hand, fluoridation of water supplies would be a potential cause of dental caries according to a population perspective. If water fluoridation happens to be more effective in addressing dental caries, this health condition should be considered a public health problem.

As we finish this subsection we could argue that, broadly speaking, a public health problem is any health condition that presents magnitude, transcendence, and vulnerability; yet we could also add that public health problems are those which are more likely to change in response to population/governmental measures. It is important to note, however, that population/governmental measures will most likely be based on scientific knowledge of what causes diseases in populations rather than in individuals (e.g., a public health measure to prevent dental caries would focus on water fluoridation rather than on individual behaviors). There are exceptions to these criteria, of course, and other factors may play an important role in setting priorities. Nevertheless, we believe that the aforementioned criteria are crucial to setting priorities, because they bring people's lives and societal impacts to the fore, while not restricting public health problems to those whose expressions are fundamen-

tally biological, physiological, biochemical, or organic. In fact, our conceptualization of public health problems may include not only health states, diseases, and their biological expressions, but also their population determinants or related processes. According to this definition, lack of sanitation (which has profound health impacts) would also fit the criteria of a public health problem, and why shouldn't it?

Practical Applications

Several diseases or health states/processes in Dermatology could be deemed public health problems. Such health conditions could be ranked from those highly lethal (e.g., cutaneous melanoma) to those with mild clinical expression (e.g., capitis pediculosis, which is frequently associated with school absenteeism in children and adolescents and secondary infection). One of the most significant and stigmatizing dermatological diseases, however, is hanseniasis, which has been a public health problem for decades or even centuries in Brazil and worldwide.

Even though hanseniasis is a treatable infectious disease, it is still highly prevalent in many populations, especially those in developing countries [7]. Hanseniasis also potentially produces negative impacts on affected individuals, including granulomas of the nerves, respiratory tract, skin, and eyes. These granulomas may result in loss of sensation and eventual limb amputations. Dermatologists are extensively trained to diagnose and treat affected individuals. Nevertheless, whenever dermatologists face a public health problem, such as hanseniasis, the clinical approach to the case should be combined with the population-based approach to the problem, as we argue above. In these cases, the reasons that turn the disease in question into a public health problem must be discussed and considered in the course of treatment and development of strategies to face it from an individual and community perspective.

We believe that medical training which combines population and clinical perspectives to address health issues is on the horizon. Once this

is achieved, we shall successfully counteract important and persistent problems in many countries, especially those that remain inexplicably high in the poorest populations of the world.

Glossary

- Causes (of diseases or health states/processes): any factor, condition, or process that is responsible for changes or specific states in a specific health outcome
- Distribution (of diseases or health states/processes): frequency of a health condition according to personal, spatial, and/or temporal characteristics
- Epidemiology: study of disease frequency, disease distribution, and the causes that determine both disease frequency and disease distribution in human populations
- Frequency (of diseases or health states/processes): number of affected individuals relative to a specific population or group
- Magnitude: extent to which a given health condition is frequent in a given population
- Prevalence: refers to a simple mathematical calculation whereby the number of affected individuals is divided by the total population in question
- Public health problem: any health condition showing magnitude, transcendence, and vulnerability. It is important to note that, according to this chapter, other criteria are commonly used to define public health problems, including social, historical, economic, and political concerns
- Public health: "[…] the science and the art of preventing disease, prolonging life, and promoting physical health and efficiency through organized community efforts for the sanitation of the environment, the control of community infections, the education of the individual in principles of personal hygiene, the organization of medical and nursing service for the early diagnosis and preventive treatment of disease, and the development of the social machinery which will ensure to every individual in the community a standard of living adequate for the maintenance of health" [1]
- Transcendence: extent to which a health condition produces expressive negative impacts on individuals and societies
- Vulnerability: availability of knowledge and resources to counteract any health issue

International Public Health Strategies in Dermatology

2

Antonio Carlos Gerbase, Gabriel Roman, and Charifa Zemouri

Introduction

Structured strategies to tackle skin diseases and related infections (e.g. sexually transmitted infections) are necessary to provide a framework and direct actions against their burden. Usually this is not perceived at the clinical care level, the curative branch of the strategies where most resources are used. However, for professionals working at ministries of health and other leading institutions, and who are responsible for a comprehensive response, an organized strategic approach is fundamental. On the other hand, health professionals on the front line must understand the general issues of the strategic interventions in order to understand their role and strengthen the effectiveness of their actions.

Strategies to treat skin diseases and related infection at an international level give directions to national strategies, which encompass not only provision of care and preventive measures but also interventions dealing with structural, environmental, cultural, and financial issues.

The WHO is the health agency of the United Nations system [1]. At an international level the WHO is the leading organization that, reacting to the global health situation and to regional and country requests, develops, updates, advocates, and disseminates international public health strategies and, subsequently, the norms, standards, and guidelines needed for their implementation. Established in 1948, it was until the end of the 1980s the only institution leading international health strategies on a global level. During the past decades other international foundations (e.g. Gates Foundation) and bilateral national agencies (from countries such as Germany, Sweden, United States, and United Kingdom) increased their role in international public health strategic interventions and frequently directly channeled resources to countries (e.g. PEPFAR). Nonetheless, the WHO is the only international public health institution that is accountable and responds to virtually all countries. Moreover, to improve the way strategies are conducted and

norms are set, the use of standard procedures has been developed in the past decade, including the use of the GRADE system for guideline development [2].

International strategies are developed by the WHO secretariat in close collaboration with the scientific community and member states. The duration of a typical WHO global strategy ranges from 5 to 10 years, although shorter or longer examples exist. The first global strategy in the modern use of the term was the Global Strategy on AIDS, developed by the Global Program on AIDS in 1991. Once a global strategy is formulated, member countries evaluate its implementation and efforts are made to measure its impact. When the new strategy is developed a consultation process is established, the drafts are widely circulated, regional and global meetings are conducted, and, finally, the strategy is presented for approval by the World Health Assembly (WHA), the main governing body of the WHO [3]. Countries approve and are committed to its implementation.

Once the strategies are approved by the WHA, specific guidelines are needed to support their implementation. The process to develop WHO guidelines follows the GRADE system, whose main characteristics are prioritization of problems; establishment of panels, developed from questions; systematic review of evidence; evidence summary; evaluation of outcomes; overall quality of evidence; evaluation of benefits/harms; strength of recommendation and implementation and evaluation of the guidelines; strict evaluation of evidence; participation of final consumers; and evaluation of quality. The guidelines using the GRADE method are strictly based on the available scientific evidence [2].

This chapter reviews the main WHO strategies related to skin diseases and related infections whose prevalence, incidence, and significant population burden permit them to be considered of public health importance.

State of the Art

WHO Strategies Related to Dermatology

Sexually Transmitted Infections

Key Point Summary
- The 2016–2021 strategy plan to end STI epidemics as a major public health concern targets the 90:90:90 reduction of the global STI prevalence and national human papillomavirus vaccine coverage.
- Standardized protocols and guidance that are people centered are needed to reach the targets as defined during the 69th WHA.
- Interventions are mainly focused on prevention, management of asymptomatic patients, reaching sex partners and treatment, access to STI services of adequate quality, reduce vulnerability and risks, and meet the needs of the general population with appropriate services.

Rationale

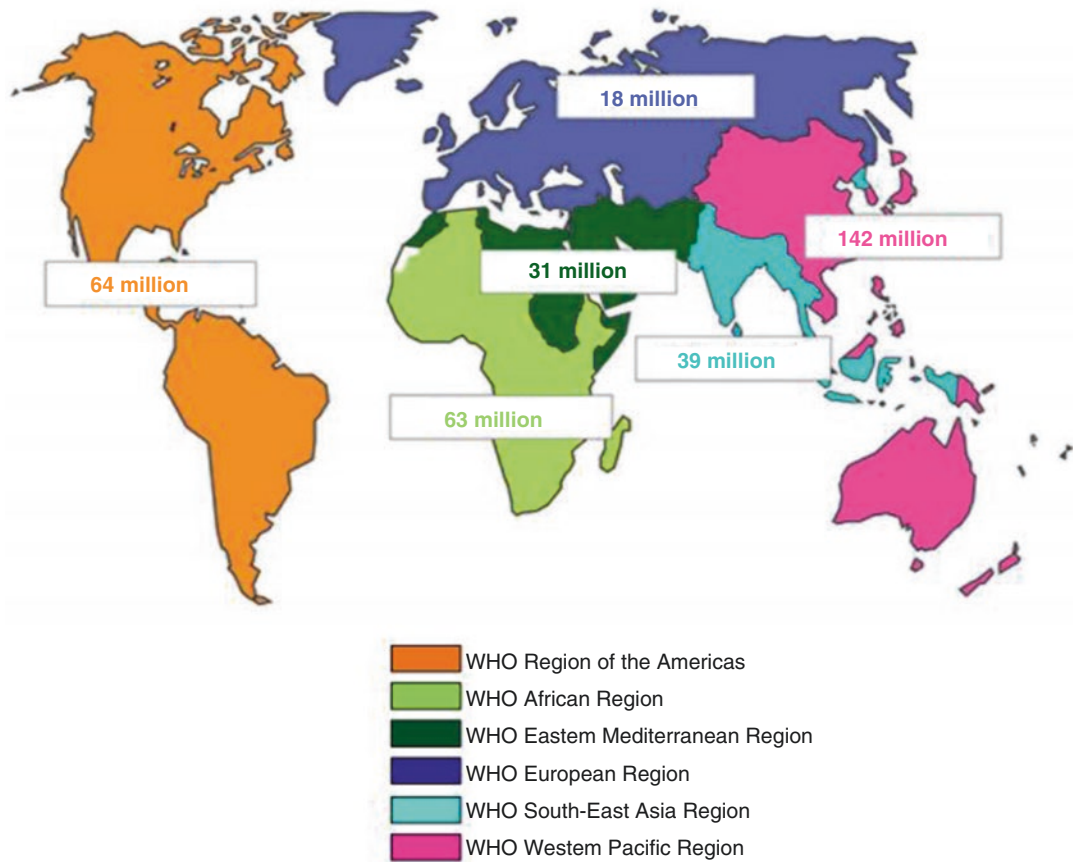
STIs result in a high burden of morbidity, mortality, quality of life, sexual and reproductive health, and newborn and child health. STIs facilitate the sexual transmission of HIV and increase the risk of some cancers through cellular changes. It is estimated that 357 million new cases of curable STIs (Fig. 2.1), *Neisseria gonorrhea*, *Treponema pallidum*, *Trichomonas vaginalis*, and *Chlamydia trachomatis*, occur every year among people aged 15–49 years. The prevalence of some viral STIs is similarly high as a result of herpes simplex type 2 virus (HSV-2) and HPV. This chapter focuses primarily on three infections, *N. gonorrhea*, *T. pallidum*, and HPV, which require immediate action for their control (see Boxes 2.1, 2.3, and 2.4).


Fig. 2.1 New cases of curable STIs: annual estimate

Targets

The WHO developed a global strategy plan for 2016–2021 on STIs, responding to requests by member states [4]. The goal is to end STI epidemics as major public health concerns. The WHO's vision is to have zero new infections, zero STI-related complications and deaths, and zero discrimination and a world with free and easy access to STI prevention and treatment services, resulting in individuals being able to live long and healthy lives. A 90:90:90 target for 2030 is set up to reach 90% reduction of *T. pallidum* (syphilis) incidence globally, 90%

global reduction in *N. gonorrhea*, and sustainment of 90% national coverage of HPV vaccination in national immunization programs. Furthermore, the WHO has set up milestones for this strategy by 2020 (see Box 2.1).

For syphilis, there is a separate strategy and target. Syphilis in pregnancy leads to more than 300,000 fetal and neonatal deaths each year with 215,000 infants at increased risk for early death. The new strategy has set up a goal of 50 or fewer cases of congenital syphilis per 100,000 live births in 80% of the countries. To eliminate mother-to-child transmission, all pregnant women should be screened for syphilis and HIV simultaneously.

Strategies

To reach the targets there is a need to improve universal health coverage with improved quality health interventions and services, reduced costs, and financial protection for those in need of the services (see Fig. 2.2). The public health approach should focus on a standardized protocol and guidance, people-centered services, focus on equity, community participation, involvement of affected individuals, ensuring free or affordable services, and focus on population-based national plans. The first strategic step is for countries to acquire knowledge of their STI epidemic and to implement a tailored response; therefore, they need strategic information for advocacy and investments. Next, understanding the epidemics includes knowing where, how, and among whom new infections occur and identifying factors to facilitate access to appropriate services. Finally, national STI surveillance is needed to monitor infections among the populations and improve the strategies and interventions.

All persons should receive STI services they require, which should be of adequate quality. Countries should promote an enabling environment which includes policies and laws that promote human rights and gender equality. They should also reduce vulnerability and risk, and meet the needs of the general population with appropriate services. Specifically men and boys should be addressed, since they have often been overlooked in STI control. Countries should therefore engage and link with communities and partners, and strengthen the health systems to ensure access to quality vaccines, diagnostics, medicines, and other commodities. To achieve this goal, persons should receive the STI services they need without experiencing financial hardship. Innovative financing and new funding approaches, financial risk protection, reduced prices and costs, and improved efficiency strategies should be implemented.

Interventions

People should receive the full range of STI services they require. Therefore, countries need to define a set of core interventions. The following intervention areas should be covered:

- Prevent STI transmission and acquisition
- Achieve early diagnosis of STI and linkage to treatment
- Manage asymptomatic patients
- Reach sex partners and offer them treatment
- Maximum impact interventions include elimination of mother-to-child transmission of syphilis and HIV; HPV and hepatitis B virus vaccination; control the spread of antimicrobial resistance of gonococcals
- Ensure quality of care by strengthening prevention, diagnosis, treatment, and care; integrated services and programs; quality assurance and improvement of programs

The main intervention is to prevent STI transmission and acquisition. Countries need innovation for acceleration by optimizing STI prevention, diagnostics, medication, and treatment regimens but also by using existing tools more efficiently and adapting them for different populations, settings, or purposes. The current intervention recommendations for STIs are summarized in Boxes 2.2 and 2.3.

Box 2.1 Milestones for 2020

- 70% of countries have STI surveillance system in place
- 70% of countries screen at least 95% of pregnant women for HIV and/or syphilis
- 70% of key population for HIV have access to a full range of services relevant to STI and HIV, including condoms
- 70% of countries provide STI services
- 70% of countries deliver HPV vaccines
- 90% national coverage of HPV vaccines
- 70% of countries report on AMR in *N. gonorrhoeae*

Vision: Zero new infections, zero sexually transmitted infection-related complications and deaths, and zero discrimination in a world where everybody has free and easy access to sexually transmitted infection prevention and treatment services, resulting in people able to live long and healthy lives.

Goal: Ending sexually transmitted infection epidemics as major public health concerns.

2030 Targets:
90% reduction of *T.* pallidum incidence globally (2018 global baseline).
90% reduction in *N.* gonorrhoea incidence globally (2018 global baseline).
≤ 50 cases of congenital syphilis per 100 000 live births in 80% of countries
Sustain 90% national converge and at least 80% in every district (or equivalent administrative unit) in countries with the human papillomavirus vaccine in their national immunization programme.

Frameworks for action: Universal health coverage, the continuum of services, and a public health approach.

Box 2.2 Chlamydia

Chlamydia accounts for 131 million STIs annually and is an important cause of infertility in women of reproductive age. It appears often as a coinfection with gonorrhea. The rate of infection is increasing in adolescents. However, the best strategy is yet to be defined. The WHO STI guideline (2016) recommends the following treatments [5].

Uncomplicated genital chlamydia:
- Azithromycin 1 g orally as a single dose
- Doxycycline 100 mg orally twice a day for 7 days
  Or one of these alternatives:
- Tetracycline 500 mg orally four times a day for 7 days
- Erythromycin 500 mg orally twice a day for 7 days
- Ofloxacin 200–400 mg orally twice a day for 7 days
  Anorectal chlamydial infection:
- Doxycycline 100 mg orally twice a day for 7 days over azithromycin 1 g orally as a single dose

Genital chlamydial infection in pregnant women:
- The WHO STI guideline recommends treatment with azithromycin over erythromycin
- The WHO STI guideline suggests treatment with azithromycin over amoxicillin
- The WHO STI guideline suggests treatment with amoxicillin over erythromycin

  Dosages:
- Azithromycin 1 g orally as a single dose
- Amoxicillin 500 mg orally three times a day for 7 days
- Erythromycin 500 mg orally twice a day for 7 days

Lymphogranuloma venereum:
The WHO STI guideline suggests treatment with doxycycline 100 mg orally twice daily for 21 days over azithromycin 1 g orally, weekly for 3 weeks.

Ophthalmia neonatorum:
The WHO STI guideline recommends treatment with azithromycin 20 mg/kg/day orally, one dose daily for 3 days, over erythromycin 50 mg/kg/day orally, in four divided doses daily for 14 days.

Box 2.3 Gonorrhea

Gonorrhea is one of the most common STIs worldwide and has a significant effect on morbidity and mortality. Together with chlamydia, it is one of the main causes of infertility in women of reproductive age. Gonorrhea has developed resistance to almost all medicines used for its treatment, which raises the prospect of untreatable gonococcal infection. Its spread and impact should therefore be controlled alongside systematic reporting and monitoring of antimicrobial resistance.

The WHO STI guideline (2016) recommends the following treatments [6]. The local AMR data should determine the choice of therapy.

Genital and anorectal gonococcal infection:
Dual therapy (one of the following)
- Ceftriaxone 250 mg intramuscular (IM) as a single dose PLUS azithromycin 1 g orally as a single dose
- Cefixime 400 mg orally as a single dose PLUS azithromycin 1 g orally as a single dose

Single therapy (one of the following)
- Ceftriaxone 250 mg IM as a single dose
- Cefixime 400 mg orally as a single dose
- Spectinomycin 2 g IM as a single dose

Oropharyngeal gonococcal infection:
Dual therapy (one of the following)
- Ceftriaxone 250 mg IM as a single dose PLUS azithromycin 1 g orally as a single dose

- Cefixime 400 mg orally as a single dose PLUS azithromycin 1 g orally as a single dose

  Single therapy
- Ceftriaxone 250 mg IM as single dose

  Gonococcal ophthalmia neonatorum: One of following
- Ceftriaxone 50 mg/kg (maximum 150 mg) IM as a single dose
- Kanamycin 25 mg/kg (maximum 75 mg) IM as a single dose
- Spectinomycin 25 mg/kg (maximum 75 mg) IM as a single dose

Box 2.4 Syphilis [7]

Recommendations

EARLY SYPHILIS (primary, secondary, or latent syphilis of not more than 2 years' duration)

  Adults and adolescents

In adults and adolescents with early syphilis, the STI WHO guideline recommends benzathine penicillin G 2.4 million units once intramuscularly over no treatment.
Remarks: This recommendation also applies to pregnant women, people living with HIV, people who are immunocompromised, and people at high risk of transmitting and acquiring STIs.

In adults and adolescents with early syphilis, the STI WHO guideline suggests using benzathine penicillin G 2.4 million units once intramuscularly over procaine penicillin G 1.2 million units 10–14 days intramuscularly.
When benzathine or procaine penicillin cannot be used (e.g., due to penicillin allergy) or not available, the STI WHO guideline suggests using doxycycline 100 mg twice daily orally for 14 days or ceftriaxone 1 g intramuscularly once daily for 10–14 days or azithromycin 2 g once orally.
Remarks: Doxycycline is preferred over ceftriaxone because of its lower cost and oral administration. Azithromycin is an option only when susceptibility to azithromycin is confirmed and resistance can be monitored. This recommendation also applies to people living with HIV, people who are immunocompromised, or people at high risk of transmitting and acquiring STIs. If the stage of syphilis is unknown, recommendations for persons with late syphilis should be followed.

  Pregnant women

In pregnant women with early syphilis, the WHO STI panel suggests using benzathine penicillin G 2.4 million units once intramuscularly over procaine penicillin 1.2 million units intramuscularly once daily for 10 days.
When benzathine or procaine penicillin cannot be used (e.g., due to penicillin allergy) or not available, the STI WHO guideline suggests using erythromycin 500 mg orally four times daily for 14 days or ceftriaxone 1 g intramuscularly once daily for 10–14 days or azithromycin 2 g once orally.
Remarks: Azithromycin is an option only when susceptibility to azithromycin is confirmed and resistance can be monitored. Erythromycin and azithromycin do not cross the placental barrier completely; therefore, treatment of the baby soon after delivery is necessary (see recommendations for congenital syphilis). Ceftriaxone is an expensive option and is injectable. Doxycycline should not be used in pregnant women.

LATE SYPHILIS (infection of more than 2 years' duration without evidence of treponemal infection)

  Adults and adolescents

In adults and adolescents with late syphilis or unknown stage of syphilis, the STI WHO guideline recommends benzathine penicillin G 2.4 million units intramuscularly once weekly for three consecutive weeks over no treatment.
Remarks: This recommendation also applies to people living with HIV, people who are immunocompromised, or people at high risk of transmitting and acquiring STIs.

In adults and adolescents with late syphilis or unknown stage of syphilis, the STI WHO guideline suggests benzathine penicillin G 2.4 million units intramuscularly once weekly for three consecutive weeks over procaine penicillin 1.2 million units once a day for 20 days.
When benzathine or procaine penicillin cannot be used (e.g., due to penicillin allergy) or not available, the STI WHO guideline suggests using doxycycline 100 mg twice daily orally for 30 days.
Remarks: This recommendation also applies to people living with HIV, people who are immunocompromised, or people at high risk of transmitting and acquiring STIs. Doxycycline should not be used in pregnant women (see recommendation for pregnant women).

Pregnant women

In pregnant women with late syphilis or unknown stage of syphilis, the WHO STI guideline suggests benzathine penicillin G 2.4 million units intramuscularly once weekly for three consecutive weeks over procaine penicillin 1.2 million units intramuscularly once a day for 20 days.

When benzathine or procaine penicillin cannot be used (e.g., due to penicillin allergy) or not available, the STI WHO guideline suggests using erythromycin 500 mg orally four times daily for 30 days.

Remarks: Erythromycin does not cross the placental barrier completely; therefore, treatment of the baby soon after delivery is necessary (see recommendations for congenital syphilis). Doxycycline should not be used in pregnant women.

Infants

Infants with confirmed congenital syphilis (symptomatic or microbiological evidence) and infants who are clinically normal, but mother with syphilis was not treated, inadequately treated, or treated with non-penicillin

In infants with confirmed congenital syphilis or infants who are clinically normal, but the mother with syphilis was not treated, inadequately treated, or treated with non-penicillin, the WHO STI guideline suggests aqueous benzyl penicillin or procaine penicillin.

Dosages:
- Aqueous benzyl penicillin 100,000–150,000 U/kg/day intravenously for 10–15 days
- Procaine penicillin 50,000 U/kg/day single dose intramuscularly for 10–15 days

Remarks: If an experienced venipuncturist is available, aqueous benzyl penicillin may be preferred over intramuscular injections of procaine penicillin.

Infants who are clinically normal and the mother had syphilis and was adequately treated with no signs of reinfection

In infants who are clinically normal and the mother had syphilis and was adequately treated with no signs of reinfection, the WHO STI guideline suggests close monitoring of the infant over treatment.

Remarks: The risk of transmission of syphilis to the fetus depends on a number of factors, including titers and stage of infection, and therefore this recommendation is conditional. If treatment is provided, procaine penicillin 50,000 U/kg/day as a single dose intramuscularly for 10–15 days is an option.

Neglected Tropical Diseases

Key Point Summary
- Vector-borne infectious protozoa causing dermal complications such as lymphatic filariasis (LF) and leishmaniasis are to be targeted for elimination.
- Since the start of mass drug administration (MDA) for LF, the transmission has dropped and resulted in economic benefits. However, adverse events in the case of double infection by the *Loa loa* worm should be considered for revised local treatment and control strategies.
- The WHO strategy for LF is to interrupt transmission and target 70% of countries verified as free of LF by 2020, 30% under post surveillance, and full coverage and access to basic care for lymphedema. As for leishmaniasis, prevention and control with adequate diagnostic tools and vaccines are essential.
- The intervention and prevention strategies set up by the WHO for both protozoal infections overlap with regard to interrupting the chain of transmission, monitoring the burden of disease, vector control of sandflies and mosquitoes, environmental management and protection, and control of animal reservoirs.

Neglected tropical diseases (NTDs) are prevalent in 149 tropical and subtropical countries and affect more than 1 billion people annually. NTDs cover the following vector-borne infectious diseases: Chagas disease; dengue and chikungunya; dracunculiasis; human African trypanosomiasis; leishmaniasis; LF; and onchocerciasis. Other diseases such as buruli ulcer, echinococcosis, endemic treponematoses, foodborne trematodiases, leprosy, rabies, schistosomiasis, taeniasis, and trachoma are airborne, zoonotic, or transmitted vertically. This subsection highlights the vector-borne infectious diseases that cause dermal manifestations: leishmaniasis and LF.

Rationale

Leishmaniasis manifests in three forms: visceral, mucocutaneous, and the most common form, cutaneous leishmaniasis, caused by the protozoa *Leishmania* transmitted by phlebotomine sand-flies [8]. An estimated 900,000 to 1.3 million new cases and 20,000–30,000 deaths occur annually and affect the poorest people on earth. The disease is associated with malnutrition, population displacement, poor housing, a weak immune system, and lack of financial resources. Cutaneous leishmaniasis causes skin lesions, mainly ulcers, leaving life-long scars and serious disability. Mucocutaneous leishmaniasis leads to partial or total destruction of the nose, mouth, and throat membranes.

LF, a painful and profoundly disfiguring disease, commonly known as elephantiasis, is caused by the thread-like nematode worms *Wuchereria bancrofti*, *Brugia malayi*, and *Brugia timori*, and is transmitted by mosquitoes infected with microfilariae. More than 1.1 billion people in 55 countries worldwide, wherefrom 80% occur in African countries such as Angola, Cameroon, and Mozambique, are at risk for acquiring LF

and require preventive chemotherapy to stop the spread. Furthermore, an estimated 25 million men suffer from genital disease and 15 million are afflicted with lymphedema by this infection. Eliminating LF prevents unnecessary suffering and stigma while contributing to the reduction of poverty [9] (Figs. 2.3 and 2.4).

Strategy

Effective control of NTDs in general can be achieved when several public health approaches are combined. The WHA adopted a resolution with strategies to target the elimination of many diseases and eradication of at least two diseases by 2020. The WHA66.12 resolution calls on Member States to intensify and integrate measures and plan investments to improve the health and social well-being of affected populations [10].

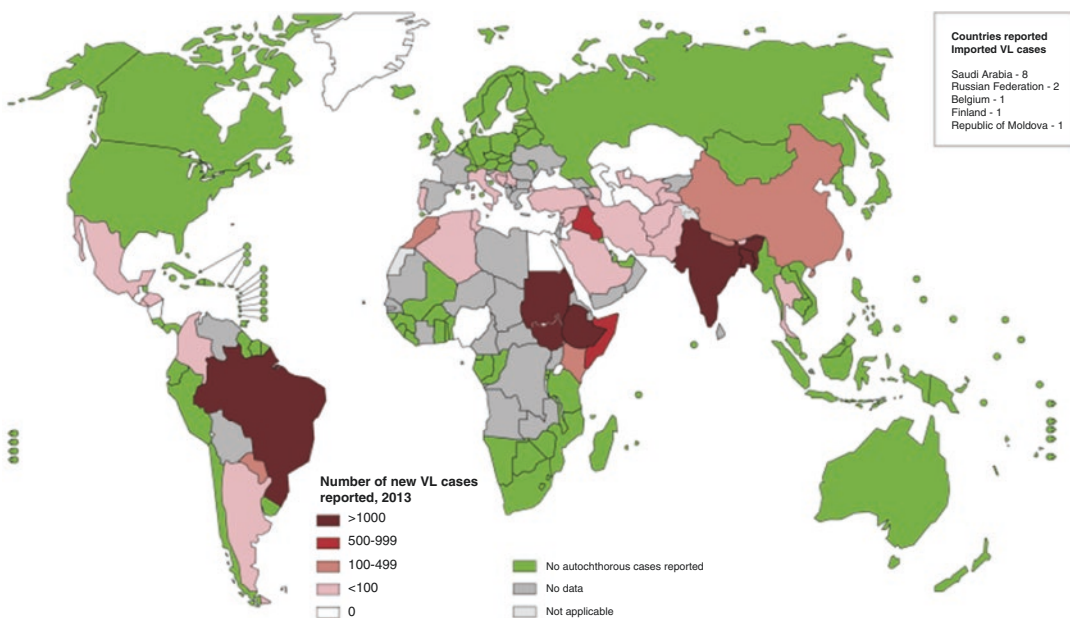
The WHO Director-General requests to sustain the leadership of the WHO in the drive to overcome NTDs. The WHO control on leishmaniasis and LF involves supporting national control programs; raising awareness and advocacy of the global burden; development of evidence-based


Fig. 2.3 Prevalence of Leishmaniasis (2014)
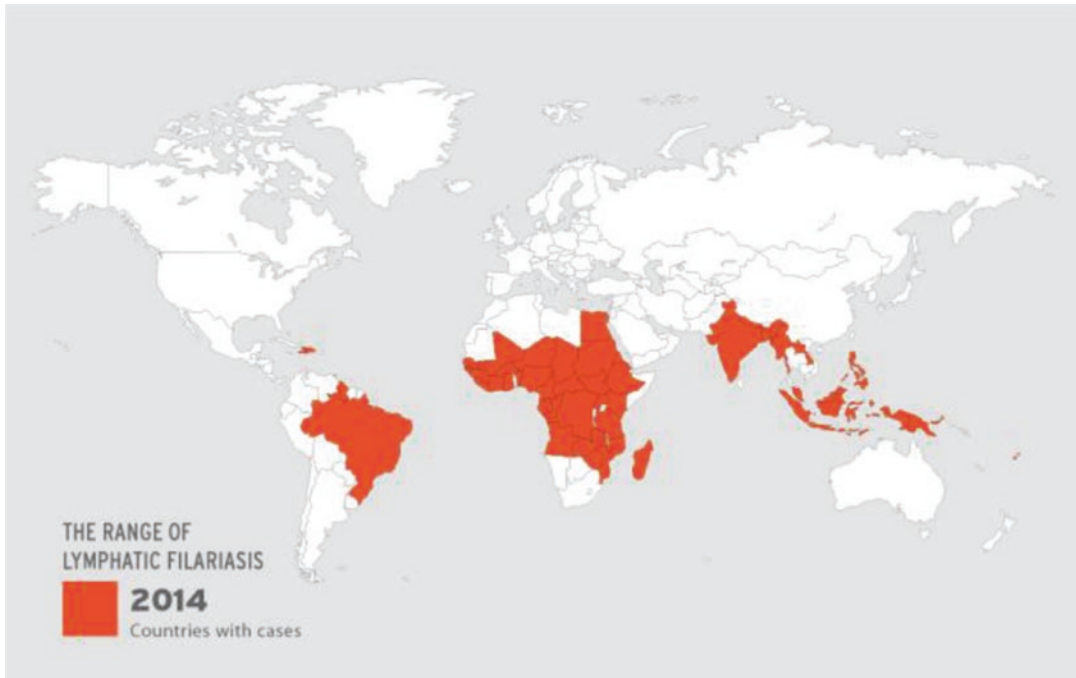

Fig. 2.4 Prevalence of LF (2014)

policy guidelines, strategies, and standards for prevention and control; monitoring implementation; technical support to Member States; and promoting research on effective leishmaniasis control as well as diagnostic tools and vaccines. In addition, the WHO strategy for LF is based on two key components: annual treatment of all eligible people in an endemic area, and alleviating the suffering caused by LF through increased morbidity management and disability prevention activities. Since the start of mass treatment, the transmission of LF in at-risk populations has fallen by 43% and the economic benefit is estimated at US$ 24 billion.

The Global Program to Eliminate Lymphatic Filariasis (GPELF), started in 2000 and continuing until 2020, delivers mass drug administration (MDA) LF endemic countries. The new strategy includes a protocol for stopping MDA and post-MDA surveillance. The programmatic steps taken to interrupt transmission are: (1) mapping geographical distribution of LF; (2) MDA; (3) surveillance; and (4) verification of elimination. The 2020 target for LF is to reach 70% of countries verified as free of LF and 30% under post

surveillance, and full geographical coverage and access to basic care for lymphedema in all countries. Moreover, the WHO calls for integrating national programs to eliminate LF and onchocerciasis within the African Program for Onchocerciasis Control (APOC).

Interventions

To control and prevent leishmaniasis and LF, a combination of intervention strategies are required which target the host, parasite, and vector, and sometimes also the animal reservoir [11, 12]. The key strategies for both infections are to reduce the prevalence of the disease and prevent disabilities and death by early diagnosis and case management. Early detection and treatment [13] of cases reduces the transmission and monitors the spread and burden of disease. For LF [14], morbidity management and disability prevention are required, alongside continuous access to care for LF patients with lymphedema to prevent disease progression to advanced stages. Simple measures of hygiene, skin care,

exercise, and elevation of affected limbs in LF help to prevent further progression.

Vector control is a key factor in reducing transmission and breaking the chain by controlling sandflies and mosquitoes. Methods such as insecticide sprays, insecticide nets, environmental management, and personal protection are to be used. Regarding the control of animal reservoirs, a complex intervention should be tailored to the local situation [15].

The treatment for LF is continued by MDA by expanding the coverage in non-participating countries and preventive chemotherapy for all LF endemic countries [16]. LF prevention is treated annually with a single dose of 400 mg albendazole with either 150–200 µg/kg ivermectin or 6 mg/kg, or annual preventive chemotherapy with diethylcarbamazine. However, coinfection with the *Loa loa* worm should be taken into consideration because of the adverse effect in ingesting ivermectin. The extensive treatment recommendations for various types of leishmaniasis are available at the following web page: http://www.who.int/leishmaniasis/research/978924129496_pp67_71.pdf?ua=1.

Partnership and collaboration with various stakeholders and other vector-borne disease control programs should be implemented together with education of the community and behavioral change interventions that are locally tailored. Furthermore, the financial burden should be lowered to make treatment and surgery possible for hydrocele or episodes of adenolymphangitis.

HIV and AIDS

Key Points Summary
- HIV Global Health Strategy for 2016–2020 is a priority for WHO and is based on accelerating actions and fast-tracking their responses
- WHO goal for HIV is the end of AIDS epidemic as a public health threat by 2030
- The Strategy 2020 global targets are: reduce new HIV infections and HIV-related deaths to fewer than 500,000 each and zero new infections among infants
- The five Strategic Directions are: information for action; interventions for impact; delivering for equity; financing for sustainability; and innovation for acceleration
- Unless intensified action occurs (hence the importance of fast-tracking), the HIV epidemics will see a rebound with current constant coverage

In May 2014, the 67th World Health Assembly requested a new strategy in the post-2015 development agenda whereby HIV continued to be a priority for the WHO [17]. The global health sector strategy on HIV/AIDS achieved 2015 targets of more than 15 million people on antiretroviral therapy (ART), with an estimated 7.8 million HIV-related deaths and 30 million new HIV infections averted since 2000. The 2030 Agenda for Sustainable Development adopted by the United Nations General Assembly in 2015 targeted the end of the AIDS epidemic by 2030. The WHO set forth to establish a new Global Health Strategy for HIV for 2016–2021, appraised during the 69th Health World Assembly in 2016 [18]. Full implementation of the draft strategy will contribute to the achievement of other sustainable development goals.

Global Health Sector Strategy on HIV, 2016–2021

Understanding that the actual steady-state response will see a rebound in new HIV infections and related deaths. Emphasis is laid on the need to fast-track the response to actions to prevent this rebound, outlining countries and WHO tasks to reach those goals [19]. The 2016–2021 strategy is based on five strategic directions to guide actions in achieving 2020 targets and goals (Fig. 2.5). Modeling undertaken by UNAIDS, estimates that an accelerated testing and treatment effort would:

Monitoring and Evaluation

Vision: Zero new infections, zero HIV-related deaths, and zero HIV-related discrimination in a world where people living with HIV are able to live long and healthy lives.

Goal: End of the epidemic as a public health threat by 2030.

2020 Targets: Reduction new HIV infection to less than 500 000; zero new infection among infants. Reduce HIV related deaths to below 500 000 90% people living with HiV tested, 90% treated, 90% virally suppressed.

Frameworks for action: Universal health coverage, the continuum of services, and a public health approach.

The three dimensions of UHC

STRATEGIC DIRECTION1

Information for focused action

The "who" and "where"

STRATEGIC DIRECTION 2

Interventions for impact

The "what"

STRATEGIC DIRECTION 3

Delivering for equity

The "how"

STRATEGIC DIRECTION 4

Financing for sustainability

The financing

STRATEGIC DIRECTION 5

Innovation for acceleration

The future

STRATEGY IMPLEMENTATION:
Leadership, Partnership, Accountability, Monitoring & Evaluation

COUNTRY ACTION

Country Partner Action

WHO ACTION HQ, REGIONS AND COUNTRIES

Global Partner Action

Fig. 2.5 Outline of the draft global health sector strategy on HIV, 2016–2021

Fig. 2.6 Projections for decline in HIV-related deaths
- Avert 28 million HIV infections between 2015 and 2030
- Avert 21 million AIDS-related deaths between 2015 and 2030 (Fig. 2.6)
- Avoid US$ 24,000 million of additional costs for HIV treatment
- Enable countries to reap a 15-fold return on their HIV investments

Strategic Direction 1: Information for Focused Action (What is the Situation?)

Focuses on the need to understand the HIV epidemic and response as a basis for advocacy, political commitment, and national planning as well as resource mobilization and allocation and program improvement. WHO guidelines recommend adoption of 50 national indicators [20] (see suggested readings, "Global Health Sector Strategy on HIV, 2016–2021"), of which the following 10 are for global monitoring (Fig. 2.7).

Strategic Direction 2: Interventions for Impact (What Services Should be Delivered?)

Addresses the first dimension of universal health coverage by describing the essential package of high-impact interventions that need to be delivered along the continuum of HIV services.

The following interventions should be included in an HIV prevention package:

- Male and female condoms
- Harm reduction for people who inject drugs
- ART-based prevention
- Vertical transmission prevention
- Voluntary male circumcision
- Injection and blood safety
- Behavioral change interventions
- Prevention and management of gender-based and sexual violence

HIV testing should be expanded, focusing on populations carrying the highest risk for HIV infection and transmission, with appropriate counseling and links to care. This is needed for the expansion of ART therapy [21, 22] to achieve the 90% people living with HIV (PLHIV) treatment goal (see Box 2.5 for first-line therapy regimens). Besides expanding ART, action should be taken to prevent and manage coinfections such as tuberculosis, hepatitis B and C, and HIV drug resistance. Chronic care for PLHIV should be person centered.

Box 2.5 First-Line Regimens (Adults and Adolescents)

Pre-exposure prophylaxis: Tenofovir (TDF)

Post-exposure prophylaxis: TDF + lamivudine (3TC) (+ lopinavir/ritonavir or atazanavir/ritonavir if possible)

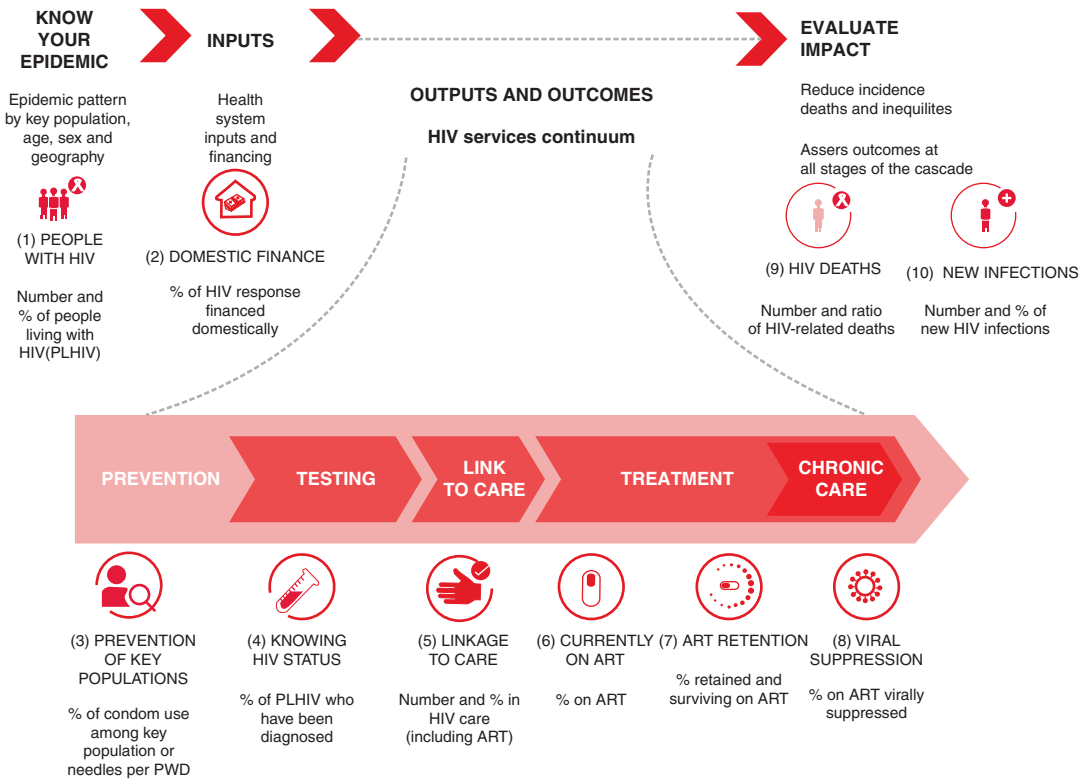
ART Therapy: TDF + 3TC + efavirenz (EFV)


Fig. 2.7 Key indicators for monitoring the HIV response across the continuum of HIV services and including the HIV care cascade

Strategic Direction 3: Delivering for Equity (How Can These Services be Delivered?)

Addresses the second dimension of universal health coverage by identifying the best methods for delivering the continuum of HIV services to different populations and in different locations. Special focus should be fixed on addressing key populations (at increased risk of HIV regardless of the local epidemic context): men who have sex with men, people who inject drugs, people in prison and other closed settings, sex workers, and transgender persons.

Strategies for achieving equity include decentralization of care, differentiated care (based on stage of HIV disease, stability of treatment and special care needs), linking HIV with tuberculosis services, community engagement and task shifting, and providing chronic care for PLHIV. Countries should also end policies and practices that reinforce stigmatization and discrimination.

Strategic Direction 4: Financing for Sustainability (How Can the Costs of Delivering the Package of Services Be Covered?)

Addresses the third dimension of universal health coverage by identifying innovative models and approaches for financing HIV responses and reducing costs without incurring financial hardship: essential HIV services should be provided free of charge. Reducing costs also mean improving efficiency of service delivery, such as decentralization, service linkage, and task shifting. Other strategies include fostering generic competition on ART drugs, applying pro-access terms of the Medicines Patent Pool,

and appropriate use of the provisions in the Agreements on Trade-Related Aspects of Intellectual Property Rights regarding flexibilities to protect public health.

However, it is acknowledged that investments in HIV will need to grow if long-term control of the epidemic is to be achieved; therefore, countries need to develop strong investment cases for HIV.

Strategic Direction 5: Innovation for Acceleration (How Can the Trajectory of the Response be Changed?)

Identifies those areas where there are major gaps in knowledge and technologies, and where innovation is required so that actions can be accelerated and 2020 and 2030 targets achieved. Research and innovation provide the tools and knowledge that can change the trajectory of the HIV response. Innovation is also required to use existing tools more efficiently and to adapt them for different populations.

Key areas for innovation are: optimizing HIV prevention; optimizing HIV testing and diagnostics; optimizing HIV medicines and treatment regimens; and optimizing service delivery.

Strategy Implementation

Finally, effective implementation of this strategy depends on collaboration between all involved parties, in which the WHO plays an important convening role. Monitoring and evaluation are done at global and regional/country level goals (Fig. 2.6), while applying WHO results-based management and UNAIDS accountability frameworks.

Key Points Summary
- Once leprosy was eliminated as a public health problem globally in 2000, WHO global leprosy strategy focused on reducing leprosy-related disabilities
- 2016–2020 WHO Global Leprosy Strategy focuses on promoting early diagnosis to reduce leprosy burden

- The Strategy 2020 targets are: zero new children diagnosed with leprosy and visible deformities, <1 per million newly diagnosed leprosy patients with visible deformities; and zero countries with legislation allowing discrimination on leprosy
- The Program five key operational strategies are: focus on early detection; increased detection and coverage; universal contacts screening; uniform leprosy treatment; and interventions against stigma and discrimination

Leprosy

Leprosy was eliminated as a public health problem globally in 2000 (defined by the WHO as prevalence less than 1 per 10,000 population). The 2011–2015 WHO strategy for leprosy focused on control with early diagnosis to reduce leprosy-related disabilities. The global leprosy strategy for 2016–2020 continues to reinforce early detection to reduce the burden of leprosy, while accelerating actions toward the vision of a leprosy-free world [23]. The strategy general overview, its three pillars and their core areas of interventions, are displayed in Fig. 2.8.

There are five key strategic operational changes in the 2016–2020 plan along with target indicators:

1. Focus on early detection to prevent disabilities, with special focus on children. The target is zero disabilities among new pediatric patients (<15 years of age) by 2020. For countries that do not detect grade 2 disability (G2D) among pediatric patients, the target shall be zero pediatric cases.
2. Increased detection, coverage, and access to treatment for high-risk groups and marginalized populations. The target is an incidence of G2D of less than 1 per million population.

VISION

- ⊙ Zero disease
- ⊙ Zero transmission of leprosy infection
- ⊙ Zero disability due to leprosy
- ⊙ Zero stigma and discrimination

GOAL

Further reduce the global and local leprosy burden

TARGETS

INDICATORSA	2020 target
Number of children diagnosed with leprosy and visible deformities	0
Rate of newly diagnosed leprosy patines with visible deformities	<1 per million
Number of countries with legislation allowing discrimination on basis of leprosy	0

PILLARS AND COMPONENTS

1. Strengthen government ownership, coordination and partnership

- Ensuring political commitment and adequate resources for leprosy programmes.
- Contributing to universl health coverage with a special focus on children, women and underserved populations induding migrants and displaced people.
- Promoting partnerships with state and non-state actors and promote intersectoral collaboration and partnerships at the international leveal and within countries.
- Facilitating and conducting basic and operational research in all aspects of leprosy and maximixe the evidence base to inform policies. strategies and activities.
- Strengthening surveillance and health information systems for programme monitoring and evaluation(induding geographical information) systems)

2. Stop leprosy and its complications

- Strengthening patient and community awareness on leprosy.
- Promoting early case detection through active case finding (e.g campaigns) in areas of higher endemicity and contact management.
- Ensuring prompt start and adherence to treatment, including working towards improved treatment regimens.
- Improving prevention and management of disabilities.
- Strengthening surveilance for antimicrobial resistance including laboratory network.
- Promoting innovative approaches for training, referrals and sustaining expertise in leprosy such eHealth.
- Promoting interventions for the prevention of infection and disease.

3. Stop discrimination and promote inclusion

- Promoting societal inclusion through addressing all forms of discrimination and stigma.
- Empowering persons affected by leprosy and strengthen their capacity to participate actively in leprosy services.
- Involving communities in actions for improvement of leprosy services.
- Promoting coalition building among persons affected by leprosy and encourage the integration of these coalitions and or their members with other community-based organizations.
- Promoting access to social and financial support services, e.g. to facilitate income generation, for persons affected by leprosy and their families.
- Supporting community-based rehabilitation for people with leprosy related disabilities.
- Working towards abolishing discriminatory laws and promote policies facilitating inclusion of persons affected by leprosy.

**Fig. 2.8** WHO 2016–2020 Global Leprosy Strategy overview (From Global Leprosy Strategy: accelerating towards a leprosy-free world. World Health Organization, Regional Office for South-East Asia, 2016)

3. National plans to ensure screening of all close contacts. The target is to have all household contacts screened.

4. Promote steps toward the use of shorter and uniform treatment regimens for all types of leprosy.

5. Incorporate specific interventions against stigma and discrimination due to leprosy. The target is zero countries with legislation allowing discrimination on the basis of leprosy.

Other relevant program performance indicators for routine monitoring are (always disaggregated by sex and age group when applicable):

- Annual new case detection and new case detection rate per 100,000 population
- Point prevalence of leprosy per 10,000 population
- Number and/or proportion of relapses among all leprosy notified cases
- Completion rate of multidrug therapy (MDT) in all cases
- Availability of web-based, case-based reporting system allowing disaggregation by age, sex, place of residence, and other relevant criteria
- Proportion of contacts screened among registered contacts
- Proportion of patients evaluated for disabilities at the end of treatment
- Proportion of patients having reactions among new cases, disaggregated by bacillary load (paucibacillary or multibacillary)
- Proportion of persons affected by leprosy in self-care support programs among patients with grade 1 disabilities and G2D
- Norms and/or regulations facilitating the inclusion of persons affected by leprosy and their communities
- Affected persons or associations of affected persons with a role in care
- Presence of a partnership with the private sector for case detection/referral, care, and/or social support
- Number and proportion of drug-resistant cases

It has also been recognized that more coordinated efforts for research with regard to new diagnostic tools, drugs, and tools to manage complications are needed.

The WHO recommended MDT regimens are shown in Box 2.6. Treatment should be provided in blister packs that make clear distinctions between once-a-month and once-a-day drugs for the patient.

Box 2.6 Adult MDT regimen

–	PB: 6 months	MB: 12 months
Monthly	Rifampicin 600 mg + dapsone 100 mg	PB regimen + clofazimine 300 mg
Daily	Dapsone 100 mg	PB regimen + clofazimine 50 mg

Skin Diseases in Primary Care

Key Points Summary
- Some non-governmental organizations, such as the International Society of Dermatology, have developed public health task forces and programs to promote skin health
- Although the WHO has no specific public health strategies for general skin diseases in primary care, it has issued simple and practical clinical guidelines in the Integrated Management of Adolescent and Adult Illness (IMAI) for such diseases

The International Society of Dermatology set the task force "Skin Care for All: Community Dermatology" [24] to promote general skin health, stating that public health strategies have not been sufficiently inclusive of skin care. The program focuses on low-cost interventions, relying on self-help and low technology, while educating a workforce for skin care among primary care health workers, nurses, and physicians, facilitating delivery of skin care to those in need. The task force is responsible for the creation of the Regional Dermatology Training Centre in Tanzania, with several dermatology graduates serving in Sub-Saharan Africa; and a 1-day training course for health center personnel in Mali for recognition and management of the three most commonest skin conditions: impetigo, superficial fungus, and scabies. It also emphasizes the "look good feel good factor" concept in advocating skin care, and promotes social marketing such as "Natural is Beautiful" to prevent the use of creams containing harmful agents.

Table 2.1 Use this table if lesion red, tender, warm, pus, or crusts (infected skin lesion—consider this in all skin lesions)

Sign	Classify as	Treatments
• Fever or • Systemically unwell or • Infection extends to muscle	**Severe soft tissue or muscle infection**	• Refer to hospital • Start IV/IM antibiotics (if not • available, give oral cloxacillin) • Consider HIV-related illness
• Size >4 cm or • Red streaks or • Tender nodes or • Multiple abscesses	**Soft tissue infection or folliculitis**	• Start cloxacillin • Drain pus if fluctuance • Elevate the lump • Follow up next day
• Only red, tender, warm, pus or crusts–none of the signs in the pink or yellow row	**Impetigo or minor abscess**	• Clean sores with antiseptic • Drain pus if fluctuance • Follow up in 2 days

Adapted from Integrated Management of Adolescent and Adult Illness. WHO; 2004

While the WHO has not developed public health strategies for general skin diseases as seen in primary care (aside from specific diseases with an important burden such as leprosy), it has issued the IMAI in 2004, with interim guidelines for primary care workers on the diagnosis and treatment of several skin diseases and conditions (see suggested readings, "Skin Diseases in Primary Care"). These guidelines are based on several algorithms for easily defining the type of skin problem (e.g., lump, itching lesion, patch, infected lesion) and tables for prompt diagnosis or classification of each type of problem along with its specific management (see Table 2.1 for an example). They should be validated in primary care intervention studies.

Future Perspectives

The WHO will continue to be a leading public health organization at international level. Its importance will depend on the capability of the new Director General, to be elected in May 2017, to mobilize financial and human resources and to continue to deliver high-level strategies and products for its member countries. The use of the GRADE methodology to develop international guidelines has been questioned as too strict and expensive. A challenge to be faced is to maintain the present high scientific standard of developing a modified and user-friendly methodology.

STIs, especially syphilis, will decrease in incidence and prevalence but will continue to be a major public health concern. The reasons for this include the lack of affordable tests to identify asymptomatic infections, difficulties in reaching sexual partners, and weak health systems not providing extended access to STI services of adequate quality to all in need.

The WHO strategy will contribute to interrupt the transmission of LF and the targets will be probably be reached (70% of countries verified as free of LF by 2020, 30% under post surveillance and full coverage and access to basic care

for lymphedema). Leishmaniasis will be more difficult to eliminate, as the diagnostic tools and vaccines are yet to reach optimal performance.

The WHO goal for HIV, the end of AIDS as a public health threat by 2030, probably will not be reached because the present international environment is not intensifying actions as required and, as is mentioned in the strategy, necessary innovations are still not in the pipeline.

Considering that leprosy was eliminated as a public health problem globally, the WHO global leprosy strategy focuses on reducing leprosy-related disabilities. This will be more difficult given the fact that disabilities are not always related to active disease. Moreover, it will be difficult to reach the ambitious target of zero new children diagnosed with leprosy and visible deformities. The strategy focuses on early detection, increased detection and coverage, universal contacts screening, uniform leprosy treatment, and interventions against stigma and discrimination. Most of the strategies rely on coverage and quality of health systems, which are not performing optimally at this stage in the most affected countries.

In relation to skin diseases a global strategy is needed, targeting primary health care, using simple and practical quality clinical guidelines. These guidelines, based on IMAI work, need to be further developed and field-tested before wide dissemination. A discussion on the role of dermatologists at different levels of health systems needs to be conducted with the participation of specialists, universities, and public health authorities.

Glossary

3TC	Lamivudine
AIDS	Acquired immunodeficiency syndrome
ART	Antiretroviral therapy

Skin Diseases in Primary Care

World Health Organization. Integrated management of adolescent and adult illness. Geneva: World Health Organization; 2004.

The User of the Public Dermatology Service

3

Heitor de Sá Gonçalves, Maria Araci de Andrade Pontes, and Gerson Oliveira Penna

Key Points

- Skin diseases are responsible for approximately one-quarter of medical appointments in primary care.
- Patients with cutaneous problems experience a reduction in their quality of life that often goes beyond other non-dermatological conditions.
- Social and demographic characteristics of the population using public dermatology services are essential to direct and plan public health policies.
- Nosologic profile in dermatology depends on many variables such as gender, age, socioeconomic status, and access to health services, among others.
- Health professionals should be able to observe and recognize symptoms of the cutaneous complaints more prevalent in the population they care for.

Introduction

Skin diseases are one of the main reasons why people seek medical care and are responsible for approximately one-quarter of primary care appointments, both in tropical countries and developed nations [1]. In fact, in the United States they are among the 15 medical conditions whose prevalence and cost have increased the most between 1987 and 2000, with approximately one in every three people in the country reporting cutaneous problems [2].

The importance of skin health is underestimated because of the chronic nature and low lethality of most cutaneous diseases, which results in their not being considered important health problems. However, skin conditions can be precursors to considerable physical and psychological deficiencies, making them a public health problem of great magnitude. Important examples of these diseases can be cited, such as Hansen's disease, psoriasis, vitiligo, lupus, genodermatoses, atopic childhood dermatitis, and skin cancer, especially melanoma.

A study conducted in Sweden, with a random sample of 8,000 individuals, assessed the impact of skin conditions on the quality of life of this population from an epidemiologic perspective. The subjects were aged between 20 and 84 years, and 20.5% reported skin problems and/or the use of topical medications, with a higher frequency among women [3].

e-mail: heitorsg@terra.com.br

G.O. Penna
Osvaldo Cruz Foundation, Fortaleza, Ceará, Brazil

Another survey, conducted in France in 2002, evaluated the prevalence, management, and impact of dermatological diseases from the patient's point of view. Of a total of 25,441 subjects, 18,137 (71.3%) returned the questionnaire. Of these, 86.8% reported at least one skin problem from birth, and 43.2% had had a skin disease in the previous 24 months. For 28.7% of the respondents, their dermatological problem had impaired their quality of life [4].

Patients with cutaneous complaints experience a reduced quality of life that often goes beyond other non-dermatological conditions, including restricted mobility, intense pruritus, and physical and psychological discomfort; the physical characteristics of the diseases related to contagion and deformity may even lead to the social segregation of individuals. Such restrictions undermine activities of daily life and have a great impact on the patient's sense of well-being [2]. Acne vulgaris and psoriasis, for example, have been linked to suicidal thoughts [5].

Although skin problems are common in the population, there is little information on the profile of users of public dermatology health services. Data on the dermatological care provided in public health services are critically important to identify and monitor the impact of dermatological diseases on the health of the population, as well as the user profile of those afflicted, with a view toward planning the treatment, prevention, and promotion of such maladies, especially among the most vulnerable population groups.

State of the Art

Health Services

The World Health Organization defines a health system as a network of organizations, people, and actions whose primary objective is to promote, restore, or maintain health [6]. This includes the public, private, and voluntary bodies that contribute to the delivery of essential health services, working to fulfill the mission of guaranteeing a healthy population. The responsibility for the public's health in each country lies with specific

agencies at different levels of management (municipal, state, federal, and international).

Health systems can vary substantially between countries, especially in terms of the responsibility for how the health services offered to the population are financed. There are primarily five forms of financing for services offered to the population (Box 3.1), although most countries offer a mixed model.

> **Box 3.1. Modalities for Financing Health Systems**
> Financing of Health Systems
>
> A. Federal, state, or municipal taxation
> B. Social health insurance
> C. Private health insurance
> D. Direct out-of-pocket payments
> E. Donation to charity

In 1948, the Ministry of Health of the United Kingdom created the British national health system (National Health Service) as a regionalized and hierarchical systemic organization of health services, arranged by level of complexity with a defined geographical base. This model has influenced and guided the organization of health services in various countries around the world. The system is structured into a stratified model. The levels of complexity are used to establish a network of services, according to the characteristics of care and the degree of specialization of the services provided [7].

The elements implied in the definition of the levels of care include the technological material used (diagnostic and therapeutic machines and equipment), staff training, and the morbidity profile of the target population. The possible arrangements of these three elements in health systems depend on the system's characteristics in terms of the financial and material means, the personnel structure available, and the health policies implemented in each country.

The primary care level represents the first contact patients have with the health system and should be capable of resolving a large portion of the health problems they present, through

non-specialized outpatient care and low-density technological clinical activities aimed at the promotion, prevention, and restoration of health. Staff qualifications for this level involve a general and comprehensive training with an emphasis on family health. It is estimated that between 85% and 90% of the patients seeking primary care are likely to be resolved at this level.

The secondary level develops activities in basic medical specialties (general medicine, pediatrics, gynecology-obstetrics, and general surgery) and strategic specialists in the form of outpatient appointments, hospitalization, and emergency and rehabilitation care. These services should have equipment with an intermediary degree of technological innovation to deal with situations that are not absorbed by the primary level.

Highly advanced technology and more specialized personnel are concentrated at the tertiary level, which is responsible for solving the more complex situations.

The Brazilian health system is composed of a free public system (Unified Health System, SUS) that cares for most of the population. A private system, or Supplementary Health System, managed by health insurers is available and can be acquired individually or as a benefit offered by employers. In 2008, the private system of supplementary health covered 25.9% of the Brazilian population [8].

The financing of SUS counts on resources from the three spheres of government (municipal, state, and federal). When considering the services according to the level of care, in general it can be said that the federal sphere concentrates on tertiary care, the state on tertiary and secondary care, and the municipal level on primary and secondary care.

Within this stratified model of care, appointments for dermatological problems are initially carried out by general practitioners in primary care. All health professionals should be able to observe and recognize the symptoms of the cutaneous complaints prevalent in the population they care for. However, most of these professionals do not feel qualified to diagnose and treat these infections and limit themselves to referring patients to dermatologists at the secondary level.

The Social and Demographic Profile of the Users

There are few data on the demographic and social characteristics of the population that uses outpatient services in the health system, despite these data being essential to direct and plan public health policies. It is even more difficult to find data relating specifically to the characteristics of dermatology patients.

A national inquiry promoted by the Brazilian Ministry of Health periodically analyses the profile of the users of the health service, using, among others, data referring to the proportion of individuals who looked for or reported having used the health service in the previous 2 weeks and those who stated they had been admitted to hospital in the previous 12 months. Women are responsible for most of the demand for health services (17% compared with 12% among men) and there is an increase in this demand due to age (12% aged 0–14, 14% between 15 and 59 years, and 23% over 60 years) [8].

A population-based study with a sample of 12,402 Brazilians aged between 20 and 59 years, living in urban areas, showed a prevalence of outpatient care in public health services of 53.6% in the 3 months prior to the interview. Women represented 55.1% of the sample and about one-third (31.8%) were aged between 20 and 29 years, with a mean age of 37.4 years. More than half (51.5%) were in social class C [9].

Few studies show the user profile of public dermatology services, but it seems that this is similar to the population that seeks public health services in general; they are predominantly women, blacks, and have a low socioeconomic and educational level [10].

A multicenter, retrospective study addressing patients who seek dermatological care in four specialized outpatient services in Australia observed, over 7 months, a total of 9,639 visits by a total of 4,875 patients. In this sample there was a predominance of males (51.4%). The mean age was 48 years (50 years for men and 45 years for women; $p = 0002$) [11].

In England, more than 50% of the population reported a skin disease in the previous 12 months,
and 24% required medical intervention to care for dermatological problems every year. Among users of dermatology services there was a predominance of women (57.6%) in all age groups, but especially between 20 and 39 years [12].

A survey conducted by the Brazilian Society of Dermatology in 2006, with data for 57,343 patients, also showed a predominance of females (66.5%) in all age groups. The mean age was 37.4 years (35.3 years for men and 38.4 years for women). Schooling was the most divergent aspect when comparing patients treated in the public sector with those in the private sector: 65.7% of patients treated in the public sector and 27.6% of those cared for in the private sector had not completed secondary education [13].

Data from a public referral service in dermatology in the Northeast of Brazil, state of Ceará, collected from a random sample of 1,530 patients who attended the service for the first time between November 2015 and March 2016, showed a predominance of women (56%).The age distribution showed no significant differences between groups (0–20, 19%; 20–40, 26%; 40–60, 25%; >60, 31%). Most were residents of the state capital, Fortaleza (68%). These data can be viewed in Graphs 3.1 and 3.2 (unpublished data).
The predominance of females in dermatological appointments may be related to the greater care take with their skin in particular, also reflecting women's greater concern with health in gen-

DISTRIBUTION BY AGE

Graph 3.2 Distribution of users by age (Source: Dona Libânia Dermatological Center, 2016)

eral. On the other hand, the larger demand by females for health services may be related to the socioeconomic and labor structure in Brazil, especially in the North and Northeast regions, where there are more women without formal employment who therefore have more time available to use the health service.

The Nosological Profile of Users

The epidemiological data of the population who use the public dermatology health services are influenced by many factors, such as socioeconomic profile, educational profile, housing and hygiene, dietary habits, and the circumstances of access to health services. It is possible to alter these data when analyzing the patient profile according to the cutaneous pathology being presented, since there are diseases that mainly affect certain age groups, such as acne, which predominates in adolescence, and skin cancer, prevalent in older age groups.

Among the infectious and parasitic diseases that most often affect the skin are the ectoparasites (scabies, larva migrans, and pediculosis), superficial fungal infections (tineas, candidiasis, and tinea versicolor), the pyoderma (impetigo and folliculitis), and dermatoviruses (herpes, molluscum contagiosum, and warts). Hansen's disease and American tegumentary leishmaniasis are dermatological diseases with compulsory notification, the former because of its magnitude,

DISTRIBUTION BY SEX

Graph 3.1 Distribution of users by sex (Source: Dona Libânia Dermatological Center, 2016)

preeminence, and its ability to cause incapacity and deformity, as well as being a transmissible disease that can be treated and controlled [14]. The notification of cases of American tegumentary leishmaniasis in all its forms is obligatory, not only because of the disease's high incidence and wide geographical distribution but also because of the possibility of it causing destructive wounds [14]. Notable among the noninfectious skin diseases are acne, psoriasis, vitiligo, skin cancer, contact dermatitis (as a work-related condition), and atopic dermatitis, particularly in children. There may or may not be a determinant socioeconomic profile for each of the aforementioned conditions.

Scabies affects all races, ages, and social classes, although it is predominant in adult individuals on a low income. Larva migrans predominates in children between 5 and 15 years from low-income families, who walk barefoot on contaminated land, as well as children from all social classes who frequent beaches where stray dogs and cats live. Pediculosis is prevalent in children between 3 and 10 years of both sexes from low-income families.

Tinea versicolor affects adults of both sexes after puberty, predominantly in hot and humid climates. The distribution of dermatophytoses (tineas) is influenced by population factors such as gender (more common in males) and age (tinea scalp is more common in children; tinea of the foot and inguinocrural tinea are more common in adults).

Impetigo is most common in children, having no gender preference. Folliculitis can affect all age groups, but some conditions have a higher affinity for certain population groups, such as hidrosadenitis, which predominates in postpubescent women, or keloid folliculitis, which mainly affects black men.

The prevalence of herpes simplex is also determined by epidemiological factors. Primary herpetic gingivostomatitis is most commonly observed in children, while oral or relapsing genital herpes manifests itself mainly in adults. Molluscum contagiosum is more common in children and can occur in adults with immunodeficiency, particularly AIDS patients. Warts can occur at any age but are more common in children and young adults.

Hansen's disease affects people of both sexes and all ages. It tends to predominate in males and the population on a low socioeconomic level, presenting a lower incidence in children younger than 15 years. Although the global trend is a reduction in new cases, the service area in question (northeastern Brazil) maintains incidence rates at very high levels.

American tegumentary leishmaniasis is found in all of the Brazilian states, with a tendency to affect people who live in rural areas and locations with old deforestation, as well as a small percentage of cases located in the urban periphery. Initially predominantly young male adults were affected; nowadays it has become more frequent to find cases in people of all sexes and ages.

As a disease of the pilosebaceous follicles, acne tends to manifest predominantly in adolescents and young adults. Although almost all teenagers develop acne, genetic and external factors (e.g., emotional stress, female androgenic syndromes) can influence both the severity and recurrence of the disease.

The prevalence of psoriasis is around 2% of the population. The disease also affects both sexes and appears at any age, although peak incidence is between 20 and 30 years, with a second peak between 50 and 60 years.

Vitiligo affects about 1% of the population and has a universal distribution, affecting all age groups and both sexes. In 30% of cases there is a family history of the condition.

Nonmelanoma skin cancer (basal cell carcinoma (BCC) and squamous cell carcinoma (SCC)) generally occurs in male individuals older than 40; the predisposing factors are exposure to sunlight and fair skin. These cancers are rare in black individuals.

To check the frequency of the main diagnoses in the practice of dermatologists in Brazil, the Brazilian Society of Dermatology conducted a survey with 932 dermatologists selected from the register of 4,400 associates, working in both the public and private sectors. In addition to private services, the sample also included 49 SUS outpatient services that offer medical residency

programs in dermatology, distributed in all regions of the country. The diagnoses relating to outpatient dermatological care were recorded during a week in May 2006 and provide a picture of the demand for specialized dermatology care in Brazil, both in the public and private systems [13]. As expected, the inclusion of private services has led to some bias regarding diseases with a higher diagnostic incidence when comparing these data with the incidence of diagnoses in the public service alone.

The results were based on 57,343 dermatological appointments. During the study period (1 week) there were more than 1,000 different diagnoses, which is to be expected as a result of appointments with specialists that involve less common diseases whose diagnosis and monitoring need specialized care. Acne was the main reason for appointments and amounted to 14% of cases, followed by superficial mycoses (8.7%), pigmentation disorders (8.4%), and actinic keratosis (5.1%). The study also examined the proportion of return visits among the 25 most frequent causes, with Hansen's disease (78%), psoriasis (68%), and vitiligo (64%) initiating the most subsequent visits. Hansen's disease was rated the 20th cause throughout the country but the fourth in the Center-West Region.

The distribution of diagnoses by age group maintains acne as first cause of visits to the dermatologist both in those younger than 15 years (13.9%) and those aged between 15 and 39 years (26.6%). Superficial mycoses remain among the five most frequent diagnoses in all age groups, although the distribution of subtypes reflects the model of referral to specialists in more complex cases, especially onychomycosis (42% of superficial mycoses) and a low proportion of candidiasis.

Bearing in mind that acne has a significant psychological impact, the high frequency of acne diagnoses, even considering the leading role of the private sector in making such diagnoses, shows the relevance of the public service offering not only clinical treatment but also psychological support and health education initiatives aimed at the teenage population.

More than one-quarter (26.8%) of patients older than 65 were diagnosed with actinic keratosis or BCC, reinforcing the need for skin cancer prevention measures in the country. Interestingly, diagnoses of BCC predominated in the public sector, whereas in the private sector actinic keratosis was more frequent. This may reflect the delay in diagnosis and treatment resulting from difficulties of access to the public sector, as well as increased awareness of health problems of the population that uses the private sector.

Tables 3.1, 3.2, 3.3, and 3.4 show the results of this study, with the main causes of consultation by age group [13].

An analysis of the profile of users in a referral public dermatological service in the Northeast region of Brazil, in the municipality of Fortaleza, state of Ceará, evaluated the diagnoses of dermatological appointments, at both the first appoint-

ment and subsequent ones. Overall 9,110 consultations were carried out, and of this total 2,738 (30%) were for the diagnosis or monitoring of patients with Hansen's disease. This high frequency of Hansen's disease cases is justified because the service is a national referral center and the main center in the state for this condition (unpublished data).

Among the other 6,372 consultations, excluding data on Hansen's disease there is a relevant incidence of psoriasis (19%), BCC (12%), vitiligo (11%), and acne (10%) (Chart 3.1).

These data reflect the chronic nature of diseases such as Hansen's disease, psoriasis, and vitiligo, which require continued treatment. They also emphasize the importance of diseases such as acne and skin cancer as a public health problem.

As already noted, the nosologic user profile in dermatology depends on many variables such as gender, age, skin color, socioeconomic status, level of education, housing and hygiene, nutrition, access to health services, and the region or country where the appointment takes place, among others. In addition, in public health the demand for dermatology services is also influenced by the resolutive capacity of primary care, the efficient functioning of the system of referral, and the response to referral by specialists.

Perspectives

The Characteristics of a Public Health Dermatology Service

Considering the epidemiological reality in Brazil, as well as the current stage of the organization and the offer of dermatological services by the Unified Health System in the country, dermatological health actions planned and offered by a public health service in a particular area should seek to attain a resolutive capacity (human resources, equipment, pharmaceuticals and biopharmaceuticals, laboratory supplies) required to treat the following priority diseases:

- Hansen's disease
- Infectious and parasitic skin diseases of childhood
- Sexually transmitted diseases/AIDS
- Skin cancer (clinical and surgical actions)
- Allergic dermatoses
- American tegumentary leishmaniasis
- Varicose eczema and other ulcerated lesions
- Superficial and deep mycoses
- Clinical dermatoses, such as acne: psoriasis, vitiligo, collagen and genodermatoses

Therefore, the resolutive capacity of a public dermatology service is linked to the basic activities necessary for the diagnosis and treatment of such diseases. In addition, these activities should not only include medical attention but also multidisciplinary care involving nurses, physiotherapists, occupational therapists, psychologists, and pharmacists, among others. These activities are summarized in Box 3.2.

> **Box 3.2. Activities of a Public Dermatology Service**
> Medical appointments
> Nursing appointments
> Psychology appointments
> Physiotherapeutic rehabilitation activities
> Occupational therapy activities
> Phototherapy
> Dermatoscopy
> Skin biopsies

> Surgery of tumors
> Noninvasive procedures
> Simple dressings
> Debridement
> Histopathology tests
> Bacilloscopy in dermal infiltrate
> Mycology tests (direct and culture)
> Hematology and biochemistry tests
> Dispensing medicines
> Immunobiological infusion

Beyond offering care actions a dermatological health center should also be able to train primary care professionals, providing them with resolutive capacity when dealing with the most prevalent diseases in each region. Such action is essential to overcome bottlenecks and the overloading of the specialized secondary care services.

Finally, it is fundamental that these services maintain a constantly evolving research sector, whether it is epidemiological, clinical, or operational, focused on overcoming the barriers to public health in the area of dermatology.

Key Points Summary

- Concepts and practices of preventive health campaigns, health promotion, and health education
- Preventive Skin Cancer Campaign: relevant historic aspects of Brazilian Society of Dermatology initiatives
- Hansen's disease: relevant historic aspects of Brazilian government campaigns and SBD participation
- Sexually transmitted infections and acquired immunodeficiency syndrome: relevant historic aspects of Brazilian campaigns and preventive measures
- The perceived impact on epidemiological indicators of each program

Introduction

Concepts and Practices of Preventive Health Campaigns in Health Promotion and Health Education

An important lesson regarding this subject in Brazil was carried out in 1902–1906, through extensive campaigns against yellow fever, smallpox, and bubonic plague, under the management of Oswaldo Cruz [1]. It was supported by a compulsory vaccination law initiated in the then capital Rio de Janeiro, which authorized sanitary officials to enter private residences for the purpose of vaccination, in addition to other human rights violations. A consequence was a historical popular revolt, also influenced by a political period of conflict.[1]

By the end of the 1970s Bandura's social cognitive *theory of self-efficacy* introduced an explanatory model of health behavior and a guide for developing effective health promotion interventions [2]. This included four broad processes through which efficacy beliefs operate: choice behavior, effort expenditure and persistence, thought patterns, and emotional reactions. Much newer research of this theory, especially from Maibach and Murphy in 2004 [3], concluded that "no standard sets of domain specific self-efficacy items [are] applicable to all people in all situations." According to the authors, efficacy judgments not only depend on specific behaviors but also on the contexts in which they occur and the type of population involved.

Over the past decades, health mass media campaigns using mainly television, radio, handouts, and more recently the internet exemplified innovation as well as a subject for communication research [4, 5]. One derived hypothesis

---

[1] Some of these procedures have been revisited because of emerging viruses.

called *the uses and gratifications* pointed out the limitations of the effects of current communication conveyed from its production source on reaching the free-thinking recipient, who selects the information according to his/her context and motivation [6]. This theoretical approach makes a connection between the mass communication process and the social context in which it occurs, highlighting the communication flow that allows for information to be shared across social media and thus increasing dissemination to more people [6].

More recently the mobile phone has played a significant role in the rapid spread of information and has started to be used in many health interventions [7]. One study concluded that interdependence exists between mass and interpersonal communication as sources of social influence and the role of media dependency in shaping media impact [8]. Another found a difference between digital natives and their older counterparts [7].

An exhaustive mass campaign evaluation performed by Backer and Rogers [9] in the State of California State in 1988 resulted in a campaign analytic framework considering 29 generalizations applied to campaign evaluations, some of them transcribed here.

Principles for what works: use multiple media, combine media and interpersonal strategies, select segment audience, use celebrities to get attention and entertainment programs to sustain attention, provide simple and clear messages, emphasize positive behavior more than negative consequences, emphasize current rewards not distant negative consequences, involve key power figures and organizations, take advantage of timing, and use formative evaluation.

To be considered in context: health care system, schools (education background), family, workplace, government, and community [9].

The same authors also highlighted the innovation proposed by campaigns termed *incremental* (short-term results) and *preventive innovation*, whose results are expected in future health campaigns. These recommendations have been adopted in the national campaign; unfortunately,

however, the understanding that health education and communication equates to the transmission from health professionals of information that aims to change the patient's behavior still persists in the health sector, including in academic institutions.

Nevertheless, comprehensive studies brought from popular educational experiences in Brazil and all Latin America contributed to clarifying the conception of health promotion, be it permanent or continuous, in service education for both health workers and the general population,[2] based on teaching/learning processes and pedagogic methodologies [10–12], as well as the experiences generated by a popular educational proposal from Paulo Freire, one principle being that education means a critical understanding of reality and dialogue [12, 13].

Bearing in mind these concepts, the first three principles mentioned [9] in addition to the context components found in different Brazilian regions show that it is vital to emphasize the importance of combining mass media propaganda with small discussion groups in each community, which is particularly applicable to the complex dermatological problems discussed in this chapter.[3]

Creative initiatives in Brazil have been produced by regional sections of the Brazilian Society of Dermatology (SBD) usually involving local universities, such as study groups of sanitary dermatology, skin disease campaigns, and educative booklets about prevalent skin diseases to be used in health education activities, mainly in schools or as a community action promoted by the Annual Brazilian Congress of Dermatologists.

---

[2]From the Ottawa letter (1986) health promotion emphasized the social dimensions and the importance of five essential strategies for achieving full health: public policies, healthy environments, reinforcement of communitarian action, creation of personal abilities, and reorientation of health services.

[3]The campaign practices in Dermatology usually combine mass media propaganda and punctual patient examinations to screen for skin cancer and Hansen's disease, which includes diagnosis and treatment of general skin diseases. This could be optimized by communication and health education activities and general health promotion policy at the local level.

Also involved are health workers from basic health system care training. In 2013 one of these initiatives from São Paulo, called GRAPE (Permanent Support Group), was institutionalized by SBD to promote guidance in health education and support to people suffering skin diseases responsible for deteriorating quality of life, such as psoriasis, vitiligo, skin cancer, blistering skin diseases, alopecia areata, Hansen's disease (HD), and severe acne (www.sbd.org.br/acoes/grape-sbd/).

The proposal is to replicate this project in all Brazilian states, reinforcing an approach toward social accountability. This is to be demonstrated by the SBD commitment to provide a good quality of service and be mindful of assisting patients in maintaining a good quality of life, stimulating the civic engagement of its members through voluntary work, and pressurizing the state health sector to meet their obligations, resulting in betterment of the community.

The scope of this chapter includes the national mass media campaigns triggered by the Government specifically for infectious disease: sexually transmitted disease, mainly acquired immunodeficiency syndrome (AIDS), Hansen's Disease (HD) and degenerative diseases. The Skin Cancer Campaign (SCC) was an initiative of the SBD later implemented by the Ministry of Health (MoH).

Current Status and Perspectives

Relevant Historical Aspects of Brazilian Society of Dermatology Preventive Skin Cancer Campaign

The prominent role of the SBD in conducting a National Skin Cancer Campaign (NSCC) has been well recognized since 1999 [14]. It is worth noting that the SCC was introduced in 1988 by a Rio de Janeiro SBD section under Professor Jarbas Porto, and became a nationwide program a decade later (www.sbd.org.br/a-sbd/institucional/historia-da-sbd/) [15]. Only in 2000 was a specific formula to collect information from diagnosed cases of skin cancer implemented and

welcomed by all Dermatology services [16]. The first historical series of data consolidation carried out in 2005 showed that of the 205,869 dermatological examinations done in this period, 17,980 (8.7%) cases of skin cancer were diagnosed (13,194 basal cell carcinomas, 2,482 squamous cell carcinomas, 1,057 melanomas, and 1,247 other neoplasms). The ratio between sexes was 1.7, and unprotected sun exposure was not yet perceived as an important health risk [17].

Currently the annual SCC is an institutionalized activity not only comprising the spreading of information about the most prevalent and serious skin cancers, but also giving specialized dermatological assistance to spontaneous and stimulated demand via thousands of voluntary dermatologists around the country as a component of the National Program of Skin Cancer Control. The latest statistics from annual campaigns by the Dermatology Service can be found on the SBD website: www.sbd.org.br/acoes/programa-nacional-de-combate-ao-cancer-da-pele/.

This potent program received the Guinness Book certification in 17 June 2010 as the biggest medical campaign performed in 1 day, called *Day C* (www.sbd.org.br/acoes/dia-de-combate-ao-cancer-da-pele/).

In general, these events took place on the last Saturday of November and involved hundreds of health units in health education activities, assisting all suspected cases of skin cancer as well as other skin diseases, with those diagnosed referred to be treated. Thus, the waiting list for this form of medical assistance was reduced alongside increased job training for young dermatologists and primary health care workers. At local level the assistance is usually provided by University Dermatology Sectors in each state, with great participation of dermatology residents, supervised by their professors [18].

Since 2009 the National Program of Skin Cancer (NPSC) has included one roaming activity, The Skin Cancer Combat Truck, which has been covering the entire Brazilian coast. This activity was launched in Rio de Janeiro city in December 2009 and is called *Orange December.* This mobile health attendance vehicle has already traveled 69,000 km, offering attendance to about

16,000 persons living in 56 small cities in 22 states, where 1,500 skin cancer cases were diagnosed (www.sbd.org.br/acoes/tour-de-combate-cancer-da-pele/) [19].

The Department of Oncology of the SBD is responsible for all planning and execution processes receiving technical support from the Brazilian Society of Surgical Dermatology. It involves 23 regional SBD sections plus the country's capital city in 24 metropolitan cities (23 out of 27 states) and also in some municipalities of more populous states. Of course the voluntary work of dermatologists should also be acknowledged.

Also worthy of mention is the study group of Melanoma-GBM (www.gbm.org.br), which has spread updated information to associated dermatologists since 1998 through its delivered bulletin and scientific national and international meetings, with prolific scientific information on this subject provided by its dermatologist and pathologist members in collaboration with the NPSC activities [20]. All societies and group studies linked to SBD exhibit skin cancer prevention information on their web sites. A quiz test of skin cancer risk is available on the SBD site with guidance in accordance with the user's results (www.sbd.org.br/informacoes/sobre-o-cancer-da-pele/calcule-seu-risco/).

On the web pages of the Brazilian MoH, the cancer institute holds national data of all forms of cancers alongside useful technical and basic information to prevent skin cancer (http://www.inca.gov.br).

The Impact Perceived by SCC on Epidemiological Indicators and Perspectives

The Brazilian MoH estimated for 2016 175,760 cases of nonmelanoma skin cancers (NMSC): 80,850 cases for men and 94,910 for women. This is the most frequent cancer in men in the Southern, Central Western, and Southeastern Brazilian regions while in the North it is ranked second. It is also the most common cancer in women from regions in the Southeast, Central West, South, and Northeast. NMSC has a low death rate in contrast to malignant melanoma

(MM), which is estimated to produce 3,000 new cases in men and 2,670 cases in women in 2016 and an incidence rate of 3.03 per 100,000 inhabitants, more prevalent in the South (http://www.inca.gov.br/estimativa/2016/) [21]. The comparison of these general data with the same MoH estimate for 2005 indicates a low impact on preventive measures against skin cancer incidence, around 60 per 100,000 inhabitants for NMSC and 3.04 per 100,000 for MM [22].

Research indicates that solar radiation is not the sole influential factor in the genesis of cancer, as skin cancer does manifest in the absence of solar elastosis [23]. Despite the controversies regarding the association of skin cancer with other risk factors besides solar exposition of skin, the campaign target is to increase awareness of disease prevention through protection from ultraviolet (UV) radiation. This consists in information on early signs and symptoms of each kind of skin cancer and its spread, and recommends adoption of new practices or modification in job routines, activities, sport, and so forth [24, 25].

Some studies to assess the knowledge about skin cancer prevention and its association with sun exposure and photoprotection were undertaken mainly in South and Southeastern Brazil where there is a predominance of European ancestries. From a case-control study of 206 melanoma patients in Porto Alegre conducted over a 3-year period from 1995 to 1998, Bakos et al. concluded that light prototypes were more prone to the development of cutaneous melanoma and that the most important associated risk factor was frequent sunburn episodes [26]. In a more recent study the same author proposed a risk score of MM for a Brazilian sample, concluding that in the population studied the best predictive variable for the risk of MM was hair color, in addition to freckles, sunburn episodes, and skin and eye color [24].

In the same city, Benvenuto-Andrade et al. interviewed 724 students about known effects of UV radiation, opinions about tanning, total time of sun exposure per day, photoprotection, and activities in the sun. The results showed that about 90% were aware of the association between sun exposure and skin cancer. The main

source of information was mass media, but only 47% reported sunscreen use in summer and only 3% reported using sunscreen during winter. The study conclusion was that although campaigns disseminated information they were not successful in changing the sun exposure habits of teenagers [27]. Fabris et al. interviewed gym members in a cross-sectional descriptive study utilizing a self-administered questionnaire during 2009 in Santa Catarina state. From 317 questionnaires studied, 94.3% of the participants reported that they had heard about the risks of sun exposure, mostly in terms of skin cancer risk (80.8%), but only 74.1%, especially women, reported using some form of sun-protective measure. A higher frequency of photoexposure was observed in individuals younger than 40 years, and the risk of daily exposure was more frequent in people between 20 and 40 years of age. The conclusion was that these individuals were aware of the risks of excessive sun exposure and skin cancer prevention, but had not yet incorporated appropriate sun-protection measures into their daily habits [28].

One avenue of research intends to correlate audience patterns on the web pages of a Brazilian MoH cancer institute (http://www.inca.gov.br), observing the interest patterns measured by the preferred topics consulted by whomever logs it. The authors monitored the skin cancer site for 24 consecutive months using a commercial software package to document electronic records analysis (log files) of all visitor traffic. Variables of interest included number of visits, time spent on each visit, and the monthly return rate to six selected pages (three relating to cancer as a disease and three to prevention measures). The authors observed peak audiences in periods during the nationwide campaigns. The topics of most interest were concentrated on pages regarding cancer diagnostics and treatment technology. Pages on preventive measures were less visited during the campaigns, and their audience varied little over the 24 months [29].

While no impact is observed in NMSC and or MM frequency, some regional and national investigations did start to show a decrease in advanced forms of MM measured by specific markers.

These data have been appropriately applied, and the improvement in observed 5-year survival and decrease in mortality as a result of early diagnosis probably is related to the SBD's continuous case-finding campaigns and primary health care implementation in Brazil. It is well known that a person with MM can be cured if diagnosed in a phase classified as 1A, whereby the success rate is about 95–97% [30]. A study from Rio Grande do Sul state focused on histopathological criteria established by GBM in a sample of 328 cases between January 1, 2000 and January 15, 2005. Although all cases belonged to a tertiary care hospital, there was a predominance (63.1%) of melanomas considered thin (Breslow thickness ≤1 mm), in comparison with a previous and similar study in the 1990s that presented 2.15% of melanomas in situ and 31.5% with Breslow thickness ≤1.5 mm. The conclusion was that the profile of melanoma cases evaluated in a tertiary referral hospital appears to be changing, with a tendency toward earlier diagnosis [31]. In the Southern region town of Florianopolis, 496 reports of two pathology laboratories on 432 patients with a pathological diagnosis of melanoma were analyzed in a 6-year period with a protocol based on the GBM questionnaire. As a result, the main histopathological profile was superficial spreading, invasive, 1.25-mm Breslow thickness, cutaneous melanomas with inflammatory infiltrate and free margin [32].

Action research performed by one non governmental organization (NGO) carried out 17,857 consultations with a total of 2,012 (11.2%) cases of skin cancer diagnosed from 2004 to 2017 in the interior of São Paulo state. The predominant histological type reported was BCC (81.6%), followed by basosquamous cell carcinoma, but no stage-III and -IV melanomas were found [33].

Regarding the incidence and mortality rate of cutaneous melanoma, a study in the city of Jaú, São Paulo, from 1996 to 2011 presented the data of 162 new cases provided by the local Population-Based Cancer Registry and Mortality Information System of the MoH (SIM). The average incidence for females was 5.1 per 100,000 and 4.8 per 100,000 for males, both showing stability during the period. The

same behavior was observed regarding the mortality rate while an increased incidence in stage 0 and a decrease in stages I and II was confirmed, leading to the conclusion that early diagnosis of cutaneous melanoma has a possible relation to the local program of continuous prevention, together with the NPSC of SBD [34]. A survival, but descriptive clinical and histopathological, study from Santa Catarina state analyzed 83 cases of primary cutaneous melanoma diagnosed in the period 2002–2003 followed for 8 years, and correlated its survival with the tumor phase: 27% presenting with stage 0 and all remaining alive in the monitored period: from 20,5% in stage I, one died (93.8% survival). From 33% in stage II and 19.2% in stage III, the survival was the same, 33.3%, and all patients in stage III died in the same year of their diagnosis. The average survival period on this casuistic was 56.7 months and the mortality rate was 7.0%. The author's conclusion was that ulceration and the final staging were statistically significant factors [35].

One epidemiological study performed in 2010 at an oncology center in Rio de Janeiro aims to evaluate aspects related to temporal trends in mortality of melanoma in the Brazilian population. The mortality data were obtained from SIM, and two groups were analyzed: one during 1997–2001 and another during 2002–2006. A total of 19,218 melanoma-associated deaths were reported in Brazil, 10,899 among males and 8,309 in females, most of them occurring in whites older than 50 years. The mortality ratio comparing South and North regions was 7 in 2005. An increase in mortality of 1.1% per year was observed in the period between 1980 and 2005 with different rates according to sex, age groups, and geographical regions. However, when only the last 10 years were analyzed a decrease of 0.6% per year in increased magnitude of mortality for the whole country was observed. Among older people (>70 years) it was 3.0% per year and among females, 1.6% per year [2] in the regions South and Central West [36, 37]. The same author investigated the role of socioeconomic factors in the evolution of melanoma in a retrospective

study of 1,083 incidental patients with melanoma treated in an oncology center in Rio de Janeiro during the period 1997–2004. From 1,083 patients with primary melanoma of the skin, 58.1% had low school attendance, and 5-year survival for the entire group was 67.0%. Males had worse survival and a protective effect was found for whites, higher educational level, and upper limb lesions. A higher risk of death was observed for patients with nodular melanoma, acrolentiginous melanoma lesions in the soles and palms, and increasing age. In conclusion, socioeconomic status as measured by educational level represented an important factor related to clinical evolution of melanoma in the cohort studied [38].

Despite this social inequity, diverse initiatives in the field, such as the Skin Cancer Combat Truck [19] and annual campaigns from SBD, the Mobile Unit (MU) of Barretos Cancer Hospital [33], and GBM actions [39], have helped to improve the inadequate public health system regarding skin cancer screening and treatment.

In conclusion, the remarkable efforts of SBD and its members should continue to emphasize robust research addressing the monitoring of skin cancer trends, as well as promoting and reinforcing sun-exposure awareness through preventive actions targeting high-risk individuals. Epidemiological studies to identify the demographic characteristics of high-risk patients in different regions will be useful to guide local preventive plans.

Relevant Historical Aspects of Brazilian Government Campaigns of Hansen's Disease

The "World Leprosy Day" at the end of January was created by Follereau in 1954, and was recognized by the International Leprosy Association (ILA) in Europe, which coordinated a media campaign to spread information about the disease. Nonetheless, the main objective was to raise funds to support leprosy projects in endemic countries (http://leprosyhistory.org/). Regrettably it was included in the agenda of

official Programs of HD in Brazil, at national and state levels, only at the end of the 1980s.[4]

Since the middle of the 1970s the term *leprosy* and all correlate adjectives were replaced by the term Hansen's disease (HD) by the MoH of Brazil after pressure from SBD and the Brazilian Leprologists Society (SBH) [40]. It was instigated by its member Rotberg, who adopted this term when in charge of the Hansen's Disease Program of Secretariat of Health, São Paulo [41]. However, only in 1995 was it legally banned under pressure from the Movement for the Reintegration of Hansen's Disease Patients (Morhan) [42], and the first mass media campaign introducing HD concepts and its images only took place in 1986/1987 [43]. This campaign included three short films for TV, jingles with regional rhymes, outdoors and indoor posters, and handouts. Its contents were deeply discussed and many local activities and health professional training sessions were conducted all over Brazil to implement a new treatment for HD (*poliquimioterapy*; PQT). The campaign proposal was to be maintained yearly for 5 years; nevertheless this regularity was not observed, despite other nationwide campaigns carried out from the MoH since then [44]. One survey performed in 1988 (1 year after the HD campaign) questioned 1,797 persons about MoH campaign memories. Among 24 diseases, HD was mentioned in ninth position.[5]

In 2001 evaluation research was conducted in four metropolitan regions of Rio de Janeiro in order to understand whether the popularization of scientific notions of HD had been assimilated by 800 interviewed housewives. The results showed that 436 (54%) promptly expressed their association with the word Hansen's disease/*hanseníase* while 358 (45.1%) expressed association only to leprosy. It was possible to infer that the common sense of HD was in transition, linked to skin patches and curable disease, while leprosy was linked to incurable dog disease.[6] The interviewees were 42 years old on average, and the HD knowledge was positively associated with education level [45].

It has been noted that since the introduction of the neologism *hanseníase*, also adopted by the communication mass media, all official information directed to health professionals, but mainly for the general population, omits the link with the term leprosy. The collective memory of leprosy in that population is mostly oral and mainly influenced by individuals' social networks. Based on the theory of social representation, we may conclude that HD is part of a process of modernization of common thinking, anchored in the traditional representation of leprosy [45]. It is well known by health workers in Brazil that even patients under treatment for HD were sometimes doubtful as to whether their illness was leprosy or not [46]. It may be that 30 years is not a sufficient time to consolidate a social representation of HD. Furthermore, the investment in social marketing to make the new terminology better known started a full decade after the neologism was implemented.

This first campaign of HD by the end of the 1980s prioritized the information of a cure,[7] and one finding from our research in the beginning of 2000 shows the absence of knowledge of skin hypoesthesia (numbness) as an HD symptom. This result was discussed and focused upon in the following campaign by MoH and BBC/Novartis in 2003. This campaign publicized loss of sensation of the skin in different situations with the objective of retaining this information (http://www.comminit.com/content/leprosy-awareness-campaign).[8]

In addition to the first national TV campaign, a great variety of learning materials for community agents, handout materials, and radio jingles produced in all regions by 27 states and some

[8]BBC Campaign run in February 2003.

municipalities has been spreading basic knowledge about HD around Brazil. The same strategy was repeated by a BBC campaign in 2003.

Usually the campaign did not comprise active "case finding" of HD before the end of the 1990s, when the World Health Organization (WHO) launched the strategies called LEC (Leprosy Elimination Campaign) and Special Projects to Eliminate Leprosy (SAPEL) [47]. The former is an initiative aimed at detecting "leprosy cases with consequences," which means advanced and undetected cases by passive Primary Health Care (PHC) assistance. SAPEL is an initiative focused on the neglected population, some of whom live in difficult-to-access areas or situations. Both target the hidden prevalence of the disease. The regional offices of WHO selected projects and some resources were addressed, mainly to SAPEL.

In Brazil the first experience of WHO/LEC was performed in Rio de Janeiro municipality with an HD campaign combined with a poliomyelitis vaccination campaign in 1997, involving all dermatologists from the municipal health network [48]. In 1998 the National HD Program planned to repeat this strategy all over the country, but unfortunately the MoH was afraid that it could jeopardize the polio campaign and did not officially support it. Despite this, 390 municipalities performed this campaign in 20 states and 2,400 new HD cases were diagnosed in a single day (5% of yearly estimated detection) [49]. Rio de Janeiro municipality maintained this strategy continuously for more than a decade, and currently many municipalities around the country carry out active case-finding campaigns. In addition to the *World Day,* some states also defined a *Hanseníase Day*, considering that January is not an appropriate month to hold this campaign in Brazil.

The Brazilian SBD even supports the national and local campaigns of HD, but only assumed its own initiatives in 2005[9] when municipal campaigns were launched involving its regional sec-

tions from the most endemic states [50]. This proposal included distributing two posters to be displayed at health units across the country, one of them focusing on stopping HD in children and emphasizing the participation of a dermatologist in this kind of activity as essential to increasing the diagnostic accuracy of HD; the other focused on resolution of other dermatoses and PHC training.[10] It is worth mentioning that one of the targets of the current strategic WHO plan for 2016–2020 is to achieve zero cases of leprosy in children [51].

Since then the SBD has been participating in these campaigns of the National Program of HD, in addition to municipal-level participation of dermatologists, residents, and medical students. As well as in one roaming activity, utilizing a truck to diagnose HD, supported by Novartis Foundation. Such strategies demands a strong integration of leprosy managers and universities in each state, thus allowing new learning and teaching opportunities. It certainly will also contribute to early diagnosis of HD, which is still a challenge for many Brazilian municipalities.

The Impact Perceived by HD Campaigns on Epidemiological Indicators and Perspectives

The first national mass media campaign of HD of the National Division of Sanitary Dermatology of (DNDS), MoH, increased by 31.5% (almost 7,000) the number of new cases in 1987 [43]. In one national survey of private dermatological clinics around the country by ordinary mail, 99% of recipients returned the forms which collected the following information: 770 persons referred to the mass media campaign as a motivation to go to the clinic while 501 presented clinical suspicion or at least a differential diagnosis of HD, 291 of which were confirmed.[11] The existence of this hidden prevalence is supported by a trend analysis which shows an increased tendency of the disease in four Brazilian regions, excluding only the South [52].

[9]SBD president and vice president (Sinésio Talhari and Gerson Penna: 2005–2006), and the HD Department consisted of Maurício Nobre (NE), Fatima Maroja (NO), Francisca Estrela, Luna Azulay, and myself.

[10]This proposal received support from the ILEP member Netherlands Leprosy Relief.

[11]Report from then the National Division of Dermatology. Document copy of this author's repository.

Nevertheless, the best indicators of this punctual strategy measurement are the proportion of disability grade in the total number of new cases diagnosed as well as its clinical form and disease features, which indicate early diagnoses or not. The impact could be measured in the longer term by reduction of the number of cases, especially the pediatric rate [53]. As mentioned earlier, the first evaluation of LEC strategy was performed in Rio de Janeiro city in 1996 by combining HD and anti-polio vaccination. The mass media campaign carried out from July to September and the intensive examination on 17 August increased the health unit locations for HD diagnosis and treatment from 28 to 70 by utilizing the vaccination venues. From the 2,511 persons assisted, 52 new cases were confirmed, 30.8% presenting an indeterminate form of the disease [48].

Other good examples exist in Acre state, which was the most endemic state of Brazil 30 years ago and managed to produce a well-conducted and continuous policy of performing active case finding across the rivers in the Amazon forest. After the municipalization, the coordinator of the Program of State Secretariat of Health invited the university service to expand the campaign to all municipalities to verify whether the decreased detection rate in passive diagnosis at PHC was true. The first campaign in 2001[12] was preceded by population domiciliary visit screening carried out by trained community agents of the Health Family Program in the two biggest cities. Of the 11,720 persons examined, 2,881 (24.58%) presented skin problems and were referred to the campaign; 11,638 (91.56%) were examined and 53 new cases of HD were diagnosed (2.01%). The early diagnosis was corroborated by the low disability grade (96.22% = 0, only one presenting grade II) and only four cases (7.5%) showing positive smears. Despite this, the number of HD cases diagnosed in this campaign was higher than the total number of new cases

during the entire previous year in the same municipalities. In addition, 5% of new cases in the previous year presented grade II disability. It could thus be inferred that there were few undetected cases by PHC [54].

The second campaign was included in the SBD Project of 2006. A task force was organized with the participation of residents of Dermatology from Rio de Janeiro and Espírito Santo states, and medical students and health professionals from Acre, supervised by professors from federal universities of Rio de Janeiro. The team was also composed of nurses, physiotherapists, and one mobile laboratory for skin smears from the State HD Program. It was not preceded by a screening process but by a mass media campaign (radio, TV, posters, handouts) covering all Acre state, besides scheduled examination in the municipal reference unit of each municipality in the 20 cities visited. In 2 weeks 10,214 examinations of referred persons was done and 318 new cases of HD were confirmed (3.11%), 0.37% of whom [32] were younger than 15 years. Only 2.20% of cases presented grade II disability and only 8.17% had positive smears. The small difference found in comparison with 2001 results could be related to the remote municipalities visited and the lesser supervision in small communities.

The TV campaign in 2008 focused on contacts surveillance; for example, a mother suffering HD alongside her children, publicizing that she must take care of her family. A more recent campaign includes HD among the neglected diseases, related to the new policy of MoH that emphasizes the persistence of clusters of the disease located in impoverished areas (http://bvsms.saude.gov.br/bvs/publicacoes/plano_integrado_acoes_estrategicas_2011_2015.pdf) [55].

Since 2011 the new policy of the Brazilian MoH for HD is defined as an "Integrated Strategic Action Plan for elimination of leprosy, lymphatic filariasis, onchocerciasis, schistosomiasis, trachoma as a cause of blindness and control of soil-transmitted helminthases (STH)" [55]. It includes a case-finding campaign aimed at 9.2 million school-aged children in 800 municipalities in 27 states. It has also allowed the early detection of leprosy cases and the reduction of morbidity

---

[12] The operational research "The social role of dermatologists: importance of early diagnosis of leprosy and prevalent skin diseases" received the award for the best community operational research from the Dermatology Residents Forum at the 56th Brazilian Congress.

caused by STH, since these parasites have a high impact on the growth and development of children under 15 years old. It is for this reason that deworming has focused mainly on this age group.

The strategy for this mobilization is for health professionals from the MoH to administer albendazole, backed by the state and the municipalities in coordination with teachers in schools. For the case finding of HD, teachers have been collecting information regarding the presence of possible signs and symptoms of this disease in students. Suspected cases are referred to the family-health teams for diagnostic confirmation while the complicated cases are referred to university hospitals as agreed by SBD/MoH and Dermatology Services.

Despite a recent reduction in detection rates of HD in Brazil, there is still active transmission and late diagnosis in many clusters located mainly in the Northeast, Center West, and Northern regions. Further specific actions must be maintained to improve early case detection and prompt treatment with the aim of reducing the disease burden in the population, considering existing social inequities in the country [56].

In addition to the impact related to endemic traits, it must be mentioned that the stigma and self-prejudice related to leprosy and compulsory hospitalization period [57, 58] filtered through to HD and consequently impaired the quality of life of its carriers, even in the absence of deformities [59].

Nonetheless, fears of exclusion are mainly associated with the physical disfigurements, development of disabilities, ability to work, contagiousness, and pain in many situations found in Brazilian studies [60–62]. This has a negative influence on the patients' treatment management and their household contacts surveillance. Therefore, all efforts addressing counseling and community-based rehabilitation to the patients and their families follow the Global Leprosy Strategy 2016–2020 [51]. This latest guideline of WHO, *Accelerating Towards a Leprosy-Free World*, includes partnership promotion "with state and non-state actors and promote intersectoral collaboration and partnerships at the international level and within countries." In Brazil the

official involvement of SBD in the MoH policy is required to guarantee best practice in early diagnosis through the integration of dermatologists in a multidisciplinary team of health workers [63].

Sexually Transmitted Infections (STIs) and AIDS: Relevant Historic Aspects of Brazilian Campaigns

Since the eighteenth century many authors, including Brazilian dermatologists [64], have encouraged medical diligence to raise governmental attention to the consequences of syphilis for humanity. The first official health policy involving dermatology was called *Inspectoria de Profilaxia da Lepra e Doenças Venéreas,* which was first formulated in 1920 and was coordinated by Eduardo Rabello [65, 66]. The internalization of assistance and preventive measures was planned through the Countryside Prophylaxis Services, and one recommendation was for centers of venereal disease for regional assistance and training [64, 66].

However, this policy did not reach all Brazilian states and was not maintained or consolidated as exemplified in the historical register of São Sebastião Hospital, also called "*Asilo das Madalenas* [67]" in Pará State, which was closed because of both local society pressure and the existence of many other health problems. However, in the then capital city, Rio de Janeiro, one good example of a private initiative was the Gafree Guinle Foundation, inaugurated in 1929 and also following the national policy [66].

After the advent of penicillin for syphilis indications in 1943, and later new antibiotics discoveries, the syphilis scourge and other STIs could be faced, despite being neglected as a public health problem [68–70]. The period of strong sanitary policy led to a strategy to control the sexual market throughout the urban spaces, creating segregated prostitution zones monitored by judiciary intervention as well as joint action of the public health department and the police. The main action was the compulsory and periodic examination of the prostitutes who, if in good health, received a green card granting permission

to work in those spaces. This was a well-documented official measure to protect men who frequented such areas, for example in Santa Catarina state [71].

The two decades of 1960 and 1970 witnessed expansion of STI related to strong behavioral changes linked to young people's freedom, sexual liberation, unsafe injection of drugs, migration to the metropolis, and globalization. Viral diseases such as human papilloma virus (HPV), hepatitis B virus (HBV), herpes simplex virus (HSV), and chlamydia trachomatis were linked to the classical STI group [72, 73]. Even though these diseases were not considered a prioritized public health problem at this time, the high level of hospital assistance rather than the health needs of the population constituted the central focus of Brazilian public health. The MoH function was restricted to formulated guidelines [74, 75] and few university services offered reference services for assistance, training, and research.[13]

Later, a new tragedy emerged in this group of diseases with the advent of AIDS in 1981 [76]. The available technology, magnitude, and transcendence of AIDS generated within a short time not only knowledge of its physiopathogenesis but also a new generation of medications to treat other diseases [77, 78].

Regarding health promotion, we could infer that AIDS provoked a well-documented revolution, obliging society to open the discussion and redefine knowledge of issues considered taboo up to this era, such as homosexuality, sexual activity out of wedlock, the ever present sexual market, and the modern ways to protect human foibles [79–81].

It is well known that despite all the suffering conveyed, in Brazil AIDS brought second-ary benefits such as blood supply, hepatitis, and tuberculosis program controls [78]. The accumulated experience with a nationwide control plan from the MoH developed with the civil society is also a model for general health policies [78, 82]. Worthy of mention is the new policy to confront and protect injecting drug users, including the harm reduction strategy, started in 1989 from one pilot and successful project in Santos in São Paulo State, adopted by the government to support the needle exchange program and later on to be included among the national program strategies [83].

After those first known cases from São Paulo[14] the disease spread promptly over the course of the next decade [78, 84, 85]. Fortunately, a relatively early and well-formulated response to the epidemic emerged from São Paulo, which was utilized over the long term as an important model for Brazilian states and even MoH plans [86, 87]. The earliest published cases of AIDS concentrated in São Paulo were followed by the emergence of powerful gay organizations in Brazil and the regrettable infection of numerous hemophilic patients, which presented an opportune moment to apply political pressure on the MoH to respond and confront the emerging epidemic [87].

By 1985 the MoH formalized the National AIDS actions in the Dermatology sector (DNDS) with the first and fragile guideline for the State Secretariat of Health, and began the mass media initiatives, which in fact were considered weak and unsuitable and usually not relevant.[15]

From 1986 to 1992, along with the political and administrative changes in a wider countrywide context, sanitary reform created the Unified Health System (SUS), and a robust nationwide

---

[13] Observations from this author's experience: (a) In the beginning of the 1970s the State Secretariat of Health of Espírito Santo state supported a reference center for diagnosis and treatment of DST, offering a field for medical student practices .(b) In the early 1980s The DNDS/MoH started offering training on Sanitary Dermatology and the trainees went to Porto Alegre in order to have practice. (c) At the same time in Rio de Janeiro city the State Blood Storage notified all blood donors who tested positive for syphilis, but there was no subsequent surveillance action.

[14] The first case of AIDS identified and released in a scientific society in Brazil comes from São Paulo, presented by Valéria Petri at the Brazilian Dermatology Society (SBD) Congress in 1982, Rio de Janeiro.

[15] I received it in Rio de Janeiro as state coordinator of Sanitary Dermatology. Also, DNDS triggered one TV campaign with Sócrates (football player) and provided an international course in 1985 for Aguinaldo Gonçalves, in charge of the National Programe, Paulo Teixeira from SP, the coordinator of DF (Brasilia) and I from RJ state. Paulo Teixeira, one technician from DF, one from MoH, and one from Rio de Janeiro.

program of AIDS and STI control was created [86–89]. This started in February 1986 with a national meeting of DNDS when two workgroups to formulate action plans for both AIDS and HD were set up. Both were officially published in April 1986 with a Disease National Advisory Committee assigned to each. The two immediate activities were to create a form and information system for AIDS case notification (manual at the time) and to start formulating a nationwide campaign.[16] The National Program for AIDS and STI Control was created out of the Dermatology sector at the end of 1986, receiving internal support from the National Institute of Medical Assistance and Social Security, and was implemented with foreign resources from the WHO and the Pan American Health Organization, before the loan agreement between the Brazilian government and the World Bank in 1992 [90]. This become an internationally referenced public health intervention plan, allowed to sponsor many civil society organization projects not only from the groups initially linked to the program but also from different parties such as sex workers, feminism groups, health promotion, and others [91, 92]. By 1992 the high number of human immunodeficiency virus (HIV) carriers and diversified profiles of AIDS patients oriented the guideline to decentralize diagnosis and treatment from reference centers to PHC of SUS [91]. As a result of the first impact on the endemics indicators, by the

end of 2000 the protagonist role of the Brazilian program was recognized worldwide, and in 2001 the Brazilian government obtained free universal access to antiretroviral drugs [93–95]. Currently the Hepatitis Combat is integrated into a larger AIDS Program and there is a discussion about the possibility to join the Tuberculosis Program in the Department of DST-AIDS and Viral Hepatitis of MoH.[17]

With AIDS renowned as the most devastating disease humankind has ever faced, the Joint United Nations Program on HIV/AIDS (UNAIDS) formed by 11 cosponsors and the Global Fund to Fight AIDS, Tuberculosis and Malaria demonstrate how it is possible to build a universal and powerful intervention plan to fight pandemics (http://www.unaids.org).

Health education and health promotion were great beneficiaries of these efforts. Many research studies, learning materials, and campaigns from the government and private organizations were triggered to deal with complex and dynamic endemics [96]. In the previously mentioned inquiry of 1,797 Brazilians about their memories of MoH campaigns performed in 1988 (1 year after the first strong AIDS campaign), AIDS was rated in second position among 24 disease campaigns.

All issues and contents of the official campaigns for STI, mainly AIDS, since 1998,[18] not only from MoH but also including UNAIDS initiatives, can be found on the web site of the National Program of MoH (http://www.aids.gov.br/campanhas). The creative and positive single-mindedness of these campaigns is perceptible, principally if compared with other countries and in contrast to the beginning when mass media connected AIDS with death and terror [97, 98]. The focus on human rights, self-esteem, disease information, and stimulus for preservative use is in agreement with the concept of vulnerability reduction, which replaced the notion of preliminary risk conception. In addition to MoH campaigns, many other Brazilian institutions also elicited its own campaigns, such as Globo televi-

---

[16]While in charge of DNDS this author first invited Dr. Paulo Teixeira to coordinate the workgroup and then Professor Lair Guerra de Macedo who was working in STI in the Women Program/MoH, to be responsible for AIDS/SDI; Dr. Miriam Franchini to be responsible for STI training; and Dr. Jair Ferreira to take part in both committees as epidemiologist. Many difficulties were encountered at the beginning, when MoH had a very poor infrastructure and budget (before SUS) and had just started working with civil organizations through DNDS (MORHAN, GAPA, ABIA, GGB, and hemophilia associations). Also important was the support from SESP Foundation Network training an all-doctors team coordinated by Dr. Pedro Chequer. Also the recognition of STI state referral centers for training in Porto Alegre (the film Love without pain – Gerbase/RGS), the Laboratory in Brasilia (Miriam Franchini), and Alfredo da Matta Reference Center (Adele Benzakem, Sinesio Talhari and JCG Sardinha).

[17]Oral information from health workers' meeting.

[18]Missed campaign from the first decade.

sion in the early 1990s and the National Bishops Conference of the Catholic Church in 2008 and 2012, despite conflicts regarding extramarital sexual activity [97–99].

During the FIFA World Cup in Brazil in 2014, UNAIDS drove the kick-off of the *Protect the Goal* world tour campaign first launched at the 2010 FIFA World Cup in South Africa to raise awareness around HIV prevention and to encourage young people to become actively involved in both the national and global response to HIV (http://www.unaids. org/en/resources/presscentre/pressreleaseand- statementarchive/2014/march/20140305 prptg) [98].

Alongside all mass media campaigns for TV and radio, there are a great number of university health and social workers performing participative research into community groups as well as many factories involved in educative experiences with its workers in each state of Brazil, as a result of NGO participation in the national policy [100, 101]. However, achieving the ideal scenario to provide early diagnosis and treatment facilities for STI patients and their partners is still a challenge [102].

The Perceived Impact on Epidemiological Indicators of STI and AIDS, and Perspectives

The special session on AIDS/HIV of the United Nations General Assembly in June 2001 concluded that there was an emerging rise in infection rates from high-income countries and absence of control in some other low-income countries, mainly in Africa, despite reasonable achievements as a result of 20 years of intense response to the disease. What is propelling this is well known: unsafe sex, reflected in STI outbreaks, and widespread injecting drug use of epidemic proportion shifting toward deprived communities. The final resolution—*stronger commitment*—was directed to develop multisector strategies to address the impact of the HIV/AIDS epidemic at the individual, family, and national levels of all endemic countries [103].

In Brazil, the increase in syphilis[19] in the last decades was considered a sentinel to intensify the surveillance for all STIs [104]. Since 1986 congenital syphilis has been included in a compulsory list of notifiable diseases, and the current recommendation is two syphilis tests during pregnancy and one at delivery, in addition to other official programs for maternal and neonatal care [105–107]. However, studies still show that women are not tested during pregnancy or at delivery. The WHO elimination target for congenital syphilis is <0.5 cases per 1,000 neonates up to 2015 [108], but despite a notable reduction over the last years the recent epidemiological and operational information demonstrates some difficulty in achieving this target in Brazil, where it was 4.7 per 1,000 neonates in 2014 [109]. A wide difference between regions was observed, but all patients not only maintained high levels of positivity rates for syphilis in pregnant women, but also a treatment gap for their partners [109]. This is justified by the weaknesses of prenatal care in the Brazilian health system, probably in addition to a penicillin shortage in 2015 creating a risk factor for syphilis infection during pregnancy. Recently, the Brazilian Medical Council circulated a recommendation to commit doctors to request standard examinations for STI [110].

The commitment of Latin American and Caribbean countries to reduce the vertical HIV transmission was to achieve a target for 2015 of ≤2%, or incidence rate of 0.3 cases per 1,000 neonates [108]. In 2006 a national prevalence study showed that even in those who were pregnant and were submitted to adequate prenatal tests, considering the moment and the number of tests done, absence of HIV testing was observed in 22.5% [104]. Although the detection rate in children (<5 years old) as a proxy indicator to monitor the vertical transmission of AIDS also underwent a significant decrease in Brazil, in the North region it increased from 2.9 to 4.4 per 100,000 inhabitants [109].

---

[19]Despite only congenital syphilis being notified, there is a consensus about diagnosis increasing in the routine consultancies of Brazilian dermatologists.

Nevertheless, some questions may arise concerning the increase in AIDS/HIV and syphilis, possibly influenced by factors such as notification improvement, interdiction to sell antibiotics in pharmacies without medical prescription,[20] notification and treatment of HIV carriers, and the use of databank linkage analysis in the AIDS Program.

The characteristics of STIs, and especially AIDS, currently affecting different vulnerable and marginalized groups in developing countries are reasonably well documented [103]. Their dynamic processes imply effective monitoring to guide regional and local action plans. An example concerns the observed increased prevalence in the elderly, which may be related to longer sex lives in persons who by and large are not users of condoms [111–113].

The men/women and hetero-/homosexual predominance in these groups has been subject to change. Dealing with injectable drug addiction requires integration with social policy areas in order to formulate a harm-reduction project for each specific situation [114].

The latest national inquiry of knowledge, attitudes, and practices related to STI/AIDS (2008) in a randomized sample of the population in the age group between 15 and 64 years from all Brazilian regions showed that sexual initiation of one-fourth of individuals was before 15 years old and in those aged 15–19 was 35%. A significant proportion, mainly men, informed that they had multiple sexual partners and that condom use was lower than recommended [115]. This was corroborated by a study of reproductive characteristics and utilization of preventive health services by childbearing-aged females, which revealed that the mean age at sexual initiation decreased, resulting in an increase in teenage pregnancies throughout the country [116]. This kind of national inquiry should be continued every 5 years, and the epidemiological and operational indicators of the endemic situation must be disseminated in timely fashion to direct the regional and local operational investigations for validation.

Taking into account the sexual desire present in everyone, all of this is understandable. Furthermore, cultural and religious influences bring acknowledged complexities and challenges to preventive measures practices. Moreover, the positive results of successful treatment interventions hide the dim realities of such a destructive disease and, therefore, young people are unaware of the true extent of the risks they take. Among the target population (sex workers of both genders, drug injectable users, teenagers, and the elderly) are truck drivers, as verified in a study by Teles et al. in 2005. From 620 who were interviewed, about 40% answered positively about STI antecedents (who had STI) and 70% stated that they were drug users [117].

In the study by Nardi and Rigoni, 11 harm-reduction interventions/programs in the Greater Metropolitan Porto Alegre, Rio Grande do Sul state were analyzed between 2004 and 2006 and compared with data from a previous study in 2003. They focused on the programs' sustainability and operational characteristics including different linked organizations. The results show a precarious professional situation; dependence on volunteer work to implement activities; and influence of turnover in Municipal and State administration on the continuity of projects and partnerships, as well as on the maintenance of human and financial resources. The authors conclude that "such factors lead to lack of continuity in the services provided to the target population" [118].

These different dimensions of vulnerability to sexually transmitted disease/AIDS imply health promotion actions that focus on social protection, which consider comprehensively the concept of the factors underlying vulnerability [119]. According to UNAIDS guidelines the ability of individuals and communities to avoid HIV risk may be reduced through factors beyond their control. These factors may include: lack of the knowledge and skills required to protect oneself and others; limited accessibility,

---

[20]Before this prohibition in 2010, it was well known that in the case of STI, regular people used to go first to the pharmacy.

quality, and coverage of services; and restrictive societal factors, such as human rights violations, punitive laws, or harmful social and cultural norms (including practices, beliefs, and laws that stigmatize and disempower certain populations). These factors, alone or in combination, may create or exacerbate individual and collective vulnerability to HIV and other STIs [103, 117, 119, 120].

Safe-sex behavior recommendations are only successful and make a difference if there is an understanding of each context. Therefore, the practices must be based on the subjects mentioned at the beginning of this chapter: dialogue (utilizing adequate communication words) [120] in different community-based actions to enhance social status and rights of the marginalized people is only possible with the recognition of its cultural identity (knowledge and autonomy). To be able to work under this socio-constructionist principle, health and social workers should be conscious of their self-discrimination deconstruction and be trained to have an attitude of respect with values and rights of its interlocutors to function as a facilitator of the health educational process.

In conclusion, in view of these activities there are many Brazilian dermatologists dealing with these three major problems in focus at different levels of public health policies nationwide. As a tropical country there is a great demand for PHC for skin diseases, and punctual campaigns to screen HD and skin cancer at local level allow the PHC team to be trained in diagnosing and treating prevalent dermatoses. Decentralization of the health services and the use of guidelines to integrate the assistance of HD and AIDS/STI programs into the PHC system should not be to the exclusion of dermatologists. The reallocation of specialists in referral units and their participation in clinical sessions to discuss the most challenging cases contribute to best practices and permanent and multidisciplinary health education [121].

Dermatologic Diseases in Public Health: Cutaneous Infectious

Hanseniasis

5

Letícia Maria Eidt

Key Point Summary
- Hanseniasis is an infectious disease, caused by *Mycobacterium leprae*, which affects principally the skin and peripheral nerves
- Reporting the disease is compulsory worldwide
- It is a public health problem because of its potential for incapacity
- Prevention of disabilities begins with the early diagnosis, followed by multidrug therapy and patient health education for self-care

Introduction

Hanseniasis (Hansen's disease) is a systemic infectious disease caused by *Mycobacterium leprae*, an intracellular and acid-fast bacterium that primarily affects the skin and peripheral nerves. If the disease progresses, other organs such as the liver, kidneys, adrenal glands, testicles, eyes, and lymph nodes can be affected. Central nervous system involvement is exceptional.

L.M. Eidt, MD, MSc, PhD
Sanitary Dermatology Service of the Department of Health of Rio Grande do Sul State,
Porto Alegre, Brazil
e-mail: leidt@bol.com.br

Hanseniasis is best understood as two conjoined diseases. The first is a chronic mycobacterial infection that elicits an extraordinary range of cellular immune responses in humans. The second is a peripheral neuropathy initiated by the infection and accompanying immunologic events, but whose course and sequelae often extend many years beyond the cure of the infection and may lead to severely debilitating physical, social, and psychological consequences [1]. Both of these aspects must be considered by clinicians and health workers who deal with persons affected by the disease.

Diagnosis in the early stages of the disease creates minimal chances of progressive disability and subsequent deformities related to the evolution of bacteria in the susceptible organism. These disabilities are responsible for the stigma and prejudice against persons affected by hanseniasis.

In Brazil the recommendation is to avoid the term "leprosy" and its derivatives because of prejudice, stigma, and discrimination. As the word "leprosy" carries a very strong anti-educational burden, to honor the discoverer of *M. leprae*, Gerhard Armauer Hansen, since the year 1975 the terms "hanseniasis" and its derivatives Hansen's bacillus, hansenology, hansenologist, hansenic, hansenoma, and hanseniasis patient have been used On August 4, 1975, President Ernesto Geisel and Minister Almeida Machado introduced the word "hanseniasis" to the federal

agencies of the Ministry of Health. The historic decree marked the end of a neologism and the official beginning in Brazil of a "disease like the others" to be controlled "like the others" by the *Divisão Nacional de Dermatologia Sanitária* (Sanitary Dermatology Division). On June 1976 Minister Machado issued a bill proscribing the term "lepra" and derivatives from the documents of the Ministry of Health [2].

Later, in 1995 President Fernando Henrique Cardoso and Minister Adib Jatene issued Law No. 9.010 that prohibited the use of adjectives related to leprosy, except in informative references to history [3].

Hanseniasis is a mandatorily reported disease in the current guidelines of the World Health Organization (WHO) [4] and the Brazil Ministry of Health [5]. In Brazil, Decree number 149 of February 3, 2016, approved the Guidelines for Surveillance, Attention and Elimination of Hanseniasis as a Public Health Problem to guide managers and professionals of health services [5, 6].

Hanseniasis is a public health problem not because of the skin lesions but because of its potentially incapacitating and physical consequences, which contribute to the prejudice, stigma, and discrimination that accompany this disease.

Epidemiology

Hanseniasis remains endemic in all countries of the Southeast Asian and African regions, and in most countries of the Eastern Mediterranean region. In the Americas, locally transmitted hanseniasis is found in all countries (except Canada and Chile) and several island countries of the Caribbean. A small number of cases have been reported in several southern and eastern European countries. In the Western Pacific the disease is endemic in most countries except New Zealand and some small island nations [7].

The global registered point prevalence at the beginning of 2011 was 192,246 cases, with 228,474 new cases detected during 2010. Of these, about 95% arose from only 17 countries. These are, in order of ranking, India, Brazil,

Indonesia, Bangladesh, Democratic Republic of Congo, Ethiopia, Nepal, Nigeria, Myanmar, United Republic of Tanzania, Sudan, Sri Lanka, Philippines, China, Madagascar, Mozambique, and Angola [7]. Figures 5.1 and 5.2 show the prevalence and incidence of hanseniasis worldwide as reported to the WHO in January 2011 and January 2012, respectively.

Based on official data from Ministries of Health in endemic countries, the global annual detection of leprosy has shown a declining trend since 2001. The number of new cases detected was 407,791 in 2004, but had fallen by 2010 to 228,474 and to 219.075 in 2011, a reduction of more than 46% [8].

In Brazil, in 2014 official data reported a detection rate for new cases of 15.32 and prevalence rate of 1.27. In this year 31.064 new cases were diagnosed, 65.91% in the multibacillary forms of the disease and 6.56% with grade 2 physical disability [9]. The most endemic region is Centro-Oeste, with a prevalence rate of 3.93, while the state of Mato Grosso has the highest number of cases, with a prevalence of 10.19.

Etiologic Agent and Transmission

Hanseniasis is caused by a slow-growing bacillus, *M. leprae*, or bacillus of Hansen, discovered in 1873 by Gerhrad Armauer Hansen in Bergen, Norway [10]. In those days this disease was thought to be hereditary.

The bacillus of Hansen is an obligate, intracellular, acid-fast bacillus multiplying mainly inside the macrophages of the skin (histiocytes) and nerves (Schwann cells). It closely resembles the bacillus that causes tuberculosis. However, *M. leprae* is less acid-fast than *Mycobacterium tuberculosis* [10]. *M. leprae* can survive up to 46 days in warm, moist soil not exposed to direct sunlight and has a generation time of 12–13 days. It produces a specific substance called phenolic glycolipid 1 (PGL-1) by which it is identified [11]. Its genome has recently been sequenced, and it is hoped that this knowledge may help in developing a vaccine to combat the disease.

M. leprae is a Gram-positive bacterium that in stained skin smears or secretions is seen lying

singly, in clumps, or in compact masses known as globi (Figs. 5.3 and 5.4). In smears stained by the Ziehl–Neelsen method, living and viable bacilli appear as solid and red staining. Dead and nonviable bacilli may be fragmented (showing smalls gaps in the stain) or granular, showing unstained zones across the width of the bacillus.

Bacilli of Hansen are scan in lesions of paucibacillary hanseniasis (indeterminate and tuberculoid), but are present in enormous numbers in the lesions of multibacillary hanseniasis (dimorphous and virchowian).

After the discovery of the hanseniasis bacilli, Hansen attempted repeatedly to grow them on artificial media in the laboratory, without success [1, 10]. He also made repeated, unsuccessful attempts to infect himself as well as his mentor
Fig. 5.3 *M. leprae* singly and in clumps
Fig. 5.4 *M. leprae* in globi

and father-in-law, Dr. Danielssen, with material from his patients. Danielssen had four inoculations, all of which ended in negative results, because hanseniasis is not easily communicable and not highly infectious [4, 10].

The precise mechanism of transmission of *M. leprae* is unknown [1]. The contact does not need to be skin to skin as was previously believed because the nose, and not the skin, is the main port of exit of bacilli from multibacillary patients [10]. Therefore the most accepted mechanism of transmission is via the upper airways with bacilli being eliminated by droplets from the nose and mouth of untreated patients with severe disease [4]. Untreated hanseniasis patients may discharge as many as 100 million (10^8) bacilli of Hansen from their nasal secretions every day, whereas these bacilli are rarely found on the intact skin of patients with multibacillary hanseniasis [10].

The inhalation of bacilli-laden droplets is currently regarded as the most likely mode of entry of *M. leprae* into contact persons. Inhaled bacilli of Hansen probably enter the body through the nasal mucosa. A scratched or abraded skin may facilitate the passage of organisms in droplets deposited on the skin surface, through the epidermis, and into the dermis. The nasal mucosa and abraded or damaged skin are the two preferred sites of entry of bacillus of Hansen. These sites have a temperature lower than the normal body temperature of 37 °C [10].

The infected human being is considered to be the only source of infection. The infective capacity of multibacillary cases is 4- to 11-times greater than paucibacillary hanseniasis [10]. Untreated patients with multibacillary hanseniasis thus constitute the main source of infection. The occurrence or non-occurrence of the disease is closely associated with the cell-mediated immune response of the host to the challenge by the bacillus of Hansen [10, 11].

In general, prolonged or close contact is considered to be necessary for transmission. However, in susceptible persons even a casual or short contact may cause the disease. An intrafamilial contact with a multibacillary patient is more risky than an occasional extrafamilial one [10]. It is assumed that 95% of the population is resistant to

infection with *M. leprae.* People of all ages are susceptible to the disease, but the age of onset is determined by the opportunities available for the person to come into contact with bacilli [11].

Although bacilli of Hansen have been detected in sperm, ovary, umbilical cord, placenta, and even the fetus, the possibility of congenital transmission of hanseniasis is remote [10].

Clinical Presentation and Classification

The clinical manifestations of hanseniasis are varied and are determined by the host–parasite relationship, which varies according to the degree of resistance possessed by the host [11]. Owing to the fact that *M. leprae* is an obligate intracellular microorganism, the resistance to illness depends on the cellular immunity of the host.

Most individuals who have been in contact with persons affected by multibacillary hanseniasis develop a subclinical infection. However, in more than 95% of such persons, the infection fails to establish itself and they never develop any manifestation of the disease [10]. In turn, less than 5% of people exposed to *M. leprae* develop clinical disease [12] and only a single or a few ill-defined hypopigmented or faintly erythematous patches of indeterminate hanseniasis may develop.

The incubation period of the disease may vary from 3 months [12] to 30 [11] or 40 [12] years, with an average of 3–5 years [11], although 5–7 years is typical [12]. For paucibacillary disease the incubation period is up to 5 years, and 20 years or longer for multibacillary hanseniasis [12].

The disease is classified by taking into account the clinical aspects, bacteriologic status, immunologic behavior, and histologic characteristics in a given individual [11]. Hanseniasis clinically manifests in a variety of clinical forms related to the type and strength of the host's immune response. A strong cellular immune response, present in those subjects with fairly high resistance, is effective in curtailing *M. leprae* multiplication and leads to a localized form of the disease. However,

in those with low resistance against *M. leprae* a severe generalized form of the disease is produced. Between the two polar forms there exists a wide spectrum of manifestations [11, 13].

Of several classifications that have been formulated over the years, two are widely accepted: the Ridley–Jopling classification and the operational classification proposed by the WHO.

The WHO classification [5, 10, 12, 13] is very simple and divides hanseniasis patients into two groups according with the number of skin lesions: paucibacillary (PB) and multibacillary (MB) (see Box 5.1).

- **Paucibacillary** (**PB**): one to five skin lesions;
- **Multibacillary** (**MB**): six or more skin lesions.

The WHO classification system is used in the field for choosing an appropriate treatment regimen. This is particularly useful when reliable facilities for skin smear examination are not available.

> **Box 5.1 Important note**
> If bacteriologic examination of skin smear shows a positive result then the patients are grouped into MB leprosy, irrespective of lesser number of skin lesions.
>
> In doubt, patients should be classified as Multibacillary.

The Ridley–Jopling classification is based on the immunity of the patient, which is reflected in the clinical, histopathologic, and bacteriologic changes. Under this classification there are two polar groups, tuberculoid and virchowian, and a spectrum of manifestation with three immunologically unstable groups: dimorphous tuberculoid, dimorphous dimorphous, and dimorphous virchowian. The earliest manifestation of the disease is termed indeterminate, characterized by a minimal clinical response to the infection, no clearly defined immune status, and sparse bacteriologic and histopathologic findings. For these reasons it offers the greatest difficulty in arriving at a diagnosis [10–12].

Indeterminate Hanseniasis

Indeterminate hanseniasis (IH) clinically manifests as one or a few hypopigmented macules with vague margins and a few centimeters in diameter. In fair skin hypopigmentation may not be clearly evident, but there may be erythema (Figs. 5.5 and 5.6). There may be sensory loss of temperature discrimination or ability to feel light touch [11, 12]. The lesions appear to be dry and

Fig. 5.5 Indeterminate hanseniasis on the extensor surface of the arm

Fig. 5.6 Indeterminate hanseniasis on the lateral surface of the leg

are usually present on the extensor surface of the extremities, buttocks, or face, which are colder body areas, although they can occur anywhere in the body [11]. The peripheral nerves trunks are normal [10].

Indeterminate hanseniasis should be self-limited or may progress to other forms of the disease [10]. However, the importance of identifying the disease at this early stage cannot be overemphasized [11]. Sometimes it is difficult to diagnose indeterminate hanseniasis with certainty and in such circumstances the patients should be examined at 3- to 6-monthly intervals to assess the progress of the lesions [10].

Skin smears are almost always negative. Histologic examination of the skin shows no significant change in the epidermis, and there is minimal inflammation in the dermis with focal collections of lymphocytes and histiocytes aggregated around blood, dermal nerves, sweat glands, and other skin annexes [11].

Tuberculoid Hanseniasis

This form occurs in individuals with high, but not complete resistance against *M. leprae*. Symptoms may be cutaneous, neural, or both. The skin lesion of tuberculoid hanseniasis is usually single, but there may be two or three asymmetrically distributed well-demarcated plaques or flat-patch lesions, seldom over 10 cm in diameter [10–12]. These characteristics of well-defined lesions, limited diameter, and sparseness occur because of the cell-immunologic response against *M. leprae*, which is an obligate intracellular bacillus.

Tuberculoid lesions may be hypopigmented, reddish or brownish lesions with well-defined margins. They are usually oval or rounded in shape and are well demarcated from the normal surrounding skin by a distinct edge [10]. The lesions are dry and tend to be hairless [11, 12]. The lesions occur on cooler areas of the body rather than warmer areas such as the scalp, axillae, groin, or perineum [12].

Sensation is markedly impaired or lost in tuberculoid lesions. Well-defined edges and sensory loss of feeling for temperature, pain, or

Fig. 5.7 Tuberculoid hanseniasis: demarcated plaques
touch are characteristic features of tuberculoid hanseniasis [10]. Temperature discrimination may be the first sensory modality lost [12]. About 30% of nerves have to be destroyed before sensory impairment can be detected; therefore, pain may be the first neurologic symptom. Often an enlarged nerve is palpable near the skin lesion. For example, if there is a skin lesion near the elbow the ulnar nerve may be enlarged [12].

Skin smears are negative for acid-fast bacilli. Histologic examination of the skin shows atrophy of the epidermis and some areas of minimal hyperplasia. There are discrete and confluent tuberculoid granulomas in the dermis, sometimes with Langhans giant cells present [11, 12] (Fig. 5.7).

Virchowian Hanseniasis

Virchowian hanseniasis occurs in those persons who possess virtually no resistance to infection by *M. leprae*. The bacilli multiply and spread to affect almost the entire skin, all the dermal and subcutaneously placed peripheral nerves, as well as the mucous membrane of the upper respiratory tract, anterior aspect of the eyes, lymph nodes, liver, spleen, bone marrow, testes, and adrenal glands [11]. It is usually a generalized disease [10].

The skin lesions are disseminated and are classified as macular, finely infiltrated, grossly infiltrated, and nodular [11]. Diffuse dermal infiltration is always present and can be nodular or non-nodular. Findings can include small hypopigmented macules, symmetrically distributed all over the body, or virchowian infiltrates that can be diffuse, plaque-like, or nodular. Macules are ill defined and show no sensory loss [10, 12], with poorly defined margins [10, 12]. Sweating is eventually lost. Hair loss starts over the lateral third of the eyebrow [10, 12] and then may involve the eyelashes (madarosis) and the body, but scalp hair is preserved [12].

Infiltrated virchowian hanseniasis is the stage that succeeds the macular form. The infiltrate plaques are glossy, soft, and slope toward the periphery. Sensory loss is slight or negligible in the infiltrated areas [10].

Nodular lesions, or hansenomas, are present in still more advanced forms of virchowian hanseniasis. These lesions are due to marked aggregation of the infiltrate and may be of the normal skin color, erythematous, or copper-colored. They may be small or large, soft or hard, and sessile or pedunculated [10]. Nodular infiltration can be seen on acral parts: earlobes, nose, chin, elbows, hands, buttocks, and knees. These nodules can enlarge and destroy underlying structures such as nasal cartilage, causing a saddle-nose deformity, and erode the alveolar ridge, leading to loss of teeth. Epistaxis is a common early finding. Leonine facial nodular infiltration can be seen in advanced disease [12].

Sensory loss tends to be symmetric over the distal limbs, starting in a glove-and-stocking distribution.

It is important to emphasize that as virchowian hanseniasis is a systemic disease, the involvement of other organs usually occurs. Bone

involvement can contribute to osteoporosis and fractures. Testicular involvement can result in gynecomastia and testicular atrophy with complaints of impotence and infertility [12]. Other complications include neuritis, laryngitis, arthritis, and iridocyclitis [11].

Skin smears are always positive (5+ to 6+) for acid-fast bacilli. Skin histology shows flattening of the epidermis with a clear Grenz zone, with a deeper diffuse foamy histiocytic infiltrate with few lymphocytes and plasma cells. The foamy appearance is a result of lipids in the *M. leprae* walls, and a Ziehl–Neelsen stain shows numerous acid-fast bacilli in globi or lying freely within the dermis [12] (Fig. 5.8).

There are two special forms of virchowian hanseniasis: Lucio hanseniasis and histoid hanseniasis. *Lucio hanseniasis* is characterized by a diffuse widespread infiltration of the skin with no formation of nodules, loss of body hair, loss of eyebrows and eyelashes, and widespread sensory loss. The skin contains numerous bacilli. This form is due to the total lack of host resistance and is rare outside Mexico and Central America. In older patients diffuse dermal infiltration may smooth out the wrinkles on the face, resulting in a youthful appearance, sometimes called "pretty leprosy" [10]. *Histoid hanseniasis* is characterized by the formation of firm, erythematous or copper-colored, glistening nodules and/or plaques in the skin of multibacillary patients who have discontinued their treatment or because bacilli have become drug resistant [10].

Dimorphous Hanseniasis

Dimorphous hanseniasis is the most commonly encountered type of the disease [10]. In this form the host immunity floats/varies, and manifestations of tuberculoid and virchowian hanseniasis can be found in the same patients. According to the extent of immunity, this group may be subdivided into dimorphous-tuberculoid, dimorphous-dimorphous, and dimorphous-virchowian.

Dimorphous hanseniasis lesions may be erythematous or copper-colored infiltrated patches, raised in the center (dome-shaped) and sloping toward the periphery, presenting an inverted saucer appearance (Fig. 5.9). Skin lesions of dimorphous hanseniasis usually have asymmetric distribution. Depending on the patients' position in the immunologic spectrum, the macular and other lesions vary greatly in number, size, and shape. The nearer the patient is to the virchowian end of the spectrum, the more numerous, shinier, less well defined, and less anesthetic they are. The nearer the patient is to the tuberculoid spectrum, the fewer are the lesions found and the more defined is the lesion margin [10].

Fig. 5.8 Virchowian hanseniasis: nodular lesions

Fig. 5.9 Dimorphous hanseniasis: infiltrated patches

The damage to nerves is widespread and frequently leads to crippling deformities. It is in this type of Hanseniasis that the most extensive and serious effects of nerve damage are seen [10].

Diagnosis

The diagnosis of hanseniasis is clinical, based on a good anamnesia and physical examination of the skin and nerve trunks. Some laboratory tests help and complement the clinical examination, but they do cannot make the diagnosis alone (see Box 5.2).

Laboratory tests (histopathology, slit skin smear, and serology), when available, may be used to help in the correct classification of these patients, especially in referral centers. However, they are not available in most health centers [14].

Approximately 70% of hanseniasis patients can be diagnosed by the single sign of skin patches with sensory loss, and the recognition of this sign should be taught as widely as possible. However, 30% of patients, including many multibacillary patients, do not present with this sign. Enlargement of one or more nerves is an important additional sign, to be supplemented by skin smears, if available and of assured quality [15].

Box 5.2 Important note
The accurate diagnosis of hanseniasis is of fundamental importance to all aspects of its epidemiology, case management, and prevention of disability. Underdiagnosis will allow continued transmission of the disease and much needless individual suffering, whereas overdiagnosis will involve overtreatment with antibiotics and unnecessary stress and stigma for some people [16].

Clinical Examination

After taking the patient's case history with regard to complaints, past treatment, places of residence, contact with other hanseniasis patients, and so forth, the entire body should be examined under adequate lighting. The examiner should look for hypopigmented areas, erythematous or copper-colored macules, infiltration, and nodules. Sensory loss is present in the majority of hanseniasis patients and often occurs in the following order: temperature → pain → touch [10].

The sensitivity screening test should be done by testing the suspected area compared with normal

skin area after correct explanation thereof to the patient (see Box 5.3). After the patient is made familiar with the test procedure it should be carried out with the patient's eyes fully closed. The diagnosis of paucibacillary forms and especially of tuberculoid hanseniasis depends on this simple procedure [10].

Box 5.3 Important note

The presence of one or more chronic skin lesions associated with anesthesia or hypoesthesia should suggest hanseniasis.

Nerve Examination

The nerves usually affected by *M. leprae* should be palpated for size, consistency, and tenderness. The nerve trunks to be examined are great auricular, supraorbital, radial, ulnar, median, lateral popliteal, and posterior tibial (Fig. 5.10). The affected nerve may be thickened and may show abscess formation. In a reactional state, the nerve will be spontaneously painful or tender to palpation.

Fig. 5.10 Enlargement of the great auricular nerve

General Examination Looking for Complications

As part of a general examination, it is important to be alert for evidence of complications of hanseniasis at the moment of diagnosis [17]. If the complications are present they should be treated with multidrug therapy (MDT).

While examining the head special attention should be paid to the eyes and the mucous of the nose and oropharynx. As part of the eye examination the clinician must look for madarosis or loss of eyebrows and eyelashes, lagophthalmos, inverted lashes of entropion, redness of conjunctivitis, and haziness of opacity of the cornea. At the nose one should look for collapsed nose, crusting, and epistaxis, and in the mouth for infiltration, nodules, or ulceration, especially on the palate.

During examination of the trunk one should check for gynecomastia, which arises secondary to orchitis and atrophy of the testes.

Complications of hanseniasis are common in the extremities as a result of nerve damage. There may be paralysis and atrophy of intrinsic muscles of the hands and feet with clawing. Because of the anesthesia, injury to hands and feet goes unrecognized by the patient, and trauma from any cause can result in ulceration.

Complementary Examinations

See Box 5.4.

Bacilloscopy

Bacilloscopy or skin smears should be taken from all patients suspected of having hanseniasis, but only in the multibacillary group (virchowian and dimorphous hanseniasis) will it be positive. Therefore, a negative result does not exclude a diagnosis of hanseniasis.

Before taking the smear, the lesion must be cleaned with alcohol or ether. The smear should be taken from the most active-looking part of the lesion. The site of the smear should be gripped between the thumb and forefinger to press out the blood. With a sterile small-bladed scalpel an inci-

sion 2–3 mm deep is made in the skin of the patient. The blade is then turned until it is at right angles to the incision and the wound is scraped firmly two or three times in the same direction so that a drop of dermal tissue collects on its tip. This drop of tissue fluid and pulp is gently smeared over a circular area on a glass slide. Skin smears should not contain blood because blood can interfere with the Ziehl–Neelsen method of staining [10].

After staining the smears are read. For this purpose the Bacteriologic Index is used, which indicates the density of Hansen's bacilli in smears and includes both solid-staining and fragmented or granular bacilli. According to Ridley's logarithmic scale, this ranges from zero (no bacilli) to 6+ (more than 1,000 bacilli on average and presence of globi). This scale is based on the number of bacilli seen in an average microscopic field of smear using an oil-immersion objective [10].

Slit skin smear is the test usually performed to confirm the operational diagnosis of leprosy. This helps to distinguish between paucibacillary and multibacillary hanseniasis. However, the test requires trained personnel for sample collection and reading, and is relatively invasive [14].

Skin Biopsy

Skin biopsy for histopathologic evaluation should be used as complementary examination for diagnosis and classification of hanseniasis. The characteristic histologic findings are as follows [10, 11].

Indeterminate hanseniasis: A diagnostic problem both for the clinician and the pathologist because the clinical picture is vague and the pathologic changes are nonspecific. The epidermis is normal. In the dermis there are small clusters of mononuclear cells (mainly lymphocytes and a few histiocytes) around blood vessels, nerves, and dermal appendages, with selective involvement of the neurovascular bundles. Usually there is no granuloma (Fig. 5.11).
Fig. 5.11 Histopathology of indeterminate hanseniasis: perineural and perivascular lymphocytic infiltrate

Tuberculoid hanseniasis: Typical tubercles comprising epithelioid cells, Langhans giant cells, and surrounding zone of lymphocytes are found in the dermis. The granuloma may extend into and erode the basal layer of the epidermis. Cutaneous nerves are infiltrated and often destroyed (Fig. 5.12).

Virchowian hanseniasis: The epidermis shows thinning and flattening of rete ridges. The characteristic histologic finding is a diffuse, highly baciliferous granuloma in the dermis. The granuloma mainly consists of macrophage cells that fail to differentiate into epithelioid cells. Instead they become mere sacs containing multiplying Hansen's bacilli. Lymphocytes are absent or scant and there is no attempt to surround macrophages. In the late stages, the cytoplasm of macrophages undergoes fatty changes, resulting in the formation of Virchow's foamy cells (Fig. 5.13).

Fig. 5.12 Histopathology of tuberculoid hanseniasis: tuberculoid granuloma
Fig. 5.13 Histopathology of virchowian hanseniasis
Fig. 5.14 Histopathology of dimorphous hanseniasis: lymphohystiocytic, superficial, and deep infiltration with giant cells (H&E). Negative BAAR (Z-N)
Dimorphous hanseniasis: As this group is inherently unstable in accordance with the immunologic response of the host against the *M. leprae*, the findings at the histologic examination are also unstable. Sometimes tuberculoid hanseniasis is brought to mind while on other occasions characteristics of virchowian hanseniasis are observed (Fig. 5.14).

ML Flow

In 2003 a method called ML Flow, an alternative to ELISA (serology) for detection of anti-PGL-1 immunoglobulin M antibodies (IgM), was described by Bührer Sékula et al. Rather than a method for diagnosis, this is an examination to classify patients as paucibacillary or multibacillary and to help decide on their therapy. It does not appear to cross-react with other mycobacterioses [14].

Pilocarpine

Testing with pilocarpine nitrate may help in the diagnosis of non-virchowian cases of hanseniasis, especially for patients in whom sensory impairment cannot be definitively determined. The use of this substance causes sweating in intact skin; in skin affected by leprosy, sweat production does not occur [10].

According to the WHO, hanseniasis should be suspected in individuals with any of the following symptoms or signs [13]:

- Pale or reddish patches on the skin
- Loss or decrease of feeling in the skin patch
- Numbness or tingling of the hands and feet
- Weakness of the hands, feet or eyelids
- Painful or tender nerves
- Swelling or lumps in the face or ear lobes
- Painless wounds or burns in the hands or feet

According to the International Leprosy Association, three cardinal signs remain the basis for the clinical diagnosis of hanseniasis [16]:

- Anesthetic skin lesions
- Enlarged peripheral nerves
- Acid-fast bacilli in the skin smear

Any one of these signs has been regarded as sufficient for the diagnosis of hanseniasis, so that sensitivity is high.

Uncomplicatedly, WHO recommends that hanseniasis diagnosis is confirmed when at least one of the following cardinal signs is present [13]:

- Definite loss of sensation in a pale or reddish skin patch
- A thickened peripheral nerve with loss of sensation and/or weakness of the muscles supplied by that nerve
- Presence of acid-fast bacilli in a slit skin smear

Differential Diagnosis

According to different authors hanseniasis may be confused with other dermatoses [10–12]. Cutaneous lesions of hanseniasis clinically mimic many common and some uncommon skin diseases. A careful clinical examination, especially to detect impairment of sensation over the lesions, is important for the diagnosis of hanseniasis lesions.

Dermatologic diseases that clinically resemble Hanseniasis are listed below.

Indeterminate hanseniasis: *Pityriasis alba*, *Pityriasis versicolor*, postinflammatory hypopigmentation, hypopigmented (early) vitiligo, seborrheic dermatitis, nutritional hypopigmentation, occupational leukoderma, and birth marks (*Naevus anaemicus* or *achromicus*)

Tubeculoid hanseniasis: *Lupus vulgaris*, *Tinea circinata*, tertiary syphilis, sarcoidosis, tuberculoid, granuloma annulare, necrobiosis lipoidica, erythema annulare centrifugum, granuloma multiforme, psoriasis vulgaris, discoid lupus erythematosus, and ptyriasis rosea

Virchowian hanseniasis: neurofibromatosis, multiple lipomatosis, keloids, lymphoma, mycosis fungoides, molluscum contagiosum, and leishmaniasis

Dimorphous hanseniasis: mycosis fungoides, pharmacodermias, and lymphoma

Treatment

Treatment for patients affected by hanseniasis consists of drugs (antibiotics), moisturizers, sunscreen, guidance for self-care, emotional support, and health education (see Box 5.5) [18–20].

Box 5.5 Important note
When a patient has completed his course of treatment, 6 blisters for the paucibacillary group and 12 blisters for the multibacillary group, he is considered to be cured and treatment is therefore stopped, regardless of the presence of residual lesions or disabilities and deformities.

The first successful drug used for the treatment of hanseniasis was dapsone at a leprosarium in Carville, Louisiana, USA in 1943, and for many years it was used as a monotherapy. It inhibits acid folic synthesis by competitive inhibition and is bacteriostatic. Clofazimine was first used for hanseniasis treatment in 1962 and its mechanism of action, though still not elucidated, is also bactericidal and anti-inflammatory. Rifampicin is currently a key bactericidal antibiotic and has been used since the 1970s [21, 22].

Prior to the advent of MDT these three drugs (dapsone, rifampicin, and clofazimine) were administered alone, although rifampicin had been used in combination with dapsone. Gradually, clinical and experimental evidence of resistance to dapsone and rifampicin came to light [23–26]. Dapsone is still a fundamental agent against *M. leprae* even in the MDT era, despite reports of resistance in 1953, less than 10 years from the beginning of its use. Although clofazimine has been used for over five decades, reported drug resistance is rare [22, 27]. Issues relating to drug resistance are so important that sentinel surveillance for drug resistance in hanseniasis by the Global Leprosy Program was launched in 2006 [28].

The situation surrounding drug resistance prompted the WHO to recommend therapeutic regimens involving two or three of these drugs. This MDT, as it is known today, was first proposed by the WHO in 1982 [10, 22, 29] and involves a combination of drugs that are safe and effective in treating hanseniasis and preventing the emergence of drug resistance [21, 27, 30].
MDT Regimens

Each blister pack contains treatment for 4 weeks.

It is crucial that patients understand which drugs they have to take once a month and which every day.

PB adult treatment:
Once a month: Day 1
– 2 capsules of rifampicin (300 mg x 2)
– 1 tablet of dapsone (100 mg)
Once a day: Days 2–28
– 1 tablet of dapsone (100 mg)
**Full course:** 6 blister packs

PB adult blister pack

PB child treatment (10–14 years):
Once a month: Day 1
– 2 capsules of rifampicin
  (300 mg+150 mg)
– 1 tablet of dapsone (50 mg)
Once a day: Day 2–28
– 1 tablet of dapsone (50 mg)

Full course: 6 blister packs

PB child blister pack

For children younger than 10, the dose must be adjusted according to body weight.

MB adult treatment:
Once a month: Day 1
– 2 capsules of rifampicin (300 mg x 2)
– 3 capsules of clofazimine (100 mg x 3)
– 1 tablet of dapsone (100 mg)
Once a day: Day 2–28
– 1 capsule of clofazimine (50 mg)
– 1 tablet of dapsone (100 mg)
Full course: 12 blister packs

MB adult blister pack

MB child treatment (10–14 years):
Once a month: Day 1
– 2 capsules of rifampicin (300 mg+150 mg)
– 3 capsules of clofazimine (50 mg x 3)
– 1 tablet of dapsone (50 mg)
Once a day: Day 2–28
– 1 capsule of clofazimine every other day
  (50 mg)
– 1 tablet of dapsone (50 mg)

Full course: 12 blister packs

MB child blister pack

For children younger than 10, the dose must be adjusted according to body weight.

Fig. 5.15 Blisters of standard multidrug therapy (MDT). Regimen treatments for adults (*green* and *pink* blisters) and children ages 10–14 (*blue* and *orange* blisters) (Source: http://www.searo.who.int/entity/global_leprosy_programme/en/)

Under no circumstances should hanseniasis be treated by a single drug [31, 32].

MDT is provided in convenient packs covering a month of treatment, is available free of charge to all who need it, and the drugs are all taken by mouth. There are different packs with the same drugs, but in smaller doses, for children.

The standard MDT (rifampicin, dapsone, clofazimine) can be used in special cases such as women and their babies during pregnancy and breast-feeding, children, HIV-positive patients on anti-retroviral treatment, and patients being treated for tuberculosis. If a patient with hanseniasis is treated for tuberculosis, the MDT regimen should omit rifampicin as long as the tuberculosis regimen contains rifampicin.

MDT treatment is provided in specific blister packs and is available for multibacillary and paucibacillary hanseniasis as well for adults and children (Fig. 5.15) [10, 31, 32]. The standard treatment regimen for multibacillary and paucibacillary hanseniasis is shown in Table 5.1:

For children under 10 years of age the appropriate dose can be decided on the basis of body

Table 5.1 Standard multidrug therapy (MDT) regimen treatment for adults and children (ages 10–14)

MDT-PB treatment regimen for adult	
Rifampicin	600 mg once a month
Dapsone	100 mg once a month and 100 mg daily
	Duration: 6 blister packs
MDT-MB treatment regimen for adult	
Rifampicin	600 mg once a month
Dapsone	100 mg once a month and 100 mg daily
Clofazimine	300 mg once a month and 50 mg daily
	Duration: 12 blister packs
MDT-PB treatment regimen for child	(age 10–14)
Rifampicin	450 mg once a month
Dapsone	50 mg once a month and 50 mg daily
	Duration: 6 blister packs
MDT-MB treatment regimen for child	(age 10–14)
Rifampicin	450 mg once a month
Dapsone	50 mg once a month and 50 mg daily
Clofazimine	150 mg once a month and 50 mg every other day
	Duration: 12 blister packs

Adapted from WHO, 2009 [32]

weight. The standard child blister pack may be broken up so that the appropriate dose is given to children younger than 10 years (Table 5.2).

Sometimes it will be necessary to treat a patient with a high bacillary index with additional 12-blister packs. However, this decision may only be taken by specialists at referral units after consideration of the clinical and bacteriologic evidence [31, 32].

Despite standard MDT being safe and serious adverse effects being rare, they may occur. The most common adverse effects are listed in Table 5.3.

If one or more of the standard drugs must be stopped, other drugs are available such as ofloxacin [33], minocilin, and clarithromycin, but these must be managed by a specialist. In the case of ofloxacin, some drug resistance has been reported [34–36]. All of these drugs have bactericidal activity (see Box 5.6).

Hanseniasis is curable with MDT recommended by the WHO since 1982. However, it is fundamental to lend emotional support to the patients, who should be treated with respect,

> **Box 5.6 Important note**
> Rifampicin is an exceptionally potent bactericidal agent against *M. leprae*. A single dose of 600 mg is capable of killing more than 99.9% of viable organisms.
>
> Because of the risk of drug resistance, under no circumstances should hanseniasis be treated by a single drug.

patience, and understanding. Besides medical treatment, they need support and reassurance from family, friends, and health workers to help them achieve self-esteem and self-respect and to lead a normal life [10, 18, 19].

MDT treatment works slowly and may not, on its own, cure anesthesia, claw hand, or ulcers. In patients who do not understand the limitations of the antibiotics they may be discouraged, stop treatment too soon, and relapse. Health education is therefore an essential part of the hanseniasis treatment. The things the patient must know are known as the "six D's of health education" [20]:

1. **D**uration: how long he will need to take his treatment
2. **D**rugs: tablets and capsules are used for curing Hanseniasis
3. **D**isappearing skin patches: the skin patches never disappear quickly

Table 5.2 Doses of MDT drugs for children under 10 years age

Rifampicin	10 mg per kilogram body weight
Dapsone	2 mg per kilogram body weight daily and monthly
Clofazimine	1 mg per kilogram body weight daily
	6 mg per kilogram body weight monthly

Adapted from WHO, 2009 [32]

Table 5.3 Adverse effects of standard MDT drugs

Drug	Adverse effects	Management
Rifampicin (RFM)	Red urine	Orientation/counseling
	Jaundice	Stop RFM
	Flu-like syndrome (shock, purpura, renal failure)	Stop RFM
	Gastro-intestinal upset	Give DDS with food
Dapsone (DDS)	Anemia	Give iron and folic acid
	Jaundice	Stop DDS
	Rash, urticaria, allergy	Stop DDS
	Gastro-intestinal upset	Give DDS with food
Clofazimine (CFZ)	Xerosis	Moisturizer/counseling
	Hyperpigmentation and brown discoloration of skin	Sunscreen/counseling

Adapted from WHO, 2009 [32]

4. **D**isability: deformity and impaired sensation which are present at the start of treatment often improve but may not recover completely even when the disease is fully cured
5. **D**iet: no diet restrictions are necessary to use dapsone, clofazimine, and rifampicin
6. **D**angers: patients should be warmed of the symptoms or reaction and advised to come for an extra anti-reaction treatment if necessary

Reactions and Its Management

During the usually chronic course of hanseniasis, acute inflammatory episodes (called reactions) may occur. These immunologic reactions are an important aspect of hanseniasis that significantly affects the course of the disease and the associated disability. It is important to remember that the impairment of nerve function occurs throughout the infectious disease course but also occurs through immunologic reactions that often rapidly accelerate the nerve damage [37].

Any type of hanseniasis, except an early indeterminate form, may undergo a sudden inflammatory phase of exacerbation. Reactions are more common in patients with multibacillary hanseniasis (virchowian and dimorphous categories) [10].

Reactions may occur spontaneously or may be precipitated by intercurrent infections, anemia, mental or physical stress, inflammatory processes, puberty, pregnancy, parturition, vaccinations, or surgical interventions. Some drugs such as vitamin A, progesterone, bromides, and iodides also may precipitate reactions [10, 12], although in some cases precipitating factors may not be obvious [10]. The reactions may occur before, during, or after treatment with MDT [37].

There are two main types of reaction that affect 30%–50% of patients: type 1 reaction (reversal reaction) and type 2 reaction (erythema nodosum hansenic) [10, 37]. To Worobec [12], at least 50% and possibly a much higher percentage of dimorphous patients will experience reactional states after initiating MDT. According to Kamath et al. [37], the third reaction (Lucio phenomenon) is relatively rare, occurring only in a diffuse non-nodular virchowian hanseniasis (lepra bonita). However, the manifestations can be dramatic, with patients developing widespread skin necrosis.

These reactions are often incorrectly viewed as complications or adverse effects of MDT and are also confused, sometimes, with relapses.

Regardless of the type of reactions or when they occur, any reaction is a medical emergency, greatly increasing hanseniasis-related morbidity. It is important to specifically recognize and treat reactions to reduce the burden of disability in hanseniasis [37].

Type 1 or Reversal Reaction

Reversal reactions most commonly occur in dimorphous forms of hanseniasis (dimorphous tuberculoid, dimorphous dimorphous, and dimorphous virchowian) [37], an may also occur in tuberculoid hanseniasis [10]. This reaction is an example of the type IV hypersensitivity (allergic) reaction of Coombs and Gell [10] and is the result of increasing (upgrading) cell-mediated immune response or decreasing (downgrading) cell-mediated immune response to *M. leprae* [12].

Clinically, patients display abrupt inflammatory changes of the skin, nerves, or both. Existing skin lesions become erythematous and edematous and resemble erysipelas. In severe cases necrosis and ulcerations may occur [10]. Associated signs include erythema and edema of hands, feet, and face (Fig. 5.16), silent neuritis, pain or tenderness of nerves, and new erythematous and edematous papules, plaques, and nodules [12]. Accompanying edema of the hands and feet is common, whereas systemic symptoms are unusual.

Fig. 5.16 Type 1 reaction

Reversal reaction is the leading cause of nerve damage in hanseniasis and may lead to permanent disability. Spontaneous nerve pain, weakness, or paresthesia signals neuritis, whereas nerve function impairment is defined as clinically detectable reduced motor and sensory function. The ulnar, median, radial, common peroneal, posterior tibial, and facial nerves are most commonly involved, leading to wrist drop, foot drop, and facial palsy. Sometimes patients can lose protective pain sensation, increasing their vulnerability to injury [37].

Type 2 or Erythema Nodosum Hansenic (ENH)

This reaction involves humoral hypersensitivity and is an example of type III hypersensitivity (allergic) of Coombs and Gell. It is mediated by circulating immune complexes [12] and is not associated with alteration in cell-mediated immunity. It was originally described by Murata in Japan in 1912 [10].

ENH presents clinically as eruptive painful erythematous nodules (Fig. 5.17) and plaques over the entire body along and with systemic symptoms: fever, malaise, anorexia, pain, and joint swelling. The nodules, in severe reaction, may develop bullae, pustules, or necrosis [12]. Eventually fibrosis, scarring, and post-inflammatory hyperpigmentation develop [37]. Unlike erythema nodosum, which has a predilection for the shins, ENH may surface on extensor surfaces of both upper and lower extremities as well as on the face and trunk [37].

Severe ENH has systemic symptoms of fever and malaise and can manifest arthritis, dactylitis, uveitis, iridocyclitis, episcleritis, neuritis, lymphadenitis, myositis, adenitis, epididymitis, and orchitis [12]. On presentation patients may have anemia, neutrophilic leukocytosis, albuminuria, painful lymphadenopathy, glomerulonephritis, and hepatosplenomegaly [37]. Periostitis, especially over the tibia, may be detected on bone. Arthralgias and dactylitis may result and be confused with rheumatologic disease such as lupus erythematosus or seronegative rheumatoid arthritis [12, 37].

Fig. 5.17 Type 2 reaction (ENH)

Treatment of Reactions

The key to successful management of hanseniasis reaction is correct and early diagnosis and the timely initiation of anti-inflammatory measures (see Box 5.7). It is also important to remove the possible precipitating factors, and MDT should be continued at full dosage if the patient is receiving it. The most important

Box 5.7 Important note
Reactions dramatically worsen the clinical course of hanseniasis. They can occur before, during, or after MDT and can cause serious nerve impairment. They may constitute a medical emergency.

These reactions are often incorrectly viewed as adverse effects of MDT and are also confused with relapses.

goal of managing reactions includes preventing nerve function impairment.

Type 1 Reaction

- Prednisone 1 mg/kg/day provides rapid symptomatic relief and helps reverse nerve function impairment [5, 10, 12]. Symptoms should be reassessed every 2 weeks. If nerve function improves, the dose can be reduced by 5–10 mg. If there is no improvement or worsening of nerve function, the dose should be increased. Treatment may last up to 6 months or even years for those with neuritis. It is also possible to use prednisolone [4, 37], dexamethasone [5], or pulse therapy with methylprednisolone [5].

Long-term corticosteroid use carries the risk of adverse effects: hypertension, diabetes, osteoporosis, peptic ulcer, hematemesis, edema due to sodium retention, hypokalemia, moon face, and striae [10]. In Brazil there is a recommendation to treat *Strongyloides stercoralis* with thiabendazole or albendazole and to prevent osteoporosis by using calcium, vitamin D, and bisphosphonates [5].

- Other therapies include azathioprine (3 mg/kg/day) [12, 37], cyclosporine (5–10 mg/kg/day) [12, 37], methotrexate [12, 37], and mycophenolate mofetil [12]. In Brazil there is no guideline for the use of these drugs.

Type 2 Reaction

- Thalidomide 100–400 mg daily, depending on the severity of the ENH.

ENH is very responsive to thalidomide, which is available in Brazil [5] and the United States [12, 37]. Because of the well-known teratogenic side effects, the WHO does not support the use of thalidomide for the management of ENH in hanseniasis.

Thalidomide was first used for ENH in 1965, by Sheskin, in Israel, with excellent response against the reaction in the first 48–72 h [38]. In Brazil this drug was first used by Sampaio and Proença in the same year, and in 1971 the WHO published a bulletin confirming the efficacy of thalidomide in the management of hanseniasis-related EN [38].

Adverse effects of thalidomide include teratogenicity, sedation, peripheral neuropathy, dizziness, orthostatic hypotension, neutropenia, and hypersensitivity reactions. Male patients using thalidomide can excrete it in semen and must use a latex condom when having sexual contact with a woman of childbearing potential, and should not donate sperm [12].

- Prednisone 1 mg/kg/day is also effective and provides rapid relief when thalidomide is unavailable or cannot be used [5, 12, 37, 39]. It should be used together with thalidomide in severe ENH with the following manifestations: arthritis, dactylitis, uveitis, iridocyclitis, episcleritis, neuritis, lymphadenitis, myositis, adenitis, vasculitis, epididymitis, and orchitis.
- Pentoxifylline 400–1,200 mg/daily used alone or in combination with prednisolone for mild ENH [5, 39].
- Other treatments include nonsteroidal anti-inflammatory drugs, methotrexate, azathioprine [12, 37]. WHO guidelines for severe ENH suggest prednisolone, prednisolone and clofazimine, or only clofazimine (100–300 mg/daily) [39].

Relapse, Reactions, and Efficacy of MDT

The principal mode of assessing the efficacy of therapy for hanseniasis is the relapse rate, and there are wide variations in estimates of relapse rates after MDT in different regions [40]. The efficacy of MDT has been demonstrated by the extremely low relapse rate: 0.1% per year for paucibacillary hanseniasis and 0.06% per year for multibacillary hanseniasis. Moreover, clinical trials have established the efficacy of the individual drugs within MDT for the treatment of hanseniasis [41].

However, relapse can occur, the most important predisposing factors of which are presence of persister bacilli, monotherapy, inadequate or irregular therapy, and presence of multiple skin lesions and thickened nerves [40].

The conventional methods of confirming activity or relapse in an infectious disease (demonstration and culture of the etiologic agent) have limited utility in hanseniasis because of the difficulty in demonstrating bacilli in paucibacillary cases and absence of a method of in vitro cultivation of *M. leprae*. Bacteriologic parameters are useful in multibacillary hanseniasis, whereas in paucibacillary cases the criteria for relapse depend primarily on clinical features [40].

The most reliable criteria for making an accurate diagnosis of relapse include clinical, bacteriologic, and therapeutic criteria [41]. Relapse in multibacillary hanseniasis is defined as the multiplication of *M. leprae*, suggested by the marked increase (at least >twofold over the previous value) in the Bacteriologic Index at any single site, usually with evidence of clinical deterioration (new skin patches or nodules and nerve damage). This can be confirmed in most cases by clinical findings and the growth of *M. leprae* in the mouse footpad system [41].

Recognition of relapse in paucibacillary hanseniasis is somewhat difficult, as it is difficult to distinguish it from a reaction. In theory, a therapeutic test with corticosteroids may be able to distinguish between these two phenomena: definite improvement within 4 weeks of corticosteroid therapy denoting reaction, and nonresponse to corticosteroids during the same period favoring the diagnosis of clinical relapse. Definite evidence of clinical deterioration (new skin patches and/or new nerve damage) is sufficient to classify it as relapse in a paucibacillary case [41].

The main differential diagnoses for relapse are reversal reactions, ENH, and a specific group under increasing study that includes reactivation, resistance, and reinfection by *M. leprae* [40] (see Box 5.8).

> **Box 5.8 Important note**
> It is important to recognize and differentiate relapse from hansenic reaction because the therapeutics are different. Reactions are treated with anti-inflammatory drugs. Relapsed cases should be put back on MDT as soon as possible to prevent further disability and transmission of infection.

Systemic Involvement in Hanseniasis

Although the major manifestations of hanseniasis are seen in the skin and peripheral nerves, there are several other organs in the body that are invaded and affected by Hansen's bacilli (when the disease progress) and the immunologic changes (hansenic reactions) caused by its antigens (see Box 5.9).

In some organs the lesions are so severe that the functions of these organs are adversely affected. In most others, however, the involvement is so minimal that they usually go unnoticed [11].

In all forms of hanseniasis, bacteremia is present at some stage of the disease. In well-established multibacillary disease, while using MDT there is bacteremia, especially during the reactive phase. A number of *M. leprae* are sequestered in blood capillaries of various organs and, if they are lodged in a suitable environment, the disease process is initiated.

In the nose and upper respiratory tract, the anterior aspect of the eyes, testes, and lymph nodes with a temperature lower than that of the body, *M. leprae* proliferate to cause extensive and often severe lesions. Where the milieu is not suitable, the organisms evoke a mild reaction forming focal microgranulomas with no obvious organ dysfunction as happens in the liver, spleen, bone marrow, and adrenal glands. There are reports of finding occasional *M. leprae* in the endothelial cells of capillaries in the lungs, gastrointestinal system, and kidneys [11].

> **Box 5.9 Important note**
> The organs mainly involved are the nose, upper respiratory tract, mouth, tongue, palate, eyes, liver, spleen, lymph nodes, testes, kidneys, adrenal, bone, skeletal muscle, and breast in males.

Nerve Damage and Disabilities

If left untreated, hanseniasis can cause nerve damage, leading to muscle weakness and atrophy, and permanent physical disabilities and deformities appropriate to the disease [39]. Table 5.4

shows the WHO classification of deformities/disabilities in hanseniasis.

Currently there is no reliable information on the number of people affected at the global and country levels. It is estimated that globally there are around 2 million people with grade 2 disabilities attributed to Hanseniasis. Between 25,000 and 50,000 new people develop hanseniasis-related disabilities every day. These numbers would be higher if grade 1 disabilities were also included [13]. According to Yawalkar [10], it is estimated that approximately 25% of the patients who are not treated at an early stage of the disease develop anesthesia or deformities of the hands and feet.

The peripheral nerves consist of sensory, motor, and autonomic nerve fibers, damage to which results in anesthesia (loss of sensation), muscle weakness or paralysis, and lack of sweat and sebum, causing dry skin [10]. Damage to sensory fibers may result in abrasions, blisters, ulcers, burns, corns, callouses, and hematomas, with or without secondary infection of these primary lesions. Damage to motor fibers of the peripheral nerves may result in weakness and paralysis of the muscles supplied by the nerve, producing deformities such as claw hand, wrist drop, foot drop, claw toes, mask face, and lagophthalmos [10].

The nerve damage in hanseniasis can occur by either direct bacterial invasion or inflammatory response that develops during leprosy reaction, and can affect peripheral nerves of the face, arms, and legs. The common nerves affected in hanseniasis are the ophthalmic branch of the trigeminal, and the facial, ulnar, median, radial, lateral popliteal, and posterior tibial. The nerves are affected in approximately the following order of frequency: ulnar, posterior tibial, lateral popliteal, median, facial, and radial [10].

The common sites of nerve damage are [10]:

- Ulnar nerve: at the elbow, above the medial epicondyle of the humerus
- Median nerve: above the wrist joint
- Radial nerve: above the elbow joint, in the radial groove
- Lateral popliteal nerve: at the neck if the fibula
- Posterior tibial nerve: near the medial malleolus of the tibia
- Facial nerve: above the zygomatic arch (Figs. 5.18, 5.19, 5.20, and 5.21)

Fig. 5.18 Facial nerve damage: lagophthalmos

Table 5.4 The 3-grade WHO classification of deformities/disabilities in hanseniasis

Grade	Hands and feet	Eyes
Grade 0	No anesthesia	No eye problem due to hanseniasis
	No visible deformity or damage	No evidence of visual impairment
Grade 1	Anesthesia present	Eye problems due to hanseniasis are present, vision 6/60 or better, patient can count fingers at 6 m
	No visible deformity or damage	
Grade 2	Visible deformity or damage present: muscle atrophy of hands and feet, foot drop, wrist drop, claw hand, clawing of the toes, collapse of foot arches and plantar ulcers	Severe visual impairment (vision less than 6/60, the patient is unable to count fingers at 6 m), lagophthalmos, iridocyclitis, and corneal opacities

Adapted from WHO [13]

Fig. 5.19 Ulnar nerve damage: ulnar claw hand

Fig. 5.20 Radial nerve damage: wrist drop

Fig. 5.21 Posterior tibial nerve damage: plantar ulcers

Prevention of disabilities begins with diagnosing hanseniasis sufficiently early, recognizing and treating reactions and neuritis, identifying patients at risk of developing secondary disabilities, and intervening in time [13].

Contacts in Hanseniasis

The contacts of hanseniasis patients are known to have a higher risk of illness than the general population [4, 13, 42, 43]. Some authors report that household contacts of multibacillary patients presented a fourfold greater risk of becoming infected with the disease compared with noncontacts [43]. Having a current case of hanseniasis in the family is associated with a 2.9-times greater risk of a healthy family member becoming infected, and the risk increases when the family has a history of the disease. Children are exposed to the highest risk of becoming infected by being

in contact with a family member or anyone close to them who has the disease [12, 43], while anyone in household contact with a person with untreated multibacillary disease in an endemic area carries a 10% risk of eventually becoming ill, with children being at greater risk.

Contact surveillance therefore is an important strategy to ensure the early diagnosis and the control of this disease [44], and the examination of household and family contacts at the time of diagnosis and annually is recommended [12, 13].

The monitoring of contacts aims at the discovery of new cases among those who live or have lived with the patient diagnosed with hanseniasis (index case). In addition, surveillance aims to discover their potential sources of infection in the household (family) or outside (social, professional), regardless of whether the operational classification of the patient is paucibacillary or multibacillary [5, 42].

Household contact is considered as any person residing or who has resided with the hanseniasis patient [5, 43]. Anyone who lives or has lived with family or relations of the hanseniasis patient, closely and prolonged, is considered a social contact. Social contacts, including neighbors, coworkers, and schoolmates, among others, should be investigated in accordance with the grade and lifestyle, as should those who have had very close and extended contact with the untreated patient. Special attention should be given to family contacts of patients (parents, siblings, grandparents, uncles, etc.) [3].

The epidemiologic investigation of contacts consists of [3]:

- Anamnesis for signs and symptoms of hanseniasis
- Dermatologic and neurologic examination of all contacts of new cases, independent of the operational classification
- BCG (Bacillus Calmette–Guérin) vaccination for healthy contacts without presence of signs and symptoms of hanseniasis at the time of evaluation, whether contacts are paucibacillary or multibacillary cases (Table 5.5, see Box 5.10).

More recent guidelines recommend chemoprophylaxis with a single dose of rifampicin for

> **Box 5.10 Important note**
> All contact hanseniasis patients should be informed that the BCG vaccine is not specific to hanseniasis.

Table 5.5 Immunoprophylaxis with BCG

No BCG scar	A dose
A BCG scar	A dose
Two scars BCG	Do not prescribe

Source: Brasil 2015 [42]

all identified contacts of an index case of hanseniasis. The chemoprophylaxis can be used as an additional intervention to reduce transmission of the disease. [6, 13, 42, 43].

The established treatment protocol consists of rifampicin 600 mg (2 tablets 300 mg) as a single dose [13, 42], to be administered in the second month of treatment of the index case (approximately 4 weeks after initiation of treatment of the index case). Children over 5 years of age are administered 450 mg rifampicin, and children or adults weighing less than 30 kg administered rifampicin 10–20 mg/kg [42].

Given the high risk of household contacts, it is important to examine the options available for preventing hanseniasis among contacts in some situations (see Box 5.11). Well-resourced programs and those detecting a significant number of new cases among household contacts may be able to consider immunoprophylaxis with BCG or chemoprophylaxis with a single dose of rifampicin for identified contacts. In addition, there is

> **Box 5.11 Important note**
> All household contacts of a new case of hanseniasis, regardless of whether paucibacillary or multibacillary, should be examined and followed for a period of 5 years after diagnosis of the index case.
>
> The surveillance of hanseniasis contacts is a priority action for control of the disease.

the question of ethics and confidentiality if some cases may not wish their diagnosis to be known to their contacts [13].

Glossary

ML Flow   Rapid test lateral flow to *M. leprae*. It is an immunochromatographic test strip comprising nitrocellulose with a detection reagent made of wool fiber with anti-human IgM antibody labeled with colloidal gold dried from one side, and an absorption strip on the other.

PGL-1 or phenolic glycolipid 1   The main antigenic glycolipid of Hansen's bacillus, the main antigenic determinant being the last part of di- and trisaccharide of the molecule. It is one of the first specific antigens isolated from *M. leprae*.

Ridley–Jopling classification   A classification of leprosy/hanseniasis for research purposes. This classification made by Ridley and Jopling was based on clinical, histologic, and immunologic differences in the disease, but they are continuous and compose a disease spectrum.

Tuberculosis

6

Josemir Belo dos Santos, Cláudia Elise Ferraz,
Matilde Campos Carrera Thouvenin,
and Vanessa Lucília Silveira de Medeiros

Key Points Summary

- Main factors involved in the increase of cases are HIV/AIDS, immunosuppressive drugs, multidrug resistance, and population migration
- Many types of clinical lesions are possible, such as inflammatory papules, verrucous plaques, suppurative nodules, and chronic ulcers
- The clinical presentation of the disease will depend on the route of infection, natural immune response, and the presence or absence of prior contact
- Endogenous cutaneous TB may occur by dissemination, contiguity, autoinoculation, lymphatic dissemination, and through hematogenous route. These include the scrofuloderma, orificial TB, lupus vulgaris, gumma TB, and acute miliary TB
- Tuberculids are hypersensitivity reactions to *M. tuberculosis* antigens, and include lichen scrofulosorum, papulonecrotic tuberculid, and erythema induratum of Bazin
- The classical tests include direct examination, culture, histopathology, and tuberculin skin test. New examinations include interferon-γ release assay (IGRA), polymerase chain reaction, and genotyping

Introduction

Tuberculosis (TB) has become an endemic disease in developing countries, and is at risk of also becoming a problem in developed countries. There is one death because of TB every 15 (more than two million/year), and eight million people

develop TB each year. Up to 60% of people with the disease will die without treatment. Essentially the majority of the cases are in the Third World, reflecting the poverty and the lack of healthy living conditions and appropriate medical care [1–4]. The main factors involved in the increase of cases are acquired immune deficiency syndrome (AIDS) due to infection by the human immunodeficiency virus (HIV), the increased use of immunosuppressive drugs, the emergence of multidrug-resistant *Mycobacterium tuberculosis* (MTB), and population migration [1, 5–7].

The cutaneous infection by MTB follows the increase of pulmonary TB. It is difficult to notice the increase because cutaneous TB (CTB) is not one of the most frequent extrapulmonary forms, occurring in 1–2% of infected patients. CTB can occur by direct introduction of the microorganism into the skin, by hematogenous spread from an endogenous focus, or even by contiguity. The pathogenicity of the agent, the immune status of the host, and the presence or absence of sensitization to MTB influences the clinical presentation [7–11]. Therefore, many types of clinical lesions are possible, such as inflammatory papules, verrucous plaques, suppurative nodules, and chronic ulcers [12]. Histologically it is characterized by the presence of varying degrees of granulomatous inflammation, necrosis, and vasculitis. Observation of the bacillus is not always possible. The examination should then be complemented by others to the correct conclusion of the diagnosis [1, 13]. These complementary methods are used to improve diagnostic accuracy. Classical tests include direct examination, culture (gold standard), histopathology, and the tuberculin skin test (TST). More recently introduced examinations include interferon-γ release assay (IGRA), nucleic acid amplification test (polymerase chain reaction (PCR)), and genotyping. The classical tests are easy to perform and inexpensive but have low sensibility. The second are less operator dependent but are not familiar to many who deal with TB. Treatment is the same as for pulmonary

TB. However, it is necessary to make definitive assessment before starting treatment, conduct monitoring when using the medication, and be aware of bacterial resistance and how to manage such cases. This complexity makes knowledge of the subject vital for a proper approach to CTB therapy [1, 2, 7, 14].

Epidemiology

The global incidence of TB currently is around 133 per 100,000 inhabitants. Areas of low incidence have rates lower than 25 per 100,000 inhabitants. Regarding regional distribution, higher incidences exist in poor and underdeveloped countries. The incidence of TB per 100,000 habitants in 2014 was 28 in the American region, 48 in Europe, 116 in the Pacific region, 117 in the eastern Mediterranean region, 281 in Africa, and 286 in southwestern Asia. The incidence in the Americas is the lowest because it includes countries with very low rates, such as Canada [1]. Brazil shows an intermediate incidence, 44 per 100,000 inhabitants, in rates of mortality from the disease and in drug resistance [1], although the trend is one of improvement. In the past 17 years the incidence has decreased 38.7% and the mortality rate has decreased 33.6% [15]. Nevertheless, Brazil remains on the list of the 30 countries classified as high-burden areas, all of which may demonstrate one of the following situations: high incidence of TB, TB-HIV coinfection, and multidrug resistance to TB. Brazil is ranked in the burden list according to the absolute number of diagnosed cases of TB and TB-HIV coinfection. CTB constitutes about 1.5% of the total of all types of extrapulmonary TB. The involvement of other systemic organs in CTB, such as the lungs, bones, and abdomen, occurs in 35% of cases and should be actively investigated, as there are no statistics on CTB incidence. The prevalence in children ranges from 18% to 54% in India, with the majority of cases between 10 and 14 years of age [4, 5, 9, 16].

Etiopathogenesis

The genus *Mycobacterium* contains more than 174 species and 13 subspecies, including pathogenic, opportunistic, and nonpathogenic species, which are separated into three major groups: *M. tuberculosis* complex (MTC), *Mycobacterium leprae*, and mycobacteria other than MTC and *M. leprae*, referred to as nontuberculous mycobacteria (NTM). The MTC includes *M. tuberculosis*, *M. bovis*, *M. bovis* BCG, *M. africanum*, *M. caprae*, *M. microti*, *M. pinnipedi*, *M. canettii*, and *M. mungi*. The species of this complex are necessarily pathogenic and cannot survive in the environment for long periods, and therefore cause infection in humans and/or animals [5, 6, 17]. MTB, the most prominent member of the MTC, is the causative agent of TB. MTB is a Gram-positive, acid-fast bacillus (AFB). *M. bovis* has also been associated with the development of cutaneous lesions. MTB, which belongs to the *Shizomycetes* class, Actinomycetales order, Mycobacteriaceae family, and *Mycobacterium* genus, has about 4000 genes, most of which are involved in MTB survival or evasion mechanisms. MTB is able to develop and multiply both outside and inside phagocyte cells, being classified as a facultative intracellular parasite [5, 6, 17–20].

The immune response in TB occurs via the T-helper (Th) 1 pathway, with little or no involvement of Th2 pathway. Mycobacteria are inhaled and activate alveolar tissue macrophages. These phagocytose the infectious agents and trigger an intracellular apparatus to try to eliminate the bacillus [6, 8, 9, 11]. In trying to avoid death, MTB uses virulence factors, especially phagosome inhibitors, apoptosis inhibitors, and oxidative stress responders at this point [20]. If the mycobacteria survive they multiply inside the macrophages, thus inducing the production of cytokines for differentiation and recruitment of monocytes, lymphocytes, neutrophils, and dendritic and natural killer cells. They generate a cytokine production cycle which includes interferon-γ (IFN-γ), tumor necrosis factor α, interleukin (IL)-17, and IL-23. The chronic presence of these cytokines stimulates the macrophages to differentiate into epithelioid and giant cells and to organize themselves, to a greater or lesser extent, into granulomas [8–11].

Effectiveness in performing the containment leads to primary infection, latency, or cure [8, 9]. If MTB is not eliminated and remains inside the granuloma, it is associated with the possibility of immunosuppression, keeping the chance of relapse lifelong. CTB is mostly commonly secondary to a preexisting systemic primary focus in individuals incapable of forming and maintaining an efficient immune cellular response. The lesions may result from contiguity to the focus (orificial TB, scrofuloderma), hematogenous spread (acute miliary tuberculosis, tuberculous gumma, lupus vulgaris), or lymphatic dissemination (lupus vulgaris). The exceptions are tuberculous chancre and TB verrucosa cutis (TVC). Chancre occurs in individuals who have never had contact with MTB, and has pathophysiologic presentation similar to that of the first lung infection. The initial phagocytosis via mononuclear process occurs in the skin, and the presentation is in a local lymph node. TVC is secondary contact in an individual with good but remedially insufficient immune response [21–25].

Clinical Presentation

The clinical presentation of the disease depends on the route of infection, the quality of natural immune response, and the presence or absence of prior contact [7, 21]. This causes a geographic variation in clinical presentation according to the immunology of the affected population [21–25]. Inherent individual factors (age, sex, race) also influence the disease process. In children, possibly because of immature immunity, scrofuloderma and primary forms are more frequent. In adults, changes in immunological status, such as malnutrition, alcoholism, silicosis, diabetes, gastrectomy, and immunosuppressant conditions,

D. Cutaneous tuberculosis secondary to BCG vaccination

are important [26, 27]. CTB has a varied clinical and morphologic spectrum. CTB subtypes have been established based on three criteria: pathogenesis, clinical presentation, and histopathology [28]. The variants of CTB can be classified in several ways. The most commonly used is based on the inoculation mechanism [7, 12, 29] (Table 6.1).

The TB variants may also be divided according to the bacterial load of the skin: the multibacillar forms are those wherein the bacillus is easily detected in the cutaneous tissue or exudate isolated; the paucibacillary are those from which it is difficult to isolate the microorganism, with scattered bacilli or absence in histology. Multibacillar forms include tuberculous chancre, scrofuloderma, orificial TB, acute miliary TB, and metastatic tuberculous abscess. Paucibacillary forms are less common and involve TVC and lupus vulgaris (LV). In addition to these clinical forms, tuberculids, a category of skin disorders associated with TB, probably represent hypersensitivity immune reactions to *M. tuberculosis* antigens. This category includes three variants: the papulonecrotic tuberculid, lichen scrofulosorum, and erythema induratum of Bazin (EIB) [10, 26] (Tables 6.2 and 6.3).

Exogenous Cutaneous Tuberculosis

Exogenous inoculation of MTB may lead to tuberculous chancre, TVC, and more rarely to some cases of LV.

Tuberculous Chancre

This is a rare form of CTB, also called TB primary inoculation chancre, since it develops in individuals not previously sensitized by mycobacteria, occurring more often in children from endemic areas [12, 30]. Tuberculous chancre develops by direct inoculation of MTB in the skin or mucosa after local trauma often unnoticed by the patient. This inoculation can also occur with the use of inadequately sterilized needles, tattoos, circumcision, piercings, surgeries, and wounds. Face and extremities are the most commonly involved sites [7, 28, 31].

Generally 2–4 weeks after inoculation a papule or nodule appears that is firm, painless, and red-brown, and slowly develops into an ulcer. The ulcer is friable and prone to bleeding, and its base has a rough granular surface [32]. After 3–8 weeks from the onset of tuberculous chancre, there is often a spread of the bacillus through the lymphatics and lymph nodes, analogously to Gohn complex in the lungs [26]. Regional lymphadenopathy becomes evident and occasionally the lymph nodes drain into the skin. This phenomenon can have a sporotrichoid aspect [33]. Without treatment, tuberculous chancre may persist for more than a year. Evolution for spontaneous healing of 3–12 months can occur, leaving atrophic scarring and calcification in regional lymph nodes [30]. If treatment is not implemented there is a potential risk of complications, such as the hematogenous dissemination of the bacillus to other organs or acute miliary disease. Another possibility is development of LV, scrofuloderma, or verrucous plaque from the chancre [7].

Tuberculosis Verrucosa Cutis (TVC)

TVC is the most common form of exogenous CTB. The lesion develops due to direct inoculation in skin of previously sensitized individuals

Table 6.2 Etiopathogenic aspects of the forms of cutaneous tuberculosis

Clinical form	Inoculation route	Concentration of bacteria in the skin	PPD	Previous sensitization to mycobacteria
Tuberculous chancre	Exogenous	Multibacillary	Strong reactor	No
TB verrucosa cutis	Exogenous	Paucibacillary	Moderate to high reactor	Yes
Scrofuloderma	Endogenous by contiguity	Multibacillary	Strong reactor	Yes
Orificial TB	Endogenous by autoinoculation	Multibacillary	No reactor	Yes
Lupus vulgaris	Endogenous by hematogenic, lymphatic or contiguity	Paucibacillary	Strong reactor	Yes
Acute miliary TB	Endogenous by hematogenic	Multibacillary	No reactor	Yes
TB gumma	Endogenous by hematogenic	Multibacillary	No reactor	Yes
Tuberculids	Distant hypersensitivity	Absent	Strong reactor	Yes

Table 6.3 Clinical characteristics of CTB forms

Clinical form	Affected population	Prevailing cutaneous clinical aspect	Most affected anatomic area	Serious systemic impairment
Tuberculous chancre	Children and young individuals	Ulcer or verrucous plaque with regional lymphadenopathy	Face and extremities	No
TB verrucosa cutis	Children	Solitary hyperkeratotic verrucous plaques	Hands and feet	No
Scrofuloderma	Children, adolescents and the elderly	Cold, painless abscesses with fistulas	Face and neck	Possible
Orificial TB	Immunocompromised individuals	Erythematous to yellowish, painful and friable nodules and ulcers	Oral, nasal, anal, perineal or vulvar mucosa	Yes
Lupus vulgaris	Children and young individuals Women> men	Papules and well-defined, erythematous brownish plates with areas of hyperkeratosis and central atrophy	Face and neck	No
Acute miliary TB	Children and immunocompromised adults	Erythematous purplish papules, upon which small vesicles	Disseminated	Yes
TB gumma	Malnourished children and immunocompromised adults	Few floating subcutaneous nodular lesions that may ulcerate	Trunk and extremities	Yes
Lichen scrofulosorum	Children and young adults	Follicular or perifollicular erythematous brownish, asymptomatic, grouped and symmetrically distributed papules	Trunk and abdomen	No
Papulonecrotic tuberculid	Children and young individuals	Symmetric and recurrent eruption erythematous purplish, pustules and necrotic papules	Face, ears, extensor areas of the extremities and buttocks	No
Erythema induratum of Bazin	Young women	Subcutaneous nodules and erythematous purplish, slightly painful plates of 1–5 cm in diameter	Posterior surface of legs and thigh	No

with moderate to high immunity against MTB [7, 13, 27, 29]. These lesions are solitary, poorly symptomatic, and painless, and predominate in extremities such as fingers and feet [27, 28, 30, 34, 35]. The literature describes lesions in children's ankles or buttocks, due to contaminated soil with tuberculous sputum, but it is not commonly seen [10, 12]. In the past, professionals such as anatomists and medical doctors were prone to this type of CTB [30, 34]. The lesions begin as erythematous papules surrounded by a purpuric inflammatory halo, which evolves to an asymptomatic hyperkeratotic verrucous plate. The size varies from 1 to 5 cm in diameter [12]. The lesion grows centrifugally, sometimes accompanied by central atrophy [10, 30]. The plates are firm with verrucous surface and often exhibit cracks followed (or not) by purulent discharge. In general, regional lymphadenopathy is not present. More rarely, CTB can ulcerate or have an extensive multifocal presentation even in immunocompetent individuals [10, 36]. There are reports of psoriasiform, sporotrichoid, and keloid forms of CTB [36]. The purified protein derivative (PPD) of MTB is strongly positive. TVC may persist for many years if left untreated, although spontaneous resolution may occur [29, 30]. Secondary bacterial infection and elephantiasis are possible complications of extensive TVC that affects the extremities [10] (Figs. 6.1, 6.2, and 6.3).

Endogenous Cutaneous Tuberculosis

Endogenous cutaneous TB may occur by dissemination, contiguity, autoinoculation, lymphatic dissemination, and through a hematogenous route from another tuberculous focus. These include LV, scrofuloderma, gumma TB, acute miliary TB, and orificial TB.

By Contiguity or Autoinoculation

The adjacent structures transmit TB to the skin. Scrofuloderma, orificial tuberculosis, and LV arise from this process.

Fig. 6.1 TB verrucosa cutis

Fig. 6.2 TB verrucosa cutis

Scrofuloderma

Scrofuloderma, also known as tuberculosis colliquativa cutis, is the most common form of CTB in developing countries such as Brazil and India [37] and can occur at any age, although children, adolescents, and the elderly are the most affected

Fig. 6.3 TB verrucosa cutis

Fig. 6.4 Scrofuloderma

Fig. 6.5 Scrofuloderma

[13, 26]. Scrofuloderma arises from the secondary involvement of subjacent tuberculous focus, such as lymph nodes, bones, or testicular disease [7, 13, 34]. The presence of scrofuloderma already suggests systemic TB infection, particularly pulmonary disease [12, 28]. The occurrence of scrofuloderma after BCG vaccination has also been reported [38].

Cervical lymph node chains appear to be the major underlying source of subjacent infection with spread of disease to the facial skin and neck, although the armpits and groin but may also be affected. There is formation in the adjacent organ of cold painless abscesses, which fistulize with discharge of purulent secretion and caseous material [7, 10, 13, 28]. Lesions may be single or multiple. Following the evolution of the disease, ulcerated purpuric plaques and the development of multiple fistulas are observed (Figs. 6.4 and 6.5). Histopathology reveals tuberculous granulomas with caseous wedge-shaped necrosis. BAAR are easily seen in the cutaneous tissue or even upon direct examination of exudate. The TST is strongly positive [8]. Scrofuloderma tends to leave keloid scars, retractions, and atrophic sequelae. Spontaneous regression can occur, but it can take years for full resolution [12, 28].

Orificial Tuberculosis

Orificial TB, or tuberculosis cutis orificialis, is a rare manifestation of CTB that affects middle-aged adults and the elderly, with severe impairment of cellular immunity and advanced

pulmonary, intestinal, or genitourinary TB [32]. The lesions result from self-inoculation of viable mycobacteria in mucocutaneous tissue near body orifices [10, 13, 29]. Therefore the lesions affect the oral, nasal, anal, perineal, or vulvar mucosa [7, 13].

Clinically they appear as erythematous or yellowish papules or painful friable nodules, measuring from 1 to 3 cm in diameter, which can lead to painful ulcers with fibrinous base [10, 13, 27, 32]. Edema and inflammation are evident in perilesional tissue [30]. Culture for MTB is usually positive [8]. The TST is negative. There is no tendency to spontaneous regression [28]. Affected individuals have a poor prognosis, since there is severe underlying visceral disease and resistance to tuberculostatic treatment [13, 29]. If medication is not introduced, the lesions progress and contribute to the development of fatal disease [10].

By Hematogenic and/or Lymphatic Dissemination

Hematogenous and/or lymphatic dissemination from a primary focus of MTB infection may lead to LV, tuberculous gumma (metastatic tuberculous abscesses), and acute miliary TB.

Lupus Vulgaris

LV is considered by some authors the most common form of CTB in Europe and India [34, 39]. It can be acquired from endogenous infection (by hematogenous/lymphatic dissemination or by contiguity) and, more rarely, by exogenous inoculation of MTB or by BCG vaccination. It is a chronic, progressive, and potentially disfiguring form of CTB, which occurs in patients with a high degree of immunity against the bacillus [7, 27, 30]. It is very common in children and young people, this group accounting for 41–68% of cases of LV [28]. For unknown reasons, women are affected two to three times more often than men [29].

Clinical findings of LV are varied. It is most commonly characterized by papules and well-defined, erythematous brownish plaques, in facial and cervical areas, which rarely ulcerate [10]. In tropical countries, the development of lesions on

Fig. 6.6 Lupus vulgaris

the legs and buttocks is common [13]. The plaque grows peripherally, with serpiginous or verrucous borders, often reaching over 10 cm in diameter with central discoloration and atrophy. Diascopy of nonkeratotic areas reveals an "apple jelly" aspect. This feature is also seen in other granulomatous diseases, such as sarcoidosis and leprosy, and is rarely found in patients with black skin (Fig. 6.6) [10, 30]. Lesions do not always present the typical forms and are described as plaques, papules, and nodules, and vegetating, tumoriform, or ulcerated lesions. They mimic diseases, such as discoid lupus erythematosus, psoriasis, sporotrichosis, actinomycosis, and mycetoma [7, 40, 41]. LV can also develop into scrofuloderma drainage scar [8, 29, 42]. The culture of the lesion to mycobacteria is usually negative and the TST is positive [7]. Untreated LV lesions persist for years, gradually growing and leading to significant aesthetic alterations, with ulceration and tissue destruction [7, 10, 12, 30]. The incidence of malignant transformation into squamous cell carcinoma in LV ranges from 0.5% to 10.5%, and usually occurs after 25–30 years of untreated lesions [43, 44]. The development of other malignancies, such as basal cell carcinoma, has also been reported [27].

Tuberculous Gumma

Tuberculous gumma, also called metastatic tuberculous abscess, is a multibacillary CTB that results from the hematogenous dissemination of the bacillus by an active TB primary focus, especially in periods of decreased cellular immunity

[10, 30, 45]. Typically it affects malnourished children and immunocompromised adults, with rare reports in immunocompetent patients [10, 46]. Scrofuloderma and tuberculous abscesses have also been described in individuals with acute miliary TB [32, 46]. Usually there are few lesions, characterized by fluctuating subcutaneous nodules, which may ulcerate and drain caseous secretion (Figs. 6.7, 6.8, and 6.9) [30, 45]. Tuberculous gumma affects the trunk and extremities, and adenopathy is usually not present.

The TST can be positive or negative. Patients diagnosed with tuberculous gumma have a poor prognosis because of their compromised immunity and/or malnourishment. In immunocompetent individuals, abscesses may persist for years without treatment, and eventually resolve spontaneously [30].

Acute Miliary Tuberculosis

This is a rare and severe form of CTB resulting from hematogenous dissemination of the bacillus from the primary focus of TB, usually the pulmonary focus. Acute miliary TB typically affects

Fig. 6.7 TB gumma

Fig. 6.9 Metastatic tuberculous abscess

Fig. 6.8 Metastatic tuberculous abscess

individuals with impaired cellular immunity or severe immunosuppression. The patients have a negative TST, demonstrating absence of immune response against MTB [8, 10, 28]. This clinical form was first described in infants and children with reduced immunity after episodes of measles or scarlatina [28]. Although it is currently considered a rare form of CTB, the number of cases is increasing because of HIV, especially in CD4 counts of <100 cells/μl [47]. Acute miliary TB is systemic, presenting fever, anorexia, asthenia, and weight loss [8, 13]. It is important to note that most patients with this form do not have CTB. When present, the cutaneous lesions can be exanthema, small erythematous whitish papules, or erythematous purplish papules. The papules can evolve with vesicles, which subsequently break down, resulting in umbilication and crust formation [10]. They tend to regress in 1–4 weeks, leaving depressed and hypochromic scars [8].

Tuberculids

Tuberculids are considered hypersensitivity reactions to *M. tuberculosis* antigens present in extracutaneous focus or, rarely, after BCG vaccination. Such reactions occur in patients with moderate to high levels of immunity against the bacillus (tuberculin skin sensitivity) [8, 10, 12, 13]. Three disorders make up this group: lichen scrofulosorum, papulonecrotic tuberculid, and EIB. The pathogenesis of tuberculids has not yet been fully clarified. Some concepts support the classification of these three conditions as tuberculids: failure to detect MTB in the affected tissue reactions or cultures; the presence of extracutaneous infection by detectable MTB, with positive TST; histopathological evidence of granulomatous inflammation in skin lesions; and frequent resolution of cutaneous lesions with treatment against TB [10, 13].

Lichen Scrofulosorum

This is the rarest tuberculid, which affects children and young adults with lymph node or bone TB [10, 13, 30]. There are reports of lichen scrofulosorum emergence in young individuals and children after BCG vaccination or in *M. avium-intracellulare* complex (MAC) infection [49, 50]. Lichen scrofulosorum is characterized by asymptomatic hardened papules, reddish-yellow or red-brown color, sometimes brilliant, sized between 1 and 5 mm. They show a follicular or perifollicular distribution, symmetrically arranged in plaques most commonly observed in the trunk and abdomen of affected individuals [10, 12, 13, 30]. Necrotic lesions that leave hyperpigmented atrophic scars can be found in the topography of elbows, knees, legs, and extremities [28]. Bacilli are rarely found, although the DNA of the bacillus has already been identified in these lesions by PCR tests [48]. Without medication the lesions regress, without leaving scars, after months or years [29].

Papulonecrotic Tuberculid

This is the most common type of tuberculid, often observed in children and young people. It presents as symmetric and recurrent eruption of erythematous purplish papules that become pustular and necrotic, and affect most commonly extensor areas of the extremities and buttocks, but can reach the trunk and the face, associated or not with lymphadenitis [8, 10, 13]. Constitutional symptoms such as fever and asthenia may precede cutaneous manifestations [29]. Eruption may resolve spontaneously after weeks to months, resulting in formation of depressed varioliform scars (Figs. 6.10 and 6.11) [10, 13, 51]. Recurrences are common without tuberculostatic treatment, although when drugs are introduced, clinical improvement in days or a few weeks can be observed [52]. There are

Fig. 6.10 Papulonecrotic tuberculid

Fig. 6.11   Papulonecrotic tuberculid

Fig. 6.12   Erythema induratum of Bazin

reports of concomitant presentation of papulonecrotic tuberculid and EIB in the same patient [53, 54].

Erythema Induratum of Bazin

EIB is a granulomatous lobular panniculitis associated with TB, which affects the lower limbs of young and middle-aged women. It is a rare cutaneous manifestation of TB and has already been described even in patients with few symptoms or no underlying TB signal. Epidemiologic studies show that there is a greater predisposition in female patients, adolescents and young adults, patients with low phototypes or circulatory disorders of the lower limbs, and obese individuals [55]. It presents in the form of subcutaneous nodules and erythematous purplish plaques, measuring 1–5 cm in diameter, slightly painful, which persist for several weeks. They are usually distributed on the posterior surface of the legs and thighs [7, 55, 56]. Nodules can grow and reach a few centime-

ters in diameter [56, 57]. Central ulceration occurs in about 30% of EIB and are characterized by shallow, violaceous edges with a granular reddish base [58]. Lesions may regress even without treatment, after weeks to months, leaving depressed scarring and postinflammatory hyperpigmentation; however, recurrences may occur in outbreaks every 3–4 months [55] (Figs. 6.12 and 6.13).

The PPD and IGRA are frequently positive. The main clinical differential diagnosis is erythema nodosum (EN), characterized by the presence of nodular swelling and hardened, nonulcerative nodules seen predominantly in the lower limbs of women. It may be preceded by flu-like symptoms. EIB can be triggered by a variety of noninfectious and infectious agents. The disorder occurs via drugs and in association with systemic diseases, such as sarcoidosis and collagen diseases. Among infectious agents, streptococcal infection and primary TB are the most common etiologic factors. Histologically EIB is characterized by septal panniculitis without vasculitis. Other differential diagnoses include

Fig. 6.13 Erythema induratum of Bazin

cutaneous polyarteritis nodosa, pancreatic panniculitis, deep lupus erythematous, subcutaneous sarcoidosis, and cutaneous T-cell lymphoma [12, 55, 58].

Anti-TB treatment of EIB is recommended when TB is demonstrated. Most cases respond to antituberculous treatment [8]. When the association with TB is not detected, the term "nodular vasculitis" is used to refer to the manifestation of clinically and histologically similar panniculitis [57]. Hepatitis C, a potential trigger of nodular vasculitis, should be investigated when the possibility of TB is excluded [56].

Cutaneous Tuberculosis Secondary to BCG Vaccination

BCG vaccine (strain 1331) is a live mycobacteria vaccine derived from attenuated strains of *M. bovis*. It has been widely used to prevent serious TB infections, such as meningoencephalitis and acute miliary TB. However, it may cause skin complications such as tuberculids, LV, scrofuloderma, and outbreaks of TB in other organs, and nonspecific reactions, such as fever, local inflammation, abscesses, and regional lymphadenitis [7, 38, 59].

Complementary Examinations

Tuberculin Skin Test

The TST is a delayed hypersensitivity type IV reaction induced by T lymphocytes. The test identifies individuals who have had contact with MTB, identifies the antigens, with restriction or not of the bacillus, and develops immunological memory. For this reason, the test becomes positive only 2–10 weeks after contact with the bacillus [60, 61]. The TST technique consists in one injection of purified protein derivative (PPD) of MTB in the superficial dermis, in the middle third of the left forearm. If there is a problem in the skin, the right side of the left forearm can be used. The patient is instructed not to apply lotions or rub the injection site. After 48–72 h, the largest diameter of induration is measured with a millimeter ruler (Mantoux technique). If the patient does not attend, the maximum time allowed until the reading is 96 h [60] (Fig. 6.14).

There are two available derivatives, the PPD-RT 23 (Statens Serum Institute, Copenhagen) and the PPD-S (Tubersol-Aventis Pasteur, Toronto). Both use 0.1 ml in the test, but this volume corresponds to different amounts of units, two for the PPD-RT 23 and five for the PPD-S [60]. PPDs are not exclusive to MTB and therefore can produce false positives due to other mycobacteria or to vaccination, especially in the first 2–3 years [61, 62]. False-negative reactions can occur in cellular immunity alterations, such as age under 3 months or over 65 years, malnutrition, diabetes, kidney disease, pregnant women, recent severe infections, and congenital, acquired, or drug-induced immunodeficiency. Negative results also can occur by conservation or technical problems of application. The PPDs can degrade if the storage temperature is above

Fig. 6.14 Tuberculin skin test

8 °C or if exposed to radiation sources. The application errors include an insufficient amount of tuberculin, delay between the suction of the material and the application, too deep an injection, or misunderstanding of the result [60].

The TST result should be cautiously interpreted in the clinical context. It is important to provide the result in millimeters and avoid the classification of negative, weak, and strong reaction. For the correct interpretation of the test result it is necessary to evaluate the presence of the population vaccination status, the immunosuppression, and the bacterial load of the clinical presentation [63].

The vaccination brings some confounding factors. It increases the frequency of positive testing above 10 mm and increases the possibility of wrong diagnosis by latent TB due to endemic contact with MTB, leading to a decrease in TST sensitivity [10, 63].

Immunosuppression can decrease the size of TST induration and produce false negatives, even in smear-positive cases. For this reason, in this situation tests above 5 mm should be considered. Therefore it is vital to evaluate immunosuppressive factors such as HIV, medications, and diabetes in all patients. Assane et al. found 14.28% of HIV-positive patients in a series of 151 cases of CTB [64].

The clinical presentation of CTB is extremely important in TST result analysis. There is a relation between the bacillary load and the TST value in millimeters. Scrofuloderma and LV most frequently show strongly positive tests. Warty TB,

primary CTB, gumma TB, and tuberculids show wide variation in results, including low positive values. Acute miliary and orificial tuberculosis commonly deliver negative tests. To conclude, the result of the TST should be evaluated individually and in the clinical context. Tests with low positive values can be considered positives in the immunosuppressed and in presentations with low bacterial load [10, 61, 62]. Tests with high values may have low positive predictive value in the vaccinated population. The best practice is to complement the test with histopathologic and other laboratory techniques (Table 6.4).

Interferon-γ Release Assay (IGRA)

IGRA are tests used to identify indirectly a cellular immune response to specific peptides present in the MTB. Currently there are two commercially available tests approved by the US Food and Drug Administration, which use different techniques [10, 65]. The QuantiFERON TB Gold In-Tube (QFT-G) measures the IFN-γ produced by T cells in response to a protein cocktail, ESAT-6, SSN-10, and 7.7 TB. The test consists in a system of three tubes. The first contains the antigens, the second a mitogen to evaluate the cellular response (a positive control), and

the third an anticoagulant (negative control). In the negative control the IFN-γ produced before the test and unrelated to MTB is quantified. The blood is collected in the tubes and can be processed for up to 16 h. After the sample is incubated at 37 °C for 16–24 h and centrifuged, the plasma is removed and the IFN-γ is quantified by ELISA technique [66].

The test is positive if the IFN-γ measured in the tube with antigens is above 0.35 IU/ml and 25% higher than the value obtained in the negative control tube. If the IFN-γ is below 0.35 IU/ml or less than 25% of the negative control, the outcome depends on the positive and negative control tubes. If the negative is less than 8 and the positive is greater than 0.5 IU/ml at the same time, the result is negative. The cellular immune response works properly and there is no production of IFN-γ. If the negative control tube is greater than 8 or the positive control tube is less than 0.5 IU/ml, the result is indeterminate. The difference between the tube test and the negative control is too small and cannot be measured or the quantity/lymphocyte activity is low [65, 66].

The other test, the T-SPOT.TB, uses only two antigens separately. The mononuclear cells are separated, counted, washed, and then equally divided in four wells to avoid difference in the response between then. One well is the negative control, two wells contain antigens, one ESAT-6 (Panel A) and the other CFP10 (Panel B), and the last well is the positive control containing a polyclonal activator to confirm the functionality of mononuclear cells. After incubation, as ELISA is performed to detect the increase in the number of cells that secrete IFN-γ (number of spots present in the pit) [65, 67].

The test is positive if one of the test wells presents an increase of more than six spots relative to the negative control. A positive test is incontestable if there is an increase of more than 20 spots. An increase of between six and seven spots is borderline. The result is indeterminate if the negative control presents more than ten spots, regardless of the outcome of the test wells. In borderlines and indeterminate tests, standard practice is to retest with another technique. The test is negative if the antigen wells have not shown an increase in the number of spots or if the difference from the nega-tive control well is less than five spots [65, 67]. The antigens used in IGRAs are not present in the BCG and in the most part of other mycobacteria, with the exception of *M. kansasii, M. szulgai*, and *M. marinum*. This limits the false positives for these agents and eliminates the interference of BCG, resulting in fewer mistakes, especially in vaccinated populations [65]. The possibility of latent TB is the same as for the TST. A systematic review of 38 studies of pulmonary TB found a sensitivity average of 76% for the QFT-G and 90% for the T-SPOT.TB, regardless the vaccination. QFT-G presented 99% specificity in unvaccinated patients and 96% specificity in vaccinated patients, while the T-SPOT.TB presented 93% specificity in both groups [65]. There are few studies evaluating the test in CTB because of the low frequency of the disease. A prospective study of suspected cases of CTB using the T-SPOT.TB found sensitivity of 91.6%, very close to that of pulmonary TB, but lower specificity, 75.8%, mostly attributable to cutaneous atypical mycobacteriosis [68]. Despite the lower frequency of false positives, the method is not free from false negatives and indeterminate results. Risk groups are patients with a history of serious illness, prior hospitalization in intensive care, malnutrition, lymphopenia (especially when there is low CD4 count), an increase in C-reactive protein, a decrease in total protein levels, and aged older than 65 years. In this age group twice as many false negatives occur and 30% of the examinations have indeterminate results, while in other age groups this index is 3.1% [68–70]. The advantage is not limited to the issue of vaccination. It can also be applied in difficult situations to complete the diagnosis, such as latent TB screening, nephropathic or transplanted patients, children, immunosuppressed, tuberculids, and erythema nodosum. The few existing data reflect the difficulty of carrying out prospective comparative studies between IGRA and TST in patients with CTB [71–74].

Direct Examination or Bacilloscopy

Direct examination generally consists in searching for bacillus in a fresh sample stained with Ziehl–Neelsen staining acid. The bacilli appear

as reddish, isolated, grouped, or fragmented. Sterile conditions are necessary to remove the sample. The sample can be a scraping from an ulcerated lesion, a biopsy fragment, or secretion obtained from suppurative lesions. After collection, the material is placed in a sterile jar with saline solution. If it is a secretion, the material is distributed in a blade homogenizer before being put in the saline solution, which is kept between 2 and 8 °C and submitted for review within 24 h [73, 74]. The method presents low sensitivity because the presence of more than 5000 bacilli is necessary for it to be positive. Because of easy sample collection and higher bacterial load, it is more suitable for humid or suppurative lesions such as primary CTB, scrofuloderma, metastatic tuberculous abscess, or orificial tuberculosis [60, 61]. In a study of 95 cases of CTB, only two demonstrated positivity in a direct exam [75].

Mycobacterial Culture

Mycobacterial culture is the gold standard to determine the presence of active TB infection, and can also distinguish between the subspecies of mycobacteria and determine the sensitivity to antibiotics. The examination is necessary in all cases, especially in patients with previous contact with resistant TB or prior TB or leprosy treatment, in immunocompromised patients, and in the event of treatment failure [60, 61, 76]. In pulmonary TB culture, sensitivity is between 30% and 85%, compared with between 9% and 85% in CTB [75, 77–79]. A study found no difference in positivity between the clinical forms of CTB [80]. The test requires only between 10 and 100 bacilli to be positive, although the material selected, time until delivery to the laboratory, and culture medium are critical to the outcome [80]. Swab, direct aspiration, and biopsy are the methods used to collect the sample. Because culture of the biopsy fragment carries superior positivity to secretions, biopsy represents the specimen of choice. After local asepsis, the secretions and the necrotic tissues are withdrawn, and a 4-mm fragment in an area without necrosis or pus is removed and placed in a sterile jar with sterile physiologic solution. The patient's name and

the time of material collection are noted on the bottle. The material is delivered to the lab in less than 30 min, refrigerated, and protected from light [60].

The cultivation can occur in traditional medium (Lowenstein–Jansen or Ogawa–Kudoh) or radiometrically (automated or semi-automated). The latter increases positivity and reduces the waiting time for the result; however, as yet this method is not widely accessible or known by everyone. The dermatologist must remember to specify the culture to the mycobacteria in the request. The results take between 6 and 15 days, with the exception of Lowenstein–Jansen medium, which needs nearly 30 days [76].

Polymerase Chain Reaction

In this method the DNA present in fresh tissues, blood, or paraffin blocks confirms the presence of mycobacteria. The oligonucleotides (primers) delimit the beginning and the end of the desired DNA sequence. The DNA polymerase replicates the fragments, and the distribution of DNA bands in the agarose gel is compared with positive and negative controls. A single DNA sequence with varying sizes or multiple sequences at the same time (multiplex PCR) can be chosen. The sequences most commonly used for MTB are IS6110, IS986, MPB64, 65 kDa, and 38 kDa. IS6110 is considered the gold standard for MTC. It is a genetic element subject to translocation that is integrated in any location and any number in the chromosome, but is easier to find at some points (hot points) [81–84].

The waiting time for the result depends on the type of technique, ranging from 1.5 h for real-time PCR to 5 days for the conventional technique. The PCR techniques [81–84] are:

- **Conventional PCR or *in-house PCR***: standardized manual system by each laboratory. After the amplification, it is possible to sequence the fragment [72, 73].
- **Real-time quantitative PCR**: Automated PCR system. The selected fragment is associated with a fluorescent system to capture the light from the amplification, allowing imme-

diate knowledge of the result. The advantages over traditional amplification are rapidity, decreased contamination of material, and fewer errors in the process.

- **PCR with hybridization:** After the amplification, the fragments bind to a probe. A marker reacts with the probe, producing colors that can be identified and quantified by a spectrophotometer. This method Increases the chance of DNA detection and reduces false negatives.
- **PCR in situ:** The amplification occurs in the tissue, including paraffin blades, enabling demonstration of the location of mycobacterial DNA in the cell. Sensitivity is similar to that of traditional PCR. The positivity increases if in situ hybridization is added.

Few studies have reported statistical data on this method in CTB. Tan et al. described mean sensitivity of 73%. Addalla et al. analyzed 14 cases of CTB and atypical mycobacteriosis and found 88% sensitivity and 85% accuracy with PCR, superior to the TST and histopathologic examination (79% each) [80]. The positivity may vary with the bacillary load. Tan et al. analyzed the data according to the clinical form and found that PCR was 100% sensitive and specific in the immunocompromised with multibacillary forms. Meanwhile the mean sensitivity for LV, TB verrucosa cutis, and erythema induratum was about 56% [85]. Supporting this idea, Hsiao et al. described 56.2% sensitivity in paucibacillary forms. Furthermore, a retrospective study of archived paraffin blocks found only one positive result in 22 confirmed cases of CTB, demonstrating a loss of sensitivity to in situ PCR over time [86–88].

Genotyping

Genotyping employs molecular methods to identify specific DNA sequences or loci of MTB. This may include PCR at any stage of the process. Genotyping is useful for diagnostic confirmation, identification of resistance genes and clonality, and evaluation of strain dispersion

[88]. The main molecular typing methods are [5, 18, 85–88]:

(a) *REA* (restriction enzyme analysis of bacterial DNA): Digestion enzymes cut the DNA. The resulting fragments are separated and visualized by electrophoresis. The default obtained from each strain of bacteria is characteristic.

(b) *PFGE* (pulsed-field gel electrophoresis): Derived from the REA. Uses large fragments to eliminate the incorrect enzymatic digestion and, consequently, problems in the diffusion in the agarose gel. Good for atypical mycobacteriosis.

(c) *RFLP* (restriction fragment length polymorphism): The gold standard technique for genotyping in TB. Differences in the amount and location of IS6110 are used to identify the strain of MTB. The IS6110 is normally present in multiple copies in the DNA of MTB, a single copy on *M. bovis*, and absent in other mycobacteria. Is better for strains with high frequency of IS6110. Difficult to use for mycobacteria derived from culture.

(d) *AFLP* (amplified fragment length polymorphism): The DNA is cut by two different enzymes and is amplified with adapters. The fragments are visualized in polyacrylamide gel and read by autoradiography or fluorescence. AFLP is subject to methodologic flaws and is better for identification of atypical mycobacterioses than MTB, especially in differentiating *M. marinum* and *M. ulcerans,* which is very difficult using conventional methods.

(e) *Spoligotyping* (Spacer oligonucleotide typing): Identifies specific polymorphisms called DR (Direct Repeat). The locus DR is one of the hot spots for IS6110 integration to DNA. The loci resemble a necklace of beads (locus) with spaces between them (spacers). The strains are differentiated by the number of spacers identified. Cheaper and faster than RFLP, requires only the equivalent of two to three mycobacterial DNA and can use fresh samples, stained or from paraffin block. This increases the sensitivity of the method and makes it good for screening. Is very useful in

differentiating mycobacteria with low frequency of IS6110 (less than five copies), such as *M. bovis*.

(f) *MIRU-VNTR* (mycobacterial interspersed repetitive units–variable number of tandem repeats): Quantifies specific sequences called varied number of tandem repeats (VNTR) or mycobacterial interspersed repetitive units (MIRU). Very useful for identification of atypical mycobacteria such as *M. ulcerans* and *M. marinum*, and good for phylogenetic studies [5, 18, 88].

Histopathologic Diagnosis

All frames of CTB feature similar histological bases composed of lymphocytes, histiocytes, and epithelioid giant cells, organized in tuberculous granulomas [18]. The histologic differences observed for each clinical form reflect the organizational ability of the immune and control process of the bacilli in accordance with the individual ratio of Th1/Th2 response (Figs. 6.15, 6.16, and 6.17). This behavior, as noted by Sehgal et al., has histopathologic representation. Lymphocyte depletion, abundant bacilli, giant cells, and caseous necrosis indicate an inefficient cellular immunity, observed in the scrofuloderma; on the other hand, in LV, rare or no bacillus is observed, caseous necrosis is almost always absent, and granulomas are well formed, reflecting the ability to contain the infection. Meanwhile, the intermediate forms commute between these two poles, with variable and individual response [21, 89].

However, it is important to note that these are not two totally opposite poles, since if there are clinically apparent diseases, even in the spectrum of greater immunity, there is somehow a deficiency in cellular immunity, otherwise it would evolve to cure all forms of TB. At the same time the types with lower immunity have some degree of cellular response, because they are capable forming at least a granulomatous infiltrate. Didactically histology of CTB is divided into paucibacillary forms (well-formed granulomas and rare bacilli), intermediate forms (can migrate to both poles), and multibacillary forms (more inflammatory and rich in bacilli) [89–92].

Paucibacillary Forms

Lupus vulgaris: Epidermis may be atrophic (more rarely) or hypertrophic (more frequently), showing acanthosis and papillomatosis, even pseudoepitheliomatous hyperplasia. In the reticular
Fig. 6.15 Lymphocytes and epithelioid histiocytes in a granulomatous infiltrate

Fig. 6.16 Langhans giant cells are frequently found in the inflammatory infiltrate
Fig. 6.17 Well-formed granulomas occupying the superficial and middle dermis
dermis there are well-formed tuberculoid granulomas with giant cells, Langhans type more frequently, or foreign-body type. Sarcoid-like granulomas may occur (Fig. 6.18). The lymphocytic infiltrate is dense and caseous necrosis is rarely present. If it occurs will be in small outbreaks, centrally to granuloma. Foreign body-type cells and fibrosis have been described. BAAR is infrequent [91, 92]. Note the that 8% of

cases can present with sarcoma, basal cell, or squamous cell carcinoma [93].

Lichen scrofulosorum: Epithelioid granulomas surrounded by lymphocytes and located more superficially in the dermis, adjacent to appendages. Despite the name, there is no lichenoid infiltrate. Normally, giant cells are absent. Caseous necrosis and BAAR are not found [94] (Fig. 6.19).

Fig. 6.18 Epidermic hyperplasia accompanied by granulomatous inflammatory process with noncaseaou necrosis foci in lupus vulgaris
Fig. 6.19 Small granulomas distributed in superficial dermis in lichen scrofulosorum
Tuberculosis verrucosa cutis: Marked by prominent alterations in epidermis such as hyperkeratosis, acanthosis, pseudoepitheliomatous hyperplasia, and papillomatosis. At the same time, in the middle dermis tuberculoid granulomas with microabscess or moderate-intensity caseous necrosis are seen. Bacilli are only rarely found [21] (Fig. 6.20).

EIB: Lobular panniculitis into the dermis, accompanied by vasculitis and foci of necrosis. Evolves to a granulomatous infiltrate over time, so the possibility of finding granulomas depends on the stage of the disease. Bacilli are not identified (Figs. 6.21, 6.22, 6.23, and 6.24) [92, 95].

Fig. 6.23 Lobular panniculitis in Bazin's erythema induratum
Fig. 6.24 Detail of the fat lobule surrounded by the infiltrate in Bazin's erythema induratum

Papulonecrotic tuberculid: Found in descending order of frequency: dermal-epidermal necrosis, granulomatous infiltrate, leukocytoclastic vasculitis, perivascular edema or necrosis, and follicular suppuration. BAAR in general are not identified [96].

Intermediate Forms

Primary tuberculosis: Histopathology varies with time from inoculation. The initial histopathology shows an acute neutrophilic inflammatory reaction, rich in BAAR and necrotic areas. After 4–6 weeks, there are caseous granulomas and the number of bacilli decreases [8, 61].

Multibacillary Forms

Scrofuloderma: Massive central caseous necrosis in the superficial dermis with abscess formation and macroscopic suppuration in many cases. On the periphery of the lesion, tuberculous granulomas occupy the entire dermis. When present, MTB can also be found in this location [61, 92] (Fig. 6.25).

Orificial tuberculosis: On the middle-deep dermis, there is a granulomatous infiltrate accompanied by focus of caseous necrosis distributed around a central and superficial ulcer. Bacilli can be identified near the infiltrate [61, 97].

Metastatic tuberculous abscesses and gumma: Central ulceration with caseous necrosis, surrounded by a crown of giant cells and macrophages. BAAR are often found [98].

Acute miliary tuberculosis: Nonspecific inflammatory infiltrate rich in lymphocytes and plasma cells. If there is caseous necrosis, this is focal and occasionally microabscesses are observed. Bacilli are usually present [99].

The histopathologic examination is crucial in the investigation of CTB and the identification of the agent is essential to conclude the diagnosis. However, in practice many cases feature great difficulty because the bacillus is not found even with special stains [25]. The bacillus is identified in from zero to 13% of histologic examinations [25, 75, 77–79, 100–103]. Only one study identified the bacillus in 50% of the examinations [102]. Among the clinical forms, the inflammatory are those in which the MTB is most commonly found, such as scrofuloderma and orificial TB [102, 103]. Regarding the histologic elements classically described in CTB, the tuberculous granulomas are the most frequently found, in between 57% and 96% of cases [25, 77–79, 100–103]. In sequence, there are the epidermal hyperplasia and caseous necrosis, ranging from 57% to
Fig. 6.25 Extensive caseous necrosis surrounded by a granulomatous process in scrofuloderma

Table 6.5 Comparative histologic studies of CTB and other infectious granulomatous diseases

Authors		Conclusions
Paksoy and Hekim Turkey, 1993	Lupus vulgaris versus cutaneous leishmaniasis	Giant cell granulomas are more frequent in TB
Nirmala et al. India, 1977	CTB versus tuberculoid leprosy	In CTB epidermal hyperplasia more frequently, small areas of ulceration, significant fibrosis, and caseous necrosis
Min et al. South Korea, 2012	CTB versus atypical mycobacteriosis	Giant cell granulomas and caseous necrosis were associated with CTB ($p < 0.05$)

86% [25, 77, 100, 103] and from 12% to 57%, respectively [25, 77, 100, 103]. The first is more frequent in the verrucous forms and the second in the inflammatory forms [77, 101, 103]. In 11–20% of the samples of confirmed CTB cases it is not possible to predict the diagnosis from the histology [77, 102, 103]. In addition, the CTB can present with atypical granulomas similar to yeast infections (mixed infiltration with suppuration), granuloma annulare, rheumatoid nodules, and sarcoidosis [103, 104].

Some studies tried to find elements that could differentiate CTB from diseases with similar histology [105–107]. Min et al. compared CTB with atypical mycobacteriosis and found the presence of neutrophils, interstitial granuloma, vascular proliferation, and a high number of bacilli were associated ($p < 0.05$) with the atypical mycobacteriosis, while giant cell granulomas and necrosis were associated with CTB also to a significant degree ($p < 0.05$) (Table 6.5). Unfortunately, the analysis is limited to the diseases studied and it is not possible to generalize these results to other diseases [105].

Differential Diagnosis

Several infectious diseases, as well as some tumor and inflammatory diseases, can simulate CTB. The correct survey of hypotheses should take into account the patient's age, clinical presentation, and anatomical location (Table 6.6).

Therapeutic Approach

TB treatment takes into account the age and weight of the patient, and lasts 6 months, regardless of TB form. The exception is meningoencephalitis, whose treatment lasts 9 months. In patients with HIV, treatment may be extended to 9 months based on the medical criteria. The treatment consists of two stages, a 2-month intensive phase and a 4-month maintenance phase. Patients under 10 years use three drugs in the intensive phase: rifampicin, isoniazid, and pyrazinamide (2RHZ). Patients older than 10 years use four drugs: rifampicin, isoniazid, pyrazinamide, and ethambutol (2RHZE). Both use two drugs for 4 months in the maintenance phase: rifampicin and isoniazid (4RH) (Tables 6.7 and 6.8). The medications should be taken together, preferably on an empty stomach, 1 h before or 2 h after breakfast or, in the case of digestive intolerance, with a meal [60, 108, 109].

The drug association, correct intake, and time indicated should be enough to cure virtually 100% of cases of TB. However, factors such as dose abstention, incorrect dose, nonstandard hours, breaks in treatment, monotherapy, and abandonment of treatment induce bacterial resistance to antibiotics and lead to more intensive care in the follow-up [27, 60].

Before starting treatment an active search should be conducted for other TB outbreaks. The involvement of other organs associated with CTB is described in between 4% and 35% of cases, the lung being the most affected organ. The identification of lesions in other organs contributes to increasing the material subjected to culture, aiding in monitoring the response to treatment and the correct indication of treatment time. The physical examination should include pulmonary evaluation, joints, and palpation of lymph node chains. If any lymph node is suspected, puncture and culture should be requested. In addition to chest X-ray, the examinations include direct examination and culture of the sputum with antibiogram and urinalysis (aseptic leukocyturia) with culture for acid-fast bacilli. Specific examinations, such as abdominal ultrasonography, excretory urography, and cranial, soft tissue, or

Table 6.6 Differential diagnosis of clinical forms

Clinical form	Differential diagnosis
Scrofuloderma	Pilonidal cysts, branchial cyst (in children), suppurative hidradenitis (Hurley 1), lymphogranuloma venereum, septic arthritis, cervical abscess, squamous cell carcinoma (SCC) of oropharynx
Nodular abscedens lesions	
Lupus vulgaris	
(Plates with live erythema, desquamation, and infiltration of varying degrees)	Hemangioma, psoriasis, rosacea, granulomatous chromoblastomycosis, erysipeloid, subacute cutaneous lupus erythematous
TB verrucosa cutis	
(Well-defined plates with hyperkeratosis of varying degrees)	Verrucous lupus erythematosus, chromoblastomycosis, SCC, verrucous leishmaniasis, wart verruca, pseudoanhum, chronic eczema
Acute miliary TB	
(Erythematous brownish small papules or pustules)	Secondary syphilis, cutaneous histoplasmosis, PLEVA
Gumma TB	
(Floating subcutaneous nodules)	Syphilitic gum, sporotrichosis, furuncle, phaeohyphomycosis
Primary tuberculosis	
(Initial phase: subcutaneous tissue inflammation)	Initial phase: bacterial or fungal mycetomas, cellulitis, *M. marinum*
(Chancre stage: ulcer of well-defined edges)	Chancre stage: leishmaniasis, chancroid, paracoccidioidomycosis, pyogenic granuloma
Orificial TB	
(Papules, nodules, and ulcers friable in semimucous)	Hidradenitis suppurative (Hurley 2–3), Crohn's disease or rectocolitis, anal fistula, mucocutaneous paracoccidioidomycosis, ulcerated hemorrhoid, Bowen's disease
Erythema induratum of Bazin	
(Infiltrated erythematous purplish plaques with areas of necrosis and suppuration)	Medium vessel vasculitis, chemical panniculitis, superficial thrombophlebitis, glomerulonephritis, subcutaneous T-cell lymphoma
Lichen scrofulosum	
(Erythematous brownish small papules, somewhat scaly)	Granuloma annulare, erythema annulare centrifugum, confluent and reticulated papillomatosis of Gougerot and Carteau, psoriasiform subacute lupus erythematous, psoriasis, lichen planus annularis
Papulonecrotic tuberculid	
(Firm papules of varying size with central small crust, tending to symmetric distribution)	Cryptococcosis, Behçet's disease, insect bite hypersensitivity

Table 6.7 Basic scheme for the treatment of TB in adults and adolescents

Scheme	Medication	Weight range (kg)	Unit/dose	Time period
2RHZE Intensive phase	RHZE 150/75/400/275 mg In fixed-dose combination tablet or capsule	20–35	2 tablets or capsules	2 months
		36–50	3 tablets or capsules	
		>50	4 tablets or capsules	
4RH Maintenance phase	RH 300/200 mg or 150/100 mg capsule or tablet	20–35	1 tablet or capsule 300/200 mg	4 months
		36–50	1 tablet or capsule of 300/200 mg + 1 comp or capsule of 150/100 mg	
		>50	2 tablets or capsules of 300/200 mg	

R rifampicin, *H* isoniazid, *Z* pyrazinamide, *E* ethambutol

joints magnetic resonance imaging (MRI), are requested according to symptoms and the first test results [78, 79, 101].

The initial evaluation also includes laboratory tests to assess the health condition of the patient, contraindications and adjustments in medication; complete blood count, liver enzymes, renal function, and uric acid. With the introduction of ethambutol in the default schema, patients must undergo ophthalmologic evaluation due to the risk of optic neuritis, more often when use of the drug extends to more than 2 months. The follow-up should be monthly to assess symptoms of adverse reactions to drugs, the presence of jaundice or rash, the evolution of cutaneous lesion and other foci if they exist, and the general laboratory and the sputum culture. The smear should be negative in the second month of treatment [60]. The patient should be asked about experience of gastric intolerance, change in urine color, burning sensation in the feet, arthralgia, myalgia, pain in oropharynx, alteration of visual acuity, or color perception. If using streptomycin, the patient should also be questioned about pain at the injection site and tinnitus [27].

Analogous to the pulmonary bacilloscopy, in most cases it is possible to notice an improvement in cutaneous lesions, decrease in lesion size, wound healing, and even clinical cure in the first 2 months of treatment [64, 77]. In 6 months about 81–100% of cases are cured. However, some authors report that about 8–15% of cases only showed healing after 8–24 months of treatment [64, 77, 101]. In the cases with slow response to treatment or not healing at the end of the standard time period, the possibility of bacterial resistance, atypical mycobacteriosis, and transformation in indolent tumors, especially in LV, should always

Table 6.9 Conduct front of mono- and multiresistance

[a]The streptomycin may be replaced by a fluoroquinolone, which should be used in the two phases

[b]The levofloxacin can substitute the ofloxacin. The intensive phase can be extended to 6 months

be remembered [93, 110]. Acute miliary tuberculosis currently has the highest reported resistance [99], but there are reports of resistance to scrofuloderma and LV [110].

In these situations, a new biopsy should be done with a request for culture and antibiogram or genotyping. If in the first 2 months of treatment no improvement is observed, in addition to the biopsy the therapeutic scheme should be replaced (Table 6.9). In the situation of slow but progressive improvement, treatment can be extended to 9 months. If the injury persists after that time, the drug schema should be changed. If the culture is negative or it is not possible to perform genotyping for resistance, the change should be discussed with a doctor experienced in treating TB [60, 110, 111].

It is important to note that clinical cure does not indicate microbiological cure, and the treatment should be continued for 2 months after complete resolution of the lesion [27]. After the end of treatment the patient should undergo regular follow-up and be instructed to return to monitor changes in scarring. Recurrences are uncommon, but are reported by some authors [64, 77].

Surgical Treatment

Surgical treatment is not indicated routinely, but can be considered in cases of therapeutic failure, small injury, and absence of disease in other organs. Surgery must be combined with drug treatment [110, 111].

Special Circumstances [60, 111]

Pregnancy

In pregnant women the standard treatment should be performed normally because there is no evidence of teratogenic effects of rifampicin, isoniazid, pyrazinamide, and ethambutol. In pregnant women using isoniazid, pyridoxine (50 mg/day) routinely is added to avoid peripheral neuritis and prevention of convulsion in newborn. Women currently breastfeeding should be directed to undergo the treatment because of the low concentration of these drugs in breast milk, but while paying attention to adverse effects. If there is a need for an alternative scheme streptomycin, ethionamide, and quinolones may be used. The agents ofloxacin, capreomycin, clarithromycin, clofazimine, and paraminosalicylic acid should have the benefit-risk evaluated before being recommended.

Elderly

The treatment is the same while adjusting the dose according to the weight. Remember that the elderly have increased frequency of adverse effects due to metabolic changes and polypharmacy.

Kidney Disease

The range or the drug dose should be adjusted in patients with creatinine clearance under 30 mL/min. If the clearance of creatinine is >30 mL/min, the standard dose should be used whenever possible with monitoring of serum levels.

Liver Disease

The medications used in the treatment for TB entail the risk of hepatotoxicity. In the first 2 months of treatment transient elevation of liver enzymes can occur. In patients without prior liver disease or liver disease without cirrhosis, treatment should be discontinued if the patient has jaundice or enzyme values three times above the normal value. If the enzymes normalize, medications must be returned in the following order: rifampicin + ethambutol, followed by isoniazid, and finally, pyrazinamide, with a 3- to 7-day interval between them.

In patients with prior liver disease with cirrhosis, enzymes persistently higher after 4 weeks of treatment, or if they rise again after re-introduction of the treatment, the schema must be changed to 3 months on streptomycin, ethambutol, and ofloxacin, followed by 9 months of ethambutol and ofloxacin.

Glossary

Acid-fast bacilli (AFB)   testing may be used to detect several different types of acid-fast bacilli, but it is most commonly used to identify an active tuberculosis infection caused by the most medically important AFB, *Mycobacterium tuberculosis*. Are called acid-fast bacilli because they are rod-shaped bacteria (bacilli) that can be seen under the microscope following a staining procedure whereby the bacteria retain the color of the stain after an acid wash (acid-fast).

Bacille Calmette-Guérin   Vaccine (strain 1331) is a live mycobacteria vaccine derived from attenuated strains of *Mycobacterium bovis* to prevent tuberculosis and other mycobacterial

infections. BCG has been recommended only for immune-competent children and adults who have high risk of ongoing exposure that cannot be avoided. In addition, it is used as an immuno-stimulant in the treatment of several diseases.

Erythema induratum of Bazin (EIB) Is a granulomatous lobular panniculitis associated with tuberculosis, which affects the lower limbs of young and middle-aged women.

Erythema nodosum Is characterized by the presence of nodular swelling, hardened, non-ulcerative nodules which are seen predominantly in the lower limbs of women.

Lupus vulgaris Is a chronic, progressive, and potentially disfiguring form of cutaneous tuberculosis, which occurs in patients with a high degree of immunity against *Mycobacterium tuberculosis*.

Tuberculin skin test (PPD, Mantoux technique, TB skin test) technique consists in one injection of purified protein derivative (PPD) of *Mycobacterium tuberculosis* in the superficial dermis, in the middle third of the left forearm. The TST is a delayed hypersensitivity type IV reaction induced by T lymphocytes.

Tuberculous gumma Also called metastatic tuberculous abscess, is a multibacillary cutaneous tuberculosis. It results from the hematogenous dissemination of the bacillus by an active tuberculosis primary focus, especially in periods of decreased cellular immunity.

Tuberculosis verrucosa cutis Is the most common form of exogenous cutaneous tuberculosis. The lesion develops from direct inoculation in the skin of previously sensitized individuals with moderate to high immunity against *Mycobacterium tuberculosis*.

Key Points Summary

- Nontuberculous mycobacteria (NTM) are generally considered to be environmental saprophytes
- *Mycobacterium fortuitum* is the most common of the rapidly growing mycobacteria (RGM) encountered in clinical practice
- *Mycobacterium ulcerans* is a slow-growing acid-fast bacillus that causes a cutaneous infection known as Buruli ulcer
- The *M. fortuitum* group is responsible for 60% of community-acquired localized cutaneous infection cause by RGM
- *Mycobacterium avium-intracellulare* complex is the most frequent bacterial opportunistic infection in persons with HIV/AIDS

Introduction

Mycobacterioses are infections caused by bacteria of the genus *Mycobacterium*, rod-shaped aerobic or microaerophilic bacteria that are Gram-positive, acid-fast members of the order Actinomycetales and family Mycobacteriaceae. They are spread throughout the environment, particularly in water reservoirs. The genus *Mycobacterium* contains more than 174 species and 13 subspecies, including pathogenic, opportunistic, and nonpathogenic species, which are separated into three major groups, *M. tuberculosis* complex (MTC), *M. leprae*, and mycobacteria other than MTC and *M. leprae*, collectively referred to as nontuberculous mycobacteria (NTM). NTM are acid-fast bacilli (AFB) commonly found in potable water. NTM include both saprophytic and opportunistic organisms. Many NTM are of low pathogenicity, and some form of host impairment is necessary to enhance clinical disease. The MTC causes tuberculosis (TB) and *M. leprae* causes leprosy, whereas NTM can cause mycobacteriosis [1–4].

The MTC includes *M. tuberculosis*, *M. bovis*, *M. bovis BCG*, *M. africanum*, *M. caprae*, *M. microti*, *M. pinnipedii*, *M. canettii*, and *M. mungi*. The species of this complex are obligate pathogenic mycobacteria; they cannot survive in the environment for long periods and therefore can cause infection in humans and/or animals. *M. tuberculosis*, the most prominent member of the MTC, is an obligate human pathogen and the causative agent of TB, which remains one of the leading global public health problems [1–3].

Runyon, in 1959, was the first to propose a classification for NTM, based on rate of growth in vitro and in pigment production, dependent or not on exposure to light. Two classifications were developed according to these criteria: (1) slow-growing mycobacteria (groups I–III), which require 2–3 weeks of incubation; and (2) rapid growers (group IV), which have the ability to grow in 3–5 days. The slow growers include three groups: group I, the mycobacteria photo-chromogens, which produce pigment after exposure to light; group II, the mycobacteria scotochromogens, which produce pigment in both the presence and absence of light; and group III, the mycobacteria nonchromogens, which are unable to produce pigment [13] (Table 7.1).

Owing to the complexity of the Runyon classification and its infrequent use in medical practice, the Kazda classification of mycobacteria is more widely used. Kazda used the pathogenicity of mycobacteria in humans and cataloged them into three groups: obligate pathogenic mycobacteria, potentially pathogenic mycobacteria, and rarely pathogenic mycobacteria. The obligate pathogenic mycobacteria include MTC and *M. leprae*. Those classified as potentially pathogenic and rarely pathogenic mycobacteria are termed NTM [1, 2] (Table 7.2).

Table 7.1 Nontuberculous mycobacteria that cause cutaneous diseases [1]

Epidemiology

The genus *Mycobacterium* comprises more than 174 species and 13 subspecies, including MTC and *M. leprae* (obligate pathogenic mycobacteria), and NTM (potentially pathogenic mycobacteria and rarely pathogenic mycobacteria) [1, 4]. NTM are generally considered to be environmental saprophytes widely distributed in nature, and can be found in numerous niches including soil, water, wild and domestic animals, fish, dust, and family and hospital settings. Mycobacteria are widespread in the environment, particularly in aquatic reservoirs. The literature includes reports of infections by *Mycobacterium abscessus* after mesotherapy, acupuncture, tattooing, insulin injections, and surgical procedures, and in patients with diabetes [5–8]. Worldwide, pulmonary disease caused by NTM seems to be increasing. Nevertheless, accurate data to support this assumption are difficult to produce. NTM disease is not a reportable condition in most countries, and is therefore not considered a public health concern. However, the organisms are ubiquitous in the environment, and substantial evidence shows that the environmental niche for *Mycobacterium intracellulare* (the most common pulmonary pathogen) is in biofilms lining suburban water pipes. The *Mycobacterium avium* complex (MAC) includes both *M. avium* and *M. intracellulare* [9–13]. Conversely to *M. tuberculosis*, for which no environmental reservoir exists, NTM are ubiquitous organisms and are readily isolated from environmental sources, including soil as well as both natural and artificial water systems [1, 3, 5, 10]. Many NTM pathogens have been isolated from drinking water. Some clinicians believe that the condition should be classified as an environmental health concern [10]. NTM can be isolated from both natural and man-made environments. Numerous studies have identified various NTM in municipal water systems as well as in hospital water systems and storage tanks. *Mycobacterium fortuitum* is the most common of the rapidly growing mycobacteria (RGM) encountered in clinical practice or in clinical microbiology laboratories [11–13]. *Mycobacterium marinum* is also considered the primary cause of mycobacteriosis in fish in aquariums, aquaculture, and natural settings. *M. marinum* can remain viable in the environment (soil and water) for 2 years. The ability of NTM to form biofilms at fluid–surface interfaces (e.g., interior surfaces of water pipes) contributes to the organisms' resistance to chemical inactivation and provides a microenvironment for growth and proliferation [1, 7, 14–18]. *Mycobacterium ulcerans* is a slow-growing acid-fast bacillus that causes a cutaneous infection known as Buruli ulcer (BU), now considered the third most common mycobacterial infection in immunocompetent humans. BU is prevalent in tropical countries, with prominent foci in West Africa, Central Africa, and the Western Pacific. Cases have also been reported from Asia and the Americas [14]. The true incidence and prevalence of MAC infection worldwide is unknown. The most common nontuberculous species causing human disease in the United States are the slowly growing species of MAC and *Mycobacterium kansasii* and the rapidly growing species *M. abscessus*. Prior to improved combination therapy for human immunodeficiency virus (HIV) infection, between 25% and 50% of acquired immune deficiency syndrome (AIDS) patients in the United States were infected with MAC, and proportions were similar in other parts of the developed world. Since the introduction of potent antiretroviral therapies, these proportions have been reduced considerably in the developed world [11–13].

Etiopathogenesis

NTM are ubiquitous organisms that cause diverse types of infectious disease in human organs, including lung, lymphatic, disseminated, skin, soft tissue, and bone disease. NTM are *Mycobacterium* species that differ from MTC. NTM are widely distributed in the natural environment but may be important pathogens in immune-compromised individuals, such as persons who have HIV or AIDS, patients with congenital and chronic degenerative diseases, and females who have chronic difficulty with expectoration. Progressive lung disease and

extrapulmonary localizations such as skin and soft tissue infections, lymphadenitis, and dissemination are clinically recognized forms, although there is no evidence of animal-to-human and human-to-human transmission. The four most common forms of human diseases associated with NTM are (a) pulmonary disease in adults; (b) cervical lymph node disease in children; (c) skin, soft tissue, and bone infections; and (d) disseminated disease in immunocompromised patients. NTM can colonize patients in healthcare facilities through consumption of contaminated water or ice or through inhalation of aerosols. Colonization following NTM exposure, particularly of the respiratory tract, occurs when a patient's local defense mechanisms are impaired [13, 18–25].

Several reports have suggested that the incidence of nontuberculous mycobacterial lung disease (NTM-LD) has recently been increasing. Although *Mycobacterium* species vary significantly by geographic region, MAC has been reported as the dominant species in NTM-LD. In Japan, *M. avium* is most commonly isolated from the respiratory tract, followed by *M. intracellulare* [9, 24–26]. *M. kansasii* is considered the most virulent of the NTM; it is the second most frequent NTM in patients with AIDS, being surpassed only by MAC [26, 27]. *M. fortuitum* is a rapidly growing NTM, often acquired from environmental sources such as soil and water. It is considered an opportunistic pathogen often associated with trauma, surgical procedures, or immunodeficiency. Skin and soft tissue infection usually is a consequence of direct inoculation. Although several mycobacterial organisms have been associated with skin lesions, only *M. fortuitum/chelonae/abscessus* (Group IV, rapid growers) and *M. marinum* are common pathogens [28, 29]. In the past, human outbreaks of *M. marinum* were sporadic and most commonly associated with contaminated swimming pools. In the last decade there has been a small but steady increase in the frequency of *M. marinum* infections. *M. marinum*

is ubiquitous and is found worldwide in bodies of fresh water, brackish water, and salt water. In humans, breaks in the skin serve as an entry point for the organism during contact with contaminated water sources or infected fish [1, 7, 18]. The infections caused by NTM are clinically indistinguishable from those caused by *M. tuberculosis*, although the therapeutic regimen differs between the MTC and NTM, even among different species of NTM [24–26, 30].

Clinical Presentation

NTM occur in the presence or absence of immunosuppression, although they are more frequent in the former situation. The immune status of the host, the type of mycobacteria, and the entry points influence the clinical presentation. The infection is usually localized in immunocompetent individuals with one or multiple entry points, such as via tattooing, mesotherapy, or acupuncture, while it is usually widespread in immunocompromised individuals.

In broad terms, NTM can cause four clinical syndromes in humans:

I. Pulmonary disease. Particularly in older persons, caused by MAC and *M. kansasii*. Lung disease can be caused by other species: *M. abscessus*, *M. fortuitum*, *M. xenopi*, *M. malmoense*, *M. szulgai*, and *M. simiae.*

II. Superficial lymphadenitis. In children, caused mostly by MAC, *M. scrofulaceum*, and, in northern Europe, *M. malmoense* and *M. haemophilum.*

III. Disseminated disease. In immunocompromised patients it is mostly caused by MAC, but also by *M. abscessus*, *M. fortuitum*, and *M. chelonae* (RGM).

IV. Skin disease and soft tissue infection (SSTI). Frequently as a consequence of direct inoculation by *M. marinum* and *M. ulcerans* (BU). Surgical site infection can be caused by RGM species [31–34].

Nontuberculous Mycobacteria of Dermatologic Interest

Mycobacterium marinum

M. marinum is the most common atypical mycobacteria (NTM) that causes opportunistic infection in humans. After an average incubation period of 2–3 weeks, the initial lesion develops. This is either a solitary nodule or pustule that may break down to form an ulcer or abscess, which can become a verrucous plaque. This lesion develops the initial injury site. *M. marinum* can cause superficial infections and localized invasive infections in humans. It can cause skin lesions which are single, papulonodular lesions, confined to an extremity, or may resemble cutaneous sporotrichosis. Deeper infection can occur as a result of direct extension of cutaneous infection and can lead to tenosynovitis, bursitis, arthritis, and osteomyelitis. Disseminated infections and visceral involvements have been reported in immunocompromised patients [35]. Lesions are most common on the elbows, knees, and feet of swimmers, and dominant hand and fingers of fish fanciers. However, nowadays, because of chlorination disinfection of pool water, *M. marinum* infection rarely occurs [36].

Mycobacterium fortuitum, M. abscessus, M. chelonae, M. smegmatis (RGM)

These species of RGM are capable of producing various diseases in humans ranging from cutaneous infection to disseminated infection; hematogenously disseminated infection is usually seen only in immunocompromised hosts [37]. The majority of infections are due to accidental inoculation from trauma, surgery, injection, or cannulation. The clinical presentation can be nonspecific, so a high index of suspicion is necessary for diagnosis. Cutaneous disease seems to follow patterns. In immunocompetent individuals an abscess is formed at the location of traumatic injury. In immunocompromised hosts (due to organ transplantation, rheumatoid arthritis, renal failure, or autoimmune disorders), patients present with disseminated dis-ease with multiple subcutaneous nodular lesions, cervical lymphadenitis, keratitis, and endocarditis (Figs. 7.1, 7.2, and 7.3). *M. chelonae* is strongly associated with concomitant corticosteroid therapy [34, 38].
Fig. 7.1   *M. abscessus* in renal transplant

Fig. 7.2   *M. abscessus* in renal transplant

Fig. 7.3   *M. abscessus* in renal transplant

The ***M. fortuitum* group** is responsible for 60% of community-acquired localized cutaneous infection cause by RGM, but is a rare cause of pulmonary disease. It accounts for the majority of nosocomial cases. Most cases present with a single lesion, usually a single subcutaneous nodule located at a site of traumatic injury, surgery, tattooing, mesotherapy, or acupuncture (Figs. 7.4 and 7.5). Disseminated disease has been documented in immunocompromised patients, particularly HIV/AIDS patients. In this population, infection due to *M. fortuitum* can present with lymphadenopathy in the absence of skin lesions [39, 40].

Fig. 7.5 *M. fortuitum* after mesotherapy

The ***M. chelonae/abscessus* group** is responsible for 95% of disseminated cutaneous infections caused by RGM and can also cause chronic lung disease.

M. chelonae

The classic cutaneous presentation is disseminated disease with multiple lesions in the form of tender, erythematous, draining nodules. Lesions are the most commonly seen on the distal parts of the limbs or in a sporotrichoid pattern. Some patients present with a chronic, nonhealing cellulitis or skin ulcers, usually painful and slowly spreading [41]. They are not normally accompanied by poor general condition or involvement of internal organs [42].

M. abscessus **Group**

Although known about 40 years ago, it was only in 1992 that *M. abscessus* was separated from *M. chelonae* and recognized as pathogen responsible for a wide spectrum of soft tissue infections (after trauma or surgery), pulmonary infections, and disseminated disease in immunocompromised patients. There are reports of infections by *M. abscessus* after mesotherapy, acupuncture, tattooing, insulin injections in diabetic patients, and other surgical procedures [8, 43, 44]. In immunocompetent individuals the initial presentation includes the formation of a tender, fluctuant, subcutaneous abscess at the inoculation site. Other presentations include ulcerations, draining sinuses, or nodules. The

Fig. 7.4 *M. fortuitum* in locale of traumatic injury

primary lesion is often followed by a sporotrichoid appearance of ascending lymphadenitis. In immunocompromised hosts, *M. abscessus* can cause disseminated disease. Patients present with systemic symptoms and often have multiple, red to violaceous subcutaneous nodules, and lymphadenopathy. *M. massiliense* (a subspecies of the *M. abscessus* complex) was identified as causative agent of surgical site infection after cesarean section [45]. Infection that involves the *M. smegmatis* group has included cellulitis, localized abscesses, and osteomyelitis after trauma.

Mycobacterium ulcerans

The main virulence factor of *M. ulcerans* is mycolactone toxin that causes extensive necrosis and local immunosuppression [46]. The disease can progress with minimal pain or fever. Infection with this agent leads to extensive destruction of the tissues with the formation of large ulcers particularly on exposed parts of the body, such as the limbs, head, and neck (BU) [47]. The disease typically begins as a painless small nodule (less than 5 cm in diameter). Other possible clinical presentations include papules, plaques, and subcutaneous edema. While the extremities are most often involved, other less affected areas are the head, neck, trunk, and genital area (Fig. 7.6). After a few days to weeks, the initial ulcer lesion develops indeterminate edges, progressing slowly and painlessly (pain may mean secondary infection). Osteomyelitis can occur in 15% of cases [48]. Healing of *M. ulcerans* lesions may occur spontaneously by secondary intention after sloughing of the epidermis and subcutaneous fat with later re-epithelialization. Scarring often leads to contractures, subluxation of joints, disuse atrophy, and distal lymphedema. Over many years, these scars may develop into squamous cell carcinoma (Marjolin's ulcer). Patients with HIV are not at increased risk of infection with *M. ulcerans* [49].

Mycobacterium avium-intracellulare Complex

MAC remains the most frequent bacterial opportunistic infection in persons with AIDS and typi-

Fig. 7.6 Ulcer with undermined edges resembling leishmaniasis in atypical mycobacteriosis due to *Mycobacterium ulcerans* (Buruli ulcer) (Courtesy, Francisco Almeida, MD)

cally causes disseminated disease in the setting of advanced immunosuppression [50]. In these patients, immune reconstitution inflammatory syndrome (IRIS), a frequent complication of MAC disease, most commonly presents with fever and lymphadenitis after the CD4 count increases in response to antiretroviral therapy (ART) [51].

In patients with AIDS who are not on ART, MAC disease typically is a disseminated, multi-organ infection. Early symptoms may be minimal and can precede detectable mycobacteremia by several weeks. Symptoms include fever, night sweats, weight loss, fatigue, diarrhea, and abdominal pain. Nowadays, disseminated MAC is becoming more common

in patients receiving immunosuppressive medications [52]. Localized manifestations of MAC disease have been reported most often in patients who are receiving and have responded to ART, and may also be manifestations of IRIS [51, 52].

In immunocompetent hosts, infection usually occurs in patients with predisposing lung conditions (silicosis, cystic fibrosis). Chronic pulmonary infection is the most common form of human disease (similar to tuberculosis). Osteomyelitis and granulomatous tenosynovitis have both been reported, and MAC is an important cause of cervical lymphadenitis in children. Involvement of the skin is uncommon, but can occur following traumatic skin inoculation in cervical lymphadenitis. Skin lesions are of variable appearance and include multiple ulcers, nodules, ulcerated nodules, abscesses, painless nodules, and plaques [53].

Mycobacterium kansasii

This bacterium typically causes pulmonary disease resembling tuberculosis. It may also cause superficial cervical lymphadenopathy in young children, meningitis, tendonitis, synovitis, tenosynovitis, arthritis, osteomyelitis, or carpal tunnel syndrome [54]. Primary skin lesions have been reported in patients exposed to contaminated water, particularly after local trauma. Disseminated disease can occur in immunocompromised patients (*M. kansasii* is the second most frequent cause of disseminated mycobacteriosis in AIDS patients after MAC), but in immunocompetent patients typically the disease is localized, indolent, and confined to skin. The lesions may be present in sporotricoid distribution, as well as ulcers that do not heal, verrucous papules, papulopustules with necrotic centers, erythematous plaques, nodules, and cellulite [55].

Mycobacterium scrofulaceum

The name *M. scrofulaceum* derives from "scrofula," an infection of the cervical lymph nodes.

Generally it affects children. Local infections resulting from contamination during surgical procedures involving lymph nodes may occur. Submandibular and submaxillary nodes are usually involved, and the disease is often unilateral with few constitutional symptoms, and can resolve spontaneously [56]. Recently, however, isolating *M. scrofulaceum* in childhood lymphadenitis has become increasingly rare, while the incidence of other nontuberculous, environmental mycobacteria, especially *M. avium* and several newly identified species, has increased [57, 58]. Skin abscesses have been reported, as well as chronic ulcerative and nodular skin lesions and pulmonary infection in a patient with AIDS. However, intrathoracic disease and, more rarely, disseminated disease are reported in children [59].

Mycobacterium szulgai

M. szulgai is an uncommon mycobacterial pathogen of humans that causes pulmonary disease resembling the common type of *M. tuberculosis* infection, as well as extrapulmonary infections. It causes mainly pulmonary infection but can also affect osteoarticular system structures (bones, tendons, and bursa), lymph nodes, and skin. Skin lesions can be of various inflammatory patterns, nodules, and cellulite [60]. *M. szulgai* was reported in one case after a previous appendectomy in an immunocompetent patient with a mixed SSTI [61].

Mycobacterium haemophilum

M. haemophilum has emerged as an important human pathogen, causing mainly opportunistic infections in severely immunocompromised patients. It mainly affects AIDS patients (most cases) and organ transplant recipients. Immunocompromised adults may present different types of skin lesions such as plaques, nodules, and bluish-red pustules, unique and painful, which progress to abscess and ulceration. Lesions, which may be multiple, are found most commonly on the extremities, often over joints. The bacilli can cause contiguous septic arthritis,

osteomyelitis, and pneumonia. Healthy children, when infected, usually have cervical lymphadenitis, submandibular and perihilar [62]. Although cervical lymphadenitis has only been described so far in immunocompetent adults and children, one case in an immunocompromised adult was reported [63].

Other Species of Mycobacteria

The clinical importance of *M. malmoense*, *M. genavense*, and *M. xenopi* has been increasingly recognized throughout the world. They rarely cause disease in humans but are increasingly clinically significant. *M. xenopi* is usually considered a commensal, saprophyte, or environmental contaminant. Its pathogenicity is relatively low, and infection requires impairment of host immunity. Infection usually occurs in the lungs in patients with chronic obstructive pulmonary disease, chronic alcoholism, diabetes mellitus, and malignancies [64]. *M. malmoense* is the second most frequently isolated NTM in northern Europe but is rare in the far north. The most common site of

infection caused by this organism is the pulmonary system, particularly in patients with chronic lung disease. However, extrapulmonary infection within lymph nodes, joints, and tendon sheaths has been reported. Of the few cases of disseminated infection with *M. malmoense* that have been published, most were in patients with an underlying immunodeficiency. Primary cutaneous infections are rare, although skin involvement due to a widespread infection may occur [65]. *M. genavense* is recognized as a life-threatening pathogen in severely immunocompromised patients, mostly in those with AIDS. The majority of reported cases are disseminated. These patients present with symptoms similar to those of disseminated MAC infection and can include fever, abdominal pain, diarrhea, weight loss, lymphadenitis, hepatosplenomegaly, and progressive anemia, the bowel being the most affected organ. In healthy patients the symptoms can be nonspecific [66]. Other less commonly reported localizations are cutaneous, cerebral as a solitary lesion, and genital tract [67] (Table 7.3).

Table 7.3 Frequent agents according to population and clinical manifestation

Syndromes	Most affected population	Main agents involved
Pulmonary	Older person	MAC, *M. kansasii*, *M. abscessus*, *M. fortuitum*, *M. xenopi*, *M. malmoense*, *M. szulgai*, *M. simiae*
	Immunocompromised	
	Predisposing lung conditions – chronic obstructive pulmonary disease, bronchiectasis, pulmonary fibrosis, silicosis, cystic fibrosis, pulmonary tuberculosis sequelae	
Lymphadenitis	Children	MAC, *M. scrofulaceum*, *M. malmoense*, *M. Haemophilum*, *M. kansasii*
	Immunocompromised HIV/AIDS	
Disseminated disease	Several immunocompromised/AIDS	MAC, *M. kansasii*, *M. abscessus*, *M. fortuitum*, *M. chelonae*, *M. genavense*
Skin and soft tissue infections (SSTI)	Exposure to water/fish environments (*M. marinum* = fish-tank granuloma)	*M. marinum*, *M. ulcerans* (Buruli ulcer)
	Trauma	*M. abscessus*
	Surgical procedures	
	Surgical site infection	
Osteoarticular disease	Trauma	*M. fortuitum*, *M. abscessus*, *M. chelonae*, *M. marinum*, *M. ulcerans*, *M. szulgai*
	Continuous seeding	

Complementary Examinations

The diagnosis of NTM disease requires caution because the isolation from non-sterile clinical specimens can lead to contamination or transient colonization. Therefore, the clinical-laboratory correlation is extremely important for establishing the diagnosis of disease by NTM and for determining the therapeutic strategy. Biopsies should be collected aseptically and placed in sterile vials containing sterile distilled water or sterile saline solution of 0.9% (never formaldehyde). Transport to the laboratory should occur immediately, at room temperature. Shaved skin or dry superficial lesions have little value in diagnostic mycobacteriosis. Diagnosis can be given through the histopathology, smear, culture, and phenotypic identification, and by molecular biology for species detection and identification. Microscopic features are considered (morphology of the bacillus, cord factor detection) and macroscopic culture (pigmentation and morphology) [68] (Table 7.4).

Table 7.4 Complementary examinations for NTM

Microbiological diagnosis
(A) Investigation of acid-fast bacilli in stained smear
(B) Mycobacterial culture
(C) Phenotypic identification of the species
(a) Production of carotenoid pigments
(b) Growth time in culture
(c) Antimicrobial susceptibility testing (AST)
Molecular diagnosis
(A) Polymerase chain reaction (PCR)
Conventional or in-house PCR
Nested PCR
Real-time PCR
Multiplex PCR
PCR with hybridization
PCR in situ
(B) Identification of mycobacterial species (genotyping)
(a) DNA (genetics) probes
(b) Gene sequencing
Mycobacteria mobility shift assay (MMSA method) – (16S rRNA gene)
Polymorphism restriction analysis of hsp65 gene (PRA hsp65 method)
Histopathologic diagnosis

Microbiological Diagnosis

Investigation of Acid-Fast Bacilli in Stained Smear

The *smear is the direct* AFB, usually by Ziehl–Neelsen staining or one of its modifications, such as the Kinyoun stain, and is examined by routine light microscopy. All mycobacteria share the characteristic of acid-fastness. Its disadvantage is limited sensitivity, requiring 5000–10,000 bacilli per milliliter of sample to obtain a positive result, and moreover requires a skilled and experience microscopist [34, 68].

Mycobacterial Culture

The *culture* is the most sensitive method available for the bacteriological diagnosis of mycobacterial infections, detecting from 10 bacilli/ml in the sample. From the culture, it is also possible to identify the mycobacteria isolated and the completion of antimicrobial susceptibility testing (AST). For most of the mycobacteria, the optimum growth temperature ranges from 35 to 37 °C, except the ones that grow *M. ulcerans* (28–33 °C), *M. marinum* (31 °C), and *M. haemophilum* (30–32 °C). For growth, solid media, such as Lowenstein–Jensen (LJ) and Middlebrook 7H10 and 7H11, and liquid media, such as Kirchner or Middlebrook 7H9 broth, can be used. The *M. haemophilum* has the unique characteristic that differentiates it from all other species of the genus: it requires hemin or ferric ammonium citrate to grow in culture media [69]. The readings should be taken 48 h after seeding and incubation (to check if there is contamination) and, subsequently, every 7 days to 8 weeks to complete. As the time of bacterial growth varies from 2 to 6 weeks, culture has the disadvantage of the prolonged time required for the release of results. Therefore, semi-automatic and automated systems have been developed to reduce the time to results to 1–4 weeks. These systems utilize radiometric and/or colorimetric assays for the detection of CO_2 produced and O_2 consumed during bacterial growth. Cases of NTM infection are considered to present a sample with positive cultures from a sterile site or two or more samples with positive culture, with more than 10 colonies, from a non-sterile site [70].

Phenotypic Identification of the Species

The earliest discriminatory methods relied upon phenotypic characteristics, such as colony morphology, susceptibility to antituberculosis drugs, or mycobacterial phage typing. The usefulness of these methods is seriously limited by the phenotypic variability of mycobacteria. The biochemical and serological characteristics of NTM produced no success [3, 26, 71].

According to the phenotypic characteristics, the NTM can be classified based on the:

(a) *Production of carotenoid pigments*
  According to these criteria, mycobacteria *slow growers* (Groups I, II, and III) require 2–3 weeks of incubation and mycobacteria *rapid growers* (Group IV) have the ability to grow in 3–5 days.
(b) *Growth time* in culture
  This *method* depends on the rate of growth in vitro and in pigment production, dependent or not on exposure to light (Runyon 1959) [1–3]. RGM are considered those which develop visible colonies on solid media in less than 7 days (*M. fortuitum*, *M. chelonae*, *M. abscessus*) and slow growth (*M. marinum*, *M. kansasii*, *M. scrofulaceum*, MAC, *M. ulcerans*) those which develop visible colonies on solid media over 7 days. These time-consuming methods are being replaced with more rapid techniques, including molecular methods.
(c) *Antimicrobial susceptibility testing*
  AST for NTM may be performed to determine which antimicrobial drugs will be most effective in treating the infection [26]. The main limitations of the phenotypic method consist in the delay in obtaining results, the differentiation of difficulty of various species, and dubious results that can be displayed by some biochemical tests, besides being laborious. There are many methods that can be applied to the determination of the isolated species. Routinely strains identified as NTM are not applied, because there are few studies on the correlation of the results of in vitro AST and

clinical prognosis. The gold-standard method for AST of NTM is broth microdilution. The technique used is the MIC (minimum inhibitory concentration in liquid medium) and is only performed for some species: MAC, *M. kansasii*, *M. chelonae*, *M. abscessus*, and *M. fortuitum*. The MIC is expressed in μg/ml and is typically indexed to base 1 (e.g., 1, 2, 4, 8, 16, and 32 μg/ml). Routine AST of MAC isolates is recommended for clarithromycin only, which can be detected by a mutation in the 23S ribosomal macrolide binding, while *M. kansasii* isolate is recommended for rifampicin only. Both taxonomic identification and treatment of RGM should be with amikacin (*M. fortuitum*, *M abscessus*, and *M. chelonae*), imipenem (*M. fortuitum* only), doxycycline, the fluorinated quinolones, a sulfonamide or trimethoprim-sulfamethoxazole, cefoxitin, clarithromycin, linezolid, and tobramycin (*M. chelonae* only) [3, 26, 71].

Molecular Diagnosis

Owing to the recent increase in the isolation of new species and the availability of modern methods for species identification, conventional methods have become inadequate. Molecular identification has greatly aided the diagnosis of mycobacteriosis to its present speed and accuracy. However, the interpretation of results should always take into account the clinical data of the patient. Among the techniques used for diagnosis are those that promote the amplification of genetic material, such as the *polymerase chain reaction* (*PCR*) and its variations (e.g., conventional or in-house PCR, nested PCR, real-time PCR, and multiplex PCR). In addition, for the identification of mycobacterial species (*genotyping*) there are techniques that employ *DNA* (*genetic*) *probes* and *Gene* (*DNA*) *sequencing* from the PCR products, such as mycobacteria mobility shift assay (*MMSA method*) and polymorphism restriction analysis of hsp65 gene (*PRA hsp65 method*). These techniques include *specific nucleic acid probes*.

Polymerase Chain Reaction

The PCR technique is based on the enzymatic amplification of a specific DNA sequence. This reaction occurs in cycles, which consist of three steps: denaturation, pairing, and extension. In the case of mycobacteria, the amplified DNA sequence can be common to all bacteria of the genus or be specific to a species or complex. An example of the latter is the insertion of IS6110, most commonly used for sequence-specific amplification DNA of MTC. Most protocols use the IS6110 insertion repetitive sequence of 1350 base pairs present in the MTC species with different numbers of copies integrated into various chromosomal sites. By being present in multiple copies in the genome, this molecular target technique provides an increase in sensitivity, which represents an advantage over other targets. However, the disadvantage lies in the existence of *M. tuberculosis* isolates that have lost the IS6110 sequence, which has been observed mainly in Asia. When the amplified sequence is common to the genus, the diagnosis is *Mycobacterium* sp. In this case, the region of 16S ribosomal DNA (rDNA) is a key target identification to be highly conserved and includes differences in the specific nucleotide sequence of a group or species. For this reason, the amplified product can also be used for further molecular species identification of mycobacteria. PCR amplifies a 1027 bp highly conserved region of the 16S rRNA gene that is present in all mycobacteria. This method presents results comparable with those of the other molecular methods of identification with the advantage of being fast, identifying mycobacteria within 6 h of the culture. *M. ulcerans* has multiple copies of IS2404 (>200) in its genome, which is not observed in any other mycobacteria [72].

Identification of Mycobacterial Species (Genotyping)

(a) *DNA* (*genetics*) *probes*, such as the AccuProbe System (Gen-Probe, USA), INNO-LiPA Mycobacteria Assay (Innogenetics, Belgium), and the GenoType *Mycobacterium* Assay (Hain Lifescience, Germany), are methods of rapid species identification, and have been available for some time for identification of clinically important mycobacterial species, including MTC, MAC, *M. kansasii*, and *M. gordonae*. The tests are based on species-specific DNA probes that hybridize with rRNA released from bacteria. However, probes are not available for all pathogenic mycobacterial species, and those isolates must be identified by other methods. In addition, the MTC probe cannot differentiate between the members of this complex (*M. tuberculosis*, *M. bovis*, *M. bovis* BCG, *M. africanum*, and *M. microti*) [26, 73].

(b) *Gene sequencing* (PCR-based sequencing) has become the gold standard for identification of mycobacterial species. The method consists of PCR amplification of mycobacterial DNA with genus-specific primers and sequencing of the amplicons. The automation of sequence analysis is enabled by the introduction of commercial systems like the MicroSeq 500 16S rDNA Bacterial Sequencing Kit (PE Applied Biosystems, USA), in which a 500-bp sequence of the NTM is analyzed and compared with a commercially prepared database. The target most commonly used is the gene coding for the 16S ribosomal RNA. Mycobacterial species identification by the *MMSA* is based on microheterogeneities in nucleotide sequences of the 16S rRNA gene with PCR amplification of a 1027 bp highly conserved region of the 16S rRNA gene that is present in all mycobacteria. The MMSA method was designed for NTM and MTC species identification using PCR products from mycobacterial DNA coding for the 16S rRNA gene derived from culture to show specific heteroduplexes formed among different *Mycobacterium* species [26, 30, 73].

Several other target genes have been characterized for this purpose. In 1993 Telenti and colleagues described PCR followed by restriction endonuclease assay analysis, the *Polymorphism Restriction Analysis* (*PRA*) *of hsp65 gene* (*PRA hsp65 method*), which differentiates most NTM species, but not the MTC. This method is based on the amplification, by PCR, of a sequence fragment of 441 bp of the *heat shock protein*

gene of 65 kDa (hsp65) containing specific epitopes shared by various species of mycobacteria. The PRA method is relatively rapid, does not require viable organisms, and identifies many NTM species that are not identifiable by phenotypic or chemotaxonomic techniques alone. This method presents as main advantages its high specificity, the release of results in a few hours, and the fact that it requires only basic PCR and agarose gel electrophoresis equipment. However, sometimes species with PRA profiles not yet described in the literature are observed, while others have a shared profile for more than one species, or the same species may even present more of a restriction profile, facts that constitute limitations.[30, 73, 74].

Histopathologic Diagnosis

The most common causes of nontuberculous mycobacteria in SSTI are RGM species (*M. fortuitum*, *M. abscessus*, and *M. chelonae*), *M. marinum*, and *M. ulcerans.* The infiltrate tends to be deeper in immunosuppressed patients, involving the subcutaneous tissue (100%) with a more diffuse distribution and constant abscess

formation (Fig. 7.7). It can include dermal granulomas (occasionally with suppuration), stellate abscesses, sinus tracts, and acute and chronic inflammation [75–77]. AFB are seen in a minority of cases (±20%) [78]. These features are not pathognomonic. The predominant histopathologic findings may vary depending upon the host's immune status. In a review of biopsy specimens from 27 patients with NTM SSTI, granulomas were more common in specimens from immune-competent patients (18 specimens), whereas deep infiltrates into the subcutaneous tissue, abscess formation, and a foamy appearance of macrophages were more common in specimens from immune-compromised hosts (10 specimens from 9 patients). A marked granulomatous inflammatory reaction was observed in 83% of immunocompetent and in 60% of immunosuppressed patients [75]. Histopathologically, the most common findings were diffuse infiltration of mixed inflammatory cells and small vessel proliferation in the dermis (100%). Epidermal proliferation (71%) and dermal granuloma (71%) were also very common. Suppurative granuloma was found in 43% of the cases, and eosinophil infiltration was uncommon (14%), as was eosinophilic infiltra-
Fig. 7.7 Infectious complications in tattooing (*M. fortuitum*)

tion. The lesions disappear after a mean of 7 months (range, 1.5–12 months) with treatment by oral clarithromycin alone or in combination with other antimycobacterial agents. These clinical and histopathologic data should assist clinicians in the diagnosis of NTM. In patients with negative cultures and PCR, histopathology of tissue specimens demonstrating AFB or granulomas supports the diagnosis. However, the absence of these findings does not exclude NTM disease [75–77].

Differential Diagnosis

M. marinum differential diagnosis should include sporotrichosis, nocardiosis, and leishmaniasis. The tenossinovite can mimic rheumatoid arthritis. On the one hand, infection by *M. fortuitum*, in general, is characterized by the appearance of solitary abscess, but similar nodules in sporotrichosis, folliculitis, and cellulitis have also been described. On the other hand, *M. chelonae* or *M. abscessus* infection is characterized by the production of multiple cutaneous abscesses that can fistulize [78]. The differential diagnosis of BU should include leishmaniasis, basal cell carcinoma, squamous cell carcinoma, gangrenous pyoderma, Kaposi's sarcoma, cutaneous tuberculosis, leprosy, syphilis, tropical ulcers, necrotizing fasciitis, anthrax, noninfectious granulomatous disease, ischemic ulcers, diabetic ulcers, necrobiosis lipoidica, cutaneous lymphoma, and polyarteritis nodosa, among others [79]. The differential diagnosis of MAC should include pyoderma, folliculitis, other causes of panniculitis and ulcers, infective dimorphic fungus, lepromatous leprosy, and tuberculous skin. *M. scrofulaceum* infection should be distinguished from other causes of cervical lymphadenopathy, particularly of *M. tuberculosis* (scrofuloderma). However, *M. tuberculosis* usually affects the (previous) tonsils and cervical lymph nodes, while *M. scrofulaceum* typically affects the submandibular and submaxillary lymph nodes. Where conditions are sporotrichoid by default, there are differential diagnoses with other atypical mycobacteriosis [26, 76–79] (Table 7.5).

Table 7.5 Differential diagnosis of mycobacteriosis

M. marinum	Sporotrichosis, nocardiosis, leishmaniasis; tenossinovite can mimic rheumatoid arthritis
M. fortuitum, *M. abscessus*, *M. chelonae*	Nodules of sporotrichosis, folliculitis, cellulitis, solitary or multiple cutaneous abscesses
M. ulcerans (Buruli ulcer)	Leishmaniasis, basal cell carcinoma, squamous cell carcinoma, gangrenous pyoderma, Kaposi's sarcoma, cutaneous tuberculosis, leprosy, syphilis, tropical ulcers, necrotizing fasciitis, anthrax, noninfectious granulomatous disease, ischemic ulcers, diabetic ulcers, necrobiosis lipoidica, cutaneous lymphoma, polyarteritis nodosa, among others
M. avium-intracellulare complex (MAC)	Pyoderma, folliculitis, panniculitis, infection dimorphic fungus, tuberculosis, tuberculous skin, lepromatous leprosy, cryptococcal disease, aspergillosis, histoplasmosis
M. scrofulaceum	Other causes of cervical lymphadenopathy, scrofuloderma, sporotricoid conditions

Therapeutic Approach

Mycobacterium marinum

Because of a lack of clinical evidence, treatment must be individualized. Isolates of *M. marinum* are susceptible to clarithromycin, as well as sulfonamides, tetracyclines, rifampicin, and ethambutol. It is necessary to administer combination therapy with two or more drugs for significant cutaneous infections or disseminated disease. For severe infections, a combination of rifampicin and ethambutol seems to be the recommended regime. Monotherapy with clarithromycin, minocycline, doxycycline, ciprofloxacin, and trimethoprim-sulfamethoxazole is typically used for patients with localized, mild, and uncomplicated cutaneous disease. Ciprofloxacin is not recommended because some strains are resistant and monotherapy and carry the risk of mutational resistance. Recent studies have documented unexplained antibiotic resistance to several drugs, including rifampicin and doxycycline. Clarithromycin is currently regarded as the single best agent for first-line monotherapy, although equal success

has been achieved using minocycline and amikacin. The typical duration of therapy is 3–6 months for localized infection and 12 or more months for disseminated disease. Surgical treatment may be required if deep structures are involved. Cryotherapy is also frequently used as a first treatment, although there are effective therapeutic alternatives.

Mycobacterium fortuitum, Mycobacterium chelonae, and Mycobacterium abscessus (RGM)

The treatment generally involves macrolide (clarithromycin 1 g/day or azithromycin 250–500 mg/day) and intravenous agents. Management of these infections requires the use of antibiotic therapy, which is different from that used in the therapy of tuberculosis and other slowly growing NTM. In vitro studies have shown that these species have different susceptibility patterns: *M. abscessus* is usually susceptible to macrolides and cefoxitin, and resistant to quinolones; *M. chelonae* is susceptible to macrolides and resistant to quinolones and cefoxitin; and *M. fortuitum* is susceptible to quinolones and resistant to macrolides. *M. fortuitum* is more sensitive to antibiotics and its recurrence rate is greater than that of *M. abscessus* and *M. chelonae* [79].

Mycobacterium ulcerans

The WHO recommends multidrug therapy for 8 weeks with rifampicin and streptomycin. The recommended doses of rifampicin and streptomycin are: rifampicin, 10 mg/kg, oral, daily; streptomycin, 15 ml/kg, intramuscular, daily. The latter drug is contraindicated in pregnant women. In 2014, a group of BU scholars in Australia, with the approval of the Australasian Society for Infectious Diseases, published guidelines for the treatment of BU, in which they recommended oral rifampicin and clarithromycin or fluoroquinolones (moxifloxacin and ciprofloxacin) [72]. In advanced cases, surgery includes debridement and skin grafting. There are no guidelines thus far for surgery. The consensus among experts is that surgery should be performed after 4 weeks of antibiotic treatment.

Paradoxic reactions are a recently recognized phenomenon, whereby worsening of a BU lesion is seen during or long after antibiotic treatment. This is now known to be an inflammatory reaction against *M. ulcerans*, and pain and pus may be present. Treatment of paradoxical reactions requires prednisolone. In the past, some cases of paradoxical reactions might have been mistakenly diagnosed as recurrence or relapse [72].

Mycobacterium avium-intracellulare Complex

Treatment includes ethambutol and rifampicin and clarithromycin or azithromycin.

Mycobacterium haemophilum

Although the optimal therapy is still unknown, most successful regimens include clarithromycin, ciprofloxacin, rifampicin, and rifabutin, and surgical treatment should be considered in some cases of localized disease. In vitro, doxycycline and sulfonamides have shown variable susceptibility, and all isolates are resistant to ethambutol. For immunocompromised patients with disseminated or pulmonary infection, it is recommended to continue the established treatment until cultures remain negative for a year. However, the trend in immunocompetent patients is for a shorter treatment duration, between 4 and 12 months depending on age and type of disease.

Mycobacterium szulgai

Therapy with combination of antituberculosis medication based on in vitro susceptibilities for 4–6 months should be successful for extrapulmonary disease (Table 7.6):

Table 7.6 Treatment of the main nontuberculous mycobacteria species

Species	Chemotherapy	Dose	Duration
M. marinum	*Uncomplicated cutaneous disease*: clarithromycin or minocycline; or doxycycline; or ciprofloxacin; or trimethoprim-sulfamethoxazole	500 mg 2×/day or 100 mg 2×/day or 100 mg 2×/day or 500 mg 2× day or 160/800 2×/day	3–6 months
	Disseminated: minocycline + amikacin	100 mg 2×/day + 10–15 mg/kg/day	12 months
M. fortuitum *M. chelonae* *M. abscessus*	Clarithromycin or azithromycin + *Parenteral medications*: amikacin or cefoxitin or imipenem	1000 mg/day or 250–500 mg/day + (10–15 mg/kg/day (max 1 g/day, 5×/ week for 2 months and 2× week from the third month) or 200 mg/day or 30 mg/day/day	6 months
M. ulcerans (BU)	*Localized extensive* rifampicin + streptomycin or clarithromycin or *fluoroquinolones*: moxifloxacin or ciprofloxacin)	Surgery 10 mg/kg oral (max. 600 mg/ day) + 15 ml/kg intramuscular (max. 1 g/day,5× week for first two months and 2× week from the third month) or 500–1000 mg/day or 400 g/day or 500 mg 2× day	2–3 months
M. avium-intracellulare complex (MAC)	Rifampicin + clarithromycin or azithromycin + ethambutol	600 mg/day + 1000 mg/day or 500 mg/ day + 15 mg/kg/day	6–12 months
M. haemophilum	Rifampicin + clarithromycin + ciprofloxacin	600 mg/day + 1000 mg/day + 500 mg 2× day	
M. kansasii	Rifampicin + ethambutol + isoniazid	600 mg/day + 15 mg/kg/day + 5–10 mg/kg/day (max. 300 mg/day)	12 or 18 months with negative culture
M. szulgai	Rifampicin + ethambutol + clarithromycin	600 mg/day + 15 mg/kg/day + 1000 mg/day	6 months

Glossary

Buruli ulcer (BU) Is a disease affecting the skin, tissues, and in some cases the bones, caused by the environmental pathogen *Mycobacterium ulcerans*. Its mode of transmission is still elusive and controversial. Infection with this agent leads to extensive destruction of the tissues with the formation of large ulcers particularly on exposed parts of the body, such as the limbs, head, and neck.

Immune reconstitution inflammatory syndrome (IRIS) Is an inflammatory reaction resulting from restored immunity to specific infectious or non-infectious antigens. It is a frequent complication of MAC disease, most commonly presenting with fever and lymphadenitis after the CD4 count increases in response to antiretroviral therapy (ART), in persons with AIDS. Localized manifestations of MAC disease have been reported most often in patients who are receiving and have responded to ART.

***Mycobacterium avium-intracellulare* complex (MAC)** Includes both *M. avium* and *M. intracellulare*, and represent the most frequent bacterial opportunistic infection in persons with HIV/AIDS.

Marjolin's ulcer Consists of the malignant transformation of a chronic ulcerative lesion. Over many years, these scars may develop into squamous cell carcinoma.

Sexually Transmitted Diseases

8

Walter Belda Jr.

Key Points Summary
- STDs are diseases transmitted from person to person, with more than 30 cataloged, including viruses, bacteria, and parasites.
- Unprotected sex increases the risk for STDs
- STDs represent a major problem in public health, causing chronic diseases, AIDS, pregnancy complications, infertility, cervical cancer, and death.

Introduction

Nowadays, sexually transmitted diseases (STDs, or sexually transmitted infections, STIs) comprise the most common group of infectious diseases reported in most countries. They maintain a high incidence despite some fluctuation. In an attempt to classify STDs, Pereira and Serruya [1], in 1982, and subsequently Belda [2], in 1999, classified them as described in Box 8.1.

Box 8.1 Update classification of STDs

Essentially transmitted through sexual contact	Frequently transmitted through sexual contact	Occasionally transmitted through sexual contact
Syphilis	Donovanosis	Molluscum contagiosum
Gonorrhea	Non-gonococcal urethritis	Pediculosis
Chancroid	Genital herpes simplex	Scabies
Lympho-granuloma venereum	Genital warts (condyloma acuminatum)	Shigellosis
	Genital candidiasis	Amebiasis
	Hepatitis B	Hepatitis C
	HIV	Emergent virus
	Trichomoniasis	

In this chapter the *essential STDs, genital warts*, and *donovanosis* are addressed.

Syphilis

A chronic infectious disease that is sexually transmitted, and occasionally of transplacental transmission, caused by *Treponema pallidum*, syphilis is characterized by long periods of medical silence and a clinical ability to affect multiple organ systems, producing skin, mucous membranes, cardiovascular, and nervous system lesions.

Epidemiology

It is a universal disease that affects all social classes, with young people being the most affected, especially those between 15 and 24 years of age, because of their more intense sexual activity; groups of lower sociocultural and economic conditions because they have a greater tendency toward promiscuity; and itinerant groups (sailors, tourists, and military troops) [4, 5]. It progresses in waves that fluctuate because of several causes. The reasons for its upsurge are manifold, being of social and medical origins. Today, sexual life begins earlier. In addition, improved living conditions provide a more prolonged period of sexual activity, increasing the number of individuals at risk of infection. Tourism and professional trips favor the appearance of cases whose contacts of infection cannot be tracked.

Etiopathogenesis

T. pallidum is a thin microorganism devoid of cell membrane, with regular spirals numbering no more than 12. It has rotational, bending, contraction, and translational movements. It reproduces longitudinally by binary fission every 32–36 h. It is very heat-labile and difficult to be cultured [1–3], and should be distinguished from saprophytic treponemas of the oral cavity (*Treponema macrodentium* and *Treponema microdentium*) and preputial area (*Treponema calligra* and *Treponema minutum*), and from genital borrelias. Under dark-field microscopy *T. pallidum* has more spirals, is thinner, does not have deformities

along its displacement, and has slower movements in relation to saprophytic treponemas. Its antigenic constitution is complex, with surface antigens and others inside it.

The infection stimulates humoral and cellular responses, with cellular immunity being established only in a late, latent, or asymptomatic stage [6]. Regarding humoral immunity, the treponemal and non-treponemal antibodies that are detected at high levels in the active stages of the disease do little to protect the host. The immobilizins help minimize the spread of disease and facilitate the destruction of treponemas through defensive mechanisms; however, no correlation exists between immunity and antilipid antibodies since their titrations are very high in recent infections, which are more widespread, and therefore resistance to infection is not developed. In contrast, titrations are low in late forms, when immunity to reinfection is high [3, 6].

The infection is transmitted by direct contact with open lesions or intact mucous membranes, transfusion of contaminated blood, and by transplacental transmission in congenital syphilis. Treponema is able to penetrate intact skin and mucous membranes. At the site of inoculation it multiplies rapidly, and reaches the regional lymph nodes through the lymphatic route, where it also multiplies quickly. Its immediate dissemination also occurs through the blood. In the lymphatic/hematogenous route it rapidly invades the whole body, so that even when the symptomatology is local the infection becomes widespread in a few hours [3, 7]. The first manifestation of acquired syphilis is the syphilitic chancre. The incubation period ranges from 2 to 4 weeks. After about 6 weeks, generalized manifestations of syphilis arise, which constitute the so-called secondary period. This period lasts about 2 years, and is characterized by the successive appearance and disappearance of different, somewhat generalized features. Following this period the clinical manifestations fully disappear, and the so-called syphilitic latency begins. The patient can remain in this state indefinitely. In about 30% of cases, and after a period of 10–30 years, the patient can pass through the tertiary stage, characterized by cutaneous/visceral manifestations, particularly of

a nervous and cardiovascular nature. Currently acquired syphilis is classified as recent and late, considering a year of progression as the boundary between these two stages. Recent acquired syphilis includes primary, secondary, and latent recent syphilis. Late syphilis includes the so-called skin tertiary, cardiovascular, nervous, and latent late syphilis [3, 4, 7].

Clinical Presentation

Primary Syphilis

Primary syphilis is characterized by the appearance of a formerly ulcerated, round or oval, granulomatous lesion with a clean and rosy background on the inoculation point, which emanates transparent *Treponema*-rich serosity, with no adjacent inflammatory phenomena and with borders gently descending to the bottom. The lesion is often single (Fig. 8.1) and painless, even when handled, but due to intense inflammatory infiltrate it presents with hard consistency and is cartilaginous upon palpation. In men it most often affects the balanopreputial sulcus, frenulum, and navicular fossa. In women it is mainly suppurative, painless, and unaccompanied by inflammatory phenomena. In general the nodes are hard, painless, and not adhered to superficial or deep planes. Evolutionarily, the hard chancre lesions tend to heal spontaneously, even with no treatment, around the fourth week after appearance, and generally without scarring [3, 7, 8].

Secondary Syphilis

Manifestations of secondary syphilis appear on average 6–8 weeks after the appearance of the hard chancre. Polymorphic lesions at this stage represent tissue reaction to the presence of *Treponema*, transmitted by lymphatic and/or hematogenous routes. The intensity of tissue reactions will occur depending on the immune status of the host, with which the variations of the various common clinical conditions will also appear. The syphilitic roseola (Fig. 8.2) is the first manifestation to appear, characterized by erythematous, lenticular, oval, or circular macules of inaccurate, isolated, or confluent limits, surrounded by mild scaling. Sometimes these macules infiltrate, gradually becoming papular (papular syphilide). These lesions affect mainly the trunk and roots of limbs, and particularly the palmoplantar regions (Fig. 8.3). In the late secondary period there is a tendency to clustering and location of the lesions, with the genital, anal, and axillary regions and submammary folds developing papular lesions that form papular, secreting plates rich in treponemas (flat condyloma). The lesions in the oral cavity (tongue and lips) have a whitish maceration area on an eroded base. Following the skin and mucosal lesions, so-called "patchy alopecia" may occur, particularly in the parietal and temporal regions; there may be widespread micropolyadenopathy, splenomegaly, hepatitis, nephrotic syndrome, iritis, or iridocyclitis [3, 4, 8, 9].

Fig. 8.1 Hard chancre on the penis

Fig. 8.2 Syphilitic roseola

Fig. 8.3 Sole lesion in secondary syphilis

Early Malignant Syphilis

This rare variant of recent syphilis is considered a variant that affects individuals in poor general condition, who are debilitated due to malnutrition or other pathologies. Today it is believed to be an expression of an immune response to *Treponema pallidum* whereby there is tissue destruction and vasculitis obliterans of medium-caliber vessels. Clinically the lesions are more destructive, are papulopustular in the beginning, and later evolve to clearly defined ulcerous-necrotic lesions covered by rupioid crusts (Fig. 8.4). They affect mainly the face and scalp and are followed by fever, headache, arthralgia, and other systemic manifestations [3, 8].

Late Syphilis

Symptoms of late syphilis arise after varying periods of latency, ranging from 10 to 30 years.

1. Skin lesions: usually arise 2–7 years after secondary nodular or nodulo-ulcerated, clustered lesions that form serpiginous patches with polycyclic halo. When they affect mucous membranes, the lesions can produce changes on the tongue (chronic interstitial glossitis),

Fig. 8.4 Early malignant syphilis

palatal perforation, and destruction of the nasal septum [3].

2. Cardiovascular: the impairment generally occurs 10–30 years after the onset of infection. It is most common in men and black individuals. The most common conditions are aortitis, aortic valve insufficiency, aortic aneurysm, and orificial coronary stenosis, which result in angina [3].

3. Nervous: impairment is found on average 30 years after the start of infection. The condition can be asymptomatic or reveal symptoms of acute syphilitic meningitis, spastic Erb's palsy, aphasia, hemiplegia, tabes dorsalis, and paralytic dementia [10].

4. Other systems: there may be impairment of bones, liver, eyes, gastrointestinal tract, and testes.

Box 8.2 lists the principal clinical manifestations of syphilis.

Box 8.2 Clinical manifestations of syphilis

Stage	Manifestations
Primary	Painless genital ulcer of clear background and hard base
	Noninflammatory regional lymphadenopathy
Secondary	Syphilitic roseola, mucous patches, flat condyloma
	Patchy alopecia, generalized micropolyadenopathy, general symptoms
Tertiary	Cutaneous gummas, interstitial glossitis, aortitis, aortic insufficiency, angina, aphasias and hemiplegias, tabes dorsalis, paralytic dementia

Complementary Examinations

Direct Demonstration of the Etiologic Agent

1. Dark-field examination: its maximum indication lies in primary syphilis. It can be used in papular-erosive lesions of secondary syphilis, but with less positivity due to secondary contamination that such lesions often present and due to the existence of saprophytic treponemas. The possibility of negative results may be related to systemic or local treponemicide medication, nonsyphilitic process, or chancre of more than 3 weeks' evolution. The search can also be performed with silver-stained material by the Giemsa method, China ink, and Levaditti's method [3, 8, 11]. All staining methods are inferior to dark field.

Serologic Tests

(A) Non-treponemal tests detect the presence of nonspecific antibodies in serum. They appear 3–5 weeks after the appearance of protosyphiloma. There are basically two types of test: flocculation (VDRL) and complement fixation test (Wasserman).

(B) Treponemal tests: specific tests based on the detection of antibodies against *T. pallidum*. These tests include direct immunofluorescence (FTA-ABS), *T. pallidum* immobilization (TPI), hemagglutination assay (TPHA), and enzyme immunoassay (EIA) methods [3, 12].

Diagnosis (Box 8.3)

Box 8.3 Types of diagnosis in syphilis patients

Clinical presentation (syndromic diagnosis)

Clinical presentation plus laboratorial examinations (etiologic diagnosis)

Laboratory examinations (diagnosis of latent disease)

Differential Diagnosis

Syphilis can occur concomitantly with other STDs or be confused with them or with similar conditions. Box 8.4 shows the main diseases to be differentiated from acquired syphilis cases.

Box 8.4 Differential diagnosis of acquired syphilis

Stage	Pathologies
Primary	Genital herpes simplex, chancroid, donovanosis, lymphogranuloma venereum, Behçet syndrome, leishmaniasis, genital traumatic lesions, other genital ulcers
Secondary	Viral and drug rashes, Gibert's pityriasis rosea, lichen planus, lymphomas, hanseniasis, sarcoidosis, mucous lesions of pemphigus vulgaris
Tertiary	Malignant tumors, sarcoidosis, tuberculosis, indurated erythema, other neurologic conditions

Therapeutic Approach

T. pallidum is one of the known organisms most sensitive to penicillin, with lesions disappearing in 12–18 h after systemic administration. Thus, the recommended dosage for the treatment of early syphilis is benzathine penicillin 2.4 million IU intramuscularly, repeated after 1 week. In late syphilis the recommended dose is 7.2 million IU intramuscularly given in three doses of 2.4 million IU per week. In cases of allergy to penicillin, the following is recommended: doxycycline 200 mg/day [13, 14] for 15–30 days; erythromycin 2 g/day for 15–30 days; ceftriaxone 1 g/day intramuscularly for 10 days [3, 8]. Clinical and serologic follow-up of syphilis patients is extremely important, especially when they are coinfected with HIV or when using regimens other than penicillin, and serological tests should be carried out at 3, 6, 9, and 12 months after therapy. (see chapter 2).

Chancroid

Epidemiology

Chancroid is a cosmopolitan disease whose prevalence has declined in the United States, with outbreaks in industrialized countries, but with a higher prevalence in Africa, the Middle East, and tropical and subtropical regions of South America, where its incidence may exceed that of syphilis as the cause of genital ulceration. Its occurrence is higher in males.

Etiopathogenesis

Acute infection characterized by genital/anal ulcers that may occasionally occur on the lips, mouth, tongue and oropharynx, with pus and regional invasion of nodes, with likely development of regional, painful adenitis with no systemic manifestations. It results from sexual transmission and is caused by a Gram-negative bacillus called *Haemophilus ducreyi* [3, 8]. It has high infectivity and low pathogenicity. The agent is a Gram-negative, intracellular, facultative anaerobic bacillus of rounded ends and devoid of capsule or motility. It is arranged in single or double chains, in arrangements that resemble a "train track" within polymorphonuclear neutrophils. *H. ducreyi* does not penetrate the intact skin, requiring the presence of solution of continuity for penetration [1, 15].

Clinical Presentation

Chancroid has a short incubation period, of about 2–5 days, after which the first signs of the disease arise, reflected by the presence of a small papule or a vesicopustular lesion that rapidly progresses into an ulcerous, shallow lesion of soft basis, and irregular, undermined, cleanly cut borders (Fig. 8.5), surrounded by an erythematosus live halo and covered with necrotic, purulent, and foul-smelling exudate (Fig. 8.6). The lesions are painful and present in varied numbers and sizes because of its characteristic autoinoculation. Clinically, chancroid can be classified as herpetic, with vesicular or vesicopustular lesions, vesicobullous, follicular, and phagedemic. In men the lesions are more frequently located near the frenulum, balanopreputial sulcus, and glans. In women, disseminated lesions are common, extending from the anus to the vulva. Occasionally the women may be asymptomatic when the ulcers occur in the vaginal wall or cervix. In 50% of cases, uni- or bilateral ganglia infarction occurs, with two-thirds of these progressing to floating

Fig. 8.5 Chancroid with multiple lesions on the penis

Fig. 8.6   Chancroid lesion with erythematous halo

and fistulization, with drainage of purulent material through a single fistula, which can aid in the differential diagnosis with lymphogranuloma venereum. About 5–30% of cases of chancroid can be associated with hard chancre of syphilis, causing ulcerated lesions with clinical features that are common to both diseases (Rollet mixed cancer). Chancroid lesions do not progress to spontaneous healing, and the ulcers of untreated patients can coalesce and lead to the formation of giant ulcerative lesions with deformities and impairment of deep tissue planes, giving rise to local fistulas. After treatment the lesions usually leave small scars after healing [15, 16].

Complementary Examinations (Box 8.5)

Examinations are conducted mainly through direct observation of the agent, whereby after collection of purulent material from the ulcer base, Gram staining is performed for observation of bacilli, which are Gram negative and arranged in a "single line" or "palisade" inside polymorphonuclear neutrophils. Despite being a bacillus of difficult cultivation, culture is the most sensitive method for its identification. The most recommended techniques are Nairobi, Johannesburg, and chocolate agar supplemented with vancomycin. Another diagnostic method is the use of genetic engineering, whereby DNA probes are used to identify the agent. This methodology has shown high sensitivity when

adapted to the polymerase chain reaction (PCR) [15–17]. Methods for antigen detection, molecular biology tests, and serologic tests still cannot be recommended for routine diagnosis due to their high costs.

Box 8.5 Chancroid diagnosis
Lesion: ulcerous, shallow of soft basis, and irregular, undermined, cleanly cut borders, surrounded by erythematosus live halo, and covered with necrotic purulent foul-smelling exudate

Gram staining: Gram negative, arranged in a "single line" or "palisade" inside polymorphonuclear neutrophils

PCR

Diagnosis

Differential Diagnosis

Differential diagnosis should include other genital ulcers of infectious and parasitic origin, including hard chancre, lymphogranuloma venereum, donovanosis, genital herpes simplex, American tegumentary leishmaniasis, paracoccidioidomycosis, and ulcerated lesions of Behcet's syndrome [8, 15, 16].

Therapeutic Approach

The recommended regimens are: azithromycin 1 g orally single dose; ciprofloxacin 1 g/day orally for 3 days; erythromycin stearate 2 g/day orally for 7 days; or ceftriaxone 250 mg intramuscularly, single dose [16–18].

Gonorrhea

Epidemiology

Gonorrhea is one of the oldest morbid states of our civilization. Urethral secretions of venereal origin, supposedly gonococcal, were already

reported by the Chinese during the empire of Huang Ti in 2637 BC [19]. See Box 8.13 for more information.

Etiopathogenesis

Gonorrhea is an infectious, inter-human disease, caused by a Gram-negative diplococcus called *Neisseria gonorrhoeae*, which produces Gram-negative, nonflagellated, nonspore-forming, aerobic, immobile cocci, with a diameter between 0.6 and 1.0 μm. It is an intracellular microorganism devoid of capsule whose incubation time is 3–10 days. Its ability to adhere to the epithelium of the anterior urethra is due to the presence of a filamentary appendix called pilli, which cannot adhere to the keratinized epithelium; therefore, lesions are rarely found in the navicular fossa in men and in the birth canal in women [20]. Approximately 70% of infected women have no symptoms, but only 3% of infected men are asymptomatic.

Clinical Presentation

After an incubation period of 2–5 days after the infectious sexual contact, tingling or intraurethral pruritus and dysuria initially develop, followed by mucosal urethral flow, which quickly becomes mucopurulent, of greenish-yellow color, with abundant and spontaneous clearance (Fig. 8.7). The edges of the urethral meatus in general are erythematous and edematous. As the process extends to the portion of the posterior urethra, suppuration increases as well as symptoms of inflammation with cutting sensation and burning on urination and urinary frequency.

The gonococcal urethritis in women does not have the clinical exuberance of that occurring in men, and the clinical picture usually consists of dysuria, urgency and, less frequently, yellowish secretion. The majority of cases are associated with inflammation of Skene glands [21–23].

The hematogenic dissemination of the gonococcus, usually by chronicity of a localized infection, begins with a bacteremia phase, with general

Fig. 8.7 Gonorrhea

symptoms of fever, arthralgia, and skin lesions characterized by papular pustulas that develop into necrotic, nonconfluent lesions, mainly affecting ends; it can also cause monoarthritis in large joints, and cases of meningitis, endocarditis, and brain processes may occur.

Gonococcal proctitis occurs as a result of anal intercourse, and occasionally in women through contamination by vaginal discharge. It is generally asymptomatic but can cause a burning sensation, pain, and presence of bloody secretion and pus.

Gonococcal oropharyngitis occurs because of the practice of oral sex, and can be found in 10–20% of heterosexual women with gonorrhea and 10–25% of men who have sex with men. It is usually asymptomatic and may result in pharynx erythema or tonsil inflammation, with conditions that range from the presence of purulent secretion to severe ulceration with pseudomembrane and cervical adenopathy [20, 24].

Gonorrhea can be transmitted from an infected mother to a child through the birth canal, and the

child may develop gonococcal ophthalmia which if undiagnosed can lead to vision loss and, if it reaches the brain, encephalitis and death.

Other clinical aspects:

Urologic sequelae

Sequelae include cases of orchiepididymitis (the most common early complication), urethral stenosis (mainly in the distal urethra), balanoposthitis, and prostatitis, usually by ascending route.

Female gonorrhea

The clinical picture in women is oligosymptomatic, with 70% of female cases of gonorrhea being asymptomatic. The canal of the cervix is the primary site of gonococcal infection. In women, cervical infections may be accompanied by vaginal discharge, abnormal vaginal bleeding, and dysuria. The main complications in women include abscess of Bartholin's glands, endometritis and salpingitis, and pelvic inflammatory disease [20–22].

Disseminated gonococcal infection

This results from gonococcal bacteremia. It can originate from infections of the pharynx, urethra, or cervical canal that are often asymptomatic. In dermatitis-arthritis syndrome, the patient has fever, skin lesions characterized as macules or pustules with central necrosis or bleeding in the extensor surface of the limbs and inguinocrural region, and arthralgia affecting the hands, feet, ankles, and elbows. In most cases there is septic arthritis with joint effusion. In 50% of cases, gonococcus can be isolated from the synovial fluid. Meningitis and endocarditis are rare [20, 22].

Complementary Examinations (Box 8.7)

1. Bacterioscopic examination: the presence of Gram-negative diplococci shown in urethral discharge by direct examination, fixed and stained by the Gram method, constitutes a sufficient basis for the diagnosis of gonorrhea [19, 20] (Fig. 8.8)
2. Culture: enriched and selective media are recommended. The selectivity ensures bacteria growth and development, which is often prevented in nonselective media, through the phenomenon of competition offered by other bacteria. Among the selective media, the most traditional are modified Thayer–Martin medium, Martin Lewis agar, and New York City agar [19, 20]
3. Carbohydrate degradation tests: these tests detect the production of acid formed in carbohydrate degradation, and are used when the confirmatory identification of the agent is required. This evidence, as well as its results, is shown in Box 8.6 [19, 20].
Fig. 8.8 Intracellular Gram-negative diplococcus

Box 8.6 *Neisseria* **carbohydrate degradation tests**

Specimen	Glucose	Maltose	Sucrose	Lactose
Neisseria gonorrhoeae	+	−	−	−
Neisseria meningitidis	+	+	−	−
Neisseria lactamica	+	+	−	+

Box 8.7 Gonorrhea diagnosis

Clinical manifestations: (a) typical mucosal urethral flow (syndromic) and (b) several systemic manifestations (need laboratory examinations)

Basic laboratory examination: Gram-negative diplococci shown in urethral discharge by direct examination

Additional laboratory examination: culture, carbohydrate degradation tests

4. DNA amplification tests: molecular biology techniques, especially PCR and ligase chain reaction (LCR). The LCR has the advantage of being performed with the urine of the patient with a suspicious clinical picture. It is a specific, sensitive, and noninvasive test [25, 26]

Diagnosis

Differential Diagnosis

The main differential diagnosis of gonorrhea is shown in Box 8.8.

Box 8.8 Differential diagnosis of gonorrhea

Causes	Agents
Bacterial	*Chlamydia trachomatis, Ureaplasma urealyticum, Haemophilus vaginalis. Staphylococcus, Streptococcus, Enterococcus*
Parasitic	*Trichomonas vaginalis*
Viral	Herpes simplex virus
Fungal	*Candida albicans*
Chemical	Introduction of irritant substances in the urethra for prophylactic or therapeutic purposes
Metabolic	Diabetes
Traumatic	Habit of expressing the glans for showing secretion (milking)

Therapeutic Approach

The recommended regimens for the treatment of uncomplicated acquired gonorrhea are: ciprofloxacin 500 mg orally, single dose; ceftriaxone 250 mg, intramuscularly, single dose; ofloxacin 400 mg orally, single dose; or spectinomycin, 2 g intramuscularly, single dose [19, 20]. (see chapter 2).

Genital Warts

Epidemiology

See Boxes 8.12 and 8.13.

Etiopathogenesis

Genital warts, or condylomata acuminata, are caused by the human papillomavirus (HPV), which infects the stratified squamous epithelium and causes a variety of skin lesions, secondary to proliferation of squamous cells [27]. HPV infects the epithelia of keratinized and nonkeratinized

surfaces through continuity solutions of the epidermal barrier. Warts are initially located in the basal layer cells, where their proliferation is stimulated by the encoded viral genes and they are transported to the upper layers of the epithelium.

The main HPVs associated with genital warts are 6, 11, 16, 18, 30,31, 34, 35, 39, 40, 42–45, 51–59, 64, 66–68, 70, and 73.

Clinical Presentation

The initial lesion presents as a papular, nonkeratotic lesion with a digitated surface, the color ranging from skin color to dark brown. The lesions can be unique, single, or multiple, and may coalesce and form large vegetating masses. The most common locations are the glans, female external genitalia (Fig. 8.9), balanopreputial sulcus, frenulum, urethral meatus, inner and outer leaflets of the foreskin, penis body (Fig. 8.10), and inguinal fold. Lesions located in the urethral meatus may occur as bright and reddish elevations on the mucosal surface of the anterior urethra. Perianal lesions may be located exclusively in the anus, being associated with anal intercourse. When present in the anal mucosa, the lesions can progress to the rectal epithelium, and

Fig. 8.10 Condyloma acuminatum on the penis

have to be researched by proctoscopy. Occasionally anogenital lesions may acquire large dimensions, resulting in the so-called condyloma of Buschke–Lowenstein, which behaves clinically and histologically as a verrucous carcinoma. Oral condyloma acuminatum mainly affects the lips, gums, and tongue, being more frequent in patients coinfected with HIV [28].

Complementary Examinations (Box 8.9)

In daily practice, the diagnosis has been based on findings of clinical examination or peniscopy

Fig. 8.9 Condyloma acuminatum in female genitalia

associated with biopsies with histopathology, revealing koilocytosis signals. Currently the methods of molecular hybridization, such as hybrid capture and PCR, which are based on viral DNA findings, are being introduced into daily practice [29].

Diagnosis

Differential Diagnosis

Solid exophytic lesions in the genital and perianal regions should be considered in the differential diagnosis of condylomata acuminata, including Tyson's glands, Fordyce granules, lichen planus, lichen nitidus, seborrheic keratosis, epidermal nevus, angiokeratomas, skin tags, and molluscum contagiosum [28].

Therapeutic Approach

The therapeutic approach is not easy and should be focused on the particularities of each case, with no treatment modality being effective in all cases. Clinical and subclinical lesions on the partner should be always looked for, and untimely therapies aimed at faster healing should always be avoided, since they lead to greater morbidity and no increase in efficacy. Therapy may be carried out as follows:

(a) Antimetabolites: 10% or 50% podophyllin in tincture of benzoin with application once a week; podophyllotoxin 0.5% in benzoin tincture, three consecutive days per week;

5-fluorouracil, daily application with removal after 2 h of application.

(b) Caustics: 50–90% trichloroacetic acid once a week; potassium hydroxide 5–10% once a day.

(c) Cryosurgery with liquid nitrogen

(d) Electrosurgery

(e) Immunomodulators: imiquimod 5% cream, three times a week

(f) Keratinization regulators (in extensive cases): retinoids 1 mg/kg/day

Lymphogranuloma Venereum

Epidemiology

Lymphogranuloma venereum (LV) is rare in industrialized countries, but is endemic in parts of Africa, Asia, South America, and the Caribbean [30].

Etiopathogenesis

This is a urogenital tract infectious disease of inflammatory and invasive nature, caused by *Chlamydia trachomatis* serotypes L1, L2, and L3, in contrast to the A–C serotypes of this agent, which cause eye infections such as trachoma, and D–K serotypes that cause genital infections.

Clinical Manifestations

The incubation period ranges from 3 to 30 days [31]. Generally the more acute symptoms occur in males, while late complications are more common among women. It can also present with a variety of acute and late manifestations, including in the form of proctitis or involvement of the anal region, resulting in stenosis and fistulas. Three stages of the disease are identified in the clinical course [31, 32, 33]:

(a) Primary stage: the first clinical lesion is a painless papule that progresses to a small ulcer unnoticed by the patient, healing spontaneously in a few days. At this stage there may be urethral or cervical mucopurulent discharge.

(b) Secondary stage: characterized by acute lymphangitis, with painful lymph nodes of enlarged volume, determining the so-called inguinal syndrome. They appear after 2–6 weeks of the primary lesion leading to femoral or inguinal adenomegaly, usually unilateral, with flotation and that can rupture, leading to the formation of fistulas draining a large quantity of purulent material (Figs. 8.11 and 8.12). Two adenomegalies separated by Poupart's ligament are characteristics of this disease, corresponding to the "Greenblatt sulcus sign." This stage may be associated with fever, arthralgia, and general malaise. This phase may be complicated by the spread of the disease, producing rare syndromes such as hepatitis, pneumonitis, salpingitis, and exceptionally meningo-

Fig. 8.11 Inguinal adenopathy

encephalitis. Men who have sex with men and women after anal intercourse may develop hemorrhagic proctitis in the acute stages of the disease, with symptoms of anal itching, and mucoid and mucopurulent rectal discharge. Proctitis may generate diarrhea, constipation, and tenesmus. The lymph node chain that is specifically affected in this disease is related to the site of primary infection. Primary infections in the penis, anterior urethra, vulva, and anus may be associated with inguinal buboes. On the other hand, the primary infection of the posterior urethra, vagina, cervix, or rectum may lead to the involvement of perirectal lymph nodes or deep inguinal lymph nodes, which are not accessible to palpation during physical examination. The involvement of these nodes will lead to pelvic pain and tenderness in the lower abdomen [32].

(c) Tertiary stage: refers to late complications that affect the rectum and genitals, including elephantiasis (esthiomene). These complications are rare in men except among homosexuals. In the male genitals, elephantiasis can affect only the foreskin, the shaft of the penis and scrotum separately, or all of the external genitalia. The genital tissues become woody and often deformed, and the surface becomes verrucous. The penis can have the shape of a "ram's horn" or saxo-

Fig. 8.12 Bilateral inguinal adenopathy

phone [33]. In women, the progressive and chronic lymphangitis and pelvic and inguinal adenitis can determine chronic edema, sclerosing fibrosis of the subcutaneous tissue, and chronic genital ulceration, called esthiomene. The esthiomene involves the labia, vulva, and clitoris. Genital elephantiasis, of both men and women, is often associated with anorectal complications, including fistula and constrictions [33].

Complementary Examinations (Box 8.10)

The complement fixation test is gender-specific and does not distinguish among species of *Chlamydia*. Thus, a complement fixation titer that is higher than 1:256 strongly suggests the diagnosis of lymphogranuloma, while a titer smaller than 1:32 virtually excludes it, except in the very early stages of the disease. The microimmunofluorescence test is able to distinguish infections of different species of *Chlamydia*. IgG titers higher than 1:128 strongly suggest the diagnosis. *Chlamydia trachomatis* may be isolated in tissue culture using the HeLa-299 strain or McCoy cells, or by direct fluorescence microscopy. PCR or LCR, which detect the specific plasmid or the DNA genome of *C. trachomatis*, are also sensitive methods for the diagnosis [30, 33].

Box 8.10 LV diagnosis

Clinical aspects depend on stage: painless papule, small ulcer, mucopurulent discharge, acute lymphangitis, "Greenblatt sulcus sign," inguinal buboes, esthiomene

Laboratory examinations: complement fixation test, microimmunofluorescence test, culture, direct fluorescence microscopy, PCR, or LCR

Diagnosis

Differential Diagnosis

The differential includes other sexually transmitted diseases such as syphilis, chancroid, gonococcal proctitis, amoebic dysentery, Crohn's disease, ulcerative colitis, anal carcinoma, and donovanosis [32, 33].

Therapeutic Approach

The therapy currently recommended is: tetracycline 1 g/day orally for 21 days; doxycycline 200 mg/day orally for 21 days; erythromycin 2 g/day orally for 21 days [33]. Ciprofloxacin and metronidazole, very useful in Crohn's colitis, are ineffective for lymphogranuloma.

Donovanosis

Epidemiology

Donovanosis is more common in individuals of low socioeconomic status, being endemic in tropical and subtropical countries [37, 38]. The incidence between the sexes varies from study to study, but there seems to be no predilection for gender. It is a disease that affects almost exclusively adults between 20 and 40 years of age. There are no reports of congenital infection, but there are reports of cases in infants and newborns [39]. In children, cases are often associated with contact with infected adults, not necessarily for sexual abuse.

Etiopathogenesis

This is a chronic, progressive, and indolent infectious disease, which mainly affects the skin and mucous membranes of the genital and perigenital areas. Often associated with sexual transmission, it has low infectivity. It is caused

by a Gram-negative coccobacilli, facultative aerobe, which stains more intensely at the ends than in the center, can be encapsulated or not, is intracytoplasmic and immobile, called *Calymmatobacterium granulomatis* [34–36].

Clinical Presentation

The period of incubation is reported as being from 1 to 360 days; however, induced lesions in volunteers suggest a period of 50 days [39].

The disease begins with papules or subcutaneous nodules at the inoculation site, which can develop to superficial ulceration. The ulcers can be of lenticular size, with everted edges and mild inflammatory reaction. Their growth is slow and painless, and they become well-defined, granulomatous, with centrifugal and serpiginous character, bleeding easily. They can be self-inoculated and multiple, with mirror configuration being frequent [39–41]. Generally the balanopreputial sulcus is affected more often (Fig. 8.13), followed by the anus, vaginal fourchette, and cervix.

Typically there is no adenitis in donovanosis. Extragenital lesions are almost always secondary to a genital focus and can affect the lips, gums, buccal mucosa, palate, pharynx, scalp, and chest. Spread into the abdominal cavity (intestine, spleen, liver, uterus, and ovary) is extremely rare and is observed

Fig. 8.13 Nodulo-ulcerated lesion with mirror image

more often in endemic areas. The clinical course involves change in general condition, with fever, anemia, night sweats, weight loss, and toxemia.

Donovanosis has a more aggressive course during pregnancy, and women with atypical lesions on the genitals should have this diagnosis considered in the prenatal follow-up.

Complementary Examinations

Direct microscopy is the fastest and most reliable diagnostic method with the use of Giemsa, Leishman, and Wright staining for the identification of Donovan bodies. Histopathologic examination is useful for cases in which the cytodiagnosis does not allow the confirmation of the clinical suspicion. The agent culture is difficult, and can be performed with cells in monolayers with human monocytes, Hep-2 cells, and mouse peritoneal macrophages [42, 43] (Box 8.11).

Box 8.11 Diagnosis of donovanosis
Lesion: papules or subcutaneous nodules at the inoculation site, superficial ulceration, everted edges, and mild inflammatory reaction. Growth is slow and painless, and they become well-defined, granulomatous, with centrifugal and serpiginous character, bleeding easily.

Direct microscopy (Giemsa, Leishman, and Wright staining): Donovan bodies
Histopathologic examination

Differential Diagnosis

Primary syphilis, chancroid, chronic herpetic ulcers, condyloma acuminatum, lymphogranuloma venereum, squamous cell carcinoma, cutaneous tuberculosis, paracoccidioidomycosis, leishmaniasis, and pyoderma gangrenosum are included in the differential diagnosis [39, 41].

Therapeutic Approach

The following therapy is currently recommended for donovanosis: azithromycin 500 mg/day orally; doxycycline 100 mg twice daily, orally; erythromycin 500 mg four times a day; or sulfamethoxazole/trimethoprim 400/80 mg, two tablets twice daily. Regardless of the treatment regimen, it should be maintained until clinical cure [44, 45].

Considerations of the World Health Organization (WHO) and Centers for Disease Control and Prevention, USA (CDC) About STDs

In Boxes 8.12 and 8.13, we highlight recent quotes from the WHO and CDC, respectively, on STDs.

Box 8.12 WHO comments about STDs [46]
More than 1 million STDs are acquired every day.

The majority of STDs have no symptoms or only mild symptoms that may not be recognized as an STD.

The most common conditions they cause are gonorrhea, chlamydial infection, syphilis, trichomoniasis, chancroid, genital herpes, genital warts, human immunodeficiency virus (HIV) infection, and hepatitis B infection.

More than 290 million women have a human papillomavirus (HPV) infection.

Several STDs, in particular HIV and syphilis, can also be transmitted from mother to child during pregnancy and childbirth, and through blood products and tissue transfer.

Drug resistance, especially for gonorrhea, is a major threat to reducing the impact of STDs worldwide.

When used correctly and consistently, condoms offer one of the most effective methods of protection against STDs, including HIV. Female condoms are effective and safe, but are not used as widely as male condoms by national programs.

Box 8.13 CDC comments about STDs [47]
Check the *Five P's* in STD assistance: *P*artners, *P*ractices, *P*revention of Pregnancy, *P*rotection from STDs, and *P*ast History of STDs

In the United States, an estimated 820,000 new *N. gonorrhoeae* infections occur each year. Gonorrhea is the second most commonly reported communicable disease.

Many cases of HIV infection continue to be diagnosed at advanced stages, as evidenced by low CD4 cell counts.

At the initial HIV care visit, providers should test all sexually active persons with HIV infection for curable STDs (e.g., syphilis, gonorrhea, and chlamydia) and perform testing at least annually during the course of HIV care.

Nongonococcal urethritis: Chlamydial infection is the most frequently reported infectious disease in the United States, and prevalence is highest in persons aged ≤24 years.

HPV causes cervical cancer, which is the fourth most common cancer in women. A large majority (around 85%) of the global burden occurs in the less developed regions, where it accounts for almost 12% of all female cancers.

Pelvic inflammatory disease: sexually transmitted organisms, especially *N. gonorrhoeae* and *C. trachomatis*, are implicated in many cases.

Sexually transmitted gastrointestinal syndromes: include proctitis, proctocolitis, and enteritis. *N. gonorrhoeae, C. trachomatis, T. pallidum*, and HSV are the most common sexually transmitted pathogens involved.

The following routine presumptive treatment after a sexual assault is recommended:

An empiric antimicrobial regimen for chlamydia, gonorrhea, and trichomonas.

- Emergency contraception. This measure should be considered when the assault could result in pregnancy in the survivor.

- Postexposure hepatitis B vaccination (without HBIG) if the hepatitis status of the assailant is unknown and the survivor has not been previously vaccinated.
- HPV vaccination is recommended for female survivors aged 9–26 years and male survivors aged 9–21 years. For MSM with who have not received HPV vaccine or who have been incompletely vaccinated, vaccine can be administered through age 26 years. The vaccine should be administered to sexual assault survivors at the time of the initial examination, and follow-up dose administered at 1–2 months and 6 months after the first dose.

Presumptive treatment for children who have been sexually assaulted or abused is not recommended because (1) the incidence of most STDs in children is low after abuse/assault, (2) prepubertal girls appear to be at lower risk for ascending infection than adolescent or adult women, and (3) regular follow-up of children usually can be ensured. However, some children or their parent(s) or guardian(s) might be concerned about the possibility of infection with an STD.

Check recommendations for postexposure HIV risk assessment of child, adolescent, and adult survivors within 72 h of sexual assault.

Glossary

Condyloma lata A cutaneous manifestation of secondary syphilis and can be misdiagnosed as genital warts. It is characterized by flat plates that occur most often in moist skin areas, especially around the genitals and anus.

Condyloma acuminata Wart-like growths around the anus, vulva, or glans penis. Genital warts are symptoms of a contagious STD caused by some types of human papillomavirus.

Donovan bodies Bacillary intracellular inclusions in macrophages are called Donovan bodies.

Esthiomene A condition in which there is chronic hypertrophy and destructive ulceration of the external genitals of the female. The labia may be enlarged, thickened, and fibrotic. It is analogous to elephantiasis.

Gumma A growth with a firm, necrotic center surrounded by inflamed tissue, which forms an amorphous proteinaceous mass. The central regions begin to die through coagulative necrosis and ulcerate. Other diseases, as well as syphilis, may exhibit gummas.

Rupioid crust The term rupioid has been used to describe cone-shaped plaques with thick, dark lamellate, and adherent crusts on the skin that resemble an oyster or shell.

Bacterial Infections

Giancarlo Bessa

Key Points Summary
- Pyodermitis is common, accounting for 0.5% of outpatient visits to primary care
- Pyodermitis is predominantly caused by Staphylococcus aureus and group A streptococci, ranging from mild superficial to life-threatening systemic infections
- Superficial manifestations include impetigo, ecthyma, and folliculitis
- Deep and systemic infections include erysipelas, cellulitis, and necrotizing fasciitis.
- Treatment of bacterial skin infections needs to consider clinical manifestations, patient factors, and local current antimicrobial resistance patterns.

Introduction

Bacterial skin and soft-tissue infections (SSTIs), or simply pyodermitis, refer to inflammation of the epidermis, dermis, subcutaneous tissue, or skin appendages caused by invasion by pyogenic bacteria, mainly *Staphylococcus aureus* and *Streptococcus pyogenes* [1, 2]. Sometimes the term

G. Bessa, MD, MSc
ULBRA, Canoas, Brazil
e-mail: giancarlobessa@gmail.com

"pyoderma" is used as a synonym for impetigo, a superficial primary infection of the skin [3].

Pyodermitis can be classified as primary, when affecting healthy skin, or secondary, when the infection occurs on preexisting dermatoses such as dermatitis and infections caused by other agents such as viruses (e.g., herpes simplex) and parasites (e.g., scabies). Reactive skin disease (cutaneous manifestations of infections in other organs) may also occur, usually mediated by toxins [4].

The guidelines of the Infectious Diseases Society of America (IDSA) classify pyodermitis into purulent and nonpurulent and stratify the condition, on the basis of clinical manifestations, as mild, moderate, and severe. Nonpurulent infections include cellulitis and erysipelas, whereas abscesses fall into the purulent category [5].

The definition of complicated SSTIs, widely used in clinical trials, is related to pyodermitis that entails complex management (including surgical procedures and systemic antibiotic treatment), and/or that occurs in patients who have significant underlying comorbidities (such as diabetes and systemic immunosuppression) [6].

Epidemiology

Pyodermitis infections are highly prevalent and represent the most common infection presentation in patients visiting the emergency room in both hospitals and outpatient practices [4].

They account for 0.5% of all outpatient visits to primary care [7]. SSTIs are responsible for about 10% of hospitalizations in North America [8]. The variable clinical presentation of the disease makes it difficult to assess its exact incidence and prevalence, but, in general, the infection is estimated to occur in about 7% of the population [2]. In the past decades a significant growing trend in the incidence of pyodermitis has been observed, both in the community and healthcare settings [9]. This may be explained by the increased number of immunosuppressed patients (e.g., transplant recipients, cancer patients, and AIDS patients), more invasive medical techniques, and increased incidence of surgical wound infections [4].

Etiopathogenesis

SSTIs usually begin with disruption of the skin barrier (Box 9.1), leading to penetration by and proliferation of the infective agent [4]. The infection rarely results from hematogenous spread of bacteria. The skin can also be affected by bacterial toxin production in extracutaneous infections, such as staphylococcal scalded skin syndrome (SSSS) and scarlet fever [1].

Box 9.1. Skin Barrier
Physical protective properties of skin and its relative impenetrability by noxious substances and infectious agents; usually considered a function of keratinized epithelial cells mainly from the stratum corneum.

The skin is colonized by saprophyte bacterial flora that live harmlessly as commensals, which typically consist of Gram-positive cocci (coagulase-negative staphylococci, especially *S. epidermidis* and micrococci), aerobic and anaerobic Gram-positive bacilli, diphtheroids (*Corynebacterium* and *Brevibacterium*), Gram-negative bacteria, and yeasts. The normal flora acts as a competitive inhibitor against the growth of pathogenic microorganisms and also

acts on lipid hydrolysis, producing free fatty acids that are toxic to some bacteria [10].

The progression of pyodermitis and its severity result from the interaction of disorders in protection mechanisms (disruption of the skin barrier: mechanical properties of the stratum corneum, changes in skin "normal flora," and colonization by pathogenic microorganisms), host factors (comorbidities, immunosuppression), and microorganism factors (virulence) [1]. The predominant pathogen in skin infections are Gram-positive cocci; *S. aureus* (Box 9.2) and group A *Streptococcus* (*S. pyogenes*; Box 9.3) are the main etiologic agents [4].

S. aureus is one of the most important bacterial causes of SSTIs [1]. This microorganism is responsible for a wide spectrum of clinical manifestations, ranging from superficial skin infections to severe invasive diseases such as sepsis and septic shock. *S. aureus* can also produce numerous toxins such as cytotoxins, pyrogenic toxin, exfoliative toxin, protease, lipase, hyaluronidase, hemolysin, leukocidin, coagulase, β-lactamases, and others, which are important in the pathogenesis of several pyodermitis presentations [11].

Box 9.2. *Staphylococcus aureus*
S. aureus comprises catalase and coagulase-positive Gram-positive cocci. It is considered a major human pathogen, often involved in cutaneous and systemic infections, and is notable for its ability to develop antimicrobial resistance. Methicillin-resistant *S. aureus* (MRSA) is resistant to many of the antibiotics used to treat ordinary staphylococcal infections, mainly the penicillinase-resistant penicillins (such as oxacillin). MRSA infections acquired in hospitals or other healthcare settings are known as healthcare-associated MRSA (HA-MRSA). MRSA infection that occurs in the community setting, frequently among healthy people, is termed community-associated MRSA (CA-MRSA). HA-MRSA and CA-MRSA have distinctive genetic and antimicrobial susceptibility characteristics.

Colonization is an important step in the pathogenesis of *S. aureus* infection, as nasal carriers and other patients colonized by the agent have been described as risk groups for developing infections [11]. Approximately one-third of the population has *S. aureus* as a transient colonizer in its cutaneous and mucous membrane flora and about 20% is persistently colonized. The remaining 50% appears not to be susceptible, for unknown reasons, to *S. aureus* carriage. The main site where it is found the anterior nasal cavities, although other body sites, such as the perineum and throat, may also be colonized [12]. Many studies have indicated the clinical benefit of mupirocin use for decolonization. A systematic review showed a significant reduction of *S. aureus* nosocomial infections associated with intranasal mupirocin decolonization [13]. The treatment of *S. aureus* infections has been more difficult over time because of its prodigious adaptability and the development of multiple antimicrobial resistance [11].

> **Box 9.3.** *Streptococcus pyogenes*
> Streptococci are catalase-negative, Grampositive bacteria that are arranged in pairs and chains. Group A β-hemolytic streptococci are one of the most important etiologic agents of human and animal infections. They are responsible for disease involving the mucous membranes, tonsils, skin, and deeper tissues and are known for nonsuppurative complications mediated by toxins.

The cutaneous manifestations of infection by *S. pyogenes* (group A streptococci) may also vary from minor superficial infections such as impetigo and erysipelas to severe diseases such as necrotizing fasciitis, which frequently results in death [14]. They are more common in childhood and adolescence, which can be assigned to the fact that successive infections confer lasting and specific immunity against this pathogen. The bacterium is acquired by direct contact, so epidemic infections are more common among people in group situations. Ten percent of the population are asymptomatic carriers, especially in the oropharyngeal region and 1% of individuals harbor it in normal skin [2]. Group A streptococci have adhesins, proteins that play critical role in adherence to the surface of human epithelial cells, and the M protein, which protects against phagocytosis and also increases adherence to epithelial tissues. *S. pyogenes* also develops exotoxins (as streptolysin O) that are toxic to numerous cells and contribute to the virulence of the bacteria [3]. Among human pathogens, *S. pyogenes* stands out for its propensity to cause nonsuppurative diseases. The most documented are rheumatic fever and post-streptococcal glomerulonephritis (PSGN). Cutaneous infections by nephritogenic strains are the major cause of PSGN [15]. Although not common, there is evidence of rheumatic fever caused by group A streptococci impetigo [16].

Diagnosis

The diagnosis of the pyodermitis is essentially based on clinical aspects. Cultural examinations may be necessary to confirm the etiologic agent when there is doubt about the diagnosis or there is suspicion of resistant bacteria. Table 9.1 lists the key points in the clinical diagnosis of pyodermitis.

Table 9.1 Clinical diagnosis of pyodermitis

Impetigo	Nonbullous impetigo: superficial erosions surmounted by honey-color. Systemic symptoms are not ordinarily present
	Bullous impetigo: vesicles and flaccid bullae progressing to erosions covered by dark-brownish crusts rounded by a "collarette" of blister remnants
	In the two variants the coalescence of lesions, central clearing, and peripheral extension can lead to circinate lesions
Ecthyma	Ulcerations with infiltrated violaceous borders, covered by dry, thick, adherent crusts that leave scars after healing, often in legs
	Ecthyma gangrenosum: necrotic skin ulcer in immunosuppressed or neutropenic patients with sepsis caused by *P. aeruginosa*

(continued)

Table 9.1 (continued)

Cellulitis	Tender, warm, erythematous area with edema. Abscess and necrosis can occur
	Erysipelas variant: erythematous plaque with well-demarcated raised borders. Bullae may appear over the lesion
	Systemic symptoms common: fever, chills, regional lymph node enlargement
	More common on face and lower limbs
Folliculitis	Superficial folliculitis: hair-centered pustules
	Deep folliculitis or furuncles ("boil"): tender inflammatory papules or nodules. May result in abscesses formation
Necrotizing infections	Necrotizing fasciitis: rapid progression from mild cutaneous signs such as erythema and edema to necrosis and anesthesia. Severe local pain and systemic toxicity with fever, disorientation, and lethargy. May be polymicrobial, involving a mixed aerobe–anaerobe bacterial flora
	Streptococcal gangrene: when associated with streptococci
	Fournier's gangrene: rapidly progressive form of necrotizing fasciitis of the perineal, genital, or perianal regions

Complementary Examinations

In patients with systemic symptoms, blood tests may be helpful. Leukocytosis with neutrophilia and increased serum C-reactive protein levels, procalcitonin levels, and erythrocyte sedimentation rates suggest a complicated infection [4]. The initial investigation for patients who require admission to hospital should include blood cultures and creatinine, bicarbonate, and creatine phosphokinase levels [1].

The diagnosis of pyodermitis is eminently clinical, but cultural examination may be necessary in some situations: when there is doubt about the diagnosis; when the evolution is not as expected (aggressive course or treatment unresponsive disease); when there is suspicion of resistant bacteria (such as MRSA); and, eventually, in immunocompromised patients.

Surface cultures, such as from swab-collected pus, more frequently do not represent the underlying etiologic agent and generally show colonizing bacteria [6]. Tissue specimens obtained by biopsy of the advancing margin of the lesion are preferred to wound swabs or drainage secretions. If there is no open wound, needle aspiration of fluid may be helpful [4]. Despite the low sensitivity of blood cultures, patients who present with severe infection or sepsis syndrome should have blood samples obtained for culture [17].

Assays of anti-streptolysin O (ASLO) antibodies are of value in the diagnosis of streptococcal pyodermitis (except for superficial infections such as impetigo, for which the ASLO response is weak) [3].

Clinical Presentation Patterns

Impetigo

Impetigo is a contagious superficial skin infection. Poor hygiene conditions constitute a risk factor. Infection is more common in economically disadvantaged children in hot climates [2, 3, 5]. In primary impetigo, which develops in normal (or apparently normal) skin, two clinical patterns are recognized: bullous impetigo and nonbullous impetigo. Nonbullous impetigo lesions can be associated with streptococci, staphylococci, or combination of both. Moreover, it is believed that the etiology of bullous impetigo is predominantly staphylococcal, although there have been reports of streptococci detected in these lesions [18].

In secondary impetigo, bacterial superficial infection occurs on pre-existing skin disease, more commonly dermatitis. In cases of impetiginized dermatoses there is a high prevalence of coinfection by two species of bacteria (*S. aureus* and *S. pyogenes*) [19, 20].

β-Hemolytic group A streptococci are the main etiologic agent of impetigo [21]. Occasionally other groups can be found (e.g., C and G) [5]. Characteristically the incidence of impetigo occurs as outbreaks. In patients with chronic dermatitis, recurrence after treatment is common (about 20% within 1 month), probably due to contact with colonized people [19]. In patients with

chronic disseminated eczematous dermatoses streptococcal impetigo can progress rapidly, culminating with systemic involvement, with the presence of fever, toxemia, leukocytosis, and elevation of C-reactive protein [20].

Impetigo lesions usually occur on exposed areas of the body, most commonly on the face and extremities [5]. The diagnosis is clinical (Table 9.1) and can be aided by bacterioscopic and bacteriologic studies [2]. It is a non-life-threatening infection, but can result in PSGN [3].

Bullous Impetigo

Bullous impetigo is caused by *S. aureus*, which produces an epidermolytic exfoliative toxin associated with the genesis of the blisters. This toxin, when spread hematogenously, is implicated in the pathogenesis of SSSS [22]. It is more common in newborns and infants. Strains of *S. aureus* types 71, 80, and 81 predominate in the genesis of bullous impetigo.

Clinically, bullous impetigo manifests as vesicles that rapidly grow to form flaccid bullae, initially with clear fluid content, progressing to yellowish to purulent secretion. The blister then breaks, leaving erosions covered by dark-brownish crusts surrounded by blister remnants (resembling "cigarette burns") (Fig. 9.1) [5].

Bullous impetigo should be differentiated from bullous drug eruptions, chickenpox, herpes infections, SSSS, and other less common bullous diseases (pemphigus vulgaris, bullous pemphigoid, dermatitis herpetiformis) [2].

Nonbullous Impetigo

Nonbullous impetigo represents 70% of impetigo cases [2]. The etiologic agent can be group A streptococci and *S. aureus* [4]. Clinically it appears as an erythematous macula surmounted by a vesicle which becomes pustulous. These vesicular lesions are evanescent and rarely clinically recognized, and evolve to form characteristic yellowish-brown crusts (Fig. 9.2) [3]. Lymphadenopathy can occur in some cases, but systemic symptoms are not ordinarily present [3, 5]. The differential diagnosis of nonbullous impetigo includes herpes simplex, herpes zoster, and scabies [2].

In the two variants the coalescence of lesions, central clearing, and peripheral extension can lead to a circinate lesion, mimicking superficial fungal infection. Treatment of nonbullous impetigo involves cleaning the lesions, removing crusts, and the use of topical or systemic antibiotics, depending on the extent of disease [2].

Ecthyma

Ecthyma is considered a "deeper" impetigo, reaching the superficial dermis. The main etiologic agents are also *S. aureus* and *S. pyogenes* [5], and it usually represents the evolution from neglected impetigo. The clinical manifestations are ulcerations covered by dry, thick, and adherent crusts (Fig. 9.3). The edges are infiltrated and purplish, resulting in scars after healing. Ecthyma occurs most commonly in patients with poor hygiene, low

Fig. 9.1 Bullous impetigo: most of the lesions are in the form of crusts (Courtesy of UFCSPA Dermatology Service)

Fig. 9.2 Nonbullous impetigo on the face: *yellowish brown* crusts on an erythematous base (Courtesy of UFCSPA Dermatology Service)
Fig. 9.3 Ecthyma. (**a**) Lesion covered by thick crust. (**b**) Crust removal reveals an ulcer with infiltrated edge (Courtesy of UFCSPA Dermatology Service)

socioeconomic status, malnutrition, and/or immunosuppression [2]. Ecthyma gangrenosum refers to a necrotic skin ulcer that can be a manifestation of secondary infection that sets in typically in the course of sepsis caused by *Pseudomonas aeruginosa*, among transplanted, neutropenic, or diabetic patients [4]. Differential diagnosis should involve ulcerous diseases, such as stasis ulcers and cutaneous leishmaniasis. Often the lesions are multiple and treatment requires systemic antibiotics for at least 10 days [2].

Erysipelas and Cellulitis

Cellulitis is classically defined as an infection involving the dermis and subcutaneous tissues [23]. Erysipelas is a bacterial infection involving superficial dermal structures and is distinguished clinically by its well-demarcated raised borders [24]. However, it is not uncommon that the two patterns coexist in the same patient. In fact, based on clinical overlap and similar bacteriology of the two conditions, cellulitis and erysipelas are now considered manifestations of the same condition, a deep skin infection associated with severe pain and systemic symptoms [25].

The erysipelas variant is almost always caused by β-hemolytic streptococci, from group A (*S. pyogenes*), B, C, or G. An etiologic study that included broad clinical variations of cellulitis patients showed that β-hemolytic streptococci are also the major causative agent in deeper cellulitis and overlapping conditions. More than 80% of the cases were of streptococcal origin, including patients without typical signs of erysipelas, those with purulent drainage, and with comorbidities such as diabetes mellitus [26]. *S. aureus* is also noted to cause cellulitis, especially when associated with furuncles, carbuncles, or abscesses [27]. However, it is important to note that swab culture is not a reliable method to define etiology in cellulitis, as the great majority of cases in which *S. aureus* or Gram-negative bacteria were detected had confirmed or probable β-hemolytic streptococcal disease, diagnosed by combining serology, profound cultures, and response to penicillin treatment [26].

Cellulitis is characterized by local pain, erythema, warmth, edema, and advancing borders [24]. Abscess and necrosis can occur (Fig. 9.4). Erysipelas is a specific type of cellulitis characterized by pronounced superficial dermal inflammation and well-defined raised edges, although in some countries the terms are used as synonyms [28]. The infectious process can lead to the formation of blisters (Fig. 9.5) [29]. The differential diagnosis of erysipelas includes necrotizing fasciitis, contact dermatitis, and deep vein thrombosis [2].

The infectious agent penetrates through skin barrier breaks such as erosions, fissures, and ulcerations [2]. Lymphedema, leg ulcers, toe intertrigo, and traumatic wounds are risk factors for the infection [30]. Patients frequently present with fever, malaise, and leukocytosis, and there is a considerable risk of bacteremia and sepsis [27, 31]. Cellulitis and erysipelas affect mainly women between 40 and 60 years old, having an estimated incidence of between 10 and 100 cases per 100,000 inhabitants per year [32].

Fig. 9.4 Cellulitis: erythematous and edematous lesion, with areas of necrosis and suppuration (Courtesy of UFCSPA Dermatology Service)

Fig. 9.5 Erysipelas bullosa: erythematous plaque with extensive blistering in the lower limb (Courtesy of UFCSPA Dermatology Service)

They can occur on any part of the body, but are more frequent in the face and lower limbs [24].

Treatment is based on a systemic antibiotic, rest, elevation of affected limbs, and local skin care. The conditions that may indicate the need of inpatient treatment include advanced age (>60 years), comorbidities (e.g., immunosuppression, cardiac or renal insufficiency), signs of instability (confusion and hypotension), facial location, or local complications (blisters and necrosis) [33]. In such cases blood cultures are recommended [5].

Recurrence is the main complication of erysipelas and cellulitis, occurring in about 20–30% of cases [2, 30]. An episode of erysipelas in the lower limb may achieve a 46% recurrence rate [34]. Patients with recurrent disease should treat all the predisposing factors for the infection for as long as possible, and may benefit from antimicrobial prophylaxis [24].

Lymphatic involvement can lead to obstruction and damage of the lymphatic system, which predisposes to recurrent infections and leaves some degree of residual chronic swelling. This lymphedema gradually increases the volume of the affected limb, resulting in skin tightening, lipodermosclerosis, and verrucous hyperkeratosis, a condition known as elephantiasis nostra [34].

Staphylococcal Scalded Skin Syndrome (SSSS)

Also known as Ritter disease, SSSS is caused by exfoliative exotoxins (mainly types A and B) produced by *S. aureus* phage group 2 [35]. The major incidence is in infants and small children, with 98% of cases occurring in children 6 years old or younger. When it affects adults it is generally associated with immunosuppression and renal insufficiency [2].
Fig. 9.6 Staphylococcal scalded skin syndrome. (**a**) Flaccid bullae and diffuse detachment of the epidermis. (**b**) Erosions after blister rupture (Courtesy of Dr. Gislaine Olm)

The disease usually begins a few days after pharyngitis, conjunctivitis, otitis, or other staphylococcal infections. The exotoxin produced by about 5% of strains of *S. aureus* is a serine protease that reaches the granular layer of the epidermis, joining desmoglein-1. These toxins are spread hematogenously, causing diffuse epidermal damage [35].

Clinically there is widespread erythema and fever, which starts after the staphylococcal infection. Within 24–48 h large and flaccid bullae develop with epidermal high cleavage and positive Nikolsky sign (Box 9.4). Rupture of the blisters results in large areas of erosions surrounded by epidermal patches (Fig. 9.6). There is no mucosal involvement [2].

The diagnosis is made by clinical observation, isolation of an exfoliative toxin producer *Staphylococcus* strain at the site of primary infection (the blisters are usually sterile), and characteristic histopathology (intraepidermal cleavage at granulosa layer). SSSS should be distinguished from life-threatening toxic epidermal necrolysis [35].

Treatment involves systemic antistaphylococcal antibiotic therapy, fluid and electrolyte control, and local care of eroded areas, with special bandages, dressings, and barrier creams. Re-epithelialization is usually rapid, occurring within 7–10 days of treatment. The mortality rate in infants and small children is approximately 4%; in adults, more than 60% [36].

Box 9.4. Nikolsky Sign

An important semiologic sign named after Pyotr Nikolsky, a Russian physician. The cutaneous rubbing of an apparently normal skin area results in the separation of part or whole epidermis. It is characteristic of acantholytic diseases, i.e., congenital or acquired diseases that compromise adhesion between keratinocytes. The prototype is pemphigus vulgaris and other autoimmune bullous diseases.

Folliculitis

The term folliculitis refers to inflammation of the hair follicle that may be caused by trauma (most commonly friction and depilation), chemical irritants, follicular obstruction and infectious agents. Infectious folliculitis is most commonly caused by *S. aureus*, and is probably the most common skin infection. Other infectious agents, including fungi, may be involved, particularly in immunosuppressed patients. Folliculitis can be classified according to the depth of the infectious process [24].

Superficial folliculitis: The most common form of folliculitis. Inflammation occurs in the upper portion of the follicle, and pus formation is restricted to the epidermis [2]. The initial lesion is a hair-centered pustule, which then forms crusts and heals without scarring. Lesions may be numerous and are located especially in the scalp, neck, buttocks, and extremities. Superficial bacterial folliculitis typically resolves spontaneously and should be distinguished from folliculitis by distinct etiologic agents (such as commensal yeasts) and from other follicular eruptions (such as acne). The use of topical antibiotics can accelerate the healing process [7].

Deep folliculitis or furuncles ("boils"): The infectious process extends through the dermis and involves perifollicular tissues, which usually destroy the hair follicle. It manifests clinically as tender inflammatory papules or nodules. The suppuration process extends to deep dermis and subcutaneous tissue may result in the formation of abscesses [5]. Carbuncles are furuncle aggregates that form broad, swollen, erythematous, deep, and painful inflammatory masses that usually have multiple pus-draining points (Fig. 9.7). In such cases there may be constitutional symptoms such as fever and prostration [24]. Most large furuncles and all carbuncles should be treated with incision and drainage. Systemic antimicrobials are usually unnecessary unless fever or other evidence of systemic infection is present [5].

Folliculitis decalvans: A form of chronic deep folliculitis of the scalp, usually associated with *S. aureus*. The inflammation process leads to follicle destruction, resulting in permanent scarring alopecia. It occurs most commonly in middle-aged men and there is a suspicion that diabetic patients are more susceptible. Differential diagnoses should include cicatricial alopecias in general, dissecting folliculitis, discoid lupus erythematosus, and tinea favosa [2].

Dissecting cellulitis: Also referred to as perifolliculitis capitis abscedens et suffodiens, this manifests with perifollicular pustules, nodules, abscesses, and sinuses that evolve into scarring alopecia (Fig. 9.8). It occurs predominantly in black men between 20 and 40 years old. The course is chronic and multiple treatment options have variable efficacy [37].

Acne keloidalis nuchae: Another clinical pattern which occurs in the lower occipital region in postpubertal black men and also can lead to scarring alopecia with keloid formation. The cause is unknown, but it has been recognized that it may

Fig. 9.7 Carbuncle: aggregates of multiple deep folliculitis, forming an erythematous edematous plaque with multiple points of purulent drainage (Courtesy of UFCSPA Dermatology Service)

Fig. 9.8 Dissecting cellulitis: nodules and sinuses with scarring alopecia

be precipitated by short-cut hair in the nuchal region and probably caused by recurving, ingrowing hair shafts [38]. The bacterial populations identified seem to be a secondary phenomenon. Treatment is difficult. Acne keloidalis is now considered a primary form of scarring alopecia, so therapies found to be useful in other forms of inflammatory scarring alopecia may be prescribed in the treatment of this disease [39].

Sycosis: Deep folliculitis of the beard region, caused by *S. aureus*, which if left untreated becomes chronic. Extensive disease is treated with oral antibiotics such as cephalexin until all signs of inflammation have disappeared. Relapses are not uncommon. The main differential diagnosis is made with dermatophyte folliculitis of the beard region [2].

Cutaneous Abscesses

Defined as pus collections in dermis or deeper tissues, cutaneous abscesses are usually painful and manifest clinically as warm palpable erythematous and edematous floating nodules.

Abscesses are typically a polymicrobial infection, although *S. aureus* is implicated in most cases [5]. The Panton-Valentine leucocid in gene has been associated to the appearance of abscesses, necrotic cutaneous lesions and furuncles caused by MRSA [40]. They may occur after deep inoculation of the infectious agent (penetrating trauma, catheters); as a secondary infection of cutaneous cysts, and as a complication of several pyodermitis conditions, such as cellulitis and deep folliculitis [41]. The treatment of cutaneous abscesses mainly involves surgical drainage of pus [5]. A systematic review found that primary closure after incision and drainage of abscesses is an alternative mode of therapy that may result in faster healing and lower recurrence rates compared with secondary closure [41]. Incision and drainage alone (in the absence of antimicrobial therapy) is generally sufficient for healthy patients with small solitary abscesses (<2 cm) without surrounding cellulitis or systemic symptoms [5].

Necrotizing Infections

Many specific variations of necrotizing soft tissue infections have been described based on multiple criteria (etiology, microbiology, and specific anatomic location). Nevertheless, the initial approach to diagnosis and treatment (antimicrobial and surgical interventions) is similar for all forms and is more important than determining the specific variant [5].

Necrotizing fasciitis is a deep life-threatening infection that extends rapidly along the superficial fascia and subcutaneous tissue planes [42]. It usually develops from an initial break in the skin related to trauma or surgery, and extension from a skin lesion is seen in most cases. Examination of the local site may reveal cutaneous erythema, edema, and discoloration or gangrene and anesthesia (Fig. 9.9). As it progresses there is systemic toxicity, often with fever, disorientation, and lethargy [5]. Paucity of cutaneous findings early in the course of the disease can delay the diagnosis, which correlates with a poor outcome, leading to major tissue destruction, sepsis,

Fig. 9.9 Necrotizing fasciitis: this ecchymosis-like lesion was hard on palpation and quickly evolved to necrosis

multiple organ failure, and death [1]. The infection can be monomicrobial (usually by streptococci, when it may be named "streptococcal gangrene") or polymicrobial, involving a mixed aerobe–anaerobe bacterial flora [4]. Plain radiographs, computed tomography, or magnetic resonance imaging may help in the diagnosis [1].

Fournier's gangrene is a rapidly progressive form of necrotizing fasciitis of the perineal, genital, or perianal regions. The mean age at onset is 53–55 years and the majority of patients have significant underlying diseases, particularly diabetes mellitus [43].

Prompt surgical debridement is the primary therapeutic intervention for necrotizing infections [5]. Appropriate antibiotics, fluid and electrolyte management, and analgesia are mainstays of therapy [1].

Differential Diagnosis

The differential diagnosis of pyodermitis varies according to the clinical pattern (see the preceding sections).

Therapeutic Approach

The empiric choice of antimicrobial therapy must cover the most likely organisms implicated in the infection, so it is important to consider clinical and epidemiologic information [4]. In general, the systemic treatment of pyodermitis, when there is no significant suspicion of MRSA, is made with empiric prescription of penicillinase-resistant penicillins, first-generation cephalosporins, clindamycin, or trimethoprim-sulfamethoxazole (TMP-SMX) [1]. The treatment of severe infections caused by MRSA is traditionally done with intravenous glycopeptides (vancomycin and teicoplanin) or more recently introduced options such as linezolid, daptomycin, and tigecycline. For outpatient treatment of MRSA infections TMP-SMX and tetracyclines can be employed with low clinical failure rates [44, 45]. When there

is a suspicion of polymicrobial infections such as abdominal surgery wound infections; proximity with the genitourinary tract, infection associated with animal or human bites, or, in cases of children under 3 years old, diabetic or immunocompromised patients, it is recommended to administer antibiotics with spectrum against Gram-negative bacteria, such as second-, third-, or fourth-generation cephalosporins, β-lactams associated with β-lactamase inhibitors, or fluoroquinolones [1, 24].

In systemic antimicrobial treatment, the choice between oral or parenteral therapy is generally suggested by the severity of the infection. Parenteral therapy is preferred when the infection is rapidly spreading and significant comorbidities are present [4]. Topical antimicrobial drugs are reserved for the treatment of superficial uncomplicated pyodermitis (namely localized impetigo or impetiginized lesions). In this context, they have some advantages: low risk of systemic adverse effects, high local concentrations, and low cost [46]. A systematic review concluded that mupirocin and topical fusidic acid are equally, or more, effective than oral treatment for localized impetigo, being considered drugs of first choice for treating this condition [47]. More recently, retapamulin, described as a new topical antibiotic to treat cases of impetigo, was recommended for topical application twice daily for 5 days [48]. In clinical trials the efficacy of retapamulin was noninferior to sodium fusidate for impetigo [49] and noninferior to oral cephalexin for secondarily infected superficial wounds caused by trauma [50]. It has not been compared with mupirocin.

In cases of ecthyma or impetigo with numerous lesions, or in outbreaks affecting several people, oral antibiotic therapy is recommended. The antimicrobial agent must be active against *S. aureus* unless cultures yield streptococci alone (when penicillin is the recommended agent). Because most *S. aureus* isolates are methicillin susceptible, dicloxacillin or cephalexin is recommended. When MRSA is suspected or confirmed, a tetracycline, clindamycin, or TMP-SMX is recommended [5].

For the treatment of erysipelas and cellulitis, a systematic review was unable to define the best antimicrobial regimen because there were no two trials that investigated the same antibiotics and there was no standard treatment regimen used as a comparison. The authors concluded that no single treatment was clearly superior, and the recommendations are mostly based on single trials [25]. The IDSA recommends that typical cases of cellulitis without systemic signs of infection should receive an outpatient-based treatment, with an antimicrobial agent that is active against streptococci. For cellulitis with edema, poor defined edges, and systemic signs of infection, many clinicians include an antibiotic with coverage against MSSA, despite the weak evidence to support this. When cellulitis is associated with penetrating trauma, evidence of MRSA infection elsewhere, injection drug use, purulent drainage, or severe systemic symptoms, vancomycin or another antimicrobial drug effective against both MRSA and streptococci is recommended [5]. Small studies support that 5 days of treatment may be as effective as 10 days [25], but treatment should be extended if there are signs of persistent infection [5].

There is evidence that prophylactic antibiotics may reduce recurrence rates of cellulitis or erysipelas in persons with previous episodes. However, the ideal type, dosage, and duration of antibiotics, as well as the group of patients who will benefit most from prophylaxis, were not determined [51]. The IDSA recommends that the prescription of oral penicillin or erythromycin, or intramuscular benzathine penicillin, every 2–4 weeks should be considered in patients who have three to four episodes of cellulitis per year despite treatment of predisposing conditions [5].

For mild, moderate, and severe purulent infections, incision and drainage of the site of infection are considered the milestone of the treatment [6]. The addition of systemic antibiotics to incision and drainage of cutaneous abscesses may improve cure rates in certain circumstances, particularly the use of anti-MRSA antibacterials in settings where MRSA is prevalent [52, 53]. In addition, systemic antibiotics are frequently needed in cases of multiple lesions, associated cellulitis, or

gangrene, in immunosuppressed patients or in the presence of systemic symptoms [5].

Necrotizing infections require aggressive treatment and early prescription of broad-spectrum antibiotics in combination with surgical debridement and hemodynamic support [1]. Empiric antimicrobial treatment should include antibiotics effective against both aerobes, including MRSA, and anaerobes: vancomycin, linezolid, or daptomycin combined with piperacillin-tazobactam, a carbapenem, ceftriaxone plus metronidazole, or a fluoroquinolone plus metronidazole [5].

The emergence of bacterial strains with resistance to multiple agents has complicated the choice of empiric therapy [1]. Many cutaneous infections are caused by MRSA [54]. Macrolide resistance among group A and group B streptococci has also risen, but organisms have remained susceptible to penicillins and cephalosporins [4]. Moreover, the increasing prevalence of infections by multidrug-resistant bacteria is associated with significantly increased morbidity, mortality, and length of hospital stay and costs, compared with infections by susceptible strains [9]. It is therefore important that a local knowledge of the epidemiology and susceptibility of pathogens guides the development of antibiotic guidelines for empiric treatment [1, 33, 55].

Glossary

Abscess Pus collections in dermis or deeper tissues.

Acne keloidalis nuchae A chronic pattern of deep folliculitis of the scalp that occurs in the lower occipital region and leads to scarring alopecia with keloid formation.

Bacteremia Presence of viable bacteria in the bloodstream.

β-lactams A class of broad-spectrum antibiotics, such as the penicillins and the cephalosporins, that chemically contain a β-lactam ring.

Carbapenems A class of β-lactam antibiotics highly resistant to β-lactamases.

Carbuncles Furuncle aggregates that form large, painful inflammatory masses.

Ceftriaxone A third-generation cephalosporin (antibiotic).

Cellulitis Deep skin infection that involves the dermis and subcutaneous tissue associated with severe pain and systemic symptoms.

Cephalexin A first-generation cephalosporin (antibiotic).

Cephalosporins A class of β-lactam antibiotics originally isolated from the fungus *Cephalosporium acremonium*. Successive generations have different antimicrobial spectra: the newer are more active against Gram-negative bacteria.

Clindamycin A semisynthetic antibiotic, derived from lincomycin and active against Gram-positive and anaerobic bacteria.

Daptomycin A cyclic lipopeptide parenteral antibiotic with bactericidal activity against a wide range of Gram-positive bacteria, including *S. aureus* resistant to methicillin and vancomycin. The mechanism of action involves disruption of the bacterial cytoplasmic membrane and inhibition of protein and nucleic acids synthesis.

Dicloxacillin A semisynthetic penicillinase-resistant penicillin.

Dissecting cellulitis Also known as perifolliculitis capitis abscedens et suffodiens, it is a clinical form of chronic folliculitis of the scalp that manifests with pus collections, sinuses, and scarring alopecia.

Ecthyma Bacterial skin infection that reaches the superficial dermis. The main etiologic agents are *S. aureus* and *S. pyogenes*.

Elephantiasis nostra Chronic lymphatic swelling of lower limbs leading to skin tightening and hyperkeratosis, induced by recurrent erysipelas that damage lymphatic vessels.

Erysipelas Deep skin infection considered a specific type of cellulitis that involves superficial dermal structures and is distinguished clinically by its well demarcated raised borders.

Erythromycin A macrolide antibiotic, obtained from the actinomycete *Streptomyces erythraeus*.

Fluoroquinolones A subgroup of quinolones, antibiotics with broad spectrum of antimicrobial activity that inhibit bacterial DNA gyrase.

Folliculitis Inflammation of the hair follicle, associated with multiple causes. Infectious folliculitis is most commonly caused by *S. aureus*. It can be classified into superficial and deep folliculitis.

Folliculitis decalvans Specific form of chronic deep folliculitis of the scalp usually associated with *S. aureus* and leading to scarring alopecia.

Fournier's gangrene A clinical form of necrotizing fasciitis of the perineal, genital, or perianal regions.

Furuncle Also known as a "boil," the deep form of folliculitis that manifests clinically as tender inflammatory papules or nodules.

Fusidic acid Antibiotic derived from the fungus *Fusidium coccineum* that interferes with the bacterial protein synthesis by preventing translocation elongation factor G (EF-G) of the ribosome. It is only active against Gram-positive bacteria such as *Staphylococcus* and can be topically or systemically administered.

Impetigo Bacterial skin infection limited to the superficial layers of the epidermis, caused by *S. aureus* and *S. pyogenes*.

Intertrigo An inflammatory process in skin folds, induced or aggravated by heat, moisture, maceration, friction, and microbial proliferation.

Linezolid A synthetic antibiotic of the oxazolidinone class that prevents formation of essential component of bacterial protein synthesis.

Lymphedema Accumulation of lymphatic fluid in the interstitial tissues of the body with accompanying swelling, often of the extremities, caused by damage in lymphatic vessels or lymph nodes.

Macrolide A class of broad-spectrum antibiotics that chemically contain a large lactone ring and act by inhibiting protein synthesis.

Metronidazole A synthetic antiprotozoal and antibacterial drug that is effective against obligate anaerobes.

Mupirocin Topical antibiotic with bactericidal activity, derived from *Pseudomonas fluorescens*. Its particular mechanism of action results from inhibition of transfer RNA and is not related to any other antibacterial. It is indicated for the treatment of skin infections by Gram-positive organisms, especially *S. aureus*, and is often formulated in cream or ointment at 2%.

Necrotizing fasciitis Deep bacterial infection that extends rapidly along the superficial fas-

cia and subcutaneous tissue planes, resulting in soft tissue necrosis and systemic toxicity.

Penicillins A class of β-lactam antibiotics that were originally isolated from the fungus of the genus *Penicillium* and later gave rise to the various semisynthetic antimicrobials.

Piperacillin-tazobactam A β-lactam antibiotic associated with a β-lactamase inhibitor.

Poststreptococcal glomerulonephritis (PSGN) Acute glomerulonephritis (glomeruli inflammation) following streptococcal infection and characterized by sudden appearance of hematuria, proteinuria, edema, and hypertension.

Retapamulin Topical antibiotic with in vitro and in vivo activity against *S. aureus* (including MRSA) and *S. pyogenes* and poor activity against Gram-negative bacteria. It is a semisynthetic derivative of pleuromutilin compound derived from the fungus *Clitopilus passeckerianus* and inhibits bacterial protein synthesis, but binds at a different site on the 50S subunit of the bacterial ribosome.

Rheumatic fever Inflammatory systemic disease induced by toxins produced by certain strains of group A streptococci. The most characteristic findings are fever, migratory arthritis, neurologic manifestations, and permanent damage to the heart structures.

Ritter disease Also known as staphylococcal scalded skin syndrome, it is characterized by diffuse epidermal detachment caused by exfoliative exotoxins produced by *S. aureus*.

Scarlet fever A bacterial illness that develops in some people who have strep throat. Also known as scarlatina, scarlet fever features a bright red rash that covers most of the body. Scarlet fever is almost always accompanied by a sore throat and a high fever.

Sepsis Systemic inflammatory response to infection.

Staphylococcal scalded skin syndrome (SSSS) See "Ritter disease."

Streptolysin O A hemolysin produced by β-hemolytic streptococci. The laboratory titration of anti-streptolysin O antibody (ASLO) are used as a diagnostic tool of recent streptococcal infection.

Sycosis Etymologically the term refers to an inflammatory process in hair follicles. However, it is most commonly used to describe a chronic deep folliculitis, most commonly in the beard region, caused by staphylococcal infection.

Teicoplanin A glycopeptide antibiotic highly effective against Gram-positive bacteria, especially against staphylococci.

Tetracyclines A class of antibiotics effective against a wide variety of organisms, acting by inhibiting protein synthesis.

Tigecycline The first drug in the glycylcycline class of antibiotics, which acts by inhibiting protein synthesis.

Trimethoprim-sulfamethoxazole (TMP-SMX) Also known as co-trimoxazole, it is a broad-spectrum combination antibiotic. The drug combination is synergistic as the drugs interfere with two successive steps in the formation/utilization of folic acid by microorganisms.

Vancomycin A glycopeptide antibiotic highly effective against Gram-positive bacteria, especially staphylococci.

Viral Infections

10

Andre Avelino Costa Beber, Ana Maria Benvegnú,
Lia Natália Diehl Dallazem, and Luiza Nunes Lages,

Key Points

- Cutaneous viral diseases comprise a heterogeneous group of diseases with different degrees of severity, ranging from a self-limited course to chronic and recurrent infection.
- The main goal of treatment is to control the outbreak, not to eradicate the virus.
- The severity of disease is related to the immune status of the affected individual.

Human Herpesvirus

Herpesviridae is a large family of viruses, also known as herpesviruses. The Herpesviridae family involves viruses that share a common virion structure. The viral particle consists of a double-stranded DNA core surrounded by an icosahedral capsid consisting of 162 capsomeres surrounded by unstructured protein matrix called tegument,

which in turn is surrounded by a lipid bilayer membrane called the envelope [1].

All herpesvirus infections share the same sequence: primary infection, latency, and reactivation, which, depending on the virus, can be localized or systemic. Some of them may be carcinogenic.

The human herpesviruses discussed in this chapter are described in Table 10.1.

Herpes Simplex (HHV-1 and HHV-2)

Epidemiology

Herpes simplex virus (HSV) comprises Herpesviruses 1 and 2. The seroprevalence in adults in the fourth decade of life for the two types of HSV reaches 90% of the world population, influenced by factors such as sex, age, and geographic location, and is higher in populations of lower socioeconomic status. HSV-1 is predominantly related to orolabial infections (80–90% of cases) and HSV-2 is mostly associated with genital infections (70–90%), although HSV-1 is entailing larger proportions of these infections and becoming more prevalent than HSV-2 in regions such as the United States and United Kingdom [2]. Worldwide HSV-1 prevalence varies with age, race, geographic location, and socioeconomic status; a higher rate of seropositivity has been reported for less industrialized countries. Risk

Table 10.1 Human herpesvirus

Human herpesvirus	Synonyms	Classification	Main clinical presentation
Human herpesvirus 1 (HHV-1)	Herpes simplex virus type 1 (HSV-1)	Alphaherpesvirinae	Orolabial herpes
Human herpesvirus 2 (HHV-2)	Herpes simples virus type 2 (HSV-2)	Alphaherpesvirinae	Genital herpes
Human herpesvirus 3 (HHV-3)	Varicella zoster virus (VZV)	Alphaherpesvirinae	Varicella and herpes zoster
Human herpesvirus 4 (HHV-4)	Epstein–Barr virus (EBV)	Gammaherpesvirinae	Infectious mononucleosis
Human herpesvirus 5 (HHV-5)	Cytomegalovirus (CMV)	Betaherpesvirinae	–
Human herpesvirus 6 (HHV-6)	–	Betaherpesvirinae	Exanthema subitum
Human herpesvirus 7 (HHV-7)	–	Betaherpesvirinae	Exanthema subitum/ Pityriasis rosea
Human herpesvirus 8 (HHV-8)	Kaposi sarcoma–associated herpesvirus (KSHV)	Gammaherpesvirinae	Kaposi sarcoma

factors for genital HSV infection include older age, female gender, poor socioeconomic status, low level of education, prior sexually transmitted disease (STD), early age at first intercourse, and a higher number of sexual partners over the lifetime [3].

Etiopathogenesis

HSV-1 and HSV-2 are enveloped alphaherpesviruses with double-stranded DNA. They are transmitted through direct contact with active lesions or through mucocutaneous secretions of asymptomatic individuals in the replicative phase of the virus, infecting mucous membranes or small abrasions on the skin [3]. HSV replicates on the inoculated surface, then follows the sensory nerves toward the dorsal nerve root, where it becomes latent. The virus remains dormant and is not removed from the body, and can remain so throughout the life of the infected individual or reactivate intermittently, depending on the cellular immunity that controls the replication of the virus. Possible triggers of relapse episodes are emotional stress, fever, tissue damage at the site of appearance of the lesion, immunosuppression conditions, and ultraviolet radiation. Serious systemic recurrence of clinical infection may occur in immunosuppressed patients [2]. HSV-1 is mainly related to oral, oropharyngeal, facial, eye, and brain lesions, whereas HSV-2 is mainly

responsible for anogenital infections, important for sexual transmission.

Clinical Presentation

The clinical presentations result from the episode of primary infection or recurrence, noting that most primary infections occur asymptomatically.

Two types of initial symptomatic presentations are possible for HSV infection. A true primary HSV infection refers to the first episode of herpes in an HSV-1- or HSV-2-seronegative individual. A nonprimary infection refers to acquisition of one type of HSV by a person already infected with the other type. True primary infections are more severe, often associated with constitutional signs and symptoms as well as longer duration of viral shedding. Analysis of acute and convalescent sera for anti-HSV antibodies is helpful in the differentiation of primary from nonprimary herpetic infections. More specifically, high levels of immunoglobulin (Ig) M are consistent with a primary infection whereas elevated, acute levels of IgG are suggestive of a nonprimary infection.

Lesions of herpetic infection are generally preceded by an incubation period of about 3–7 days, after which a painful cluster of vesicles on an erythematous base appear at the injection site, progressing to erosions, pustules, and crusting, which resolve in about 2–6 weeks (Figs. 10.1

and 10.2). Lesions may be preceded by fever, local lymphadenopathy, and symptoms of pain or numbness at the site where the vesicles appear. In childhood, it is common for a form of primary infection to manifest as herpetic gingivostomatitis, whereby quite painful eroded and edematous lesions on the lips, oral cavity, and oropharynx occur and can cause major drooling and dysphagia. In young adults, it can also sometimes appear as pharyngitis similar to mononucleosis. In geni-

tal herpetic primary infection in women, vulvitis or vaginitis, or injuries to the perineum or even the cervix, can occur. In men, the lesions are located on the penis (glans or body) and in the perineal region (Fig. 10.3).

After primary infection the virus becomes latent, and there may be clinical or subclinical reactivations, and in both the virus can be transmitted [4]. The symptomatic episodes usually have lesions similar to those of the primary infection, but prodromal symptoms of pain or numbness can also occur in the location, although generally the clinical presentation is less extensive and symptomatic, and less durable. Despite the higher prevalence of the disease in orolabial and anogenital regions, the infection can occur in any region of skin or mucous membranes. Infection by either of the HSVs does not generate immunity to protect from infection by the other HSV.

Some special forms of herpetic infection are described below.

- In immunocompromised patients, the lesions may present as extensive ulcerations, and vegetative and exophytic lesions, and may affect

Fig. 10.1 Oral primary HSV infection

Fig. 10.2 Genital primary HSV infection

Fig. 10.3 Recurrence of genital HSV

more than one location or even be disseminated. There may be gastrointestinal and respiratory tract involvement.

- Herpetic whitlow occurs in children or professionals in the medical and dental fields after direct digital contact with infected individuals without the use of gloves. It presents vesicular lesions in the fingers, with pain and swelling (Fig. 10.4).
- Herpes gladiatorum is the term used for infection that occurs in athletes participating in contact sports, such as fights, with injuries in different places of the body where the contact and viral inoculation occurred.
- Eczema herpeticum (Kaposi varicelliform eruption) is a complication that usually occurs in patients with atopic dermatitis, but also in patients with other diseases of compromised skin barriers, such as pemphigus, Darier's disease, Hailey–Hailey disease, burns, ichthyosis, or mycosis fungoides. It is more often apparent on the face, characterized by HSV-1-related eroded and crusty lesions, these being more evident than the vesicles; an overlap of the bacterial infection on the clinical presentation or spread of HSV can occur.

Fig. 10.4 Herpetic whitlow

- Erythema multiforme has HSV as one of the main triggers, accounting for about 80% of recurrent cases. The target lesions, especially in the legs and arms, appear approximately 10 days after viral reactivation and last about 2 weeks. There are generally no associated systemic symptoms [3].
- Extracutaneous forms, such as an eye infection, can cause keratoconjunctivitis and may lead to ulcers and corneal scarring with consequent blindness, and herpes encephalitis, which can have high mortality and morbidity with neurologic sequelae in survivors.

- Neonatal infection presents a higher risk in pregnant women who acquire the infection in the genital area in the peripartum period, with a low risk in cases of recurrent genital herpes. The clinical presentation starts at around 5 days of newborn life, with localized or disseminated lesions, more on the scalp and trunk, and there may be ocular, oral cavity, or multiple organ involvement, much like the central nervous system (CNS). Mortality is high without treatment (>50%), and in survivors the occurrence of neurological and/or ocular sequelae is common.

Diagnosis

In most cases, the diagnosis is based on the patient's history and the clinical signs and symptoms. Laboratory confirmation, however, may be required in immunocompromised patients if the clinical presentation is atypical [5].

Viral etiology can be confirmed by the Tzanck smear and pathology. The confirmation of the causative agent is obtained through viral culture, which is the gold-standard method, or by polymerase chain reaction (PCR). Serologic tests have high sensitivity and specificity, but have limited usefulness because of the high prevalence of the virus.

Differential Diagnosis

The orolabial lesions of the primary infection should be differentiated from aphthous stomatitis, pemphigus vulgaris, erythema multiforme, Stevens–Johnson syndrome, herpangina, and hand-foot-and-mouth disease. Lesions only involving the face and lips should also be differentiated from impetigo.

Genital herpes should be mainly differentiated from other STDs, such as syphilitic chancre, chancroid, or lymphogranuloma venereum. Other conditions to bear in mind are erosive lichen planus, lichen sclerosus, atopic dermatitis, and urethritis.

Therapeutic Approach

An overall evaluation of the clinical signs, symptoms, and general health of the patient is essential to the success of therapeutic interventions for HSV infection. Other factors influencing treatment selection include the site of infection and the primary or recurrence status. The current management approach to HSV infection does not target viral eradication, but rather the prevention of transmission, suppression of recurrence, attenuation of clinical course, viral shedding, and complications, as well as palliation and promotion of healing [3].

Antivirals used in the primary infection and recurrent genital or orolabial episodes are the same, with the route of administration and the treatment time determined by the severity of the disease and the patient's condition. In primary and recurrent uncomplicated infections, the most effective treatment is oral antivirals [6]. When used early, preferably within 48 h of onset (higher viral replication period), the duration of symptoms and potential transmission are reduced [3, 7]. Acyclovir is the oldest antiviral used, but its short half-life requires it be taken several times a day. Famciclovir and valacyclovir have a longer half-life and allow fewer doses per day, which may offset their higher costs and ensure adherence to treatment [8]. Therapeutic options and dosages of the main antivirals for the treatment of HSV are summarized in Table 10.2.

Treatment with topical medications, namely acyclovir 5% and penciclovir 1%, may be used in minor recurrent episodes. However, this route is less effective than systemic treatments for not reaching viral replication sites beyond the visible lesions [3, 5, 8].

Relief measures for local symptoms can be used, such as topical anesthetics. Ingestion of cold food and cold compresses are also valid, as well as the use of topical antiseptics to minimize the risk of bacterial infection.

Chronic suppressive therapy is indicated for patients with genital or orolabial herpes who present six or more episodes per year. This reduces the risk of transmission of infection and improves quality of life. The same medications used in the episodes are used indefinitely in continuous regimens, ranging from 4 to 12 months in studies already conducted [4, 7, 8].

New drugs under study attempt to reduce the severity of the attacks and the risk of transmitting the virus. A recently published study suggested an efficacy of approximately 51% for

Table 10.2 Treatment of herpes simplex

Primary infection in immunocompetent patients	Acyclovir 200 mg 5×/day or 400 mg 3× or 5×/day for 7–10 days
	Children: 15 mg/kg
	Valacyclovir 500–1,000 mg/day for 7 days
	Famciclovir 250 mg tid for 7–10 days
Recurrence in immunocompetent patients	Acyclovir 400 mg tid or 200 mg 5×/day for 5–10 days or 800 mg tid for 2 days
	Valacyclovir 500 mg bid for 3 days or 1 g/day for 5 days or 2 g bid for 1 day
	Famciclovir 125 mg bid for 5 days or 1 g bid for 1 day or 1500 mg 1× in 1 day
Infection in immunocompromised patients	Acyclovir 400 mg tid or 200 mg 5×/day or 5–10 mg/kg IV 8/8 h until lesions improve
	Valacyclovir 500–1000 mg bid until lesions improve
	Famciclovir 500 mg bid until lesions improve
Chronic suppression	Acyclovir 400 mg bid
	Valacyclovir 500–1000 mg/day
	Famciclovir 250 mg bid
Eczema herpeticum	Acyclovir 15 mg/kg (maximum 400 mg) 3–5×/day for 7–14 days. Consider IV if generalized
	Valacyclovir 1 g bid 7–14 days
	Famciclovir 500 mg bid 7–14 days

Dosage for oral use, unless IV use is stated
bid twice daily, *IV* intravenously, *tid* three times a day

tenofovir gel topically applied before intercourse to reduce transmission of HSV-2 in South African women [9].

Pritelivir is a new drug that inhibits viral replication by inhibiting the helicase-primase enzyme, which does not require activation by phosphorylation. A recent study of 156 participants showed superiority over the placebo in reducing viral replication and the number of days with lesions in patients with a history of recurrent genital herpes without comorbidities, with better results at a dose of 75 mg/day [10].

Intravenous acyclovir is indicated for severe disease or immunocompromised patients (10–20 mg/kg thrice daily for 7–14 days). Acyclovir resistance may occur mainly in immunocompromised patients, requiring treatment with intravenous drugs such as foscarnet (40 mg/kg intravenously (IV) every 8–12 h for 14–21 days) and cidofovir (5 mg/kg/week IV for 2 weeks an afterward, every other week). Both medications are nephrotoxic, requiring hydration and monitoring of renal function [2–4].

There is currently no licensed vaccine available for HSV. The development of vaccines capable of preventing infection by HSV-1 and -2 remains a challenge [6, 11]. The vaccine models tested thus far have not achieved the same results obtained in laboratory animals and have not reached phase II clinical studies [11].

Varicella Zoster Virus (HHV-3 or VZV)

Introduction
Varicella zoster virus (VZV) is the cause of two diseases, varicella and herpes zoster, also popularly known as chickenpox and shingles, respectively. Varicella is highly contagious and affects a younger age group, with predominance in children under 10 years of age. Herpes zoster, which is the result of viral reactivation, affects more adults and elderly after the sixth decade of life, with a greater frame of morbidity [2, 12].

Epidemiology
VZV is present throughout the world. United States data show that more than 95% of its population is seropositive for this virus. Some differences are noteworthy in relation to varicella and herpes zoster.

Varicella occurs predominantly in children under 10 years of age, reaching 90% of cases in this age group. The risk of acquiring the disease is higher the closer the contact with the infected individual. The disease has a peak incidence in winter and spring in populations of temperate climates, with epidemics occurring every 2–5 years [2, 13]. Before the introduction of the vaccine against the virus, global rates were estimated at 4 million cases per year including all age groups. These numbers decreased drastically after the

start of the administration of the vaccine, which was validated in the United States in 1995, with a decrease of 97% in incidence between 1995 and 2010. The most severe forms usually occur in people older than 12 years of age, immunocompromised patients or those with immune deficiencies, fetal exposure between 8 and 26 weeks of gestation, and fetal exposure to maternal infection from 5 days before to 2 days after birth [13].

Etiopathogenesis

VZV is an enveloped neurotropic virus with double-stranded DNA, and belongs to the Herpesviridae family and the Alphaherpesvirinae subfamily, with humans as the specific reservoir, although some mammals may carry the latent virus [12].

Varicella is highly contagious, transmitted through contact with infected people who expel the virus through the respiratory route (droplets). Transmission may also occur through direct contact with the secretions of the skin lesions, the transplacental route, during a blood transfusion or contact with people with herpes zoster. Transmission starts 1–2 days before the onset of a rash and continues until all lesions are at the crust stage. The incubation period can range from 10 to 21 days. After contact, through an inhalation route, infection occurs in the respiratory mucosa and replication in the regional lymph nodes, and the virus is transported to the liver and spleen, which constitutes the first viremia. During the second viremia, the virus is transported via capillary endothelial cells to the skin and mucous membranes, and subsequently migrates into dorsal root ganglion cells. The virus can remain latent after infection or after the vaccination [2, 12, 13].

Herpes zoster has the characteristic of being significantly less contagious than varicella, transmission occurring by direct contact with the fluids of cutaneous lesions. The virus is neurotropic and can maintain latency for long periods. The major sites where the virus lodges are the ganglia of the cranial nerves, dorsal root ganglia, and autonomic ganglia of the neuraxis. In addition to the risk factors mentioned above, herpes zoster can be triggered by stress, trauma, immunosuppression, or fever [12].

Clinical Presentation

Varicella presents prodrome of fever, malaise, headache, and abdominal pain 1–2 days before the onset of a vesicular rash. The fever lasts around 3–5 days. Lesions begin on the face and scalp, evolving into the trunk and extremities, and can affect the mucous membranes, such as the oropharynx, conjunctiva, and genital region. Initially the lesions are erythematous and pruritic maculopapular rashes, after which vesicles of clear serous content and an erythematous halo appear; in the terminal stage crusts are formed, which after healing can progress to scars (Fig. 10.5a–d). Crusts can last up to 2 weeks before total disappearance. Characteristically the patient has skin lesions at various stages of evolution, since new lesions may appear up to 7 days after the onset of the infection. Usually 250–500 vesicles are observed, which may surpass 1000. In healthy children the infection is benign and self-limited, evolving to curability within 7–10 days [2].

In adults and immunocompromised patients, the infection can show a longer period of fever, a greater number of lesions, longer duration, and increased risk of secondary infection.

Congenital infection is more serious if the mother is affected in the first trimester of pregnancy. The risks to the fetus include skin scars, hypoplasia of limbs, neurological disorders (cortical atrophy and psychomotor retardation), and ocular changes [13, 14].

The most common complication of cutaneous lesions is secondary bacterial infection associated with Gram-positive organisms. Varicella-associated pneumonia is most common in adults and immunocompromised patients. The involvement of the CNS, although rare, may occur, manifesting as cerebellar ataxia, encephalitis, and Reye's syndrome. Other rare complications include purpura, thrombocytopenia, ischemic stroke, cerebral venous thrombosis, transverse myelitis, Guillain–Barré syndrome, premature birth, and ocular changes (unilateral anterior uveitis, corneal lesion, optic neuritis, acute retinal necrosis, and necrotizing scleritis) [2, 13].

Herpes zoster, consisting of the reactivation of latent varicella infection, most often begins with

Fig. 10.5 (**a–d**) Varicella: cutaneous and oral lesions

neuralgia prodromes (severe pain, itching, tingling) that precede the appearance of skin lesions at 1–5 days. The lesions are characterized by grouped vesicles on an erythematous base, following the distribution of a dermatome, usually without crossing the midline (Fig. 10.6a, b). Rare cases manifest as pain without cutaneous lesions, known as "zoster sine herpete" (i.e., zoster without cutaneous eruption). Lesions present remission in 2–4 weeks and most patients do not assume significant systemic symptoms [14].

The most affected areas are the chest, skull (especially the trigeminal nerve), lower back, and cervical region. Ocular involvement should be suspected, given the risk of blindness. Lesions in the nasal wing may suggest eye involvement even before the emergence of lesions around the eyes. Ophthalmic herpes zoster normally presents with vesicles on an erythematous base in the periorbital region, eyelid edema, and conjunctival edema. Eye pain or blurred vision may indicate retina necrosis. Evaluation by an ophthalmologist is indicated when there is suspicion of ocular involvement. When reactivation occurs in the geniculate ganglion, it is called Ramsay–Hunt syndrome and is characterized by lesions in the ear canal, tongue, and/or hard palate, and facial nerve paralysis may occur. Neurologic involvement may be manifested by altered mental state, headache, focal deficit, paresis, muscle weakness, ataxia, and tremors, which may correspond to vasculopathy, myelopathy, radiculopathy, or cerebellitis [12].

Fig. 10.6 (**a**, **b**) Herpes zoster

Other complications of herpes zoster can occur at the site of eruption, such as bacterial superinfections by *Staphylococcus aureus* and *Streptococcus pyogenes*, hyperpigmentation, and evolution of cutaneous scar, besides postherpetic neuralgia, which will be mentioned later.

Diagnosis and Complementary Examinations

The diagnosis of varicella and herpes zoster is clinical, based on history and physical examination, which shows the characteristics of the lesions and their distribution. Diagnostic confirmation may require other methods, including serology, viral culture, direct immunofluorescence staining, indirect immunofluorescence, PCR, and Tzanck smear performed with material collected from the fluid of the vesicles, crusting lesions, skin or oropharynx swab, cerebrospinal fluid, tissue samples, saliva, or blood. For faster results the Tzanck smear and direct immunofluorescence staining is used. The Tzanck smear reveals giant multinucleated epithelial cells, which does not differentiate between infection by the VZV and herpes simplex. Direct immunofluorescence staining differentiates the infection of HSV from VZV and is more sensitive than cultures, but less so than PCR. PCR is the most suitable approach because of its high sensitivity and specificity. The culture is the most specific, although it takes about a week for the result, which makes it unfeasible to plan the antiviral therapy [2, 12, 14].

Differential Diagnosis

The differential diagnosis of varicella includes vesicular rash caused by enterovirus or *S. aureus*, herpes simplex, insect bites, erythema multiforme, scabies, papular urticaria, drug eruption, contact dermatitis, herpetiformis dermatitis, Stevens–Johnson syndrome, guttate psoriasis, pityriasis lichenoid, syphilis, smallpox, and congenital histiocytosis.

Herpes zoster should be differentiated from HSV, smallpox, contact dermatitis, impetigo, cellulitis, bites and stings, candidiasis, autoimmune bullous disease, dermatitis herpetiformis, drug reactions, and Sweet's syndrome.

Therapeutic Approach

Varicella in immunocompetent children can be treated symptomatically with antipyretics (e.g., acetaminophen), antihistamines, calamine lotion, and tepid baths [2].

The use of acyclovir in chickenpox is approved by the FDA for children over 2 years of age and for adults because of its potential to reduce the time of infection and severity. Ideally it should be started within 24 h of onset of cutaneous lesions, with a margin of up to 72 h. In adults, because of the higher risk of severity, treatment with antiviral drugs is always recommended. In children 2–16 years of age, 20 mg/kg four times a day for 5 days is utilized, with a maximum of 800 mg/day [2, 3]. In persons over 16 years of age, 800 mg five times a day for 5 days is recommended [2, 12, 13].

In herpes zoster lesions, one can make use of aluminum or Burow acetate solution. For the pain one can use the same medications as for varicella, but often, because of its greater intensity, medications such as opioids and tramadol may be included. Opioid options for moderate to severe pain include codeine, hydrocodone, oxycodone, methadone, and morphine. The use of acyclovir, as well as in varicella, reduces the duration, severity of the infection, and pain, but there is no evidence that it can prevent postherpetic neuralgia [15]. It is indicated to be started within 72 h, but it is accepted that its introduction can occur within the first week. Formal indications for the use of acyclovir include immunocompetent adults older than 50 years with moderate to severe symptoms, ophthalmic herpes zoster, disseminated herpes zoster, and immunocompromised patients. Antiviral and available doses are summarized in Table 10.3. In cases of severe disease, CNS involvement, disseminated varicella zoster, or herpes zoster in immunocompromised patients, intravenous acyclovir is indicated. In children under 12 years of age the acyclovir dose is increased to 20 mg/kg. In cases of resistance to acyclovir, the patient will benefit from the use of foscarnet 40 mg/kg intravenously every 8 h for 10 days. Approved in some countries, brivudine 125 mg orally, once daily for 7 days, is another option. In cases of eye or hearing impairment, the ophthalmologist and otolaryngologist should be consulted. For herpes zoster with involvement of the retina, intravenous acyclovir is preferred over oral administration [2, 13].

Prevention

Vaccine: For the prevention of the disease and severe forms, the Advisory Committee on Immunization Practices (ACIP) recommends two doses of the live attenuated Oka varicella zoster virus vaccine, with seroconversion rates of up to 96% in healthy children [16]. The first dose should be administered between 12 and 15 months of age and the second between 4 and 6 years of age. The second dose of vaccine may be combined with the measles, mumps, and rubella (MMR), forming the MMRV. In children under 13 years of age, the second dose of vaccine should be administered within a range of 3 months or more from the first dose. In persons older than 13 years, doses should be spaced 4–8 weeks apart. ACIP emphasizes the importance of the vaccine in special situations, such as health professionals, carers of immunocompromised people, teachers, carers of children, college students, institutionalized patients or employees of these institutions, military personnel, and international travelers [16]. The vaccine is contraindicated in pregnant women, blood dyscrasias, leukemia, lymphoma, malignant neoplasm of the bone marrow or lymphatic system, use of drugs at immunosuppressant doses, severe disease carriers, history of anaphylaxis or anaphylactoid reaction to gelatin, neomycin, or other components of the vaccine, and history of having received red blood cells, plasma, or immunoglobulin in the last 3–11 months [17]. Postexposure prophylaxis should be carried out with the vaccine in indi-

Table 10.3 Treatment of varicella and herpes zoster

Age group	Disease	Antiviral dose
2–16 years	Varicella	Acyclovir 20 mg/kg po 4×/day × 5 days (maximum: 800 mg/day)
<12 years	Herpes zoster	Acyclovir 20 mg/kg IV q8 h × 7–10 days
>16 years	Varicella and herpes zoster	Acyclovir 800 mg po 5×/day × 7 days
		Valacyclovir 1 g po tid × 7 days
		Famciclovir 500 mg po tid × 7 days
		Acyclovir 10 mg/kg IV q8 h × 7–10 days
		Foscarnet 40 mg/kg IV q8 h × 10 days
		Brivudine 125 mg po qd × 7 days

Recommended dose of antivirals based on disease and age group [2, 3]
IV intravenously, *po* orally, *q8 h* every 8 h, *qd* once a day, *tid* three times a day

viduals who show no evidence of immunity and in susceptible patients, and ideally up to 3–5 days after exposure to prevent disease or severe forms [18].

The vaccine for herpes zoster was developed for the prophylaxis of herpes zoster and showed a 50% reduction in the incidence of the disease in the treated group compared with the control group. It is recommended for adults older than 60 years [19]. The FDA had approved it for adults aged 50 through 59 years but the ACIP declined to recommend the vaccine for this age group because of short-term vaccine efficacy. Contraindications to vaccine for herpes zoster include immunosuppression (e.g., HIV infection with CD4 lower than 200/mm^3, hematologic or lymphatic malignancies, and using immunosuppressive therapy), acute herpes zoster infection, or other active severe acute disease [19, 20].

Varicella zoster immune globulin: The varicella zoster immune globulin (VZIG), which is prophylactic through passive antibodies, provides temporary passive immunity. It should be administered 96 h after exposure and lasts 3 weeks. It is indicated as prophylaxis in immunocompromised patients or pregnant women without evidence of immunity to varicella zoster, newborns of mothers who had chickenpox 2 days before to 5 days after birth, premature newborns of 28 weeks or more who were exposed to varicella during the neonatal period with mothers without evidence of immunity, and preterm infants of less than 28 weeks or weighing less than 1000 mg that were exposed during the neonatal period [2, 12, 13]. Immune globulin is administered as a single intramuscular dose, according to Table 10.4.

Table 10.4 Varicella zoster immune globulin

Weight	Dose
Below 2 kg	62.5 IU
2.1–10 kg	125 IU
Above 10 kg	625 IU

Single intramuscular dose

Postherpetic Neuralgia

Postherpetic neuralgia (PHN) is the most common complication of herpes zoster, and is defined as pain that persists for more than 3 months after the resolution of cutaneous lesions. The incidence is estimated at 9–34%, and the risk is higher in the elderly and in persons with shingles with severe acute pain, exacerbated cutaneous eruptions, ophthalmic herpes, and intense prodromal pain. Generally pain is resistant to commonly used pain relievers, so some alternative medications become necessary [21]. Therapeutic options for PHN are listed in Table 10.5.

Epstein–Barr Virus (HHV-4)

Epidemiology

Epstein–Barr virus (EBV) is also known as human herpes virus type 4 (HHV-4) of the Gammaherpesviridae family.

EBV has a worldwide distribution and high epidemiological prevalence, with about 95% of infected adults around the world, and in developing countries transmission occurs almost universally in childhood [22–24].

EBV is transmitted primarily by the saliva of infected individuals, and hence the infectious mononucleosis (IM) is also called "kissing disease." The virus is secreted by saliva in high concentrations for longer than 6 months after primary infection. The infection tends to be mild and with nonspecific symptoms in children under 4 years of age, while the characteristic clinical presentation of IM occurs mainly in adolescents and young adults [22, 24]. Sexual transmission does not seem to play an important role. Human beings are the only natural reservoir of the virus [2, 22].

Etiopathogenesis

After inoculation of EBV via infected saliva, the virus infects mucosal epithelial cells of the oropharynx and B lymphocytes (connection with the CD21 receptor), where it initiates replication [2, 22]. The virus still has the capacity to infect other leukocytes, such as T cells and natural

Table 10.5 Treatment of postherpetic neuralgia

Medications	Observation
Amitriptyline 10 mg/day (initial) to 50–100 mg/day	Tricyclic antidepressants are effective in treating chronic pain. They should be started at low doses. A baseline ECG is required
Nortriptyline 10–25 mg/day (initial) to 30–75 mg/day	
Desipramine 10–25 mg/day (initial) to 50–150 mg/day	
Venlafaxine and duloxetine	Serotonin reuptake and noradrenaline are effective in treating chronic pain
Pregabalin 150–300 mg/day up to 600 mg/day	Anticonvulsant with good patient acceptance
Gabapentin up to 1800 mg/day divided into 3 doses daily	
Carbamazepine and valproic acid	Anticonvulsants with less patient acceptance
Opioids	Good option, requiring concomitant prophylaxis for constipation
Tramadol	Cholinergic syndrome risk if administered concurrently with serotonin reuptake inhibitors or tricyclic antidepressants
5% topical lidocaine	Has low systemic absorption and significantly reduces pain and allodynia
Capsaicin	After repeated application on site, causes depletion of substance P and other neuropeptides of the nociceptive fibers, which causes analgesia
	Owing to the possibility of local irritation and stinging, its use is indicated after treatment with lidocaine
Other treatments	Observation
Epidural blocks, intrathecal injection, and sympathectomy	Have not shown favorable cost-benefit because of adverse effects presented
Spinal cord stimulation	Encouraging results in intractable pain and the incidence of postherpetic neuralgia
Botulinum toxin	Reduction in pain and improved quality of sleep, lasting about 3–4 months

killer (NK) cells, as well as endothelial and smooth muscle cells. After an incubation period of about 30–50 days, symptoms due to high viremia occur: pharyngitis, fever, and lymphadenopathy, which characterize the infectious mononucleosis picture, albeit less severe [2, 23, 24]. After resolution, some B cells become infected and the latency of the virus is established throughout the life of the individual. Immunocompetent patients, through preserved cellular immune response, can prevent the replication of the virus in the infected cells according to the actual status of latency. Especially in immunocompromised patients, failure to control the replication of cells chronically infected with the virus results in these cells continuing to express their proteins, leading to the risk of lymphoproliferative disorders related to infec-

tion. Reactivation of latent virus present in infected lymphocytes in the oropharynx may occur, causing viral excretion during the entire life of the host [2, 23].

Clinical Manifestations

Infectious mononucleosis is the manifestation of primary EBV infection in about 30–50% of those infected, and occurs most commonly in adolescents and young adults between the ages of 15 and 25 years [2, 24].

The incubation period in adolescents and adults lasts approximately 30–50 days, after which the characteristic triad of fever, pharyngitis, and lymphadenopathy (especially cervical) is seen in >80% of patients. Common accompanying symptoms include malaise, fatigue, chills, and headache. Fever can last up to 10 days. Splenomegaly

is found in >50% of patients and can be accompanied by hepatomegaly. Other clinical findings may include exudative pharyngitis (often gray–white), anorexia, nausea, vomiting, cough, and arthralgia. Symptoms usually improve in about 2–4 weeks, while lymphadenopathy may last up to 6 months.

The cutaneous manifestation associated with IM is a morbilliform eruption (in approximately 3–15% of cases) on the trunk and upper extremities, which may spread to involve the face and forearms, typically lasting up to 7 days [25]. The occurrence of a maculopapular rash, which occurs 7–10 days after administration of antibiotics (prescribed, in most cases, for the treatment of symptoms of IM that are associated with streptococcal pharyngitis) is very characteristic of IM (Fig. 10.7a–c). It was first observed with the use of ampicillin (occurring in up to 95% of cases), but can occur with various other antibiotics. The rash lasts about 1 week. Hemolytic anemia and thrombocytopenia with associated thrombocytopenic purpura and disseminated intravascular coagulation can occur. Neurologic complications are rare (Guillain–Barré syndrome, facial palsy, aseptic meningitis, and encephalitis) [24].

Other manifestations resulting from infection with EBV related to acute or chronic infection/viral reactivation are:

- Lipschütz ulcers: Acute genital ulcers not related to sexual transmission. They occur as a complication of acute infection in adolescents or prepubescent girls, are usually located in the region of the labia minora, and are painful. They have important differentiation with STDs and suspected sexual abuse [22].
- Oral hairy leukoplakia: Benign change related to immunosuppression, indicative of disease progression to AIDS in HIV-positive individuals. White or gray plaques, firmly adhered to the mucosa of the dorsal or lateral side of the tongue, are characteristic. They are mostly asymptomatic.

- Gianotti–Crosti syndrome: EBV has increased in incidence as a result of this disorder (see Gianotti–Crosti syndrome in this chapter).
- Other skin manifestations related to EBV are hydroa vacciniforme, erythema multiforme, erythema nodosum, erythema annulare centrifugum, pityriasis lichenoides, drug reaction with eosinophilia and systemic symptoms (DRESS) syndrome, and vasculitis purpura, among others [22, 23].
- Neoplastic diseases associated with EBV are oropharynx carcinoma, B- and T-cell lymphomas, NK cell lymphoma, Burkitt's lymphoma (especially the African endemic form), Hodgkin's lymphoma, and hemophagocytic syndrome. The causal relationship between the EBV and cutaneous T-cell lymphomas is still controversial [26, 27].

Diagnostic and Complementary Examinations

Clinical and laboratory data are important for IM diagnosis (see Box 10.1).

Leukocytosis with the presence of atypical lymphocytes (20–40%), thrombocytopenia, and lightly to moderately elevated transaminases may occur in IM in 50% of patients.

Heterophile antibody titers >1:40 are considered positive for IM. The most widely used method for detecting heterophile antibodies is the qualitative rapid slide test, known as the mono-

---

Box 10.1 Laboratory Diagnosis Key points

EBV infection

Up to 10% of patients with IM are heterophile negative

For suspected primary EBV infection, a heterophile antibody test should be performed, followed by EBV serology when the heterophile test is negative, but clinical suspicion remains high

EBV-encoded RNA in situ hybridization is considered the gold standard for detecting and locating latent EBV in tissue samples

Fig. 10.7 (**a–c**) Amoxicillin-induced maculopapular rash in a child with IM caused by EBV

spot test, a latex agglutination assay, which has reported sensitivity of 85% and specificity approaching 100%.

Despite high sensitivity and specificity, the heterophile antibody tests have several limitations. The test has a significant false-negative rate during the first week of infection, and is of limited use in children under 4 years of age. False-positive results have been reported in some diseases, such as malaria, rubella, and primary HIV infection.

Acute EBV infection is uniformly characterized by a rapid IgM and IgG antibody response to the viral capsid antigen (VCA). Anti-VCA IgM is the single most valuable and specific serologic test in confirming primary EBV infection. The response appears before the onset of symptoms and remains positive for up to 3 months. IgG-VCA peaks later in the acute phase, declines over several weeks to months, and then remains positive for life [22].

Differential Diagnosis

IM must be differentiated from other viral infections that present skin rash, lymphadenopathy, and pharyngitis, such as streptococcal infection, CMV, toxoplasmosis, HHV-6, acute viral hepatitis, and acute retroviral syndrome from HIV, which require a combination of clinical and laboratory examinations for diagnosis [24, 25].

Therapeutic Approach

Only supportive treatment is needed for most patients suffering from IM, with medication to control the symptoms, proper hydration, and nutrition. Relative rest is recommended, but without the necessity of restriction to bed rest. Acyclovir did not show a reduction of viral replication or a significant alteration to the course of infection [24].

One study showed that valacyclovir used for 1 year in chronically infected patients with EBV reduced the frequency of infected B lymphocytes detected in the peripheral blood in comparison with controls without treatment. The authors estimated that it would take 11 years of daily treatment to cure the infection in an individual [8].

The use of corticosteroids is reserved for complicated cases of IM, such as the obstruction of the upper airways, hemolytic anemia, and thrombocytopenia due to its adverse effects. However, in both complicated cases and cases without gravity, studies with the highest level of evidence based on its use are lacking. Associated lymphoproliferative disorders can achieve resolution with an improvement in immunosuppression, common in these cases, or the need for associated chemotherapy [2, 24].

Cytomegalovirus (HHV-5)

Epidemiology

Also known as human herpes virus type 5 (HHV-5), cytomegalovirus (CMV) is an endemic DNA virus worldwide. The infection is inversely related to socioeconomic status, approaching up to 100% in low-income countries and about 60–70% in developed countries [2, 28]. The risk of acquisition of the infection is higher in childhood (especially children who attend daycare centers) and in adolescence, as well as during a period of sexual

activity. CMV transmission by blood transfusion may occur in about 3% of transfused blood units, owing to the presence of infected leukocytes [2].

The prevalence of clinically evident infections has increased with the growing phenomenon of immunodepression (such as in HIV infections, organ transplants, immunosuppressive treatments), representing an important cause of morbidity and mortality in these populations. Congenital infection occurs in about 0.5–2% of gestations [29].

Etiology

CMV is transmitted by saliva, blood, urine, breast milk, semen and cervicovaginal fluids, solid organs, or transplanted stem cells. Vertical transmission is more probable during a primary infection of the mother (about 40%, versus <1% of infection in the case of recurrent infection), which occurs principally by transplacental transmission, early in gestation [2]. After the infection it enters an incubation period of 4–8 weeks and spreads through the body by leukocyte infection. It displays tropism for various cells (endothelial, epithelial, smooth muscle, macrophages, and neuronal). The virus becomes latent and temporary reactivations may occur, asymptomatic in most cases, with viral shedding in the urine or saliva, enabling the transmission of CMV. Cellular immunity, primarily mediated by $CD8^+$ T cells, presents a major role in the immune control of the infection. In weak immune conditions, persistent viral replication leads to sustained viremia and viral dissemination to various organs, causing cellular damage and an inflammatory response that causes clinical manifestations.

Reinfection can also occur by another antigenic type of CMV with features similar to viral reactivation. In immunocompetent children and adults the most frequently infected organs are lymphoid tissues, while in immunocompromised patients the retina, lungs, liver, and gastrointestinal tract can be affected. Congenital and neonatal infection commonly involves the nervous system [2, 29].

Clinical Manifestations

Clinical presentation varies widely among immunocompetent and immunocompromised patients. In immunocompetent patients, in about 90% of

cases an acute infection is asymptomatic, and when symptomatic is manifested as a syndrome similar to mononucleosis by EBV, with fever, myalgia, nonexudative pharyngitis, lymphadenopathies as well as morbilliform skin rash, urticaria, or purpura [29]. Hepatosplenomegaly may occur.

A skin rash, similar to the occurrence in EBV infection, may appear after the use of ampicillin or other antibiotics in approximately 80–100% of cases. A similar picture is also observed after blood transfusion with CMV-contaminated blood.

The infection is self-limiting, and usually benign, with only rare occurrence of complications such as fulminant hepatitis, Guillain–Barré syndrome, encephalitis, meningitis, retinitis, myocarditis, pneumonia, gastrointestinal disorders, and hematologic abnormalities (hemolytic anemia and pancytopenia).

When there is impairment of cellular immunity, replication and persistent viral dissemination occur, causing lesions in the primary infection and, principally, in reactivation/recurrence of the infection.

The main manifestations in HIV patients occur at CD4 levels below 100, and consist of chorioretinitis, esophageal ulcers, colitis, pneumonitis, and adrenal and CNS involvement. Mortality can be high (up to 80%). In transplant patients, viral reactivation by the required posttransplant immunosuppression or infection acquired from infected donor organ to a seronegative receiver may occur.

The most prevalent and more severe manifestations are that of the gastrointestinal tract and interstitial pneumonitis.

Congenital CMV infection may be asymptomatic at birth, with only 10% of infants manifesting symptoms such as jaundice, hepatosplenomegaly, cardiovascular and gastrointestinal abnormalities, chorioretinitis, and intracranial calcifications, constituting the so-called cytomegalic inclusion disease. Many asymptomatic cases at birth may present posterior sequelae, being one of the major infectious causes of sensorineural deafness and mental retardation. Cutaneous manifestations may or may not be specific to the infection, the former being more related to immunosuppression. Nonspecific is a rash of the acute infection (described above) and lesions of the CMV inclusion disease, such as petechiae, purpura, jaundice, and papular-nodular lesions related to hemopoiesis in the dermis ("blueberry muffin" lesions). The lesions specific to cytomegalovirus, most common in immunocompromised patients, are ulcerations, especially in the anogenital region and thighs. Nodular disseminated cutaneous lesions, warty morbilliform urticaria, and bullae are also described as being related to CMV.

Many of these lesions are associated with HSV infection, especially in HIV-positive patients [30], and studies in the literature question the actual role of CMV in many cutaneous lesions found [31].

Diagnostic and Complementary Examinations

The diagnosis is made by clinical suspicion and confirmation of etiology through laboratory tests. Laboratory alterations such as lymphocytosis, thrombocytopenia, and elevated liver transaminases may occur. CMV culture, performed on human fibroblasts, conducted by collecting lesion material of affected organs or blood, urine, cerebrospinal fluid, semen, or cervicovaginal fluid, is considered the gold standard but is time consuming, requiring at least 2 weeks for results. In lesions of the oral cavity, the test may not be specific because of the possible excretion of the virus from other regions of the upper gastrointestinal tract.

Histopathology is of great value, and shows the cytopathic changes in CMV upon hematoxylin–eosin (HE) staining as extended endothelial cells with characteristic intranuclear inclusions ("owl eyes") considered pathognomonic of infection [2]. Although specific, this finding has lower sensitivity than the culture. Electron microscopy shows no ability to differentiate from other herpesviruses.

PCR is very specific and fast, but does not distinguish primary infection from reactivation.

Specific serologic tests can help distinguish between recent infection or reactivation, the former by detection of IgM and IgG antibodies in high titers and the latter by detection of only IgG. Serology is also useful in the evaluation of congenital infection by the presence of IgM antibodies in newborns [29].

Differential Diagnosis

The differential diagnosis is made with IM by EBV, acute toxoplasmosis, acute viral hepatitis, acute retroviral syndrome by HIV, and DRESS syndrome in acute infections. Ulcerous cutaneous lesions should be differentiated from HSV. Since several atypical cutaneous manifestations may occur, CMV must always be considered in dermatologic disseminated disease in immunocompromised patients.

Therapeutic Approach

Prevention and Treatment

Since CMV is a benign, self-limiting disease, immunocompetent patients generally do not require treatment, only supportive care.

Treatment in immunosuppressed patients consists of pre- and posttransplant antiviral prophylaxis in those susceptible to infection, and antiviral treatment in patients with manifestations of the active disease. The drugs used are intravenous ganciclovir and oral valganciclovir for about 14–21 days. In the congenital infection, the same drugs are also used in symptomatic neonates for 6 weeks [2, 28]. A recent study showed moderate benefit from the use of valganciclovir for 6 months for hearing loss outcomes and neurologic changes compared with 6 weeks of treatment [32]. Resistant infections to ganciclovir and valganciclovir can be treated with foscarnet or cidofovir. Anti-CMV immunoglobulin can be used in more severe cases for prophylaxis or treatment, in combination with antiviral agents.

Several experimental CMV vaccines have advanced to clinical evaluation. The aim of CMV vaccine is disease prevention in congenital infection and post-transplant disease.

Human Herpesvirus 6 (HHV-6)/ Exanthema Subitum

Synonyms: Roseola infantum, sixth disease

Introduction

Human herpesvirus 6 (HHV-6) has two variants, A and B, although new evidence suggests that these subtypes are distinct viruses, each with its own strains. HHV-6A has been found more commonly in skin biopsy specimens from immunocompromised patients and is considered a possible cofactor in AIDS progression. In comparison, HHV-6B is thought to be the primary etiologic agent in exanthema subitum, also known as roseola infantum or sixth disease [33].

Epidemiology

HHV-6A and HHV-6B are ubiquitous viruses that are detected in human populations worldwide. Current serologic assays do not permit discrimination of HHV-6A and HHV-6B infections [34]. HHV-6 infection is usually acquired very early in life, between 6 months and 2 years of age, following the loss of protective maternal antibodies. At an even earlier period of life, congenital infection following intrauterine transmission has been reported in about 1% of children. Around 21% of patients present the typical clinical picture of exanthema subitum in the primary infection, while in approximately 20% of cases the disease is asymptomatic. Data from the adult population in developed countries have shown that infection in this age group exceeds 90% [34].

Etiopathogenesis

HHV-6 is a double-stranded DNA virus, of the Roseolovirus genus and a member of the Betaherpesviridae subfamily (see Box 10.2) [35].

> **Box 10.2 Roseolovirus**
> The Roseolovirus genus of the Betaherpesvirus subfamily is composed of three enveloped, double-stranded DNA viruses: HHV-6A, HHV-6B, and HHV-7.

Transmission occurs via the oral route, purportedly by saliva. The incubation period may vary between 10 and 15 days. The virus replicates in the salivary glands and satellite lymphoid tissues of the oropharynx, probably the tonsils and cervical lymph nodes. Systemic diffusion of infection would then occur by the blood route. This spread leads to the active, abortive, or latent infection of susceptible cells in other organs, including T lymphocytes and monocytic cells in lymphoid tissue and the liver, kidney, and skin epithelial cells, hematopoietic stem cells in bone marrow, and neuroglial cells in the CNS [34].

After primary HHV-6 infection, the virus establishes lifelong latency in CD4+ T lymphocytes, with the potential for reactivation. Immunosuppressed patients are at particular risk for HHV-6 reactivation, sometimes with severe consequences.

Recent studies have shown that HHV-6 has the unique ability to integrate into chromosomal telomeres of infected cells. When this occurs in a germ cell, vertical transmission of inherited chromosomally integrated (ci)HHV-6 results in offspring with latent HHV-6 DNA in every nucleated cell of the body. Studies have shown that 0.2–3% of the study population harbors the entire genome of HHV-6A and HHV-6B integrated at different chromosomal locations. There is evidence that biologically active HHV-6 can reactivate in individuals with inherited HHV-6 and cause disease [34].

Clinical Presentation

Exanthema subitum is the disease caused by HHV-6 during the primary symptomatic infection. The classical clinical picture is of an infant with a high fever (38.9–40.6 °C) that lasts for 3–5 days, followed by a characteristic rash on defervescence. The fever may be intermittent and tends to peak in the early evening. The cutaneous eruption usually lasts for 24–48 h and may develop before the temperature returns to normal or up to 2 days afterwards. The lesions are discrete, circular, or elliptical "rose-red" macules and papules that are 2–5 mm in diameter and occasionally surrounded by a white halo. The cutaneous eruption commonly affects the trunk, proximal extremities, neck, and less often the face. An enanthem of red papules on the soft palate (Nagayama's spots) may also be seen, and

ulcers on the uvula and at the palatoglossal junction represent a characteristic finding. Eyelid edema, mild upper respiratory symptoms, injection of the tympanic membranes, cervical or occipital lymphadenopathy, and a bulging anterior fontanelle may also be evident [2].

Serious complications are rare, although there are reported cases of hepatitis, thrombocytopenia, mononucleosis-like syndrome, colitis, gastroenteritis, myocarditis, febrile seizures, meningoencephalitis, and encephalitis [33, 34].

It has been hypothesized that HHV-6, as well as HHV-7, has a role in the pathogenesis of pityriasis rosea and DRESS syndrome, as well as other conditions such as Stevens–Johnson syndrome, thrombocytopenic purpura, purpura fulminans, gloves and socks syndrome, scleroderma, and Gianotti–Crosti syndrome [33].

Diagnosis and Complementary Examinations

The diagnosis is clinical by the history of high fever for 3–5 days that ceases with the appearance of the characteristic rash [33, 36].

In the acute infection, the presence of IgM antibodies confirms the diagnosis. In reactivation, the fourfold increase in IgG titers in sequential samples retrospectively confirms the diagnosis. In complicated cases or in immunocompromised patients, other techniques may be needed, such as PCR, electron microscopy, and viral culture, this being the gold standard in the active infection [33, 35, 36].

Leukocytosis, thrombocytopenia, and elevated transaminases in febrile phase followed by relative neutropenia and mild atypical lymphocytosis may be present.

Differential Diagnosis

The differential diagnosis is made with the diseases that present fever and rash, such as rubella, scarlet fever, measles, varicella, and erythema infectiosum.

Therapeutic Approach

The treatment consists of supportive care including antipyretics, since the disease often follows a benign and self-limited course. Hydration and hygienic care are also included [37].

Human Herpes Virus 7

Human herpes virus 7 (HHV-7) belongs to the genus Roseolovirus and subfamily Betaherpesviridae with tropism for CD4 T lymphocytes [38]. It is transmitted by saliva and its replication occurs in the salivary glands [33].

HHV-7 was originally isolated from T cells purified from the peripheral blood mononuclear cells of a healthy donor following incubation of the cells. It was then isolated from the peripheral blood mononuclear cells of a chronic fatigue syndrome patient and in healthy children and adults. Subsequently the virus was isolated in peripheral blood of one patient with exanthema subitum. Recent studies suggest a relationship between the virus and pityriasis rosea [33, 38, 39].

HHV-7 is a virus of global distribution and high prevalence in children under 6 years of age. Studies have reported the presence of the virus in the salivary glands and saliva of up to 80–90% of the population. The virus is related to HHV-6 in the etiology of exanthema subitum, and the involvement of both in pityriasis rosea has been suggested [33, 38, 39].

Studies linking HHV-6 and HHV-7 with pityriasis have involved tissue, whole blood, and serum analysis. Although some studies showed a clear association with HHV-6 and HHV-7, others found HHV-6 and HHV-7 to occur more commonly in controls than in persons with pityriasis. Given the nearly universal prevalence of HHV-6 and HHV-7, their association with pityriasis rosea remains under discussion. HHV-7 appears to have an association with lichen planus because of the more frequent presence of the virus in biopsy of lesions in healthy skin. It also may be related to graft-versus-host disease and DRESS syndrome [33, 38, 39].

Human Herpesvirus Type 8

Epidemiology

Human herpesvirus 8 (HHV-8, also known as Kaposi sarcoma–associated herpesvirus (KSHV)), is associated with the etiology of Kaposi sarcoma (KS) and other lymphoproliferative disorders, such as multicentric Castleman disease and pleural effusion lymphoma, and is most frequently found in immunocompromised patients, particularly by the HIV virus [40].

KS was first described in 1872 by Moritz Kaposi as a tumor of extremities among elderly men; this form became known as classic Kaposi sarcoma. KS was subsequently noted to be a relatively common tumor in sub-Saharan Africa in the 1950s–1970s, prior to the HIV epidemic [41].

In 1981, an unexpected increase of KS cases among young men who had sex with men in the United States was the harbinger of the AIDS epidemic. In 1994, HHV-8 was isolated from KS lesions in patients with HIV/AIDS, enabling the causal relationship between HHV-8 and KS to be established. At the start of the AIDS epidemic in the United States, between 20% and 50% of patients with AIDS developed KS and the disease is considered an AIDS-defining malignancy [41].

The incidence of KS associated with HIV declined significantly after the introduction of combination antiretroviral therapy (ART) in 1996, but remains the most common malignancy in HIV-infected patients. The classic form still occurs in regions endemic for HHV-8, and KS is still a serious public health problem in sub-Saharan Africa, where access to ART is restricted [40]. It now represents about 50% of tumors diagnosed in men in some central African countries [42].

Etiopathogenesis

The pathogenesis of tumors associated with HHV-8 involves the ability of the virus to infect lymphatic and vascular endothelial cells and induce the transcriptional reprogramming of certain human genes, many of which have immunologic and angiogenic properties. HHV-8 is the necessary but not sufficient cause for the development of KS, as only a small proportion of those infected by HHV-8 develop associated tumors [41].

In adults, the main mode of virus transmission is through sexual contact. Receptive anal intercourse is the main risk factor, since the seroprevalence of HHV-8 is larger in homosexual men than among HIV-positive women. The number of sexual partners proportionately increases the risk of acquiring the virus. Both

infected saliva and semen are carriers of the virus, with a much higher viral load for the former. In endemic areas, transmission occurs mainly during childhood, the nonsexual horizontal transmission being greater than the vertical route. Domiciliary living with those seropositive for HHV-8 and low socioeconomic and health status are important risk factors in this scenario. Less common but possible forms of transmission are through blood transfusion and solid organ transplants [2, 41].

Clinical Presentation

Four variants of KS are described: classic, HIV/AIDS-related, immunosuppression-associated, and African-endemic. All of them share the same cutaneous lesions: red, brown, or violaceous papules, plaques, and nodules, often associated with edema. However, they have different presentations and clinical courses [2].

The typical patient with classic KS is an elderly man of Mediterranean or eastern European descent who presents with multiple discrete red to blue-purple or black patches on the lower extremities. The lesions can initially appear as bruises. Early macules or patches coalesce into characteristic plaques and nodules and can later become brown, hyperkeratotic, and/or eczematous. In its classic form, KS can be considered a benign neoplasm because affected persons tend to die of other causes [33].

There are four subtypes of African-endemic KS: nodular, lymphadenopathic, florid, and infiltrative. The nodular subtype is characterized by a small number of well-circumscribed cutaneous nodules and typically has an indolent course in young adults (Figs. 10.8a, b and 10.9a–c). The fulminant lymphadenopathic subtype predominantly affects the lymph nodes of children and is often fatal. The florid and infiltrative forms frequently have a large number of cutaneous lesions on one or more extremities. These latter two types are aggressive and may spread deeply into the subcutaneous tissue, muscle, and bone [2].

AIDS-related KS typically presents as more widely distributed macules, patches, or plaques (Fig. 10.10a, b), which occasionally become exophytic or ulcerative. Involvement of the oral cavity and face occurs more often than in classic KS
Fig. 10.8 (**a, b**) Kaposi sarcoma in an HIV-negative patient

and may be one of the first indications of HIV infection. Involvement of the genital mucosa, lungs, and gastrointestinal tract (particularly the stomach and duodenum) is common. Approximately 80% of AIDS patients with KS develop gastrointestinal involvement. Oral lesions can cause significant discomfort as well as difficulties with speech and eating; gastrointestinal involvement may lead to nausea, vomiting, bleeding, perforation, and/or ileus; and pulmonary involvement can result in persistent cough, bronchospasm, or dyspnea. AIDS-related KS has a variable clinical course, and prognosis is generally related to the degree of immune impairment and overall health of the patient. However, flares of KS can occur as a manifestation of immune reconstitution following initiation of ART [2].

KS associated with immunosuppression develops in patients after solid organ transplantation or the use of immunosuppressive therapy for various diseases. The cutaneous presentation resembles that of classic KS, but the site of manifestation is much more variable. It is more aggressive by nature and tends to affect lymph
Fig. 10.9 (**a–c**) Same patient shown in Fig. 10.8, 1 year later

Fig. 10.10 (**a, b**) AIDS-related Kaposi sarcoma

nodes, mucous membranes, and viscera, even in the absence of detectable cutaneous lesions [42]. However, as is the case for AIDS-associated KS, the prognosis for patients with transplant-associated KS is also much poorer than that for patients with classic KS [33].

Diagnosis

Biopsy is required for definitive diagnosis. Characteristic angioproliferative histologic features include a variable combination of spindle-shaped cells, aberrant proliferation of leaky blood vessels with extravasated erythrocytes,

and inflammatory infiltrates, in accordance with the stage of development of the lesions. Immunohistochemical staining of biopsy specimens is generally performed to confirm diagnosis by detection of antibodies against latent nuclear antigen (LANA) within the spindle cells. KS spindle cells are proliferating KSHV-infected endothelial cells that have undergone reprogramming and differentiation [41].

> **Box 10.3 Diagnosis of KS**
> The diagnosis of KS is confirmed by biopsy of the suspected cutaneous lesion. Serology for HHV-8 is not required

Complementary Examinations

The complete physical examination with inspection of the oral cavity and occult blood in the stool are essential for all patients. Those who present gastrointestinal symptoms, positive occult blood in the stool, or unexplained iron-deficiency anemia should undergo endoscopic examination of the digestive tract. Patients with respiratory symptoms should undergo imaging of the thorax and fiberoptic bronchoscopy, and patients with lymphadenopathy or B symptoms should undergo cervical, thoracic, abdominal, and pelvic tomography to search for lymphadenopathy or lymphoproliferative neoplasm associated with HHV-8 [41].

Differential Diagnosis

The differential includes acroangiodermatitis (pseudo-Kaposi sarcoma), bacillary angiomatosis, ecchymosis, hemangioma, angiosarcoma, pyogenic granuloma, and pseudolymphoma/lymphoma [2].

Therapeutic Approach

The objective of the specific therapy for KS for all patients is to improve symptoms and quality of life and slow the disease progression. For patients with KS associated with AIDS or any other immunosuppression, correcting immune deficiency when possible is recommended. ART for viremia control is mandatory and may

be sufficient in HIV-positive patients with limited disease. In immunocompetent patients with limited disease, few symptoms, and slow progression, the strategy can be expectant. Localized symptomatic lesions can be addressed with intralesional injection of vinblastine or interferon-α (IFN-α), topical alitretinoin, liquid nitrogen, laser therapy, or radiotherapy.

Surgical intervention is rarely indicated, except to make a pathological diagnosis or to remove or debulk a single lesion that is dangerous or particularly symptomatic by virtue of its location (e.g., urethral or airway obstruction). Systemic therapy is indicated in cases of extracutaneous involvement and in rapidly progressive cutaneous disease, voluminous cases or those that causes pain, lymphedema, functional limitation, or emotional stress. Liposomal anthracyclines (doxorubicin or daunorubicin) are first-choice therapies. The second line of therapy uses paclitaxel and alternatives include vincristine, vinblastine, vinorelbine, etoposide, and bleomycin. IFN-α, interleukin (IL)-2, thalidomide, and others that target KS and immunomodulatory approaches have been evaluated. The best-studied agent, IFN-α, is a cytokine with immune-modulatory, antiviral, and antiangiogenic activity. In HIV-associated KS it is best utilized for patients with limited disease and preserved CD4 counts. Antiherpetic agents have not been shown to have activity in treating established KS [41].

Human Papillomavirus

Introduction

Papillomaviruses are a large group of DNA viruses that are widely distributed in animals and humans. By infecting the basal cells of the epithelial mucosa, papillomaviruses cause malignancies (cervical, penile, vulvar, vaginal, anal, and oropharyngeal) and noncancerous cutaneous manifestations. Noncancerous cutaneous manifestations include common warts (verruca vul-

garis), plantar warts, plane warts, and anogenital warts. Cutaneous and anogenital warts are common reasons for a dermatology office visit. Although there are various therapies available, they are extremely difficult to treat and none of the treatment modalities are curative [43].

STDs caused by human papillomavirus (HPV) are discussed in Chapter 9.

Epidemiology

Cutaneous warts occur more in children, adolescents, and young adults, with its prevalence estimated to be between 3% and 20% in schoolchildren. The HPV virus is found globally, and its transmission occurs by direct interpersonal contact and indirect contact through contaminated objects and surfaces, such as swimming pool surrounds [44, 45]. The presence of lesions in individuals of the same school or family is frequent, with the frequent observation of more infected individuals in the same household [46]. Transmission also occurs by self-inoculation of HPV from affected areas to healthy and perilesional areas. They also have clinical importance in the immunocompromised, in whom the lesions tend to be more extensive and of a more prolonged course [45].

Etiopathogenesis

HPV is a nonenveloped, double-stranded DNA virus. The capsid has a viral coverage that, besides being the protection of the viral DNA, allows their binding to target cells in the infection process. The virus enters the epithelial basal cells by microabrasions in the most superficial skin layers, which serve as a mechanical barrier to the penetration of the microorganism [44, 45].

After penetration of the basal keratinocytes, the viral DNA is incorporated into the genomic material of the cell, initiating replication. The cellular immune response is the most important pathway in the immune control of the HPV infection, which explains the persistence of infection and more exuberant lesions in patients deficient

Table 10.6 HPV subtypes related to nonanogenital cutaneous disease

Cutaneous disease	HPV types associated most frequently detected
Common warts	1, 2
Flat warts	3, 10
Epidermodysplasia verruciformis (EV)	3, 5, 8
Heck's disease (focal epithelial hyperplasia)	13, 32
Oral papillomas	2, 6, 7, 11

in this response, such as those infected with HIV. Up to 90% of the cutaneous warts disappear spontaneously within 2 years [45]. The humoral immune response does not seem to play an important role in the immune control of the infection.

To date, more than 120 different types of HPV are known and completely characterized. The types 1, 2, 4, 7, 27, and 57 are the most commonly detected in common, plantar, and palm warts, whereas types 3 and 10 are associated with flat warts [45, 47] (see Table 10.6).

Some types have oncogenic potential, such as HPV-5 and -8, related to the development of squamous cell carcinoma (SCC) in patients with epidermodysplasia verruciformis, a predisposing condition addressed below, in addition to those associated with anogenital malignancies (discussed in another chapter).

Clinical Presentation

• *Common warts*: Common warts are usually exophytic, multiple, irregular, rough nodules that show a variety of clinical patterns at different sites of trauma particularly on fingers, but also on other frequently rubbed and abraded skin surfaces such as hands, elbows, and knees (Fig. 10.11a–e). They range from small papules to large, hyperkeratotic, fissured, cauliflower-like lesions [45]. Black dots corresponding to thrombosed capillaries are typical findings on dermoscopy, and an important clue for diagnosis. Filiform warts can occur in periorificial areas of the face. (Fig. 10.11f) "Butcher's

Fig. 10.12 (**a–c**) Flat warts

warts" occur in professionals who deal with the processing of meat and fish. Warts are extensive on sites of trauma, such as fingers and the periungual area, and are related to HPV-7 [44, 45] (Fig. 10.11g).

- *Flat warts***:** Skin-colored papules or slightly hypochromic or pinkish, slightly elevated, flat lesions usually located on the face, back of the hands and feet, and arms. These warts are common in children and in adult women. There may be a phenomenon of regression of the lesions, preceded by rash and swelling in the affected areas [45] (Fig. 10.12a–c).
- *Palmoplantar warts*: Hyperkeratotic papules with deep inward growth, slightly raised edges, and depressed center (called "myrmecia") (Fig. 10.13a–c). They cause significant pain when walking due to pressure on the affected sites. Thrombosed capillaries are found and effect differentiation with palmarplantar calluses. The warts may coalesce to

form mosaic warts [44] (Fig. 10.13d–f). They rarely occur in children younger than 5 years [45].

- *Epidermodysplasia verruciformis*: A rare autosomal recessive genetic disorder whereby there is a susceptibility to infection with certain types of HPV that commonly do not produce clinical lesions in individuals without the disease. Types 5 and 8 are most often related to the development of skin cancers, especially on sun-exposed areas [45]. Characteristically patients have widespread papular lesions that are confluent, flat, and pink, often resembling tinea versicolor, but may present diverse types of skin warts. Early-appearing lesions of actinic keratosis gradually transform into squamous cell carcinoma (Fig. 10.14a–d).
- *Oral papillomas*: The most common benign tumors of the oral mucosa. Common warts can spread from the hands to lips by finger

sucking and nail biting, with cutaneous HPV types identified in the lesions (Fig. 10.15a, b). They can become warty on the tongue and hard palate which has a stratum corneum. Other HPV-induced oral lesions include common warts on the oral mucosa associated with HPV-2 (Fig. 10.16), and the multiple soft papules of Heck's disease (focal epithelial hyperplasia) found most commonly in Eskimos and North American Indians and associated with HPV-13 or -32 [45].

Diagnosis and Complementary Examinations

In most cases, the diagnosis of the cutaneous warts is carried via dermatologic examination. With the aid of dermoscopy it is possible to see

the darkened points on the corresponding lesion to thrombosed capillaries, typical of HPV lesions. Anatomopathologic examination, viral typing, or other complementary tests are used in doubtful cases or to exclude dysplasia or malignancy.

Differential Diagnosis

The main differential diagnoses to consider are actinic keratosis, cutaneous horn of other etiologies, SCC, keratoacanthoma, palmoplantar calluses, hyperkeratotic lesions related to psoriasis and hypertrophic lichen planus, and palmoplantar keratoderma. Flat lesions can frame differentiation with Gottron's papules of dermatomyositis, as well as lichen planus or lichen sclerosus [44].

Therapeutic Approach

For the therapeutic approach to lesions, each patient and case should be individualized taking into account the number of lesions and their location, the patient's pain tolerance, risk of scarring, and cost to the patient in addition to the experience of the professional.

There are numerous treatment modalities, although there are few well-designed studies in the literature supporting their use (see Table 10.7).

In minimally symptomatic lesions in an immunocompetent patient, only an expectant approach can be maintained because of the possibility of spontaneous regression. Symptomatic, unaesthetic lesions in immunocompromised patients or those at risk for malignancy can be treated by a variety of therapies [48].

There is no antiviral treatment that is specific for HPV, but some of the available therapies interfere with the viral life cycle. The most common approach to treatment is to damage or destroy the infected epithelium. This can also induce cell death and antigen exposure and presentation, thereby potentially inducing an immune response.

Destructive Chemical Agents

Salicylic acid (SA) is the most commonly used formulation for skin wart treatments for which studies with a higher level of evidence exist. SA promotes exfoliation of epithelial cells. It is an

Table 10.7 Classification of the main therapeutic agents for cutaneous warts

Destructive chemical agents
Salicylic acid
Trichloroacetic acid
Glycolic acid
Cantharidin
Phenol
Silver nitrate
Destructive physical agents
Cryotherapy (liquid nitrogen)
Curettage

Antiproliferatives
Podophyllin/podophyllotoxin
5-fluorouracil
Bleomycin
Retinoids
Immunostimulants
Imiquimod
Zinc sulfate
Intralesional immunotherapy
Diphencyprone

irritant at high concentrations, which can promote an additional effect of stimulating the immune response of an affected individual [48]. It is used in a variety of vehicles (collodion, ointments, gels, patches, and creams in concentrations of 10–50%). SA can be associated with other keratolytic substances, most commonly with lactic acid between 4% and 17% [49]. Variations in the form of application, concentration, and solvent vary according to the kind of wart. In plantar or thicker common warts, the treatment is optimized with prior mechanical exfoliation with sanding of the region to be treated. One should be careful to protect the skin around the lesion before application to avoid irritation and erosions.

Trichloroacetic acid is classically used to treat genital warts, with little evidence for use in nongenital warts [43, 48].

Other chemical agents are described in the treatment of skin warts, but with a lower level of evidence in the literature, such as cantharidin, phenol, 10% silver nitrate, 5% glycolic acid, 70% pyruvic acid, citric acid, and formic acid [48].

Destructive Physical Agents

- *Cryotherapy*: This is the most commonly used form of treatment for skin warts. Liquid nitrogen or even carbon dioxide are utilized. It can be applied by spray or contact with a cotton swab, with evidence showing equal efficacy between both [48]. It causes irreversible damage to cell membranes by freezing, with inflammation and stimulus of cellular immune response. In general, the application should be maintained for 10–30 s, depending on the treated region, followed by formation of a perilesional halo of about 1–2 mm. The freezing time ranges from 10 to 15 s up to 30 s or more in more aggressive applications. After thawing, the application is repeated. An interval of 2–3 weeks between each application is recommended until complete resolution [49]. Its efficacy is comparable with that of SA, and there is evidence showing optimum results with the combination of both therapies. Adverse effects include pain during the application (limiting its use in children), discomfort by postapplication inflammation (patients should be alerted to the occurrence of blisters and erythema), hyper- or hypochromia (especially in patients with high skin phototypes), and scarring [48].
- *Surgical treatment*: Manual curettage, electrodesiccation, electrocautery, and conventional resection are alternatives in localized and resistant lesions. Curettage is a method widely employed for plantar warts, and may be combined with other treatments for best results.
- *Laser*: Pulsed dye laser at 585 nm acts in the blood vessels of the warts and also by thermal injury to HPV. The use of CO_2 laser and Nd:YAG is also described in a few studies. Combination therapies before and after laser treatment, such as with bleomycin and SA, have been described [48, 49].
- *Photodynamic therapy*: Studies with different protocols suggest the efficacy of treatment using 10–20% aminolevulinic acid [48]. A significant adverse effect during the procedure is pain.

Antiproliferatives

- *Podophyllin and podophyllotoxin*: The first is no longer recommended because of its potential toxicity and considerable local irritation. Podophyllotoxin, the active component of podophyllin, is still used for the treatment of anogenital warts, but has limited use in skin warts. The assumption is that penetration of the thick, cornified layer of cutaneous warts is poor compared with that achieved at mucosal sites [43, 48].
- *5-Fluorouracil*: this agent blocks the synthesis of DNA, damaging the cell division of basal cells. It can be used as a cream in a concentration of 5% for 4–12 weeks, with better results if used under occlusion. It may be associated with 10% SA [49]. Association with cryotherapy does not appear to improve results. It can cause severe irritation and erosions in the treated areas, with subsequent formation of hyperpigmentation or, less frequently, hypopigmentation [48].
- *Bleomycin*: This is a systemic chemotherapeutic agent that has also been used through an intralesional pathway in warts, although its management is very painful and produces necrosis in the applied region which can be excessive [48]. The wart cure rate is very variable (14–99%) [43].
- *Retinoids*: These agents act on the replication and differentiation of keratinocytes, reducing viral replication and reducing the thickness of the lesions. They can be used topically, such as adapalene and tretinoin in flat warts, while isotretinoin and acitretin are used orally for immunosuppressed patients with severe disseminated warts [48].
- *Cidofovir*: A nucleoside analog that inhibits viral replication. It is used topically, with some reports of systemic use in the immunocompromised. Cream containing 1–3% can be used five times a week every other week for about 8 weeks [48]. It seems to be well tolerated topically, but systemic use can cause nephrotoxicity and neutropenia. Its use is off-label for the treatment of skin warts [43].

Immunostimulants

- *Imiquimod*: Well-known for the treatment of anogenital warts, its use is described for the treatment of persistent nongenital skin warts or therapeutic failure by other methods. It stimulates the inflammatory response against infected keratinocytes by inducing IFN-α, IL-12, and tumor necrosis factor α, with NK cell stimulation. Studies with a lower level of evidence showed over 50% improvement in lesions with applications two times a day for a maximum of 24 weeks. It is generally used in

a 5% cream [43, 48]. The side effects are discomfort through irritation and erosions in the application region during the treatment.

- *Zinc sulfate*: The mechanism of action of this agent is not well established, but it is known that zinc plays an important role in leukocyte function and NK cell activity. It can be used topically or systemically, although without consistent studies in the literature evaluating its use. Described treatments are topical from 5% to 20% [48] and oral supplementation (10 mg/kg/day) [8, 43].
- *Diphencyprone*: This agent induces local hypersensitivity, stimulating the immune response against the HPV lesions. Its efficacy has been shown in some retrospective studies. It may provoke erythema, desquamation, itching, and discomfort, and in some cases allergic contact eczema beyond the area of application [48].
- *Intralesional immunotherapy*: Mumps, *Candida*, and *Trichophyton* antigens are allergenic extracts that are thought to act by inducing a delayed hypersensitivity reaction. A review found clinical resolution after local injection into the base of warts, with remission rates of 60% for mumps/*Candida*/*Trichophyton*, 82% for *Candida*, and 84.6% for measles, mumps, and rubella. Advantages of this method include lack of scarring and minimal pain. Disadvantages include erythema at the injection site, and systemic effects such as fever and myalgias [49].

Enterovirus

Introduction

Enteroviruses are composed of about 70 serotypes belonging to the Picornaviridae family, and are present worldwide. These viruses are responsible for a wide spectrum of diseases and usually affect children [50].

Epidemiology

Enteroviruses are ubiquitous and can cause illness in any age group, but are more common in children 1–4 years of age [51].

Enterovirus infections (enteroviruses) may occur throughout the whole year, but the largest number of cases and epidemics occur in the summer and fall. The highest-risk groups are children and those who live in settlements of low socioeconomic status [50].

Etiopathogenesis

Enteroviruses are small, single-stranded RNA viruses, nonenveloped, of the Picornaviridae family. They are composed of about 70 serotypes, including echovirus, coxsackievirus A and B, enterovirus 68–71, and poliovirus. They cause various diseases, some having tropism for certain tissues, but not of specific form.

Transmission occurs between humans through a fecal-oral pathway, respiratory pathway, and from mother to child during and after birth. The incubation period ranges from 3 to 6 days [50, 52]. After the initial contact, through the respiratory mucosa or lower digestive tract, the virus replicates in the lymphoid tissues and spreads through the blood, causing low-level viremia. Subsequently, the virus reaches the CNS, heart, liver, lungs, adrenal, and skin, transitioning to the phase of clinical symptoms. When the virus replicates in these sites, the phenomenon known as high-level viremia occurs [50, 52].

Clinical Presentation

The clinical manifestations of infection by enterovirus are quite varied, from a simple respiratory infection to aseptic meningitis. Among the mild infections one observes fever with or without rash, hand-foot-mouth syndrome, herpangina, pleurodynia, pharyngitis, conjunctivitis, and croup. Among the serious infections, meningitis, encephalitis, acute palsies, neonatal sepsis, myocarditis, pericarditis, hepatitis, and chronic infections in immunosuppressed patients have been reported [51].

Hand-Foot-Mouth Disease
Hand-foot-mouth disease is caused by various strains of enterovirus, most commonly by coxsackie A16 virus (CAV16) and enterovirus 71 (EV71), and mainly affects children under 10 years

of age. The disease can present prodrome of fever, malaise, coughing, loss of appetite, abdominal pain, myalgia, or fever odynophagia for 12–36 h. It is usually self-limited, resolving in 48 h [53]. One to 2 days after the onset of disease painful lesions appear in the mouth, tongue, palate, anterior tonsillar pillars, and oral mucosa. When broken these vesicles form painful ulcers that resolve in 5–7 days [52, 53]. After the appearance of oral lesions, vesicles arise with adjacent erythema on the hands and feet (Fig. 10.17a–c), which are not itchy and may be painful, resolving in around 7–10 days.
Fig. 10.17 (**a–c**) Vesicles on the hands and feet

Less commonly these lesions can be nodules, papules, or vesicles grouped and located in the gluteal and genital regions.

Complications are uncommon and involve the cardiopulmonary and neurologic system. Onychomadesis may persist for up to 4 weeks after infection because of the arrest of ungueal matrix growth [53].

Herpangina

Another frequent enterovirus, herpangina has coxsackievirus A1–A6, A8, A10, and A22 as the most common viruses, although it can also be caused by coxsackievirus B1–B4, echovirus, and other enteroviruses. The incubation period varies from 1 to 10 days [52]. It affects children aged 3–10 years with prodrome of fever, headache, malaise, and pain in the cervical region, followed by the appearance of painful oral lesions in 2–3 days. These are usually papules, which evolve into vesicles, and later ulcers in the soft palate, uvula, tonsils, pharynx, and oral mucosa, accompanied by erythematous pharyngitis. The fever usually has spontaneous remission in about 4 days and oral lesions in around 7 days [52].

Diagnosis and Complementary Examinations

The presumptive diagnosis is made by clinical signs and symptoms, season of the year, geographic location, and contact history [52].

Diagnostic confirmation can be reached by culture, serology and PCR. The main indication of confirmation is in cases of complications. The virus is found in the oropharynx, blood, cerebrospinal fluid, urine, and the tissues affected by the disease. Culture plays an important role in the epidemiology once it can identify the virus serotype. However, it is scarcely applied in practice because of the time required (4–8 days) to obtain the result, which is unhelpful for treatment decisions in daily practice.

Serology has limited usefulness because of the time required for the result and the diversity of the serotypes.

PCR is the method of choice in the diagnosis because of its high sensitivity and specificity; besides being rapid, it requires small samples and detects the virus in the cerebrospinal fluid [52, 53].

Differential Diagnosis

The differential diagnosis is broad and is performed according to the clinical manifestation of the enterovirus. It includes papular urticaria, impetigo, measles, rubella, scarlet fever, roseola, pityriasis rosea, aphthous stomatitis, erythema multiforme, herpetic gingivostomatitis, drug eruption, and other forms of herpesvirus infection.

Therapeutic Approach

The majority of diseases caused by enterovirus are self-limiting, so the main treatment consists of supportive measures and more intensive measures in cases of complications.

In serious infections caused by EV71, in vitro studies showed benefit from the use of IgG, IgG3 subclass [53]. Pleconaril, an antiviral that acts on protein binding of the viral capsid and has a broad spectrum, has been studied for use in severe infections and showed satisfactory results [54].

Measles

Introduction

Measles was first described as an entity distinct from other rashes in 900 BC by the Persian physician Muhammad Rhazes [36].

It is an extremely contagious exanthematous viral disease distributed worldwide. After the introduction of the vaccine in 1963, the profile of incidence, morbidity, and mortality decreased dramatically, but persists within the ten most infectious diseases of highest mortality in the world [52, 55].

Epidemiology

A disease of worldwide distribution, more common in children and highly contagious, measles can be considered endemic and epidemic in the European, African, and Asian continents and features outbreaks in America [55].

The elimination of measles in the United States occurred in 2000 and since then there have been no epidemics, but the number of cases appears to be increasing in recent years: from January to November of 2015, 189 cases were reported. Of these, the highest percentage is in the age group between 20 and 39 years and the most affected did not have the vaccine or were unaware of the status of vaccination. The vast majority of cases were associated with patients from endemic countries [55].

Data from Canada, from the period 2002 to 2013, show an incidence of 0.29 cases per 100,000 people. In 2011, Brazil notified 18 cases brought to the exterior. In Europe there were 27,134 cases from January 2014 to March 2015.

In Africa, in 2013, data from the Democratic Republic of Congo, Nigeria, Angola, and Uganda showed 158,361 cases. In Asia the 2014 data, including suspected and confirmed cases, demonstrated 112,483 in China, 58,010 in the Philippines, and 18,597 in Vietnam [56].

The risk of infection is associated with contact between people who have traveled or travel to endemic or epidemic areas. In temperate climates, epidemics usually occur in late winter and early spring and in tropical climates, during the period of rainfall. However, the main risk of contamination occurs in patients who have not undergone vaccination. Data show that a substantial proportion of measles cases the United States in the era after elimination was intentionally unvaccinated [52].

Etiopathogenesis

Measles is caused by an RNA virus, enveloped, single-stranded, with 19 genotypes of the Paramyxoviridae family and a member of the genus Morbillivirus [36]. It has two membrane proteins that mediate entry into the host cell, the hemagglutinin that fixes the virus in host cell and fusion proteins, responsible for the fusion of the viral membrane into the cell, virus penetration, and hemolysis.

Contact with the virus occurs through the air from one person to another, via large droplets of saliva, and, less commonly, via small aerosol particles when coughing, sneezing, talking, or breathing.

The expelled virus can stay alive for up to 2 h on a surface or in the air. Man is the reservoir and the source of infection. The incubation period ranges from 7 to 18 days, with an average of 10 days until the onset of fever and 14 days until the onset of the rash.

The transmission period is 4 days before the onset of the rash to 4 days after the disappearance, although immunosuppressed patients can transmit the virus for more prolonged periods [55].

Penetration occurs in the mucosa of the upper respiratory tract. Viral replication starts at this site and in the lymph nodes, causing the first viremia after 2–3 days. The virus reaches the reticuloendothelial system, where it spreads after 5–7 days in a second viremia to the respiratory tract and other organs. Mothers, previously vaccinated, may pass antibodies to newborns through immunity induced by the vaccine [57].

Clinical Presentation

Measles has two clinical presentations, classical and atypical [36].

Classic measles has an evolution in stages. In the prodromal period, about 10 days after infection, the patient presents with fever, productive cough, coryza, nonpurulent conjunctivitis, photophobia, slight increase in cervical lymph nodes, abdominal pain (caused by the increase in intraabdominal lymph nodes), and the appearance of white spots with an erythematous halo in the oral mucosa, known as Koplik's sign. Koplik's sign is pathognomonic of measles and may arise in the days before the rash or after its appearance.

The second stage is the exanthema, which appears 2–4 days after the onset of fever, while other symptoms are accentuated. It is characteristically maculopapular, reddish, and with a cranial-caudal distribution. It starts in the retroauricular region and face and spreads to the trunk and extremities, lasting 5–6 days.

The third phase is the period of convalescence or furfuraceous desquamation, when the stains disappear through a fine desquamation, disappearing in the same order they appeared. Anorexia, diarrhea, and lymphadenopathy may also be present [52].

Atypical measles occurs in individuals with partial immunity to the virus, when exposed to wild-type virus. It has been reported in patients who received inactivated (or killed) measles vaccine (used in the 1960s), or persons who were given attenuated (weakened) live measles vaccine that was, by accident, inactivated during improper storage, in unvaccinated and immuno-compromised patients. It presents fever, pneumonia, pleural effusion, edema, and exanthema, maculopapular or petechial, with initial appearance in the extremities, hands, and feet [36].

Complications occur in up to 40% of patients, and the factors that increase risk are:

- Age: children under 5 years of age (especially in children <1 year) and people over 20 years of age
- Malnutrition
- Immunosuppression
- Gestation

The most common complications are bacterial respiratory tract infections (otitis media and pneumonia), pneumonia being the leading cause of death in children. Subacute sclerosing panencephalitis is a delayed neurodegenerative disorder that can occur as a complication of measles many years after the acute disease. It is characterized by seizures, personality changes, coma, and death [55].

Diagnosis and Complementary Examinations

The diagnosis of measles is based on clinical and epidemiological findings. The Table 10.8 summarizes the situations where one should suspect a case of measles. Outside of an outbreak of the disease, it should be confirmed by laboratory examinations.

The diagnostic test considered the gold standard is the evaluation of serum IgM antibodies, which can be detected in acute infection after

3 days of exanthema onset, becoming undetectable after 30 days.

The detection of IgM antibodies in oral fluids is an option with specificity comparable with that of the blood test, but with a slight reduction in sensitivity.

Increase in IgG titers of more than fourfold in sequential samples also confirms diagnosis.

The reaction by PCR is another alternative for confirmation, which uses the material collected by nasopharyngeal swab, blood, or urine from 1 to 3 days after exanthema onset up to a maximum of 7 days [55, 57].

Differential Diagnosis

The differential diagnosis is made with other diseases with maculopapular exanthema, such as rubella, infectious erythema, roseola, enteroviruses, infectious mononucleosis, cytomegalovirus infection, staphylococcal toxic shock syndrome, scarlet fever, Kawasaki disease, acute HIV infection, dengue, secondary syphilis, and hepatitis B.

Therapeutic Approach

Treatment

Treatment consists of supportive care, since there is no recommended specific antiviral therapy.

Hydration, nutritional support, hygiene of the eyes, skin, and airway, and antithermic medication are options. In cases of complications such as pneumonia or otitis media, antibiotics should be used [52].

The World Health Organization (WHO) recommends the use of vitamin A for children in developing countries, as its use is associated with decreased mortality and morbidity. It should be administered once a day for 2 days; the recommended doses are summarized in the Table 10.9 [58].

Table 10.8 When to suspect and test for measles

Typical or atypical clinical presentation	Unvaccinated
	Unknown vaccination status
	Residence or travel to endemic area
	Living/residence in agglomerations

Table 10.9 Recommended doses of vitamin A

Children under age 6 months	50,000 IU/day
Children between the ages of 6 and 11 months	100,000 IU/day
Children 12 months of age or more	200,000 IU/day

Vaccination

The vaccine against measles is a combination that besides measles also protects against rubella and mumps (MMR). The child should receive two doses, the first between 12 and 15 months of age and the second from 4 to 6 years of age [6]. There are currently MMR options associated with varicella vaccine (MMRV), which can be administered in children 1–12 years of age, and the current recommendations are employed in the second dose [6]. Pregnant women, immunocompromised patients, and patients with history of anaphylactic reaction to neomycin should not receive the vaccine.

The MMR vaccine is recommended as postexposure prophylaxis in persons 12 months of age or older, preferably within 72 h after initial contact. Patients who have received only one dose of the vaccine can receive the booster after exposure within 72 h. Immunoglobulin is recommended as postexposure prophylaxis for up to 6 days after initial contact in children under 12 months of age, pregnant women without evidence of immunity, and immunocompromised patients. The administered dose is 0.5 ml/kg intramuscularly or 400 mg/kg intravenously [59].

Rubella

Introduction

Rubella, also known as German measles, is a highly contagious viral disease that affects both children and adults. Although usually benign, infection in pregnant women, especially during the first trimester, may result in stillbirth, fetal death, or congenital rubella syndrome (CRS).

Epidemiology

The incidence of rubella has greatly reduced since the vaccine was licensed in 1969. In 2006, 58% of countries in the world already counted on rubella immunization programs, including 100% of industrialized countries [60]. However, there are still numerous records of outbreaks of the dis-

ease around the world. In Poland, in 2013, there was a rubella outbreak in adult men as a result of the restricted vaccination program established before 2004, which covered only girls of 13 years of age [61]. For similar reasons, there was an outbreak in middle-aged men in Japan in 2012/2013. Also, in 2012 in China there was an epidemic in young adults related to inadequate vaccination coverage [62].

Rubella was declared eliminated from the United States in 2004 and from the Americas in 2012, although CRS cases continue to occur, especially in countries where universal vaccination coverage is not routine [60].

Etiopathogenesis

An RNA virus of the genus Rubivirus belonging to the Togaviridae family causes rubella. The transmission occurs via nasopharyngeal droplet secretions from infected individuals who are transmitters from 5 to 7 days before and up to 7 days after exanthema onset [63].

Hospitalized patients must remain in isolation for 7 days, while children should be excluded from school activities for 7 days after the onset of rash. Children affected by CRS can remain transmissive throughout the first year of life [52].

Clinical Presentation

Rubella has an incubation period of approximately 18 days and may be preceded by nonspecific prodromal symptoms such as slight fever, eye pain, arthralgia, and sore throat.

The rash consists of discrete, pink maculopapules spreading from the face to the trunk and extremities within 24 h. The rash is pink and is not followed by desquamation (which may occur following measles).

Postauricular and suboccipital lymphadenopathy is common. Palatal enanthem (Forchheimer spots) and conjunctivitis may occur, but up to half of the patients have no symptoms at all.

Adolescents and adults are more likely to be symptomatic and have fever [60].

Box 10.4 Congenital Syndrome Rubella

The rubella virus is still a major public health problem due to teratogenic effects, and risk of miscarriage and stillbirth caused by maternal infection during pregnancy, especially in countries where immunization coverage is not universal. In maternal infection, the virus crosses the placenta and may infect the developing fetus with devastating effects when the infection occurs in the first trimester. In infected pregnant women who develop a rash within the first 12 weeks of gestation, the frequency of congenital infection is greater than 80%, decreasing thereafter, given that after the 16th week of gestation there is no risk of CRS development [64].

The manifestations of CRS may be present at birth or appear after months or years of life. It includes purpuric rash, hepatosplenomegaly, bone lesions, eye and hearing defects that can lead to blindness and deafness, cardiovascular abnormalities, and CNS disorders such as microcephaly and mental retardation. In countries without adequate vaccination coverage, CRS is the leading cause of nongenetic congenital deafness. Immune disorders are associated with the development of diabetes mellitus type 1 as a late manifestation of CRS [65].

Diagnosis and Complementary Examinations

The diagnosis of rubella cannot be established solely on clinical findings (see Box 10.5).

An elevated rubella-specific IgM antibody or a fourfold or greater rise of rubella- specific IgG antibody in paired sera obtained 2 weeks apart is generally diagnostic.

False-positive test results can be seen with other viral infections. Positive rheumatoid factor may be seen in rubella patients. Low-avidity IgG is seen with recent primary infection and high-avidity rubella IgG is associated with past infection or reinfection. PCR can detect rubella virus from nasal, throat, and urine specimens [60].

For congenital infection, the diagnostic method of choice is a viral culture from the naso-

pharynx, and after the fifth month of life a serological test may be performed [36].

Box 10.5 Laboratory diagnosis of Rubella

Diagnosis by ELISA (enzyme-linked immunosorbent assay)
Specific IgM elevation
Specific IgG elevation ≥4 times in a 2-week interval

Differential Diagnosis

The differential diagnosis is made with other causes of febrile exanthemas. Parvovirus B19 infection, HHV-6, dengue, and measles must be considered according to the age group and geographic area.

Therapeutic Approach

Treatment

The treatment for both the acquired and congenital form is symptomatic and supportive. To date there is no effective antiviral therapy available [65].

Vaccine

The rubella vaccine is highly effective and remains a key strategy for the control and elimination of rubella and CRS. Active immunization with the live attenuated virus is available. The first dose is recommended between 12 and 15 months of age and the second dose between 4 and 6 years of age [65].

The vaccine provides immunity for about 20 years, but for less time than the acquired immunity after infection, which explains increased susceptibility among women of reproductive age who were vaccinated only in infancy. The recommended additional dose of the vaccine in late adolescence as a part of the immunization program is justified [66].

Erythema Infectiosum

Epidemiology

The infection is most common in childhood and in most cases is asymptomatic. Seropositivity is

found in about half of adolescents younger than 15 years and in more than 80% of the elderly population. Distribution is global, with higher incidence in the winter and spring, and small outbreaks occur in a cyclical pattern approximately every 6 years [52, 60, 67].

Etiopathogenesis

Parvovirus B19 (PVB19) is the only parvovirus known to infect humans. This virus is responsible for a broad spectrum of clinical manifestations, erythema infectiosum – or "fifth disease" – being the main one.

The virus is transmitted through respiratory tract droplets eliminated by sick patients in the viremic phase. Vertical transmission can occur in 30% of infected pregnant women, especially in the second trimester of pregnancy, and a fetal infection can lead to miscarriage, stillbirth, severe anemia, and fetal hydrops [67]. Less commonly there may be transmission through blood transfusion or bone marrow transplantation [68].

The clinical manifestations of the PVB19 infection can be caused both by the direct effects of the virus and by immunological phenomena in response to antigen, and the symptoms also depend on the age and immunity of the host and associated comorbidities [60]. It is believed that the erythema infectiosum occurs through the formation and the deposition of immune complexes, as there is a temporal disconnect between viremia and clinical symptoms [52, 67].

PVB19 has strong tropism for erythroid precursor cells by binding to the erythrocyte P antigen, also known as globoside. This antigen can also be found in the placenta and fetal myocardium, and occasionally in megakaryocytes [67]. In patients with highly progressive disease or red blood cells of lower half-life, the infection may be responsible for transient aplastic crisis, caused by an abrupt halt of the production of erythrocytes [68].

Clinical Presentation

Erythema infectiosum is the most common clinical presentation of the PVB19 infection. See Box 10.6 for another clinical presentation, the papular-purpuric gloves and socks syndrome.

The incubation period ranges from 6 to 18 days. The viremia lasts 7–10 days after infection presenting reticulocytopenia, ceasing with the emergence of IgM anti-B19 around the 10th day. A week later, IgG antibodies arise and skin manifestations begin. It is important to note that patients with rash are no longer contagious once viremia has ceased [52, 68].

A prodrome of low fever and flu-like symptoms may be present, and 2–3 weeks later a characteristic exanthema surges, which starts with prominent macular erythema on the cheeks, sparing the nasal crest and the perioral region ("slapped cheek") (Fig. 10.18a).

The second stage occurs within 1–4 days, with erythematous papules and macules in a lace pattern mainly in the extremities and less intensely on the trunk (Fig. 10.18b, c). This exanthema is evanescent, lasts 1–3 weeks, and can reoccur with exposure to the sun or heat [52].

Arthralgia or arthritis occurs in 10% of cases of erythema infectiosum, involving small joints of the hands, wrists, ankles, and knees. They also have a self-limiting character.

In adults the rash is more subtle and systemic and articular manifestations are more prominent [68].

> **Box 10.6 Papular-Purpuric Gloves and Socks Syndrome**
> Also caused by parvovirus B19, papular-purpuric gloves and socks syndrome usually occurs in young adults, with the highest incidence in the spring, and is characterized by edema and erythema on the palms and soles, with petechiae and purpura. Patients complain of a burning and itching sensation. Erosive enanthem and petechiae on the palate, pharynx, and tongue may be present, besides mild systemic symptoms. It evolves with spontaneous resolution within 1–2 weeks and the treatment is supportive. There is evidence that the disease occurs during the viremic phase and can thus be infectious in the clinical phase. Other infectious etiologies have been reported, such as coxsackievirus B6 and HHV-6 [52].

Fig. 10.18 (**a**) Erythema on the cheeks ("slapped cheek"). (**b**, **c**) Lacy, reticulated erythematous eruption on the arms

Diagnosis and Complementary Examinations

The diagnosis is based on medical history and clinical examination. Serology may be helpful in severe or atypical cases. Enzyme immunoassay for specific IgG and IgM has high sensitivity and specificity. The detection of IgM is more clinically useful since it remains positive for up to 2–3 months after acute infection [68]. DNA hybridization techniques and PCR are particularly useful in immunocompromised patients [52].

Anemia, reticulocytopenia, thrombocytopenia, or even pancytopenia may be present. A skin biopsy is not very useful in diagnosis [68].

Differential Diagnosis

The differential diagnosis includes mainly scarlet fever, enterovirus infections, and rubella.

Therapeutic Approach

The treatment of PVB19 infection is symptomatic and supportive. There is no specific antiviral therapy and the majority of infections are self-limiting.

Nonsteroidal anti-inflammatory drugs can be used in cases of symptomatic arthropathy.

In immunocompromised patients at risk of severe complications, intravenous immunoglobulin

may be an option for the treatment of anemia, assisting in the recovery of hematopoiesis.

Whenever PBV19 infection is diagnosed, the physician must ensure that neither the patient nor his or her contacts is a member of certain vulnerable populations. In these populations, infection with PVB19 may result in devastating complications. The vulnerable populations include those with hematologic disease, immunosuppressed patients, and pregnant women [68].

Gianotti–Crosti Syndrome

Epidemiology

Gianotti–Crosti syndrome (GCS), or papular acrodermatitis of childhood, is a self-limited exanthem of acute onset with a characteristic acral distribution, which mainly affects children aged between 2 and 6 years, and more rarely young adults [69].

It is distributed worldwide and tends to predominate in spring and early summer.

Although it is an unusual dermatosis, five epidemics have been recorded, three of which occurred in Japan, with most affected persons closely associated with hepatitis B virus (HBV). The other two, with fewer affected patients, occurred in India and Italy; in the latter, all cases were associated with EBV [70].

Etiopathogenesis

Although the pathophysiologic mechanism is not fully understood, it is believed that the rash is a cutaneous response to certain immunologic triggers using a Type IV hypersensitivity reaction against antigens: viral, bacterial, or recent immunizations [69].

The syndrome is classically described in association with HBV, but today EBV is the most commonly identified agent. A list of viruses, bacteria, and vaccinations reported to be associated with GCS is given in Table 10.10 [71].

Regarding the relationship with immunizations, the incidence of SGC seems to be higher with combined vaccines or when there is a viral infection present at the time of vaccination, suggesting that

perhaps more than one immune stimulus is necessary for the development of the syndrome [72, 73].

One study showed a high prevalence of atopic dermatitis, family history of atopy, and elevated total and specific IgE levels within SGC cases, suggesting atopy as a predisposing factor [69, 74].

Clinical Presentation

The disease is characterized by the acute onset of multiple monomorphous, pink to red-brown papules or papulovesicles that may become confluent. The papules are distributed symmetrically on the face, extensor surfaces of the extremities, and buttocks (Fig. 10.19a–d). The rash is usually asymptomatic but may be pruritic.

The trunk, palms, and soles are usually spared, although some extension onto the trunk does not exclude the diagnosis.

Fig. 10.19 (**a–d**) Gianotti–Crosti syndrome. *Pink* to *red-brown* papules and papulovesicles distributed symmetrically on the extremities and buttocks

The eruptions can persist longer than 6 weeks in more than 50% of patients, and complete resolution typically takes more than 2 months.

The cutaneous manifestations can be preceded by an upper respiratory tract infection or diarrhea. The rash may be accompanied by a low-grade fever, hepatosplenomegaly, or cervical, inguinal, or axillary lymphadenopathy. Koebner's phenomenon may also be present.

Recurrence can occur rarely [69–71].

Diagnosis and Complementary Examinations

GCS is diagnosed clinically by the presence of a characteristic rash and its distribution. Lesion biopsy is usually not necessary. Histopathologic findings are nonspecific and include epidermal acanthosis, hyperkeratosis, and dermal perivascular lymphohistiocytic infiltrate, with dilatation of dermal capillaries. Investigation for hepatitis or identification of the causative agent is generally not required, but may be indicated in select cases [52, 70].

Differential Diagnosis

The GCS frame makes differential diagnosis with other viral rashes, drug eruptions, erythema multiforme, eczema herpeticum, Henoch–Schonlein purpura, papular-purpuric gloves and socks syndrome, Kawasaki disease, hand-foot-mouth disease, lichen planus, papular urticaria, and atopic dermatitis.

Therapeutic Approach

No specific treatment is necessary because of its benign nature.

Oral antihistamines and topical antipruritic may be useful for symptomatic relief.

The effectiveness of topical corticosteroids is not well established. Ribavirin has been used in prolonged or debilitating cases, but further study is needed as to its effectiveness [69, 71].

In vaccine-induced cases, there is no contraindication for subsequent doses [75].

Smallpox

Introduction

The first reports of the disease date back to 1500 BC and, until the last century, smallpox plagued humanity and accounted for more than half a million deaths per year in medieval Europe. Some authors consider it the worst epidemic worldwide to date. The last registered case of smallpox occurred in 1977, and in 1980 the disease was declared eradicated by the WHO, following a major global vaccination campaign during the 1960s–1970s [76, 77].

Etiology

Smallpox is caused by *Poxvirus variolae*, an orthopoxvirus of the Poxviridae family. It exclusively infects humans and is highly contagious and progressive, with high mortality rates.

Clinical Manifestations

Infection with the smallpox virus occurs through droplet or aerosol exposure. After an incubation period that lasts up to 14 days, the prodrome of fever and constitutional symptoms begins.

Rash appears 1–4 days after the onset of fever. The rash is characteristically centrifugal, with lesions progressing from macules to papules to umbilicated vesicles to pustules to scabs over a period of 2–3 weeks.

A person is contagious during the period when the rash is present, and infectiousness ceases after the scabs have sloughed.

The fatality rate of smallpox is approximately 25%, and severe complications such as blindness can also occur [76, 78].

Diagnosis

The suspicion is clinical and diagnosis can be made by serology, cell culture, PCR, or electron microscopy. Suspected cases should be immediately reported to the authorities [78].

Therapeutic Approach

Treatment

There is no specific treatment approved, although two drugs, tecovirimat and liposomal cidofovir, are in the testing phase, and may be useful in the event of new outbreaks of the disease [78].

Vaccine

Vaccination is still the most effective method of prevention. It is also useful for administration in the first days after exposure; it may alleviate or abort the symptoms of infection [76].

Vaccinia

Vaccinia virus (VACV) and Cowpox virus are causative agents of disease in cattle, and display serologic cross-reactivity with other members of the Poxviridae family. The bovine disease progresses with lesions in the cow's udder and can be transmitted to humans through direct contact during milking, resulting in lesions to the hands and arms [79].

In 1796 the English physician, Edward Jenner, observed that workers who came into contact with sick animals did not acquire smallpox or had a milder form of the disease. This finding led to the creation of an immunization method from the inoculation material collected from lesions, which was called "vaccination," derived from the Latin *vacca*, meaning "cow" [80, 81].

The traditional vaccine to prevent smallpox contains the VACV; it is administered via scarification of the skin and causes an infection by VACV that stimulates the immune system. Although highly effective, the replicative capacity of the virus can generate nonlocalized infection and significant adverse effects (Table 10.11) [82].

Given these considerations, the routine use of the vaccine was discontinued after eradication of the disease. This creates concern about the chances of re-emergence of smallpox from strains preserved in laboratories, since most of the population is susceptible. There is great fear about the use of the smallpox virus as a biological weapon in wars or terrorist attacks [78].

New vaccines with attenuated viruses have been studied, with a good safety profile for atopic

Table 10.11 Adverse effects of the smallpox vaccine

Progressive vaccinia: necrosis in the area of vaccine
Generalized vaccinia: scattered skin lesions, not necessarily related to the vaccination site
Eczema vaccinatum: local or generalized spread of the virus in atopic patients
Myocarditis/pericarditis
Encephalitis

patients or HIV-infected populations more prone to developing adverse effects to traditional vaccines [78, 82, 83].

Cowpox

Cowpox is a zoonotic dermatitis affecting, despite its name, mainly cats and humans. The disease is caused by the cowpox virus (CPXV), a close relative of vaccinia, smallpox (variola), and monkeypox viruses within the Orthopoxvirus genus. It is usually self-limited except in immunocompromised and atopic patients, particularly children, who may develop a severe and even fatal form of the disease [84, 85].

CPXV is transmitted to humans through contact with infected animals. It was believed initially that cattle were the natural reservoir of the virus.

Today it is considered that the true natural reservoirs are wild rodents, transmitting it to domestic animals, especially cats, which in turn transmit the disease to humans [84–86].

The vaccination for elimination of smallpox led to the suppression of cases of cowpox by cross-reactivity with the VACV. Currently, with the abandonment of the smallpox vaccination, the number of cases of cowpox in humans is increasing. The disease is more prevalent in Europe, Russia, and in the central and northern regions of Asia [85].

The virus infects humans through skin abrasions, resulting in successive lesions of macular, papular, vesicular, pustular, ulcerous, and eschar stages for 2 weeks, located mainly in the hands and face. The incubation period ranges from 7 to 12 days. Lymphadenopathy and symptoms such as myalgia, headache, and nausea are common.

The diagnosis can be done by PCR, virus isolation, serology, and electron microscopy [84].

There is no specific treatment established. Cidofovir has shown efficacy in in vitro tests and can be an option in difficult cases [85].

Milker's Nodules and Orf

Orf, or ecthyma contagiosum, is a zoonosis caused by the Orf virus, a Parapoxvirus that infects sheep and goats, and eventually humans. Transmission occurs through direct or indirect contact with infected animals or contaminated objects (see Box 10.7) [87].

After an incubation period of 3–14 days, it is manifested as skin lesions at the sites of cutaneous inoculation, usually unique, especially on the hands, arms, and forearms, although rarer locations have been described. It begins as an erythematous papule and progresses to a target lesion, evolving to exudative nodules that spontaneously regress with the formation of dry crust, until complete resolution in 6–12 weeks [52, 88].

Orf and milker's nodules, caused by the paravaccinia virus, another parapoxvirus, are clinically and histologically very similar and are differentiated by epidemiologic data. The first is endemic among sheep and goats and the second in cattle [52, 87].

Diagnosis is based on clinical history associated with contact with animals. In questionable cases it can be confirmed by histopathology, electron microscopy, serology, or PCR of lesional fluid.

Treatment is supportive, since it usually regresses spontaneously. Topical imiquimod can be used in select cases.

Shepherds, butchers, veterinarians, and farmers are occupations of risk for these diseases, and the appropriate use of gloves is the main preventive measure [52, 88].

Box 10.7 Exposure to Orf
Orf is a common occupational disease in New Zealand.

In countries with a Muslim population, it is common to find Orf unrelated to occupational exposure, but related to the slaughter of sheep in religious festivals of animal sacrifice [88].

Molluscum Contagiosum

Epidemiology

Molluscum contagiosum (MC) is a viral disease that mainly affects children, with peak incidence between 1 and 4 years of age, with no difference between boys and girls [89]. It can affect adolescents and adults, usually associated with sexual transmission. In the immunodeficient (e.g., in HIV patients), MC tends to be more severe and widespread [90, 91].

The annual incidence, including all age groups, is estimated at 2.01 in 1000 patients. In the 1–4 years age group the incidence rises to 10.2 in 1000 patients [89]. The overall reported prevalence of MC in children is between 5.1% and 11.5%.

In immunocompromised patients prevalence is between 5% and 18% and appears to be greater in warm climates. Specifically in HIV-positive patients, the prevalence increases significantly, reaching values of up to 33% in patients with CD4$^+$ T-cell counts below 100/µl [90].

MC is associated with atopic dermatitis. The lesions tend to arise in the areas of dermatitis or eczema, and children with atopic dermatitis may have a more disseminated presentation. Other MC associations are observed in children attending swimming pools, in patients with diseases that compromise immunity, or with the use of immunosuppressive drugs [36, 89, 90].

Etiopathogenesis

MC is an infection caused by the molluscum contagiosum virus (MCV), a large double-stranded DNA virus that is the sole member of the Molluscipoxvirus genus in the Poxviridae family.

Of the four identified subtypes, genotype 1 is responsible for about 90% of reported cases in the United States. Transmission occurs by direct contact with the skin of the infected person (which may be through sexual intercourse), fomites (towels, pools) or autoinoculation [36, 90, 92].

The incubation period ranges from 7 days to 3 months and the transmission occurs as long as the lesions exist. The disease has an indolent course and tends to disappear spontaneously within 2 years [90].

Clinical Presentation

MC is characterized by a typical, benign papular rash with pearly, centrally umbilicated lesions, reaching 1 mm to 1 cm, which can be found anywhere on the epidermis and more rarely on the mucous membranes (Fig. 10.20a–f).

Pruritus is also sometimes a clinical feature, and the lesions are usually painless. It more often affects the face, eyelids, axillary regions, antecubital and popliteal fossa, trunk, and extremities [36, 90, 91].

When it affects the mucosa, the most common sites are the perianal, orbital, and oral regions. Genital lesions occur in adolescents and adults (Figs. 10.21a, b and 10.22). When seen in children, it may suggest sexual abuse. The disease is rare in the palms and soles [36, 91].

Fig. 10.20 (**a–f**) Molluscum contagiosum. Pearly, centrally umbilicated lesions
Fig. 10.21 (**a**, **b**) Molluscum contagiosum. Genital lesions in an adult

Fig. 10.22 Molluscum contagiosum. Genital lesions in an immunosuppressed girl

Diagnosis

Diagnosis is clinical, through history and evaluation of the lesions. Dermatoscopy may help to identify central umbilication and typical vascular pattern. However, biopsy with findings of Henderson–Patterson bodies, PCR to identify the MCV, or preparation of the sample on a slide with potassium hydroxide for visualization of the cells can be used for confirmatory methods [36].

Complementary Examinations

Usually not required. Investigation of immunodeficiency is suggested in atypical presentations.

Differential Diagnosis

The differential diagnosis varies according to age, immune status, and location of lesions, and is summarized in Table 10.12, adapted from Hanna et al. [92].

Therapeutic Approach

MC in healthy people is a self-limiting, relatively harmless viral skin infection. Since most lesions will resolve within months, MC can be left to heal naturally unless better evidence for the superiority of other treatment options emerges. People may seek treatment for social and aesthetic reasons and because of concerns about spreading the disease to others. Treatment is intended to speed up the healing process [93].

Pharmacologic treatment includes cantharidin, podophyllotoxin, imiquimod, potassium

Table 10.12 Differential diagnosis of MC

	General patients	Children and adolescents	Immunocompromised patients	Genital lesions
Differential diagnosis	Cysts	Nevus	Penicilliosis	Ectopic sebaceous gland
	Abscesses	Juvenile xanthogranuloma	Cryptococcosis	Vulvar lymphangioma circumscriptum
	Basal cell carcinoma	Milium	Histoplasmosis	Condyloma acuminate

	Keratoacanthoma		*Pneumocystis carinii*	
	Verruca vulgaris		Aspergillosis	

Table 10.13 Comparison between some therapeutic modalities for MC

No. of visits required	Curettage	Cantharidin	Salicylic acid	Imiquimod
1	80.6%	36.7%	53.6%	55.2%
2	16.1%	43.3%	46.4%	41.4%
3	3.2%	20.0%	0%	3.4%
Satisfaction[a]	86.7%	60.0%	32.1%	44.8%
Adverse effects	4.7%	18.6%	53.5%	23.3%
Change of treatment	7.4%	18.5%	50.0%	38.5%

Adapted from Hanna et al. [92]

[a]Patients' and parents' satisfaction

hydroxide, SA, topical retinoids, and oral cimetidine. Cantharidin requires two applications and should preferably be done by a physician. It is contraindicated for lesions on the face, genitals, and perianal region. Podophyllotoxin is applied twice daily for 3 days each week for three additional weeks and can be self-administered [36]. Topical imiquimod appears to have better results in the lesions of the face, neck, and genitals [91]. Potassium hydroxide 5% solution must be applied by parents using a tooth pick (after covering the surrounding area with petrolatum), at night, three times a week for 12 weeks or until the lesions have cleared, and washed off in the morning [92]. Retinoids also help the immune system in clearing the virus but may cause skin irritation.

Nonpharmacologic options include cryotherapy, curettage, electrodesiccation, and manual extraction. Cryotherapy is the treatment of choice for many clinicians, performed in the office with one to three sessions indicated. The procedure causes pain, which is a limiting factor for treatment in children.

Curettage is a fast and reliable treatment performed by a medical professional with local anesthesia, usually suitable for a small number of injuries. It may leave a scar and is contraindicated for genital lesions.

Nonpharmacologic options should be considered for pregnant women [90–92]. Comparison of efficacy for some modalities of treatment is described in Table 10.13.

Prevention is achieved by avoiding manipulation of the lesions, communal use of objects with contaminated persons, and direct contact with carriers of the disease.

Prions

Abbreviations used:
PrP: Prion protein
PrP^C: Cellular prion protein
PrP^Sc: Prion protein from scrapie
CJD: Creutzfeldt–Jakob disease

Prion proteins (PrP) are part of membrane cell structure, naturally present in animal cells such as neurons and keratinocytes.

The prion protein can occur in either of two structural conformations, one that is normal (but

of unknown function), designated PrP^C, and one that results in disease, called PrP^{Sc} (Sc from the word scrapie).

PrP^{Sc} are small proteinaceous infectious particles, devoid of nucleic acid, with self-replicative capacity, which are responsible for serious neurodegenerative disorders in animals and humans. The infectious protein is able to modify the spatial structure of the prion protein PrP^C, naturally present in animal cells. This new conformation of the protein is insoluble, resistant to proteases, and toxic to the affected cells [94].

The incidence of prion-related disorders is relatively stable worldwide and has been estimated at 1 case per 1 million inhabitants annually. Most common forms are sporadic, accounting for 85% of all cases, whereas approximately 10–15% of instances are inherited forms and less than 2% are acquired forms [95].

In animals prions cause scrapie, the prototype disease of this group that affects sheep and goats, and bovine spongiform encephalopathy (mad cow disease). Human prion diseases include Creutzfeldt–Jakob disease (CJD), Gerstmann-Straussler-Scheinker syndrome (GSS), kuru, fatal familial insomnia (FFI), PrP cerebral amyloid angiopathy, and variably protease-sensitive prionopathy [96]. The explanation of these diseases is beyond the scope of this book.

Transmission occurs through direct contact with brain-derived materials and affected corneas, such as the transmission of kuru through cannibalism among tribes in New Guinea and CJD by eating contaminated beef [97].

Iatrogenic transmission can occur through surgical manipulation with contaminated instruments. Prions are able to adhere to metal surfaces and are extremely resistant to conventional decontamination methods. Bovine products used in health, such as cell culture media, catgut, and collagen implants used in dermatology, present an active risk of disease transmission [94, 98].

The presence of native PrP protein in skin keratinocytes makes the skin a possible point of entry, by scarifying or inoculating infected materials. Skin affected by psoriasis, eczema, or chronic ulcerations hyperexpresses PrP, becoming a target for prion infection [94].

Emerging Viruses

Abbreviations used:
Dengue virus:DENV
Zika virus: ZIKV
Chikungunya virus: CHIKV
Ebola virus: EBOV

Emerging viral diseases are a constant challenge in medicine. Tourism, economic globalization, immigration, and climate change are factors that contribute to the spread of infectious diseases.

New pathogens are being identified, the geographic distribution of diseases is constantly changing, and new clinical syndromes caused by known pathogens are being discovered [99].

This section addresses Ebola, dengue, chikungunya, and Zika. The main aspects of these diseases are listed in Table 10.14.

Table 10.14 Emerging viruses: main features

	Transmission	Cutaneous manifestations	Noncutaneous manifestations	Diagnosis	Endemic areas
Ebola	Direct contact with bodily fluids	Nonspecific macules and papules	Flu-like symptoms and hemorrhages	RT–PCR[a], antigen-capture ELISA[b], antibody-capture ELISA, and virus isolation	Guinea, Liberia, Sierra Leone (last endemic area)
		Pinpoint papules around hair roots and proximal extremities			
		Diffuse erythroderma			
		In darker skin: fine scaling			
		Petechiae, purpura, ecchymoses, and hematomas, particularly around needle or puncture sites			

Table 10.14 (continued)

	Transmission	Cutaneous manifestations	Noncutaneous manifestations	Diagnosis	Endemic areas
Dengue	Bite of infected mosquitoes of the genus *Aedes*	Classic dengue: maculopapular rash that mainly affects the trunk – describe as "islands of white in a sea of red." This may be pruritic and heals with desquamation	Classic dengue: fever for 2–5 days, severe headache, intense myalgia, arthralgia, retro-orbital pain	Rapid test; RT–PCR if <7 days after symptom onset (or NS1 antigen ELISA); antibody testing if ≥4 days after symptom onset or if molecular testing is negative: IgM[c] ELISA and PRNT[d]	Tropical and subtropical areas of Asia, Americas, Africa
		Discrete hemorrhagic manifestations	Hemorrhagic dengue: more severe course, vomiting, weakness, hemodynamic instability		
		Hemorrhagic dengue: facial flushing, circumoral cyanosis, petequias, equimoses, and vibices in different topography			
Zika	Bite of infected mosquitoes of the genus *Aedes*; sexual contact; vertical; (saliva, semen, breast milk, urine?)	Blanchable macules and papules that start on the face or trunk and extends to extremities. The eruption may be pruritic and heals with desquamation. Typically spares the palms and soles	Fever, arthritis or arthralgia, and conjunctivitis	RT–PCR in urine; antibody testing if ≥4 days after symptom onset or if molecular testing is negative: IgM, ELISA, and PRNT	South and Central America, Caribbean, Pacific Islands
		Mild hemorrhagic manifestations			
Chikungunya	Bite of infected mosquitoes of the genus *Aedes*	Morbilliform rash, which can become confluent	Symmetric polyarthralgia, most frequently in the hands, wrists, and ankles	RT–PCR if <7 days after symptom onset; antibody testing if ≥4 days after symptom onset or if molecular testing is negative: IgM, ELISA, and PRNT	Asia, Africa, Latin America, Caribbean, Florida, Puerto Rico, US Virgin Islands
		In male: aphthous-like ulcers in the scrotal region, associated with scrotal erythema and pain and swelling of the scrotum and groin	High grade fever		
		Xerosis of skin with scaling, desquamation of palms	Severe malaise		
		Acute intertrigo-like lesions			
		Lymphedema in an acral distribution			
		Nasal hyperpigmentation			
		Vesiculobullous lesions			
		Itching, generalized urticaria			
		Purpuric patches, rarely			
		Exacerbation of a patient's underlying dermatoses			

[a]*RT–PCR* reverse transcriptase–polymerase chain reaction
[b]*ELISA* enzyme-linked immunosorbent assay
[c]*IgM* immunoglobulin M
[d]*PRNT* plaque reduction neutralization test

Ebola

The Ebola virus disease (EVD), formerly known as Ebola hemorrhagic fever, is caused by the viruses of the Ebolavirus genus. Ebola was first discovered in 1976 near the Ebola River in the Democratic Republic of Congo. Since then sporadic outbreaks have occurred in Central Africa, and a major epidemic occurred in 2014, affecting several countries in Africa.

The disease is transmitted through direct contact with the blood or bodily fluids. It is initially presents with sudden nonspecific flu-like symptoms, and nonspecific cutaneous manifestations appear 4–5 days after the fever. Bleeding is frequently observed, causing petechiae, purpura, and ecchymoses. The clinical course is severe and lasts about 14–21 days, and mortality rates reach 90% [55].

Dengue, chikungunya, and Zika virus are transmitted by the bite of the same vector, the *Aedes* mosquitoes, mainly *Aedes aegypti*, an anthropophilic species that is an aggressive daytime biter well adapted to urban environments. This enabled the occurrence of simultaneous outbreaks of these diseases in tropical countries such as Brazil, other countries in Latin America, Asia, and Oceania.

These viruses cause quite similar febrile clinical syndromes, making differential diagnosis difficult [100, 101].

Furthermore, the emergence of new complications such as congenital Zika syndrome, and the occurrence of disease in travelers around the world, is making this a public health concern of global proportions [102].

Dengue

Dengue virus (DENV) belongs to the family of Flaviviridae, and DENV complex is composed of five serotypes. Infections are transmitted by the bite of infected mosquitoes of the genus *Aedes*, primarily *Aedes aegypti*. Dengue is the most prevalent mosquito-borne viral disease and an important cause of morbidity and mortality in tropical and subtropical regions. Clinical manifestations of the disease vary and include asymptomatic infection, classic dengue, dengue hemorrhagic fever (DHF), and dengue shock syndrome. Most dengue infections are asymptomatic and a mild disease resembles any acute febrile illness, with high-grade fever, malaise, and retro-orbital pain [103].

Patients should to avoid aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs).

Chikungunya

Chikungunya is an acute febrile illness caused by the Chikungunya virus (CHIKV) of the Togaviridae family, and also transmitted by *Aedes* mosquitoes. The illness was initially discovered in Africa in 1952 and is endemic to many countries in Asia, Africa, Latin America, and the Caribbean [55, 104].

The name chikungunya, which is used to describe both the virus and the disease, is derived from a Swahili or Makonde word *kun qunwala*, meaning "to become contorted" or "that which bends up." The most characteristic symptom of chikungunya is severe and symmetric polyarthralgia (see Box 10.8). Although most symptoms resolve, some patients have joint pain that can continue for years and can be so severe that they adopt a bent or stooping posture [105].

Box 10.8 Key points for Chikungunya clinical presentation
Severe joint pain
   High fever, headaches, photophobia
   Maculopapular rash in legs and arms that lasts for 2–3 days

Zika

Zika virus (ZIKV) is a single-stranded RNA virus in the genus Flavivirus, which originated in the Zika forest in Uganda and was discovered in a rhesus monkey in 1947. The disease now has "explosive" pandemic potential, with outbreaks in Africa, Southeast Asia, the Pacific Islands, and the Americas. Since Brazil reported Zika virus in May 2015, infections have occurred in at least 20 countries in the Americas [106].

The transmission of ZIKV has been associated with several *Aedes* mosquito species, notably *A. aegypti* and *A. albopictus*. However, other factors may contribute to the rapid spread of the virus. ZIKV is detectable in blood, urine, semen, breast milk, and saliva from patients and can persist in urine for several months after clinical resolution of the disease [107].

Although transmission through blood transfusion has not been reported, it is likely to occur. Spread of the virus through sexual contact has been reported, and viral RNA has been detected in semen 62 days after symptom onset. Men who have had a diagnosis of ZIKV disease must wait at least 6 months after symptom onset before attempting conception [55].

Several reports demonstrated vertical transmission of ZIKV to the fetus in pregnant women. Intrauterine infections are associated with the occurrence of microcephaly, other congenital malformations, and miscarriages, which is being called "Zika congenital syndrome" [102, 108, 109]. The actual magnitude of these complications cannot yet be estimated. There is also an association with ZIKV infection and postinfectious GBS under investigation [106].

On February 1, 2016, the WHO declared that the rapid spread of ZIKV in the Americas and the increasing reports of cases of congenital malformations and neurologic complications in ZIKV-affected areas constitute a "public health emergency of international concern." Box 10.9 shows the main clinical aspects of ZIKV.

> **Box 10.9 Key points for ZIKV clinical presentation**
> Mild symptoms, conjunctivitis usually present
>   ZIKV present in breast milk, semen, saliva, urine
>   Guillain–Barré syndrome
>   Congenital Zika syndrome

Diagnosis

Diagnosis of dengue, chikungunya, and Zika is based on anamnesis, symptoms, and test results (see Box 10.10 and Fig. 10.23 with CDC algorithm).

Zika can be difficult to differentiate from dengue and chikungunya infections. Compared with dengue, Zika virus infection has a mild to moderate clinical picture and conjunctivitis is common.

Dengue usually presents with retro-orbital pain, not associated with conjunctivitis, and a more severe muscle pain.

Chikungunya presents with higher fever and more intense joint pain [55].

ZIKV is more frequently detected in urine and saliva than in blood using ZIKV RT–PCR tests.

Patients exhibit the highest concentrations of ZIKV in saliva at disease onset while in urine; ZIKV possibly remains detectable for longer periods [111].

A point-of-care (POC) assay to specifically detect IgM and IgG antibodies to ZIKV and a multiplex POC assay to simultaneously detect antibodies to ZIKV, DENV, and CHIKV are in development. The multiplex POC assay could be of particular utility in areas where these arboviruses cocirculate [112]. Rapid tests for dengue are available and can be used in field settings.

> **Box 10.10 Tips for differential diagnosis**

> | Dengue | Retro-orbital pain |
> | Chikungunya | Polyarthralgia |
> | Zika | Conjunctivitis |

Tiered algorithm for arbovirus detection for suspected cases of chikungunya, dengue, or Zika (Testing only performed if patient symptomatic and travel history indicates travel to affected area.)

Molecular testing[1] (<7days after symptom onset)

Antibody testing[1] (≥4days after symptom onset)

RT-PCR/NS1 dengue — (Real time) PCR-Zika virus — (Real time) PCR-chikungunya virus

IgM dengue — IgM Zika virus — IgM chikungunya virus

Positive: dengue virus Confirmed | Negative: Perform antibody testing[2]

Positive: Zika virus Confirmed | Negative: Perform antibody testing[2]

Positive: chikungunya virus Confirmed | Negative: Perform antibody testing[2]

Positive: Presumptive dengue virus[3] | Negative

Positive: Presumptive Zika virus[3] | Negative

Positive: Presumptive chikungunya virus | Negative

PRNT[4]   PRNT[4]   PRNT

- [1]Due to extensive cross-reactivity in flavivirus serological assays, for samples collected <7 days post illness onset, molecular detection should be performed first.
- [2]Perform if sample ≥4 days after symptom onset.
- [3]Extensive cross-reactivity would be expected in samples from DENV/ZIKV circulation areas. A positive IgM assay with either antigen should be confirmed by using PRNT against both ZIKV and DENV as well as any other flavivirus (eg. SLEV, ZIKV, WNV, etc.) that might be found in that geographic area (including travel areas).
- [4]PRNT should include any flavivirus (eg. SLEV, ZIKV, WNV, etc.) that might be found in that geographic area (including travel areas).

Fig. 10.23 CDC algorithm for suspected cases of chikungunya, dengue, or Zika [110]

Therapeutic Approach

Treatment is nonspecific and supportive.

Aspirin and other NSAIDs should be avoided until dengue is excluded.

A dengue quadrivalent vaccine was approved recently in Brazil, Mexico, and the Philippines.

There is no vaccine for CHIKV or ZIKV.

The prevention or reduction of transmission of DENV, ZIKV, and CHIKV is completely dependent on the control of mosquito vectors and limiting person-mosquito contact.

Fungal Infections

11

Raíssa Londero Chemello,
Rafaella Daboit Castagna, Taciana Cappelletti,
and Juliana Mazzoleni Stramari

Key Points Summary

- Superficial fungal infections are caused by pathogenic fungi and are limited to the human hair, nails, epidermis, and mucosa
- Superficial fungal infections are caused by dermatophytes, which require keratin for growth, *Candida* sp., which infect warm areas, and various yeasts and lipophilic fungi of the genus *Malassezia*
- Subcutaneous mycoses include a heterogeneous group of infections that often result from direct penetration of the fungus into the skin through trauma
- Systemic mycosis is characterized by infections caused by truly pathogenic fungi as well as those produced by fungi with small intrinsic pathogenicity, enhanced by immunocompromised hosts
- Subcutaneous and systemic fungal infections are caused by numerous fungi, which invade the skin, mucosal sites, and CNS
- Fungal infections can have various clinical presentations
- Diagnosis of mycoses is made from mycologic studies, direct examination, stains, and isolation and identification of the fungi

Superficial Mycosis

Superficial mycoses are fungal infections of the skin, hairs, and nails that invade only the stratum corneum and the most superficial layers of the skin, and include dermatophytoses, tinea versicolor, candidiasis, tinea nigra, and piedras (white and black).

Dermatophytosis

Dermatophytosis, also known as tinea, is a superficial fungal infection of the stratum corneum, nails, and hair caused by dermatophytes, which includes three genera: *Trichophyton* sp., *Microsporum* sp., *and Epidermophyton* sp.

Epidemiology

Of the 40 different species of dermatophytes, about 30 have been known to cause human infections. They are distributed worldwide, although dermatophytosis is more prevalent in hot, humid tropical and subtropical climates.

Dermatophyte infections can be transmitted from person to person through fomites, especially among family members; from animals to humans; and acquired from soil [1, 2]. The most important sources of fungal infection are the bath, showers in fitness studios, changing rooms at public pools, and mats in sports facilities. Dermatophytosis infection can be either direct (rarely, via skin contact from one person to another) or indirect (most common, from walking barefoot on surfaces that have been contaminated with infectious material from the skin, floors, rugs, etc.). Children and adolescents are frequently affected by zoophilic dermatophytes, whose sources are house pets, especially cats and rodents, and less often, farm animals, or outbreaks among the family or at a school/daycare [2].

Members of the same species can produce quite different clinical pictures, including age-group selectivity: *Tricophyton tonsurans*, for example, can produce tinea capitis in children and tinea corporis in adults.

Trichophyton rubrum is the most common cause of tinea pedis, nail infection, tinea cruris, and tinea corporis worldwide, once it targets structures of the stratum corneum of the epidermis and the nail keratin. However, *T. rubrum* only rarely causes thricophytosis [1, 2].

Etiopathogenesis

Dermatophytes can be separated into three groups based on their habitat. Anthropophilic dermatophytes are restricted to human hosts, producing mild chronic inflammation, and are the main cause of chronic infections. *T. rubrum*, *Trichophyton concentricum*, *Trichophyton schoenleinii*, *T. tonsurans*, and *Trichophyton mentagrophytes* var. *interdigitale* are the most involved species. Zoophilic dermatophytes (*Microsporum canis*, *Trichophyton verruco-*sum, *Trichophyton mentagrophytes* var. *menta-grophytes*), the main reservoirs of which are pets, livestock, and horses, usually cause infection with marked inflammatory reaction in humans [3]. *Microsporum gypseum* is the most common geophilic dermatophyte. It usually causes tinea manus and has been reported in infections after contact with soil, for example, when gardening [2].

In addition, reactions to a dermatophyte infection may range from mild to severe as a consequence of the host's reactions to the metabolic products of the fungus, the virulence of the infecting strain or species, the anatomic location of the infection, and local environmental factors [4].

The dermatophytes target the hard, firm cyto-keratin found in the skin, hair, and nails in order to proliferate in the stratum corneum. They destroy the complex protein keratin via keratinase and adhere to the epithelial tissue of the host by mannan glycoproteins in the cell wall of the fungus. The nutritive medium for the fungus and the host–pathogen interaction are also important factors, among others [2].

Dermatophytes are restricted to the stratum corneum because keratinocytes act as a physical barrier against them and are also involved in cutaneous immune reactions. They express pattern recognition receptors, which promote the release of various proinflammatory cytokines and chemotactic factors and cause inflammatory reactions, such as redness and swelling. To prevent fungal infection, keratinocytes also release antimicrobial peptides. Chemotactic factors recruit inflammatory phagocytes, which engulf dermatophytes, release cytokines, and produce reactive oxygen species that cause damage in proteins, lipids, and DNA, thereby destroying the phagocytosed pathogens. Local fungal infections induce the production of circulating antibodies and activate T lymphocytes, leading to various localized or generalized inflammatory reactions called "id reactions" [5].

Table 11.1 shows main fungal species of dermatophytosis.

Table 11.1 Commonest etiologic agents causing dermatophytosis

Diagnosis	Etiologic agents
Tinea barbae	*Trichophyton verrucosum*, *T. mentagrophytes*
Tinea capitis	*T. tonsurans*, *Microsporum canis*, *M. audouinii*, *T. verrucosum*, *T. violaceum*, *T. soudanense*
Tinea corporis	*T. rubrum*, *M. canis*, *T. tonsurans*
Tinea cruris	*Epidermophyton floccosum*, *T. rubrum*, *T. interdigitale*
Tinea incognito	Potentially any cutaneous dermatophytosis that has been inappropriately treated with topical steroid
Tinea manuum	*T. rubrum*, *T. mentagrophytes*
Tinea pedis	*T. rubrum*, *T. interdigitale*, *E. floccosum*
Onychomycosis	*E. floccosum*, *T. interdigitale*, *T. rubrum*, *T. verrucosum*

Fig. 11.1 Tinea corporis in a diabetic patient with eruptive xanthomas

Clinical Presentation

Dermatophytoses are classified according to the affected area of the body in tinea corporis, tinea pedis, tinea cruris, tinea capitis, and tinea unguium (dermatophyte onychomycosis) [1].

Tinea Corporis

Ringworm of the body, usually involving the trunk, shoulders, or limbs, and occasionally the face (excluding the bearded area), may be caused by any dermatophyte. The infection has a broad range of manifestations, with lesions varying in size, degree of inflammation, and depth of involvement. In classic ringworm erythemato-squamous, scaly plaques grow centrifugally (Fig. 11.1). They are initially flat, scaly spots that then develop a raised border that extends out at varying rates in all directions. The advancing, scaly border may have red, raised papules or vesicles, while the central area turns brown or hypopigmented and becomes less scaly as the active border progresses outward, forming an annular, irregular plaque (Figs. 11.2 and 11.3). Lesions can be single or multiple, asymptomatic, or mildly itchy, and can self-resolve or enlarge, covering large areas of the body [1, 6] (Figs. 11.4 and 11.5).

Fig. 11.5 Extensive tinea corporis (*T. rubrum*) in a pregnant patient

Fig. 11.6 Tinea circinata on the back (*T. tonsurans*)

Fig. 11.7 Tinea faciei in a malnourished patient

Tinea circinata (Fig. 11.6) is a specific form of tinea corporis frequently caused by *T. tonsurans* that has a peculiar ring-like morphology. It is difficult to differentiate from tinea imbricata (tokelau), which is caused by the slow-growing dermatophyte *Trichophyton concentricum* and occurs in Southeast Asia (Vietnam, Polynesia), Africa, and South America [6].

Tinea faciei appears as erythematous, centrifugally growing, discretely scaly patches with prominent borders, frequently on the cheeks, but also on the eyelids and the submandibular region (Fig. 11.7). It can be mildly or even nonpruritic. In children, zoophilic dermatophytes are the primary pathogens [6].

Tinea Cruris ("Jock Itch")

Infection of the groin, perianal, and perineal areas, and occasionally the upper thighs, is usually seen in adult men. *T. rubrum* and *Epidermophyton floccosum* are the most frequent etiologic agents. Lesions are erythematous to tawny brown and covered with thin, dry scales. They are usually bilateral and often asymmetric, extending down the sides of the inner thigh and exhibiting a raised, sharply marginated border that is frequently studded with small vesicles [4]. The promoting factor is the presence of a warm, moist environment, such as excessive sweating or wearing wet clothes. Itching becomes worse as moisture gathers and macerates the intertriginous area [1].

Tinea of the Hand

The palmar and interdigital areas of the hand are usually involved in tinea manus, most frequently presenting as unilateral diffuse hyperkeratosis with accentuation of the flexural creases. Most infections are caused by *T. rubrum* [4].

Tinea Pedis

Tinea pedis is the dermatophyte infection of the foot, also called athlete's foot. Predisposing factors are warmth and sweating. Locker room floors and communal baths are important sources for this infection. Most cases occur in late childhood and young adulthood [1].

The soles and toe webs are most frequently involved in tinea pedis. The most common clinical manifestation is the intertriginous form, which presents with maceration, peeling, and fissuring, mainly in the spaces between the fourth and fifth toes. Another common presentation is the chronic, squamous, hyperkeratotic type in which fine silvery scales cover pinkish skin of the soles, heels, and sides of the foot (moccasin foot) (Fig. 11.8). An acute inflammatory condition (dyshidrotic type), characterized by the formation of vesicles, pustules, and sometimes bullae, is most frequently caused by *Trichophyton mentagrophytes*. The more chronic agents of tinea pedis are *T. rubrum*, *T. mentagrophytes* var. *interdigitale*, and *E. floccosum* [1, 6].

Tinea Capitis

Tinea capitis, an infection commonly involving the scalp, is usually caused by members of the genera *Microsporum* and *Trichophyton*. It is the most relevant dermatophyte infection in children between 3 and 8 years of age. The infection is related to poverty, large family size, and crowded living conditions. It originates from contact with a pet or an infected person, by direct contact, or from contaminated clothing. Untreated asymptomatic scalp infections in schoolchildren and adults are important contributing factors to disease transmission and reinfection [1, 6].

The infection may range from mild, almost subclinical, with slight erythema and a few patchy areas of scaling with dull gray hair stumps (Figs. 11.9 and 11.10), to a highly inflammatory

Fig. 11.9 Tinea capitis in a preschool child (*M. canis*)

Fig. 11.8 Tinea pedis, "moccasin foot" (*T. rubrum*)
Fig. 11.10 Tinea capitis (*M. canis*): bright green Wood's light fluorescence

reaction with folliculitis, kerion formation, and extensive areas of scarring and alopecia, sometimes accompanied by fever, malaise, and regional lymphadenopathy. Dermatophytes show either an endothrix or an ectothrix pattern of hair root involvement. In endothrix infections by *T. tonsurans*, *Trichophyton violaceum*, *Trichophyton soudanense*, and *T. verrucosum*, (arthro)spores and mycelia may be microscopically detected inside the hair shaft, without any destruction of the cuticle. In ectothrix infections by *M. canis*, *Microsporum audouinii*, and *Trichophyton interdigitale* (zoophilic strains), spores and hyphae aggregate in a cuff-like fashion outside the hair shaft [6].

The current predominant cause of tinea capitis in most of North, Central, and South America is *T. tonsurans* (endothrix) [4]. In Brazil, *M. canis* (ectothrix) is also an important etiologic agent.

Tinea Barbae

Tinea barbae, an infection of the bearded area, may be mild and superficial or a severe inflammatory pustular folliculitis (resembling fungal kerions seen in tinea capitis). The latter form is more commonly caused by the zoophilic dermatophytes *T. verrucosum* and *T. mentagrophytes* var. *mentagrophytes* [4]. Bacterial folliculitis and inflammation secondary to ingrown hairs may be complications of tinea. The deep follicular infection has an appearance similar to that of bacterial folliculitis but is slower to evolve and usually restricted to one area of the beard.

Tinea Incognito

Tinea incognito, or tinea atypica, is a term used to describe a tinea infection modified by topical steroids. It is caused by prolonged use of topical steroids, sometimes prescribed as a result of incorrect diagnosis. Topical steroids decrease inflammation and give the false impression that the rash is improving while the fungus continues to thrive secondary to cortisone-induced immunologic changes. Clinically, lesions initially resemble eczema-like and psoriasis-like dermatoses as well as lupus erythematosus. Tinea incognito is usually seen on the groin, face, dorsal aspect of the hands, and trunk [1, 6].

Tinea Unguium or Onychomycosis

Invasion of the nail plate by a dermatophyte is referred to as tinea unguium; onychomycosis is a word often used as a general term for a nail fungal infection.

Onychomycosis may involve a single nail or all nails. Toenails are seven times more likely to be affected than fingernails. The first and fifth toenails are the most commonly affected, often following an episode of tinea pedis. Fingernail infection is, in contrast, usually associated with tinea corporis or capitis, and is often unilateral [7].

Four types of onychomycosis are recognized. Distal and lateral subungual onychomycosis (DSO) is the most common form of onychomycosis. It clinically appears as hyperkeratosis of undersurface of distal nail plate and bed; onycholysis and dyschromias (Fig. 11.11). It is associated with one hand–two feet syndrome and tinea pedis is often present. Proximal (white) subungual onychomycosis, a relatively uncommon subtype, occurs when organisms invade the nail unit via the proximal nail fold and migrate distally. The clinical presentation includes subungual hyperkeratosis, proximal

Fig. 11.11 Tinea pedis and onychomycosis: hyperkeratosis of undersurface of distal nail plate and bed

onycholysis, leukonychia, and destruction of the proximal nail plate. It is common in acquired immune deficiency syndrome (AIDS) patients and is considered an early clinical marker of human immunodeficiency virus (HIV) infection. White superficial onychomycosis is less common than DSO and occurs when certain fungi invade the superficial layers of the nail plate directly. It can be recognized by the presence of well-delineated opaque "white islands" on the external nail plate, which coalesce and spread as the disease progresses. The nail becomes rough, soft, and crumbly. It usually affects children and the most common etiologic agent is *T. mentagrophytes*. Total dystrophic onychomycosis is used to describe end-stage nail disease may be the end result of any of the main patterns of onychomycosis. The entire nail unit becomes thick and dystrophic [8].

Dermatophytid or Id Reactions

Dermatophytid is a hyperergic reaction to dermatophyte components as a result of antimycotic treatment of extensive tinea. Id reactions present clinically as symmetric dyshidrotic eruptions on hands and feet, or as nodular and multiform eruption, predominantly on the extremities. It can be falsely misdiagnosed as adverse drug reaction or intolerance to antimycotic agents, but lesions slowly resolve, even if the drug is continued [6].

Box 11.1 Specific Forms of Dermatophytosis
Majocchi's granuloma: a form of inflammatory tinea usually caused by *T. rubrum* and originally reported as occurring on the lower leg of women who shave, but is also seen at other sites on men and children. The primary lesion is a pruritic, scaly, follicular papulopustule or inflammatory nodule. Subsequently deep infiltration of mycelia along hair follicles results in their rupture, leading to a granulomatous follicle-associated inflammatory reaction. Intracutaneous and subcutaneous granulomatous nodules arise. It particularly affects immunosuppressed patients. Lesions have

necrotic areas containing fungal elements which are surrounded by epithelioid cells, giant cells, lymphocytes, and polymorphonuclear leukocytes [1, 6].

Two feet–one hand syndrome: a dermatophyte infection of both feet and one of the palms. Nail infection of the hands and feet can also be present. It usually occurs in men and *T. rubrum* is the causative organism in most cases [1].

T. rubrum syndrome: represents a chronic and generalized dermatophytosis, also referred as chronic dermatophytosis syndrome, generalized chronically persistent rubrophytia, tinea corporis generalisata, and dry-type *T. rubrum* infection. *T. rubrum* syndrome is characterized by infection of at least four body sites: feet (plantar), hands (palmar), nails, as well as one other site. The inguinal region is not affected. Other diagnostic criteria are microscopic fungal detection from all four sites and cultural detection of *T. rubrum* from at least three out of four sites. Predisposing factors includes Down syndrome, HIV infection, diabetes mellitus, and corticosteroid treatment [6].

Complementary Examinations

The most important test for the diagnosis of dermatophyte infection is direct visualization under microscopy of the branching hyphae in keratinized material [1].

Scale from the active border of a lesion (collected with a scalpel blade), pulled-out hairs from the affected area or, in the case of nails, subungual debris should be placed on the center of a microscope slide and covered with a coverslip. Then potassium hydroxide, 5–20% solution, should be applied at the edge of the coverslip. Under microscopy, dermatophytes are identified as septated, tube-like structures called hyphae and mycelia [1].

Fungal cultures are slow and expensive and are usually not needed in cases where the same oral and topical agents are effective against all of

the dermatophytes. However, it can be useful in cases of tinea capitis and onychomycosis, when long-term oral therapy is considered. Fungal cultures are grown on Sabouraud's glucose medium and usually take 7–14 days to be declared positive; culture must be held 21 days to be declared negative [6].

A Wood's lamp (filtered UV light) can be used to visualize hairs infected with *Microsporum* species, which fluoresce in a greenish color in a dark room (Fig. 11.10). *Microsporum* is a very common cause of tinea capitis in many parts of the world, including Brazil. Favus, a rare chronic form of tinea capitis caused by *Trichophyton schoenleinii*, will fluoresce a pale green with examination under Wood's light. A Wood's lamp can be also used to differentiate tinea and intertrigo from erythrasma, which fluoresces a brilliant coral red color [9].

Diagnosis

> **Box 11.2 Diagnosis of Dermatophyte Infection**
> Dermatophyte infections can be readily diagnosed based on the history, physical examination, and potassium hydroxide (KOH) microscopy. Diagnosis occasionally requires Wood's lamp examination and fungal culture or histopathologic examination.

Differential Diagnosis

TINEA CORPORIS – psoriasis vulgaris; impetigo; atopic dermatitis; contact dermatitis; erythema multiforme; and granuloma annulare [6].

TINEA FACIEI – contact dermatitis; atopic dermatitis; lupus erythematosus; granuloma faciale; herpes zoster; impetigo; perioral dermatitis; polymorphous light eruption; psoriasis vulgaris; rosacea; sarcoidosis; and seborrheic dermatitis [6].

TINEA CRURIS – intertrigo and erythrasma [1].

TINEA MANNUM – palmar psoriasis; atopic hand dermatitis; and contact dermatitis.

TINEA PEDIS – Interdigital: erythrasma; and interdigital candidiasis [6]. Moccasin-type: atopic dermatitis; plantar psoriasis; and pitted keratolysis.

[6] Dyshidrotic type: dyshidrotic eczema; contact dermatitis; impetigo; juvenile plantar dermatosis; and keratolysis exfoliative [6].

TINEA CAPITIS – alopecia areata; bacterial abscess of the hairy scalp; impetigo; furuncle/carbuncle; seborrheic dermatitis; pityriasis amiantacea; pityriasis capillitia; psoriasis; syphilis; and trichotillomania [6].

TINEA UNGUIUM – psoriasis; lichen planus; yellow nail syndrome; and alopecia areata [7].

Therapeutic Approach

Topical Treatment

Topical antifungals are effective in the treatment of tinea and they should generally be applied twice daily in the involved area for 2–4 weeks, including 1 week after lesions have disappeared. Topical antimycotics that can be used against dermatophytes include imidazoles (such as bifonazole 1%, clotrimazole 1%, econazole 1%, miconazole 2%, and sertaconazole), ciclopirox olamine 1%, terbinafine 1%, amorolfine 0.025% (nail lacquer 5%), and tolnaftate 1%. Available presentations are cream, lotion, spray, powder, and solution nail lacquer. Combination of an antimycotic and a corticosteroid is effective in treating inflammatory forms of tinea pedis, but should not be used for longer than 14 days [1, 10] (Table 11.2).

Systemic Treatment

Both systemic antifungal and topical agents should be used together. Oral treatment is imperative for tinea capitis, extensive tinea corporis, onychomycosis (indications for oral treatment include proximal subungual onychomycosis, at least 50% of the nail plate affected, involvement of the nail matrix or multiple nails, and no response to topical treatment after 6 months), and chronic tinea pedis.

Tinea Corporis

Tinea corporis is treated by 150–200 mg of fluconazole once weekly for 2–4 weeks, by 200 mg itraconazole daily for 7 days, or by 250 mg terbinafine daily for 1 week. Deep inflammatory lesions require 1–3 or more months of oral therapy [1].

Table 11.2 Tinea treatments

	Topical treatment	Systemic treatment
Tinea pedis	Bifonazole 1× daily for 2–4 weeks	Terbinafine 250 mg daily for 1–2 weeks
	Clotrimazole 2–3× daily for 2–4 weeks	
	Econazole 2× daily for 2–4 weeks	
Tinea corporis	Miconazole 1–2× daily for 2–4 weeks	Itraconazole 200 mg daily for 1 week
	Sertaconazole 1× daily for 2–4 weeks	
Tinea manuum	Ciclopirox olamine + terbinafine 1× daily for 2–4 weeks	Fluconazole 150–200 mg once weekly for 2–6 weeks
	Amorolfine 2× daily for 2–4 weeks	
	Tolnaftate 2× daily for 2–4 weeks	
Tinea cruris	Available presentations: cream, lotion, spray, powder, gel	
Tinea capitis	Ketoconazole 2% shampoo 2–3× weekly for 2–4 weeks	Terbinafine 250 mg daily for 4–6 weeks in adults
		Children according to weight:10–20 kg, 62.5 mg/day; 20–40 kg, 125 mg/day; >40 kg, 250 mg/day
	Selenium sulfide 1% shampoo 2–3× weekly for 2–4 weeks	Griseofulvin 1,000 mg daily for 6–12 weeks in adults and 20–25 mg/kg/day (max 1 g) daily in children
	Povidone–iodine 2.5% shampoo 2–3× weekly for 2–4 weeks	Fluconazole 6 mg/kg per day for 3–6 weeks or once weekly for 6–12 weeks
	Ciclopirox 1% shampoo 2–3× weekly for 2–4 weeks	Itraconazole 5 mg/kg (maximum 400 mg) 1× daily for 2–4 weeks in adults and 3–5 mg/kg/day 1× daily for 2–4 weeks in children
Tinea barbae		Terbinafine 250 mg 1× daily for 4 weeks
		Itraconazole 200 mg 1× daily for 2 weeks
Onychomycosis	Amorolfine 5% lacquer 1–2× weekly for 6–12 months	Terbinafine 250 mg 1× daily for 12 weeks for toenails or for 6 weeks for fingernails
		Or
	Ciclopirox 8% lacquer 1× daily for 24 weeks on fingernails and for 48 weeks on toenails	Intermittent treatment option: terbinafine 250 mg 1× daily for 5–14 days, followed by 250 mg weekly until clinical cure is achieved
		Or
	Keratolysis with 20% or 40% urea cream applied under occlusion	Terbinafine 500 mg 1× daily for 1 week every month for 3 consecutive months
	Miscellaneous: surgical nail removal, phonophoresis, manual and electrical nail abrasion, acid etching, microporation, ultrasonography, laser nail ablation, iontophoresis, lasers (Nd:YAG short pulse and Q switch 1,064 nm and the diode 870, 930, and 980 nm), photodynamic therapy, topical germicidal ultraviolet C light58	Itraconazole 100 mg 2× daily for 3 months
		Or
		Intermittent treatment option: Itraconazole 200 mg 2× daily for 1 week, followed by an interval of 3 weeks for 3 months
		Fluconazole 150 mg 1× weekly (one single dose) for 3–6 months for fingernails and 6–12 months for toenails
		Or
		Fluconazole 300 mg (up to 450 mg) single weekly dose for 3–6 months for fingernails and 6–12 months for toenails

Tinea Pedis

Terbinafine, 250 mg tablet daily for 2 weeks; itraconazole, 200 mg twice daily for 1 week; or fluconazole, 150 mg once weekly for 2–6 weeks [1, 10].

Tinea Capitis

Griseofulvin is the current drug of choice in children, in dosages of 20–25 mg/kg/day for 6–12 weeks, especially in cases of *M. canis*. The recommended daily dose in adults is 1,000 mg per day divided in two doses.

In 2007, terbinafine became the second drug approved by the US Food and Drug Administration to treat tinea capitis in children [9]. Safety, efficacy, and cost data favor terbinafine for treatment of *T. tonsurans* infections [1]. General guidelines for tinea capitis are treatment for 4–6 weeks, with dosage determined by body weight: 62.5 mg/day in patients weighing from 10 to 20 kg, 125 mg/day from 20 to 40 kg, and 250 mg/day over 40 kg [1]. There is also some evidence that itraconazole and fluconazole are effective and safe for tinea capitis caused by *M. canis* and *Trichophyton* species [11].

Prednisone (1–2 mg/kg/day) for 1 or 2 weeks in addition to griseofulvin and adjuvant topical therapy can be used in patients with kerion [9].

Tinea Unguium; Onychomycosis

The two main systemic drugs indicated for the treatment of onychomycosis are terbinafine and itraconazole. Terbinafine, given as 250 mg daily for 6 weeks for fingernails and for 12–16 weeks for toenails, should be considered as first-line treatment because of fewer drug interactions and because it is superior both in vivo and in vitro for dermatophyte onychomycosis. Regular monitoring of liver function tests after 4–6 weeks of oral treatment is recommended [7].

Itraconazole is less active than terbinafine against dermatophytes. It is given as 200 mg/day (12 weeks for toenails, 6 weeks for fingernails) or as a monthly pulsed treatment of 400 mg/day for 1 week of each month (two pulses for fingernails, three pulses for toenails) [7].

Fluconazole seems to be less effective than either itraconazole or terbinafine, although it remains a potential third-line treatment. Fluconazole is inexpensive, has good compliance rates, has few drug interactions, and also is highly effective against both dermatophytes and *Candida* species [7].

Griseofulvin is authorized in children but is no longer suggested as first-line therapy because of long treatment duration and poor efficacy. If there are no contraindications, terbinafine, itraconazole, or fluconazole with dose adjustment according to weight and age can be used to treat onychomycosis [7] (Table 11.2).

Pityriasis Versicolor

Pityriasis versicolor (PV), or tinea versicolor, is a common superficial fungal infection of the skin caused by *Malassezia* yeasts, that presents as flaky round or oval macular elements, usually located in the upper aspects of the trunk, neck, and arms (Fig. 11.12) [1, 12, 13].

Epidemiology

The prevalence of PV varies by geography and age, The disease is thus more frequent among people living in a hot and humid climate in tropical parts of the world. It can occur at any age but is more common in adolescents and young adults, and is equally distributed between men and women [1, 12, 13].

The etiology is multifactorial and genetic susceptibility seems to play a role. Other recognized risk factors are malnutrition, oral contraceptives,

Fig. 11.12 Pityriasis versicolor lesions on the upper trunk

immune suppression, hyperhidrosis, and use of oil or greasy skincare products as well as topical corticosteroids [13].

Etiopathogenesis

PV is caused by various yeasts and dimorphic lipophilic fungi of the genus *Malassezia*, previously known as *Pityrosporum* sp. The most important species are *Malassezia globosa*, *Malassezia sympodialis*, and *M. furfur* [12].

The organism is part of normal skin microflora. It lives within the stratum corneum and hair follicles in areas of high sebaceous activity where it feeds off free fatty acids and triglycerides [1].

Malassezia pathogenicity mechanisms and their relation to disease and clinical manifestations remain to be elucidated. However, it is known that the yeasts become pathogenic when the immune balance is disturbed.

When the predisposing factors are present, the yeast converts from the budding form to its mycelial form, which leads to the formation of tinea versicolor [1].

Dicarboxylic acids produced by the fungus, i.e., azelaic acid, can have a cytotoxic effect on melanocytes and prevent dopa tyrosinase reaction, causing a reduction in number, size, and aggregation of melanosomes in melanocytes and surrounding keratinocytes. This is the cause of hypopigmented lesions, which are more apparent as unaffected skin tans. Inflammatory skin response can be seen as red or hyperpigmented macules, another presentation of the disease [1].

Clinical Presentation

PV presents as multiple, circular, or oval macules which may be hypochromic or hyperchromic (versicolor), covered with fine scales. The spectrum of colors of the lesions includes: red to fawn-colored macules, patches, or follicular papules; hypopigmented lesions, which generally occurs in dark-skinned individuals; and tan to dark-brown macules and patches. Mixed cases can be found, especially in the axillae, groin, and submammary folds [1, 12].

Lesions initially are small but rapidly enlarge, forming large, irregular patches. The most affected area is the upper trunk, but it can spread to the upper arms, neck, and abdomen. Facial lesions, especially in the forehead, are more common in children. The lesions are generally asymptomatic but can be pruritic [1, 12]. Box 11.3 shows the Malassezioses.

Box 11.3 Malassezioses

Malassezioses are a group of diseases related to *Malassezia* spp. infection with increasing importance in the medical scenario.

- Seborrheic dermatitis is a benign, chronic, multifactorial erythematosquamous dermatosis. It is related to hormonal, environmental, psychological, immunologic, and infectious (*Malassezia* spp.) factors. Clinically its most common manifestation is scalp flaking ("dandruff"), but it can also affect the nasolabial folds, eyebrows, glabella, the retroauricular region, and the central area of the chest. It usually asymptomatic, but mild pruritus can be reported. *Malassezia* spp. are found in most cases, especially *Malassezia restricta*, *M. globosa*, and *M. furfur*. The use of topical and systemic antifungals decreases the signs and symptoms [12, 14].

- Folliculitis due to *Malassezia* is a superficial infection of the pilosebaceous unit. It is an opportunistic infection related to *M. globosa*, *M. furfur*, and *Malassezia pachydermatis* that affects young adults. Clinically it presents as pustules localized around the follicles without comedones in the trunk, the shoulders, and exceptionally, the face, and must be distinguished from acne. Histologically, there is follicular dilatation and inflammatory infiltrate with yeast colonization [12].

- Onychomycosis due to the *Malassezia* spp. is a rare and controversial dermatomycosis. *M. globosa* and *M. furfur* infection have been reported, and some authors consider it a true infection, whereas others believe that the yeasts

found are only carriers. Clinically it is a distal subungual onychomycosis that is similar to dermatophytic infection [12].

- *Malassezia* yeasts have also been associated with many diseases, including atopic dermatitis, psoriasis, blepharoconjunctivitis, dacryocystitis, confluent and reticulated papillomatosis (Gougerot–Carteaud), systemic infections, endocarditis, and bloodstream infection [12, 14].

Complementary Examinations

Skin scraping should be examined by light microscopy: *Malassezia* cells reproducing by unipolar budding and hyphae in a meatballs and spaghetti pattern are typical when *Malassezia* is more than just a colonizer [13].

Wood's light (filtered UV light) may be used as a diagnostic tool. Under Wood's light, PV lesions present a typical yellow-green fluorescence, which can help to visualize the extent of the affected skin areas. However, a negative Wood's light examination does not exclude PV as not all *Malassezia* species fluoresce [13].

Diagnosis

Box 11.4 Diagnosis of Pityriasis Versicolor
Clinical findings, "Zireli sign", fungal microscopy. Wood's light can help to visualize the extent of the affected skin areas.

Differential Diagnosis

Pityriasis alba, hypochromic solar dermatitis, pityriasis rosea, vitiligo, seborrheic dermatitis, secondary syphilis, and postlesional melanodermas [1, 12].

Therapeutic Approach

Malassezia yeasts could be susceptible to a wide variety of antifungal agents. However, relapse rates remain high [14, 15].

Topical agents are based on an antifungal and/or a keratinolytic effect and will usually be sufficient, whereas systemic treatment alone or in combination with topical treatment should be reserved for severe cases or infections refractory to topical treatment [13].

Ketoconazole is the most extensively studied antifungal therapy. Ketoconazole 2% shampoo can be used once daily for 5 days (level of evidence A I) and ketoconazole 2% cream one to two times daily for 2 weeks (level of evidence B I). Based on limited data, other effective options are zinc pyrithione shampoo, selenium disulfide shampoo, and propylene glycol in aqueous solution [13] (Table 11.3).

The three most recommended oral antifungals are ketoconazole, itraconazole, and fluconazole. Oral ketoconazole (once the first line of systemic treatment) is no longer approved for superficial fungal infections in Canada, the United States,

Table 11.3 Treatment of pityriasis versicolor

Topical treatment	Systemic treatment
Antifungal agents	
Ketoconazole 2% shampoo 1× daily for 5 days	Fluconazole 300 mg weekly for 2–4 weeks
Ketoconazole 2% cream one to two times daily for 2 weeks	Fluconazole single dose of 400 mg
Ciclopirox olamine 1.5%	Itraconazole 200 mg daily for 1 week or 100 mg daily for 2 weeks
Shampoo two times weekly for 2 weeks	Itraconazole single dose of 400 mg
Miconazole cream twice daily	Pramiconazole 200 mg/day over 2–3 days
Clotrimazole cream twice daily for 2 weeks	
Terbinafine cream or gel twice daily for 1 week	
Miscellaneous products	
Selenium sulfide 2.5% shampoo once daily for 3 days followed by the same procedure one week later	
Zinc pyrithione 1% shampoo two to three times weekly	
Propylene glycol 50% in water twice daily for 2 weeks	

and Europe, owing to the risk of its associated hepatotoxic side effects. A systematic review and meta-analysis of clinical studies indicated that itraconazole and fluconazole seemed equally effective for the treatment of PV. Hald et al. has recommended fluconazole as a preferred agent, based on its lower potential for drug interaction and side effects (Table 11.3). Pramiconazole, a new oral agent introduced since 2005, has also been described as effective, but may be associated with many adverse side effects [12, 13, 15].

Few studies have focused on maintenance therapy. Itraconazole 200 mg twice daily 1 day per month for 6 months and topical treatment with selenium disulfide (2 years of treatment every third month) have shown satisfactory results. Prophylactic daily treatment with ketoconazole 2% shampoo for up to 3 days in the beginning of the summer season has also been recommended [13]. Finally, it should be noted that it may take several months to regain a normal skin appearance despite successful treatment, especially for hypopigmented lesions.

The primary treatment objective is the mycologic cure rate. In addition, patients should be strongly advised that because relapses are common they should avoid predisposing factors [12, 13].

White Piedra

White piedra is a chronic, asymptomatic, superficial mycosis of the hair shafts, causing concretions or soft, whitish nodules [12].

Epidemiology

Most cases occur in tropical and temperate regions, and are observed in young men and women and in children.

The most important predisposing factors are humidity, hyperhidrosis, and poor personal hygiene. Long hair, excessive use of hair oil, and cultural practices such as tying of a veil, especially when done on wet hair, have also been reported [12, 16].

The most affected hairs are those of the scalp, but it can also occur in the pubis, axillae and, more rarely, beard, moustache, eyebrows, and eyelashes [12].

Etiopathogenesis

It is caused by yeast-like organisms of the genus *Trichosporon*, mainly *Trichosporon cutaneum*, *Trichosporon ovoide* and *Trichosporon inkin* [12].

Clinical Presentation

White piedra presents as asymptomatic, small, soft concretions that initially can only be palpated. A 1- to 3-mm, visible, whitish concretion with well-defined borders then develops. A single shaft may have several concretions. The nodules can be white, tan, or even reddish-green, and do not fluoresce on Wood's light examination. On microscopy, they are arranged circumferentially around the hair shaft and can easily be detached. The affected hairs can become brittle and break at points of cuticular invasion and swelling [12, 17].

Complementary Examinations

Microscopic examination reveals masses of septate hyphae with arthrospores, blastoconidia, and arthroconidia. Cultural techniques are not usually required to diagnose piedra.

Diagnosis

> **Box 11.5 Diagnosis of White Piedra**
> Whitish, small, soft concretions on the hair shafts and direct microscopic examination with masses of septate hyphae with arthrospores, blastoconidia, and arthroconidia.

Differential Diagnosis

Pediculosis (nits), trichorrexis nodosa, monilethrix, and hair caps [12].

Therapeutic Approach

Piedra is best treated by shaving or clipping the hair and, subsequently, topical antifungal azole lotions/shampoos must be used. If the disease is disseminated, the whole affected area should be shaved. The use of 2% ketoconazole shampoo is extremely practical and effective, and oral antifungals such as terbinafine and itraconazole have been used successfully in resistant cases [12, 16].

Black Piedra

Black piedra is a superficial mycosis that usually affects the hair shafts of the scalp in the form of black, hard concretions or mycotic nodules [12].

Epidemiology

Most cases occur in tropical regions with high rainfall in young men and women and in children. Humidity and poor personal hygiene are the most important predisposing factors [12].

Etiopathology

It is caused by *Piedraia hortae*, a pigmented fungus [12].

Clinical Presentation

Black piedra presents as asymptomatic, brown or black, limited, spindle-shaped, hard concretions, most frequently located on the hairs of the scalp, consisting of dark-colored thick hyphae. The stone-like nodules are tightly adherent to the hair shaft [12, 17].

Complementary Examinations

Potassium hydroxide preparation of a crushed nodule from an infected hair: when crushed, the dark-colored, branching, thick (4–8 μm) septate pigmented hyphae can be seen, usually with large oval asci, and ascospores. Cultural techniques are not usually required to diagnose piedra except for confirming the diagnosis.

Diagnosis

> **Box 11.6 Diagnosis of Black Piedra**
> Asymptomatic, brown or black, limited, spindle-shaped hard concretions, most frequently located on the hair shaft. Microscopy: dark-colored, branching, thick, septate pigmented hyphae, large oval asci, and ascospores.

Differential Diagnosis

Pediculosis (nits), trichorrexis nodosa, monilethrix, and hair caps [12].

Therapeutic Approach

Treatment of black piedra includes clipping infected hairs and applying topical antifungal or keratolytic [12].

Tinea Nigra

Tinea nigra is a rare superficial dermatomycosis caused by a pigmented yeast *Hortae werneckii* [12].

Epidemiology

Most cases occur in the coastal areas of tropical and subtropical regions. It occurs predominantly in children and young men and women [12].

Etiopathogenesis

Tinea nigra is caused by *H. werneckii*, a dematiaceous fungus that grows in an aqueous medium and adapts easily to hypersalinity. Hyperhidrosis of the hands and feet is the most important predisposing factor. In fact, this is considered to be indispensable for the development of the fungal infection [12].

Clinical Presentation

This dermatomycosis is an asymptomatic, chronic condition that presents as a gradually enlarging, hyperpigmented, irregular, circumscribed

patches or spots, ranging in color from tan to dark brown or black, covered with fine scales; that is, it can be confused with melanocytic lesions. It usually affects the palms, generally unilaterally, but can also manifest on the dorsal aspects of the hands, soles, arms, legs, neck, and trunk [12].

Complementary Examinations
Direct microscopic examination, which shows multiple dark, septate hyphae and yeast cells, and culture on Sabouraud agar medium confirm the diagnosis. Dermoscopy is useful to differentiate tinea nigra from nevi and melanoma. The characteristic dermatoscopic pattern of tinea nigra is an almost reticulated patch formed by pigmented spicules that do not respect the dermatoglyphic lines. Biopsy specimens are not necessary for diagnosis [12, 18].

Diagnosis

> **Box 11.7 Diagnosis of Tinea Nigra**
> Hyperpigmented, irregular, circumscribed patches or spots, ranging in color from tan to dark brown or black, covered with fine scales. Direct microscopy: multiple dark, septate hyphae and yeast cells. Culture on Sabouraud agar medium confirms the diagnosis. Dermoscopy is useful to differentiate tinea nigra from nevi and melanoma.

Differential Diagnosis
The differential diagnosis is made with melanocytic lesions and exogenous pigmentation.

Therapeutic Approach
Treatment is based on the control of hyperhidrosis. Keratolytics, such as 3% salicylic acid, Whitfield ointment, and topical antifungals, such as bifonazole, clotrimazole, ketoconazole, terbinafine, and ciclopirox olamine may be used. Oral itraconazole (100 mg/day) is also effective [12].

Candidiasis

Candidiasis is a fungal infection caused by any of the species from the genera *Candida*, which includes about 150 different species of yeast, amongst which *Candida albicans* is the most common causative species, accounting for up to 80% of cases [19, 20].

Epidemiology
Candida, a yeast-like fungus, is a common organism present in the reproductive and gastrointestinal mucosa. *Candida* species are commensal and colonize the skin and mucosal surfaces of healthy humans, and may cause infections that range from non-life-threatening mucocutaneous illnesses to invasive conditions, which may involve severe infection to destruction of vital organs infection. Critically ill or otherwise immunocompromised patients are more prone to develop both superficial and life-threatening *Candida* infections. *Candida* infections also constitute the most common fungal infections in AIDS patients, predominantly causing oropharyngeal candidiasis. Candidiasis is also more frequent in prematurity, exposure to broad-spectrum antibiotics, diabetics, and older patients [19, 21].

Etiopathogenesis
Of the possible 150 different species of the genus *Candida*, few have been known to cause human infections; with *C. albicans* being the most pathogenic. The few other species found to be pathogenic to humans include *Candida krusei*, *Candida glabrata*, *Candida tropicalis*, *Candida parapsilosis*, *Candida lusitaniae*, *Candida dubliniensis*, *Candida kefyr*, *Candida guilliermondii*, and *Candida stellatoidea* [19].

The main transmission mechanism is through endogenous candidemia, whereby *Candida* species that constitute the microbiota of various anatomic sites under conditions of host weakness behave as opportunistic pathogens. Another mechanism for transmission is exogenous, occurring mainly through the hands of health

professionals who care for patients or healthcare materials such as contaminated catheters and intravenous solution [21].

Clinical Presentation

Infections caused by *Candida* are broad-spectrum, ranging from superficially oral thrush or vaginitis to systemic infection, commonly referred as candidemia, which are mostly life threatening. Depending on the site, signs and symptoms of infection can vary from septicemia (systemic) to itching, burning, pain and a white curd-like substance at the site of the infection/lesion (mucosal). Mucosal lesions can be of the pseudomembranous (white patches) or erythematous (reddened area) type [22].

Oral Candidiasis

Oral candidiasis (candidosis) presents in a variety of clinical guises and may affect one or more mucosal surfaces. Pseudomembranous candidiasis, commonly called thrush, presents clinically as confluent whitish-yellow creamy plaques on the surface of the oral mucosa and tongue that can be readily removed to reveal an area of inflammation in the underlying membrane. This form is most common in immunocompromised individuals, particularly with HIV infections and AIDS. In fact, more than 90% of HIV-positive persons will acquire at least one episode of oropharyngeal candidiasis during progression to AIDS, while esophageal candidiasis is considered an AIDS-defining illness. Erythematous, hyperplastic, angular cheilitis and glossitis are other clinical presentations of candidiasis [22].

Vulvovaginal Candidiasis and Candidal Balanitis

About 75% of all women experience at least one episode of vulvovaginal candidiasis (VVC) in their lifetime. The clinical symptoms of VVC are nonspecific and can be associated with a variety of other vaginal diseases, such as bacterial vaginosis, trichomoniasis, and gonorrhea. The most common clinical manifestations are vulvar pruritus and burning accompanied by vaginal soreness and irritation, leading to dyspareunia and dysuria.

The discharge is usually white, thick, and odorless. Vulvar and vaginal erythema, edema and fissures are also commonly found [23].

Proposed host-related risk factors include pregnancy, hormone replacement, uncontrolled diabetes mellitus, immunosuppression, antibiotic and glucocorticoid use, and genetic predispositions [23].

Candidal balanitis is particularly seen after intercourse, following antibiotic therapy, and in diabetes, for which it may be the presenting symptom. The typical case is mild, with a dry, glazed, erythematous surface to the glans penis and on the undersurface of the prepuce. In addition, very small, irregular, eroded papules and a dispersed vesicular eruption may be present, often with plaques of white, cheese-like matter. Itchy and scaly erythematous lesions may also be present on the penile and scrotal skin [24].

Intertriginous Candida Infection

Cutaneous candidiasis predominantly affects intertriginous areas, i.e., groin, abdominal skin folds, inframammary skin, but also interdigital spaces (interdigital candidiasis). It is typically characterized by erythematous (bright red to purple-red), erosive, dry, scaly lesions, but sometimes also oozing as well as macerated especially in intertriginous candidiasis lesions with prominent borders. Pustules are also typical of cutaneous candidiasis. The risk of infection is increased by humidity, poor hygiene, obesity, pregnancy, and diabetes. For more informations, to see chapter 41 and figure 41.27.

Candidal Onychomycosis

Candidal paronychia is the most common type of candidal onychomycosis, and its incidence is higher among individuals whose nails are constantly exposed to moisture. It is characterized by *Candida* invasion of the nail plate after having affected the soft tissue around the nail. Surrounding soft tissues demonstrate inflammation and will be red and edematous. If the nail matrix is infected, transverse depressions, known as "Beau's lines," can appear. Progressive infec-

tion results in a rough, irregular, convex, and finally dystrophic nail [25].

Chronic Mucocutaneous Candidiasis

Chronic mucocutaneous candidiasis is a syndrome resulting from such fungal proliferation in which the skin and nails as well as oral, esophageal, and genital mucosa become chronically infected. It is not a single disease entity but represents the final common clinical pathway resulting when one or more of the complex defense mechanisms restricting *C. albicans* proliferation is defective. The major clinical symptoms of patients with this disorder are the disfiguring lesions of the skin and nails, the dysphagia resulting from ulcerative and inflammatory lesions of the buccal cavity and esophagus, and the symptoms that may be secondary to associated disorders such as endocrinopathies.

Complementary Examinations

Direct microscopic examination is a cost-effective, rapid method for the diagnosis of candidiasis and demonstrates rounded yeast cells with single or multiple budding, pseudohyphae, and/or blastoconidia. *Candida* species readily grow on Sabouraud dextrose agar (SDA) medium, the most commonly used medium for the isolation of the yeast. Aerobic culturing on SDA at approximately 37°C for 24–48 h results in the formation of convex cream colonies. Differentiation between strains of *Candida* may be required in refractory lesions or in immunocompromised individuals. While some media may differentiate between several species through macroscopic colony characteristics, complete differentiation between different strains of *Candida* requires immunohistochemical techniques. In addition, antifungal sensitivity testing may be useful in resistant

lesions to determine susceptibility and to direct definitive antifungal therapy [26].

Diagnosis

Therapeutic Approach

Oral Candidiasis

Nystatin 100,000–400,000 IU/ml and 4–6 ml four to five times a day for 14 days should be administered. Successful treatment depends on the time of contact with the oral mucosa for at least 2 min. Therapeutic options are oral fluconazole 200 mg in the first day and 100 mg/day for 7–14 days, itraconazole, and voriconazole; the other options are considered only in patients unresponsive or intolerant to fluconazole [27].

Vaginal Candidiasis

There is evidence that topically applied azole therapy over a period of 3–7 days is more effective than nystatin. The options for topical therapy are clotrimazole vaginal tablets, 500 mg/day; miconazole 2% cream, 5 g/day; miconazole, 100 mg, 200 mg, or 1,200 mg (single dose), vaginal suppositories; nystatin, 100,000 IU vaginal tablets (10–14 days). Oral triazoles are a safe and efficient alternative to topical therapy: fluconazole 150 mg once a day, single dose, and itraconazole 200 mg once a day for 3 days or 400 mg single dose are commonly used [27].

Intertriginous Candida Infection

Nystatin, clotrimazole, ketoconazole, or oxiconazole may be used for *Candida* infections. Topical treatments are applied twice daily until the rash resolves. Fluconazole, 100–200 mg daily for 7 days, is used for resistant fungal infections.

Candidal Onychomycosis

Topical antifungal has been used for the treatment of mild to moderate candidal onychomycosis. For instance, amorolfine, which exhibits fungicidal activity against *C. albicans*, is available as a 5% lacquer and is applied to the affected nail once or twice weekly for 6–12 months.

Box 11.8 Diagnosis of Candidiasis

Clinical presentation and direct microscopic examination (rounded yeast cells with single or multiple budding, pseudohyphae, and/or blastoconidia). Culture: SDA.

Itraconazole (200 mg per day or as pulse therapy 400 mg per day for 1 week each month) should be considered the first-line treatment for *Candida* onychomycosis, since it is more cost-effective and more likely to be associated with greater compliance. Fluconazole can be used as an alternative if there are contraindications to using itraconazole [28].

Systemic Candidiasis

For the treatment of invasive candidiasis, amphotericin B and its formulations, fluconazole, voriconazole, and echinocandins are the available drugs. The recommended doses for non-neutropenic patients are: caspofungin, loading dose 70 mg, then 50 mg daily; fluconazole, 800 mg (12 mg/kg) loading dose, then 400 mg (6 mg/kg) daily; lipid formulation amphotericin B, 3–5 mg/kg daily; voriconazole 400 mg (6 mg/kg) twice daily for two doses, then 200 mg (3 mg/kg) twice daily [29].

Subcutaneous and Systemic Mycoses

Subcutaneous mycoses include a heterogeneous group of infections that often result from direct penetration of the fungus into the skin through trauma. Systemic mycosis is characterized by infections caused by truly pathogenic fungi and also those produced by fungi with small intrinsic pathogenicity, enhanced by immunocompromised hosts. In the majority of cases, the respiratory tract may be the first site of entry; fungi then usually spread hematogenously to other organs.

Sporotrichosis

Sporotrichosis is the most reported subcutaneous mycosis worldwide [30] and is characterized by the subacute and chronic evolution of cutaneous or subcutaneous nodular lesions.

Epidemiology

This fungal dermatosis is caused by the thermally dimorphic fungus *Sporothrix schenckii*, which is found throughout the world as a saprobic organism, particularly in subtropical and tropical areas [31].

It develops mainly through penetration of the fungus into the dermis after wounds or abrasion of the skin produced by infected materials or contact with cattle and feed; or inhalation of spores through the respiratory tract [31].

No age, gender, or race is spared of this infection as its occurrence depends upon the fungus in the environment and the portal of entry. The preponderance of males in most reported cases is attributed more to their higher exposure risk than gender susceptibility [30].

Animals are not a significant source of infection in humans. However, cats have been found to be important vehicle in dissemination of *S. schenckii* in a long-lasting epidemic of sporotrichosis in Brazil, diagnosed by isolation of *S. schenckii* from different types of samples, both from humans and felines, indicating the emergence of another risk factor in the epidemiologic setting [30].

Etiopathogenesis

S. schenckii complex comprises more than six species of closely related dimorphic fungi, already identified: *S. schenckii*, *Sporothrix brasiliensis*, *Sporothrix globosa*, *Sporothrix mexicana*, *Sporothrix albicans*, and *Sporothrix luriei* (rare) [32].

Clinical Presentation

Sporotrichosis is classified as a primary cutaneous disease, with three different clinical presentations: lymphocutaneous, fixed, and disseminated. Extracutaneous disease includes osteoarticular, which is the most common, pulmonary, mucosal, or systemic [32].

Lymphocutaneous

It is the most common variety and accounts for 70–80% of the cases of cutaneous sporotrichosis. The extremities are affected most frequently. The sporotrichotic chancre, a noduloulcerative lesion, at inoculation site and a string of similar nodules along the proximal lymphatics, with or without transient satellite adenopathy, characterizes this
Fig. 11.13 Sporotrichosis: lymphocutaneous form

Fig. 11.14 Sporotrichosis: fixed cutaneous form

form (Fig. 11.13). These secondary lesions that appear along the lymphatics have varied morphology of erythematous papules, plaques, or nodules, having smooth or warty surface, and may soften and ulcerate, discharging seropurulent material. They are mostly asymptomatic and have an indolent clinical course similar to that of the primary lesions [30].

Fixed Cutaneous

In some patients there is no lymphatic dissemination during the course of the disease, with the lesion remaining confined to the site of initial inoculation. This is known as fixed cutaneous sporotrichosis. This form occurs less commonly, and facial involvement occurs more frequently than in the lymphocutaneous variety. The lesions may be papular, plaque-like, nodular, verrucous, or ulcerated, and can also occur in the neck, trunk, or legs (Fig. 11.14).

Often they become chronic because there is no tendency for spontaneous resolution [30, 33].

In children, the fixed cutaneous form is more common than in adults, accounting for more than 30% of cases [32].

Disseminated

Disseminated or multifocal *S. schenckii* infection is rare. When it does occur it is usually in the context of cellular immunodeficiency. The clinical picture is multiple subcutaneous nodules, gummatous lesions, or abscesses, affecting at least two anatomic sites, which develop through hematogenous dissemination or autoinoculation. The disease can affect the skin, lungs, meninges, and osteoarticular system [31, 33].

Extracutaneous

The extracutaneous form is even rarer and is difficult to diagnose because of the absence of skin lesions. It is caused by inhalation of spores or by hematogenic dissemination from a deep inoculation site and usually occurs in the setting of immunosuppression such as alcoholism, diabetes, and AIDS. Although sinusitis, pulmonary, ocular, or central nervous system (CNS) disease, meningitis, and endophthalmitis are the usual manifestations, osteoarticular sporotrichosis remains the most common systemic manifestation, found in up to 80% of cases of extracutaneous disease [30, 33].

Complementary Examinations
Culture

Pus, synovial fluid, sputum, blood, or tissue fragment is suitable for culture. Incubation is performed at 25°C using SDA or potato dextrose agar. Colonies usually appear within 3–5 days and are characterized by pigmented, membranous, radiated growth, and the characteristic microscopic features of sympodial conidia resembling daisy flowers (Fig. 11.15) [32, 33].

Histologic Examination

Histopathologic findings are generally nonspecific because the fungus, most of the time, cannot be visualized in the granulomas (even in silver-stained histologic sections), especially when suppuration is missing. This fungal derma-
Fig. 11.15 Yeast form of *Sporotrix schenkii* (Courtesy of Prof. Sydney Hartz, Alves/UFSM)

tosis produces granulomatous inflammation associated with epithelial hyperplasia and a histiocytic plasma cell infiltrate. Asteroid corpuscles can be seen and constitute the fungal element, surrounded by an eosinophilic material resulting from protein deposition that is responsible for the antigen and antibody reaction [33].

Sporotrichin Reaction
This is a skin test antigen with *Sporothrix* obtained by culture and a positive reaction suggests the diagnosis of sporotrichosis. In cases of disseminated disease in which there is anergy, the cutaneous sporotrichin test is not useful [33].

Serologic Tests
Serologic studies to detect antibody titers can also be done, but low sensitivity and cross-reactions must be considered [32].

Diagnosis

> **Box 11.9 Diagnosis of Sporotrichosis**
> Correlation of clinical, epidemiological, and laboratory data. Fungal culture provides a definitive diagnosis of this mycosis.

Differential Diagnosis
Lymphocutaneous form: cat scratch disease (bartonellosis), lymphangitis, bacterial infec-

tion, leishmaniasis, tularemia, nocardiosis, typical mycobacterial infection. *Fixed cutaneous form:* syphilis, leishmaniasis, paracoccidioidomycosis, chromoblastomycosis, cutaneous tuberculosis, leprosy, squamous cell carcinoma.

Therapeutic Approach
Potassium Iodide
Potassium iodide is still considered first-line treatment in many third-world countries because of its low cost, efficacy, and safety profile. Its mechanism of action remains unknown and it is used in cutaneous forms, especially for fixed cases. The dosage is 3–6 g daily for 3–6 months, increasing from 5 to 40 drops three times a day or the maximally tolerated dose. Treatment should be continued until at least 4 weeks after apparent clinical cure. The mechanism of action is unknown [32, 33].

Side effects include gastric intolerance, edema, rash, and erythema nodosum. Thyroid suppression or thyrotoxicosis must be avoided, detected, and treated [32].

Itraconazole
The most effective triazole by far is itraconazole, for both lymphocutaneous disease (responses 100% at 6 months' treatment) and osteoarticular disease (about 85–100% response in several series) [35].

It is administered at a dose of 100–200 mg/day for 3–6 months. For children, the recommended dose is 5 mg/kg/day [33].

Amphotericin B
For patients with the most acutely life-threatening disseminated disease, and those few with meningitis, amphotericin B has been recommended. The recommended dose is 0.5–1 mg/kg/day [33, 34].

Fluconazole
Fluconazole is less effective than itraconazole and is given to patients who do not tolerate or have drug interactions with itraconazole. The recommended dose is 400 mg/day for 6 months [35, 36].

Terbinafine

Terbinafine has high activity against *S. schenckii* in vitro, but is reserved for cutaneous disease only at a daily dosage of 250–500 mg for 3 or 4 months [32].

Thermotherapy

Thermotherapy may be given as local heat or cryotherapy. Heat (42°C for 30 min twice a day) can also be used in combination with antimycotics or alone in cases where they are contraindicated, such as pregnancy or when poorly tolerated [32].

Chromoblastomycosis

Chromoblastomycosis (CBM) is a chronic fungal infection of the skin and subcutaneous tissue. The infection usually results from a traumatic injury and inoculation of microorganism from a specific group of dematiaceous fungi. In the tissues, fungi produce characteristic dark-colored, thick-walled, muriform cells, i.e., sclerotic cells (Medlar bodies).

Epidemiology

Originally described by Pedroso e Gomes in 1914 in the city of São Paulo (Brazil), CBM is distributed worldwide, being more prevalent in tropical and subtropical countries, mainly Brazil, Mexico, Cuba, and the Dominican Republic. In Brazil, Rio Grande do Sul, São Paulo, Rio de Janeiro, Minas Gerais, and states of the Amazonian region are endemic areas [37].

Fungi responsible for CBM are part of the microbiota, which decomposes organic matter in soil and water, and they also appear on the plants [38].

The disease is predominantly found in males from 30 to 50 years of age, especially rural workers, such as farmers and loggers. It mostly affects lower limbs, especially feet, which are most frequently exposed to contact with the infected material, e.g., soil, plants, or rotting wood [38].

Etiopathogenesis

The most frequently isolated organisms in CBM are *Fonsecaea pedrosoi*, *Phialophora verrucosa*, *Cladosporium carrioni*, and less frequently, *Rhinocladiella aquaspersa* [37].

The fungus penetrates the skin usually as a result of traumatic implantation. Especially in areas not protected by vestments, lesions develop on the site of the inoculation, locating themselves in the skin and, sometimes, in the subcutaneous tissue.

Clinical Presentation

A primary lesion is represented by an erythematous papule or a warty growth, which gradually enlarges from the site of infection, assuming various forms and sizes.

In advanced stages of the disease, dissemination may occur in the form of satellite lesions that arise from scratching autoinoculation and spread via the lymphatic system. Clinical changes progress slowly and frequently; the period from infection to diagnosis is 10 years [38].

CBM can present clinically in five different forms: nodular, tumoral, verrucous, plaque, and cicatricial (Fig. 11.16a, b). Severe secondary infection, lymphedema, elephantiasis and, more rarely, squamous cell carcinoma may occur secondarily [38].

Complementary Examinations

Potassium hydroxide-cleared specimen obtained from skin scrapings or histopathologically: presence of Medlar bodies (Fig. 11.17). Microbiological culture is essential to determine an etiologic agent. Culture is performed in Sabouraud agar and Sabouraud with antibiotics, where the fungi grow slowly and form black colonies [38, 39].

CBM is histopathologically characterized by pseudoepitheliomatous hyperplasia with histiocytes and neutrophils surrounding distinct copper-colored Medlar bodies (6–12 μm), which are fungal spores [40].

mycosis: sclerotic bodies
(Courtesy of Prof. Sydney
Hartz, Alves)
Differential Diagnosis

The most important differential diagnoses are
tuberculosis, sporotrichosis fixed form, leish-
maniasis, paracoccidioidomycosis, squamous
cell carcinoma, keratoacanthoma, sarcoidosis.
and lupus erythematosus.

Diagnosis

> **Box 11.10 Diagnosis of Chromoblastomycosis**
> Standard diagnosis is based on clinical pre-
> sentation and on the presence of Medlar
> bodies (skin scrapings or histopathologic
> sample). Culture determines the etiologic
> agent.

Therapeutic Approach

The therapeutic approach to CBM can be chal-
lenging, as no standard treatment has been estab-
lished and therapy can be complicated by low
cure rates and high relapse rates, especially in
chronic and extensive disease.

Treatment options can include thermotherapy,
cryotherapy, or surgical excision for small lesions
in combination with systemic antifungals.
Itraconazole (200–400 mg daily) for at least
6 months has been reported to have up to a 90%
cure rate with mild to moderate disease, but less
than 50% with severe disease. Combination oral
antifungal treatment with itraconazole and terbi-
nafine (250–1,000 g/day) has been recommended
[38, 40, 41]. Fluconazole 200–600 mg/day,
posaconazole 800 mg/day, and 5-flucytosine

50–150 mg/kg/day can also be prescribed. There are reports of progression of chromoblastomycosis to squamous cell carcinoma, which is rare and occurs after long-standing, inadequately treated lesions [38, 40, 41, 42].

Phaeohyphomycosis

The term phaeohyphomycosis (from the Greek *phaios*, meaning dark or darkish) was introduced by Ajello et al. in 1974 to designate infections by phaeoid or pigmented filamentous fungi that contain melanin in their walls [43–45].

The designation of tinea nigra, black piedra, and chromoblastomycosis (CBM) should not be replaced by phaeohyphomycosis. For example, in cases of chromoblastomycosis, muriform cells with septation along one or two planes in different levels are observed in the tissue (Medlar bodies), which do not fall into this classification [46].

Epidemiology

Subcutaneous manifestations of this mycosis are more frequent and develop among healthy individuals. On the other hand, systemic phaeohyphomycosis mainly occurs in immunocompromised patients. Phaeohyphomycosis may affect adult individuals of both genders and all races and is considered rare, especially in healthy individuals. In recent years the frequency of fungal infections has been increasing, as a consequence of interventions that affect the host's immune system [45].

The mycosis is more prevalent in humid tropical and subtropical climates, and the fungi are commonly found in soil [44].

Etiopathogenesis

It has been described 109 species and 60 genera. The most frequent etiologic agents described worldwide belong to *Alternaria* sp., *Exophiala* sp., and *Phialophora* sp. genera, among some 40 other organisms. *Phialophora verrucosa* has also been commonly described [44].

Virulence factors for the development of the disease include the production of melanin and carotenoids, which are deposited in the cell walls of melanized fungi and play an important role in pathogenicity [44, 46].

Clinical Presentation

Subcutaneous

The most common presentation is the mycotic cyst, which presents itself as a nodule or subcutaneous cyst, usually single and asymptomatic, after inoculation of the fungus by trauma on site. Most frequently, it affects the ends (Fig. 11.18a, b) [44].

Systemic

This is an uncommon presentation form and is more prevalent in immunocompromised patients, who may have very severe cases. It can reach
Fig. 11.18 (**a**) Purple painless nodule under the skin on the sole of the left foot, caused by *Alternaria* sp., in a neutropenic patient. (**b**) Ulcer on the anterior shin in the same patient (*Alternaria* sp.)

several organs, particularly the lungs and CNS. *Cladosporium bantianum* has been implicated most frequently [47].

Complementary Examinations

Pathologic examination of clinical specimens and careful gross and microscopic examination of cultures, which identifies the agent. Dematiaceous fungi can frequently be discerned in tissue specimens stained with conventional hematoxylin and eosin (HE); they appear as septate, brownish hyphae or yeast-like cells, reflecting their high melanin content. Masson–Fontana staining for melanin confirms their presence [44, 48].

Diagnosis

> **Box 11.11 Diagnosis of Phaeohyphomycosis**
> Clinical presentation, histopathologic examination, and microscopic examination of cultures, which identifies the agent.

Differential Diagnosis

Lipomas, fibromas, foreign body granuloma, epidermal cysts, and bacterial abscess.

Therapeutic Approach

Surgical excision is the standard treatment for localized lesions, which may be associated with an oral antifungal, such as itraconazole (200–400/day), for 6 months at least [44]. There are no standardized therapies for treatment of systemic phaeohyphomycosis. However, the triple combination of amphotericin B, 5-fluorocytosine, and itraconazole has been associated with improved survivalin this scenario. In addition, combination antifungal therapy (two or three drugs, at least one of which is an azole) is recommended for cerebral abscesses when surgery is not possible. In immunocompromised patients, clinical outcomes are generally poor regardless of treatment [46].

Hyalohyphomycosis

Unusual fungal agents that exist environmentally as saprophytes can often lead to opportunistic infections. Hyalohyphomycosis is a group of fungal infections caused by fungi characterized by colorless cell walls (hyaline septate hyphae) and can infect both immunocompetent as well as immunocompromised patients [49, 50].

Epidemiology

These fungi are ubiquitous in soil and decaying vegetable matter, and also can be found in polluted water [49–51]. They are capable of causing a wide variety of infections: disseminated infection occurs mainly in immunocompromised patients, the majority being stem cell and solid organ recipients. Diabetes and renal failure have also been described as risk factors [52].

Etiopathogenesis

The most frequent etiologic agents described worldwide belong to *Scedosporium* sp. (*Scedosporium apiospermum* and *Scedosporium prolificans*), *Fusarium* sp. (*Fusarium solani*, *Fusarium oxysporum*, and *Fusarium moniliforme*), *Paecilomyces* sp. (*Paecilomyces lilacinus* and *Paecilomyces variotii*), *Acremonium* sp., and *Trichoderma* sp., among some 40 other organisms [49–51].

Clinical Presentation

Localized

Cutaneous mycosis results from inoculation of the fungi into disrupted dermis and can occur in patients with little or no underlying immunodeficiency. The extremities and the corneas are often affected sites, and *Fusarium* is one of the more common causes of keratitis worldwide. These molds can also produce superficial cutaneous infections, such as onychomycosis, with or without paronychia, and toe-web intertrigo [50, 51].

Systemic

Systemic disease occurs mostly in immunocompromised patients and can cause invasive and disseminated infection with high mortality rates. It can affect many organs and systems, but the CNS and lungs are the most frequently involved sites [51]. Fusariosis has been described as a life-threatening and increasingly important mycosis in immunocompromised hosts, since
Fig. 11.19 (**a**, **b**) Ecthyma gangrenosum-like lesions caused by *Fusarium solani* in an immunocompromised patient
Fig. 11.20 (**a**, **b**) Biopsy specimen from ecthyma gangrenosum-like lesion caused by *Fusarium*: abscessed material and presence of nonpigmented, septate hyphae with acute-angle branching

these fungi are angiotropic and angioinvasive, leading to hemorrhagic infarction and low tissue perfusion, which results in tissue necrosis (Fig. 11.19a, b) [52]. Because the clinical presentation of fusariosis may be nonspecific, differentiating fusariosis from invasive aspergillosis can be challenging since these molds are clinically and histopathologically indistinguishable (Fig. 11.20a, b) [52, 53].

Complementary Examinations

In localized forms, diagnosis can be easily confirmed by direct microscopic examination. Otherwise, in systemic disease, confirmation of the diagnosis is obtained by culture to identify the fungus, owing to histopathologic similarities among the molds and the variable susceptibility of these fungi to antifungal agents [49, 51].

Diagnosis

> **Box 11.12 Diagnosis of Hyalohyphomycosis**
> Clinical presentation, direct microscopic examination, culture (more important for systemic disease).

Differential Diagnosis

Bacterial infection, atypical mycobacterial infections, aspergillosis and other fungal infections, amoebiasis, lipoma, panniculitis, lymphoma, pseudolymphoma, and sarcomas.

Therapeutic Approach

Hyalohyphomycosis treatment depends on the site of the infection. Surgical removal with or

without azole antifungal topical therapy is the choice for local disease. Systemic disease carries a poor prognosis despite aggressive antifungal therapy. Treatment options are limited by the lack of consistent and reliable activity of antifungal agents against these molds, and drugs such as the newer azole antifungals and amphotericin B lipid complex may be attempted. Results may vary, depending on the causal agent and its susceptibility to the drug [49, 51].

Lobomycosis (Jorge Lobo's Disease)

Lobomycosis is a chronic fungal infection also known as Jorge Lobo disease, Jorge Lobo mycosis, lacaziosis, keloidal blastomycosis, false leprosy, blastomycoid granulomatosis, and Amazon blastomycosis [54, 55].

Epidemiology

Lobomycosis is caused by the fungus *Lacazia loboi*, whose biogeographic complex is situated in rainforest areas. Most of the cases have been described in the tropical region of the Amazon region (Brazil and Colombia) where hot and humid climate favor the development of fungus. There are cases reported in other countries (e.g., Central America). Furthermore, imported cases have been reported in North America and Europe [54, 55].

This fungal infection is more common in males (male to female ratio 10:1), between 20 and 40 years old. Classically it affects people who live or work in forest or rural areas, such as gold and precious stone prospectors, rubber tappers, forest exploiters, and hunters. However, the ecologic niche of the fungus is expanding and cases have been described in dolphins [54, 55].

Etiopathogenesis

L. loboi is a saprophytic fungus in soil, vegetation, and water. Transmission occurs by inoculation from a bite or sting from an arthropod, snake, or stingray, or trauma from a cutting instrument. There are no reports of person-to-person transmission [56]. Once on the dermis, the pathogen stimulates the development of a granulomatous reaction, and after the proliferative phase there is a possibility of a dissemination phase through lymphatics [55].

Clinical Presentation

Lobomycosis is classified as localized or isolated disease, multifocal disease (restricted to an anatomic area), or disseminated disease (more than one anatomic segment). Lesions can be infiltrative, gummatous, ulcerative, verrucous, tumoral, sclerodermiform, macular, plaques, or nodular, the most common presentation. Often the lesion resembles a scar or a keloid. The surface color varies from normochromic to erythematous-brownish or red-wine, with or without telangiectasia. It is preferably located in the lower limbs, ears, and upper limbs. Lesions are generally asymptomatic, but pruritus and dysesthesia can occur [54, 55].

Complementary Examinations

L. loboi is found in great amounts upon direct examination and histologic preparations. Direct examination reveals an abundance of fungi with thick refringent and double-contour walls. Histopathologic examination is pathognomonic and reveals granuloma with a dense histiocytic infiltrate composed of multiple epithelioid and multinucleated giant cells. The parasites are inside the histiocytes in the dermis and among the scales and scaly crusts of the stratum corneum, observed as black spots on the skin that covers the ulcerated crusted lesions. Fungi can be better visualized with silver stains [54–56].

Diagnosis

> **Box 11.13 Diagnosis of Lobomycosis**
> Clinical aspects of lesions, epidemiologic date, provenance of endemic areas, direct mycologic and histopathologic examination.

Differential Diagnosis

The differential diagnosis must include keloid, leprosy, mucocutaneous leishmaniasis, other deep mycoses, lymphomas, and cutaneous metastases, among others [54].

Therapeutic Approach

Surgical excision, electrocauterization, and cryo-surgery are treatment options, particularly for minor lesions. At present there is no optimal drug treatment. Clofazimine 100–300 mg daily is indicated, although the treatment time is not well established. Itraconazole has been shown to be partially effective as an adjuvant to prevent recurrence of surgically removed lesions, while posaconazole has been reported to be effective in reducing the lesions after 75 weeks of treatment [55, 56].

Mycetoma

Mycetoma is an uncommon chronic infective disease of the skin and subcutaneous tissues characterized by the triad of tumefaction, draining sinuses, and presence of colonial grains in the exudates. Infection can be caused by true fungi in 40% of cases when it is known as eumycetoma, and by filamentous bacteria of the order Actinomycetes (actinomycetoma) in 60% of cases [57].

Epidemiology

Minor trauma allows the causative organism from the soil to enter the skin (e.g., cut on the hand, foot splinter, local trauma related to carrying soil-contaminated material). A neutrophilic response initially occurs, which may be followed by a granulomatous reaction. Spread occurs through skin facial planes and can involve the bone [57, 58].

Mycetoma typically presents in young men and rural workers or in individuals who walk barefoot in dry, dusty conditions. The most common site of occurrence is the foot (approximately 70% of cases) or lower leg, with infection of the dorsal aspect of the forefoot being typical. The hand is the next most common location; however, mycetoma lesions can occur anywhere on the body [57, 59].

It is endemic in the tropics and subtropics, and is named after the region of India (Madura: "Madura foot") where it was first described in 1842 [57, 59].

Etiopathogenesis

More than 30 species have been identified to cause mycetoma. Actinomycetoma is caused by a group of filamentous bacteria, among which *Nippostrongylus brasiliensis* and *Streptomyces madurae* are the most common. Eumycetoma is often due to *Allescheria boydii*, *Madurella griesia*, and *Madurella mycetomatis*: the most isolated agent worldwide [60].

Clinical Presentation

The clinical presentation of eumycetoma and actinomycetoma is similar.

The earliest sign of mycetoma is a painless subcutaneous swelling. Following the initial injury the disease typically follows a slow chronic course over many years with painless swelling and intermittent discharge of pus. After some years massive swelling of the area occurs, with induration, skin rupture, and sinus tract formation. As the infection spreads, old sinuses close and new ones open [58, 61].

The exudates are typically granular and pain may occur because of secondary bacterial infection or bone invasion.

Complementary Examinations
Direct Examination

Direct examination is essential for diagnosis, which reveals the presence of grains in the secretion obtained from injury. The size, shape, and color of the grains are important in the identification of the causative agent: tissue Gram stain to detect fine, Gram-positive, branching filaments within the actinomycetoma grain and Gomori methenamine silver or periodic acid-Schiff (PAS) stain to demonstrate the larger hyphae of eumycetoma. The presence of a black grain directs the diagnostic of eumycetoma, since actinomycetoma grains do not produce this color [58, 62].

Culture

The cultures can be performed using SDA, brain heart infusion (BHI) agar, and blood agar. Superficial samples of the draining sinuses are inadequate for culture because of frequent contamination with bacteria. Sample to culture should be obtained from a deep-wedge biopsy or via puncture and fine-needle aspiration [62].

Histopathology

Biopsy material stained with HE shows grains or colonies within abscess cavities with or without surrounding granulomatous reaction. There is no difference between the granulomas of actinomycetomas and eumycetomas. However, if the colonies are Gram-positive and show filamentous bacteria less than 1 μm thick, actinomycetes should be considered. If the colonies show PAS-positive hyphae 2–6 μm thick, eumycetes should be considered [57].

Image

Plain X-rays are used to assess for evidence of bone involvement. Computed tomography scanning may be more sensitive in the early stages. Magnetic resonance imaging scans can provide a better assessment of the degree of bone and soft tissue involvement, and may be useful in evaluating the differential diagnosis of the swelling [57, 58].

Diagnosis

> **Box 11.14 Diagnosis of Mycetoma**
> Clinical presentation, microscopy and culture of exudates, histopathologic examination, and culture from sample of skin biopsy.

Differential Diagnosis

Differential diagnosis includes chronic bacterial osteomyelitis, cutaneous tuberculosis, chromomycosis, botryomycosis, coccidioidomycosis, leishmaniasis, sarcomas, and other malignancies of bone and soft tissue [57, 58].

Therapeutic Approach

Because of the slow, relatively pain-free progression of the disease, mycetoma is often at an advanced stage when diagnosed. In addition, medical treatment of mycetoma depends on its fungal or bacterial etiology. Bone involvement complicates clinical management, often leaving surgical amputation as the only treatment option.

Eumycetoma

The combination of medical and surgical treatment is the usual management of this fungal infection.

Treatment is based on prolonged administration of imidazoles such as itraconazole, alone or combined with terbinafine. Posaconazole and voriconazole are available but are expensive; amphotericin B is rarely used [63].

Actinomycetoma

Actinomycetoma must be treated with trimethoprim-sulfamethoxazole alone or in combination with other available antibiotics. Amikacin has been proved effective in disseminated infections or cases resistant to previous therapy. Carbapenems are useful in some disseminated infections [63].

Mucormycosis and Entomophthoromycosis (or Entomophthoramycosis)

Epidemiology

Zygomycota is an artificial grouping that contains a heterogeneous group of fungi; for this reason, the name zygomycosis is out of date. The disease is very rare; however, it is importantly severe, with a mortality rate higher than 50%. Immunocompromised hosts, transplant recipients, and diabetic patients are more predisposed to this infection. Malnutrition, cytomegalovirus infection, trauma, and extended wounds/burns are also predisposing conditions. Patients with AIDS are not more predisposed than other people, because T lymphocytes are not key players in fighting against Zygomycota infection [64].

Orders Mucorales and Entomophthorales contain most of the human pathogenic Zygomycota. The true prevalence among the general population is not known, since published data are conflicting. In patients with hematologic diseases, Mucorales are one of the most common agents of systemic mycoses, as well as *Aspergillus*, *Candida*, and *Fusarium*. Since the higher incidence of hematologic malignancies in men, these fungi are also more prevalent among males [64].

Mucorales are ubiquitous in the environment and present worldwide in the soil, infecting plants and other fungi. Entomophthorales are fungi of tropical or subtropical distribution that represent more than 250 entomopathogenic, soil, and litter-associated species. While mucormycosis is a very aggressive invasive fungal infection, entomophthoromycosis is usually localized [64, 65].

Etiopathogenesis

The main route of infection for Mucorales and Entomophthorales is the respiratory system, from the inhalation of spores; direct inoculation and ingestion of fungal propagules have also been described. Innate immunity is imperative to fight this fungal infection, while the involvement of acquired immunity is not so pronounced [64].

Mucormycosis

Mucorales have great capacity for hematogenous dissemination, enabling rapid spread to organs and adjacent structures. This fact has contributed to the high mortality rate of this disease. *Rhizopus oryzae* and *Rhizopus rhizopodiformis* are the most prevalent species in human infections. Other genera implicated are *Lichtheimia*, *Mucor*, *Rhizomucor*, *Cunninghamella*, and *Apophysomyces* [65].

Entomophthoromycosis (or Entomophthoramycosis)

Entomophthorales produce chronic, usually subcutaneous infections without invasion of blood vessels [65]. *Basidiobolus* and *Conidiobolus* are the genera that cause human infection. These fungi have a predilection for areas with adipose tissue, which would justify the development of more restrictive disease than Mucorales. Immunocompetent individuals are more commonly affected, but the infection is not restricted to them [66].

Clinical Presentation

Mucormycosis

The clinical presentation of mucormycosis includes five forms: rhinocerebral, pulmonary, gastrointestinal, cutaneous, and disseminated. Rhinocerebral mucormycosis is the most common clinical presentation in both neutropenic hematologic and diabetic patients. It manifests by necrotic black lesions on the hard palate, necrotic turbinates, and septum perforation. Patients report headaches, altered mental status, fever, and ocular symptoms as lacrimation, irritation, and periorbital anesthesia. The symptoms of pulmonary and gastrointestinal mucormycosis are nonspecific. In immunocompetent and otherwise healthy patients, the most prevalent presentation is the cutaneous/subcutaneous form. Ulcer, cellulite, ecthyma gangrenosum-like lesion, and necrotic abscess may occur. Disseminated mucormycosis is characterized by the involvement of two or more noncontiguous organs [64, 67].

Entomophthoromycosis

There are two clinically distinct forms: basidiobolomycosis and conidiobolomycosis. Basidiobolomycosis manifests as an erythematous and warm, disc-shaped, rubbery, mobile masses that may be quite large. This subcutaneous form presents as painless firm erythematous plaques, with eventually significant non-pitting edema. It can evolve with skin ulceration and lymph node enlargement. The most common sites are shoulder, hips, and thighs. The evolution is slowly progressive and the systemic dissemination is extremely uncommon [66].

Conidiobolomycosis is usually restricted to the rhinofacial area and presents as a firm swelling of the upper lip or face. It can spread by contiguity through the nasal bridge and the upper and lower face, including the orbit. Intracranial extension is uncommon. The symptoms implicated are nasal drainage and obstruction. There may be paranasal sinus pain [66].

Complementary Examinations

Although direct examination has been limited, it is useful for the diagnostic suspicion. Cultures are often negative even though direct microscopy is positive. When culture is positive, it can help in the species identification and antifungal drug susceptibility testing.

Histopathologic analysis reveals broad, non-septate hyphae, which branch at a right angle. The presence of tissue infarction, necrosis, and thrombosis are characteristic [64, 66, 68].

Diagnosis

Box 11.15 Diagnosis of Mucormycosis and Entomophthoromycosis
Clinical suspicion, imaging studies, culture, and histopathology. The direct identification of the characteristic hyphae or retrieval of the organism in culture allows conclusive diagnosis. Tissue specimens, sputum, paranasal sinus secretions, and bronchoalveolar lavage fluid are appropriate samples for this analysis.

Differential Diagnosis

Mucormycosis
The clinical picture can be similar to other deep mycoses caused by *Aspergillus*, *Scedosporium*, and *Fusarium* [64].

Basidiobolomycosis
The main differential diagnoses are tuberculosis, localized elephantiasis, onchocerciasis, scleroderma, Burkitt's lymphoma, and Wegener granulomatosis [66].

Conidiobolomycosis
The differential diagnoses include cellulitis, rhinoscleroma, lymphoma, and sarcoma [66].

Therapeutic Approach
Early diagnosis and treatment are critical to avoid an unfavorable outcome. The combined treatment, including antifungal therapy and surgical debridement, is the outstanding option. The resistance to the routinely used antifungals, such as azoles (except posaconazole) and echinocandins, is high, which hampers proper treatment. Amphotericin B is the gold standard of therapy. Liposomal amphotericin B is most suitable because of fewer side effects. Optimal dosage is not known, ranging between 5 and 10 mg/kg intravenously per day. Posaconazole must be regarded as a second therapeutic choice, alone or in combination with amphotericin B, especially in severe cases of invasive mucormycosis. The recommended dose of posaconazole is 200 mg orally four times per day. The combination of liposomal amphotericin B and echinocandin is the most promising combined therapy because of bioavailability of parenteral formulations and synergy. The optimal duration of the therapy has not been established, and continuation of the treatment until resolution has been proposed [64, 65, 67].

Paracoccidiodomycosis

Paracoccidioidomycosis (PCM) is a human systemic mycosis whose etiologic agent is *Paracoccidioides brasiliensis*, a thermodimorphic fungus that promotes a chronic inflammatory granulomatous disease [69].

Epidemiology
This is the most important systemic mycosis in Latin America with Brazil, Venezuela, and Argentina being the countries with the greatest number of patients. The occurrence in Brazil, which accounts for 80% of the cases, is concentrated in its southeastern, southern, and midwestern regions. PCM is an endemic mycosis that is responsible by the highest cause of mortality and the eighth most important cause of mortality from chronic infectious diseases. An estimated 3,360 new cases per year reflect the fatality and mortality rates attributed to PCM in Brazil. Nonautochthonous cases have been described outside endemic areas in patients who have lived in or visited Latin America. The disease is not restricted to humans, also being described in different species of domestic and wild animals [70, 71].

PCM infection does not favor gender or ethnicity, whereas PCM disease affects mainly adult male rural workers in constant contact with vegetation and soil during the most productive period of their lives, which implies important economic

repercussions for patients and their dependents. Poor hygiene, malnutrition, smoking, and alcohol consumption are considered risk factors for the manifestation of the disease [69, 72].

The clinical forms of PCM were classified based on the relationship between clinical aspects and the natural history of the disease. Thus, the infection is related to the patient without signs and symptoms of the disease but with a positive paracoccidioidin skin test reaction. Patients with PCM disease are divided into two groups: the subacute variety, which accounts for 5% of cases, affects mostly young adults, and is associated with a high mortality rate; and the chronic progressive adult form, which accounts for the majority of cases and affects predominantly males between the ages of 30 and 60 years [71, 72].

Paracoccidioidomycosis is an AIDS-associated opportunistic infection. However, the incidence is lower than that expected by comparison with other endemic fungal infections [70, 71].

Etiopathogenesis

P. brasiliensis is a dimorphic fungus implicated as a cause of this disease. *Paracoccidioides lutzii*, whose endemic area involves the midwestern and northern regions of Brazil, is another species recently identified within the genus *Paracoccidioides*. However, the characteristics of the disease caused by *P. lutzii* are still poorly known [70, 71].

P. brasiliensis infection occurs through the respiratory tract: when infectious propagules (hyphal fragments or conidia) are inhaled, they are deposited in the human lungs and the morphology of the fungus differentiates to yeast form by increasing the temperature to 36°–37°C, thus establishing the disease. Infection by traumatic injury is unlikely. There is no evidence of human transmission of paracoccidioidomycosis [70, 73].

P. brasiliensis express cell surface proteins called adhesins, which are responsible for the first contact with the host cells and contribute to host colonization and cell invasion. The immune response against *P. brasiliensis* infection will define the disease. When Th1 cytokine profiles prevail, notably interleukin (IL)-12, interferon-γ, and tumor necrosis factor α, a subclinical infection will develop. On the other hand, expression of a dominant T-helper 2 immunity consisting of production of specific immunoglobulin (Ig)E and IgG antibody subclasses and high levels of IL-4, IL-5, and IL-10, the evolution will transition to clinical disease. In acute/subacute form, the disease develops a few weeks or months after infection with *P. brasiliensis*. The chronic form of the disease manifests only months to years after *P. brasiliensis* infection [70, 72].

Clinical Presentation

The *P. brasiliensis* infection may be classified as shown in Table 11.4 [71].

The less common form of PCM is the subacute variety (juvenile type), which affects mostly young adults, has a rapidly progressive course, and is associated with a high mortality rate. It is characterized by involvement of the phagocytic-mononuclear system, and symptoms include fever and weight loss and mild/moderate anemia for 2–3 months or longer. Cervical, axillary, and inguinal nodes are the most commonly enlarged. Lymph nodes are initially hard but evolve with inflammatory signs and sometimes become fluctuant. The liver and spleen are often moderately enlarged and bone marrow may be involved. Multiple skin and mucosal lesions may occur. In approximately 50% of cases, the digestive tract is also affected [71, 74, 75].

Table 11.4 Classification of *P. brasiliensis* infection

Clinical manifestation	Description
Paracoccidioidomycosis infection	Subclinical, detected only by skin-test positivity
Paracoccidioidomycosis disease	Acute or subacute form: there is a tropism of the fungus to the reticuloendothelial system
	Chronic form: usually unifocal when a single organ is affected, such as lungs, or multifocal, affecting more than one organ, mainly the lungs and the oral mucosa
Sequelae of paracoccidioidomycosis	Features as chronic obstructive pulmonary disease, dysphonia, and laryngeal scarring may be present

The chronic form of the disease accounts for more than 90% of cases and characteristically presents an insidious and chronic evolution, usually with mild or moderate severity but resulting in sequelae in about one-third of cases. The lungs are the most commonly affected organ (80%), followed by the skin and mucous membranes (oral, larynx, trachea, and digestive tract). Adenopathy, occasionally complicated by draining sinuses, may involve cervical, axillary, or mediastinal lymph nodes. Adrenal involvement can range from subtle adrenal dysfunction to overt insufficiency. Involvement of the vascular system, CNS, spleen, liver, and male genitourinary tract have been reported less commonly. Patients may complain of weakness, weight loss, dyspnea, cough, sometimes purulent sputum, and, rarely, hemoptysis. Fever is uncommon and, when present, secondary pulmonary infection or association with TB should be suspected. As the course is chronic, when patients present with dyspnea a marked contrast is observed between the paucity of clinical symptoms and signs and the multiple findings on chest radiography. The oral, pharyngeal, and laryngeal mucosal tissues are involved in up to 70% of adult patients. The classic clinical presentation is a superficial ulcer with granular appearance and hemorrhagic points (mulberry-like stomatitis/infiltrative moriform stomatitis). Hoarseness and dysphonia occur in association with laryngeal lesions and may evolve with laryngeal obstruction. PCM frequently attacks the skin. Cutaneous lesions may originate from contiguous lesions (neighboring mucosae, fistula formation from lymph nodes, or from a focus of osteomyelitis), from hematogenous dissemination, or, rarely, from direct inoculation of *P. brasiliensis* into the skin. Lesions can be extremely polymorphic but often appear as warty, hyperkeratotic plaques or ulcerative, crusted lesions, mainly on the face around the mouth and nose (Fig. 11.21). Lesions caused by hematogenous dissemination tend to be multiple, initially papuloacneiform, and later ulcerative or even verrucous [71, 74, 75].
Fig. 11.21 Paracoccidiodomycosis: ulcerative, crusted lesion on the face around the nose

Patients with AIDS acquire a form of PCM that resembles the subacute juvenile type with tropism to the phagocytic-mononuclear system, and probably results from reactivation of a latent focus [70, 75].

Complementary Examinations

The gold standard for diagnosis is based on correct identification of *P. brasiliensis* in clinical specimens or in tissue. Direct examination, using 10% potassium hydroxide applied to a smear sample, is effective and inexpensive (Fig. 11.22) [71, 76].

Histologic examination using silver methenamine or PAS stain tests is inexpensive and allows identification of the fungus. Spores are roundish and 6–20 mm in diameter. Budding is not common, but when seen is usually multiple and evidenced around the whole spore, so the whole budding structure can be up to 60 mm in diameter (Fig. 11.23). In the chronic form, the inflammatory infiltrate is composed mainly of epithelioid granulomas. Culture in Sabouraud agar should always be ordered but has low sensitivity [71, 72, 76].

Serology in PCM, besides helping to make the diagnosis, has application during and after the treatment, and in the follow-up. Currently double immunodiffusion, counter-immunoelectrophoresis,

Fig. 11.22 Potassium hydroxide (KOH) preparation; note the variation in cell size with Paracoccidioides
Fig. 11.23 *P. brasiliensis* budding yeasts are observed free on the stroma (Courtesy of Pathology Department, UFSM)
enzyme-linked immunosorbent assay (ELISA), and immunoblotting methods are available. The antigenic substrate is a fundamental part of these techniques, and *P. brasiliensis* has a complex antigenic structure. Thus, the fungus cell wall glycoprotein of 43 kDa, gp43, considered specific to *P. brasiliensis*, is the most important antigen for recognition of this fungus, representing the main antigen for the PCM diagnosis [69, 72, 74, 75].

X-ray imaging or computed tomography studies may be useful in diagnostic suspicion and show bilateral infiltrate, which is interstitial, micronodular, reticulonodular, or nodular, generally in perihilar or basal areas of the lungs [75].

Diagnosis

> **Box 11.16 Diagnosis of Paracoccidioidomycosis**
> Clinical presentation, and identification of *P. brasiliensis* in clinical specimens or in tissue.

Differential Diagnosis

The differential diagnosis must be made with tuberculosis, leishmaniasis, Hodgkin's disease, sarcoidosis, several systemic and subcutaneous mycoses, lung cancer, and squamous cell carcinoma, when the skin presentation is an isolated verrucous or ulcerative-necrotic lesion [71].

Therapeutic Approach

Treatment must be based on the severity in every individual and the affected organs. Itraconazole is considered the best option for mild to moderate clinical forms. The recommended dose is 200 mg daily for 6–9 months for mild disease and 200 mg daily for 12–18 months for moderate disease. Sulfamethoxazole-trimethoprim 2,400 mg plus 480 mg orally, daily for 12 months for mild cases is also a useful option. Moderate clinical forms are treated for 18–24 months at least. Voriconazole, a new second-generation triazoic antifungal, constitutes an important therapeutic alternative; however, its high cost is an important limitation [71].

Amphotericin B has been recommended since 1958 for the treatment of the most severe PCM cases, in conventional or lipid formulations. The dose varies from 0.5 to 1 mg/kg intravenously, daily until a total dose of 30 mg/kg is reached [71].

CNS disease treatment should include drugs that reach higher concentrations in cerebrospinal fluid and parenchyma. Fluconazole 400 mg daily for 3–6 months, with a maintenance dose of 100–200 mg daily for 6–12 months, has been successfully used as it presents good CNS penetration [71].

Coccidioidomycosis

Valley fever, also called coccidioidomycosis, is an infection caused by the fungus *Coccidioides*, which is known to live in the soil in the southwestern United States and parts of Mexico and Central and South America. Features such as high temperatures, low rainfall, and alkaline soil contribute to the development of the fungus [77].

Epidemiology

The incidence of *Coccidioides* spp. infection has increased in recent years, reaching annual rates close to 60 per 100,000 population in some regions. The most important risk factor is dust exposure in endemic areas, usually because of occupational and recreational activities. People at greatest risk include farmers, construction workers, and archaeologists. Travelers are at increased risk if they participate in activities that expose them to dust. Most cases follow a benign course, since only around 5% of cases become symptomatic and chronic. Pregnant women and immunosuppressed patients are considered risk groups for severe or disseminated disease [77, 78].

Etiopathogenesis

Coccidioides immitis and *Coccidioides posadasii* are the species highlighted as causes of coccidioidomycosis. They are dimorphic fungi and belong to the phylum Ascomycota. Although there are genetic differences between these species, they are clinically and microbiologically indistinguishable. Transmission of the disease occurs through inhalation arthroconidia, so the lung is the most commonly affected organ [77, 78].

Clinical Presentation

Coccidioidomycosis can be classified into two clinical spectra. Primary disease affects initially the lungs and patients develops a flu-like syndrome (fever, headache, profound fatigue, cough, pleuritic pain, and arthralgia), commonly known as "San Joaquin valley fever." Secondary disease is characterized by a chronic process or disseminated disease and involves other organs, including bones, joints, nervous system, and meninges [77].

Skin involvement includes a wide variety of clinical presentations. Cutaneous lesions include reactive manifestations of lung infection, such as erythema nodosum, erythema multiforme, acute

generalized exanthema, and Sweet's syndrome. Primary cutaneous infection by direct inoculation of the fungus is extremely rare and typically manifests as a painless, indurated nodule with ulceration (chancroid lesion). Secondary nodules may arise in a linear lymphatic sporotrichoid distribution [77].

Polymorphic and nonspecific skin lesions, such as papules, nodules, gummas, acneiform lesions, ulcerated and verrucous plaques, scars, abscesses, and fistulas reflect disseminated disease. In this case the face, neck, scalp, and chest wall are the most common sites, especially the nasolabial region [77].

Complementary Examinations

Direct mycology examination revels double-walled refractile spherules and endosporulation as characteristic. In culture at room temperature it grows as a white, cottony mold, with septate hyphae and barrel-shaped arthroconidia. Histopathology findings usually show suppurative granulomas that contain double-walled refractile spherules (10–80 μm) with endospores [77].

Serologic tests identifying anticoccidioidal antibodies represent optimal assays for the diagnosis and prognosis of coccidioidomycosis [77, 79].

Diagnosis

> **Box 11.17 Diagnosis of Coccidioidomycosis**
> Clinical presentation, culture, microscopy, and serology. Other diagnostic tools such as cutaneous tests, molecular diagnosis, and imaging studies are also used.

Differential Diagnosis

Important differential diagnoses include histoplasmosis, blastomycosis, cryptococcosis, tuberculosis, sarcoidosis, and primary skin malignancies [77].

Therapeutic Approach

Coccidioides infection is often self-limited and spontaneous resolution is common. When treatment with antifungal is indicated, treatment options are as follows [77, 79].

- Primary cutaneous coccidioidomycosis: itraconazole at doses of 400 mg per day for 6 months
- Primary pulmonary coccidioidomycosis without risk factors for dissemination, or less severe: fluconazole or itraconazole 400 mg per day for 3–6 months
- Primary coccidioidomycosis with risk factors: fluconazole or itraconazole 400 mg per day for 4–12 months
- Chronic pulmonary coccidioidomycosis: fluconazole or itraconazole 400 mg per day for 12–18 months
- Meningeal infection: fluconazole 400 mg per day (with initial doses of up to 1,000 mg per day) or itraconazole 400–600 mg per day for lifelong treatment
- For pregnant women and severe or refractory infections, the treatment of choice is intravenous deoxycholate amphotericin B at 0.7 mg/kg daily or a lipid preparation at 3 mg/kg daily

Histoplasmosis

Histoplasmosis, an infection caused by the dimorphic fungus *Histoplasma capsulatum*, is considered one of the most common fungal respiratory infections worldwide.

Epidemiology

The fungus is distributed worldwide but is endemic in certain areas of North and South America. In the United States, histoplasmosis is known to affect up to 90% of the residents of the Mississippi and Ohio River valleys [80].

H. capsulatum feeds on nitrogen-rich soils, especially those replete with bird and bat droppings. When inhabited soils such as these are disturbed, spores can become airborne and inhaled. Severity of illness after inhalation exposure to *H. capsulatum* varies depending on the intensity of exposure and the immunity of the host. Disseminated disease predominates in the immunocompromised individuals, particularly during infancy, HIV infection, hematologic malignancy, solid organ transplantation, and treatment with corticosteroids [80–82].
Fig. 11.24 (**a**) Histoplasmosis: disseminated papules with crusts on the face in an HIV-positive patient. (**b**) Disseminated giant molluscum-like lesions in the same patient

Etiopathogenesis

Humans are infected via inhalation of airborne microconidia, which the wind can carry for miles. Once in the lung the microconidia are converted into pathogenic yeast forms that disseminate hematogenously to multiple organs, including the spleen, liver, bone marrow, and lymph nodes [80, 81].

Clinical Presentation

The predominant clinical manifestation of histoplasmosis is pneumonia, but most patients have either no symptoms or mild pulmonary complaints. Hematogenous dissemination is common in the early stages of infection, but almost all people in whom this occurs remain asymptomatic. Symptomatic acute disseminated infection occurs almost entirely in those who are immunosuppressed. On the other hand, chronic progressive disseminated histoplasmosis occurs mostly in elderly individuals who have no known immunosuppression but who are unable to contain the organism.

Mucous membrane ulcers and skin lesions appear as subacute or chronic disseminated histoplasmosis [81, 82]. Skin lesions are polymorphic and nonspecific, such as papules, plaques with or without crusts, nodules, erosions or ulcers, pyoderma gangrenosum-like, molluscum-like lesions, or acneiform eruptions (Fig. 11.24a, b). The most commonly affected sites are the face, extremities, and trunk [82, 83].

Complementary Examinations

Direct microscopic examination using silver methenamine stain or Giemsa generally reveal intracellular yeast. Histopathologic examination with special staining (PAS and Gomori Grocott) allow the differential diagnoses, such as *Leishmania* and *Trypanosoma*. *H. capsulatum* is found in the yeast form inside or outside of macrophages, as budding, encapsulated yeasts [81–83].

Microscopy of culture shows microconidia and typical macroconidia, with tuberculated projections (echinulations) [81, 83].

Diagnosis

Box 11.18 Diagnosis of Histoplasmosis
Clinical presentation and all tissue or body fluid serve to direct microscopic examination, which is a simple and rapid diagnostic method. However, the gold-standard diagnosis is culture. Serology and antigen testing also may be useful [81, 82].

Differential Diagnosis

Especially in disease-endemic areas, tuberculosis is the main differential diagnosis of histoplasmosis, since symptoms of both are nonspecific. Skin lesions need differential diagnosis with molluscum contagiosum, pyoderma gangrenosum, and other deep mycoses [81, 83].

Therapeutic Approach

Early treatment allows better prognosis, since the mortality of disseminated disease is high. In view of the risk of relapse and severity of disseminated disease, a lifelong maintenance phase is indicated after the induction phase. For patients who are mildly or moderately ill, oral itraconazole, 200 mg three times daily for 3 days thence reducing dose to 200 mg, once or twice daily, is recommended. Fluconazole (800 mg daily) is indicated in patients who cannot take itraconazole. Amphotericin B is the therapeutic agent of choice for induction therapy in moderate to severely disseminated histoplasmosis. Conventional amphotericin B intravenously at 0.7–1 mg/kg daily should be used in initial phase for 12 weeks. The liposomal amphotericin B dose is 3–5 mg/kg daily. Itraconazole (200 mg, once or twice daily) is indicated in maintenance therapy [82].

Cryptococcosis

Cryptococcosis is a globally distributed invasive fungal infection caused by species within the genus *Cryptococcus*, which presents substantial therapeutic challenges.

Epidemiology

Cryptococcosis is the third most prevalent disease in solid organ transplant (SOT) recipients and HIV-positive individuals. HIV-positive individuals with a CD4 lymphocyte count of <100 cells/mm^3 are at highest risk for developing this disease, especially cryptococcal meningitis. End-stage liver disease, renal insufficiency, and sarcoidosis are also risk factors for this systemic mycosis. However, it can also affect patients without any recognized immunologic defect. Skin involvement is seen in 10–20% of systemic cryptococcosis [83–85].

The etiologic agents are the species *Cryptococcus neoformans* and *Cryptococcus gattii* (formerly designated as *C. neoformans* var. *gattii*). These bacilli can inhabit diverse environmental niches and substrates. *C. neoformans* is more commonly found in soil contaminated by the feces of birds in temperate climates and cold, urban areas. The main niche of *C. gattii* is the hollows of eucalyptus trees. This explains why *C. gattii* is more frequent in rural areas of tropical and subtropical regions as Brazil, Africa, Australia, and Southern California, although this yeast may adapt to a temperate climate [84, 85].

Etiopathogenesis

Cryptococcus are basidiomycetes and are encapsulated yeasts. Based on the capsule structure, they are grouped into the two varieties, *neoformans* and *gatti*, which include five serotypes [85].

These yeasts have a polysaccharide capsule, which increases their invasiveness and pathogenicity, and confers resistance to the environment and the host. Primary pulmonary infection occurs as a result of inhalation of fungus and may progress to disseminated disease, spreading to the CNS, bone, genitourinary tract, and skin. Primary cutaneous cryptococcosis from traumatic inoculation of the fungus is rare [83, 84].

Clinical Presentation

In immunocompetent hosts the infection is usually limited to the lungs, with minimal or no symptoms [85].

Skin has also been identified as a portal of entry of cryptococci. However, cutaneous lesions
Fig. 11.25 (**a**, **b**) Cryptococcosis: disseminated molluscum-like lesions in an HIV-positive patient

largely represent hematogenous dissemination, involving mainly the scalp and the face. They present usually as acneiform lesions, but other presentations include nodules, ulcers, cellulitis, subcutaneous abscesses, pseudofolliculitis, and keloid-like or molluscum contagiosum-like lesions (Fig. 11.25a, b) [83, 86].

Complementary Examinations

Histopathologic analysis reveals microorganisms that are PAS-positive, presenting budding yeast cells with capsules, 2–20 mm in diameter. The fungi stain with Masson–Fontana and their capsule stains with Alcian blue and mucicarmine [83, 87].

Latex agglutination (LA) and ELISA have overall sensitivity and specificity of 93–100% and 93–98%, respectively. However, they are expensive and require a cold chain and significant technical expertise. Lateral flow immunoassay for the detection of CrAg (LFA CrAg) is a newly developed test that is sensitive and

specific, and simple to perform without field equipment, with results available in 10–15 min [85, 87].

Diagnosis

> **Box 11.19 Diagnosis of Cryptococcosis**
> Clinical presentation, diagnostic methods including microscopy and culture of fluids and/or tissues, histopathology, and detection of cryptococcal antigen (CrAg) by using either LA or ELISA in serum and cerebrospinal fluid [85, 87].

Differential Diagnosis

It is important to differentiate from other fungal infections caused by dimorphic fungi, such as histoplasmosis, coccidioidomycosis, and blastomycosis [83].

Therapeutic Approach

The treatment of disseminated disease/meningo-encephalitis consists of [85]:

- Induction phase: deoxycholate amphotericin B (AmB) 0.7–1.0 mg/kg (or liposomal AmB 3–4 mg/kg) intravenously, daily, plus flucytosine 100 mg/kg orally, divided into four doses for 2 weeks in HIV-positive or SOT patients, extending for at least 4 weeks in others
- Consolidation phase: oral fluconazole 400 mg daily for 8 weeks in HIV-positive, 400–800 mg daily in SOT, 800 mg daily in other patients
- Maintenance in HIV-positive patients: oral fluconazole 200 mg daily for a minimum of 12 months and CD4 >100 cells/mm^3 and an undetectable viral load for 3 months
- Maintenance in SOT recipients: oral fluconazole 200–400 mg daily for 6–12 months
- Maintenance in other patients: oral fluconazole 200 mg daily for 6–12 months

Some researchers recommend prophylactic treatment for asymptomatic HIV-positive patients who are CrAg-positive, especially if CD4 count is <100 cells/mm^3, with fluconazole 400–800 mg daily for 2 weeks followed by fluconazole 400 mg daily for 8 weeks. This strategy aims to reduce treatment costs and mortality associated with cryptococcal meningitis [85].

Glossary

Anthropophilic (dermatophytes) Restricted to human hosts, produce a mild, chronic inflammation.

Cytokine Any of a class of immunoregulatory proteins such as interleukin or interferon that are secreted by cells, especially of the immune system.

Ectothrix A fungus that grows inside the shaft of a hair but produces a conspicuous external sheath of spores.

Endothrix Dermatophyte infections of the hair that invade the hair shaft and internalize in the hair cell.

Folliculitis Common skin condition whereby hair follicles become inflamed, usually caused by a bacterial or fungal infection.

Geophilic (dermatophytes) Usually recovered from the soil, occasionally infect humans and animals; they cause a marked inflammatory reaction.

Hyperkeratosis Hypertrophy of the corneous layer of the skin.

Hypha (plural form hyphae) Name of the long, individual pieces that comprise a mycelium, overall a fungus; often described as strings and thread-like filaments.

Keratinocyte The predominant cell type in the epidermis.

Kerion The most severe form of tinea capitis, characterized by an abscess-like deep infection of the scalp. Clinically it is seen a boggy, indurated, tumor-like mass that exudes pus.

Leukonychia White spotting, streaking, or discoloration of the fingernails.

Mycelium Mass of hyphae that forms the body of a multicellular fungus; it enables either sexual or asexual reproduction of fungi.

Onycholysis Spontaneous separation of the nail plate, usually starting at the distal free margin and progressing proximally; the nail plate is separated from the underlying and/or lateral supporting structures.

Onychodystrophy Widely used, yet rarely defined term; it describes any kind of irregular difference in the nail, apart from modifications in color (called nail dyschromia).

Spore Specialized cell of the fungus that can function as resting or dispersal propagules; each spore has the capacity to generate another individual of the species.

Zoophilic (dermatophyte) Found primarily in animals, it causes marked inflammatory reactions in humans who have contact with infected cats, dogs, cattle, horses, birds, or other animals.

Parasitic and Protozoal Infections

12

Carolina Talhari, Sílvia Nakajima,
and Bernardo Gontijo

Key Points Summary

- Scabies is a skin infestation caused by *Sarcoptes scabiei* var. *humanus* that affects more than 130 million people worldwide; topical permethrin is more effective than oral ivermectin, topical crotamiton, and topical lindane for the treatment of scabies
- Head lice predominantly infest schoolchildren from any socioeconomic group, and *Pediculus humanus* var. *capitis* is a parasitic insect that infests the hair and neck regions
- Chagas disease is endemic to Latin America but has spread to other continents because of population mobility.
- Bed bugs inject anticoagulant, hyaluronidase, proteases, and kinins into the skin and feed from the extracted blood or by directly collecting blood from the capillaries. The skin reactions are induced by the injected substances, and their type depends on the patient's immunocompetence and previous exposure, which represents a delayed reaction
- The most common type of myiasis is cutaneous myiasis, which includes localized furuncular myiasis, creeping dermal myiasis (migratory), and wound and body cavity myiasis
- Larva migrans is caused by cats' and dogs' intestinal hookworms. Humans are not the final hosts, explaining why it is a self-limited disease. The disease is endemic in tropical climates
- Leishmaniasis is a group of diseases caused by protozoan parasites of the genus *Leishmania*, and the WHO ranks cutaneous leishmaniasis as a category 1 (severely neglected) emerging and uncontrolled disease.

Arthropod Infections

Scabies

Epidemiology

Scabies is a skin infestation caused by *Sarcoptes scabiei* var. *humanus* that affects more than 130 million people worldwide, especially in developing countries [1], where it is associated with low socioeconomic status and domestic crowding [2].

Etiopathogenesis

S. scabiei var. *humanus* is a parasitic mite that is round [3], has eight legs, and burrows into the stratum corneum of the skin, causing intense itching [4]. Female species of these mites have a size of approximately 0.4 mm, lay four eggs per day, and burrow under the stratum corneum for 6 weeks before dying [5, 6]. These mites feed on the host's epidermal cells and plasma, and take only 2 weeks to transform from the egg to the adult phase [5].

Scabies is transmitted by direct skin-to-skin contact from an infested to a susceptible person [5] and is less frequently caused by fomites [7]. Eggs can stay alive at low temperatures for up to 10 days outside of the host [5], whereas scabies mites do not survive more than 2–3 days away from human skin [3].

There are three clinical types of scabies: classical or ordinary, nodular, and crusted. Ordinary scabies (OS) is the most common type of skin infestation and presents a protective response mediated by Th1 cells. Crusted scabies (CS) affects immunosuppressed patients, such as individuals with developmental disability and leprosy [5], and is associated with a nonprotective T-helper 2 (Th2) response, eosinophilia, and extremely high levels of immunoglobulin G4 and total and scabies-specific immunoglobulin E in human serum [4].

Clinical Presentation

During the first infection, symptoms appear after 14 days and for up to 2 months [3, 5]. In subsequent infections the incubation period is 2 days. The main symptom of OS is severe itching, especially at night. Small excoriated papules and pustules (<5 mm) are commonly observed between the fingers (Fig. 12.1) and on the wrists, elbows, shoulders, genitalia (Fig. 12.2), breasts, ankles, waist, buttocks, shoulder blades, and armpits [3, 5]. Small burrows ending in a papule or pustule are difficult to observe and correspond to the course of the mite in the epidermis [5]. One clue to the proper diagnosis is the presence of itching with or without skin lesions in other household

Fig. 12.1 Scabies. Erythematous papular and eroded lesions in the interdigital web spaces of the hand

Fig. 12.2 Scabies. Erythematous crusted papular lesions on the penile shaft

members. Infestations in the head region are uncommon, but this type of infection is frequent in infants and babies [5]. Moreover, an average of 10–15 mites tends to appear in cases of OS [6].

Nodular scabies occur in some late infections in the form of larger and itchy papules or small nodules on the buttocks, genitalia, groin, and axilla. These lesions are called postscabetic nodules and represent a developing immune reaction to mite allergens [5, 7]. Mites are rarely found [7], but the search for the burrows is important, since they indicate active infection. Nodular scabies can also be found after the treatment [5].

CS, also known as Norwegian scabies, is a superinfection of mites (thousands to millions) during which patients are highly contagious [5–7]. In many cases other household members are also affected, mostly with OS [5]. The same areas are affected, although lesions may be smaller or may not present an itchy sensation (because of immunosuppression or neurologic disability). In these cases, dry scales and crusts generally appear, especially on the face, dorsum of the fingers, wrists, and ears, and some nails present hyperkeratosis [3, 5].

Diagnosis
The diagnosis is clinical.

Complementary Examinations
Direct examinations can confirm this infection: after scratching the end of the burrow [3], the material should be mounted in potassium hydroxide and observed under a microscope to search for mites, eggs, or feces [3, 5, 7]. Dermoscopy reveals an image that is similar to vapor trails from jet planes, which represent the burrow, whereas a brown triangular structure in the papule corresponds to the mouth of the mite [8]. In the burrow ink test, the papule is first marked with ink and then removed with an alcohol pad. A positive result shows a dark, zigzagged line that can be viewed by the naked eye, which corresponds to the burrow [9].

Histologically, when mites, eggs, or scybala are not found, pink "pigtails" connected to the stratum corneum are clues that represent the hatched and empty egg [10].

Differential Diagnosis
Folliculitis, insect bites, impetigo, papular urticaria, tinea corporis, contact dermatitis, bullous pemphigoid, and pityriasis rosea are part of the differential diagnosis [11]. CS can be misdiagnosed as psoriasis, hyperkeratotic eczema, Darier disease, or ichthyosis [12].

Therapeutic Approach
Treatment should be given to the patient and all household members, regardless of the symptoms [3, 5]. Topical agents are the first line of treatment, and oral ivermectin is reserved for recurrent and difficult-to-treat cases, CS, and epidemics [5, 7].

Topical agents are highly effective and should be applied to a clean body [3], including all body areas, from the neck to the feet and toes. The period of time that these agents are in contact with the skin must be strictly respected and then completely washed off [3, 5, 6]. In addition,

when treating infants and the elderly, scabicides should also be applied to their entire head and neck regions, avoiding the eyes, mouth, and non-intact skin [3, 5]. All of the topical agents used in a single application must be repeated 7–14 days after the first treatment [5].

Because the symptoms of scabies are caused by a hypersensitive reaction to mites and their feces, itching may continue for several weeks after treatment, even if all mites and eggs are killed. If itching persists for more than 4 weeks after treatment, or if new burrows or papules/pustules continue to appear, retreatment is necessary [3].

A systematic review of the literature [13] showed that topical permethrin is more effective than oral ivermectin, topical crotamiton, and topical lindane for the treatment of scabies, making permethrin the drug of choice [3]. It has also been proved to be safe in pregnant and lactating woman [5].

For CS, oral and topical agents should be used together [3]. Oral ivermectin (200 μg/kg/dose) should be taken with food and, depending on the severity of the infection, must be taken in three doses (approximately days 1, 2, and 8); five doses (approximately days 1, 2, 8, 9, and 15); or seven doses (approximately days 1, 2, 8, 9, 15, 22, and 29) [3]. Topical permethrin should be administered every 2–3 days for 1–2 weeks [3]. Keratolytic agents must be used to help the penetration of permethrin [3]. Patients must be isolated until both therapies are completed, providers must use gloves, and close contacts must be treated [6].

Demodicosis

Epidemiology

Demodex folliculorum and *Demodex brevis* are mites that are part of the human skin microbiota and inhabit the pilosebaceous unit of the face [14]. Demodecidosis, or demodicosis, is a pilosebaceous unit disease caused by human *Demodex* spp. mites, predominantly involving the face and head regions [15]. There are two types of demodicosis: primary and secondary. The former is more common in patients over 40 years of age, while the latter occurs earlier in life [16].

Etiopathogenesis

The symbiosis among humans, human *Demodex* mites, and the pathogenesis of demodicosis are still unclear [17]. A pathogenic role occurs when *Demodex* sp. penetrates the dermis, which is quite rare, or when it multiplies and its density is high (>5 mites/cm^2), which tends to occur more frequently [18].

Clinical Presentation

The diagnostic criteria for primary demodicosis include: (1) the absence of pre-existing or concurrent inflammatory dermatoses (acne, rosacea, or perioral dermatitis); (2) an increase in mite colonization; and (3) the control of the disease only after treatment with topical or systemic acaricides but not with antibiotics [16]. Clinically, the lesions involve periorificial sites of the face, have an asymmetric distribution and irregular shape, are bound by follicles, and are asymptomatic or mildly itchy [16]. Many definitions of the clinical presentation of primary demodicosis have been reported in the literature. Chen and Plewig [16], for example, proposed a didactic nomenclature for this condition (Table 12.1).

In secondary demodicosis, skin lesions have increased the density of mites and are associated with other concurrent skin or systemic diseases

Table 12.1 Primary human demodicosis: proposed classification and nomenclature

Proposed nomenclature	Definition and clinical manifestations
Spinulate demodicosis	Discrete fine, whitish to yellowish, spiky, changes involving sebaceous hair follicles, with or without faint erythema and little inflammation
Papulopustular demodicosis, perioral demodicosis, periorbital demodicosis, periauricular demodicosis	Papulopustules mostly involving the face (predilection for perioral, periorbital, and periauricular regions), in patients without (primary form) or with pre-existing inflammatory dermatoses (secondary form)
Nodulocystic/conglobate demodicosis	Intense immune reaction with massive follicular and perifollicular inflammatory infiltrates caused by *Demodex* proliferation, pus accumulation, and suppurative succulent changes

Adapted from Chen et al. [16]

(usually human immunodeficiency virus [HIV] and leukemia) or the use of topical (corticosteroids/calcineurin inhibitors) or systemic immunosuppressants [16]. Lesions have diffuse facial or truncal distribution and present greater inflammation [16]. *Demodex* spp. cause blepharitis, meibomian gland dysfunction, recurrent chalazia, and refractory keratoconjunctivitis [16, 19].

Diagnosis

The gold-standard diagnostic tool is a standardized skin surface biopsy, which should show >5 mites/cm^2 in demodicosis [16]. A noninvasive examination can also be performed whereby a drop of cyanocrylic adhesive is placed on a microscope slide, applying the adhesive-bearing surface of the slide to the skin and removing it gently after it is dry. On the other side of the slide, a waterproof draw of 1 cm^2 must be made. After its removal from the skin, the sample is clarified with two to three drops of immersion oil, covered with a coverslip, and observed under a microscope at standard magnification (×40, ×100) [20].

Differential Diagnosis

Perioral dermatitis, rosacea, folliculitis, and acne [17].

Therapeutic Approach

The treatment of human demodicosis is based on case reports and considers the same standard treatment as that applied for scabies [21]. However, evidence of the efficacy of these acaricides in the treatment of demodicosis is quite limited [16], whereas a single dose of ivermectin (200 µg/kg body weight) has been proved effective in the treatment of demodicosis [21]. Concurrent diseases in secondary demodicosis must also be treated [15].

Insect Infections

Head Lice

Epidemiology

Head lice, the most common type of lice, predominantly infest schoolchildren from any socioeconomic group [22].

Etiopathogenesis

Pediculus humanus var. *capitis* is a parasitic insect that infests the hair and neck regions. Adults feed on human blood and lay eggs in the base of hair shafts. They do not hop or fly, but rather crawl. Their main form of transmission is by direct contact with the hair of an infested person; pets do not transmit these parasites. Indirect transmission (combs, brushes, towels, hats, clothes) is less common, since the adult insects do not survive after 2 days if they fall off the child's head or their nits cannot hatch at temperatures lower than the human scalp [23].

Head lice have three forms: eggs (or nits), nymphs, and adults. Nits firmly attach to the hair shaft. They tend to have an oval shape, are very small, and take on a yellow, white, or hair-shaft color. Viable eggs are normally located 6 mm from the scalp and hatch in 8–9 days. Nymphs become adults 9–12 days after hatching. Adult head lice are 2–3 mm in size, have six legs, are grayish-white, and live up to 30 days in the head of the infested child. Adult lice and nits are found on the scalp, around the ears, and on the back of the neck. The former use their claws to firmly attach themselves to the scalp while the later firmly attach themselves to the hair shaft [23].

Clinical Presentation

Upon first infestation itching appears after 4 weeks, which is caused by sensitivity to the saliva from the head lice [24]. Erythematous papules, with a central excoriated point around the ears and the posterior portion of the neck, are common [24]. Secondary bacterial scalp infection may result from scratching and must direct attention to this diagnosis [22].

Diagnosis

The ability to see the nymph or adult head lice on the scalp or hair is one diagnosis. These lice move quickly and avoid light. The ability to see the nits attached to the hair shaft (Fig. 12.3) suggests the diagnosis of head lice but does not confirm it [23, 25].

Differential Diagnosis

Nits can be mistaken for black and white piedra, dandruff, hair casts (which are easily moveable while nits are not), hairspray droplets, monilethrix, and trichorrhexis nodosa [25].

Fig. 12.3 Head lice. Nits firmly attached to the hair shaft

Therapeutic Approach

Some pediculicides have an ovicidal effect. For pediculicides that are weakly ovicidal or nonovicidal, retreatment is necessary. For those that are strongly ovicidal, retreatment is recommended only if live lice are found several days after treatment [23].

Pyrethrines, extracted from chrysanthemum flowers, are neurotoxic to lice, since they connect themselves to the voltage-gated sodium channels, keeping them open and leading to spastic paralysis [26, 27]; however, they are associated with low toxicity to mammals. The shampoo or mousse must be applied to dry hair, maintained for 10 min, and rinsed off. Retreatment is necessary between 9 and 10 days [23, 24].

Permethrins are synthetic pyrethroids. Instructions for use are the same as for pyrethrines, but these must be applied to damp hair [23, 24].

A 5% benzyl alcohol lotion must be applied to dry hair for 10 min to saturate the scalp and the entire length of the hair, and then rinsed off. Retreatment should be performed 9 days after the first treatment [23, 24].

Malathion at 0.5% is an insecticide that, when ingested by lice, is converted into its active metabolite, malaoxon, a cholinesterase inhibitor that causes spastic paralysis and kills lice [27, 28]. This insecticide is considered safe because, when used topically, malathion is metabolized into its inactive metabolites rather than into its active metabolites, and these inactive metabolites can be excreted by the kidneys [28]. It must be applied to dry hair and left to air dry for 8–12 h, then washed off. Caution must be exercised while the product is in use because the solution is inflammable (78% isopropyl alcohol): the hair must dry naturally; there should be no smoke near the patient; hair dryers, curling irons, and flat irons must not be used. This treatment has been proved to produce good ovicidal activity [23].

Ivermectin at 0.5% increases the chloride ion permeability of muscle cells, resulting in the paralysis and death of the lice. This must be applied to dry hair and scalp and left for 10 min before rinsing off. Only one application is necessary because, when the nits hatch, nymphs are not able to feed because of pharyngeal muscle paralysis [26, 29]

Systemic ivermectin is an off-label treatment for head lice. A single oral dose of 200 µg/kg body weight should be applied and repeated after 10 days [26].

Spinosad at 0.9% is derived from the fermentation of the *Saccharopolyspora spinosa* bacteria [24]. Its mechanism of action is not completely known, but it appears to indirectly interfere with a subset of nicotinic acetylcholine receptors, as

well as with γ-aminobutyric acid gated chloride channels, leading to motor neuron excitation and involuntary muscle contraction with paralysis [30]. This solution must be kept in dry hair for 10 min and then rinsed off. A second treatment is necessary after 7 days only if live lice can still be seen [30]. This medication is classified as pregnancy category B [30].

The widespread use of insecticides for this treatment has led to the emergence of resistance to the pediculicides in many parts of the world. Three point mutations in the voltage-gated sodium channels are associated with permethrin-resistant phenotypes, which were suggested to be responsible for kdr-type resistance. In the United Kingdom, where malathion has been used for a longer period of time, resistant cases were proposed to be linked to modified acetylcholinesterase [27].

Since by the time the infestation is diagnosed the child has been infected for at least 1 month or more, and considering that the risk of transmission at school to other children is small, the child must remain in class [24]. Close contact should be checked and the infested child should be treated at the same time [23].

Body Lice

Epidemiology

Pediculus humanus var. *corporis* is an ectoparasite that only infests humans and is usually found in the homeless, refugees, victims of war, or natural disasters, since it is associated with poverty, crowded places, and poor hygiene [31]. The infestation can be transmitted either by direct contact with the infested person or by indirect contact (clothes, beds, and bath clothing) [32]. The ectoparasite transmits diseases such as epidemic typhus, trench fever, endocarditis by *Bartonella quintana*, and relapsing fever [31, 33].

Etiopathogenesis

The adult parasites are 2–4 mm in size; other than their length, it is not possible to distinguish them from head lice. The insects attach themselves to hair shafts of the body to feed on blood [33], and lay their eggs in hair shafts and in the seams of clothing [32, 33]. The eggs hatch in about 7 days [32]. The nymphs mature into adult parasites in about 2 weeks [33] and live an average of 30 days [32].

Clinical Presentation

The infested patient presents intense pruritus, excoriation, rash stemming from reaction to the bite, secondary skin bacterial infection, and chronic lichenification [31, 34].

Diagnosis

The diagnosis is made by identifying body lice or eggs in the skin or in the seams of clothing [32–34].

Differential Diagnosis

Atopic dermatitis, contact dermatitis, viral exanthem, rash from medication, and scabies [32].

Therapeutic Approach

A body lice infestation is treated by improving the personal hygiene of the infested person, including assuring a regular (at least weekly) change of clean clothes. Clothing, bedding, and towels used by the infested person should be laundered using hot water (at least 54.5 °C) and machine dried using the hot cycle. The use of pediculicides is not necessary, but if chosen should follow the same instructions as those for the treatment of head lice [31].

Hemiptera Infestations

Triatomine Bug Infestations

Epidemiology

Triatomine bug, also called the kissing bug, reduviid bug, assassin bug, cone-nosed bug, and blood sucker, is an insect that transmits Chagas disease, caused by *Trypanosoma cruzi*, a protozoan parasite. This disease is endemic to Latin America but has spread to other continents because of population mobility. Estimates quote that 6–7 million people worldwide are infected,

and the insect can be found throughout the Americas [35]. *T. cruzi* can also be transmitted by the consumption of food contaminated with triatomine's feces or urine, blood transfusion, vertical transmission, organ transplants, and laboratory accidents. Since the 1990s, in Latin America there has been an important reduction in transmission by vectors, via vector control, and by blood transfusion, by means of compulsory blood screening in blood banks [35].

Etiopathogenesis

Triatomines are 10–30 mm in size; their wings rest on their back, the lateral portion of their abdomen is not covered by wings, and they have tiger-like stripes [36]. The insects are attracted by houselights [37]. Indoors, they live in cracks of substandard housing, pets' resting areas, in rodent infestation, and in and around beds. Outdoors, they live beneath porches, between rocks, under cement, in wood and brush piles, beneath bark, in rodent nests, in animal burrows, in outdoor dog houses, and in chicken coops [38].

Triatomines have nocturnal habits and feed on the blood of mammals (including humans), birds, and reptiles [38]. People become infected when they ingest *T. cruzi* from the blood of an infected mammal [37]. *T. cruzi* must be in the bug's feces to be transmitted. Triatomines frequently defecate while feeding [36–38] on a person who is sleeping. They produce painless feeding bites [36], and protozoa transmission occurs when feces are rubbed into the bite wound or into a mucous membrane, thus allowing the parasite to enter the body. However, it is important to note that not all triatomines are infected with *T. cruzi* [38].

Clinical Presentation

The incubation period of the acute disease is 1–2 weeks [39] and is marked by Romaña's sign, a unilateral periocular swelling caused by a conjunctival edema due to contamination from triatomine feces [37]. Chagoma is a mild swelling at the site of the parasite's inoculation. About 30–40% of the patients develop this chronic disease after 10–30 years with cardiac and digestive infections [39].

Even though the triatomine may not be infected, antigens from saliva can induce allergic reactions [36–38]. Initially the lesions are pruriginous and made up of erythematous papules with a central punctum that emerges 24 h after the bite; with multiple exposures, reactions may appear as hemorrhagic nodules, bullae, diffuse urticaria, erythema multiforme, and, more rarely, anaphylactic shock [37].

Chagoma and Romaña's sign have less pruritus and last longer (weeks) than do allergic reactions (hours to several days) [37]. Romaña's sign can occur without the transmission of *T. cruzi* [37].

Diagnosis

During the acute phase of Chagas disease, diagnosis is made by the identification of the parasites in a blood smear by microscopic examination or molecular study. In chronic stages, at least two different serologic tests are necessary [38].

Differential Diagnosis

Romaña's sign must be differentiated from allergic reactions to insect bites or stings, pollen, aspirin, or foreign bodies [37].

Therapeutic Approach

The treatment of the acute phase of Chagas disease is curative with benznidazole or nifurtimox [38]. In case reports, allergic reactions were managed with oral prednisone and antihistamines. The treatment of anaphylactic reaction was performed in the emergency room [37].

Bed Bugs

Epidemiology

Bed bugs belong to the Cimicidae family and are wingless ectoparasites that feed on the blood of humans, mammals, and birds [40], but do not transmit disease [41].

Bed bugs have a worldwide distribution and are common in developing countries, but have recently spread to developed countries because of international travel and immigration. Their infestation is not associated with poor hygiene [41, 42], as they have even been found in five-star

hotels and resorts, since they can be transported in bags and furniture [41]. The two species usually responsible for human infestation are *Cimex lectularius* (worldwide distribution) and *Cimex hemipterus* (tropical climates) [40].

Etiopathogenesis
Bed bugs usually hide 1–2 m from the victim in crevices, bed cracks, seams of mattresses, box springs, headboards, loose wallpaper, and behind hanging pictures where they avoid daylight [43]. They feed from blood during the night, especially before dawn [40, 42].

The eggs are deposited in crevices and hatch 4–12 days later [41]. Nymphs become adults after the fifth molting. The adults are 5–8 mm in size and can easily be seen; the parasites have three pairs of legs, are flat and reddish-brown [42, 43], live from 6 to 12 months, and can survive up to 1 year without feeding [41, 43]. They can also produce a pungent odor [40].

Bed bugs inject anticoagulant, hyaluronidase, proteases, and kinins into the skin and feed from the extracted blood or by directly collecting blood from the capillaries. The skin reactions are induced by the injected substances, and their type depends on the patient's immunocompetence and previous exposure, which represents a delayed reaction [40].

Clinical Presentation
Some patients are asymptomatic. The signs and symptoms of the bite may appear the next day or up to 14 days after the initial bite [41]. Lesions are found in exposed areas, such as the face, neck, hands, and arms. They can be distributed randomly or placed in linear disposition ("breakfast, lunch, and dinner") (Fig. 12.4) [41, 42]. Asymptomatic macules, hemorrhagic puncture, erythematous wheals centered by a punctum, urticarial papules, or bullous lesions at the site of the bite associated with pruritus are to be expected. Anxiety, lack of sleep, and anaphylaxis, though rare, can also occur [40].

Diagnosis
The inspection of the possible infested area is necessary to ensure a proper diagnosis. Signs that

Fig. 12.4 Bed bug. A linear pattern of papular erythematous lesions on the leg

must be searched for include: the bed bugs' exoskeletons after molting; bed bugs in the fold of mattresses and sheets; rusty-colored blood spots resulting from the blood-filled fecal material that they excrete on the mattress or in the furniture; and the pungent odor they produce [41]. A quick search during the night with a flashlight (especially at 4:00 am) may aid in identifying these parasites [42].

Differential Diagnosis
Bites of fleas, parasitic mites, scabies (usually affects covered skin), dermatitis herpetiformis [42], and papulovesicular dermatitis of Gianotti–Crosti [40].

Therapeutic Approach
Bites and pruritus can be treated with systemic antihistaminic or topical corticosteroids and good hygiene to prevent any secondary infection of the skin. The infestation must be managed by a pest control professional [42]. The best way to prevent this infestation is to inspect the location for

signs of parasite. When sleeping in hotels or other unfamiliar places, a prudent approach is to check the premises for bed bugs and their excreta: mattress cords, crevices, cracks, headboards, and so forth [43].

Dipterous Larvae Infestations

Myiasis

Myiasis (from the Greek word for "fly," *myia*) refers to an infestation of human tissue by fly larvae, within the Diptera arthropod order, which feed on living tissue, body fluids, or ingested foods. The most common type of myiasis is cutaneous myiasis, which includes localized furuncular myiasis, typically caused by *Dermatobia hominis*, *Cordylobia anthropophaga*, *Wohlfahrtia vigil*, and *Cuterebra* spp.; creeping dermal myiasis (migratory) caused by *Gasterophilus* spp. and *Hypoderma* spp.; and wound and body cavity myiasis caused by screwworm flies *Cochliomyia hominivorax*, *Chrysomya bezziana*, and *Wohlfahrtia magnifica* [44, 45]. Less common types of infestation include enteric, ophthalmic, nasopharyngeal, auricular, oral, and urogenital myiasis [46].

Follicular Myiasis

Epidemiology

Myiasis is a worldwide infestation with seasonal variation; its incidence is higher in the tropics and subtropics of Africa and the Americas. The Tumbu fly, *C. anthropophaga*, is the most common vector for myiasis in Africa, while the human botfly, *D. hominis*, is endemic throughout Central and South America [45]. The *Cordylobia* genus also contains two less common species (*Cordylobia ruandae* and *Cordylobia rodhaini*). Infection by *C. rodhaini* (Lund's fly) is less common [47]. Autochthonous furuncular myiasis caused by accidental infestation of humans by larvae of flies belonging to the genus *Cuterebra*, commonly known as "rabbit botflies" or "rodent

botflies," has been reported in the United States [48]. Cutaneous myiasis is usually an uncomplicated and self-limiting disease.

Etiopathogenesis

D. hominis larvae are indirectly transmitted to vertebrate animals by blood-feeding arthropods such as mosquitoes, on whose abdomens the adult female botfly has deposited her eggs (means of transportation known as phoresy). When the blood-feeding arthropod takes a blood meal from a warm-blooded animal, the change in temperature causes the botfly eggs to hatch. The larvae painlessly enter the vertebrate host through a hair follicle or the bite site or by directly burrowing into the skin. Over the next 4–18 weeks, the larva grows by eating the flesh of its host and becomes pyriform to ovoid in shape until it reaches full development at lengths of 15–20 mm. At maturity, the larva emerges from the wound and falls to the soil where it pupates to form flies in 2–4 weeks [45, 46].

Clinical Presentation

In humans, the skin lesion starts within 24 h of penetration as a pruritic erythematous papule that gradually enlarges and develops into a furuncle. Typically, the center of the lesion has a central punctum (Fig. 12.5) from which serosanguinous fluid may be discharged and through which the larva breathes; the movement of the larva may be noticed by the patient. Lymphangitis and regional lymphadenopathy may be noted [45, 46].

Fig. 12.5 Follicular myiasis. Furuncular lesion on the back

Diagnosis

Diagnosis is typically made by identifying the fly larvae or maggots. The exact type of species can be difficult to determine by examination. A leucogram may show leukocytosis and eosinophilia. Histopathologic examination is not necessary, but if performed cutaneous biopsy findings include an ulcerated epidermis with an inflammatory infiltrate of neutrophils, lymphocytes, giant cells, mast cells, plasma cells, and eosinophils that occur in stages. The larvae can be seen in cross-section. Ultrasonography can also be very useful in establishing the diagnosis and determining the size of the larvae [46, 48].

Differential Diagnosis

Abscess, cellulitis, exaggerated arthropod reaction, furunculosis, ruptured epidermoid cyst, and tungiasis [45, 46].

Therapeutic Approach

Treatment for myiasis can be conservative or surgical. Noninvasive approaches include the application of heavy oil, occlusive ointment, pork fat, or bacon strips over the central punctum to interrupt the larva's respiration and forcing it to migrate to the surface of the lesion, from which it can be removed easily. Surgical treatment consists of the mechanical removal of the larva, which may be performed by the use of local anesthesia with lidocaine followed by primary wound closure. Lidocaine can also be injected forcibly into the base of the lesion in an attempt to create enough fluid pressure to extrude the larva out of the punctum [45, 46].

An alternative treatment for all types of myiasis is oral ivermectin or topical ivermectin (1% solution), which has proved especially helpful with oral and orbital myiasis [45].

Creeping Myiasis

Migratory myiasis, also called "creeping dermal myiasis," is caused by flies belonging to the *Gastrophilus* and *Hypoderma* genera. The first are usually gastrointestinal (*Gasterophilus intestinalis*) or nasal (*Gasterophilus nasalis*) parasites from horses; human myiasis caused by horse botflies (*Gastrophilus* species) is very rare. In humans the larvae initially produce a papular lesion, which resembles those seen in cases of furuncular myiasis, and then burrow and wander intradermally, creating narrow, tortuous, erythematous, and linear lesions with intense pruritus. This form of myiasis resembles cutaneous larva migrans [49].

The larvae of *Hypoderma* species are parasites from deer, cattle, and horses. Humans are abnormal hosts in which the parasite is unable to fully mature. In humans, the larvae migrate rapidly and erratically through the subcutaneous tissues, producing intermittent, painful swelling over months. The larvae may emerge spontaneously from the furuncles or die within the tissues. In rare cases the larvae are seen to invade the orbit, pharyngeal region, and spinal canal [49].

Wound Myiasis

Wound myiasis occurs when female flies deposit the eggs near poorly managed wounds, and the larvae feed on necrotic tissue. The majority (85–90%) of cases are caused by fly larvae belonging to the Calliphoridae family. The diagnosis is obvious when larvae are visible on the surface within or around the wound (Fig. 12.6) and more difficult when they have burrowed beneath the surface. Wound myiasis requires debridement with irrigation to eliminate the larvae from the wound or surgical removal [50].

Fig. 12.6 Wound myiasis. A traumatic ulcer from where larvae were removed

Helminthic Infections

Hookworm-Related Cutaneous Larva Migrans

Epidemiology

Hookworm-related cutaneous larva migrans is caused by cats' and dogs' intestinal hookworms *Ancylostoma braziliense*, *Ancylostoma caninum*, and *Uncinaria stenocephala*. Humans are not the final hosts, explaining why it is a self-limited disease. The disease is endemic in tropical climates; in developed countries this parasite normally only affects tourists returning from endemic areas [51].

Etiopathogenesis

When the infected animals defecate in the sand or soil, the eggs are eliminated through feces. In the environment they hatch and larvae should, under appropriate conditions (moisture, warmth, and shade), molt into the third stage, when human skin can be infected during direct contact with the contaminated soil or sand, into which the larvae actively penetrate. Since humans are not the definitive hosts, the larvae migrate within the epidermis and do not complete the hookworm's life cycle; therefore, the larva dies after 5–6 weeks [51].

Clinical Presentation

Feet, buttocks, and thighs are usually the most commonly affected parts, as they come into contact with contaminated soil. Intense pruritus starts shortly after the larval penetration within the epidermis, which seems to be caused by substances released by the larvae that irritate itching fibers [52]. A reddish papule indicates the site of penetration. After a variable period of time a serpiginous, erythematous, and elevated plaque is visible (Fig. 12.7) [53] and moves from one location to another, as the larva migrates aimlessly within the epidermis until it dies. Lesions are extremely itchy and bacterial secondary infection may occur [51]. Papular lesions may occur (Fig. 12.8); vesicobullous lesions have also been described in prior case reports, whose pathophysiology is still unknown [54].

Folliculitis is an uncommon manifestation associated with a serpiginous track and resistance to treatment [55].

Fig. 12.7 Cutaneous larva migrans. Erythematous, single-track linear and serpiginous lesions

Fig. 12.8 Cutaneous larva migrans. Papular erythematous lesions on the face

Diagnosis

The diagnosis is clinical [51–53].

Differential Diagnosis

Scabies, loiasis, myiasis, cercarial dermatitis, tinea corporis, and contact dermatitis [53]. Larva currens affects the thighs, perianal

Table 12.2 Treatment for cutaneous larva migrans

Drug	Adult dose	Pediatric dose
Albendazole	400 mg/day orally for 3–7 days	Children >2 years of age: 400 mg/day orally for 3 days
		Contraindicated for children <2 years of age
Ivermectin	200 μg/kg body weight orally in a single dose	Children >15 kg body weight: 200 μg/kg/day orally in a single dose
	Contraindicated in pregnant and lactating women	Contraindicated in children <15 kg body weight

Source: Centers for Disease Control and Prevention [51]

region, and trunk; larvae migrate faster than animals' hookworms, and lesions last for just a few hours [56].

Therapeutic Approach

Freezing the lesions is not recommended; this treatment has proved ineffective, since the larva is usually located beyond the visible track and causes pain, ulcers, and blisters [55].

A 10–15% topical thiabendazole solution applied three times daily for 1 week has the advantage of the absence of systemic side effects. Its disadvantages include a limited effect against multiple lesions and folliculitis and necessity of its application several times a day [55].

Treatment with systemic albendazole or ivermectin is curative. In cases of folliculitis, additional doses may be necessary. Children under 2 years of age or under 15 kg body weight may be treated with topical preparations. Albendazole is a pregnancy category C agent and should only be prescribed if the potential benefit justifies the potential risk to the fetus [51]. These drugs are curative choices. Systemic thiabendazole is associated with several side effects; therefore, its use is not recommended [52]. Table 12.2 shows the different dosage regimens.

Protozoal Infections

Leishmaniasis

Epidemiology

Leishmaniases are a group of diseases caused by protozoan parasites of the genus *Leishmania*. The disease is transmitted to humans by the bite of infected female sandflies (*Phlebotomus* or *Lutzomyia* spp.). The clinical manifestations depend on the extent of the involvement and can be broadly classified as cutaneous leishmaniasis (CL), the most common variety, visceral leishmaniasis (VL) or kala-azar, the most deadly parasitic infection after malaria, and mucocutaneous leishmaniasis (MCL), with its disfigurement potential [57].

The World Health Organization (WHO) estimates the global incidence of VL as 300,000 cases with over 20,000 deaths annually, and 1 million cases of CL have been reported in the past 5 years [58]. The WHO ranks CL as a category 1 (severely neglected) emerging and uncontrolled disease [59] and has created the slogan "Small bite, big threat" to highlight the increasing burden of vector-borne diseases [60, 61].

Globally, human leishmaniases are endemic in 98 countries and three territories, with the exception of Antarctica and Australia [62]. VL exists in the eastern and western hemisphere and more than 90% of the cases are reported in poverty-stricken countries such as India, Bangladesh, Sudan, Ethiopia, and Brazil, with a mortality rate of 10–20% [63]. CL is more widely distributed, with about one-third of the cases occurring in the Americas, the Mediterranean Basin, and Western Asia from the Middle East to Central Asia. The ten countries with the highest estimated case counts (Afghanistan, Algeria, Colombia, Brazil, Iran, Syria, Ethiopia, North Sudan, Costa Rica and Peru) together account for 70–75% of the estimated incidence of CL worldwide [62]. New World CL extends from Central and South Texas throughout Latin America, with the exception of Chile and Uruguay. Nearly 90% of MCL cases are from Bolivia, Brazil, and Peru [58].

Historically regarded as a disorder of tropical and subtropical regions, leishmaniasis has dramatically

expanded its boundaries. This change in the epidemiologic profile is largely favored by climate changes, increased touristic and work-related traveling, uncontrolled urbanization, deforestation, and massive migration caused by civil conflict and war [64–67].

Etiopathogenesis

Leishmaniasis is caused by different protozoa of the genus [68]. All species involved in Old World leishmaniasis are distinct from those found in New World leishmaniasis, with the exception of *Leishmania infantum*, which has been proved to be indistinguishable from *Leishmania chagasi* [69]. Two morphologic forms are recognized in the lifecycle of *Leishmania*: an extracellular, motile, 15–20 μm long, flagellated promastigote (leptomonad form) found in the invertebrate host, and an obligate intracellular, nonmotile, 3–5 μm long, nonflagellated amastigote (leishmanial form) observed inside the macrophages of the mammalian host [79]. During a sandfly's blood meal on an infected host, ingested amastigotes are retransformed back in promastigotes into the insect gut, multiply, and are ready to be injected in silvatic or human hosts. Once in the mammalian host, promastigotes are captured by macrophages and turned into amastigotes. Both amastigote and promastigote forms multiply by binary fission in the vertebrate host's macrophages or in the sandfly digestive tube, respectively [70].

A wide range of animals, with remarkable geographic variations, can serve as vertebrate hosts, such as rodents, marsupials, dogs, bats, baboons, leopards, sloths, foxes, and hyenas [62]. New World leishmaniasis is fundamentally a zoonosis; i.e., parasites causing the infection are those from wild animals. Whether infected humans can be a source of protozoa for sandflies is still a matter of dispute [61]. Old World leishmaniasis occurs as a zoonosis and, occasionally, as an anthroponosis (*Leishmania tropica*).

In natural silvatic hosts, the disease is usually benign or unapparent. Peridomiciliary animals such as horses, mules, and dogs may eventually present with lesions demonstrating that they are, like humans, unnatural hosts to *Leishmania*. Most of the reported cases are caused by *Leishmania braziliensis* [61].

Genomic differences acquired during the evolution of *Leishmania* may well explain the preference of some species to target the skin or invade visceral organs [71]. *L. tropica*, *Leishmania major*, and *Leishmania aethiopica* cause skin lesions in the Old World, while infection by *Leishmania donovani* results in visceralization and *L. infantum* can promote both visceral and skin involvement. Anergic diffuse CL (ADCL) has been associated with infection caused by species of the *Mexicana* complex (*Leishmania amazonensis*, *Leishmania mexicana*, and *Leishmania pifanoi*) in the New World, and *L. aethiopica* in the Old World [61]. Mutilating, destructive MCL is observed only in New World and is related to *L. braziliensis*, *Leishmania guyanensis*, *Leishmania panamensis*, and *Leishmania peruviana* infection, whereas *L. aethiopica* may cause localized anatomic distortion because of oronasal lesions.

Murine models for CL have shown the key role of Th1 CD4+ cells. In brief, interacting with an antigen-presenting cell exposed to the parasites, CD4+ Th lymphocytes release interferon-γ which, in turn, activates the production of nitric oxide by macrophages, resulting in the killing of the amastigotes [72]. Localized, self-healing lesions have a predominant Th1 profile, while the Th2 profile is found in diffuse and nonhealing lesions. These immune responses also account for the diverse clinical manifestation of leishmaniasis [73].

Clinical Syndromes

Infection by *Leishmania* in humans produces a full spectrum of manifestations, ranging from asymptomatic to lethal. This fact is strikingly remarkable since leishmaniases are caused by morphologically similar organisms living in a single series of cells [74]. The resulting clinical

Fig. 12.9 Cutaneous leishmaniasis. An ulcer with slightly elevated and indurated borders with a *reddish* and crusted base

presentation depends on a complex interplay involving infecting species, vector, immune response mounted by the host, nutritional status, age, inoculation site, and genetic background [64, 75]. Three clinical syndromes (VL, CL, and MCL) and two distinct entities (ADCL and post-kala-azar dermal leishmaniasis, PKDL) are recognized. VL clinical manifestations, diagnosis, and therapeutic approaches are not discussed in this chapter.

Cutaneous Leishmaniasis

CL is the most common and the least severe form of the disease. It is characterized by one or more lesions that develop from weeks to months after the bite and favor exposed areas (face, upper and lower limbs). The initial lesion, a patchy erythema with variable induration, is quite nonspecific and rarely seen by the examining physician. From this starting point the disease may run a variable course, ranging from spontaneous healing to progression to papules, nodules, ulcers, and mucous membrane involvement [76]. Enlargement of lymph nodes adjacent to skin lesions may be occasionally observed.

The typical ulcer is rounded, crater-like, with a raised (framing) border (Fig. 12.9). As it is

Fig. 12.10 Cutaneous leishmaniasis. Keratocanthoma-like tumoral lesion

observed in both Old World and New World forms, the causative species may not be inferred by the appearance of the lesion [61].

The polymorphous status of cutaneous lesions is expressed by a vast array of adjectives employed in their description: impetigoid, lupoid, verrucous, lichenoid, framboesiform (raspberry-like), tumoral, vegetative, verrucous, and so forth (Figs. 12.10, 12.11, and 12.12). Of note, all lesions in CL share the common feature of being asymptomatic.

the lower leg

Fig. 12.11 Cutaneous leishmaniasis. Sporotrichoid-nodular form of leishmaniasis on the lower leg

Fig. 12.12 Cutaneous leishmaniasis. Vegetating knee ulcer

Mucocutaneous Leishmaniasis

Although MCL has been attributed, in rare instances, to *L. guyanensis* and *L. panamensis*, the vast majority of cases in the New World are caused by *L. braziliensis* [61]. Mucosal lesions may result from the extension of a contiguous skin lesion (Fig. 12.13) or by hematogenic or lymphatic dissemination (Fig. 12.14). Early signs include nasal congestion, bleeding, and hoarseness. Rapid invasion of the nasal mucosa with mutilation may ensue. It is not clearly understood why some patients infected by *L. braziliensis* develop MCL while others remain with lesions restricted to the skin. Associated risk factors include incomplete or missing treatment of the primary CL, malnutrition, large and multiple lesions, male gender, and genetic background [64, 77].

Anergic Diffuse Cutaneous Leishmaniasis

Characteristically, multiple skin-colored, painless papules and nodules, with no tendency to ulcerate, appear on the face, ear, elbows, and knees and may slowly progress to involve the entire body surface and, eventually, mucous membranes. Colonic infiltration has been reported in patients with immune reconstitution inflammatory syndrome after initiation of highly active antiretroviral therapy [78]. The multiple nodules on the face are reminiscent of leonine

Fig. 12.13 Mucocutaneous leishmaniasis. Nasal erythema and edema, ulceration, and bleeding of the nasal septum as well as erythematous infiltration of the skin around the nose

Fig. 12.14 Mucosal leishmaniasis. Granulomatous gingival enlargement

facies, hence the term lepromatous leishmaniasis. ADCL has also been simply referred to as diffuse or disseminated leishmaniasis. These are clearly misnomers given that immunologically competent patients may present perfectly curable multiple lesions [61]. Therefore the term anergic, which denotes the defective cell-mediated response (a Montenegro skin test is always negative), the hallmark of ADCL, should be compulsory.

The lesions contain an enormous number of large-sized parasites, and treatment resistance is common. New World ADCL is caused by *L.*

amazonensis, *L. mexicana*, and *L. pifanoi* (all belonging to the *Mexicana* complex) while *L. aethiopica* is the offending species in Old World ADCL.

Diagnosis

The diagnosis is based on clinical features, epidemiologic data, and laboratory tests. As with any other infectious disease, the diagnosis can only be formally confirmed by the demonstration of the parasites. The most effective and less expensive method is the identification of parasite by light microscopic examination of a stained specimen (Giemsa, Wright, or Feulgen stain) [80]. The edge of a recently appeared lesion is the site of choice to obtain tissue samples by scraping, biopsy, or needle aspiration. On light microscopy, the amastigotes within the cytoplasm of tissue macrophages are seen as pale-blue oval bodies measuring 2–3 μm in length and present a dark-blue nucleus and a deep red or violet rod-like paranuclear body called a kinetoplast (Fig. 12.15) [81]. ADCL is known for its abundance of parasites, whereas the chances of detection in CL and MCL are inversely proportional to the duration of the infection.
Fig. 12.15 Cutaneous leishmaniasis. Skin biopsy examination shows an inflammatory perivascular and interstitial infiltrate consisting of plasmocytes, lymphocytes, and vacuolated histiocytes which contained amastigotes (hematoxylin–eosin, ×40)

Complementary Examinations

Leishmania can be cultured in monophasic (Schneider's insect medium, M199, or Grace's medium) or diphasic media (Novy-McNeal Nicolle medium and Tobies medium). Cultures should not be discarded as negative before 4 weeks. Some strains will not grow in culture and require inoculation into susceptible animals, such as hamsters. Because of the prolonged time required to obtain results (7–9 months), animal inoculation is not employed in routine clinical practice.

The polymerase chain reaction (PCR), the most sensitive, specific, and fastest method currently available, is the best approach to diagnose leishmaniasis but requires adequate infrastructure and technically skilled operators [59, 82]. In cases where the parasite load is low, such as in long-standing cutaneous lesions, mucosal impairment, and immunosuppression, PCR is especially useful [83]. As an additional advantage, PCR can also identify *Leishmania* species. This may be relevant in areas where leishmaniasis is caused by different parasites with distinct treatment response [84].

Different evaluated PCR methods demonstrate superior sensitivity when compared with microscopy smear and in vitro cultures [85, 86]. However, the best diagnostic approach is the combination of different laboratory tests to increase detection sensitivity [87]. In an endemic area of CL due to *L. guyanensis* and *L. braziliensis*, the combination of skin smear, PCR, and histopathology increased diagnostic sensitivity to 94% [88].

Serologic assays are rarely used for CL and MCL because of the poor humoral response generated by the infection and, therefore, low sensitivity [89]. The Montenegro skin test, also known as the leishmanin test, is used to measure the cell-mediated immune response by injecting 0.1 ml of a phenol-killed preparation of *Leishmania* promastigotes in the anterior aspect of the forearm. After 48–72 h, the reaction is measured and an induration of 5 mm or more is considered positive. However, this test does not differentiate past exposure from active disease and may remain positive after cure [90]. Active PKDL and ADCL show a negative intradermal test.

The histopathologic findings of the skin specimen depend largely on the stage of development of the lesion, host response, and degree of cellular immunity [64]. A spectrum of features, similar to that observed in leprosy, can be found. The anergic pole shows abundant parasites in the cytoplasm of macrophages, no giant cell or ulceration, and little necrosis. The opposite hyperergic pole is tuberculoid, displays epithelioid cell granulomas, large Langerhans cells, and few or no detectable parasites. Between these stable poles a wide variety of histopathologic changes, such as hyperplasia, polycellular infiltrate, necrosis, ulceration, and healing can be observed [74].

Differential Diagnosis

Initial papules or crusted lesions should be differentiated from arthropod bites and impetigo. Buruli ulcer, stasis ulcer, and pyoderma gangrenosum should be included as differential diagnoses of ulcerated lesions, while the possibility of neoplastic

skin conditions (basal and squamous cell carcinoma, lymphoma) or sarcoidosis should be considered when verrucous, plaque, or nodular lesions are present. Sporotrichosis, North and South American blastomycosis, chromomycosis, leprosy and other mycobacterioses, botryomycosis, syphilis, myiasis, tungiasis, furuncle, ecthyma, and carbuncle may resemble CL. ADCL may be difficult to distinguish from lepromatous leprosy and lobomycosis.

Therapeutic Approach

There are multiple therapeutic options for CL and MCL. Since treatment is often prolonged and potentially toxic, species determination may be desirable as some drugs are only effective against certain *Leishmania* species and only in the geographic region of the infection [87, 90].

Antimonial chemotherapy remains the most commonly used therapeutic option for New World CL because this disease tends to be more long-lasting and severe, and poses a higher risk of mucous involvement than its Old World counterpart [80]. Amphotericin B deoxycholate and pentamidine have been used as second-line drugs. Over the past 10 years, lipid formulations of amphotericin B and miltefosine have been approved for the treatment of all clinical forms of leishmaniasis. However, the efficacy and required dosage of several of these agents have not been established in all endemic areas and may even differ from area to area [90].

Pentavalent antimonials include meglumine antimoniate (Glucantime®; 81 mg Sb^{v+}/ml) and sodium stibogluconate (Pentostam®; 100 mg Sb^{v+}/ml). The recommended dose for New World CL is 10–20 mg Sb^{v+}/kg/day of Glucantime for a period of 20 days, with an efficacy of 53.6% [91] to 56.9% [99] for *L. guyanensis*, compared with 78% for *L. braziliensis* [92]. The recommended dose for MCL treatment is 20 mg Sb^{v+}/kg/day for a period of 30 days. Side effects include arthralgia, myalgia, loss of appetite, nausea, vomiting, abdominal pain, pruritus, fever, weakness, headache, dizziness, insomnia, edema, hepatitis, acute renal failure, pancreatitis, electrocardiographic changes, and bigeminal, polymorphous, and polyfocal extrasystoles [90].

Amphotericin B deoxycholate is a polyene antibiotic whose recommended dose is 0.5–1.0 mg/kg by intravenous infusion in 5% dextrose for 4 h, daily or every other day, in 15–20 doses. Fever, nausea, vomiting, and phlebitis at the infusion site are common side effects; nephrotoxicity may also occur. Other uncommon toxic effects include anemia, leukopenia, hypokalemia, and myocarditis [90].

Several formulations, including liposomal amphotericin B, amphotericin B lipid complex, and amphotericin B colloidal dispersion have been used for the treatment of all clinical forms of leishmaniasis. Their efficacy is similar to that of the deoxycholate drug, but lipid formulations of amphotericin B are significantly less toxic [93].

Pentamidine is a synthetic derivative of amidine administered intramuscularly or intravenously. The recommended schedule is a 3-dose regimen of 4 mg/kg every 72 h, with an efficacy of 60.3% for New World CL due to *L. guyanensis* [84]. A recent phase II pilot study showed that a single dose of 7 mg/kg might be as effective and safe as the three-dose regimen for the treatment of CL in the same geographic area [94]. Adverse effects are sterile abscesses at the injection site, nausea, vomiting, dizziness, adynamia, myalgia, headache, hypotension, syncope, transient hyperglycemia, and hypoglycemia.

Miltefosine is a phospholipid drug originally developed as an antineoplastic agent. It is the first clinically active oral antileishmanial drug commercially available for the treatment of CL [95]. The drug is registered for treatment of leishmaniasis in several countries and has been recently approved by the US Food and Drug Administration for the treatment of CL and MCL (due to *L. braziliensis*, *L. panamensis*, and *L. guyanensis*) [87]. Miltefosine is administered orally for 28 days at the daily dosage of 2.5 mg/kg for children aged 2–11 years; for patients aged ≥12 years, 50 mg/day for those weighing <25 kg, 100 mg/day for 25–50 kg body weight, and 150 mg/day for >50 kg body weight. The drug is contraindicated in pregnant women, and nursing mothers should be advised not to breastfeed during the treatment course and for 5 months thereafter. Common

reported gastrointestinal side effects are anorexia, nausea, vomiting, and diarrhea, which are usually brief and tend to resolve as treatment is continued [90]. The effectiveness of miltefosine has been variable in different *Leishmania* species causing CL. In CL caused by *L. guyanensis* its clinical efficacy was 71.4% [91], from 33% [57] to 75% [58] for *L. braziliensis*, 60% for *L. Mexicana* [57], 91% for *L. panamensis* [96], and 81.3% *L. major* [97]. Therefore, physicians should be aware that identification of *Leishmania* species may be necessary to better treat patients or tourists, especially those living in or traveling to Central and South America.

Ketoconazole, itraconazole, fluconazole, and allopurinol, all with discordant results, are reported as oral treatment options. Local therapeutic approaches include intralesional pentavalent antimonials [60, 61], topical application of paromycin sulfate [98, 99] and physical modalities such as cryotherapy, thermotherapy, curettage, and electrodissection [80].

In HIV-CL coinfected patients, the therapeutic options are mainly pentavalent antimony and amphotericin B in the same regimen used for immunocompetent patients. Pentamidine is not recommended as it may cause sterile abscess. Coinfected patients require close monitoring of CD4 cell count, and secondary prophylaxis with pentavalent antimony should be considered.

Prevention

To date, no vaccine or drugs to prevent *Leishmania* infection are available. Preventive measures are aimed at reducing the contact with sandflies. Travelers should be advised to avoid outdoor activities whenever possible, wear protective clothing, apply insect repellent, and sleep in air-conditioned or well-screened areas [100]. Measures to combat the vectors should be also employed.

Glossary

Amastigote Two developmental stages are formed (*Leishmania*): the amastigotes are small spherical nonflagellated cells ranging from 2 to 4 μm in diameter. The nucleus and kinetoplast are surrounded by small ring of vacuolated cytoplasm and the cells are among the smallest nucleated cells known.

Anergic pole/hyperergic pole The two pathogenicity extremes of the spectrum generally recognized are represented at the hypersensitivity pole by mucocutaneous leishmaniasis (MCL) and at the hyposensitivity pole by anergic diffuse cutaneous leishmaniasis (ADCL).

Colonization The human body harbors a large number of bacteria but their localization in healthy individuals is normally restricted to certain body areas such as the skin, the mucosae of buccal and nasal cavities, vagina, and, most importantly, the gastrointestinal tract. Colonization is the act of setting up a colony away from one's place of origin.

Ectoparasite A parasite that lives on or in the skin but not within the body.

Fomite A fomes or fomite is any nonliving object or substance capable of carrying infectious organisms, such as germs or parasites and hence transferring them from one individual to another. Skin cells, hair, clothing, and bedding are common hospital sources of contamination.

Hyaluronidase A family of enzymes that degrade hyaluronic acid.

Infestations Parasites, including harmful nanites, cause infestations, which are a type of affliction similar to diseases. Also known as or related to infestation by pediculus, pubic louse infestation, pediculosis pubis, and pediculosis.

Monilethrix A condition that affects hair growth. Its most characteristic feature is that individual strands of hair have a beaded appearance like the beads of a necklace.

Promastigote Two developmental stages are formed (*Leishmania*): amastigotes and promastigotes. Promastigotes are thin elongated cells with an anterior kinetoplast and an emergent free flagellum.

Proteases Any enzyme that performs proteolysis, that is, begins protein catabolism by hydrolysis of the peptide bonds that link amino acids together in a polypeptide chain.

Skin microbiota The skin flora, more properly referred to as the skin microbiota, are the microorganisms which reside on the skin.

Th1 response The Th1 response is characterized by the production of interferon-γ, which activates the bactericidal activities of macrophages, induces B cells to make opsonizing (coating) and complement-fixing antibodies, and leads to cell-mediated immunity.

Th2 response The Th2 response is characterized by the release of interleukin-5, which induces eosinophils in the clearance of parasites. Th2 also produce interleukin-4, which facilitates B-cell isotype switching. In general, Th2 responses are more effective against extracellular bacteria, parasites including helminths, and toxins.

Trichorrhexis nodosa A defect in the hair shaft characterized by thickening or weak points (nodes) that cause the hair to break off easily.

Part III

Dermatologic Diseases in Public Health: Neoplasias

Precursor Lesions of Skin Cancer

13

Majoriê Mergen Segatto
and Eloísa Unfer Schmitt Botton

Key Points
- Review the relevant skin lesions that are skin cancer precursors
- Facilitate the clinical recognition of skin cancer precursor lesions
- Summarize the current treatment modalities and conduct of each skin cancer precursor lesion
- This chapter is divided into three main groups of precursor lesions: cutaneous melanoma, basocellular carcinoma, and spinocellular carcinoma.
- In the cutaneous melanoma precursors lesions group we discuss congenital melanocytic nevus, dysplastic nevus, and acquired melanocytic nevus.

- In the basocellular carcinoma precursor lesions group we discuss nevus sebaceus.
- In the spinocellular carcinoma precursor lesions group we discuss actinic keratoses, porokeratosis, cutaneous horn, chronic scars, oral leukoplakia and erythroplakia, oral lichen planus, lichen sclerosus, and precursor lesions of skin cancer related to human papillomavirus.

Introduction

Skin cancer, more common than any other type of cancer [1], can be divided into two main groups: cutaneous melanoma (CM) and nonmelanoma skin cancer (NMSC), which includes basocellular carcinoma (BCC) and spinocellular carcinoma (SCC).

CM is the sixth most common neoplasia in men and the fifth most common in women. It comprises 5% of diagnosed skin cancers but is responsible for most of the deaths in this group [2]. According to the International Agency for Research on Cancer, 232,100 new cases of

melanoma were estimated worldwide in 2012, considering both sexes [3].

On the other hand the figures for NMSC are very difficult to estimate, as it is not mandatory to record these cases [4, 5]. The most recent study estimated 3.5 million new cases in 2.2 million people in the United States in 2006 [6]. Moreover, very significant costs are associated with skin cancer treatment, and it is among the five neoplasias that are most expensive to treat in the United States [7].

Although NMSCs usually grow slowly and do not often metastasize, especially BCC, these tumors may insidiously invade the local tissue, causing tissue destruction, functional impairment, and body disfigurement. BCC can also invade nerves and other vital structures, such as the eyes [8].

In view of the impact of skin cancer on public health, this chapter is dedicated to the recognition and treatment of melanoma and NMSC precursor lesions.

Cutaneous Melanoma Precursor Lesions

Approximately 65–80% of CMs begin in healthy skin (de novo melanoma) and thus 20–25% of these develop from a previous skin lesion that we can define as a precursor lesion [9–13].

Three main groups of pigmented cutaneous lesions can be CM precursors: congenital melanocytic nevus (CMN), dysplastic/atypical nevus, and acquired melanocytic nevus (AMN).

Congenital Melanocytic Nevus

CMN is a melanocytic nevus that is present at birth or, rarely, up to 2 years of age [14, 15]. Some researchers proposed a classification of CMN according to their larger diameter in adult life: small (<1.5 cm), intermediate (or medium) (1.5–19.9 cm), and large (or giant) (≥20 cm) [14, 16] (Fig. 13.1a, b).

CMN begins between the 5th and 24th week of pregnancy [17] and is believed to result from the rapid proliferation of melanocytic lineage cells resulting from some morphologic error of the neuroectoderm during the migration of the melanoblasts from the neural crest to the skin [14, 18, 19]. The earlier the acceleration process begins during embryogenesis, the larger and deeper the nevus will be [14].

The potential risk of developing melanoma from a CMN is probably related to its size; that is, the larger the nevus, the greater the risk. The risk of melanoma associated with a small CMN is considered low and probably no greater than that of an AMN [15].

On the other hand, controversy exists regarding intermediate CMN. A study followed 230 intermediate CMN in 227 patients over 6.7 years and did not detect the onset of melanoma during this period [20]. Another study evaluated the incidence of melanoma and mortality in 265 patients and did not detect melanoma in CMN of <5% of body area [21]. According to Alikhan et al. [22], most studies show a melanoma incidence <1% in small and medium-sized CMN, which is similar to the risk of CM over a lifetime (1.97%). Thus, recent studies suggest that the medium-sized (and small) CMN are not associated with a significant risk of CM [15].

On the other hand, the risk of CM associated with giant CMN (GCMN) is well established [14–16, 21, 22], and in up to 70% of cases it can occur before puberty [23]. Although the real incidence is still controversial, the estimated risk of patients with GCMN developing CM during their lifetime is 5–10% [14].

The incidence of GCMN is estimated as less than 1 in 20,000 newborns [6], and the prevalence varies from 0.5% to 31.7% [22].

Clinically, GCMN generally presents as a brownish lesion with defined margins and hypertrichosis [14]. However, its clinical presentation may vary individually and change with age. At birth they are usually lighter-colored, flat, and with little or no hairs, but over time their appear-

ance can change [14, 22]. A common change is the onset of macules or small papules, darkish brown and flat or slightly elevated in the initial lesion [22]. Most nevi become elevated, forming a plaque that may have a warty, papular, rough, or cerebriform surface [14, 22]. The most frequent site is the trunk, followed by the extremities and head, but it may affect more than one body segment [14]. It is common for benign melanocytic growth to occur, known as "proliferative nodules" in GCMN, which may be clinically and histologically confounded with CM. Moreover, GCMN are often associated with satellite CMN, smaller lesions that may be multiple [15, 22]. The presence of these satellite lesions may increase the risk for CM [23].

The diagnosis of GCMN is basically clinical [14]. Histologically, peculiar findings that may be present are nevic cells in the deep reticular dermis, which may reach the subcutaneous fat and fascia in addition to the adnexal structures, vascular walls, eccrine glands, collagen fibers, and cutaneous nerves [14, 15, 22]. The fact that nevic cells are deeper in the dermis is one of the reasons why dermatoscopy of little use in these cases. In addition, because of this particularity the CM related to GCMN are not of epidermal origin in up to two-thirds of cases, and generally occur in deeper layers of the dermis [24]. This leads to a later diagnosis of the neoplasia, since it is more difficult to detect through clinical tests [14], and contributes to a worse prognosis, because the presence of neoplastic cells in the deeper layers makes it easier for early metastasis to occur from tumor propagation via blood vessels and lymphatic vessels [25].

One of the serious complications of GCMN is neurocutaneous melanosis, a rare syndrome characterized by the presence of malignant or benign proliferations in the central nervous system (CNS), associated with melanocytic congenital lesions and clinical manifestations that are usually the consequence of increased intracranial pressure because the proliferations obstruct the ventricular system [14].

An interesting finding demonstrated by DeDavid et al. [26] was that only 50.7% of CM in individuals with GCMN involved the nevus. The remainder was primary tumor of the CNS, a metastatic tumor without a primary site, and CM unrelated to the nevus.

No single validated approach is used to manage GCMN [22]. The decision to remove a GCMN is individualized and based on the patient's age, site of the lesion, risk for CM, presence or absence of neurocutaneous melanosis, complexity of removal, cosmetic result, and the presence of modifications suggesting malignancy [14, 15]. Theoretically, prophylactic excision would provide the best chance of reducing malignant change in the GMN because it removes the tissue (and the nevic cells). However, no evidence indicates that removing the nevus is prophylactic for the occurrence of CM, and no study has documented the benefit of excision over clinical observation [14, 27].

It is important to carry out periodic follow-ups, besides palpating the lesion and lymph nodes and photographing the nevus to make monitoring easier. Even the patients who have had the nevus completely removed must be monitored periodically for easier early detection of malignancies [14].

Dysplastic Nevus

Dysplastic nevus (DN) is described as a continuum between the common acquired nevus and the melanoma, since it is morphologically and biologically the intermediate between these two entities [28]. Since it was reported for the first time by Clark in 1978, its definition, classification, and biological importance have been discussed, and so far there is no consensus about its nomenclature [28, 29].

Often the terms atypical nevus and dysplastic nevus have been used inadequately as synonyms, since the former is a clinical finding and the latter a histologic finding. Moreover, a few lesions without clinical atypia can reveal dysplasia, and the contrary may also occur [30]. However, as yet there is no single definition of nomenclature for these lesions accepted by all dermatologists and pathologists [28]. For didactic reasons, in this chapter we use the term dysplastic nevus.

The mean clinical prevalence of DN has been reported as between 2% and 18% of the Caucasian population with histologic findings of dysplasia in 10% [31].

DN is important primarily because it simulates CM, besides being a phenotypic marker of individuals at increased risk for CM [30–34]. The largest meta-analysis performed until now showed that, among 13 studies with dichotomic data, the presence of any DN (the article uses the term atypical nevus) increased the risk for melanoma tenfold compared with the absence of DN (relative risk (RR) = 10.12; 95% confidence interval (CI) 5.04–20.32). When 15 studies were evaluated with continuous data according to the number of dysplastic nevi, patients with a history of a single nevus showed RR = 1.60 (95% CI 1.38–1.85) for developing CM, rising to 10.49 (95% CI 5.05–21.76) for those with five DN [34].

DN syndrome, characterized by the presence of more than 100 common nevi including at least one dysplastic and one larger than 8 mm, carries an even greater risk for CM. This syndrome may be sporadic or familial, with different classifications based on the degree of relationship and the personal history of DN or melanoma [31].

The role of DN as a precursor is less important because there is little evidence that a DN will progress to a CM at a greater rate than a common nevus [30, 32]. A calculation based on the fre-

quency of DN and CM estimated that only 1 in 10,000 DN will progress to CM per year [35].

Clinically, the Agency for Research on Cancer proposed a protocol that includes the following characteristics: presence of a macular component in at least one area of the lesion plus the presence of one of the following: ill-defined border, size ≥5 mm, varied colors, irregular border, and erythema [36] (Fig. 13.1c). The DN typically becomes visible in puberty and predominates in people younger than 30–40 years, compared with older populations [31].

There is an extensive discussion regarding the histologic criteria of DN. The most important are the presence of cytologic atypia and architectural disorder [32]. According to the World Health Organization (WHO), two major criteria and at least two minor ones are needed for its diagnosis (Table 13.1). Using these criteria, there is 92% concordance in distinguishing between the common melanocytic nevi, DN and CM [37]. Some studies have also already shown a relation between the degree of dysplasia and the risk for CM, which was greater in moderate and severe dysplasias [38, 39].

According to the available evidence, the clinical diagnosis of DN (or DN syndrome) does not require histologic confirmation, since most of the DN will not progress to CM unless there is clinical suspicion of the latter [30–33, 35]. Therefore prophylactic removal is not cost effective, besides giving the patients a false feeling of safety, since the risk for melanoma may remain after the nevus is removed [35].

The general approach to the care of patients with DN includes obtaining a detailed history, including information on the history of skin cancer, previous removals of nevi, episodes of sunburn and exposure to ultraviolet (UV) radiation, and family history of melanoma and DN [31, 35]. This information will help stratify the risk for CM.

It is necessary to perform a complete examination of the skin including protected areas and the scalp. The revisions can be done 6 months after the initial baseline examination and then once a year, or more frequent follow-up if there is a personal history of melanoma. Patients should be advised to request an earlier visit if they notice a newly appearing lesion to be suspicious or a change in a pre-existing lesion [35]. At each visit it is important to reiterate preventive and educational measures regarding protection and precautions against sunlight [31, 35].

We can use diagnostic aids such as dermoscopy, total body photography, and digital imaging devices to facilitate the early detection of melanoma. Dermoscopy has been shown to significantly improve diagnostic accuracy, although the diagnostic performance depends on examiner experience [40]. Similarly, using photography has been shown to improve the diagnosis of subtly changing melanocytic lesions that do not meet clinical criteria for melanoma, facilitating early diagnosis as well as limiting unnecessary biopsies of clinically suspicious lesions that are stable over time [41].

When any suspicious lesions are detected, biopsy is necessary. The recommendation is an excision with 1- to 3-mm margins and also a deep margin of subcutaneous fat. However, if the suspicion for melanoma is low or excisional biopsy is unreasonable based on anatomic location, other techniques such as shaving or incisional biopsy may be appropriate [42, 43].

Acquired Melanocytic Nevus

It has already been demonstrated in several studies that AMN is a risk marker for CM, especially when a large number of them are apparent [44, 45].

Table 13.1 World Health Organization (WHO) histologic criteria for dysplastic nevus

Major criteria	Minor criteria
Basilar proliferation of atypical melanocytes that must extend at least 3 rete ridges beyond the dermal component	Lamellar fibrosis or concentric eosinophilic fibrosis
	Neovascularization
Organization of this proliferation in a lentiginous or epithelioid-cell pattern	Inflammatory response
	Fusion of rete ridges

A meta-analysis performed in 2005 observed a dose-response pattern with increased RR for the development of CM as the number of common nevi increased. When individuals with up to 15 nevi all over their body were considered as baseline, an RR of 1.47 (95% CI 1.36–1.59) was obtained for patients with 16–40 common nevi, 2.24 (1.90–2.64) for those with 41–60 common nevi, 3.26 (2.55–4.15) for those with 61–80 nevi, 4.74 (3.44–6.53) for those with 81–100 nevi, and 6.89 (4.63–10.25) for patients with 101–120 common nevi [34].

Melanomas associated with nevi occur more frequently on the trunk and in younger patients, and are more commonly of the superficial spreading type [46–49] (Fig. 13.1d).

However, their role as precursors is still controversial [50, 51]. The most convincing evidence in favor of this theory is the association between nevus and CM observed both clinically and histologically, since approximately 20–30% of the melanomas are associated with nevi in histology [46, 47, 50].

A study evaluated the frequency of the histologic association of benign melanocytic lesions with 289 cases of CM that were at most 1 mm thick, and detected that 41% of the cases were associated with AMN [50].

Moreover, information about the molecular profile of the associated CM and AMN can help clarify the pathogenesis of this subtype of melanoma [50]. In a recent study, the status of six genes was evaluated in 61 cases of melanomas and their associated nevi, whereby a concordance rate of 66.7% was found: 46.6% of the CM and 51.6% of the nevi showed mutations in BRAF V600E, and 17% of the melanomas and 12% of the nevi showed mutations in NRAS [52]. These data supported the hypothesis that nevus associated with melanoma is their precursor [50].

Given these data, when a nevus has changed over time or clinically leads to a suspicion of melanoma, it is indicated for removal [15].

Basocellular Carcinoma Precursor Lesions

Nevus Sebaceus

Nevus sebaceus (NS) is a hamartoma of epithelial and nonepithelial origin that is often referred to as an organoid nevus because it may contain any or all components of the skin [53, 54]. It usually presents as a round, oval, or linear, smooth, yellowish-orange plaque on the head, neck, and scalp (87–95% of cases) leading to alopecia [55] (Fig. 13.2). Histology reveals hyperkeratosis, acanthosis, increased sebaceous lobules, primitive hair follicles, and apocrine proliferation [56].

The natural history of NS may be divided into three stages. Early in life, the lesion is characterized by papillomatous hyperplasia and the presence of immature hair follicles. Then at puberty, when hormonal changes result in the development of the sebaceous glands and apocrine glands, the lesion is transformed from a smooth into a verrucous plaque. Finally in the third stage, various benign and malignant neoplasms may occur within the lesion [57].

In a revision that compiled a list of the reported malignant tumors developing within NS, the most common malignancy observed was BCC (119 reported), more than all of the other kinds of malignant tumors together [57]. It is interesting

Fig. 13.2 Nevus sebaceus on the scalp of a child

that in this review it was observed that the earlier studies report more malignant growths compared with more recent studies. It is likely that the incidence of BCC has been overestimated, as basaloid proliferation is a common finding, and some pathologists may label this condition as BCC rather than benign trichoblastoma [58].

Otherwise, in a retrospective study of 596 surgical excision specimens of NS, more than 90% of the associated tumors were benign. The three most common tumors were syringocystadenoma papilliferum, trichoblastoma, and trichilemmoma. There were only five cases of true BCC (0.8%) and no other malignant tumors [59].

A more recent retrospective analysis reviewed 707 cases and malignant tumors were present in 2.5% of the specimens, almost exclusively in adults. BCC represented 1.1%, followed by spinocellular carcinoma (0.57%) [60].

The definitive treatment of NS is full-thickness dermal and epidermal excision, although there is an ongoing debate regarding whether NS should be excised and, if so, when. Excision may be justified for cosmetic reasons or to avoid the formation of tumors [57].

According to the finding that trichoblastomas predominate within NS, not BCC, close observation of the lesion may be a better approach than prophylactic excision. Nevertheless, authors who report the development of invasive malignant tumors in NS still recommend prophylactic excision [57].

The unknown risk of malignant transformation, lesion expansion, increased lesion friability, associated bleeding or itching, and the aesthetic concerns associated with scalp alopecia might influence the decision for early excision. However, the risks of general anesthesia in children and the risks of excision, such as bleeding, infection, and scarring, also need to be considered [61].

Ultimately, the decision of whether to excise prophylactically should be determined after a thorough review of the options as well as personal and medical evaluation of the patient [57].

Spinocellular Carcinoma Precursor Lesions

Actinic Keratosis

Actinic keratoses (AK) are epidermal lesions at the initial clinical stage of a biological continuum that may culminate in SCC [62]. They generally result from prolonged exposure to nonionizing radiation, especially UV radiation from the sun [2]. AK has been characterized historically as a premalignant or precursor lesion of skin cancer, because it presents atypical keratinocytes confined in the epidermis [63].

More than 1 million new cases are reported annually and it thus represents approximately 14% of the visits to the dermatologist [64]. Besides its epidemiologic impact, AK is also a marker of photodamage representing the main risk factor for SCC [62]. The probability that an AK will develop into an SCC was estimated as 0.075–0.096% per lesion per year [65]. Thus, for a person with an average of 7.7 AK lesions on their skin, the incidence of SCC would be 10.2% in 10 years [66]. Hurwitz and Monger reported that 97% of SCC are associated with previous AK [67]. Although the rate of regression of single AK lesions was generally seen to be 20–30% with up to 63% in one study, spontaneous regression of complete fields of AK was only seen in 0–7.2% of patients [68].

Risk factors for the development of AK include old age, male gender, cumulative sun exposure, and fair skin type. Immunosuppression and genetic syndromes associated with impaired DNA repair mechanisms, deficiency in melanin biosynthesis, or an increased vulnerability to UV radiation damage also result in a higher risk for the development of AK [69].

The classical primary lesion is characterized by a rough erythematous papule covered with white to yellow scale that can vary from millimeters to confluent plaques several centimeters in diameter [63] (Fig. 13.3). The lesions are typically concentrated in areas with greater
Fig. 13.3 Actinic keratosis. Multiple rough erythematous plaques covered with scale

exposure to sunlight, and 80% are on the head, neck, and upper limbs [62]. There are other variations in the clinical presentation, and they can present as hyperkeratotic, pigmented, lichenoid, and atrophic AK, and as actinic cheilitis [63]. Most of the lesions are asymptomatic, but some may cause pruritus or a burning sensation [70].

The essential alterations in histopathology are atypical keratinocytes, hyperkeratosis, parakeratosis, especially covering the atypical keratinocytes, perivascular or lichenoid lymphocytes, and solar elastosis in the dermis [71].

The available data indicate that the presence of AK without adequate treatment is a dynamic but chronic condition, with a low chance of sustained spontaneous complete regression. This, associated with the risk of progression to invasive SCC, makes the treatment of the AK lesions necessary [68].

Protection from sunlight is an important part of management of patients with AK. There are three components to photoprotection: behavioral modification by seeking shade during the peak ultraviolet B (UVB) hours of 10 am–2 pm, wearing photoprotective outfit (including clothing, wide-brimmed hat, and sunglasses), and application of broad-spectrum sunscreens with a sun protection factor 30 or higher [69].

Currently there are several types of therapy available, the optimum choice depending on the

number of lesions and regions involved, whether the lesions can be distinguished from each other or not, and whether there are contiguous areas with chronic actinic damage and hyperkeratosis.

According to the guideline published in 2015, for up to five visible or palpable lesions per field or region of the body affected, the best recommendations are cryotherapy followed by curetting, 5-fluorouracil (5-FU) 5% or 0.5%, imiquimod 3.75 or 5%, ingenol mebutate 0.015/0.05%, and photodynamic therapy [69].

Otherwise, for multiple lesions (six or more) and contiguous areas with actinic damage and hyperkeratosis, the strongest recommendations are for 5-FU 0.5%, imiquimod 3.75%, ingenol mebutate 0.015/0.05%, or photodynamic therapy followed by cryotherapy, diclofenac sodium 3%, 5-FU 5%, imiquimod 5%, and CO_2 laser or Er:YAG-laser [69].

Porokeratosis

Porokeratosis (PK) is a group of cutaneous entities characterized by disordering of epidermal keratinization, presence of a cornoid lamella, and a predisposition to develop malignant transformation [72].

The most commonly reported malignant lesions are carcinoma in situ, SCC and, more rarely, BCC [73]. There are five major clinical variants of PK that are differentiated purely on clinical criteria [74, 75], and malignant degeneration has been found in all forms with a reported incidence of 6.9–11.6% [73].

Disseminated superficial actinic porokeratosis (DSAP) is the most common type, representing 42% of cases [76]. DSAP consists of multiple annular, hyperkeratotic, brownish macules measuring 2–5 mm in diameter with a bilateral distribution on sun-exposed areas, particularly the extremities. The center of the lesion is minimally atrophic or depressed and the border spreads centrifugally in raised ridges [77] (Fig. 13.4a). DSAP can affect people of all ages, but it affects more women in their third to fourth decade of life [77].
Fig. 13.4 Porokeratosis. (**a**) Disseminated superficial actinic porokeratosis with typical peripheral keratotic rims. (**b**) Porokeratosis of Mibelli, a large plaque with keratotic borders

Other variants are the classic plaque form of Mibelli (PM) and linear porokeratosis (LP), accounting, respectively, for 35.5% and 13% of cases [76]. PM begins in childhood as an asymptomatic, small, brown to skin-colored keratotic papule that gradually enlarges and over time can form a plaque that may measure several centimeters in diameter [78] (Fig. 13.4b).

Other less common types are porokeratosis palmaris and plantaris disseminata (PPPD) and punctate porokeratosis [75, 79]. Simultaneous presentation of several types of PK can occur but is rarely reported [75].

The diagnosis of all types of PK is typically based on clinical examination and the typical histologic feature is the cornoid lamella, a narrow column of tightly packed parakeratotic cells that correspond to the clinically observed raised hyperkeratotic border [78].

Although the pathogenesis is unknown, immunosuppression and actinic exposure predispose to their development [72].

Malignant transformation has been reported to occur in 7.6% of PM, 3.4% of DSAP, 19% of LP, and 9.5% of PPPD cases [79] and the average latency period is 36 years [72].

The precise mechanism by which malignant degeneration develops in PK is not yet completely understood. A genetic mechanism of allelic losses at an early stage of embryonic development has been suggested [80]. However, no molecular data have been presented to support this hypothesis [72].

Malignant lesions seem to be more frequent in nonexposed skin, in large PK lesions, in patients with a history of ionizing radiation exposure, in the linear type, and in multiple patterns of PK [72, 81].

PK does not usually need treatment, but in some cases may be necessary because of its potential for malignant progression and for cosmetic purposes [77]. No controlled studies are available in the literature. Although several therapeutic options have been reported, none of them has shown consistent and long-lasting efficacy [82].

The local destructive modalities include surgical excision, especially when few lesions are present, curettage, dermabrasion, cryotherapy (freezing cycle of 30 s), laser ablation (including erbium, CO_2, or Q-switched ruby), and photodynamic therapy [82–84].

Among the topical agents, 5-FU 0.5–5% applied once or twice daily for 3 weeks to several months has proved effective in some cases of PM, DSAP, and LP. Imiquimod 5% cream once daily 3–7 days/week for 4–24 weeks, also has been reported with a good response [81, 85]. Other options such as local retinoids, keratolytic agents, steroids, and emollients have been used in PK with variable results [82].

Systemic treatment with oral retinoids has been described with conflicting results. These agents have been given at doses varying from 20 to 75 mg/day over 1–5 months [82, 84].

Patients at risk, for instance with long-standing and large lesions, should be followed to detect any malignancies, which should be given specific treatment [81, 82].

Fig. 13.5 A cutaneous horn with a keratotic plaque. (Courtesy of Dermatology Service of UFCSPA)

Cutaneous Horn

Cutaneous horn (CH) is a clinical term for a firm, white to yellow, conical, keratotic papule or plaque ranging from a few millimeters to several centimeters in size [78]. CH resembles animal horns at first glance and is mainly composed of compact keratin [86] (Fig. 13.5).

Most of the lesions develop on the face and scalp (about 30%), but any part of the body can be involved, usually sun-exposed areas [86, 87].

Although the precise pathogenesis of horn formation is not fully understood, abnormal accumulation, excessive adhesiveness, and compaction of keratin have been suggested [88].

CH can be derived from a variety of epidermal lesions. According to Yu et al., the primary lesions associated with CH may be benign, premalignant, or malignant in 61%, 23.2%, and 15.7% of cases, respectively. These conditions include seborrheic keratosis, viral warts, molluscum contagiosum, trichilemmoma, hemangioma, sebaceous adenoma, BCC, actinic keratosis, Bowen's disease, keratoacanthoma, Kaposi's sarcoma, SCC, and sebaceous carcinoma [89]. Schosser et al. evaluated 230 lesions of CH, of which the most common horn base entity was actinic keratoses in 37.4% of cases [90].

SCC is the most common neoplasia associated with malignant-based horn [86]. A retrospective histopathologic study of 222 cases of CH found that SCC was present in 93.75% of the malignant cases evaluated [91].

Risk factors for underlying malignancy include advanced age, male sex, wide base or a low height-to-base ratio (large or giant horns), presence on a sun-exposed location, and history of actinic keratosis or skin cancer [87, 88]. Surrounding inflammation and an infiltrated base may indicate malignancy [87].

Findings from a study that correlated clinical and dermoscopic features of CH with histopathology showed that, when presenting as a horn, SCC tends to have height less than the base diameter, less terrace morphology, a higher incidence of base erythema, and more pain [92].

Histopathology shows a compact, diffuse hyperkeratosis with parakeratosis, and the findings at the lesion base will vary according to the underlying process [87].

The treatment for cutaneous horns is excision achieving a good specimen from the base for histopathologic evaluation, to rule out underlying malignancy and guide potential further therapy [78, 87].

Chronic and Burn Scars

Malignant degeneration of chronic ulcers and burn scars has been described extensively in the literature. The first description dates from the first century AD by Celsus, and the term 'Marjolin's ulcer' to describe malignant change of chronic ulcer was created in 1903 by Da Costa [93, 94]. Today this term refers to carcinomas arising both from chronically inflamed and scarred skin [95] (see Fig. 13.6).

The incidence is of 0.1–2.5% and the main etiology tends to be postburn scars and traumatic wounds [96].

In a review of 412 cases of neoplasms from burn scars, 71% of the cases were SCC, followed by BCC (12%) and melanoma (6%) [93]. The average latency period from injury to onset of malignancy is 31 years and the average age at onset is in the fifth decade of life [93, 94]. Poor prognosis compared with conventional skin cancer is another characteristic, attributable to the
Fig. 13.6 Spinocellular carcinoma arising from a burn scar

high rate of recurrence (16%), lymph node metastasis (22%), distant metastasis (14%), and mortality (21%) [93]. Moreover, their aggressive nature contributes to the poor prognosis since SCC arising from scars are ten times more likely to metastasize than those arising from actinic damage [95].

Anatomically there is a preponderance of carcinomas on the extremities in contrast to spontaneously occurring SCC, which usually appears on the head and neck [97]. Burn scar cancer is typically seen on the lower extremities (43.7%), upper extremities (22.4%), trunk (11.5%), and head (22.4%), respectively [94], and occurs mostly in burns that have not been grafted [97].

The pathogenesis is not completely known. Repetitive trauma, long-standing epidermal hyperplasia, and increased mitotic activity at the edges of these chronic wounds may predispose to malignant transformation [94, 97]. Another possibility is that the reduced vascular tissue and lymphatic channels in scars may make it easier for the tumor to resist the body's usual defenses [97].

At the molecular level, some studies discussed the abnormalities in the p53 gene in patients with burn scar carcinoma [98]. Besides this, Lee et al. showed that burn scar SCC cases have Fas gene mutations in the apoptosis function region [99].

Factors such as high histologic grade, tumor location (especially on the lower extremities), large tumor diameter (>10 cm), and regional lymphadenopathy on presentation are poor prognostic factors. Acute type, location on the head, neck, or upper limbs, exophytic form, well differentiated grade, peritumoral T-lymphocyte infiltration, and absent metastasis on presentation have a better prognosis [94, 97].

If the neoplasia is confirmed, surgery is the treatment of choice. Wide surgical excision with margins of 2–4 cm is generally recommended [95, 96]. Lymph node dissection is advised in the presence of clinically palpable nodes, but not as a prophylactic measure. Moreover, Marjolin's ulcers have a poor response to radiotherapy and chemotherapy, probably because of poor vascularity caused by extensive fibrosis [95].

Excision and grafting of deep burns and unstable scars, as well as close follow-up of nonhealing ulcerated burn scars, is essential for the prevention and early detection of neoplasia [93].

Oral Leukoplakia and Erythroplakia

Oral leukoplakia (OL) is currently defined by the WHO as "a white plaque of questionable risk having excluded (other) known diseases or disorders that carry no risk" [100] and erythroplakia as "a fiery red patch that cannot be characterized clinically or pathologically as any other definable disease" [100, 101]. Both are classified as oral potentially malignant disorders (OPMDs) [100].

OL is the most common OPMD [102]. According to a systematic review, the global prevalence is estimated as 2.6% (95% CI 1.72–2.74%) [103]. The frequency of epithelial dysplasia, carcinoma in situ, or invasive oral spinocellular carcinoma (OSCC) in leukoplakias varies from 8.6% to 60.0% [102]. The global malignant transformation rate is estimated as 1.36% per year (95% CI 0.69–2.03%) [103].

Erythroplakia is rarer, with a prevalence that varies between 0.02% and 0.83% [103]. Nevertheless, the risk of malignant progression is the highest among OPMD, which approaches 55–65% in some studies [102].

OL are usually found in middle-aged and elderly persons in developed nations, mostly occurring between the fourth and seventh decades

of life, while in the developing world they may occur some 5–10 years earlier. Males are predominantly affected, but most studies record the development of OSCC more frequently in females [105].

The vast majority of lesions are associated with tobacco use (previous or current), although around 10% of lesions appear to have no known cause. The regression/disappearance of many lesions following abstinence supports the importance of tobacco in the etiology of leukoplakia [105]. Areca nut use is also an etiologic factor [100]. The roles of alcohol and human papillomavirus (HPV) infection in the etiology of OL are unclear at present [105].

There are two main clinical variants of OL: homogeneous leukoplakia, presenting as a uniformly white, flat, or slightly wrinkled plaque, containing many fine cracks or fissures and with a low risk of malignant transformation, and non-homogeneous leukoplakia, with a higher risk of malignancy (four- to sevenfold) [100, 105].

The latter can present a warty or nodular appearance, perhaps predominantly white with red areas or largely red with white speckles (erythroleukoplakia). Those containing nodular or red areas have been shown to have a greater risk of malignant transformation than the uniformly white ones [105].

Another form of OL is proliferative verrucous leukoplakia (PVL), which presents with multiple, simultaneous leukoplakias, as the disease is visibly multifocal and frequently covers a wide area [100]. It has a high risk of becoming dysplastic and turning into SCC [104].

Factors apparently associated with an increased likelihood of development of OSCC are anatomic site (tongue, floor of mouth, and retromolar/soft palate complex appear to be twice as likely to develop OSCC as those on the buccal mucosa, palate, or gingiva), non-homogeneous type, larger lesions covering several intraoral subsites, duration of the lesion, and age of patients (older patients, particularly females, are more at risk than younger patients). Those who have never used tobacco are paradoxically at greater risk than smokers [105].

On the other hand, erythroplakia is clinically characterized by a flat or even depressed erythematous change of the mucosa, usually solitary and asymptomatic, most commonly affecting the soft palate, floor of the mouth, and buccal mucosa [104, 106]. As OL, it occurs mainly in middle-aged and elderly men, and alcohol consumption and tobacco are possible etiologic factors [104, 106, 107].

Both OL and erythroplakia must be biopsied. The definitive diagnosis is made when any etiologic cause has been excluded and histopathology has not confirmed any other specific disorder [100]. The next step is to evaluate the presence of dysplasia, as it is the strongest predictor of future malignant transformation. Thus, lesions with the highest grade of dysplasia are thought to have the greatest probability of malignant transformation [100, 101]. Dysplasia is observed in nearly all cases of erythroplakia and 1–30% of oral leukoplakia cases at the time of diagnosis [101]. Erythroplakia also presents as carcinoma in situ or invasive carcinoma at the time of biopsy, and for this reason should be excised with a clear margin [100, 106].

There is no consensus regarding the management of leukoplakia, with some favoring an observational attitude toward dysplasia while others favor excision. Among the arguments against removal are the high rate of recurrence and that some dysplasia (especially mild dysplasia) regresses [102]. Besides this, surgical intervention reduces the risk but does not completely eliminate it [101]. Nevertheless, usually moderate or severe dysplastic lesions are removed, but there is no scientific basis from a prospective, randomized controlled trial for this conduct.

Local excision is desirable if the lesion is small and when it would cause minimal morbidity to the patient. When the lesion is large and a resection would compromise the patient functionally, laser ablation (usually CO_2) is recommended [108].

The follow-up intervals are not evidence based but based on clinicians' subjective assessment [100]. Rhodus et al. recommend frequent follow-up examination (<6 months) depending on the diagnosis and clinical scenario, with rebiopsy of any suspicious areas if indicated [109].

An educational as well as a personalized approach is recommended with counseling to stop smoking and consuming alcohol [110].

Oral Lichen Planus

Lichen planus is a mucocutaneous disease characterized by an unspecific chronic inflammatory process, culminating in intense destruction of the basal layer of the epithelium [111]. Here we discuss a specific type of lichen planus, oral lichen planus (OLP).

The prevalence of OLP reported in the literature is between 0.5% and 2.2% with a mean age of 55 years. It affects women more than men, and rarely children and adolescents [112].

The first case of SCC arising in OLP was described by Hallapeau in 1910, since when numerous retrospective studies and case reports have been published [112].

However, it is a subject with controversial results in the literature, owing to the great variability of its incidence across populations, criticism regarding the inclusion criteria used in most studies, lack of adequate data in the initial diagnosis of OLP, lack of information such as historical exposure to carcinogens, and the development of carcinomas at anatomic sites remote from the OLP in some of these studies [112, 113].

Nevertheless, the WHO classifies OLP as a potentially malignant disorder, the range of malignant transformation varying between 0.04% and 1.74% per year [112, 113].

A review of 11,225 OLP cases found that a malignant transformation occurred in 183 (1.63%) approximately 6 years after the initial diagnosis, with a mean rate of 0.27% per year [113]. By comparison, the estimated incidence of oral cancer in Brazil according to the National Cancer Institute (INCA) in 2016 for males is approximately 0.008% [114].

OLP presents as white striations/papules/ plaques, erythema, erosions, or blisters affecting predominantly the buccal mucosa, tongue, and gingiva. Lesions are typically bilateral and often appear as a mixture of clinical subtypes. The most common clinical presentation is a reticular form with interlacing white keratotic lines (known as Wickham's striae) with an erythematous border (see Fig. 13.7). Symptoms such as sensitivity and pain may occur [115, 116].

Fig. 13.7 Oral lichen planus. White striations on the oral mucosa

Malignant transformation is more likely to occur in atrophic, erosive, or ulcerative lesions [112, 113, 115]. The last two predispose the mucosa to damage from carcinogenic agents such as tobacco and alcohol. However, other unknown extrinsic factors may be involved as some patients do not have a history of exposure [112].

It is possible that *Candida albicans* has a role in the development of malignancy because it is able to produce carcinogenic substances such as acetaldehyde [112, 117]. Another factor that may be involved is immunomodulating agents used in the treatment of LP. They have a potent anti-inflammatory effect that could promote the progression of LP to malignancy by way of reduced symptoms [112]. Furthermore, the presence of chronic inflammation and the continuous epithelial wound healing may increase the likelihood of cancer-forming gene mutations [115].

Biopsy is important to exclude malignancy and to differentiate OLP from other diseases. The histology is characterized by a dense subepithelial band of chronic inflammatory cells, usually T lymphocytes, which can transgress the basement membrane and reach the epithelium. Another feature is the degeneration of basal keratinocytes, forming the colloid bodies (eosinophilic globules) [112, 115].

Investigating the use of any systemic drug is also important in a patient with a suspicion of OLP, as oral mucosal lichenoid lesions may simulate OLP [115].

Treatment aims to control the symptoms and monitor dysplastic changes [112, 116]. Topical corticosteroids are the mainstay in controlling mild to moderately symptomatic lesions. Options include 0.05% clobetasol propionate gel, 0.1% or 0.05% betamethasone valerate gel, 0.05% fluocinonide gel, 0.05% clobetasol butyrate ointment or cream, and 0.1% triamcinolone acetonide ointment. These agents can be used up to three times a day since a thin layer is applied [116, 118]

Other topical options include tacrolimus or pimecrolimus in solution or cream, retinoic acid, and cyclosporine [112].

In patients with a widespread symptomatic lesion, options such as 1.0 mg/ml aqueous triamcinolone acetonide or 0.1 mg/ml dexamethasone elixir are possible. It is recommended to gargle with 5 ml of the solution for 2 min after meals. For recalcitrant or extensive lesions, subcutaneous injection of 0.2–0.4 ml of a 10 mg/ml solution of triamcinolone acetonide is another option [116].

For recalcitrant lesions that fail to respond to topical therapy, systemic corticosteroids can be tried, but with low evidence (there are no controlled studies evaluating this treatment).

Prednisone in a dose of 0.50–0.75 mg/kg per day can cause a significant response within 1–2 weeks. For longer periods the steroid dosage must be gradually tapered off [112, 116]

Other treatment modalities include retinoids and vitamin A analogs, psoralen combined with UV-A (PUVA), griseofulvin, levamisole, dapsone, and thalidomide. However, the evidence of the efficacy of these treatment approaches is not established [112, 116].

Because of the possible risk of SCC in patients with OLP, long-term follow-up is essential. Biannual evaluation is recommended and lesions should be rebiopsied as indicated [112, 115]. Also important is the advice to eliminate smoking and alcohol consumption [115].

Lichen Sclerosus

Lichen sclerosus (LS), also known as lichen sclerosus et atrophicus or balanitis xerotica obliterans, is an autoimmune, inflammatory dermatosis, characterized by a lymphocytic response that has a predilection for the genital skin in both sexes and an association with several other autoimmune diseases [119].

Its precise prevalence and incidence is unknown. Women are more affected than men, and both females and males have two peak ages of presentation: in the prepubertal and postmenopausal years, and in young boys and adult men, respectively [119, 120].

The etiology is unknown, although autoimmune, genetic, hormonal, and infectious factors have been implicated in its pathogenesis [121, 122].

The genital skin is mainly affected, although extragenital involvement is also possible [121, 123]. The typical lesions are porcelain-white papules and plaques but telangiectasias, fissures, ulcerations, and erosions can occur (Fig. 13.8). When symptoms are present, itching is the most common. Pain and dyspareunia may be a consequence of erosions, fissures, and introital narrowing. Phimosis can be a result of LS in men, leading to erectile dysfunction and painful erections [119, 121].

Fig. 13.8 Lichen sclerosus. White and atrophic plaque on genital skin

The presence of epidermal atrophy, superficial dermal edema associated with an underlying chronic inflammatory infiltrate, classically described as a "band-like" pattern, is characteristic at histology. Vacuolization of the basal layer, flattening of rete ridges, loss of elastic fibers, and homogenized dermal collagen can also be present [124, 125].

The association between SCC has been described principally with female genital LS and less commonly in penile LS. Extragenital lesions appear to carry no risk of malignancy [119, 120].

Despite the low related risk of between 1% and 7% [119, 120, 126], studies indicate that LS is present in up to 61% of histopathologic examinations of vulvar SCC [127].

In vulvar SCC two pathogenic pathways are involved: HPV-dependent and HPV-independent. The HPV-dependent pathway accounts for 20–40% of cases, is more common in younger women, and usually has vulvar intraepithelial neoplasia as a precursor lesion [128].

The non-HPV pathway is associated with LS and occurs in older women [119, 128]. In this case, the precursor lesion is the differentiated vulvar intraepithelial neoplasia, with a higher malignant potential and worse prognosis compared with SCC associated with HPV [128]. It appears that the chronic inflammation of the LS may cause molecular alterations that facilitate neoplastic proliferation [121].

In men, although less common, the association between SCC and LS has also been described. Barbagli et al. reviewed clinically and histologically 130 cases of male genital LS and found 11 cases (8.4%) with premalignant or malignant histopathologic features including 7 (64%) with SCC [129]. Another retrospective study evaluated 18 cases of histologically proven penile SCC and found histologic features of LS in 8 (44%) [130].

HPV also seems to exert a role in the pathogenesis of SCC, although this issue is controversial. Nasca et al. evaluated the presence of HPV by polymerase chain reaction (PCR) in 46 penile LS cases and compared them with a control group. They detected the presence of HPV in eight cases (17.4%) and in four controls (8.7%),

with an odds ratio of 2.55 and 95% CI of 0.73–8.89 [131].

Biopsy is indicated for patients with persistent ulcers, erosions, hyperkeratosis, and fixed erythematous areas to exclude intraepithelial neoplasia or invasive SCC [119].

According to the latest guideline to date, very potent or potent topical corticosteroids are the first line of therapy for LS. Long-term use appears safe and effective if needed, especially in active disease. Clobetasol propionate 0.05% cream or preferably ointment is the most studied. Although the frequency of application and maintenance treatment is under discussion, a common practice is to use it once or twice daily for 3 months, with a possible reduction in frequency after 1 month, and then as necessary [122].

Intralesional corticosteroids such as triamcinolone acetonide injections or a solution containing 2 mg of dexamethasone had a positive effect on pruritus and physical signs such as disease progression and scarring in vulval and penile LS, and may be an option in patients unable to use topical corticosteroids or with a resistant itch [122].

Topical calcineurin inhibitors (tacrolimus and pimecrolimus) seem to be an effective alternative to strong topical steroids in the treatment of genital LS, especially in children [119, 122]. Another recommendation is to use emollients to relieve the symptoms.

If standard therapy for LS is unsuccessful, other options include PUVA, photodynamic therapy, oral retinoids, systemic glucocorticosteroids, oral cyclosporine, methotrexate, hydroxycarbamide, cycloferon, ceftriaxone, penicillin G, sulfasalazine, and vitamin A combined with vitamin E or vitamin D. However, most of these have a very low level of evidence and grade of recommendation [119, 122].

Surgery is reserved for penile LS with symptoms due to persistent phimosis or meatal stenosis, and in women is only indicated for premalignant change or an invasive SCC and for highly selected symptomatic LS with complications of scarring [119, 122].

Long-term follow-up is appropriate for patients with genital LS associated with symptoms, localized skin thickening, previous cancer, or vulval intraepithelial neoplasia [119].

Precursor Lesions of Skin Cancer Related to Human Papillomavirus

The HPVs consist of a heterogeneous group of nonenveloped, double-stranded DNA viruses that display a distinct tropism for mucosal or cutaneous squamous epithelia [132, 133].

To date nearly 200 types of HPV have been discovered, of which approximately 50 infect the genital area and are related to a variety of skin manifestations ranging from common warts to malignancies [134].

The risk for persistence and progression to cancer precursor lesions varies according to HPV type, host factors, and the presence of cofactors such as smoking, immunosuppression, high parity, and hormonal contraceptive use [135], but the strongest risk factor for the development of malignancies associated with HPV is persistent oncogenic HPV infection (defined as HPV positivity at two or more visits) [136, 137]. Infection by specific high-risk types of HPV, particularly 16 and 18, is strongly associated with cancer. Together they account for about 70% of cervical cancers worldwide [136, 138]. Moreover, other cancers such as anal, penile, vulvar, vaginal, and oropharyngeal have been associated with high-risk HPV [132, 136]

HPV 16 is the most common type with a prevalence ranging from 3% to 4% in North America, followed by HPV 18. The prevalence shows a peak in women up to 25 years of age with a subsequent decline until age of 35–44 years. The infection is transmitted through direct skin-to-skin or skin-to-mucosa contact, and the number of sexual partners has been shown to be the main determinant of anogenital HPV infection both in women and men [136].

The virus specifically infects the stratified epithelium, and systemic dissemination does not occur [134]. Most HPV infections are self-limited and are asymptomatic or unrecognized, and take years or decades to undergo malignant transformation [134, 137].

Most of the clinically apparent anogenital warts are caused by low-risk HPV types 6 or 11 and are rarely associated with high-risk type HPV (Fig. 13.9). When it happens it is usually a

Fig. 13.9 Multiple genital warts. Both exophytic and sessile lesions are present. (Courtesy of Dermatology Service of UFCSPA)

coinfection with HPV 6 or 11, and foci of high-grade squamous intraepithelial lesions, particularly in persons who have HIV infection, may occur in these cases [137].

Outstanding among the lesions caused by low-risk HPV types but with a possible malignant transformation is the Buschke–Löwenstein tumor or giant condylomata accuminata. This is a large destructive tumor on the genitalia associated with HPV types 6 or 11 and despite its histologic benign presentation, focal malignant transformation into squamous cell carcinoma can occur.

Other rare skin manifestations of oncogenic strains (16 and 18) are Bowenoid papulosis and erythroplasia of Queyrat, no longer considered precursor lesions but SCC in situ. They are, therefore, discussed in another chapter.

Subclinical lesions are also possible, which are visible only with the use of enhancing techniques, such as colposcopy, when the application of 3–5% acetic acid for 5–10 min might turn the affected areas white [134].

Anogenital warts are usually diagnosed by inspection and can be confirmed by biopsy in specific cases: atypical lesions (pigmented, indurated, affixed to underlying tissue, bleeding, or ulcerated), lesions that do not respond to standard therapy, when the disease worsens during therapy, and if the diagnosis is uncertain [137].

Table 13.2 Patient-applied treatment options for anogenital warts caused by HPV

Treatment modality	Posology	Adverse effects
Imiquimod 5% cream	Once at bedtime, 3 times per week for up to 16 weeks. Wash the area with soap and water 6–10 h after the application	Local inflammatory reactions such as redness, irritation, induration, ulceration/erosions, vesicles, and hypopigmentation
Imiquimod 3.75% cream	Once at bedtime for up 8 weeks. Wash the area with soap and water 6–10 h after the application	
Podophyllotoxin 0.5% solution or gel or Podophyllotoxin 0.15% cream	Twice daily for 3 days, followed by 4 rest days	Mild to moderate pain and local irritation
	Can be repeated for up to four cycles	
	Do not exceed 10 cm² of treated area	
Sinecatechins 15% or 10% ointment	Three times daily for 12–16 weeks. Do not wash after use	Erythema, pruritus/burning, pain, ulceration, edema, induration, vesicular rash

Currently there are two HPV vaccines that can prevent diseases and cancers caused by HPV (but not treat existing HPV or genital warts): the bivalent vaccine (Cervarix), which prevents infection with HPV types 16 and 18, and the quadrivalent vaccine (Gardasil), which prevents infection with HPV types 6, 11, 16, and 18. These vaccines are recommended routinely for boys and girls aged 9–13 years in a scheme of a 3-dose series of intramuscular injections over a 6-month period, with the second and third doses given 1–2 and 6 months after the first dose, respectively [135, 137]

The treatment options for anogenital warts include destructive methods that may reduce but probably do not eradicate HPV, thus leading to possible recurrence after treatment, especially in the first 3 months [137].

Therapy can be performed at home or in the clinic. Among the home options are imiquimod, podophyllotoxin, and sinecatechins (a green-tea extract with an active product called catechins) (see Table 13.2). Among the options for therapy in the clinic are cryotherapy, surgical removal (by tangential excision, curettage, laser, or electrosurgery), and trichloroacetic acid 80–90% solution applied once per week for a maximum of 8–10 weeks [137, 139].

The choice of treatment depends on wart size and number, and anatomic site, patient preference, cost, convenience, adverse effects, and provider experience [137]. Follow-up is recommended every 4 weeks, switching treatments if the response is inadequate [139].

Using condoms and limiting the number of sexual partners can decrease the chances of infection but do not fully protect against HPV [137].

Glossary

Actinic keratoses Epidermal lesions at the initial clinical stage of a biological continuum that may culminate in spinocellular carcinoma. They generally result from prolonged exposure to nonionizing radiation, especially ultraviolet. It has been characterized as a premalignant or precursor lesion of skin cancer, because it presents atypical keratinocytes confined in the epidermis.

Congenital melanocytic nevus Melanocytic nevus that is present at birth or rarely up to 2 years of age. It is believed to result from the rapid proliferation of melanocytic lineage cells due to some morphologic error of the neuroectoderm, during the migration of the melanoblasts from the neural crest to the skin.

Cutaneous horn A clinical term for a firm, white to yellow, conical, keratotic papule or plaque ranging from a few millimeters to several centimeters in size. Spinocellular carcinoma is the most common neoplasia associated with malignant-based horn.

Dysplastic nevus Described as a continuum between the common acquired nevus and the melanoma, since it is morphologically and biologically the intermediate between these two entities.

Erythroplakia A fiery red patch that cannot be characterized clinically or pathologically as any other definable disease. It is classified as an oral potentially malignant disorder.

Giant congenital melanocytic nevus Congenital melanocytic nevus of ≥20 cm that generally presents as a brownish lesion with defined margins and hypertrichosis. The association with melanoma is well established.

Human papillomaviruses Consist of a heterogeneous group of nonenveloped, double-stranded DNA viruses that display a distinct tropism for mucosal or cutaneous squamous epithelia. They are associated with development of malignancies, particularly high-risk HPV types.

Lichen sclerosus An autoimmune, inflammatory dermatosis, characterized by a lymphocytic response that has a predilection for the genital skin in both sexes, and an association with several other autoimmune diseases.

Marjolin's ulcer This term refers to carcinomas arising both from chronically inflamed and scarred skin.

Nevus sebaceus A hamartoma of epithelial and nonepithelial origin that is often referred to as an organoid nevus because it may contain any or all components of the skin.

Oral leukoplakia A white plaque of questionable risk having excluded (other) known diseases or disorders that carry no risk. It is classified as an oral potentially malignant disorder.

Porokeratosis A group of cutaneous entities characterized by disordering of epidermal keratinization, presence of a cornoid lamella, and a predisposition to develop malignant transformation.

Basal Cell Carcinoma

14

Roberto Gomes Tarlé, Wagner Bertolini,
Luciano José Biasi,
and José Roberto Toshio Shibue

Key Points

- Basal cell carcinoma (BCC) of the skin is the most frequent cancer in the Caucasian population
- BCC has been related to increased ultraviolet (UV) exposure
- Mutated *PTCH1* gene is associated with BCC in patients with Gorlin's syndrome as well with sporadic BCC
- BCC's classical clinical presentation is a slow-growing pearly papule, showing telangiectatic vessels
- Dermoscopy is an important technique, enhancing sensibility and specificity in the diagnosis of BCC

- The anatomopathologic examination is central to the diagnosis and classification of BCC
- The gold-standard approach and the most often used for BCC is surgical treatment
- High-risk tumors should be approached preferably with Mohs micrographic surgery

Epidemiology

Basal cell carcinoma (BCC) of the skin is the most frequent cancer among the Caucasian population, and its incidence is still growing [1]. Precise epidemiologic data could be underestimated as a result of undernotification, great variability exists between different geographic regions.

BCC is responsible for 25% of all types of cancer, being the most frequent of the skin cancers, representing 70% of all nonmelanoma skin cancers, with a ratio of 4:1 in relation to squamous cell carcinoma (SCC) [2]. In Brazil 80,850 new cases in males and 94,910 in females were estimated in 2016 [3].

The incidence of BCC is increasing. A North American study showed a 15% incidence

elevation in the 15 years from 1998 to 2012 [4]. The increased longevity of the population and concomitant elevated incidence of BCC in the older population, especially those older than 40 years, may explain the recent increased incidence [5].

Pathogenesis

The origin of BCC cells is still a matter of controversy. For a long time it was supposed to originate from pluripotent cells of the bulge in the hair follicles; recently it has been related to pluripotent cells from interfollicular epidermal cells and the hair follicle infundibulum [6].

Although the etiologic evidence of actinic damage in SCC is more obvious, BCC has also been related to increased ultraviolet exposure, either in sporadic or continuous form, with outdoor workers showing a higher incidence of BCC [7].

Genetic factors are also important in the pathogenesis of BCC. The evidence for the association of a mutated *PTCH1* gene with BCC in patients with Gorlin's syndrome as well as the association of other mutations in this biological pathway with sporadic BCC supports its etiologic importance [7].

Clinical Presentation

BCC is described classically as a slow-growing pearly papule, showing telangiectatic vessels that can progress to nodules and ulceration. The clinical presentation may vary according to different histologic subtypes. It occurs predominantly on the face, especially on the nose, not always showing preference for sun-exposed areas [8].

BCC can be classified clinically as nodular, superficial, morphoeic, and fibroepithelioma of Pinkus. The presence of melanin is related to the presence of brown or bluish coloration seen in the pigmented variant, and the clinical types are described here [9].

Nodular BCC

Nodular is the most frequent clinical type of BCC. In early stages it is represented clinically by a pearly papule with variable degrees of telangiectasia, distinctive clinical findings of this tumor (Fig. 14.1). The lesion progresses slowly to a nodule, sometimes ulcerating (Fig. 14.2). The presence of melanic pigment characterizes the pigmented variant BCC (Fig. 14.3). Neglected lesions can grow significantly, resulting in extensive necrosis and ulceration, defined clinically as *ulcus rodens* (rodent ulcer), in analogy to a rat bite.

Superficial BCC

Superficial BCC is characterized clinically as a red scaly patch, sometimes showing a discrete pearly, elevated border. This clinical type is frequently located on sun-exposed areas (Fig. 14.4).

Fig. 14.1 Pearly papule with telangiectasia in a nodular BCC on the left nasal ala

Fig. 14.2 Nodular ulcerated BCC on the nasal tip

Fig. 14.3 Pigmented BCC on the nasal ala

Fig. 14.5 Ill-defined plaque on the forehead and eyebrow region of a morphoeic basal cell carcinoma
Fig. 14.4 Red scaly patch on a sun-exposed area in a superficial BCC on the temporal region

Table 14.1 Diagnostic criteria for basal cell carcinoma

1. *Clinical presentation:*
Pearly papule with telangiectasias that can progress to nodules and ulceration
Morphoeic BCC usually presents as an ill-defined plaque
Superficial BCC presents as a red scaly plaque
Pigment can be present in all variants, being defined as pigmented BCC
Dermoscopic findings: short fine telangiectasias, leaf areas, and blue-gray ovoid nests
2. *Pathology:*
Confirmation of diagnosis by biopsy and definition of histologic risk factors
3. *Radiologic findings:*
To investigate invasion to deeper anatomic structures or to investigate local dissemination

Morphoeic BCC

The morphoeic variant is represented clinically as an atrophic plaque, similar to morphoea, showing a scar-like surface with ill-defined margins and a firm consistency on palpation (Fig. 14.5). In this variant ulceration tends to be a late event.

Pinkus Fibroepithelioma

Fibroepithelioma of Pinkus is a rare variant of BCC frequently located on the lower back, and characterized clinically as a slightly erythematous pedunculated papule or nodule with a rubbery consistency.

Diagnosis

The diagnosis of BCC is essentially clinical (Table 14.1). As suggested by the clinical findings described, it occurs predominantly on individuals with a clear complexion. Dermoscopy is an important technique, enhancing sensibility and specificity in the diagnosis of BCC, either pigmented or not [10]. The most validated findings are short fine telangiectasias, leaf areas, and blue-gray ovoid nests [11].

Complementary Examinations

Biopsy and pathology are essential for the diagnosis and subtype definition, with a direct impact on treatment decision [12]. Imaging methods are used to enhance diagnostic specificity and sensibility, as well as for defining clinical margins; the methods used are confocal microscopy, optical coherence tomography, and radiologic examinations that can be used for staging.

Histopathology

Histopathology is the gold-standard complementary examination for the diagnosis and staging of BCC. Nests of basaloid cells with peripheral palisade and clefts between the stroma and tumor cells are typical findings. BCC can be classified histologically by its growth pattern or histologic differentiation. Expansive growth is related to a less aggressive form of BCC (Fig. 14.6); the chordonal or infiltrative variants have more subclinical extension, behaving as high-risk lesions (Fig. 14.7) [13].

Classification according to histologic subtype can be subdivided into nodular, superficial, infiltrative, morphoeic, micronodular, and mixed type, the latter being a combination of two or more subtypes [14]. The nodular variant is the less aggressive subtype. Superficial BCC sometimes shows ill-defined borders enhancing the risk of recurrence, while infiltrative and morphoeic subtypes are aggressive [14].

Metatypical BCC, also known as basosquamous cell carcinoma, is a more aggressive form of BCC that shows areas of squamous differentiation, with a variable degree of keratinization [13].

Perineural and/or angiolymphatic invasion are important findings that correlate with a more aggressive behavior and subclinical extension [15].

Imaging Methods

The use of medical imaging methods are indicated for advanced cases when deep structural invasion is suspected clinically. In such situations computed tomography and magnetic resonance imaging are the most commonly used methods.
Fig. 14.6 Histopathology of basal cell carcinoma showing expansive growth pattern (hematoxylin–eosin) (Courtesy of Lismary Mesquita, MD)

Fig. 14.7 Histopathology of basal cell carcinoma showing infiltrative growth pattern (hematoxylin–eosin) (Courtesy of Lismary Mesquita, MD)
Table 14.2 Differential diagnosis of BCC according to clinical subtype and nature of the lesion

		Nature of lesion	
		Benign	Malignant
Clinical subtype	Superficial	Eczema, psoriasis	SCC in situ
	Nodular	Sebaceous hyperplasia, intradermal melanocytic nevus tricoepithelioma, molluscum contagiosum	SCC, Merkel cell tumor, amelanotic melanoma
	Morphoeic	Scar, dermatofibroma	Adnexal microcystic carcinoma, DFSP
	Pigmented	Melanocytic nevus, seborrheic keratosis	Melanoma
	Fibroepithelial	Fibroepithelioma	

SCC squamous cell carcinoma, *DFSP* dermatofibrosarcoma protuberans

High-frequency ultrasonography (15–22 MHz) is also indicated to evaluate deep invasion [16].

Other imaging methods such as confocal microscopy and optical coherence tomography have been used to enhance diagnostic accuracy and definition of surgical margins, although their use is limited because of high cost and low availability.

Differential Diagnosis

Differential diagnosis of BCC must be divided by its clinical subtypes and will include benign and malignant lesions (Table 14.2). Papular lesions

must be differentiated from nodular BCC, erythematous scaly plaque from superficial BCC, and atrophic and depressed lesions from morphoeic BCC [17].

Therapeutic Approach

A great variety of techniques are available for the treatment of BCC. Prior to choosing the treatment method a biopsy must be performed to confirm the diagnosis and define the histologic subtype, which will define the biological behavior of the lesion (Table 14.3). Nonsurgical

Table 14.3 Classification criteria for BCC biological behavior

		BCC risk factors				
		Anatomic location	Diameter	Histologic subtype	Primary/recurrent	Perineural invasion
Biological behavior	Nonaggressive	Low risk	<20 mm	Nodular	Primary lesion	No
		Moderate risk	<10 mm			
	Aggressive	Low risk	>20 mm	Morphoeic, micronodular, metatypical, or infiltrative	Recurrent lesion	Yes
		Moderate risk	>10 mm			
		High risk	Any size			

High-risk areas: facial "H" region, pre- and postauricular, temporal, eyelids, nose, lips, chin, mandible, genitalia, hands, and feet
Moderate-risk areas: cheeks, forehead, neck, scalp, and pretibia
Low-risk areas: trunk and limbs (excluding hands and feet) (Fig. 14.9)
Note: superficial BCC can be ill defined, presenting a higher risk of recurrence

Table 14.4 Treatment modality recommended according to the biological behavior of the BCC

Biological behavior	Non-aggressive	Aggressive
Treatment modality	Surgical excision (4-mm margins)	Surgical excision (at least 6-mm margins)
	Curettage and electrodesiccation[a]	Mohs micrographic surgery
	Cryosurgery[a]	

Note: superficial BCC can be treated by nonsurgical methods such as photodynamic therapy or imiquimod, when located in low-risk areas
[a]Curettage and electrodesiccation and cryosurgery are only suited for primary BCC, smaller than 1 cm in low-risk areas

methods such as methyl aminolevulinate photodynamic therapy (MAL/PDT), cryosurgery, curettage, and electrodesiccation are blind methods without control of histologic margin. Surgical excision with conventional pathologic margin control are indicated for low-risk lesions, whereas higher-risk lesions must be submitted to extensive surgical margins or preferentially to Mohs micrographic surgery because of the higher rate of recurrence (Table 14.4) [12].

Nonsurgical Treatment Methods

Nonsurgical treatments such as MAL/PDT and imiquimod are indicated for superficial BCC with recurrence rates of 27.2% and 16.6%, respectively, in a 1-year follow up study [18]. A randomized 5-year follow-up study showed a recurrence rate of 22% in the treatment of superficial BCC with MAL/PDT [19]. These modalities are indicated for the treatment of superficial BCC without other risk factors and if located in a low-risk anatomic region.

Curettage and Electrodesiccation

This technique is based on the principle of a defective cellular adhesion between BCC cells and the surrounding stroma, which would facilitate the shedding of tumoral cells. The curettage must be performed in a vigorous way, in different directions, followed by eletrocauterization of the wound, a procedure that should be repeated for three times. It is contraindicated in high-risk BCC, especially in lesions with a fibrous stroma, such as the morphoeic subtype, whereby tumor removal is highly unexpected [7].

Cryosurgery

This treatment modality is based on the principle of selected cryonecrosis, whereby a cryogene, such as liquid nitrogen, induces necrosis of tumoral tissue by freezing it to −50° to −60 °C, preserving the surrounding tissue. A double freeze cycle is recommended for the treatment of BCC, but this technique is only indicated for non-aggressive lesions in a low-risk area [7].

Surgical Excision

Surgical excision consists in surgical removal of the lesion with safe surgical margins of surrounding normal tissue, which may vary according to the aggressiveness of the lesion; the resulting specimen is then submitted for conventional histopathologic analysis. The safety margins recommended for a 95% chance of completely removing the lesion are 4 mm for low-risk lesions and those smaller than 2 cm, while for larger lesions with other risk factors margins of at least 6 mm are recommended. The rate of complete removal of high-risk lesions with 5-mm margins is 82%, while margins of 11–13 mm will remove 95% of the lesions [20], indicating that the subclinical invasion of the lesion can be extensive.

In conventional surgical excisions, the histologic margins are sampled by the bread-loaf section or cross-section techniques; these methods will examine less than 1% of surgical margins, which could result in a false-negative margin in the pathologic analysis.

Mohs Micrographic Surgery

Micrographic surgery is a term used to describe techniques of surgical removal of skin cancer, the use of a graphic reference map, and complete histologic control of surgical margins. Acknowledging the work of Doctor Frederic Mohs, his name is used to define this important technique for skin cancer removal.

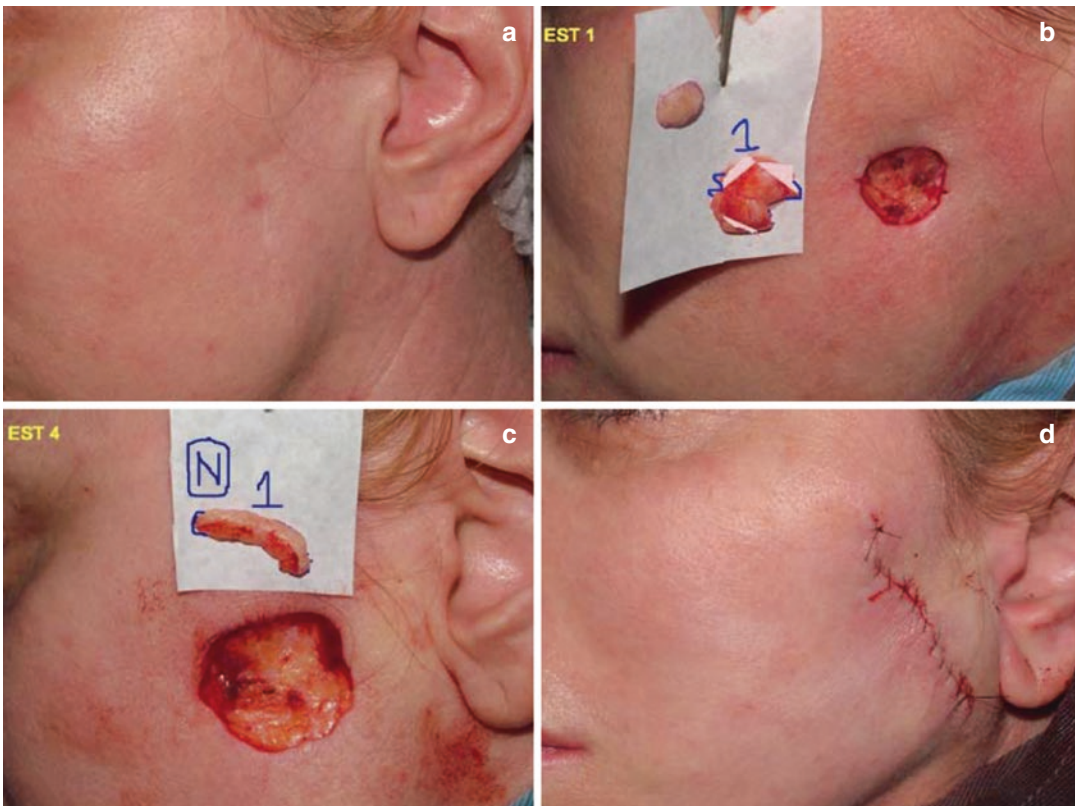
The technique involves the surgical removal of the tumor in a specialized way in order to obtain a specimen that will be oriented and submitted to frozen sections, sampling the totality of its margins and maintaining a rigorous orientation control (Fig. 14.8).


Fig. 14.8 Recurrent superficial BCC treated by Mohs micrographic surgery. (**a**) Recurrent superficial BCC. (**b**) Digital map of the first stage of the lesion removal. (**c**) Free margins after the fourth stage of Mohs surgery. (**d**) Simple suture repair
Fig. 14.9 Risk areas

The Mohs technique is indicated for aggressive lesions, lesions in areas of higher recurrence risk, and areas where tissue sparing is vital for functional and cosmetic preservation. A 5-year follow-up study showed a 99% cure rate for primary BCCs and 94.4% for recurrent lesions [12].

Follow-up

All individuals submitted to treatment of BCC should be followed for at least 5 years because of the recurrence risk, and be submitted to a complete body inspection because of the risk of a second primary lesion.

Glossary

Confocal microscopy Noninvasive imaging technique that enables in vivo visualization of the skin structure in real time.

Dermoscopy Noninvasive diagnostic technique for the in vivo observation of skin lesions with a dermatoscope, allowing magnification of the lesion.

Gorlin's syndrome Also known as nevoid basal cell carcinoma syndrome, it is characterized by developmental anomalies, such as odontogenic keratocysts of the mandible, bifid ribs, palmoplantar pits and tumors, and especially multiple BCCs.

Mohs micrographic surgery A microscopically controlled surgery used to treat different types of skin cancer, developed in 1938 by Frederic Mohs.

Optical coherence tomography Noninvasive imaging examination that uses light waves to take cross-sectional pictures of the skin structure.

Photodynamic therapy Treatment that uses a photosensitizer or photosensitizing agent that will be absorbed by the target cell, and a particular type of light that will react with the photosensitizer and cause cellular death.

PTCH1, **patched 1 gene** This gene encodes the protein receptor for the sonic hedgehog, a molecule implicated in the formation of embryonic structures and in tumorigenesis. Mutations of this gene have been associated with basal cell nevus syndrome and sporadic BCC.

Telangiectasias Dilated capillaries that appear clinically as red linear vessels with spidery appearance on the surface of the skin.

Squamous Cell Carcinoma

15

Roberto Gomes Tarlé, Wagner Bertolini,
Luciano José Biasi,
and José Roberto Toshio Shibue

Key Points
- SCC incidence has increased over the last decades
- UV radiation induces mutations of the *TP53* tumor supressor gene
- HPV is more present in SCCs than in patients' nonlesional skin
- Actinic keratosis, traditionally regarded as a premalignant condition, is nowadays classified by many as an intraepithelial form of SCC
- SCC occurring in an area previously affected by trauma or burn scarring is called Marjolin's ulcer
- The anatomopathologic examination is central to the diagnosis and classification of SCC

- The gold-standard and most often used approach for SCC is surgical treatment
- High-risk tumors should be dealt with preferably by using Mohs micrographic surgery

Epidemiology

Squamous cell carcinoma (SCC) of the skin is a malignant neoplasia presenting a classical multistage behavior involving carcinogenesis, precursor lesions, tumoral progression, and potential for the development of metastatic disease [1]. SCC is the second most common type of skin cancer after basal cell carcinoma (BCC); these two neoplasias belong to a group known as nonmelanoma skin cancer (NMSC).

In Brazil, NMSC is the most frequent neoplasia in both sexes, corresponding to 25% of all malignant tumors registered; BCCs represent 70% and SCCs 25% of all NMSCs. It is noteworthy that the lack of compulsory notification may underestimate its incidence. In Brazil 175,760 new cases were expected in 2016, 80,850 in males and 94,910 in females [2]. In the United States in 2012, 5.4 million cases of NMSC among 3.3 million people were diagnosed [3, 4].

SCC is frequently located in the head and neck and limbs, especially in photoexposed areas

[5]. It is three times more frequent in men than in women, and its incidence increases with age. Individuals with a light complexion are affected more frequently; SCC is rare in blacks and Asian ethnic groups; nevertheless, it is still the most commonly found skin cancer in those populations [6, 7], in whom SCC often occurs in nonexposed skin regions [8].

The increased incidence of SCC over the past decades may be explained by earlier detection, increased outdoor activities, artificial tanning, frequent use of immunosuppressive drugs, and increased average life expectancy [4, 9]. Despite the higher incidence of SCC, a decrease in mortality has been observed, possibly attributable to early detection and effective treatment in the early stages of the disease [10, 11]. Approximately 30–50% of SCC carriers may develop another primary SCC in 5 years [12, 13].

The exact incidence of SCC mortality is unknown, although a retrospective cohort study with a median of 50 months of follow-up showed a 3.7% incidence of metastasis and a 2.1% disease-specific death risk [14].

Etiopathogenesis

Extrinsic and intrinsic factors may be involved in the etiopathogenesis of SCC; the main factors are described above.

Ultraviolet Radiation Exposure

Ultraviolet radiation (UVR) is the most important environmental risk factor for SCC and is involved in all stages of carcinogenesis, initiation, promotion, and progression, being defined as a complete carcinogen. UVR causes DNA damage, leading to important mutations, mainly in proto-oncogenes and tumor-suppressor genes [15]. The greatest carcinogenic potential is in the ultraviolet B radiation spectrum, although ultraviolet A also acts as a cocarcinogen [16].

UVR acts cumulatively, inducing mutations in the *TP53* tumor-suppressor gene and compromising control of the cell cycle, leading to clonal expansion of neoplastic keratinocytes and induc-

ing cellular immunosuppression in a dose-dependent manner by interfering with neoplastic immunosurveillance [17–19].

Immunosuppression

In immunosuppressed individuals SCC is the most commonly detected skin cancer, with a 3:1 ratio compared with BCC, in contrast to the general population where ratio is of four BCCs to one SCC [20–23]. The longer the immunosuppression, the higher the risk of SCC development [24–26]. The higher incidence may be related to a decrease in the immunosurveillance.

Human Papillomavirus

A systematic revision showed, by gene amplification, that Human Papillomavirus (HPV) is more prevalent in lesional than nonlesional skin of patients with SCC and that SCCs in immunosuppressed patients have a higher prevalence of HPV compared with those of immunocompetent patients [27]. The HPV subtypes 6, 11, 16, and 18 are usually found in genital SCCs and type 16 in periungual SCC [28]. Failure to show an association between SCC and HPV in other studies suggests that more investigation is needed [29, 30].

Other Etiologic Factors

Other predisposing factors for the development of SCCs are genodermatoses (xeroderma pigmentosum) [15], chronic dermatoses (lichen sclerosus) [31], arsenic exposure [32], and ionizing radiation [31].

Clinical Presentation

SCC occurs preferentially in photoexposed regions, the most frequently affected being, in decreasing order, head and neck, extension surfaces of the hands and forearms, legs, shoulders, lower back, upper limbs, and other areas [33]. Its subtypes are as follows.
Fig. 15.1 Field of cancerization. Presence of multiple lesions of actinic keratosis (*asterisks*), photodamage, and palpable lesions of invasive SCC (*arrowheads*)

Actinic Keratosis

Actinic keratosis (AK), traditionally regarded as a preneoplastic condition, is now considered an intraepithelial form of SCC and the initial manifestation of a spectral disease concept, with a 0.1–20% risk of evolving into an invasive SCC [34, 35]. It presents clinically as erythematous papules or plaques with variable degrees of hyperkeratosis, resulting in thin scales or a warty aspect (hypertrophic actinic keratosis). In the lip region, especially the lower lip, it is called actinic cheilitis, presenting as a whitish plaque (leukoplakia), sometimes accompanied by fissures and erosions.

Multiple AKs are often found on photoexposed skin, with other signs of photodamage and lesions of invasive SCC. A region with clinical evidence of photodamage, multiple AK, and risk of developing SCC is defined as the field of cancerization (Fig. 15.1) [36–38].

SCC In Situ

In situ SCC, or Bowen's disease, is histologically characterized by atypical keratinocytes throughout the epidermal thickness, without dermal invasion. Usually asymptomatic, it presents as a papule that may progress to an erythematous plaque with variable scaly surface, which when detached can expose a red surface (Fig. 15.2). With time the lesion can be

Fig. 15.2 In situ SCC in the anterior thorax region manifesting as an erythematous, scaly plaque

more elevated with hyperkeratosis and crusts [39]. Discharge and symptoms such as pain and discomfort may be present in certain cases [33].

Bowen's disease can have peculiar presentations in intertriginous, periungual, and mucosal regions [40]. In situ SCC of the mucosal male genitalia, known as Queyrat's erythroplasia, manifests as an erythematous plaque with a velvety surface and delimitated margins, and sometimes erosion. Bowenoid papulosis is subtype of in situ SCC that occurs on the genital area, has a warty aspect, and is associated with some oncogenic HPV types such as 16 or 18 [41].

Invasive SCC

The evolution of lesions restricted to the epidermis into invasive SCC is defined clinically by the presence of infiltration as a solid consistency on palpation, at the base of the lesion. The clinical presentation can be a warty, hyperkeratotic plaque, sometimes ulcerated and having varying degrees of perilesional erythema (Fig. 15.3). Well-differentiated tumors present usually a hyperkeratotic crust, sometimes hypertrophic, characterized by cutaneous horn. Less differentiated lesions usually are ulcerated, with minor keratinized crust, being frequently found on the lips and genital areas [39].

When SCC occurs in an area of previous trauma or burn scar, it is known as Marjolin's ulcer (Fig. 15.4). This subtype shows aggressive behavior and a higher risk for local recurrence and metastases [42].

Fig. 15.3 SCC of the malar region manifesting as erythematous plaque with a keratotic surface
Fig. 15.4 Marjolin's ulcer. SCC in a burn scar area

Fig. 15.5 Type IV verrucous carcinoma

Verrucous carcinoma is a variant of SCC that develops in chronically irritated sites and shows a cauliflower-like exophytic growth with intense hyperkeratosis. It can be subdivided into four types [43]:

Type I: Flower-like oral papillomatosis (oral region)
Type II: Buschke–Loewenstein tumor (genital region)
Type III: Epithelioma cuniculatum (plantar region)
Type IV: Other regions (Fig. 15.5)

Cautious palpation of regional lymph nodes can detect regional metastasis or evidence of reactive inflammatory lymph nodes, the former presenting with a hard, irregular consistency, and sometimes adhering to adjacent structures [39].

Complementary Examinations

Anatomopathology

The anatomopathologic examination is central to the diagnosis, staging and classification of SCC. A lesion biopsy can be carried out with a scalp or punch, with attention paid to obtaining a sample that is representative of all skin layers, including the epidermis, dermis, and subcutaneous tissue.

The histologic findings are atypical keratinocyte proliferation with loss of polarization. When still restricted to one-third or two-thirds of the epidermis it is called AK, and is termed in situ SCC when the whole thickness of the epithelia is involved (Fig. 15.6). When the dermis is invaded
Fig. 15.6 Anatomopathologic examination displaying an in situ SCC (hematoxylin–eosin) (Courtesy of Dr. Lismary Mesquita)

Fig. 15.7 Anatomopathologic examination displaying a well-differentiated SCC (hematoxylin–eosin) (Courtesy of Dr. Lismary Mesquita)

it is known as invasive SCC. Other histopathologic characteristics are nuclear pleomorphism, apoptosis, atypical mitoses, and variable degrees of hyperkeratosis, parakeratosis, lymphocytes, plasmocytes, and histiocyte dermal infiltrates. Invasive SCC is classified according to the degree of differentiation: well differentiated (Fig. 15.7), moderately differentiated (Fig. 15.8), less differentiated (Fig. 15.9), and anaplastic or undifferentiated [39–41]. When perineural invasion is present it must be described in the pathology report, as well as the acantholytic and desmoplastic findings, as these aspects could influence clinical behavior.

Imaging Examinations

Complementary examinations are indicated in the staging of SCC when there is invasion of adjacent structures, such as deep soft tissues, cranial, axial, and appendicular skeleton, orbital content, parotid gland, auditory meatus, and

perineural infiltration; perineural invasion is an important prognostic factor in head and neck SCCs [44].

For the assessment of bone and soft tissue invasion computed tomography (CT) may be indicated, as well as in advanced disease located on the lower and upper limbs, where tendons, muscles, and bones may be involved. In patients with SCC that has developed in chronic cutaneous ulcers, the assessment of deep structures can be challenging; long-standing chronic inflammatory reactions could lead to scarring and subcutaneous fibrosis, and sometimes even adhesion to muscles or bones without necessarily being a result of tumoral infiltration. Imaging assessment or oriented biopsies could help to define whether to carry out conservative surgery or even a partial limb amputation [45].

If extension to head and neck structures is suspected, such as the orbit, the auditory meatus, the cranial base, intracranial extension, and perineural infiltration, nuclear magnetic resonance imaging (MRI) is preferred [46]. In specific cases

Fig. 15.8 Anatomo-pathologic examination displaying a moderately differentiated SCC (hematoxylin–eosin) (Courtesy of Dr. Lismary Mesquita)
Fig. 15.9 Anatomo-pathologic examination showing a poorly differentiated SCC (hematoxylin–eosin) (Courtesy of Dr. Lismary Mesquita)
concerning the therapeutic strategy, as in more extensive facial or cranial resections, CT scan and MRI should be combined [47].

There is a greater risk of local recurrence when invasion of deep structures is present. The delimitation of surgical margins could be challenging because of the presence of scar and prior tissue movement resulting from previous surgery. Imaging analysis could help to define the deep extension of the relapsing disease.

When metastatic regional lymph nodes are clinically and radiologically suspected, fine-needle aspiration (FNA) biopsy or ultrasound-guided core biopsy (CB) helps in staging the lymph node status. In positive metastatic lymph nodes, radiographic assessment with CT or MRI of the involved nodal chain must be added to the assessment for the therapeutic plan. Clinical and radiologic reassessment should be carried out in cases with negative biopsies but clinical

suspicion. It is interesting to note that SCCs, especially when ulcerated with inflammatory reaction, could induce reactive lymph node enlargements that could be misinterpreted as metastatic lymph nodes. Careful evaluation is therefore necessary in this situation [48].

If distant metastasis is suspected, the lungs and bones being the most affected sites, thoracic and abdominal imaging studies are necessary for the correct staging, preferably using CT. In doubtful cases of the metastatic nature of the findings, positron emission tomography combined with CT may be indicated [49].

Thoracic and abdominal X-ray can be used when CT is not available, although these examinations are limited for small lung lesions and investigation of retroperitoneal lymph nodes.

Diagnosis

SCC diagnosis is mostly clinical, and histopathology will confirm the diagnosis and histologic subtype (Table 15.1).

The degree of differentiation is related to its biological behavior. Well-differentiated cells retain their cellular function, i.e., the ability to produce keratin, and will translate clinically into a more hyperkeratotic crust. Less-differentiated lesions will produce less keratin, showing their inability to exercise its paramount function, presenting usually as an ulcerated lesion. Palpation of regional lymph nodes is important for the cor-

Table 15.1 Diagnostic criteria for squamous cell carcinoma

1. *Clinical manifestations of the lesion:*
Erythematous-keratotic papule that may evolve into plaque with variable ulceration
Well-differentiated lesions tend to be more hyperkeratotic; less-differentiated lesions will show less keratotic and more hemorrhagic surfaces
Lymph node palpation for the correct staging
2. *Anatomopathologic examination:*
Confirmation of diagnosis by biopsy and definition of histologic risk factors
3. *Imaging examination:*
When deep structures and dissemination are suspected

rect staging. When deep invasion is suspected, because of adherence on palpation, imaging examinations may be useful.

Differential Diagnosis

The SCC differential diagnosis varies according to clinical type (Table 15.2).

Therapeutic Approach

The main goals of SCC treatment are: total removal of the tumor; minimizing the risk for recurrence and metastasis; preservation of normal tissue; and provision of the best possible functional and aesthetic outcome.

The therapeutic modality is based on the lesional classification of risk (Table 15.3),

Table 15.3 Risk factors associated with high risk SCC for local recurrence and metastases

Tumor characteristics
High-risk areas[a]: any size
Medium-risk areas[b]: >1 cm
Low-risk areas[c]: >2 cm
Ill-defined margins
Fast growth
Perineural invasion
Recurrence
Histology
Depth of invasion: >4 mm
Poorly differentiated
Aggressive pattern (acantholytic, desmoplastic fusiform cells SCC)
Perineural or vascular invasion
Patient aspects
Prior radiotherapy
Immunosuppression
Lesions in scars, chronic ulcers- or inflammation sites
Predisponent genetic syndromes (xeroderma pigmentosum)

[a]High-risk area: facial "H," auricular, pre- and postauricular, nose, temporal, eyelids, lip, chin, mandible, genitalia, hands, and feet
[b]Medium-risk area: cheeks, forehead, neck, scalp, and pretibia
[c]Low-risk area: trunk and limbs (except for the hands, feet, and pretibia) (Fig. 15.10)

approaching high-risk tumors with therapies of highest efficacy (Table 15.4). The first treatment is the best opportunity for cure and preservation of the normal tissue; subsequent approaches for affected margins or recurrences show worse cure rates and higher risks for metastases.

The gold standard and the most used treatment for SCC is surgery [50]. Topical nonsurgical treatments can be used in the cancerization field, in low-risk tumors, and in early-stage tumors such as AK and in situ SCC [51].

Topical therapies such as 5-fluorouracil (5-FU), imiquimod, ingenol mebutate, and photodynamic therapy are indicated in the treatment of field of cancerization, AK, and low risk in situ SCC located in low-risk areas. Local treatments are contraindicated for high-risk tumors [50].

Surgical procedures used for nonaggressive lesions include electrodesiccation and curettage, and cryotherapy. The proper use of these

High risk area
Medium risk area
Low risk area
Fig. 15.10 Risk areas

techniques results in the local control of the disease in more than 90% of the cases [52]. These techniques should be avoided in hair-bearing areas (scalp, genitals, axillae, and beard) because of the risks of scarring alopecia and deep invasion.

Aggressive SCC usually shows ill-defined margins affecting the accuracy of the definition of surgical margins for the adequacy of tumor removal, especially in treatments such as conventional surgery, electrodesiccation and curettage, and cryotherapy. Another drawback of techniques such as cryosurgery, curettage, and electrodesiccation is the lack of specimen for histologic and margin assessment; these are therefore defined as blind methods.

Table 15.4 Clinical presentation of SCC and treatment modalities

	Treatment modalities
Actinic keratosis	Fluorouracil cream
	Imiquimod cream
	Ingenol mebutate gel
	Cryosurgery
	Curettage and electrocoagulation (electrodesiccation)
	Photodynamic therapy
In situ SCC	Fluorouracil cream
	Cryosurgery
	Curettage and electrocoagulation (electrodesiccation)
	Surgical excision
	Mohs micrographic surgery
Low risk SCC (trunk and limbs, except for the hands and feet, and pre-tibial)	**<1 cm**: Cryosurgery
	Curettage and electrocoagulation
	Surgical excision (4–6 mm margins)
	≤ 2 cm: surgical excision (4–6 mm margins)
High-risk SCC[a]	Mohs micrographic surgery
	Surgical excision (>6 mm margins)

[a]High-risk areas: any size; medium-risk areas: >1 cm; low-risk areas: >2 cm; ill-defined margins; fast growth; perineural invasion; recurrence; histology (depth >4 mm, less differentiated, aggressive pattern, perineural or vascular invasion), prior radiation sites; immunosuppression; scars, chronic ulcers, or inflammation sites; predisponent genetic syndromes

Recent review studies report good results for the surgical treatment of low-risk SCC treated with conventional surgery using 4- to 6-mm surgical margins, mainly in nonaggressive lesions, such as well-defined primary tumors less than 2 cm in diameter, and located in areas not including the ears, lips, eyelids, nose, and scalp and without invasion of the subcutaneous layer, showing cure rates of 95% [53–55]. Conventional techniques used for anatomopathologic sampling, such as the "bread-loaf section" or "cross-section," assess less than 5% of the specimen margins, increasing the risk of false-negative margins, especially in aggressive and infiltrative tumors [55]. The minimal surgical margins for high-risk tumors are 6 mm, or preferably the use of Mohs micrographic surgery (MMS), a surgical technique that yields the highest cure rates [56] The complete histologic margin control, the use of histographic mapping, and the possibility of staged excisions oriented by peroperative frozen pathology make MMS the treatment with highest cure rates for all kinds of SCC [57]. A comparative study showed that in primary SCCs the recurrence rate in 5 years was 3.1% for MMS against 7.9% for non-Mohs surgeries, and for recurrent SCCs 10% for MMS and 23.3% for non-Mohs surgeries [53]. SCC in burn scars, Marjolin's ulcer, recurrence of radiotherapy, solid organ transplant, less differentiated tumors, recurrent lesions, and lesions with positive surgical margins are indications for MMS [58, 59].

Radiotherapy is best reserved for patients at surgical risk and should be avoided in young patients (<50 years of age), owing to the risk of induction of a secondary cancer induced by the radiation. Aggressive SCCs have a 30% risk of perineural invasion, which increases the risk of recurrence and metastasis; in this setting postsurgical adjuvant radiotherapy should be considered.

Suspected regional lymph nodes must be investigated by FNA biopsy; in the presence of lymph node metastasis or highly suspected negative cases, lymphadenectomy of the affected chain is indicated. In head tumors, especially on the anterior scalp and ears, careful examination of the parotid region must be carried out to assess the risk for intraparotid lymph node metastatic involvement [60]; if present, partial or complete parotidectomy must be conducted, along with cervical lymphadenectomy [61, 62].

The use of postsurgical adjuvant radiotherapy of regional lymph nodes is indicated for multiple metastatic lymph nodes or extracapsular extension in the axillar and inguinal region [63]. Radiotherapy for cervical lymph nodes is indicated when two or more lymph nodes are affected or when there is extracapsular involvement [52, 64].

Follow-Up

All patients treated for SCC have to be followed-up for at least 5 years because of the risk for recurrence and development of other primary lesions.

Glossary

Acantholytic squamous cell carcinoma
   Variant of SCC characterized by a cleavage of the intercellular bridges, resulting in acantholysis.

Apoptosis   Programmed cell death.

Core biopsy   The removal of a tissue sample with a large needle for examination under a microscope.

Desmoplastic SCC   Variant of SCC characterized by a prominent trabecular growth pattern, narrow columns of atypical epithelial cells, and a marked desmoplastic stromal reaction.

Hyperkeratosis   Thickening of the stratum corneum, often associated with the presence of an abnormal quantity of keratin, frequently accompanied by an increase in the granular layer.

Leukoplakia   White patch or plaque of the mucosa and mucocutaneous junction.

Lichen sclerosus A chronic atrophic disorder mainly of the anogenital skin of females but also of males and of the general skin. Whitish, ivory or porcelain-white, sharply demarcated, individual papules may become confluent, forming plaques.

Nuclear pleomorphism   Marked variation of nuclear size, nuclear shape, or nuclear staining, a common finding in malignant lesions.

Parakeratosis   A disturbance of keratinization characterized by the retention of nuclei in the stratum corneum.

Photodamage   Skin changes consequent to exposure to the sun's ultraviolet radiation.

Positron emission tomography (PET)   A nuclear medicine, functional imaging technique that is used to observe metabolic processes in the body.

Punch biopsy   Use of a specialized surgical instrument (punch) for the removal of a full-thickness specimen of the skin (epidermis, dermis, and fat) in a defined area.

TP53 **tumor supressor gene**   Mutation of the *TP53* tumor suppressor gene is a frequent event in tumorigenesis; the many roles of the protein p53 as a tumor suppressor include the ability to induce cell cycle arrest, DNA repair, senescence, and apoptosis.

Xeroderma pigmentosum   A rare hereditary skin disorder caused by a defect in the enzymes that repair DNA damaged by ultraviolet light and resulting in hypersensitivity to the carcinogenic effect of ultraviolet light.

Melanoma

16

Thais Corsetti Grazziotin, Louise Lovatto,
Felice Riccardi, Antônio Dal Pizzol,
and Alexei Peter dos Santos

Key Points

- Melanoma is responsible for 75% of deaths from skin cancer and its incidence has rapidly been increasing
- Although the increasing incidence of thinner melanomas represents improved surveillance and earlier diagnosis, the overall mortality rate has not declined
- Dermoscopy and reflectance confocal microscopy are noninvasive techniques that increase accuracy in melanoma diagnosis and reduce unnecessary biopsies
- The definitive treatment of primary melanoma is wide local excision associated with sentinel lymph node biopsy when indicated
- The identification of genetic mutations has led to the development of target

drugs to better guide therapy for patients with advanced melanoma
- Advances in the understanding of immunologic mechanisms in melanoma have promoted the development of interventions with impact on clinical endpoints

Epidemiology

Melanoma incidence has rapidly been increasing over the past 50 years, especially in fair-skinned populations [47]. It is the second most diagnosed cancer among patients under 30 years old and one of the cancers with more years of productive life lost, representing a significant public health problem [122]. Even though it represents less than 5% of all cutaneous malignancies, because of its aggressiveness melanoma is responsible for 75% of deaths from skin cancer [117, 122]. When invasive, melanoma is the cutaneous tumor with the highest metastatic capacity, since it increases by 10% per millimeter of thickness [122].

Despite changes in attitudes toward increased recreational exposure to ultraviolet (UV) radiation, the current trend of increased melanoma is predominantly explained by an increasing incidence of thinner melanomas as a result of improved surveillance and earlier diagnosis [47].

alexeipeterdossantos@gmail.com

Annually this incidence increase varies between populations, ranging from 3% to 7%, with the highest rates in Australia and New Zealand, with up to 60 cases per 100,000 inhabitants per year [56, 102, 117]. In the United States, in the past 10 years the incidence of melanoma has been increasing an average of 2.6% each year [111]. In the age group older than 60 years, the estimated average annual percentage rate was 6.15% for the period between 1992 and 2005 [117].

Moreover, melanoma remains the only preventable cancer for which the mortality rate has not declined [103, 117, 122]. Mortality rates have remained relatively stable since the 1980s, which reflects improved survival due to earlier detection of thin melanomas at a curable stage, in view of the increasing incidence of the disease [117]. However, population-based studies have shown significant increases in tumors of all histologic subtypes and thicknesses, including thick melanomas (more than 4 mm), especially in older men [80, 114, 156]. The increase in incidence has been higher in men aged 65 years and older (five-fold in men versus three-fold in women), and mortality rates increased by 157% (from 7.5 to 19.3 per 100,000) among this age group [6, 57]. However, there is a trend toward a decrease in mortality in persons aged 20–44 years, by 39% (from 1.3 to 0.8 per 100.000) in women and by 29% (from 1.7 to 1.2 per 100.000) in men in the United States [57].

Fortunately, over the past 20 years overall 5-year survival has increased in the United States by nearly 91%, likely a result of earlier diagnosis [6]. The association between increased incidence of and survival for melanoma and stabilization of the mortality rate suggests overdiagnosis from increased early detection, either from screening or incidental detection [33].

Etiopathogenesis

Melanoma is a malignant neoplasm of melanocytic lineage that most frequently arises from melanocytes in the skin, but can also arise from autochthonous melanocytes from internal organs, including the central nervous system [14].

Although melanoma can arise from nevi, most primary melanomas do not show an associated precursor nevus [14].

Melanoma as a heterogeneous disease can present with different clinical, histopathologic, and biological aspects [121]. Most melanomas show an intraepithelial component, and the malignant cells are thought to initially proliferate along the basal layer (melanoma *in situ*) [14, 170]. After a period of months to years, the malignant melanocytes not only proliferate radially but also acquire the capacity to invade vertically into the dermis (invasive melanoma) [169]. However, lesions of intraepithelial origin are distinct from melanocytic neoplasms, which consistently lack epithelial involvement; these include uveal melanoma and intradermal melanocytic proliferations [14]. Nodular melanomas (NMs) lack substantial epidermal involvement and radial components, proceeding directly to vertical and rapid growth. Furthermore, NMs frequently present amelanotic coloration [103, 169] (Fig. 16.1).

Genetic profiles and molecular data have been identified for each of the different types of melanomas and have been correlated with distinct clinical and histopathologic aspects and biological behaviors of tumors [121]. Cutaneous primary melanomas usually present typical UV radiation–induced mutations in the mitogen-activated protein kinase (MAPK) pathway, with mutually exclusive driver mutations in BRAF, NRAS, c-KIT, GNAQ, or GNA11 [39]. Melanomas associated with intense, intermittent sun exposure (usually at the trunk and extremities) have high rates of *BRAF* (50%) or *NRAS* (20%) mutations. On the other hand, mucosal and acrolentiginous melanomas have lower rates of *BRAF* mutations (5–20%) and higher rates of *c-KIT* mutations (5–10%). Uveal melanomas usually show mutations in *GNAQ* or *GNA11* [39, 157, 158].
Fig. 16.1 Clinical and dermoscopic presentation of superficial spreading melanoma in three different evolutionary growth stages: incipient, radial growth, and vertical growth. (**aI**) Clinical image of a macular brown pigmented lesion on the abdomen (*blue arrow*). (**aII**) Dermoscopic image of an incipient (clinically featureless) superficial spreading melanoma presenting reticular pattern with atypical network and segmented clods and subtle bluish focal pigmentation. (**bI**) Clinical picture of a dark pigmented macular lesion on the back (*blue arrow*). (**bII**) Dermoscopic image of a superficial spreading melanoma in radial growth phase presenting an atypical network, radial lines and pseudopods, a blue-whitish veil, and structureless areas. (**cI**) Clinical picture of a macular-nodular pigmented lesion on the leg. (**cII**) Dermoscopic image of a superficial spreading melanoma in vertical growth phase presenting a peripheral atypical network and central diffuse blue-white pigmentation with ulcerated areas

Risk Factors

Melanoma etiology is complex and involves environmental, phenotypic, and genetic risk factors [122]. The main risk factors for developing cutaneous melanoma are described here.

Environmental Risk Factors
- Intense UV radiation exposure (e.g., sunburn history)
- Chronic, cumulative sun exposure
- Indoor tanning, especially in youth (before age 35 years)
- Immunosuppression (e.g., organ transplantation)

Phenotypic and Genetic Factors
- Phototype I (fair skin, inability to tan)
- Light hair (red or blond)
- Light eyes (blue, green, or gray)
- Increased common nevus count (>100 nevi)
- Atypical melanocytic nevus (>5 nevi)
- High density of freckles
- Premalignant and skin cancer lesions
- Actinic damage indicators (e.g., solar lentigines)
- Personal history of melanoma
- Family history of melanoma (≥1 affected first-degree relative)

Environmental Risk Factors

Exposure to UV radiation is the best-known exogenous risk factor for developing melanoma [6]. UV radiation causes DNA damage and induces melanoma carcinogenesis through the

formation of pyrimidine dimers, photoproducts, gene mutations, oxidative stress, inflammation, and immunosuppression [122]. Both intermittent, intense UV exposure (e.g., sunburn history) and chronic, cumulative sun exposure play a role in the pathogenesis of melanoma [54].

Melanomas developing in continuously sun-exposed areas such as the head and neck are more likely to be of the lentigo maligna melanoma subtype and to occur in older patients with a history of solar damage and nonmelanoma skin cancer. On the other hand, individuals with a high number of nevi tend to develop melanomas on intermittently sun-exposed body sites such as the trunk and extremities, mostly belonging to the superficial spreading melanoma or nodular melanoma histologic subtypes [54].

Indoor tanning is considered directly linked to the development of melanoma by the International Agency for Research on Cancer, which classified the whole UV spectrum and indoor tanning devices as carcinogenic to humans (group 1) [44, 53, 81]. A meta-analysis showed a 75% increase in the risk for melanoma (from 40% to 228%) when indoor tanning started during adolescence and young adulthood [20]. More recently a systematic review and meta-analysis found an association between use of sunbeds and a summary relative risk (RR) of 1.25 (1.09–1.43) for melanoma. This risk almost doubled (RR = 1.87) in youth (before age 35), with a 1.8% (0–3.8%) increase in melanoma risk for each additional session of sunbed use per year [20]. A 10-year follow-up study demonstrated that the daily use of sunscreen reduces the melanoma detection rate, suggesting that regular sunscreen use may prevent melanoma development and should be encouraged [64].

Besides UV exposure, other potential environmental risk factors are under study. Occupational exposure to pesticides was associated to a fourfold greater risk of melanoma compared with no occupational exposure (odds ratio [OR] 4.23, 95% confidence interval [CI] 1.94–6.31) [145]. Furthermore, indoor use of pesticides (four or more times per year) was associated with a 44% higher risk of melanoma (OR 1.44, 95% CI 1.11–3.49) [145].

Phenotypic and Host Factors

Melanoma occurs more frequently in Caucasians than other races. Phenotypic features associated with increased risk of melanoma are phototype (I vs. IV: RR = 2.09, 95% CI 1.67–2.58), skin color (fair vs. dark: RR = 2.06, 95% CI 1.68–2.52), hair color (red vs. dark: RR = 3.64, 95% CI 2.56–5.37), eye color (blue vs. dark: RR = 1.47, 95% CI 1.28–1.69), high density of freckles (RR = 2.10, 95% CI 1.80–2.45), presence of premalignant and skin cancer lesions (RR = 4.28, 95% CI 2.80–6.55), and actinic damage indicators (RR = 2.02, 95% CI 1.24–3.29) [54]. Ephelides and solar lentigines were shown to be independent risk factors for cutaneous melanoma related to sun exposure [54].

The number of melanocytic nevi represents a good predictor for cutaneous malignant melanoma, as the risk increases almost linearly with the number of common melanocytic nevi [18]. The presence of a high nevus count (more than 100 nevi) is associated with an almost seven-fold significant increased risk of melanoma compared with <15 nevi (RR = 6.89; 95% CI 4.63–10.25) [54, 127]. A high number of nevi on the arms may represent an increased total nevus count. People with 11–15 common nevi on the arms present an almost five-fold greater risk of melanoma than those with no nevi (RR = 4.82; 95% CI 3.05–7.62) [127].

Atypical nevi may play an independent role in melanoma risk, as the presence of five atypical nevi increases the risk ten-fold compared with the absence of atypical nevi (RR = 10.12; 95% CI 5.04–20.32) [54, 127]. Atypical nevi are usually larger than common nevi with a border not well defined, size 5 mm or more, color variegated, contour uneven, and presence of erythema [54].

Sporadic atypical melanocytic nevi outside the context of dysplastic nevus syndrome and/or familial melanoma are considered independent risk markers for sporadic melanoma [18].

Giant congenital nevi are also associated with increased risk, with a cumulative 5-year risk of cutaneous melanoma estimated at 5.7% [6, 41].

Persons with the atypical or dysplastic nevus syndrome (Clark nevus syndrome) present multiple atypical moles that continue to appear in adulthood and are at much higher risk of melanoma [54]. Individuals with atypical nevus syndrome and at least two family members with melanoma have a 500-fold increase in melanoma risk [127].

Personal or Family History of Melanoma and Genetic Factors

The presence of a history of melanoma or nonmelanoma skin cancer is associated with a three-fold relative risk of melanoma [6]. Personal history of melanoma increases 5–8% the risk of developing a second primary melanoma 49, 94, 122).

Approximately 5–10% of melanoma cases occur in a familial setting [122]. A family history of melanoma is considered positive if the patient has reported one or more affected first-degree relative [53]. Patients with a positive family history of melanoma have an RR of 1.74 compared with those with a negative family history [58].

In high-risk families, melanoma susceptibility is inherited following an autosomal dominant inheritance pattern with incomplete penetrance [19]. Multiple primary melanoma patients may also have inherited melanoma susceptibility and often present atypical mole phenotype [3, 20, 122, 126].

Two main genes are described as melanoma high-susceptibility genes: cyclin-dependent kinase inhibitor 2A (*CDKN2A*) and cyclin-dependent kinase 4 (*CDK4*). Germline CDKN2A mutations have been described in 20–50% of melanoma-prone families and in up to 15% of multiple primary melanoma patients irrespective of family history [62, 83]. However, the probability to have *CDKN2A* mutations in sporadic melanoma patients without personal or family history of melanoma is about 1% [122]. The penetrance for melanoma in *CDKN2A* carriers at the age of 80 years was reported to be 58% in Europe, 76% in the United States, and 91% in Australia [17]. Carriers of *CDKN2A* mutations also have an increased risk for developing pancreatic, breast, lung, and other tobacco-related cancers [21, 76, 123].

Another gene, the α-melanocyte-stimulating hormone (α-MSH) receptor 1 (*MC1R*), is considered a low to moderate gene risk and its variants are associated with skin and hair pigmentation. *MC1R* is one of the key regulatory genes in human pigmentation and is highly polymorphic in the Caucasian population [123]. The R variants are highly associated with red hair color phenotype (p.D84E, p.R142H, p.R151C, p.I155T, p.R160W, p.D294H) and are those most implicated with melanoma susceptibility. Carriers of two R alleles are at four- to six-fold higher risk of developing melanoma compared with individuals without these variants [123]. Recently it was shown that carriers of *MC1R* variants had increased melanoma risk independent of sun exposure [166].

Germline mutations in other genes such as breast cancer 1 (*BRCA1*) associated protein 1 (*BAP1*), telomerase reverse transcriptase (*TERT*), protection of telomeres 1 (*POT1*), and microphthalmia-associated transcription factor (*MITF*) were described in *CDKN2A* wild-type melanoma-prone families and may be responsible for a lower number of familial melanoma cases.

Genetic counseling and specific dermatologic follow-up should be offered to individuals belonging to melanoma-prone families or families with melanoma-related cancers (sarcoma, early-onset breast cancer, brain tumors, or pancreatic cancer) and/or with multiple primary mel-

anomas [128, 173]. Genetic testing should only be performed in individuals with at least a 10% chance of carrying a mutation before the test is done [7, 71].

Other Factors

There is an increase in incidence and poorer prognosis of melanoma in patients after organ transplantation associated with medical immuno-suppression. On the other hand, the scarcity of evidence does not permit us to establish a clear association between pregnancy or hormones and the risk or prognosis of melanoma [6]. Recently, a systematic review and meta-analysis showed increased risk of melanoma death (pooled hazard ratio [HR] 1.56, 95% CI 1.23–1.99) for pregnancy-associated melanoma compared with other melanomas, although this is debatable on a methodological level [26, 172].

Clinical Presentation

The World Health Organization (WHO) classification distinguishes four major clinical-histopathologic subtypes of melanoma: superficial spreading melanoma (SSM), NM, acral lentiginous melanoma (ALM), and lentigo maligna melanoma (LMM) [35, 65, 161]. Although these proposed categories represent distinct clinical and histopathologic presentations that are valuable for recognition and diagnosis, the impact of this classification on predicting prognosis and defining clinical management has been limited [18, 161].

SSM is the most frequent histopathologic subtype of melanoma in fair-skinned individuals [18]. It accounts for approximately 65% of all melanomas and the median age of diagnosis is between 40 and 60 years [18, 65]. SSM is most frequently seen on intermittently sun-exposed skin of the trunk of men and the legs of women, but may arise at any site. It usually begins as an asymptomatic brown to black mac-

ule with color variegation and irregular borders, sometimes also exhibiting pink discoloration. After a slow macular radial growth phase, a papular or nodular vertical growth phase develops (Fig. 16.1). Gray pigmentation and hypopigmentation are signs of regression associated with a host immune system response. Early-stage melanomas of ≤5 mm diameter may present asymmetry of pigmentation and borders [18].

NM represents around 20% of all primary melanomas diagnosed and often fails the ABCD categorization of suspicious lesions. The more aggressive biology of NM accounts for a shorter duration and advanced thickness of NM at presentation, and supports the importance of the "E" for evolution to the ABCD criteria [65]. Nodular melanoma usually presents as a black or blue nodule, sometimes pink to red (amela-notic), which may be ulcerated or bleeding (Fig. 16.2) [18].

Usually NM is firm and elevated with a history of fast growth. The acronym "EFG" (E = elevated, F = firm, and G = growing progressively for more than a month) indicates clinical clues for diagnosis [30, 60].

LMM represents approximately 10% of melanomas and usually develops in the seventh decade and later (Fig. 16.3) [18].

LMM occurs in chronically sun-exposed areas such as face and neck, and less frequently in the upper trunk and extremities [124]. Recognition of LMM in early stages is often difficult because its presentation can be quite subtle, and delayed diagnosis is common [124]. According to the English language literature, the entity is called "lentigo maligna" when it is confined to the epidermis (in situ) and as "lentigo maligna melanoma" when it invades the dermis. Currently it is generally believed that lentigo maligna and LMM belong to the same evolutionary spectrum, i.e., the same entity at different stages of development [124, 154]. In daily clinical practice, the diagnosis of facial lentigo melanoma may be a diagnostic challenge because of its similar clinical features to
Fig. 16.2 Clinical and dermoscopic presentation of pigmented and amelanotic nodular melanoma. (**aI**) Clinical picture of a pigmented nodular lesion on the back. (**aII**) Dermoscopic image of a nodular melanoma presenting blue color, polymorphic vessels, shiny white streaks, and a small ulceration. (**bI**) Clinical picture of a nodular red tumor on the lumbar region. (**bII**) Dermoscopic image of an amelanotic melanoma presenting white and red colors, atypical linear and dotted vessels, and large ulcerated areas

other lesions such as solar lentigines and pigmented actinic keratosis [2].

ALM is an infrequent subtype of melanoma arising on the palms, soles, and nail apparatus. It represents approximately 5% of all melanomas and up to 70% of melanomas diagnosed in black individuals. At acral sites melanoma typically presents as an asymmetric brown to black macule with color variation and irregular borders (Fig. 16.3). ALM may be amelanotic and are easily misdiagnosed as verrucae or other benign conditions [18].

NAM is rare and accounts for 0.18–2.8% of all melanomas. The relative incidence of NAM among Africans and Asians is much higher than that found among Caucasians [132]. Melanoma mainly arises from the nail matrix but it is also found in the nail bed and lateral folds [132]. NAM of the nail matrix can present as longitudinal pigmentation (also known as melanonychia striata longitudinalis), as shown in Fig. 16.3. Early pigmented nail-unit melanoma is characterized by brown background associated with longitudinal lines that are irregular in color, width, spacing, and parallelism. Nail melanoma may also present as a black background with areas of different hue of pigmentation, with barely visible lines. About 20–30% of cases of NAM are amelanotic [132]. When arising in the nail bed NAM presents as a nodule that can be
Fig. 16.3 Clinical and dermoscopic picture of melanoma at special sites: facial, nail, and acral. (**aI**) Clinical picture of a macular brown-black macule on the face. (**aII**) Lentigo maligna melanoma showing annular-granular pattern with gray dots, asymmetric pigmented follicular openings, rhomboidal structures, and obliterated hair follicles. (**bI**) Clinical picture of a melanonychia striata longitudinalis on the index finger. (**bII**) Dermoscopy shows a nail apparatus melanoma with brown background of pigmentation and irregular pattern of the longitudinal microlines that are irregular in color, thickness, and spacing; there is also erosion of the nail plate with dystrophy. (**cI**) Clinical picture of a black- to brown-colored pigmented patch on the lateral plantar region. (**cII**) Dermoscopy of an acral lentiginous melanoma with parallel ridge pattern and irregular diffuse pigmentation

ulcerated and bleeding with partial destruction of the nail plate. The use of the "ABCDEF" rule was suggested to evaluate suspicious melanonychia: A stands for "age, Asian and African American"; B for "brown, black, breadth, and borders"; C for "change or absence of change, despite adequate treatment"; D for digits (thumb, hallux, index finger); E for extension of pigment (Hutchinson sign); and F for familial history of melanoma [97]. The Hutchinson sign describes the presence of pigment on the proximal, lateral, or distal fold, which represents the radial growth phase of subungual melanoma.

Mucosal melanomas account for approximately 1.3–1.4% of all melanomas. In early stages mucosal melanoma presents clinically as brown-black macules with shades of gray, sometimes with multifocal distribution. Advanced mucosal melanomas usually develop black to dark brown nodules combined with the macular part at the base of a tumor [79].

Less prevalent melanoma variants with distinct clinical-epidemiologic presentations are spitzoid, nevoid, desmoplastic, malignant blue nevus, and ocular melanoma.

Diagnosis

Melanoma diagnosis is a constant challenge in clinical practice, since it represents a potentially fatal skin cancer and the prognosis is strictly related to early detection.

Clinical recognition is classically associated with the ABCD(E) mnemonic of melanoma, which was designed to provide simple criteria for early diagnosis by physicians and general population. Friedman et al. [52] published the ABCD acronym (asymmetry, border irregularity, color variegation, diameter >6 mm). The letter E (for evolution) was subsequently added in order to include some tumors that could be missed by

other criteria, especially small and nodular melanomas. Clinicians and patients should be attentive to changes (evolving) of size, shape, color, and symptoms such as itching or bleeding [1, 61, 75, 133]. The EFG rule stands for an Elevated, Firm, or Growing lesion and helps to identify amelanotic and nodular melanomas, which are often clinically symmetric and uniform in color.

Another important clinical clue for suspicious lesions is the "ugly duckling sign." In a person with multiple nevi, lesions tend to resemble one another. A mole that deviates from that nevus pattern should be carefully analyzed [66, 144]. The main concepts regarding melanoma diagnosis are described in Box 16.1.

Box 16.1 Diagnosis of Cutaneous Melanoma

Clinical presentation: ABCDE rule (asymmetry, border irregularity, color variegation, diameter >6 mm, evolution/ evolving); nodular melanoma: EFG rule (elevated, firm, growing)

Dermoscopy: noninvasive technique that increases accuracy in melanoma diagnosis

Total-body photography and digital dermoscopy: used for surveillance of high-risk patients, allowing diagnosis of "featureless" melanomas, while minimizing unnecessary biopsies

Reflectance confocal microscopy: noninvasive technique that allows the skin evaluation at cellular level and quasi-histologic resolution, improving diagnostic accuracy for melanoma and reducing unnecessary excisions

Histopathology: excisional biopsy and histopathologic evaluation is the gold standard for melanoma diagnosis

---

Dermoscopy

Incipient melanomas often do not fulfill some of the clinical ABCD criteria [141]. Dermoscopy increases sensitivity in the clinical diagnosis of melanoma from 60% to up to 90% [4]. It has been proved by three meta-analyses to be more accurate than naked eye examination for the diagnosis of cutaneous melanoma [8, 87, 160], and is now widely accepted by dermatologists in routine tumor screening. This noninvasive and low-cost technique allows the recognition of morphologic structures not visible to the naked eye, allowing the detection of clinically unsuspected lesions. Besides the proven value in differentiating benign and malignant melanocytic lesions, it is also very useful in the differential diagnosis with nonmelanocytic melanoma simulators such as pigmented basal cell carcinoma, which have specific dermoscopic features that can lead to a straightforward diagnosis [104].

Multiple algorithms were created and validated to guide the differentiation between benign and malignant melanocytic lesions and help in the decision to perform a biopsy, including the ABCD rule, Menzies method, the seven-point checklist, pattern analysis, and more recently Kittler's algorithm based on pattern analysis. Pattern analysis is the preferred method by experienced dermatologists and has the same sensitivity with higher specificity [4]. This method describes global and local features to be analyzed. Global patterns related to melanoma are multicomponent (association of three or more dermoscopic structures), atypical starburst or starburst pattern in adults, atypical reticular, atypical globular, and nonspecific pattern. Local features that should raise concern for melanoma are atypical pigmented network, irregular dots, globules, streaks or blotches, atypical vessels, and blue-white structures (including blue-white veil and regressive structures).

Total-Body Photography and Digital Dermoscopy

Despite the great benefit provided by dermoscopy, there remains a small proportion of difficult-to-diagnose melanomas that could require a different approach for recognition. Incipient melanomas may lack dermoscopic features specific to this disease [86, 125], and patients can present multiple clinically and dermoscopically atypical nevi, sometimes impossible to distinguish from early melanomas [15, 106]. Total-body photography (TBP) and digital dermoscopy (DD) are the most reliable
Fig. 16.4 Clinical and dermoscopic picture of an incipient melanoma detected by digital dermoscopy follow-up. (**a**) Clinical picture of a high-risk patient with increased nevus number and atypical melanocytic nevi (dysplastic nevus syndrome). Atypical melanocytic lesion on the left forearm (*arrow*) is followed by digital dermoscopy. (**b**) Dermoscopic image shows a predominant reticular pattern at baseline with discrete white network and irregular clods. (**c**) The same lesion at 8-month follow-up developed focal hyperpigmentation, dotted vessels, and accentuated white network; the diagnosis of an early invasive melanoma (Breslow 0.4 mm) was confirmed on histopathology

approaches to detect initial melanoma in high-risk patients [139, 140]. TBP consists of baseline body photographs for follow-up comparison that facilitate the detection of new and changing lesions. This information is very important, as it is well known that melanoma often develops de novo in clinically normal-appearing skin rather than in pre-existing melanocytic nevus [164]. DD allows the capture and storage of the dermoscopic images and its monitoring over time, enabling the detection of subtle changes associated with melanoma (Fig. 16.4).

A meta-analysis of digital follow-up demonstrated that this technique allows the diagnosis of "featureless" melanomas, recognized only because of changes [142], while minimizing unnecessary biopsies, since stable atypical lesions are considered benign and can be followed without excision.

Reflectance Confocal Microscopy

Recently, reflectance confocal microscopy (RCM) has been introduced in dermatologic research to provide important additional information in equivocal melanocytic lesions [59, 120]. This noninvasive technique allows skin evaluation at the cellular level and quasi-histologic resolution with histopathologic correlation. Many studies have demonstrated that RCM is particularly useful as a second-level examination of doubtful lesions selected by dermoscopy or DD

[69, 101], increasing sensitivity and avoiding unnecessary biopsies.

Histopathology

Melanoma diagnosis is established by histopathologic examination. Atypical melanocytes are seen singly and in small nests in the epidermis and papillary dermis in radial growth phase, and characteristically atypical cells show upward (pagetoid) migration in multiple layers within the epidermis. In situ lesions are confined to the epidermis. In the vertical growth phase nests/nodules of malignant melanocytes expand further into the reticular dermis and beyond. Numerous mitotic figures often are noted and there is absence of maturation at deeper levels of the dermis.

Breslow tumor thickness (depth of invasion in millimeters), ulceration and mitotic rate are the three most important characteristics of the primary tumor for predicting outcome [9] and should always be mentioned. It is also recommended for the pathology report to include deep and peripheral margin status, microsatellites, pure desmoplasia if present, and Clark (invasion) level for nonulcerated lesions 1 mm or less where mitotic rate is not determined. Microsatellitosis is defined as the presence of tumor nests greater than 0.05 mm in diameter, in the reticular dermis, subcutaneously, or vessels beneath the principal invasive tumor but separated from it by at least 0.3 mm of normal tissue [116].

Some melanocytic lesions can be very challenging and simulate melanoma histopathologically, requiring evaluation by an experienced pathologist, as in the case of atypical nevi and spitz nevi, recurrent, traumatized and UV-exposed lesions, and specific locations such as genital and acral nevi.

Immunohistopathology

Immunohistochemical stains usually are not necessary for diagnosis of cutaneous melanoma, but can be useful in difficult cases to help the differentiation from benign lesions and especially from nonmelanocytic tumors. S-100 is the most sensitive marker for melanocytic lesions, although not specific, and HMB45 is highly specific but has limited sensitivity. Ki67 is a proliferation marker and can help to distinguish nevi from melanoma [118].

Complementary Examinations

Although there is scarce epidemiologic data regarding the use of laboratory and imaging tests in the initial evaluation of melanoma patients, they may be necessary to accurately stage patients prior to definitive treatment [34]. The general approach according to clinical/pathologic stage is summarized in Table 16.1.

Differential Diagnosis

Differentials to consider in the diagnosis of malignant melanoma include many melanocytic and nonmelanocytic conditions, as follows:

Melanocytic:
- (Atypical) Melanocytic nevi
- Spitz nevi
- Blue nevi
- Combined nevi
- Recurrent nevi
- Congenital nevi
- Halo nevi

Table 16.1 Imaging and laboratory evaluation for workup of cutaneous melanoma according to stage

Stage	Evaluations
0 (in situ)	Routine imaging or laboratorial tests are not recommended
I–II	Baseline chest X-ray
	CT and PET/CT scan: limited value for detecting unsuspected visceral metastases in asymptomatic patients
	Imaging tests only to evaluate specific signs and symptoms
III	Baseline imaging for staging and to evaluate specific signs and symptoms:
	CT of the chest and abdomen
	PET/CT in high-risk patients: may be preferred if available
	Bone scans: have not had any clinical value in asymptomatic patients
IV	Baseline imaging for staging and to evaluate specific signs and symptoms:
	LDH serum levels
	MRI of the brain and CT of the chest, abdomen, and pelvis
	PET/CT: patients who have solitary or oligometastatic disease, where the issue of surgical resection is more relevant

CT computed tomography, *PET* positron emission tomography, *LDH* lactate dehydrogenase, *MRI* magnetic resonance imaging

- Ink-spot lentigo
- Melanosis of mucosal regions

Nonmelanocytic
- Basal cell carcinoma
- Bowen's disease
- Seborrheic keratosis
- Pigmented actinic keratosis
- Thrombosed hemangioma, angiokeratoma
- Paget's disease
- Metastatic tumors to the skin
- Adnexal tumors
- Pyogenic granuloma
- Dermatofibroma
- Dermatofibrosarcoma protuberans
- Kaposi's sarcoma
- Subungual hematoma
- Black heel (hemorrhage in stratum corneum caused by trauma)
- Tinea nigra

Staging

The staging system is essential for the best therapeutic choice, owing to the strong correlation between the clinical and pathologic characteristics with the prognosis. In 2017, the American Joint Committee on Cancer (AJCC) 8th Edition updated the TNM staging system [1, 2] (Tables 16.2 and 16.3 [171]).

Therapeutic Approach

Surgical Treatment of Cutaneous Melanoma

Despite the clinical advances in the differentiation of a suspicious lesion on skin, biopsy is required for the evaluation of histology and determining the diagnosis [55, 134]. The treatment of cutaneous primary melanoma is fundamentally surgical. After initial biopsy, the definitive treatment of primary melanoma is wide local excision associated with sentinel lymph node biopsy (SLNB) when indicated. It is important to note that the surgery in two stages is a key concept in the treatment of cutaneous melanoma.

Excisional Biopsy

Excisional biopsy is considered the gold standard in the diagnosis of cutaneous melanoma [155]. It consists of complete resection of suspicious skin lesion, usually through a fusiform incision with scant side edges (2 mm), including the subcutaneous tissue. The analysis of the completeness of the primary tumor is the most accurate way for the recognition and evaluation of the microstaging criteria, especially the depth of invasion (Breslow), which is the most important factor in defining the prognosis (chance of lymph node and systemic involvement) and final resection margins [5, 36].

The incision in the trunk, head, and neck, generally elliptical, must be directed toward the skin tension lines (Langer's lines) to facilitate subsequent surgical treatment (margins of expansion), reaching improved functional and cosmetic results [82, 155]. In the limbs the guidance should be longitudinal, following and preserving the

Table 16.2 TNM staging system for cutaneous melanoma according to AJCC 2017

Primary tumor (T)	
Tx	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Melanoma in situ
T1	≤1 mm
T1a	Without ulceration and <0.8 mm in thickness
T1b	<0.8 mm in thickness with ulceration or 0.8–1.0 mm in thickness regardless of ulceration
T2	1.0–2.0 mm
T2a	Without ulceration
T2b	With ulceration
T3	2.0–4.0 mm
T3a	Without ulceration
T3b	With ulceration
T4	>4.0 mm
T4a	Without ulceration
T4b	With ulceration
Regional lymph nodes (N)	
NX	Regional nodes cannot be assessed
N0	Absence of lymph node involvement
N1	One tumor involved lymph node or in-transit, satellite, and/or microsatellite metastasis with no tumor-involved nodes
N1a	One clinically occult (detected by SLNB)[a]
N1b	One clinically detected
N1c	In-transit, satellite, and/or microsatellite metastasis with no tumor-involved node
N2	Two or three tumor-involved nodes or in-transit, satellite, and/or microsatellite metastasis with one tumor-involved node
N2a	Two or three clinically occult (detected by SLNB)[a]
N2b	Two or three, at least one of which was clinically detected
N2c	One clinically occult or detected with in-transit, satellite, and/or microsatellite metastasis
N3	Four or more tumor-involved nodes or in-transit, satellite, and/or microsatellite metastasis with two or more tumor-involved nodes or any number of matted nodes without or with in-transit, satellite, and/or microsatellite metastasis
N3a	Four or more clinically occult (detected by SLNB)[a]
N3b	Four or more, at least one of which was clinically detected, or presence of any number of matted nodes
N3c	Two or more clinically occult or clinically detected and/or presence of any number of matted nodes with in-transit, satellite, and/or microsatellite metastasis

Table 16.2 (continued)

Distant metastasis (M)	
M0	No distant metastasis
M1	Evidence of distant metastasis
M1a	Distant metastasis to skin, soft tissue including muscle, and/or nonregional lymph node
M1a(0)	LDH level not elevated
M1a(1)	LDH level elevated
M1b	Distant metastasis to lung, with or without M1a sites of disease
M1b(0)	LDH level not elevated
M1b(1)	LDH level elevated
M1c	Distant metastasis to non-CNS visceral sites with or without M1a, M1b, or M1c sites of disease
M1c(0)	LDH level not elevated
M1c(1)	LDH level elevated
M1d	Distant metastasis to CNS with or without M1a, M1b, or M1c sites of disease
M1d(0)	LDH level not elevated
M1d(1)	LDH level elevated

lymphatic path, preventing loss in detection of SLNB and allowing a less complex subsequent definitive intervention [155].

Incisional Biopsy

In extensive lesions in specific locations (face/distal end) and in those with low index of suspicion for melanoma, where complete removal can cause serious sequelae, incisional biopsy may be indicated [82, 151, 155]. The removal of a fragment of skin lesion containing part of the tumor with positive lateral margins should reach the subcutaneous tissue and include the thicker or darker area, sometimes selected by dermoscopy. Technically it may be realized with a scalpel through an elliptical incision or "punch." However, it has been shown that the Breslow index (BI) is underestimated in a significant number of cases of incisional biopsy [19].

Shave Biopsy

There are two distinct types of shave biopsy: in the first, the withdrawal of a portion of the skin lesion into the dermis with a straight sharp blade positioned at 45° to the epidermis (incisional) is indi-

Table 16.3 Stage groupings for cutaneous melanoma

Stage	Clinical staging[a] T	N	M	Stage	Pathologic staging[b] T	N	M

[a]Clinical staging includes microstaging of the primary melanoma and clinical/radiologic evaluation for metastases
[b]Pathologic staging includes microstaging of the primary melanoma and pathologic information about the regional lymph nodes after partial or complete lymphadenectomy.

cated in the diagnosis of benign skin tumors or when the suspicion of melanoma is low [115, 116]. The second, called saucerization, consists in complete removal of the lesion with a straight blade and convex borders with lateral margins of at most 2 mm, reaching adipose tissue (excision) [134]. The latter technique is accepted as part of the procedure to diagnose cutaneous melanoma [116].

Fine-Needle Aspiration

Fine-needle aspiration is an accurate method for the diagnosis of possible metastatic lesions of cutaneous melanoma, but except in rare situations should not be used to confirm the primary tumor [36, 155]. Although this procedure is able to precisely identify the presence of melanoma, it does not allow the evaluation of relevant information such as the thickness (Breslow), ulceration, and so forth. This technique is valuable for the identification of subcutaneous metastases, soft tissue, and clinically positive nodes, with a high accuracy of 92.1% sensitivity and 99.2% specificity [112, 135].

Biopsy of Special Sites

Melanocytic lesions suspicious located on the mucosal surfaces of the oral or genital cavity should be biopsied by the same techniques as those for the skin. Because of the vascularity of these regions, careful local hemostasis should be performed after the procedure.

In suspected cases of ungual melanoma one fusiform excision biopsy is recommended, being narrow, longitudinal, and extending deep into the periosteum. Thus, information is obtained from all elements of the nail unit: proximal nail fold, matrix, bed, and plate [131]. Pigmentation on the matrix provides valuable guidance during surgery, although it is not always present. To minimize the subsequent nail dystrophy biopsy, repositioning of the lateral margins should always be carried out. The use of a "punch" can be advantageous when there is a chance of nail matrix melanoma. This procedure is performed with or without avulsion of the ungual plate [13].

Treatment of the Primary Lesion

In the definitive surgical procedure with wide local excision, all layers of the skin to the muscle fascia should be removed (deep margin) [143]. With respect to radial margins, in melanomas in situ the recommended removal is 0.5 cm in complex areas (e.g., on the face) at 1 cm from the lesion or site of

Table 16.4 Surgical margins for wide excision of primary melanoma

Tumor thickness	Recommended margins
In situ	0.5–1 cm
≤1.0 mm	1 cm
>1–2 mm	1–2 cm
>2–4 mm	2 cm
>4 mm	2 cm

Adapted from NCCN [116]

biopsy [5, 116]. In tumors of thickness up to 1 mm, the lateral margin recommended is 1 cm [36]. In tumors of thickness 1–2 mm, a resection margin of 1 cm (e.g., on the face) to 2 cm is recommended [116, 159]. Above 2 mm of tumor thickness it is established that 2 cm is adequate. In thick tumors ≥4 mm, a 2-cm excision margin is appropriate (Table 16.4).

Local recurrences are considered recurrences within 2 cm of the scar from the primary melanoma excision. Local recurrence is reported to be strongly associated with the development of in-transit, regional, and distant metastasis [18].

Sentinel Lymph Node Biopsy

This technique is used in an attempt to show early lymph node metastases (micrometastases), identifying which individuals need to undergo radical surgery of the lymph nodes and who will benefit from adjuvant systemic treatment. SLNB is considered the standard of care in evaluating the staging and prognosis of patients with cutaneous melanoma in whom there is a substantial risk of regional node metastasis [70, 147].

As the BI is the main factor associated with SLNB positivity, patients with in situ melanoma (Stage 0) should not undergo SLNB. For patients with melanoma under 0.76 mm and no factors for increased risk of nodal involvement such as ulceration of the primary tumor, a mitotic rate ≥1/mm^2, or lymphovascular invasion, SLNB is not indicated. In the rare event that a conventional high-risk feature is present in melanomas ≤0.75 mm, the decision regarding SLNB should be considered on an individual basis. In patients with melanoma Stage IA that are 0.76–1.0 mm thick with

no ulceration and mitotic rate <1 per mm^2, the recommendation is not fully uniform (most guidelines do not recommend the procedure, although the NCCN latest update enters the possibility to be discussed with the patient). For patients with Stage IB or II melanoma (0.76–1.0 mm thick with ulceration or mitotic index ≥1 and/or lymphovascular invasion or >1.0 mm, any feature), SLNB is recommended [116, 163, 167]. For patients with thick tumors (>4 mm) SLNB provides prognostic information, regional disease control, and identification of candidates for adjuvant therapies.

The procedure has three distinct phases: lymphoscintigraphy, radio-guided detection of the ganglion, and pathologic evaluation of the specimen. In the first step, conducted in the nuclear medicine sector, identification of the path of lymphatic drainage is made by intradermal injection around the scar of previous biopsy of a radioactive contrast agent (technetium-99m and phytate, or dextran or sulfur colloid) for identification of the nodal basis [149]. In a second step, an intradermal injection of a bluish dye (isosulfan blue or patent blue) is realized intraoperatively for 10–20 min before the incision in the area previously identified by lymphoscintigraphy. After this time, with the aid of a probe that detects radiation (gamma-probe), it proceeds to location of the labeled node. The injection of the radiopharmaceutical added to the blue substance allows the location of the lesion in 98% of cases [27]. The third phase comprises the histologic and immunohistochemical evaluation of the surgical specimen.

The risk of a positive result on SLNB in melanomas 1.01–2.0, 2.01–4.0, and ≥4.01 mm in size is approximately 12%, 28%, and 44%, respectively [138]. In patients with melanoma 0.75–1.0 mm thick, the positivity of SLNB is around 6.2% [116]. The prognostic significance of SLNB and its impact in survival was accessed by the Multicenter Selective Lymphadenectomy Trial I (MSLT-I) [110]. SLNB was confirmed as a prognostic tool for patients with intermediate (1.2–3.5 mm) and thick (>3.5 mm) melanomas. The melanoma-specific survival rate at 10 years was significantly worse in patients with a positive lymph node biopsy than in those with a negative lymph node biopsy [110]. Although for the overall study population no treatment-related difference

in the 10-year melanoma-specific survival was shown, the 10-year melanoma-specific survival rate was significantly improved in patients with intermediate-thickness melanomas (1.20 to 3.50 mm) found to have nodal metastases who underwent SLNB and immediate lymphadenectomy compared with those initially managed with observation followed by treatment when they developed clinical disease. More recently, the international trial MSLT-II has shown that in patients with melanoma and sentinel-node metastasis the immediate completion lymphnode dissection increased the rate of regional disease control at three years but did not increase melanoma-specific surviva l, which contrasts with MSLT-I results [179] . It is possible that a survival benefit with early surgery occured among patients with disease that was limitated to the sentinel node and in MSLT-II it was not seen due to a dilution of therapeutic effect, since the majority of the study population did not have melanoma in nonsentinel nodes

If SLNB is negative, regional lymph node dissection is not indicated. Patients with positive SLNB (Stage III) should undergo a complete lymph node dissection of the involved nodal basin with risk of additional positive nonsentinel nodes in 18% of cases [116].

Clinically Detectable Regional Lymph Nodes

Complete regional lymphadenectomy is the first-line therapy for patients presenting positive nodes proved by clinical examination, cytology (fine-needle aspirate), or histology (lymph node biopsy) without radiologic evidence of distant metastases [162]. Surgical management in this setting is associated with improved long-term disease-free survival and decreased morbidity caused by mass effect from involved nodes [116]. The prognosis of patients with lymph node metastasis varies with the number of positive lymph nodes, their presentation (micro- or macrometastasis), and characteristics of the primary lesion (thickness, ulceration, and mitosis). Therefore, the surgical approach provides an accurate staging in addition to local control of the disease.

Locoregional Advanced or Metastatic Disease

Melanoma usually metastasizes first to lymph nodes and then to secondary sites such as skin, subcutaneous soft tissue, brain, and lung. Metastatic spread is mainly regional in about 70% of patients, presenting as rapidly growing lymph nodes or as in-transit metastasis [18]. Cutaneous metastasis appears as a dermal nodule or plaque, more often in the proximity of the primary tumor. In-transit metastasis is defined as intralymphatic tumor in the skin or subcutaneous tissue more than 2 cm from the primary tumor but not beyond the nearest regional lymph node basin [116].

Surgical indication may have curative intent (completely resectable) or be palliative (quality of life). For individuals who have unresectable disease, an isolated limb perfusion (ILP) or isolated limb infusion (ILI) are alternative treatments with the intention of avoiding amputation. These techniques consist in treatment of the affected limb with regional chemotherapy (with melphalan) associated with hyperthermia, keeping it isolated from the rest of the body by a tourniquet [16, 153]. Another method is electrochemotherapy, a nonsurgical procedure used for palliation in patients unable to undergo ILP or ILI with unresectable lesions or metastases in transit (cutaneous and/or subcutaneous) [85, 108]. By this method the output of electrical pulses through electrodes placed on or near lesions increases cell membrane permeability; it is associated with intravenous chemotherapy, usually bleomycin and cisplatin [152]. In selected patients with Stage IV melanoma, when the molecular biology is favorable, the "performance status" is adequate, and the lesions are completely resectable, surgery may be indicated.

Adjuvant Treatment

Adjuvant therapy aims to improve the cure rate for melanoma patients who have already undergone a definitive surgical procedure. Various strategies have been tested over the years, including chemotherapeutic (such as cyclophosphamide and dacarbazine) and immunotherapeutic

agents [10, 148]. However, consistent benefit in overall survival in unselected melanoma patients has never been detected. Risk stratification and case individualization seems to be the best approach in adjuvant treatment for melanoma.

There is no benefit of adjuvant treatment in melanoma patients with BI ≤0.75 mm, without ulceration, and mitotic activity <1 mm^2. Cases with BI >0.76 mm and ≤4 mm, or BI <0.75 mm with ulceration or mitotic activity ≥1/mm^2 were studied in low-dose interferon-α (IFN-α) trials with different treatment durations. Although increased disease-free survival was observed [6–8], adjuvant treatment indication remains controversial in this scenario and observation or inclusion in clinical trials remain a viable, and usually preferred, option [67, 74, 119].

Predictive factors such as BI larger than 4 mm, presence of ulceration, and regional node involvement are strongly associated with a higher risk of local and systemic recurrence. This population was enrolled in trials of IFN-α at higher doses. In the ECOG 1684 trial, patients were randomly assigned to 1 year of high-dose IFN-α2b (20 million units/m^2 5 days per week for 4 weeks followed by 10 million units/m^2 subcutaneously three times weekly for an additional 11 months) or close observation. An increase in relapse-free survival (median 1.7 versus 1.0 years) and prolongation in median survival (3.8 versus 2.8 years) in the IFN-α group was detected. In a subsequent analysis with extended follow-up, the overall survival improvement in the treatment arm was no longer statistically significant [89, 90].

The Intergroup E1690 study compared high-dose IFN-α with low-dose IFN-α or observation only. The eligibility criteria for this study were similar to those for ECOG 1684, except that patients with clinically normal regional nodes were not required to undergo staging lymph node dissections. There was a significant increase in relapse-free survival for high-dose IFN-α in comparison with the observation group (HR = 1.28). Again, no overall survival benefit associated with high-dose IFN-α was observed [88].

IFN-α exposure is associated with significant rates of toxicity and the consequent need of dose reductions and treatment discontinuation. Fatigue, depression, myelosuppression, thyroid

dysfunction, and liver failure are among the more prevalent clinical manifestations. Systematic laboratory and clinical monitoring should be carefully pursued. Strategies such as the use of pegylated forms of IFN-α were tested in an attempt to address this issue. The EORTC 18991 study used 6 μg/kg weekly subcutaneously for 8 weeks (induction) followed by 3 μg/kg weekly subcutaneously up to 5 years (maintenance) and showed an increase in disease-free survival, particularly in the microscopic nodal disease subgroup (N1) [43].

For patients with impaired macroscopic or multiple lymph nodes (N2 and N3), there is meta-analytic proven benefit with adjuvant high doses of IFN-α. A meta-analysis that included 14 studies with a total of 8,122 patients compared the use of IFN-α with observation only, placebo, or GM2-KLH vaccine (considered inactive). This survey demonstrated increased disease-free survival (HR with recurrence 0.82, 95% CI 0.77–0.87) and overall survival (HR for death 0.89, 95% CI 0.83–0.96) with IFN-α treatment [109]. The adjuvant IFN-α at high doses consist of an induction phase of 20 million units/m^2 intravenously 5 days a week for 4 weeks followed by a maintenance phase with 10 million units/m^2 subcutaneously three times a week for an additional 11 months based on the ECOG 1684 trial [90].

Recently, ipilimumab, an anti-CTLA4 monoclonal antibody, was approved by the US Food and Drug Administration for adjuvant therapy. This approval was based on the EORTC 18071 clinical trial. The study included stage III patients and compared placebo with ipilimumab. With a mean follow-up of 2.7 years, an increase in relapse-free survival (HR 0.75, 95% CI 0.64–0.90) was detected. Long-term monitoring is still necessary to assess the impact on overall survival. Furthermore, it is important to emphasize the significant treatment-related toxicity: 90% of the patients had some immune-related effect. Moreover, five cases of death were related to the treatment with ipilimumab [42]. Trials comparing IFN-α and ipilimumab are currently in progress (ECOG 1609, NCT01274338).

Radiation therapy may have a role as adjuvant therapy after primary surgery for melanomas, but is associated with a higher rate of local recurrence despite adequate excision, such as those with positive margins. Adjuvant radiotherapy after lymph node dissection can also be considered when factors that impact negatively on local control (such as extranodal tumoral extension) are present. Data showing a decreased rate of local occurrence is available, but no difference in improved overall survival was detected [25, 68]. Thus there is no routine indication for the use of adjuvant radiotherapy in unselected cases and treatment should be individualized, considering margins and lymph node dissection findings.

Palliative Treatment

For many years, cytotoxic chemotherapy had been widely used as the main therapeutic strategy in patients with advanced melanoma. Although response rates were associated with chemotherapy exposure, no schedule has demonstrated an increased overall survival. Nowadays, with advances in immunotherapy and molecularly targeted therapy, the roles of chemotherapy are restricted to later treatment lines.

There is no consistent clinical benefit with single-agent versus combination chemotherapy. The agent most commonly used in patients with metastatic melanoma is dacarbazine [38]. Temozolomide, fotemustine, platinum compounds, vinca alkaloids, and taxanes also have experimental data describing limited activity [50, 150]. Combinations including cytotoxic agents and interleukin-2 and/or IFN-α (biochemotherapy) were previously evaluated with promising results, but with limited incorporation into routine clinical practice because of frequent and severe toxicity and the need for complex and intensive clinical management [48, 82].

The identification of genetic mutations on the genesis of melanoma and the understanding of the role of MAPK pathway activation have led to the identification of several target drugs and a paradigm shift in advanced melanoma treatment over the last decade. Molecular targets such as BRAF, MEK, RNA, and KIT were evaluated, and many predictors are being routinely used in the initial workup of patients with advanced melanoma as a tool to aid better therapy guidance.

BRAF mutations are found in approximately 50% of patients with cutaneous melanoma, and are more frequent in young patients and skin lesions without chronic sun damage [39, 40, 105], The presence of a V600 BRAF mutation predicts a higher response to BRAF and/or MEK therapeutic inhibition. Clinical activity of vemurafenib, dabrafenib, trametinib, and cobimetinib is being described by clinical trials in this scenario.

Vemurafenib is a potent inhibitor of BRAF. It was compared with dacarbazine in a phase III trial and showed increased overall survival (13.6 vs. 9.7 months, HR 0.70, 95% CI 0.57–0.87) [31, 107]. QT interval prolongation was described, requiring electrocardiogram monitoring. Sun-exposure avoidance and careful skin examination is mandatory since photosensitivity reactions and a high risk of cutaneous squamous cell carcinoma were strongly associated with vemurafenib use.

Dabrafenib is another inhibitor of BRAF that showed activity in patients with advanced melanoma BRAF V600E mutation. Dabrafenib was compared with dacarbazine and showed increased progression-free survival (6.7 vs. 2.9 months, HR 0.35, 95% CI 0.20–0.61) [73]. Preliminary assessment on updated data from the study showed promising results regarding overall survival benefit [72].

Trametinib is a MEK inhibitor initially evaluated in combination with dabrafenib in an attempt to retard the development of resistance BRAF inhibition. The COMBI-d trial showed that the combination led to an increased progression-free survival (median 11.0 vs. 8.8 months, HR 0, 67, 95% CI 0.53–0.84) and a tendency toward better overall survival. Furthermore, there was a reduction in the cutaneous toxicity incidence rate with the combination approach [51, 99]. Other studies have shown similar results [100, 136]. The vemurafenib–cobimetinib (a MEK inhibitor) combination was also tested, with a similar increase in disease-free survival, improvement in response rate, and tendency to increase overall survival compared with single-use vemurafenib [91, 95].

Advances in the understanding of immunologic mechanisms in melanoma tumorigenesis and progression also promoted the development of interventions capable of inducing significant impact on clinically useful endpoints. Ipilimumab is a monoclonal antibody directed against cytotoxic T-lymphocyte antigen 4 (CTLA-4) tested in clinical trials in the second line following chemotherapy or in combination with dacarbazine. Increased survival was observed in both settings [78, 137, 168]. As observed with many similar immunologic interventions, a slower pattern of response rates and a protracted clinical course of the disease, with longer periods of stable tumoral volumes, may be observed. In this setting, palliative surgical resections can be considered using an individualized approach.

Anti-PD1 antibodies, such as pembrolizumab and nivolumab, are one of the most recent therapeutic innovations in advanced melanoma care. Pembrolizumab showed increased progression-free survival and objective response rate in patients previously refractory to ipilimumab [130]. Similarly, when compared directly with ipilimumab, greater progression-free survival and overall survival was observed with pembrolizumab [136]. Nivolumab demonstrated increased overall survival in treatment-naive patients when compared with chemotherapy and an increased response rate in patients previously treated with ipilimumab [136, 165]. In addition, the combined administration of nivolumab and ipilimumab showed a higher response rate than these agents used alone, and mature overall survival data are promising [95]. Pharmacoeconomics concerns, long-term toxicities, optimal management of acute adverse effects, and the development of an optimal treatment sequence based on clinical and molecular stratification remain challenging issues in this rapidly changing scenario.

Follow-Up

Although the prognostic impact of a systematic follow-up approach, in particular with the introduction of new adjuvant interventions, is debatable, the early detection of a resectable locoregional recurrence or a second primary melanoma may lead to a more favorable outcome. The possibility of introducing any of the highly active new interventions before organ dysfunction secondary to metastatic disease may also represent a theoretical goal. Consensus recommendations tend to rely on clinical history and physical examination, saving laboratory tests (particularly serum lactate dehydrogenase) and

Table 16.5 Follow-up for cutaneous melanoma stages I to III

Stage	Evaluations
0 (in situ)	Clinical history and physical examination every 6–12 months during the first 5 years and every year after 5 years
	Routine imaging or laboratorial tests are not recommended
I	Clinical history and physical examination every 4–6 months during the first 2 years, then every 6 months for 5 years and every year after 5 years
	Routine radiologic imaging is not recommended
II	Clinical history and physical examination every 3 months during the first 2 years, then every 6 months for 5 years and every year after 5 years
	Consider routine LDH, chest X-ray, CT, brain MRI, and/or PET/CT scans every 3–12 months for up to 5 years
III	Clinical history and physical examination every 3 months during the first 2 years, then every 6 months for 5 years and every year after 5 years
	Routine LDH, chest X-ray, CT, brain MRI and/or PET/CT scans every 3–12 months for up to 5 years

Consider routine radiologic imaging in Stage ≥IIB according to [116]

CT computed tomography, *PET* positron emission tomography, *LDH* lactate dehydrogenase, *MRI* magnetic resonance imaging

imaging studies for patients at high risk of recurrence (Table 16.5) [29, 116] (Ryan et al. 2011).

Regional lymph node ultrasonography may be considered in Stage IB or higher and/or in patients with an equivocal lymph node physical examination or in whom SLNB was not possible (or not successful), according to the availability and accessibility of the method (grade of recommendation C) [29, 116].

Dosage of S100 protein serum levels may be valid in Stage IB or higher as a progression marker if available (level of evidence C) [29].

Prognosis

According to AJCC Melanoma Staging Database, among patients with T1 melanomas the 10-year survival rate was 92%, while it was 80% in T2

patients, 63% in T3 patients, and 50% in T4 patients. Five-year survival rates for Stage III were 78%, 59%, and 40% for patients with Stage IIIA, IIIB, and IIIC melanoma, respectively. In the absence of nodal metastases, patients with intralymphatic metastases have 5-year survival rates of 69%. One-year survival rates among Stage IV patients were 62% for M1a, 53% for M1b, and 33% for M1c melanomas [9].

Prevention and Screening

There is no consensus as to whether screening in the general population for melanoma is likely to be effective in reducing mortality, owing to the absence of randomized trials. However, there is current evidence that melanomas detected by the physician are thinner than those detected by patients or family members and that access to and the use of a dermatologist are correlated with a better prognosis [22, 46, 58, 146].

Based upon the available evidence, it is reasonable to recommend to high-risk individuals with a family history or presence of multiple and/or atypical moles to undergo at least annual full-body skin examination for routine screening of melanoma by a trained physician.

For the general population, educational measures such self-examination and careful observation of the skin may be encouraged. Clinicians should remain vigilant for skin lesions during routine or opportunist visits.

The "ABCD Rule" has been shown to be a valuable tool for teaching patients to identify changes that suggest melanoma. Trained people were more often able to diagnose melanoma than those who did not receive any information about the ABCD Rule [112].

Prevention measures for cutaneous melanoma are:

- Avoiding artificial tanning (tanning beds)
- Avoiding excessive sun exposure
- Wearing sunscreen and protective clothing
- Participating in skin cancer education programs
- Being familiar with the A, B, C, D, and E signs of melanoma
- Close monitoring of any changes in skin examination and seeking medical care

- Patient-based skin self-examination and periodic physician-based total-body skin examination are recommended in patients with multiple and/or atypical nevi
- Individuals at high risk (e.g., with many atypical nevi) may use TBP and DD for surveillance
- The strategy of prophylactic excision of all atypical melanocytic nevi in patients with multiple lesions is not proven to decrease risk

Glossary

Confocal microscopy Noninvasive technique using a confocal laser microscope that allows in vivo evaluation at cellular level and quasi-histologic resolution, improving diagnostic accuracy of melanocytic and nonmelanocytic skin lesions and reducing unnecessary excisions.

Dermoscopy Noninvasive technique that increases diagnostic accuracy of melanocytic and nonmelanocytic skin lesions using a magnifier polarized or nonpolarized light source.

Dysplastic nevus Atypical nevus or Clark's nevus. Melanocytic lesions that are larger than 5 mm, have irregular shape, indistinct borders, and variable pigmentation. Histologic features include disordered growth pattern, random cytologic atypia of melanocytes, and lymphocytic host response.

Sentinel lymph node The first lymph node or group of nodes draining the tumor site.

Target molecular therapy Drugs that block the growth and spread of cancer by interfering with specific molecules ("molecular targets") that are involved in the growth and spread of cancer.

Introduction

Primary cutaneous lymphomas (PCLs) are a group of extranodal non-Hodgkin lymphomas characterized by early accumulation of mononuclear cells, most of them lymphocytes, on skin, with no evidence of extracutaneous disease at diagnosis [1–4].

Epidemiology

PCL has an annual incidence estimated at between 0.3 and 1 per 100,000 inhabitants in North America and western Europe. Skin is the second extranodal locale most affected by lymphoma after the gastrointestinal tract. Approximately 75–80% of PCLs are classified as cutaneous T-cell lymphomas (CTCLs) and natural killer (NK) cell lymphomas, with an absolute predominance of mycosis fungoides (MFs), which corresponds to approximately 44% of all PCLs [2–9].

Etiopathogenesis

The etiology and the exact steps in the pathogenesis of CTCLs are not understood. It is more reasonable to assume that these diseases represent the end point of several different processes. The following factors should be considered in the etiology of CTCL [10].

Genetic Factors Including Chromosomal Abnormalities

The pathogenesis of CTCL is characterized by altered immune biology and the accumulation of cytogenetic abnormalities during disease progression, including increased transcription factor activity, such as amplification of JUNB, which is involved in T-cell proliferation, differentiation, and apoptosis [11, 12].

Changes in a number of tumor-suppressor and apoptosis-related genes (such as *p16*, *p15*, *p14*, *PTEN*, *p53*, *JunB*, *HLA-G*, *Fas*, Fas ligand, and *Nav3*) have been recorded in patients with MFs, Sézary syndrome (SS), and other CTCLs, although how most of these alterations affect T-cell behavior is still not clear [13]. In 50–85% of patients with MFs and SS who were tested, one frequent genetic abnormality seems to interfere with expression of NAV3, which might act as a tumor suppressor in T cells [14].

In addition to multiple defects in apoptosis, aberrant cell-cycle regulation, including inactivation of the CDKN2A-CDKN2B locus, is frequently observed in CTCLs [9]. Cyclin upregulation, including cyclin D1, and loss of RB1 have also been described [9, 15].

Furthermore, clonal T-cell receptor gene rearrangements are detected in most cases of CTCL [16, 17].

Environmental Factors

CTCL occurs more often than expected in immune-suppressed patients [18]. Transplant patients sometimes develop lymphomas, 30% of which are CTCLs, and these prognoses seem to be worse [19]. In addition, a number of CTCL cases have been described in the setting of human immunodeficiency virus [18, 20].

Furthermore, studies suggested associations of CTCL with industrial exposures, suggesting the role of environmental factors in triggering disease carcinogenesis. Subsequent case-control studies designed to explore such hypotheses have yielded mixed results. Some have failed to pro-

vide evidence for relationships between occupational, recreational, or chemical exposure history and development of CTCL [18]. By contrast, a multicenter European study showed that employment in the paper, glass, pottery, and ceramics industries [21] and occupational exposure to halogenated hydrocarbons [22] were associated with increased MF risk. However, such investigations have been difficult to execute and are complicated by the low prevalence of CTCL.

Infectious Factors

Numerous studies have illuminated the impact of human T-cell leukemia virus (HTLV) type 1 in the pathogenesis of adult T-cell leukemia/lymphoma (ATLL) [23, 24].

It has been proposed that antigens related to the Epstein–Barr virus (EBV) may be driving this abnormal interaction in CTCL, especially extranodal NK/T-cell lymphoma, nasal type [25–27]. Other members of the Herpesviridae family, such as human herpesvirus, also have been reported in patients with MF and parapsoriasis. A superantigen effect associated with *Staphylococcus aureus* has been proposed, based on the increased usage of V-beta families associated with *Staphylococcus* in MF cells as well as nonclonal T cells in MF lesions [28]. Other investigators have made associations between MF and SS, and the common cytomegalovirus.

Classification

The current classification for PCLs was proposed in 2005 by the World Health Organization (WHO) and the European Organization for Research and Treatment of Cancer (EORTC). This was the first classification that was accepted and used worldwide by pathologists, oncologists, hematologists, dermatopathologists, and dermatologists. According to this classification, PCLs were subdivided into NKTCL, cutaneous B-cell lymphoma (CBCL), and neoplasia of hematologic precursor [29]. In 2008 the WHO updated this classification with a few modifications of terminology [30] (Box 17.1).

Cutaneous T-Cell Lymphomas

Mycosis Fungoides

Clinical Presentation

MF usually affects adults, with an average age at diagnosis between 55 and 60 years old, but it may also occur in children and adolescents [11, 16, 31].

There is a predilection for male patients (2:1) [4, 11, 16, 25, 31]. It is more common in black persons (2:1) and less frequent in Asian and Hispanic individuals [4, 25].

Clinically, MF is characterized by patches, plaques, and/or tumors, which are usually erythematous and brownish [32, 33], with initial preference for covered areas of the body, such as buttocks, torso, and breasts [11, 16] (Figs. 17.1, 17.2, and 17.3). Other variables include the hypopigmented, hyperpigmented, vesicular, pustular, bullous, and granulomatous forms. MF is associated with follicular mucinosis, with or without alopecia, ichthyosis, and lichenoid-like pityriasis [4, 25, 32, 34–36].
Fig. 17.1 Erythematous and squamous plaques in a patient with mycosis fungoides

MF d'emblée is defined by the appearance of tumors without pre-existing lesions [32, 37]. Some authors argue that this can be a form of peripheral T-cell lymphoma, not MF [4, 16, 19].

Hypopigmented MF is characterized by lesions that may clinically resemble tinea versicolor, pityriasis alba, vitiligo, leprosy, sarcoidosis, and postinflammatory hypopigmentation. Although the patient may have only hyperpigmented lesions, the presence of concomitant erythematous lesions is common [25, 36].

Granulomatous cutis laxa is characterized clinically by large erythematous plaques that coalesce to form loose and hanging skin folds,

Fig. 17.2 Erythematous plaque in a patient with mycosis fungoides

similar to cutis laxa, located in intertriginous areas, such as inguinal regions and armpits or flexion areas [16, 19, 32, 38].

Folliculotropic MF is a variant whereby patients may have patches and plaques of classical MF, but hardened plaques, nodules, or tumors can also occur simultaneously, usually on the head and neck, with associated alopecia, since there is preference for the hair follicles. It mainly affects adults, but occasionally can occur in children and adolescents. Men are more frequently affected. Keratotic follicular papules, acneiform lesions, cysts, and comedones may be present in the lesion or perilesionally. As the disease progresses, bulky tumor masses occur [16, 17, 19, 34, 39].

Pagetoid reticulosis is by definition an MF variant restricted to cases with erythematous and scaly, solitary, well-circumscribed, slow-growing, lesions usually on the extremities [11, 16, 19, 29]. Extracutaneous dissemination or deaths related to the disease, contrary to classical MF, have not been reported [16].

Complementary Examinations

Histopathologic Examination

MF is characterized, in the stage of plaques, by a dense superficial infiltrate, frequently in band or lichenoid, of small lymphocytes, with atypical

Fig. 17.3 Tumoral mycosis fungoides

Fig. 17.4 Epidermotropism in a patient with mycosis fungoides
cerebriform nuclei, usually followed by a variable number of eosinophils. The epidermotropism of atypical lymphocytes, with Pautrier's microabscesses, is a histologic mark (Fig. 17.4). However, in the early stages of patches of MF, histologic findings are subtle, with atypias of absent or less prominent lymphocytes, vacuolization with interface changes, and alignment of lymphocytes across the junction. In the early MF, epidermotropism with Pautrier's microabscesses is found in only 19% of the biopsies [16, 19, 29, 32, 40].

With the progression to the tumor stage, the dermal infiltrate becomes diffuse and the epidermotropism may disappear. The tumor cells increase in number and size, presenting variable proportions of small, medium, and large cerebriform cells, and blastic cells with prominent nuclei and intermediate forms [16].

In ichthyosiform MF, a rare variant of MF, although the clinical features are indistinguishable from acquired ichthyosis, the histopathologic findings may be different. These findings reveal epidermotropic infiltrates composed of cerebriform lymphocytes typical of MF [25, 37]. The ichthyosiform area shows compact orthokeratosis and hypogranulosis, characteristic findings of acquired ichthyosis, beyond epidermotropic band-like infiltration, typically MF bands [25].

Granulomatous MF histologically presents with infiltrate similar to sarcoidosis or annular granuloma. Epidermotropism of atypical lymphocytes is present in only half of the cases. The granulomatous MF and granulomatous cutis laxa may overlap and often have identical histologic characteristics, so that a distinction must be based on clinical manifestations with occurrence of voluminous skin folds in the intertriginous areas in the cutis laxa [29].

In folliculotropic MF histology is diagnostic, with minimal epidermal involvement and prominent lymphocytic infiltrate of cerebriform cells inside and around follicles, with variable deposition of mucina, and follicle tropism instead of epidermotropism [16, 17, 19, 34]. Most cases show mucinous degeneration of the hair follicles (follicular mucinosis) upon Alcian blue staining and are traditionally categorized as MF associated with follicular mucinosis [16]. In some cases, prominent infiltration of the follicular epithelium and eccrine sweat glands may be observed [34]. Similar cases with prominent infiltrate of eccrine glands, often associated with alopecia, are called syringotropic MF [41].

In pagetoid reticulosis, histologically there is a hyperplastic epidermis with marked infiltration by isolated pagetoid cells or nests. Atypical cells

have small, medium, or large size and sometimes hyperchromatic and cerebriform nuclei, besides abundant vacuolated cytoplasm. The upper dermis may show lymphocytic or histiocytic infiltrate, but does not present with neoplastic T cells [16, 29].

Immunohistochemistry

MF is a neoplasia that classically presents predominantly the CD4+ phenotype. In addition to CD4, CD2, CD3, CD5, b-F1, and CD45RO are positive (Figs. 17.5 and 17.6). The phenotype CD8 is usually negative. Recently, several other phenotypes

Fig. 17.5 CD45 positive in a patient with mycosis fungoides
Fig. 17.6 CD3 positive in a patient with mycosis fungoides
were described, such as CD8+ and CD56+ MF with CD4− and CD8−. The difference in these markers does not seem to influence the prognosis or course of the disease [16, 29, 42]. The CD7 marker is usually deleted in MF [19, 32, 42]. Demonstration of an aberrant phenotype, for example, the loss of pan-T antigens CD2, CD3, and CD5, is frequently observed, and is an important adjunct to diagnosing MF. The expression of cytotoxic proteins (TIA1 and granzyme B) by neoplastic T cells is detected in 10% of MF plaques, but is more frequent in tumors with blastic transformation [16]. Sporadically, reactivity for CD15 is observed in advanced tumor stages of MF. Tumor cells may also show reactivity for CD30 in the stage of plaques and tumors.

Folliculotropic MF has neoplastic cells with phenotypes CD3+, CD4+, and CD8−, in most cases, as well as classic MF [16]. Pagetoid reticulosis is an MF variant with variable phenotypes, including CD3+, CD4+, and CD8− or CD3+, CD4−, and CD8+. The phenotype CD30 is also frequently expressed [16, 29].

Atypical cells of granulomatous cutis laxa express phenotypes CD3+, CD4+, and CD8− [16, 32].

Diagnosis

> Clinical manifestation + histopathologic examination, with immunohistochemistry.

Differential Diagnosis

Fungal infections, eczemas, pityriasis (rosea, lichenoid), psoriasis, leprosy, neoplasias.

Investigation

Lactate dehydrogenase (LDH), hepatic function, total blood cell count (all cases), Sézary cell count or immunophenotyping of blood cells, thorax and abdomen computed tomography (CT), lymph node biopsy (if palpable), bone marrow biopsy (tumoral stages).

Prognosis

For MF, the classification TNM (T, extension of the primary tumor; N, absence or presence and the extension of regional lymph nodes metastasis; M, absence or presence of distant metastasis) is used to estimate prognosis. However, this staging system is primarily used to define the extent of the disease and not as a prognostic guide [3, 43].

The most important predictors of survival in the MF are the T (tumor, in the TNM classification), extracutaneous manifestations, and age of the patient. Other independent factors of adverse prognosis include thickness of tumor infiltration, loss of T-cell markers, such as CD5 and CD7, existence of a T-cell clone in the peripheral blood in any stage of the disease, and chromosomal abnormalities in T cells [32, 44]. Blood involvement considered leukemic, with a large number of tumor cells in the blood, is considered comparable regarding prognosis with nodal involvement [44]. Marked eosinophilia is also a factor associated with worse prognosis [32].

Serum markers, such as lactate dehydrogenase (LDH), β2-microglobulin, and interleukin-2 are associated with a more aggressive disease. Multivariate analyses reveal that Stages IIb (tumors with or without lymph node compromise or metastases) and IV (any cutaneous lesion with metastasis or lymph node compromise) and age older than 60 years are independent predictors of worse survival [44]. Generalized cutaneous involvement is also considered a factor for worse prognosis [43].

Patients with MF in the stage of patches and plaques have life expectancy similar to persons without the disease. In the tumor stage, the 5-year survival rate is 70–80% [16]. Those with erythrodermal MF also generally have a worse prognosis [32].

There are at least two histologic findings that seem to be implicated, as independent factors, in a worse prognosis in MF: folliculotropic involvement (follicular mucinosis) and transformation to large cells [32, 44]. CD30 expression in MF

previously negative is frequently associated with progression to large cell lymphoma and presents a worse prognosis [42].

Moreover, the ulceration which can occur in the plaques and tumors of MF is usually a marker of worse prognosis. However, ulcerations caused by infection or necrosis because of multivariate analyses do not seem to change the prognosis. Studies using multivariate analyses also did not show independent prognostic value of bone marrow involvement [44].

Therapeutic Approach

Treatment of early MF, with skin-confined lesions, uses potent topical corticosteroids, calcineurin inhibitors, topical bexarotene, topical chemotherapy with nitrogen mustard (mechlorethamine or carmustine), phototherapy with ultraviolet B (UVB), narrow-band UVB, psoralens with ultraviolet A (PUVA), or localized irradiation or total skin electron irradiation (electron bath). In the cases with infiltrated plaques and tumors, there is preferential indication for total skin electron irradiation. The biological response modifiers, such as interferon (IFN)-α, bexarotene, and interleukin-2 fused to diphtheria toxin (denileukin diftitox) are increasingly used alone or in combination with topical treatments in advanced skin disease, systemic disease, and refractory cases, with partial remission rates. Polychemotherapy schemes similar to the ones used for non-Hodgkin nodal lymphomas are indicated in the cases of lymph node and/or visceral compromise and "advanced cutaneous disease refractory to the schemes directed to the skin" [3, 17, 19, 28, 32, 45–48].

The treatment for pagetoid reticulosis consists in surgical excision of single lesions or localized radiotherapy [16, 17]. In some cases, topical nitrogen mustard or topical steroids can be acceptable alternatives [16].

The treatment for granulomatous cutis laxa, although the clinical course is indolent, is difficult. Surgical excisions are followed by relapses. Radiotherapy can control the localized disease, but experiments with this method are limited [16, 17]. Other treatment options include radiation, PUVA, IFN, retinoids, and steroids, none of which show strong evidence of efficacy [32].

Sézary Syndrome

Clinical Presentation

SS, occurring exclusively in adults, is historically defined by the triad erythroderma, generalized lymphadenopathy, and presence of neoplastic T cells (Sézary cells) on skin, lymph nodes, and peripheral blood. Erythroderma is intensely itchy and may be associated with severe edema, exfoliation, and lichenification (Figs. 17.7 and 17.8). Moreover, alopecia, palmoplantar hyperkeratosis, and onychodystrophy are frequent clinical findings [16, 17].

Complementary Examinations

The recommended criteria for the diagnosis of SS include the presence of one or more of the following: (i) an absolute Sézary cell count of at least 1,000 cells/mm³; (ii) a CD4/CD8 ratio of 10 or higher caused by an increase in circulating T cells and/or an aberrant loss or expression of pan-T-cell markers by flow cytometry; (iii) increased lymphocyte counts with evidence of a T-cell

Fig. 17.7 Sézary syndrome, Exfoliative erythroderma in face

Fig. 17.8 Sézary syndrome. Exfoliative erythroderma in lower limbs

clone in the blood by the Southern blot or polymerase chain reaction technique; or (iv) a chromosomally abnormal T-cell clone [16, 49].

Histopathologic Examination

It can be similar to that for MF, but specific characteristics, such as epidermotropism of atypical lymphocytes, are found in only 40% of biopsies, and the cell infiltrate is more monotonous [16, 29, 32]. In the other cases infiltrates are found in the band of small lymphocytes, with or without nuclear atypia, and absence of epidermotropism or only a subtle perivascular infiltrate. There is leukemic dissemination of atypical tumor cells with large lymphocytes, called Sézary cells [29, 32].

Immunohistochemistry

SS presents a rise in CD4/CD8 count and aberrant CD3+, CD4+, CD5+, and CD45RO+ rates. CD7, CD8, and CD26 phenotypes are usually negative in circulating Sézary cells, although especially CD7 has been described as positive in some cases. In cases with CD3+, CD4+, and CD8+ predomi-

nantly on the T-cell population in the skin and peripheral blood, actinic reticuloid dermatosis must be considered [16, 19, 31, 32, 44, 47].

Diagnosis

One or more of the following: (i) an absolute Sézary cell count of at least 1,000 cells/mm³; (ii) a CD4/CD8 ratio of 10 or higher caused by an increase in circulating T cells and/or an aberrant loss or expression of pan-T-cell markers by flow cytometry; (iii) increased lymphocyte counts with evidence of a T-cell clone in the blood by the Southern blot or polymerase chain reaction technique; or (iv) a chromosomally abnormal T-cell clone.

Differential Diagnosis

Causes of erythroderma, for example, drug eruption, eczemas, and psoriasis.

Investigation

LDH, hepatic function, total blood cell count (all cases), Sézary cell count or immunophenotyping of blood cell, thorax and abdomen CT, lymph node biopsy (if palpable), bone marrow biopsy.

Prognosis

Unlike MF, SS is an aggressive disease with reserved prognosis, with 5-year survival rates ranging from 10% to 20%. As for MF, the TNM classification can also be used to estimate the prognosis. Other prognostic factors are similar to those of MF, as mentioned above [16, 17].

Absence of markers such as CD5 and CD7 in SS are factors independent of worse prognosis. Presence of CD8+ cytotoxic T lymphocytes infiltrating the dermis is associated with a better prognosis [45].

Therapeutic Approach

Extracorporeal photopheresis, when available, is the therapy of choice, either alone or in combination with other therapeutic modalities, such as IFN-α, with variable response rates. Treatment

with PUVA in association with IFN-α, isolated IFN-α, and combination of chlorambucil and prednisone or methotrexate may be used, but have low complete remission rates [3, 16, 17, 32]. PUVA alone or potent topical corticosteroids may be used as adjunctive therapy. Recent studies show beneficial effects of bexarotene and alemtuzumab (anti-CD52) [3, 16, 50, 51].

Adult T-Cell Leukemia/Lymphoma

Clinical Manifestations and Complementary Examinations

ATLL has, in 100% of the cases, evidence of integration of the virus of the HTLV-1 in the host genome [23–25]. Lymphoma develops in about 5% of seropositive individuals, typically after more than two decades of viral persistence [17].

ATLL appears on the skin in various forms: as erythroderma, infiltrated plaques, papules, nodules, tumors, or patches. Less commonly, the lesions may appear as purpuric plaques or in the form of vesicles. They are always multiple and are generalized in 50% of cases. The tumors and nodules appear in the more aggressive forms (acute, lymphomatous).

ATLL has a broad clinical spectrum divided into four clinically distinct entities (acute, chronic, smoldering, and lymphomatous) that differ in their presentation, progression, and response to treatment. The characteristics of these clinical types are as follows.

Acute ATLL: characterized by fever, cough, lymphadenopathy, skin lesions, hepatosplenomegaly, marked leukocytosis, and hypercalcemia; high serum levels of LDH; atypical lymphocytes with characteristic convoluted or lobulated nuclei and basophilic cytoplasm (flower cells), characteristic of this type of ATLL.

Lymphomatous type: lymph node enlargement with or without extranodal lesions; no lymphocytosis and hypercalcemia; sporadic circulating leukemia cells may be seen (<1%).

Chronic-type: presence of lymphocytosis; LDH value up to twice the normal upper limit; no hypercalcemia; 5% or more of atypical lymphocytes in peripheral blood; no involvement of central nervous system, bone, or gastrointestinal tract; no body effusions.

Smoldering type: few leukemia cells in the peripheral blood (<5%); no lymphocytosis and hypercalcemia; LDH levels either slightly elevated or normal; skin and or pulmonary lesions may be present; no involvement of other organs. The leukemic smoldering type is characterized by the presence of 5% or more atypical cells in peripheral blood [52].

Histopathologic Examination

Biopsy, especially of erythematous areas, may not be specific and also has histologic features indistinguishable from MF, presenting dermal and epidermal infiltration with atypical lymphocytes with polylobulated or pleomorphic nuclei, with or without Pautrier's microabscess [19, 24, 25]. The chronic form may show sparse dermal infiltrate with only slightly atypical cells [16].

Immunohistochemistry

Histology may be indistinguishable from MF, although negative cutaneous lymphocyte antigen (CLA) and the presence of HTLV-1 integrated to the lesions favor lymphoma/leukemia [16, 19]. Neoplastic T cells express phenotypes CD3[+], CD4[+], CD8−, and CD25[+] [16].

Diagnosis

Clinical manifestation + histopathologic examination, with immunohistochemistry.

Differential Diagnosis

Fungal infections, eczemas, pityriasis (rosea, lichenoid), psoriasis, leprosy, neoplasias, drug eruption.

Investigation

HTLV serology, LDH, hepatic function, total blood cell count (all cases), Sézary cell count or immunophenotyping of blood cells, thorax and abdomen CT, lymph node biopsy (if palpable), bone marrow biopsy.

Prognosis

In adult T-cell leukemia/lymphoma the prognosis depends on the clinical subtype. The acute and lymphomatous forms present survival rates ranging from 2 months to just over a year. The chronic and smoldering forms present more protracted course and longer survival, with transformation to acute and aggressive course occurring [1, 16, 17, 31].

Therapeutic Approach

In most forms of adult T-cell leukemia/lymphoma, there is the indication for systemic chemotherapy. In chronic forms, skin lesions may be treated with skin-targeted therapies classically used for MF. The combination of IFN-α and PUVA and the use of antiretroviral drugs, such as zidovudine, seem to benefit patients [16, 17, 53, 54].

Primary Cutaneous CD30+ Lymphoproliferative Diseases

Primary Cutaneous Anaplastic Large Cell

Clinical Manifestations

Anaplastic large cell PCL presents with large solitary or grouped tumors, which are frequently ulcerated. It is more common in young adults, with males being two to three times more frequently affected than females. Spontaneous, partial, or complete regression may occur [17].

Complementary Examinations

Histopathologic Examination

Diffuse and dense, nonepidermotropic, large pleomorphic tumor cells, and anaplastic or immunoblastic infiltrate with high mitotic index is found, with possible eosinophils [16, 29]. Reactive lymphocytes are often present on the periphery of the lesions [16].

Immunohistochemistry

By definition, more than 75% of the tumor cells must express the CD30 antigen, hence the name CD30+ large T-cell PCL [16, 29, 42].

Other antigens expressed include CD4, CD25, HLA-DR, CD71, and EMA, although the latter has already been reported as negative in other studies [16, 19, 29, 32, 42, 55]. There is a variable loss of CD2, CD5, CD3, and CD7 and frequently the expression of cytotoxic proteins (granzyme B, TIA-1, and perforins). Less than 10% of the cases have phenotype CD8+ and most express CLA, but do not express ALK [16, 29, 42]. CD56 expression is rare, CD15 is negative [42], and ALK-1+ has been observed more frequently in pediatric cases [56].

Diagnosis

Clinical manifestation + histopathologic examination, with immunohistochemistry.

Differential Diagnosis

Lymphomatoid papulosis, B lymphoma, fungal infections, leprosy, neoplasias.

Investigation

LDH, hepatic function, total blood cell count (all cases), Sézary cell count or immunophenotyping of blood cells, thorax and abdomen CT, lymph node biopsy (if palpable), bone marrow biopsy.

Prognosis

CD30+ T-cell PCL has better prognosis when compared with PCL that do not express CD30+ [55].

Anaplastic large cell PCL is an indolent neoplasia with good prognosis and 10-year survival rate of more than 90%. Cutaneous relapses are frequent and extracutaneous dissemination occurs in about 10% of the cases, mainly to regional lymph nodes. Multifocal skin disease or involvement of regional lymph nodes does not appear to change the prognosis of patients with localized cutaneous lesions [16, 17, 42].

Therapeutic Approach

In anaplastic large cell PCL, radiotherapy or surgical excision is the treatment of choice when the lesions are located. Methotrexate in low doses or radiotherapy may be alternatives for patients with

multiple lesions without curative therapeutic modality. Rapidly progressive or extracutaneous disease must be treated with systemic polychemotherapy using doxorubicin [16, 17, 25, 32, 45, 57].

Lymphomatoid Papulosis

Clinical Manifestations

Lymphomatoid papulosis (LP) is characterized by multiple papulonodular lesions, sometimes papulonecrotic, chronic lesions, tending to spontaneously regress after some weeks or months, and to recur (Fig. 17.9). These can ulcerate and settle with pigmented scars. They predominate on the torso and limbs and usually persist for years or decades. Vesiculopustular lesions may also be seen [16, 29, 42, 58].

LP usually occurs in adults with an average age of 45 years, with a male/female ratio of 1.5:1, and can occur in children. In up to 20% of LP cases this may be preceded, associated with, or followed up by another type of cutaneous malignant lymphoma, usually MF, anaplastic large cell PCL, or Hodgkin lymphoma [16].

Complementary Examinations

Histopathologic Examination
LP exhibits a range from large CD30+ anaplastic or pleomorphic tumor cells, sparse or grouped, followed by neutrophils and eosinophils, with

Fig. 17.9 Lymphomatoid papulosis. Papulonodular lesion

infiltrate similar to Reed-Sternberg cells (type A); epidermotropic infiltrate of small lymphocytes with cerebriform nuclei similar to MF (type B) (Fig. 17.10); or cohesion of CD30+ tumor cells with few mixed reactive cells, similar to large anaplastic cell PCL (type C) [16, 29, 42, 58].

Immunohistochemistry
LP is among the CD30+ lymphoproliferative diseases. The classic type of LP (type A) besides CD30+ has phenotypes CD3+, CD4+, and CD8−. Aberrant phenotypes may occur, with loss of one or more of these antigens. In LP, cells usually express TIA, perforin, and granzyme B [42]. Other phenotypes with CD8+ or CD56+ are also observed. Tumor necrosis factor associated with factor 1 (TRAF-1) and MUM1 are also described as markers for differentiation between LP and PCL with anaplastic large cell, but contradictory results are observed regarding the diagnostic value [29]. One type of LP has lesions with phenotypes CD3+, CD4+, and CD8− and does not express the CD30 antigen [16].

Apoptosis markers such as caspase-3 are increased in the LP when compared with anaplastic large cell PCL, suggesting that apoptosis is a mechanism involved in the spontaneous regression of the LP lesions [16, 19].

Diagnosis

> Clinical manifestation + histopathologic examination, with immunohistochemistry.

Differential Diagnosis
Anaplastic large cell PCL, fungal infections, ecthyma, lichenoid pityriasis, vasculitis, neoplasias.

Investigation
LDH, hepatic function, total blood cell count (all cases), Sézary cell count or immunophenotyping of blood cells, thorax and abdomen CT, lymph node biopsy (if palpable), bone marrow biopsy.

Fig. 17.10 Lymphocytes with enlarged and hyperchromatic nuclei infiltrating the epidermis (epidermotropism) in a patient with lymphomatoid papulosis
Fig. 17.11 Nodules and ulceration in a patient with subcutaneous panniculitis-like T-cell lymphoma
Prognosis

LP has an excellent prognosis, with a survival rate of 100% in 5 years, although 10–20% of the patients can develop a secondary lymphoid neoplasia [16, 17, 45]. Borderline cases between LP and PCL with anaplastic large cell have excellent prognosis, which is similar to that of LP [19].

Therapeutic Approach

There is no curative treatment for LP. Oral methotrexate in low doses (5–20 mg/week) is the most effective therapy to prevent the appearance of new lesions [16, 59]. The use of topical and systemic corticosteroids, PUVA, chemotherapy, or radiotherapy can induce temporary remission. The risk/benefit of these therapies must be carefully evaluated. Periodic clinical follow-up of these patients is recommended [16, 17, 32, 42, 45, 57].

Subcutaneous Panniculitis-Like T-Cell Lymphoma

Clinical Manifestations

This lymphoma is clinically similar to a panniculitis. It manifests with subcutaneous solitary or multiple nodules and plaques, which are occasionally ulcerated, predominantly in the lower limbs of young adults (Fig. 17.11). Constitutional symptoms such as weight loss, fatigue, and low-grade fever may be present [16, 19, 32, 60]. Both sexes are equally affected [16, 60].

The disease can be complicated by a hemophagocytic syndrome, which is generally is associated with a rapidly progressive course [31, 60, 61]. Dissemination to extracutaneous locals is rare and can be preceded by years or decades of a seemingly benign panniculitis [61].

Complementary Examinations

Histopathologic Examination

Histology demonstrates lobular and septal infiltrate of small and medium, and sometimes large lymphoid cells, with pleomorphic nuclei, without dermoepidermal involvement, often with many macrophages. Karyorrhexis, cytophagocytosis, and necrosis may be present. Tumor cells can be surrounded by lymphocytes, but this is not a specific characteristic of the disease since it can be observed in the lupus panniculitis, which is one of its main differential diagnoses [29, 32, 61]. Involvement of individual fatty cells by neoplastic T cells is useful for the diagnosis, although it is also nonspecific. In the first stages neoplastic infiltrates may lack significant atypia, and a dense inflammatory infiltrate may be prevalent [16, 61].

Immunohistochemistry

The panniculitis-like T-cell lymphoma has variable phenotype, usually CD8+, but may be CD4− and CD8− and less commonly CD4+, with variable deletion of CD5 and CD7. It also expresses cytotoxic proteins CD2 and CD3. CD30 and CD56 are rarely expressed [16, 29, 32]. According to the WHO/EORTC, this lymphoma is by definition restricted to cases expressing T-cell receptor (TCR) phenotype α/β. The demonstration of TCR-α/-β expression by immunohistochemistry is the main diagnostic marker of this entity [29]. In panniculitis-like T-cell lymphoma, TIA-1 and granzyme B are also frequently positive in the atypical lymphocytes [19].

Diagnosis

Clinical manifestation + histopathologic examination, with immunohistochemistry.

Differential Diagnosis

Fungal and bacterial infections, vasculitis, panniculitis, neoplasias.

Investigation

LDH, hepatic function, total blood cell count (all cases), Sézary cell count or immunophenotyping of blood cells, thorax and abdomen CT, lymph node biopsy (if palpable), bone marrow biopsy.

Prognosis

In contrast to initial studies indicating a rapidly fatal course in the subcutaneous panniculitis-like T-cell lymphoma, recent studies suggest an usually protracted evolution with recurring subcutaneous lesions, without extracutaneous dissemination and with 5-year survival rate of more than 80% [16, 17]. CD56 expression may be associated with a low survival rate [16, 29, 31, 32].

In contrast to the rapidly fatal course of this disease earlier described, studies have shown that cases with the phenotype CD8+, α/β+ have a longer course, with recurrent subcutaneous lesions and no extracutaneous dissemination [16].

Therapeutic Approach

Treatment for subcutaneous panniculitis-like T-cell lymphoma usually employs polychemotherapy, with doxorubicin and radiotherapy. However, many patients can be controlled with prolonged systemic corticosteroid therapy [16, 17, 32, 42, 60].

Extranodal NK/T-Cell Lymphoma, Nasal Type

Clinical Manifestations

ENKL nasal type occurs in middle-aged to older adult patients, predominantly male, with nodules or solitary or multiple, erythematous red and purpuric tumors, forming extensive necrotic areas, sometimes being ulcerated and rapidly progressive, involving usually the nasal cavity and nasopharynx, but also the torso and extremities. The involvement of the skin may be a primary or secondary manifestation of the disease. Occasionally,

patches and plaques similar to those of MF may be present.

It is known by its strong association with the EBV and was previously called "lethal midline granuloma" when located in the nasal cavity [16, 25, 26]. The main differential diagnosis is the MF tumor stage [56]. Systemic symptoms such as weight loss, indisposition, and fever may be present, and some cases are followed by hemophagocytic syndrome. The disease is closely related to aggressive NK-cell leukemia, which can also present cutaneous manifestations and is also associated with EBV [16].

Complementary Examinations

Histopathologic Examination
Histology shows a cell infiltrate, which is variable (angiocentric and angiodestructive, superficial and deep), composed of histiocytes, plasma cells, and granulocytes, and mainly eosinophils, involving the dermis and frequently subcutaneously, with vascular destruction and sometimes extensive necrosis [17, 19]. It may be similar to the histology of MF, with epidermotropism, although the infiltrate tends to extend deeply [26, 56]. It has a wide cytologic range, from small to large cells, with most cases involving medium-sized cells. Cells may have irregular or oval nuclei, moderately dense chromatin, and pallid cytoplasm. In some cases a dense inflammatory infiltrate of small lymphocytes, histiocytes, plasmatic cells, and eosinophils can be observed [16]. There is usually marked angiotropism or angiodestruction [56].

Immunohistochemistry
Atypical cells of ENKL nasal type usually have immunophenotype with positivity of CD2, DC56, and cytoplasmic proteins (TIA-1, granzyme B, perforin), and negativity of CD3 on the surface (cytoplasmic positivity). In rare CD56− cases, EBV detection by in situ hybridization and the expression of cytotoxic proteins are necessary for diagnosis. CD5 and TCR gene rearrangements are generally negative. Antigen latent membrane protein 1 (LMP-1), related to the EBV, can be expressed in these lymphomas [16, 19].

Diagnosis

> Clinical manifestation + histopathologic examination, with immunohistochemistry.

Differential Diagnosis
Fungal and bacterial infections, syphilis, leishmaniasis, leprosy, vasculitis, neoplasias.

Investigation
LDH, hepatic function, total blood cell count (all cases), Sézary cell count or immunophenotyping of blood cells, cranial, thorax, and abdomen CT, lymph node biopsy (if palpable), bone marrow biopsy.

Prognosis
ENKL nasal type usually has a rapid and aggressive course with a high mortality rate despite treatment. The average survival rates reported are between 5 and 27 months, with the best rates for cases with exclusively cutaneous lesions. The main factor in poor outcome and low survival rate is the presence of extracutaneous involvement at the time of the diagnosis [16, 17].

Some cases of expression of CD30+ and CD56+ have reported a better prognosis and can be large T-cell PCL with co-expression of CD56 [16].

Therapeutic Approach
The treatment indicated is systemic chemotherapy, but the results are disappointing [3, 16, 17]. For patients in the early stage, radiation therapy is the first choice of treatment [3].

Epidermotropic CD8+ Cutaneous T-Cell Lymphoma (Provisional Entity)

Clinical Manifestations
It presents with nodules, tumors, and ulcerated or eroded plaques with central necrosis, and disseminated or localized, rapidly evolving papules [16, 17, 29]. Keratotic plates may occur [16, 17].

This type of lymphoma can disseminate to other sites such as lung, testicle, central nervous system, and oral mucosa; however, nodes are usually spared [16].

Complementary Examinations

Histopathologic Examination
In general, there is an atrophic or acanthotic epidermis, epidermotropic infiltrate of small and medium lymphocytes with pleomorphic nuclei, numerous necrotic keratinocytes, erosion, ulceration, and variable spongiosis. Invasion and destruction of cutaneous appendages are commonly observed, and angiocentricity and angioinvasion can be present [16, 17, 29]. This subtype of PCL must be distinguished from CD8$^+$ MF, which also shows epidermotropic infiltrate in bands, but few or no necrotic keratinocytes. In contrast with PCL of aggressive (epidermotropic) CD8$^+$ cells, CD8$^+$ MF clinically manifests with hyper- or hypopigmented patches and plaques, but not with erosions, necroses, or ulcerations [29].

Immunohistochemistry
The tumor cells of aggressive PCL of epidermotropic CD8$^+$ T cells express phenotype β-F1$^+$, CD3$^+$ CD8$^+$, TIA1$^+$, granzyme B$^+$, perforin$^+$, CD45RA$^+$, CD45RO$^-$, CD2$^-$, CD4$^-$, CD5$^-$, and CD7$^-$, with EBV usually being negative [16, 29].

Diagnosis

> Clinical manifestation + histopathologic examination, with immunohistochemistry.

Differential Diagnosis
Other cutaneous T-cell lymphomas, fungal and bacterial infections, vasculitis, neoplasias.

Investigation
LDH, hepatic function, total blood cell count (all cases), Sézary cell count or immunophenotyping of blood cells, thorax and abdomen CT, lymph node biopsy (if palpable), bone marrow biopsy.

Prognosis
The aggressive epidermotropic CD8$^+$ cutaneous T-cell lymphoma usually has acute evolution with rapid systemic disseminations. The median survival is 32 months [16, 17, 62].

Therapeutic Approach
In the PCL of epidermotropic CD8$^+$ T cells, the treatment of choice is systemic chemotherapy with regimens containing doxorubicin [16, 17].

Cutaneous γδ T-Cell Lymphoma (Provisional Entity)

Clinical Manifestations
It usually presents with disseminated plaques, nodules, or ulcerous and necrotic tumors, particularly in the extremities, although other areas may be affected. The involvement of mucosa is frequently observed, but the involvement of lymph nodes, bone marrow, and spleen is not common. Hemophagocytic syndrome can occur in patients with tumors of the panniculitis type [63].

Complementary Examinations

Histopathologic Examination
Three major histologic patterns may be present in the biopsy: epidermotropic, dermal, and subcutaneous. Often, more than one histologic pattern is present in the same patient in different biopsies or a single biopsy [63]. Neoplastic cells are generally medium to large, with coarse chromatin [16]. Apoptosis and necrosis are common, often with angioinvasion [16, 29].

Immunohistochemistry
The cutaneous γδ T-cell lymphoma has tumor cells that express CD2, CD3, CD56, and cytotoxic proteins, but they are mostly negative for b-F1, CD5, and EBV. Most cases lose CD4 and CD8. CD7 can be positive or negative [16, 29, 33].

Diagnosis

> Clinical manifestation + histopathologic examination, with immunohistochemistry.

Differential Diagnosis

Other cutaneous T-cell lymphomas, fungal and bacterial infections, vasculitis, neoplasias.

Investigation

LDH, hepatic function, total blood cell count (all cases), Sézary cell count or immunophenotyping of blood cells, thorax and abdomen CT, lymph node biopsy (if palpable), bone marrow biopsy.

Prognosis

In cutaneous γδ T-cell lymphoma, most patients have an aggressive chemo- or radiotherapy-resistant disease, with average survival of 15 months [16, 17, 63].

Therapeutic Approach

The treatment of choice is systemic chemotherapy, even though it has produced disappointing results [16, 17].

Cutaneous Lymphoma of Small and Medium Pleomorphic CD4+ T Cell (Provisional Entity)

Clinical Manifestations

It presents, in most cases, with lump, plaque, papule, or solitary erythematous tumor, with no patches and preliminary plates, usually on the face, neck, or upper torso [16, 29, 56, 57]. Less commonly it presents with multiple lesions [57] and, rarely, with ulceration [56].

Complementary Examinations

Histopathologic Examination

Nodular infiltrates of small and medium-sized pleomorphic lymphocytes, eosinophils, erythrocytes, and histiocytes are found in the dermis, with a tendency to infiltrate the subcutaneously. Epidermotropism may be present focally [16, 29]. A small proportion (less than 30%) of large pleomorphic cells may also be present [16].

The distinction with the nodular form of pseudolymphoma T cells is challenging [29]. The prominence of B-cell components is common, sometimes inducing an erroneous diagnosis of cutaneous B-cell lymphoma [56].

Immunohistochemistry

PCL cells of small and medium CD4+ T cells, by definition, express the phenotypes CD3+, CD4+, CD8−, CD30−, CD5+, and CD7+, especially in localized lesions [16, 32, 42, 56]. Sometimes there is loss of pan-T-cell markers, especially in multiple tumor lesions. Cytotoxic proteins are usually not expressed [16, 42].

Diagnosis

Clinical manifestation + histopathologic examination, with immunohistochemistry.

Differential Diagnosis

Other cutaneous T-cell lymphomas, fungal and bacterial infections, vasculitis, neoplasias.

Investigation

LDH, hepatic function, total blood cell count (all cases), Sézary cell count or immunophenotyping of blood cells, thorax and abdomen CT, lymph node biopsy (if palpable), bone marrow biopsy.

Prognosis

Cutaneous lymphoma of small and medium CD4+ T cell has a favorable prognosis, particularly for cases with single or localized lesions. The estimated 5-year survival rate is approximately 60–80% [16, 17].

Therapeutic Approach

For localized lesions of cutaneous lymphoma of small and medium pleomorphic CD4+ T cell, surgical excision or radiotherapy is recommended [16, 17, 32]. Cyclosporine or IFN-α can be effective in generalized disease. However, the best treatment for these patients is yet to be defined [16, 32].

Glossary

Angiocentric Arrangement of cells around the vessels; perivascular.

Epidermotropism Movement toward the epidermis, as in the migration of T lymphocytes into the epidermis in mycosis fungoides.

Immunohistochemistry A process of detecting antigens (e.g., proteins) in cells of a tissue section by exploiting the principle of antibodies binding specifically to antigens in biological tissues

Immunophenotyping A process used to identify cells, based on the types of antigens or markers on the surface of the cell. This process is used to diagnose specific types of leukemia and lymphoma by comparing the cancer cells with normal cells of the immune system.

Pautrier's microabscess A well-defined collection of cells within the epidermis in T-cell lymphoma and mycosis fungoides.

Reed–Stenberg cell A giant binucleated or multinucleated macrophage, characteristic of Hodgkin's disease.

Sézary cell An atypical mononuclear cell seen in the peripheral blood in Sézary syndrome; has a large, convoluted nucleus and scant cytoplasm containing vacuoles that test positive with the periodic acid-Schiff stain.

Dermatologic Diseases in Public Health: Inflammatory and Autoimmune Diseases

Eczemas

18

Rosana Lazzarini, Mariana de Figueiredo Silva Hafner, Vanessa Barreto Rocha, and Daniel Lorenzini

Key Points

- Eczemas are one of the most often seen forms of skin diseases and can be classified as acute, subacute, and chronic
- Eczemas can be classified according to clinical and etiopathogenic criteria: eczema or contact dermatitis, eczema or atopic dermatitis, nummular eczema, stasis dermatitis, and dyshidrotic eczema
- There are four different types of eczema or contact dermatitis according pathogenic aspects: irritant contact dermatitis, phototoxic contact dermatitis, allergic contact dermatitis, and photoallergic contact dermatitis

- Atopic dermatitis (AD) is an inflammatory skin disease, often related to asthma or allergic rhinitis
- AD results from the complex relationship involving genetic, immune, environmental, psychosomatic, and pharmacologic factors, and changes in the skin structure
- The two main AD disorders are dysfunctional skin barrier and immunologic reaction, both interrelated.
- In nummular dermatitis the dry skin may be a significant predisposing factor, mainly among older individuals
- Stasis dermatitis or eczema is a chronic condition often seen on the lower limbs, resulting from venous stasis. Multiple factors are important for its etiopathogenesis: lower limb varices, obesity, congenital skeletal and muscular alterations, lower limbs fractures, and planovalgus feet.
- Dyshidrosis can be classified as idiopathic or true, and also as dyshidrosiform eruption if associated with other dermatoses (contact dermatitis, AD, drug eruption, or irritant dermatitis)

Introduction

Eczemas, or eczematous eruptions, are part of a group of dermatoses characterized by the presence of erythema, edema, infiltration, vesicles, oozing, crusting, flaking, and lichenification. Such changes can occur concomitantly or alternatively according to different evolutionary phases. The word *eczema* comes from the Greek word *eczein* (*ek* – outside, and *zein* – boil), thus characterizing the most usual symptom of dermatosis, pruritus.

Eczemas can be classified as acute, sub-acute, and chronic, depending on their clinical presentation. The acute form shows erythema, edema, vesicles, and oozing. The subacute form of the condition is apparent when the edema and the erythema are less evident and oozing and crust development are prevalent. The chronic forms are characterized by the presence of lichenification.

Eczema is one of the most often seen forms of skin disease resulting from exogenous or endogenous agents, which operate by different pathogenic mechanisms despite showing certain similar clinical aspects.

Eczemas can be classified according to clinical and etiopathogenic criteria, such as:
1. Eczema or contact dermatitis
2. Eczema or atopic dermatitis
3. Nummular eczema
4. Eczema or stasis dermatitis
5. Dyshidrotic eczema

Contact Dermatitis

Contact dermatitis is a kind of eczema caused by exogenous agents in contact with the skin.

There are four different types according to pathogenic aspects:
(a) Irritant contact dermatitis
(b) Phototoxic contact dermatitis
(c) Allergic contact dermatitis
(d) Photoallergic contact dermatitis

Irritant Contact Dermatitis

Introduction

Irritant contact dermatitis (ICD) is an inflammatory skin response to contact with a wide range of possible chemical or physical irritants. It arises as a result of activated innate immunity to direct injury to the skin without prior sensitization [1, 2].

ICD is the most common type of contact dermatitis, representing approximately 80% of occupational contact dermatitis cases. The risk is higher in occupations that involve repeated hand washing or repeated exposure of the skin to water, food, and other irritants, such as cleaning, healthcare, food preparation, and hairdressing [3, 4].

The estimated annual cost of occupational contact dermatitis in the United States exceeds \$1 billion, including medical expenses, workers' compensation, and lost work time. It is therefore a major public health problem. Box 18.1 summarizes the main concepts of the disease [5].

Predisposing Factors

ICD is a multifactorial disorder influenced by both endogenous and exogenous factors. The predisposing host-related susceptibility factors include age (skin reactivity to irritants tends to decrease with age); sex (it occurs more frequently in women); body site (face, dorsum of the hands, and finger webs are more prone to chemical irritants); atopy (individuals with atopic dermatitis have increased susceptibility to irritants as a result of an impaired barrier function); and genetic factors (as shown by twin studies) [1, 5].

The most important predisposing exogenous factors are properties of the irritating substance (molecular size, liposolubility, concentration); and environmental conditions, such as temperature, airflow, humidity, and occlusion (higher temperatures and occlusion increase sweating that may cause disruption of the skin barrier and enhance the inflammatory response to chemical or mechanical irritants; on the other hand, cold temperatures and low ambient humidity increase transepidermal water loss and subsequently skin susceptibility to irritants) [1, 2].

Etiopathogenesis

Unlike allergic contact dermatitis, the immunological reaction in ICD does not require previous sensitization, immunologic memory, or presence of antigens in order to activate lymphocytes [2].

The pathophysiologic mechanisms involved in ICD are complex and can be summarized in the following events: disruption of the epidermal barrier, cytokine release from keratinocytes, and activation of innate immunity [6].

Integrity of the epidermal barrier function plays an important role in the interaction and the response of the human skin to irritants; the disruption (by chemical or physical irritants) results in increased skin permeability and transepidermal water loss (TEWL), which is considered the initiating event of ICD [6, 7].

The disruption of the skin barrier leads to release of preformed interleukin (IL)-1α by keratinocytes, which represents an initial step in the inflammatory cascade of ICD. The primary cytokines involved are IL-1 and tumor necrosis factor α (TNF-α). The synergistic effects of these two cytokines result in the further activation and release of secondary cytokines such as IL-2, IL-6, granulocyte macrophage colony-stimulating factor, interferon (IFN)-γ, vascular endothelial growth factor (VGEF), CXCL8, CCL2, CCL5, and CCL20 by keratinocytes, fibroblasts, and endothelial cells; upregulation of adhesion molecules on endothelial cells; and the subsequent recruitment of leukocytes, thereby perpetuating ongoing inflammation [6].

Common Irritants

Irritants are capable of producing cellular perturbation if applied to the skin for a sufficient time and in sufficient concentration [8]. A primary irritant can cause injury on any skin if exposure takes place. These substances are classified as absolute and relative primary irritants.

Absolute primary irritants cause a strong reaction (chemical burn or severe irritation) on almost anyone's skin. Acids and alkalis are some examples. Cutaneous lesions are acute, appearing rapidly after contact. They are usually associated with accidental exposure [2, 5].

Some absolute primary irritants may cause a delayed response, after 12–24 h of contact with the skin, such as podophyllin and anthralin [2, 5].

Substances with a weak capacity to irritate are classified as relative primary irritants; these are the most common irritants. The dermatitis results from repeated exposures, and in these cases appear in a chronic form. Common relative irritants include water, detergents and surfactants, solvents, food, urine, and feces [2, 5]. Physical irritants include metal, wood, fiberglass, and paper, among others.

Clinical Presentation

The reaction is generally limited to the site of contact, and typically presents as eczema in acute or chronic form. Clinical manifestations may vary according to the type of inflammatory response as well as the kind of irritant and exposure.

Acute ICD often results from a single exposure to an absolute primary irritant. Clinical features usually include erythema, edema, vesicles, bullae, and oozing. In cases of contact with strong irritants, necrosis and ulceration may appear (chemical burn). Patients sometimes report a sensation of burning, stinging, or pain [1, 2, 5].

On the other hand, chronic ICD results from repeated exposures to mild irritants (relative primary irritants), such as soaps and detergents. ICD is characterized clinically by erythema, scaling, lichenification, hyperkeratosis, and fissures [1, 2, 5].

Specific Clinical Examples

Irritant Contact Diaper Dermatitis

Irritant contact diaper dermatitis affects up to 25% of infants wearing diapers, and is the most common cause of diaper dermatitis. It is triggered mainly by prolonged contact between the skin and urine and feces, but other irritants, such as soaps, may contribute. Occlusion raises the local pH and exposure to fecal enzymes damages the integrity of the skin barrier, increasing the susceptibility to irritant and microbial invasion [9, 10].

Clinically, irritant contact diaper dermatitis is most prominent in areas where the diaper is in direct contact with the skin, particularly on the convex surfaces, typically sparing the inguinal creases and gluteal cleft. Clinical manifestations are variable and include redness, papules, scaling, maceration, superficial erosions, and, less commonly, ulceration or elevated papules/pseudoverrucous nodules [9, 10] (Fig. 18.1).

Prevention is key in the management of irritant contact diaper dermatitis. Frequent diaper changes are important for minimizing skin exposure to urine and feces and keeping the infant dry. It is recommended that newborns be changed hourly and older children every 3–4 h. Recent studies have shown that superabsorbent disposable diapers cause less erythema than cloth diapers when changed at appropriate intervals [9–12].

Fig. 18.1 Irritant contact diaper dermatitis

Irritant Contact Hand Dermatitis

Hand eczema is a common condition seen in dermatologic practice, affecting up to 10% of the population, with a negative impact on quality of life. ICD is the main cause (approximately 80% of all cases), frequently aggravated by work (occupational dermatitis) [13, 14].

Irritant contact hand dermatitis is particularly common in people with jobs that involve repeated hand washing (wet work), such as cleaning, catering, hairdressing, healthcare, and mechanical work. Wet work can be defined as activities for which workers have to immerse their hands in liquids for >2 h per shift, or wear waterproof (occlusive) gloves for a corresponding amount of time, or wash their hands >20 times per shift. The most common irritants include water, detergents, solvents, acids, alkalis, cold, heat, and friction [15, 16].

Clinically it is usually a chronic eczema, with erythema, scaling, lichenification, and fissures. Sites commonly affected are fingertips and the dorsum of the hands, usually sparing the palms [13, 14] (Fig. 18.2).

Hand dermatitis may be associated with more than one concomitant kind of dermatitis, so patch testing is always recommended in chronic cases to exclude allergic sensitization.

Management is not always easy as it involves not only symptomatic treatment but also changes in habits and daily work routine.

Therapeutic Approach

The management of ICD includes avoidance of the culprit irritant, treatment of skin inflammation, restoration of the epidermal barrier function, and prevention of further exposure.

After identification of the irritant, alternatives should be given for avoiding direct contact with the substance, such as replacement of products, use of barrier creams, and use of personal protective equipment such as suits, face masks, and goggles.

The occupational physician, who would assist in adapting the work routine, sometimes should also follow occupational irritant contact dermatitis cases.

Emollients are used to decrease irritation, improve or restore the skin barrier function in ICD, and prevent new exposure. Petrolatum-based

Fig. 18.2 Irritant contact hand dermatitis

products are preferred to emollients containing lanolin or fragrances to reduce the risk of contact sensitization [5].

Treatment of cutaneous lesions includes the use of topical corticosteroids for 2–4 weeks. While for severe and chronic cases with lichenification high-potency topical corticosteroids are recommended, for milder forms and sensitive areas (such as face or flexure), medium- or low-potency topical corticosteroids are suggested. Calcineurin inhibitors (pimecrolimus or tacrolimus) may be used in the maintenance phase [5].

Phototherapy is a reasonable option for patients with refractory symptoms.

For severe chronic irritant contact hand dermatitis with conspicuous skin thickening (lichenification), the use of systemic retinoids (acitretin and alitretinoin) or immunomodulators (such as methotrexate and cyclosporine) must be considered [5, 17, 18].

The prognosis of acute ICD is usually good if the offending irritant is removed and preventive measures are adopted. However, for chronic cases the evolution is variable, and the recovery of the barrier function in affected areas may persist for 10 weeks. Negative prognostic factors include history of atopy, disease duration, female gender, and association with allergic contact dermatitis [5, 19].

Detailed orientations regarding avoidance of the irritant and prevention measures are essential for the success of treatment, as it usually depends on behavior changes.

Phototoxic Contact Dermatitis

Phototoxic dermatitis is an inflammatory reaction that occurs when the irritant is activated by sunlight. It has a mechanism similar to that of ICD. The interaction between ultraviolet (UV) radiation (absorbed by chromophores) and the photosensitive substance produce free radicals that cause cytotoxic damage [2, 20, 21].

Some of the main substances that may cause phototoxic contact dermatitis are topical nonsteroidal anti-inflammatory drugs, psoralens, promethazine, sulfadiazine, sulfacetamide, and perfumes (especially those containing oil of bergamot, causing berloque dermatitis).

Clinical presentation is similar to sunburn, with erythema, edema, and sometimes vesicles and bullae restricted to sun-exposed areas (Fig. 18.3).

Phytophotodermatitis is a subtype of phototoxic contact dermatitis caused by plants, vegetables, or fruits containing furocoumarins, such as

Fig. 18.3 Phototoxic dermatitis
Fig. 18.4 Hyperpigmentation after acute dermatitis

lemons and oranges, activated by UVA radiation. The most common presentation is linear streaks of pruritic dermatitis on a sun-exposed area. After the acute phase heals, marked hyperpigmentation usually develops [20, 21] (Fig. 18.4).

Allergic Contact Dermatitis

Introduction

Sensitizing contact dermatitis or allergic contact dermatitis (ACD) is a type IV or cell-mediated immune reaction according to the Gell and Coombs classification, whereby the subject reacts to certain substances to which he/she has been previously sensitized [22 23]. It is a latent condition that can persist throughout life, and every exposure to a sufficient amount of allergen manifests as eczema [24].

The patch test remains the gold standard in the diagnosis of ACD, although it is still underutilized worldwide [25].

Studying ACD is an exciting work that involves investigative skills to interpret the patch test, relating it to the clinical picture and the activities or occupations of the patient. Educating the patient with ACD is an art and a key to the resolution of the disease. Box 18.2 summarizes the main concepts of disease.

> **Box 18.2 Concepts of Allergic Contact Dermatitis**
> 1. Allergic contact dermatitis is an immune reaction type IV according to Gell and Coombs in an individual previously sensitized
> 2. Itching is a constant symptom
> 3. The patch test remains the gold standard in the diagnosis of ACD, although it is still underutilized
> 4. Nickel remains the most common allergen, followed by fragrances and preservatives
> 5. The main therapeutic measure is the removal of the contact

Epidemiology

In 2010, Lopes et al. reported that eczema generally accounted for 14.6% of the dermatologic consultations in a Brazilian public clinic [26]. Duarte et al. reported a frequency of 5.1% of ACD among patients treated for 10 years at a private practice in Brazil [27].

In 2006, a study was conducted by the Brazilian Society of Dermatology with 932 dermatologists and 49 hospitals that offer residency program, which included 57,000 consultations a week. In this study, 3.9% of consultations were due to contact dermatitis [28]. Although there were no concrete and systematized data in Brazil,

both ICD and ACD are important causes of dermatologic consultations. They even hinder patients from performing their usual activities, causing a great impact on patients' occupation and quality of life [28, 29].

ACD may occur in any age or sex [25, 30]. The frequency of allergen varies with the population and geographic region under study. However, nickel remains the most common allergen in several series [31–35], particularly among children [30, 36] and the elderly [37]. The next most common allergens are fragrances and preservatives [38]. Allergens vary according to periods of time during which certain epidemics are reported: currently the ACD epidemic related to methylisothiazolinone [31–36], which was the 2013 American Contact Dermatitis Society allergen of the year [39–45].

Etiopathogenesis

The mechanisms underlying this chemical-triggered delayed hypersensitivity reaction are not yet fully understood. In recent years, basic research demonstrated that the immune system reacts to combat allergens by activating signaling pathways that are normally used to combat infections [38].

Allergens are substances with physicochemical characteristics such as low molecular weight (less than 500 Da) and low affinity and solubility in lipids, the so-called haptens. These features allow them to cross the skin barrier and stimulate the immune system in susceptible individuals, sensitizing them [23, 46, 47]. The haptens form covalent bonds with the skin proteins, forming the antigen, and this conjugate binds to glycoproteins of the plasma membrane of antigen-presenting cells, such as Langerhans cells (LCs) or dendritic cells [46]. These cells act to internalize, process, and transport the antigens bound to the major histocompatibility complex (MHC) and present them to T lymphocytes from regional lymph nodes through afferent lymphatics. It thus produces the sensitization process [48], and the lack of integrity of the epidermal barrier appears to be the first step in its triggering [48, 49]. Activation and induction of migration of LCs seem to depend on the capacity of haptens to induce the secretion of IL-1β in LCs. IL-1β induction of an event is connected to the hapten contact with the skin and does not occur with irritant substances [25]. Other cytokines, such as TNF-α, may contribute to the activation of LCs.

Haptens can be classified as classic, pro-haptens, and transition metals. The classic haptens follow the path described above. The pro-haptens (for example, urushiol and drugs) need to undergo transformation to become active. Some authors classify haptens based on the type of transformation required: pro-haptens when the process is enzymatic, and pre-haptens when the transformation occurs by environmental action, such as light or oxygen. Since transition metals, such as nickel, chromium, and cobalt, unlike classic haptens, form ionic bonds with their carriers, this class of haptens is considered weaker and less stable [47].

The induction phase, also called the elicitation phase or afferent pathway of ACD, includes the events described from initial contact, often repeated, with the allergen, and ends when the individual is sensitized and able to respond positively to a new contact. For the sensitization to occur, the hapten must remain on the skin for 18–24 h. The least time required to complete the afferent pathway ACD is 4–5 days, and 14–21 days are required for the effector cells to recirculate on the skin [46].

The second step is the ACD elicitation or efferent phase. The elicitation phase starts after re-exposure to the allergen and results in clinical manifestations of ACD.

The antigen recognition is given by the T-cell antigen-specific memory heading toward the site of skin contact and within 24–48 h, the inflammatory reaction develops [46].

At this stage, the main cytokines are IL-1, IL-2, IL-3, IL-6, IFN-γ, and TNF-α [46].

More than 3,700 allergens have been reported as a cause of ACD in humans [50].

Cross-Reactions

It is common for the allergens to initiate cross-reactions with each other, which have important clinical implications.

Strictly speaking, the cross-reactivity occurs when an individual, who was initially sensitized

to a substance, reacts to a second allergen with which he/she never had contact [51]. However, the term cross-reaction is widely used by dermatologists to report simultaneous reactions to two or more substances indiscriminately.

According to Johansen et al., the basis of cross-reactions lies in the fact that two substances of different structures, but with similarity in chemical reactivity and molecular shape, can activate the same T-cell receptors. This could be interpreted as follows: X and Y substances are chemically and structurally similar; X is metabolized similarly to a Y component, or vice versa; or X and Y are both metabolized by similar components. It is often extremely difficult to differentiate between co-reactions or concomitant reactions (simultaneous reactions that occur with substances that are absolutely unrelated) and true cross-reactions mainly because the metabolites are structurally very different from the initial substances and it is very difficult to know what the primary sensitizing agent is: the multiplicity of substances with which humans have contact [49].

Clinical Presentation

ACD typically presents as a well-demarcated, itchy rash usually confined to the site of contact with the allergen. However, there may be diffuse or widespread distribution, depending on the nature of the causal agent [25].

It can be classified as acute, when there is predominant erythema, edema, and vesiculation; subacute, when the edema and erythema are less intense and dominant with demonstrations of secretions with crusting; and chronic, when there is prolonged evolution, with lichenification, variable hyperkeratosis, and cracks [25, 50, 52]. Itching is the constant symptom [52].

As with exogenous eczema, the main locations correspond to parts of the body with greater exposure to the environment: hands, face, neck, feet, and torso. The region involved corresponds to the principal location of contact exposure, especially at the early stage when limited to the contact area of the allergen, which may suggest the source of the substance [50, 52]. With the evolution of the process there may be involvement of other areas, especially in cases of long-term or untimely treatment [52]. Erythrodermia can occur in some cases [53]. It is not uncommon for secondary infection plus regional lymphadenopathy to complicate the picture [52, 53].

With the wide range of possible allergens, the clinical presentation can also vary greatly [50]. The more ubiquitous is the allergen, the more difficult the clinical correlation with exposure, e.g., balsam of Peru (*Myroxylon pereirae*), metals, formaldehyde, and rubber [50] (Fig. 18.5).

The face and eyelids are exposed to a large number of allergens, such as rubber additives (i.e., makeup sponges and toothbrushes), toiletries, cosmetics (i.e., preservatives and fragrances), and metals, which in addition to the direct contact can be easily carried by hand without any injury to these (ectopic contact dermatitis) [50] (Fig. 18.6).

Fig. 18.5 Allergic contact dermatitis
Fig. 18.6 Ectopic contact dermatitis

Scalp ACD has lower sensitivity, possibly due to the greater thickness of the region, changes because of the follicular units, changes in vascularization, and the dilution effect of perspiration [50]. Thus, allergens applied there, such as paraphenylenediamine of hair dyes, fragrances, preservatives, and surfactants of shampoos and conditioners, can cause eczema in adjacent areas, such as the deployment of the hair, eyelids, and retroauricular regions, without causing lesions on the scalp.

In the armpit the major allergens are fragrances, in particular Lyral® [50, 54], but preservatives also have a prominent place. It is common for injuries to spare the axillae, diluting the allergen in perspiration. In the case of aeroallergens, satellite papules may occur due to spreadability [50].

The neck also presents great exposure to environmental allergens and indirect exposure by hands. Frequently, metals and fragrances can lead to the development of Berloque (which comes from a French word that refers to pendant-like pigmentation) dermatitis [50, 52].

Hands are our greatest source of contact with the environment and the pathogenesis is primarily occupational, as can be seen in the case of construction workers, in whom the main allergens are potassium dichromate [55] in cement, and rubber or leather gloves [56]. In the case of hairdressers, paraphenylenediamine, cocamidopropyl betaine, and glycerol monothioglycolate are possible sources [23, 50]. In the literature the major allergens of the hands are metals, fragrances, *Myroxylon pereirae,* and rosin. The latter three are primarily related to soaps, detergents, and cleaning products [24, 57] (Fig. 18.7).

The dorsum of the feet is the preferred location of involvement of ACD and the main allergens refer to footwear, such as rubber, adhesives, and leather [23, 50, 52, 55].

In chronic long-lasting or recurrent cases of ACD the patients can develop sensitivity to multiple agents. The vicious circle of self-eczematization can also occur through scratching-lichenification-scratching, so even when the causative agent is removed the disease persists [52].

Fig. 18.7 Hairdressers: occupational allergic contact dermatitis

Systemic contact dermatitis usually occurs in sensitized individuals in whom topical drugs are given systemically (either orally or parenterally) [50]. A common example is promethazine.

Recall reaction: eczema on sensitization site after systemic exposure (oral, parenteral, or inhalation) [50, 53]. Prolonged exposure can lead to erythroderma. Box 18.3 shows noneczematous variants of ACD.

Box 18.3 Noneczematous Variants of ACD

Contact leukoderma: postinflammatory hypopigmentation or direct chemical toxicity (hydroquinone and rubber) [29, 52].

Contact hyperchromia: mainly caused by fragrances, [52] bleaching clothes, and textile dyes.

Pigmented purpuric eruption: caused by rubber oxidizing agents, cobalt, wool, and some medications (quinidine) [52].

Erythema multiform-like eruption: usually triggered by contact with plants, topical medications, woods, formaldehyde and resin-epoxy, metals, pesticides, and soap [23, 50, 52, 58, 59].

Lichenoid eruption: caused by metals such as nickel and copper, paraphenylenediamine, photographic developers, and resin-epoxy [23, 52].

Granulomatous dermatitis: caused by metals such as mercury, chromium, gold, cobalt, palladium, wool, zirconium, and beryllium [23, 50, 59].

Acneiform contact dermatitis: caused by cosmetics, medicines, oil and oil products, and coal tar [58, 59].

Pustular contact dermatitis: rare; caused by contact with some topical medications and metals, causing follicular obstruction [23, 58].

Contact urticaria: there are two mechanisms:

(a) Immune contact urticaria: immunoglobulin E (IgE)-mediated reaction is the least common form of ACD that occurs mainly by contact with proteins, such as latex [23, 50]. Other causes are foods (eggs, milk, potatoes, meat, seafood, and fruits), medicines, and preservatives.

(b) Nonimmunological contact urticaria: results from the release of vasoactive substances (such as histamine and bradykinin) directly by contact with the substance. It does not require prior sensitization. Examples of substances are preservatives (sorbic and benzoic acids), fragrances (cinnamic acid, cinnamic aldehyde, and *Myroxylon pereirae*), and dimethyl-sulfoxide (DMSO).

Diagnosis

Clinical history should include the onset of lesions, number of episodes, evolution, occupational history, hobbies and leisure activities. The physical examination should pay attention to the description and location of the lesions. Box 18.4 defines the ACD diagnosis.

Box 18.4 Allergic Contact Dermatitis: Diagnosis

Diagnosis is mainly clinical, based on a good anamnesia and location of the lesions, which can be complemented by histopathology and patch test.

Complementary Tests

Patch Test

The gold standard in the diagnosis of ACD is the patch test [48, 52, 60]. Assuming that the patient had prior contact with it, placing the suspected allergen on a body part, typically the torso, will induce the formation of eczematous lesions at the site of application after a standard period. The elucidation of exposure to the allergen source is the core process for establishing the clinical relevance of patch testing and the diagnosis of ACD [32, 61]. Although many allergens are common in different parts of the world, the applied allergens series are variable among them. For example, Europe (European Society on Contact Dermatitis, ESCD) and North America (North American Contact Dermatitis Research Group, NACDRG) have basic series and a variable range of complementary ones. In Brazil, the Brazilian standard patch test series and the cosmetic series [46, 48, 62] are used, composed of 30 and 10 substances, respectively (Tables 18.1 and 18.2).

The test is applied to the patient's back, left for 48 h, then removed so the first reading from the test can be taken. Between 72 and 96 h a second reading should be performed, from which the final test result is provided. The result follows the criteria of the International Contact Dermatitis Group (Table 18.3; Figs. 18.8, 18.9, and 18.10).

A positive patch test does not necessarily mean that the allergen in question is the cause of eczema. It is necessary to correlate the test and the clinical history, at which time the relevance of the test will be established. The relevance can be current or past and the substance may be causing or aggravating the clinical framework [52].

The relevance of the test may be possible, probable, or definite. Possible relevance occurs when there is a possibility of the presence of the allergen in the patient's environment. Probable relevance occurs when the allergen is present in the patient's environment. Definite relevance occurs when there is worsening with the use of the product or the patch test carried out with the product is positive.

Table 18.1 Brazilian standard patch test series

#	Substance	Concentration	Vehicle
1	Anthraquinone	2%	Petrolatum
2	*Myroxylon pereirae*	25%	Petrolatum
3	PPD (mix)[1]	0,4%	Petrolatum
4	Hydroquinone	1%	Petrolatum

Histopathology

Histopathologic examination generally reveals spongiosis, superficial perivascular inflammatory lymphocytic infiltrate in the acute stage, eosinophils that can be observed in the infiltrated areas as spongiosis, and intraepidermal edema, developing into vesicles. In the chronic phase, hyperkeratosis, acanthosis, parakeratosis and hypergranulosis, and fibrosis in the dermal papillae can be seen [52].

Differential Diagnosis

The differential diagnosis includes all forms of eczema: dermatitis and irritant contact, atopic, stasis, and xerotic eczema, and seborrheic dermatitis.

Face ACD should also be differentiated from rosacea, psoriasis, and tinea.

Toes ACD should be differentiated from tinea, palmoplantar dyshidrosiform eczema, and psoriasis. The disseminated disease requires differential diagnosis with erythroderma, such as mycosis fungoides, Sézary syndrome, psoriasis, and pemphigus.

Therapeutic Approach

The most important aspects of the treatment are to remove the contacts and to educate the patient to acknowledge the contact sources and avoid them.

There are databases for consultation by member dermatologists, such as CAMP (Contact Allergen Management Program), operated by the American Contact Dermatitis Society (ACDS) and CARD (Contact Allergen Replacement Database) from the Mayo Clinic [63–67]; more recently in Brazil there is PPAC (www.ppac.com.br). Through these databases, the doctor may provide the patient with a list of products that do not contain the allergen in question so that they can be avoided.

Once parted from the contacts, patients may take a few weeks until they achieve remission.

Repair of the damaged skin barrier through moisturizing is also a crucial factor.

For topical medication, corticosteroids and immunomodulators such as tacrolimus or pimecrolimus can be used.

Phototherapy, such as narrow-band UVB, can be very useful, especially in chronic cases.

For systemic treatment, systemic corticosteroids may be used for short periods if necessary, depending on the severity of the condition.

For chronic and recurrent cases, even when there is longer avoidance of contacts, as in the case of allergy to potassium dichromate, or in cases where there is no other therapeutic option, methotrexate or cyclosporine can be used, bearing in mind their side effects. Methotrexate can be used at a dose of 15 mg/week per os to control the disease. The recommended dose of cyclosporin is between 2 and 3 mg/kg/day orally for 6–8 weeks.

Photoallergic Contact Dermatitis

Etiopathogenesis

Photoallergic contact dermatitis (PACD) is a Gel–Coombs type IV hypersensitivity response resulting from exposure to a photoallergen, with previous sensitization to ultraviolet (UV) radiation. The length of the UV radiation wave is a significant factor for lesion triggering, given that most of the substances require UVA radiation [68, 69].

The photoallergen absorbs the UV radiation, is activated, and releases energy; the molecules then bind to transport proteins and make up complete antigens. The subsequent events are similar to what happens in ACD with participation of specific T lymphocytes [69].

The incidence is unknown for many reasons, among which the diagnostic difficulty related to the tests used for etiologic research.

Clinical Presentation

Symptoms start 24–48 h after exposure with lesions predominantly seen on exposed areas, although covered areas can also be affected in the most acute cases.

Diagnosis and Complementary Examinations

The diagnosis is made through contact phototesting (photopatch test), although there are methodologic variations and variation in interpreting the results of tests.

The methodology is the same used as for the contact test, but the allergens are applied in tandem onto the upper torso, and 48 h later one of the sides undergoes UVA (5–15 J/cm^2) radiation while the other side is protected from the application with opaque material. The radiation equipment is the same used for phototherapy. Reading occurs 48 h after exposure and is compared with the results obtained from the covered side, and follows the same methodology proposed by the ICDRG [48].

Photoallergens

There are many substances involved which depend on the time of the year, the geographic location where they occur, and the habits of affected individuals.

The most common substances are shown in Box 18.5.

Box 18.5 Main PACD Causative Agents
    Photoprotectors
    Topical antibiotics
    Topical antifungals
    Topical anti-inflammatories

Histopathology

The findings resemble those of the ACD, with epidermal spongiosis and dermal mononuclear infiltrate.

Therapeutic Approach

Treatment is based on identification of the causative agent and contact prevention. Identification of UV radiation as a causative agent of the process is extremely important. Therefore, avoiding sun exposure is essential for therapeutic success. When conditions for the exact identification of the etiologic agent are lacking, the use of photoprotectors must be limited since they can also be one of the etiologic agents. The therapeutic treatment follows the same rules as for ACD.

Atopic Dermatitis

Atopic Dermatitis (AD) is an inflammatory skin disease, often related to asthma or allergic rhinitis. It is a condition of chronic and recurrent development, beginning in early childhood as a result of a complex interrelationship between the environment, immunologic and genetic factors [70].

Epidemiology

AD prevalence has increased in recent years from the World War II on, and estimates today report that to up to 20% of the general population is affected [71, 72]. The reason for this rapid increase is still unknown, but is believed to be related to environmental changes [71, 72]. Fabric floor covering in apartments, for example, has increased humidity and buildup of dust, and less space in homes has decreased air circulation and increased conditions favorable for mite propagation [73].

Nearly 50% of all individuals with AD develop symptoms over their first year of life, and possibly 95% may display symptoms before 5 years of age. About 75% will show spontaneous remission before adolescence, whereas 25% will remain symptomatic throughout adulthood [74, 75]. A child with moderate to severe AD has a 50% possibility of developing asthma and a 75% chance of developing allergic rhinitis [76].

Two risk factors seem strongly related with AD development: family history of atopy (two to three times greater possibility with an atopic parent, and three to five times with both parents atopic) [76] and filaggrin gene mutation (*FLG* gene that codifies profilaggrin into filaggrin) in some AD patients. Filaggrin is necessary for the epidermal differentiation and development of the skin barrier, thus impairing skin hydration of those patients presenting with mutation [77].

Etiopathogenesis

The etiopathogenesis of AD is not totally clear, and a complex relationship involving genetic, immune, environmental, psychosomatic, and pharmacologic factors, in addition to changes in the skin structure itself, have been shown. The two main DA disorders are dysfunctional skin barrier and immunologic reaction, both interrelated, thus triggering a vicious circle.

Skin Barrier Change

The skin barrier comprises the stratum corneum that is made up of a double heterogeneous compartment, of which the main elements are corneocytes and extracellular lipids. The extracellular lipids of the stratum corneum are basically composed of ceramides (45–50%), cholesterol (25%), and free fatty acids (10–15%). The ceramides are crucial to the barrier function. One of the main roles of the skin barrier is permeability control. When this function is lost the skin undergoes physical, chemical, and biological aggression [78].

AD xerosis, or dry skin, is related to changes in epidermal differentiation, the epidermal lipid metabolism, and increased transepidermal water loss [79].

Immunological Changes

AD is an inflammatory biphasic skin disease characterized by an early phase when there is prevalence of T-helper 2 (Th2) cytokines and a later chronic phase when Th1 is prevalent.

The antigens that penetrate the epidermis resulting from a decrease of the skin barrier function are captured by the IgE molecules via receptors of the Langerhans cells (LCs), which are the main cells that introduce the epidermis antigens. The antigen is internalized and processed. The LCs introduce antigens to the Th2 lymphocytes, which start the cytokine synthesis (IL-4, IL-5, IL-13, and IL-16). IL-4 stimulates the B lymphocytes to produce IgE, while IL-5 induces the eosinophil synthesis and maturation [80, 81].

The mastocyte-related IgE brings about their degranulation by releasing their mediators, such as histamine, thereby causing pruritus and edema noticed during the AD acute phase. In the chronic phase a change in the cytokine pattern by the T lymphocytes occurs from the Th2 to the Th1, freeing IL-12 [82].

Many etiopathogenic factors in AD remain a controversial issue. *Staphylococcus aureus* is considered a triggering and/or aggravating factor, able to be isolated from the skin in 90–100% of sick individuals who undergo the specific IgE synthesis [83]. Most AD patients display high levels of total IgE with part of this IgE oriented against domestic dust mites [84]. It has been shown that contact with air allergens can exacerbate AD, with *Dermatophagoides pteronyssinus* as the main representative allergen [85]. Intra- and extradomestic home fungi have also been involved in the condition, as well as skin colonizers such as *Candida albicans*, *Malassezia furfur,* and *Trichophyton* spp. [84]. Emotional stress can also exacerbate AD, although the exact mechanism of the skin immune system and the nervous system interaction has not been identified yet; it is believed that such a phenomenon is mediated by neuropeptides [86].

Diagnostic and Clinical Presentation

No laboratory or histologic test has been described; therefore, the diagnosis is based on clinical characteristics. The most frequently used diagnostic criteria were developed by Hanifin and Rajka in 1980 [70], and reviewed in 2004 by the American Academy of Dermatology (AAD) [87]. Box 18.6 presents the Hanifin and Rajka criteria for AD.

Box 18.6 AD Diagnosis
Essential features:

Itch
Eczema with typical morphology and age-specific pattern

Important features:

Early age of onset
Atopy (family or personal history)
Dry skin

Related characteristics:

Atypical vascular response (facial pallor, white dermographism)
Keratosis pilaris, palmar hyperlinearity, ichthyosis
Ocular and periorbital changes
Other regional findings (perioral or periauricular lesions)
Perifollicular accentuation, lichenification, and excoriations

Developed by Hanifin and Rajka and modified by the AAD [70, 87].

AD injuries are no different from those of other eczemas such as contact eczema. In severe forms, erythema, edema, vesicles, oozing and crusts, lichenification, abrasions, papules, and nodules dominate the subacute and chronic forms. The typical AD patient is a person which has "an eczematous, pruriginous, early beginning disease, typically located in the antecubital and popliteal flexures of a patient with atopical or family readiness disease" [88]. Box 18.7 presents the phases of DA.

AD has a chronic course in many patients because of the difficulty in predicting periods of activity or discerning the aggravating factors. Some patients are sensitive to woolen clothing, which aggravates itching, hot water and longer showers/baths that aggravate the symptoms and the xerosis; therefore, they must be avoided. Some staphylococcal infections may trigger crises. Food must not be avoided unless the patient has a confirmed allergy. There are reports of worsening symptoms caused by life stress [88].

The most frequent complications are *S. aureus* secondary infections, herpesvirus infection resulting in herpetic eczema (widespread vesicular eruption on the face, scalp, and upper chest), mainly in severe forms of the disease, and molluscum contagiosum.

Differential Diagnosis

An AD-resembling eruption can be seen in many diseases, but a careful evaluation of the morphology and localization of the rash combined with information about each patient often leads to the correct diagnosis [87]. Box 18.8 lists diseases that must be left out.

Complementary Tests

The diagnosis of AD remains clinical because there are no reliable biomarkers that can distinguish it from other diseases. The most commonly associated laboratory feature, an elevated total and/or allergen-specific serum IgE level, does not affect about 20% of individuals. The prick test (immediate puncture test) is useful mainly when it results as negative to some allergens, thus removing its participation in the disease origin [89]. The contact test for atopy (atopy patch test) is a new procedure still being standardized; the most advanced tests aim at the *Dermatophagoides pteronyssinus and farinae* mites [90].

Histopathology is typical to eczema; hyperkeratosis and papillomatosis are prevalent in the chronic lesions.

Therapeutic Approach

Nonpharmacologic Interventions

Xerosis resulting from a dysfunctional skin barrier is one of the characteristics of the AD patients. The use of an emollient and a moisturizer (glycerin, for example) lubricates and softens the skin. Occlusive-acting emollients (vaseline, dimethicone) make a barrier to delay water evaporation. Using a formula with these two types of substance is effective and must be applied two to three times a day. Its use decreases AD signs and symptoms, such as pruritus, erythema, fissures, and lichenification, as well as

the need for pharmacologic intervention [91]. The use of urea and ammonium lactate at high concentrations has to be avoided as they can result in skin rash; scent moisturizers must also be avoided.

Showers (baths) are useful for skin crust and rash agent removal; tepid and quick (5 min) showers (baths), with little soap, are recommended to preserve most of the skin barrier. A moisturizer must be applied to the skin immediately after the shower (bath) [92].

Light clothes are also recommended to avoid excessive sweating leading to pruritus. Cotton clothes are suggested. The patient's environment has to be airy, with no carpets or curtains, to make cleaning easy.

The wet-wrap technique may be used, with moisturizer or topical corticosteroids, consisting of the applying the agent followed by occlusion with a wet bandage and subsequent dry bandage. The topical-corticosteroid bandage is more effective when compared with the use of moisturizer only, but care has to be taken regarding adverse effects [93].

Topical Corticosteroid Therapy

Topical corticosteroids are anti-inflammatory agents that control pruritus and eczematous lesions by inhibiting the dendritic cells and lymphocyte activity, thereby avoiding interleukin synthesis. The most common local adverse effects include purpura, telangiectasia, striae, and cutaneous atrophy.

Corticosteroid therapy is recommended to patients who have failed emollient treatment. A range of factors has to be considered for prescription, such as age, application sites, costs, and patient preferences. Application usually occurs twice a day. A proactive treatment can be made when the corticosteroid is applied for two consecutive days, over a week, on the affected areas, even when there is no active lesion, to prevent new crises. As the genital area, the face, and the folded areas display high absorption rate, low- or medium-potency corticosteroids are recommended for use on these areas. Monitoring of local adverse effects is advisable [94].

Topical Immunomodulators

Calcineurin inhibitors are a class of drugs used in AD. Calcineurin is found in the lymphocytes acting in the inflammatory interleukin transcript.

There are two calcineurin inhibitors for topical use: 1% pimecrolimus (from 3 months old), 0.03% tacrolimus (from 2 years old), and 0.1% tacrolimus (patients older than 15 years of age). Given twice a day, they do not have the side effects of corticosteroids and can be used for longer periods, even on the face. Their most widely known side effects are pruritus and burning. A relationship between topical use and systemic immunosuppression and malignancy has not been established. These agents can be used in proactive treatment with topical corticosteroids [95–97].

Phototherapy

Phototherapy is a second-line treatment used in the absence of topical corticosteroids or calcineurin inhibitors, and can be useful for maintenance of chronic patients. UVB narrow band, UVA 1, and PUVA (UVA + psoralen) can be used by physicians with experience in these techniques. The therapeutic approach must take into account factors such as availability, costs, phototype, and family history of skin cancer. Local erythema, pruritus, and burning are the most often seen adverse effects; nonmelanoma skin cancer; melanoma, and lentigo are seldom seen [98].

Systemic Immunosuppression

Systemic immunosuppression is used for those patients who do not respond to the usual treatment.

Cyclosporin

Cyclosporin is the most assessed substance in research studies in both adults and children, in intermittent and continuous courses. The standard doses vary from 3 to 6 mg/kg/day, over 12 weeks, which may be repeated after a 7-day interval or sustained for 1–2 years. Unfortunately, recurrence ensues after treatment interruption. Periodically the renal function, arterial pressure, and cyclosporine serum levels should be monitored [99].

Azathioprine

Azathioprine is used at a 1–3 mg/kg/day, for 12 weeks or more, until the clinical benefit is reached, with AD improvement from 25% to 37%. Nausea, vomiting, and anorexia are the most frequent side effects. There are reports of hepatic enzyme increase, leukopenia, cephalea, and even lymphoma in patients treated with this agent [100].

Methotrexate

Methotrexate is an antifolate metabolite that blocks DNA, RNA, and purine synthesis, whose efficacy in treating AD remains unknown. Some studies have shown improvement in 52% of patients who used the drug over 24 weeks. The regimen varies from 7.5 to 25 mg/week, divided into three doses, with a 12-h break between each. Improvement is often noticed in the tenth week of treatment, and once obtained the dosage must be tapered until its discontinuation. Nausea and other gastrointestinal symptoms are the most common adverse effects. Hepatotoxicity needs to be monitored. Folic acid supplementation is suggested to reduce hematologic and gastrointestinal toxicity [101].

Oral Antimicrobials

Antibiotics have to be used when there is clinical evidence of bacterial infection (*S. aureus*), or antivirals when herpetic eczema caused by the herpes simplex virus is diagnosed, in combination with traditional treatment for AD [102, 103].

Oral Antihistamines

Oral antihistamines do not show properly verified clinical benefits, and have been used for their sedative effect, thus improving the quality of sleep [104].

Oral Corticosteroids

Oral corticosteroids are used by some physicians to rapidly improve clinical symptoms. Rebound flare and worsening of the disease severity are observed phenomena after drug discontinuation. Although temporarily effective, this treatment must be avoided in both adults and children because of the potentially adverse effects over short-term use. Oral corticosteroids may be used for short periods in cases where another systemic treatment or phototherapy has been started or optimized. Hypertension, glucose intolerance, gastritis, weight gain, and adrenal suppression are the most common adverse effects [105].

Other drugs, such as mycophenolate mofetil and IFN-γ, have been used in trials involving a small number of patients, with improvement noticed in certain cases [87].

Support Groups

A support group is an extremely valuable measure, since AD patients and their families often need a multidisciplinary approach that comprises not only the physician but also other specialty area professionals, mainly psychologists and nurses. Furthermore, it is an opportunity to share the complexity of a chronic disease that affects their quality of life with individuals and relatives going through a similar life experience [106, 107].

Nummular Eczema

Introduction

Nummular eczema, which has received this name because of the lesion's clinical aspect, of a round or oval shape resembling coins. Marie Guillaume Alfonse Devergie described it during the mid-1990s [108].

It is an idiopathic, inflammatory, and recurrent dermatosis with pruritus as its most prevalent clinical sign.

Epidemiology

Nummular eczema is more often found in male adults, although peaks of incidence occur both in men and women from the ages of 50 to 65 years [108].

Etiopathogenesis

The etiology is unknown, although many isolated or associated factors – nutritious, infectious, and emotional – are involved in its genesis. It is already known that the dermatosis is more frequent in alcohol-abusing individuals [109]. It can also be an atopic dermatosis manifestation during childhood.

Dry skin may be a significant etiologic factor mainly among older individuals, an occurrence that makes the interruption of skin barrier easier.

The fibrinogen and fibronectin bacterial receptors in these patients bestow more pathogenic adherence, thus promoting early and persistent *S. aureus* skin colonization [110].

Some drugs, such as gold, isotretinoin, pegylated IFN-α2b, ribavirin, and, more recently, infliximab, are associated with the appearance of nummular eczema [111, 112].

Contact allergens can aggravate or induce the primary lesions. Frequency of sensitization has varied from 30.1% to 77.9% in different studies. The most commonly involved allergens are nickel, potassium bichromate, cobalt chlorate, paraphenylenediamine, ethylenediamine, and neomycin. The authors have suggested the study of contactants mainly in chronic and treatment-resistant cases [113].

Clinical Presentation

Dermatosis can occur on any part of the tegument, although the torso and the lower limbs are the preferred parts. Papules and papulovesicles make up well-delimited plates of varied sizes. Oozing and crust-composition areas can be seen. Chronic plates are dry, scaling, and lichenified (Fig. 18.11).

Fig. 18.11 Nummular eczema

Differential Diagnoses

The diseases that may lead to confusion with nummular eczema are summarized in Box 18.9.

> **Box 18.9 Differential Diagnoses for Nummular Eczema**
> Allergic contact dermatitis
>   Stasis dermatitis
>   Atopic dermatitis
>   Tinea corporis
>   Mycosis fungoides (old lesions)
>   Paget disease (unilateral involvement of the nipple/areola)
>   Fixed drug eruption
>   Pityriasis rotunda

Therapeutic Approach

Treatment involves the use of topical corticosteroids of medium strength, although the calcineurin inhibitors tacrolimus and pimecrolimus play a major role in cases of longer treatment. Emollients are key when there is concomitant xerosis, but not before improvement of the oozing lesion if it is present.

Oral antihistamines are important for decreased pruritus. Systemic antibiotics are indicated when conspicuous secondary infection is seen. For extensive or traditional treatment-resistant forms, good results can be obtained with UVB narrow-band phototherapy.

Stasis Dermatitis (Stasis Eczema)

Introduction

Stasis dermatitis or eczema is a chronic condition often seen on the lower limbs, resulting from venous stasis. It is more often found in women than in men. The most frequent cause of venous stasis is lower limb varices, resulting from vascular insufficiency or thrombophlebitis. Other factors, such as obesity, congenital skeletal and muscular alterations, lower limb fractures, and planovalgus feet are involved.

Etiopathogenesis

In cases of lower limb varices, the inability of venous valves increases the intravascular pressure, leading to its insufficiency, thereby leading to pitting edema caused by fluid extravasation. Varicose varices can become evident mainly on the malleolar regions. Hyperpigmentation occurs in the same region, owing to hemosiderin deposition from extravasated red blood cells, a process that may reach all of the limb affected [114]. Chronic edema can present abrupt worsening episodes; the skin becomes erythematous and scaly, and the diagnosis can be confused with erysipelas/cellulitis.

Chronic venous stasis changes microcirculation inducing fibrinogen extravasation through the venules and the consequent deposition of pericapillary fibrin, thus making a barrier for the diffusion of oxygen and other nutrients and thereby resulting in stasis dermatitis that can ultimately lead to tissue necrosis and ulcer formation [115].

Clinical Presentation

Clinically, stasis dermatitis is manifested as acute, subacute, and chronic eczema. Symptoms such as pruritus are conducive to exulceration. Exulcerations make bacterial infections more likely, which may evolve to erysipelas, a common complication in such cases. Lipodermatosclerosis is another complication that also mimics cellulitis/erysipelas, a condition resulting from necrosis and fibrotic inflammation of the subcutaneous cellular tissue. The acute form occurs with localized pain mainly in the lower third of the legs. It has a slow evolution and can be bilateral, conditions that make it different from cellulitis. Skin hyperpigmentation and stiffness can be seen in the chronic forms,

Fig. 18.12 Stasis dermatitis

which compress the ankle region thus creating an inverted champagne-bottle shape. The aggravating crises can overlap in the chronic forms [114] (Fig. 18.12).

Therapeutic Approach

The acute forms of dermatitis have to be treated with topical or systemic corticosteroids over a short period of time. The use of emollients can be encouraged mainly in cases of concomitant localized xerosis. The edema can be controlled with interventions such as limb elevation above

heart level, which is not always possible at home. Compressive methods, such as the Una boot or compression stockings, make the venous return easier and are useful for presentation control [116].

Dyshidrotic Eczema

Introduction

Dyshidrotic eczema, or pompholyx, is a form of recurrent eczema more often found on the palmoplantar regions. The early suggested nomenclature refers to the presence of multiple vesicles on the affected regions; the alteration is due to the presence of intraepidermic spongy vesicles and not to the eccrine sweat glands that heavily populate the area.

Epidemiology

Universal dermatosis can affect both men and women mainly in their twenties to forties [117]. Some studies estimate its prevalence from 0.05% to 10.6% of the population [118]. In 2006, a Chinese study [119] identified a family with an autosomal dominant type of pompholyx, a genetic locus in the 18q22.1–18q22.3 chromosomes between the D18S465 and D18S1362 markers. Most cases are sporadic.

Pathogenesis

The exact mechanism that accounts for the vesicles' development is still unknown, although various factors are implicated in their pathogenesis, such as contact dermatitis (nickel, cobalt, Balsam of Peru, *p*-phenylenediamine, rubber vulcanization agents), atopic dermatitis, drug eruption (highly active antiretroviral therapy, piroxicam, immunoglobulin), distant hypersensitivity reaction resulting from fungal infection (feet tinea due to dermatophytes), and post-HIV infection [120].

Other factors are seen as aggravating conditions of the disease, such as tabagism, stress, and longer use of protective gloves [117, 120].

Soler and cols. have recently studied the role of the aquaporins (AQP) in the dyshidrosis pathogenesis. They found that excessive expression of AQP3 and AQP10 occurs in the affected areas of the dyshidrotic patients, a fact also noticed in AD patients [121].

The AQP are proteic channels that increase cell membrane malleability bidirectionally and osmotically driven for small molecules, such as water, glycerol, and urea. They regulate skin moisture by changing the TEWL, which plays a major role in disease intensity and aggravation [121].

With tissue water loss, changes in the protease balance occur which degrade the desmosomes, leading to an increase in the intracellular calcium concentration and activation of the transglutaminases involved in corneocyte maturation. These effects increase xerosis, resulting in aggravation of dermatosis [121].

Clinical Presentation

Dyshidrosis can be classified as idiopathic or true, and also as dyshidrosiform eruption if associated with other dermatoses (contact dermatitis, AD, drug eruption, or ICD).

It is characterized by the presence of vesicles with clear and colorless content on the palmoplantar area, with no erythema, mainly located on the lateral and dorsal areas of the fingers. They can be grouped and turn into blisters. Secondary infections are a common complication (Fig. 18.13).
Fig. 18.13 Dyshidrotic eczema

Diagnosis

The diagnosis is based on a detailed anamnesis and observation of recent recurrent outbreaks. Research on the associated factors must be conducted by direct mycologic examination of the feet vesicles, presence of the diagnostic criteria for AD, investigation of ingested drugs before the beginning of the disease, and contact tests in the chronic cases.

A biopsy may be needed to confirm the diagnosis or to omit other diseases considered in the differential diagnosis.

Differential Diagnosis

Many cutaneous diseases may mimic dyshidrotic eczema (see Box 18.10).

Box 18.10 Differential Diagnoses for Dyshidrotic Eczema

Acropustulosis of childhood
 Lymphoma/T-cell adult leukemia
 Bullous impetigo
 T-cell bullous lymphoma
 Dyshidrosiform pemphigoid
 IgA linear dermatosis with dyshidrosis
 Bullous epidermolysis
 Erythema multiforme
 Hand-foot-mouth disease
 Herpes simplex

Fixed drug eruption
Attrition blisters
Pemphigus vulgaris
Pustular psoriasis
Scabies
SAPHO syndrome

Therapeutic Approach

Disease management is difficult and encompasses general measures, such as quitting tobacco; proper hand and foot drying; hand washing when strictly necessary; avoidance of direct contact with soaps, detergents, fresh fruit, and meat; use of protective gloves even during hair shampooing; and use of cotton socks with frequent and regular changes. Topical or systemic drugs may be indicated depending on the acuteness of the condition.

Topical corticosteroids or calcineurin inhibitors can be an option to contain new vesicle development. Associated measures are sometimes necessary, such as the use of medication under occlusion. Bexarotene gel 1% has been described as a therapeutic option, either in isolation or combined with topical corticosteroids.

Systemic treatments can be implemented in the more acute forms, or in the nonreactive forms for topical drugs, when drugs such as corticosteroids (prednisone) can be used for limited periods to avoid unwanted adverse effects. Immunosuppressive drugs, such as azathioprine (100–150 mg/day) and methotrexate (15–25 mg/w), can be useful, as well as mycophenolate mofetil (2 g/day).

Antihistamines are important for symptom control. Botulinum toxin type A is applicable in cases when hyperhidrosis is an aggravating factor (162 U per palm). UVB narrow-band phototherapy (311 nm) and UVA-1 (320–400 nm) are considered good therapeutic options.

Psoriasis

André Vicente Esteves de Carvalho

Key Points
- Psoriasis is an immune-mediated inflammatory disease whereby erythematous scaling plaques appear on otherwise healthy skin
- Besides skin lesions, psoriatic patients may develop arthritis and are prone to developing several other comorbidities
- Immunosuppressive and immunomodulatory treatment targeted to key molecules in psoriasis pathophysiology are highly efficacious in treating severely affected patients

Epidemiology

The prevalence of psoriasis may range from 0.4% to as much as 4.7% depending on the population studied. Some reviews found that the prevalence among Africans (and African Americans), Norwegian Lapps, and Asians to range from 0.4% to 0.7%, whereas Americans (United States) and Canadians have a prevalence of 4.6% and 4.7%, respectively. In general it is accepted that 2% of the world's population may suffer from the disease and two-thirds of these patients develop a mild form of psoriasis, whereas one-third will have the severe form of the disease [1–3].

There is no difference between genders regarding psoriasis prevalence. Alcohol and tobacco consumption is thought to be associated with the development of lesions in men. The disease may arise in any age group, and cases have been described in infants and in the elderly, but two peaks of onset have been reported, the first between 15 and 30 years of age and the second between 50 and 60 years. Seventy-five percent of patients develop first lesions before the age of 40 [4]. Pustulosis of the palms and soles, a form of localized pustular psoriasis, differs in its epidemiology from the other clinical presentations of psoriasis. It tends to present at a later stage of life, affects more females than males, and is highly associated with tobacco consumption [5].

Arthritis may be found in up to 30% of psoriatic patients, and nail psoriasis, a known risk for arthritis development [6], occurs in almost 80% of psoriatic patients [7]. AIDS patients frequently develop psoriasis, and the prevalence of the disease is higher when the CD4$^+$ T-lymphocyte cell count falls below 200 cells/mm. Studies of HIV-positive patients show a 4% increased psoriasis prevalence over that of the general population [8].

Having psoriasis may be a risk for developing associated comorbidities, such as Crohn's disease, ulcerative colitis, rheumatoid arthritis, ankylosing spondylitis, nonalcoholic fatty liver disease, high blood pressure, diabetes, high levels of blood lipids, and obesity (metabolic syndrome) [9]. The inflammatory burden that follows the psoriasis onset, together with the deleterious effect of the comorbidities, especially metabolic syndrome, increase the risk for death by acute myocardial infarction in severe psoriatic patients, this risk being higher for younger patients. After 60 years of age, the role of psoriasis in cardiovascular risk is overtaken by the risk of the components of the Framingham risk score [10, 11]. The prevalence of depression and suicidal ideation is also higher among psoriasis patients [9].

Etiopathogenesis

Psoriasis is an immune-mediated systemic inflammatory disease of polygenic origin that is triggered by several environmental factors (see Box 19.1) mainly affecting the skin. The major candidate gene for psoriasis is *HLA-Cw6* (locus PSORS1), although several others are implicated [12] (see Box 19.2). Family history of psoriasis is described in at least 35% of patients, although some studies report up to 90%. When both parents are affected, the risk of psoriasis on the offspring seems to be 41%, whereas it is 14% if only one parent is affected [13, 14].

Box 19.1 Factors Triggering the Development/Worsening of Psoriasis
- Physical stress/trauma (Koebner phenomenon)
- Psychogenic stress/trauma
- Infections
  - Bacterial (streptococcal, staphylococcal)
  - Viral (HIV/AIDS)

- Drugs
  - Antimalarials
  - β-Blockers
  - Systemic corticosteroids (after rapid withdrawal)
  - Interferons
  - Lithium
  - Terbinafine
- Pregnancy (impetigo herpetiformis)
- Hypocalcemia (inducing general pustular psoriasis)
- Alcohol and tobacco consumption
- Obesity

Since the introduction of cyclosporine as an antipsoriatic drug [15], it has been known that psoriasis is an immune-mediated disease rather than a disorder of keratinization. In fact, the hyperkeratosis featured in the psoriatic lesion has an underlying immune imbalance that explains its development [15]. A dysregulation between the innate and the adaptive immunity, mediated through specific resident cutaneous cell types (such as dermal plasmacytoid dendritic cells) and a cascade of proinflammatory cytokines (interleukin (IL)-17, IL-23, and tumor necrosis factor α (TNF-α)), for example [14].

Fig. 19.1 Plaque type psoriasis. Characteristic erythematous scaling lesion on typical sites, such as the elbow

The initiation of the process is thought to be the stimulation of plasmacytoid dendritic cell in the dermis by a complex formed by the antimicrobial peptide LL-37 (cathelicidin) and the host DNA. Stimulated plasmacytoid dendritic cells produce interferon-(IFN)-α, which activates dermal dendritic cells, hence the current supposition that IFN-α is a key factor in the beginning of the disease and in its flares [16]. Activated dermal dendritic cells migrate to the lymph node where, stimulated by IL-6 and transforming growth factor β, it acts to differentiate naive T lymphocytes into specific subsets of T-helper cells called Th1, Th17, and Th22. The maintenance of the Th17 response is achieved through IL-23 release, making this cytokine a target for the treatment of chronic stable psoriasis [17, 18]. This Th1, Th17, and Th22 cells subset travel through the circulation until being recruited via a series of chemokines and cytokines to act on specific sites of the skin. There they amplify inflammation through the release of TNF-α and IFN-γ, with subsequent release of a cascade of proinflammatory cytokines such as keratinocyte growth factor, epidermal growth factor, and vascular endothelial growth factor, leading to vasodilatation, ectasia, keratinocyte stimulation, and epidermal proliferation. This process represents the underlying etiology of the clinical features seen on psoriatic plaques: redness, infiltration, and scaling [7] (Fig. 19.1).

Clinical Presentation

The characteristic lesion is a red, scaly, infiltrated lesion with well-demarcated borders, although the clinical features may vary among the distinct forms of the disease. Typical sites for the development of lesions are the scalp, elbows, and knees, although they can also frequently appear on the genitals and the lower back. Extension of the disease may range from a single lesion to erythroderma (all or almost all the skin is affected). Acute flares and unstable lesions tend to show prominent signs of inflammation with an intense erythema but less desquamation and infiltration. Pinpoint erythematous lesions around a previous plaque may be a sign of expansion of

the disease. Sometimes, if the inflammatory infil-
trate is important, pustules may arise and the
lesion may be tender or itchy. Chronic stable
lesions present variable degrees of erythema,
scaling, and infiltration. Itching is variable on
chronic lesions [1, 7].

The subtypes of the disease are as follows.

– *Plaque type psoriasis*

The most common type of the disease, plaque
type psoriasis is characterized by round or oval
erythematous, infiltrated scaly lesions that may
vary in size from a few centimeters to large con-
fluent plaques that may affect almost all the skin
surface. According to the extension of the dis-
ease it can be classified as localized (<10% of
the body surface area (BSA)) or generalized
(≥10% of BSA). Knees, elbows, scalp, genitalia,
and the lower back are usually involved. Lesions
on the palms and soles can be painful and be a
cause of social embarrassment or work absentee-
ism. Lesions tend to resolve leaving a hypochro-
mic patch, especially on darker-skinned
individuals [2, 19] (Figs. 19.1, 19.2, 19.3, 19.4,
and 19.5).

– *Guttate psoriasis*

Guttate psoriasis is a subtype of the disease
whereby an abrupt eruption of small (0–2 cm
diameter), round, erythematous, scaly plaques
appear usually after a streptococcal upper respi-
ratory tract infection. It affects children and
young adults, being less frequent in older indi-
viduals. Antistreptolysin, streptozyme, and anti-
DNase B titers can be found in the blood,
corroborating a previous occurrence of a strepto-
coccal infection [19].

– *Erythrodermic psoriasis*

Erythrodermic psoriasis is a generalized vari-
ant (>90% of the body surface area affected)
characterized by intense erythema and scaling
and little to no infiltration. Pruritus can lead to
scoriation. The face is usually spared and sys-
temic corticosteroid withdrawal is a known pre-
cipitant (see Box 19.1). It is a critical condition,
usually leading to hospitalization because of

Fig. 19.6 Erythrodermic psoriasis. Lesion on 90% or more of the body surface area. Note that erythema and scaling are prominent over infiltration

impairment of the skin's barrier function and further hydroelectrolytic imbalance. Fever or hypothermia may be signs of systemic infection [7] (Fig. 19.6).

– *Generalized pustular psoriasis*

Several sterile pustules arise from an intensely erythematous skin, without scaling. The von Zumbusch subtype is a much more severe form of the disease and, as in the erythrodermic form, leads to hospitalization. Sometimes if not well treated it may lead to death, mainly by subsequent infection. The patient may experience fever and malaise. Withdrawal or rapid tapering of systemic corticoids is the main triggering factor.

Pregnancy, infections, and hypocalcemia are also precipitants. IL-8 and IL-1β are involved and IL-36 gene receptor antagonist may be found in some of these patients. Impetigo herpetiformis is a form of generalized pustular psoriasis that affects pregnant women. It may represent a risk for the fetus and preterm labor, and miscarriages eventually can occur. A more restricted form ("localized") of pustular psoriasis can occur over pre-existing lesions, on the outer edges of the plaques, especially in unstable disease. An annular subtype is described as pustules and scaling on the advancing borders of the plaque, while the center of the lesion can be spared or show advanced healing. The exanthematic variant may arise abruptly after triggering factors such as infections or lithium. It may also overlap with other pustular drug-induced eruption, such as AGEP (acute generalized exanthematous pustulosis) [1, 19].

– *Palmoplantar pustulosis*

Classification of palmoplantar psoriasis is controversial as it is a disease without PSORS1 (HLA-Cw6) positivity. Its association with tobacco smoking and metal allergy also led some authors to consider palmoplantar pustulosis as a separate entity [5]. On the other hand, the fact that 18% of patients show characteristic lesions of plaque-type psoriasis elsewhere in the body and 20% present a family history of psoriasis are arguments in favor of classifying the disease as a subset of pustular psoriasis [20]. Sterile pustules arise over erythematous or even clear skin and are limited to the palms and soles, with predilection to the cavum. Pustules may coalesce to form lake-like collections in severe cases. Resolving lesions leave brownish macules [21] (Fig. 19.7).

– *Acrodermatitis continua of Hallopeau*

This is a rare subtype of localized pustular psoriasis that affects the tips of the fingers. Toes are less affected. The involvement of one or two fingers is usual. Sterile pustules arise in the fingertips, sometimes involving the entire fingertip including the nail bed, leading to the destruction of the nail unit. Lesions resolve with crusts, and sometimes bone reabsorption of the distal phalanx can occur if the inflammation is intense and chronic [21].

– *Flexural psoriasis*

Also called "inverse," flexural psoriasis can affect 2–6% of all psoriatic patients. Lesions are shiny erythematous plaques with variable infiltration and almost no scaling. The absence of desquamation is a valuable diagnostic clue and is due to maceration of the horny layer caused by humidity and friction of the flexural areas. Axillae, intergluteal cleft, inframammary region, and inguinal crease are commonly affected areas [7] (Fig. 19.8).

– *Nail psoriasis*

The nail can be affected in up to 80% of psoriatic patients and is a risk factor for the develop-

Fig. 19.7 Pustular psoriasis. Localized palmoplantar lesions. Pus is formed by intense exudation of neutrophils

Fig. 19.8 Inverse psoriasis on the axillae

ment of psoriatic arthritis. The clinical manifestation depends on where the inflammation affects the nail unit: matrix, nail bed, and hyponychium. Onycholysis (separation of the nail plate from the nail bed), "oil spots" (inflammatory

Fig. 19.9 Nail psoriasis. Onycholysis and nail pitting

exudate from the nail bed), nail pitting (dome-shaped depressions of the nail plate caused by altered keratinization of the proximal matrix), and subungual hyperkeratosis (altered keratinization of the nail bed) are common signs [22] (Fig. 19.9).
– *Psoriatic arthritis*

Presently characterized as a seronegative spondyloarthropathy, psoriatic arthritis is, in most cases, an asymmetric mono- or oligoarthritis. Up to 30% of psoriatic patients can develop arthritis. Nail psoriasis, intergluteal psoriatic lesions, and scalp psoriasis are thought to be risk factors. The most common sites affected are the proximal and distal interphalangeal joints of the hands and feet. The arthritis almost invariably begins as an enthesitis, which may result in a swollen digit called "sausage finger." Rheumatoid factor is almost invariably negative and metacarpal involvement, typical of rheumatoid arthritis, is also absent. Exclusive disease of distal interphalangeal joint can lead to rigidity of the joint in a flexed position, and nail psoriasis is often present. Axial arthritis can occur, resulting in spondylitis and sacroiliitis, which occurs along HLA-B27 positivity. Larger joints such as the knee and the ankle are also affected, and enthesitis of the Achilles tendon is sometimes the first manifestation of the disease [7, 23, 24].

Diagnosis

The diagnosis of psoriasis is eminently clinical. The presence of a characteristic lesion at preferential sites is usually enough to confirm the suspicion. The Auspitz sign (methodic curettage of silver scales leading to bleeding through pores), Koebner phenomenon, and nail lesions may help consideration of psoriasis. Resolving psoriatic lesions may resemble tinea, as they may become tricophytoid, with an "active" border circumscribing an already healed center. Palmoplantar lesions also can be misinterpreted as tinea pedis. In both cases, a scraping with further direct examination and culture can elucidate the case. As candidiasis may be confounded with flexural psoriasis, KOH examination for yeasts can elucidate the diagnosis. Nevertheless, the concomitance of candidiasis and flexural psoriasis is often seen. Other erythematous squamous diseases that can mimic the clinical features of psoriasis can be investigated through a skin biopsy [7].

The severity of the disease is usually measured in clinical trials by the Psoriasis Area and Severity Score (PASI), a score that ranges from 0 to 72; patients with a score of 10 or higher are considered as having a severe disease (Table 19.1). The PASI is also used to evaluate response to treatments, and a usual primary endpoint in clinical trials that evaluate antipsoriatic drugs is the PASI75 (75% improvement over baseline PASI). Other instruments to measure severity are also used, such as the BSA and the Physician's Global Assessment (PGA). The DLQI (Dermatology Life Quality Index) is a self-administered 10-question questionnaire that ranges from 0 to 30 and evaluates the impact of any dermatology condition on the quality of life. A score of 10 or more determines that the disease has major impact on the patient's quality of life [25].

Diagnosis of psoriatic arthritis is made using the CASPAR criteria (Table 19.2) and the efficacy of treatment in most clinical trials is measured by the American College of Rheumatology score (ACR 20) [26].

Table 19.1 Psoriasis Area and Severity Score (PASI)

	Erythema[a]	Induration[a]	Scaling[a]	SUM	X Area[b]	Result	Factor[c]	Total

Table 19.2 Cl**AS**sification criteria for **P**soriatic **AR**thritis (CASPAR) criteria

To be classified as having psoriatic arthritis, patient must have inflammatory articular disease (joint, spinal, entheseal) with 3 or more of the following 5 points:	
Criterion	*Description*
1. Evidence of psoriasis (one of a, b, or c):	Psoriatic skin or scalp disease currently present, as judged by a dermatologist or a rheumatologist
(a) Current psoriasis[a]	
(b) Personal history of psoriasis	A history of psoriasis obtained from patient or family physician, dermatologist, rheumatologist, or other qualified healthcare professional
(c) Family history of psoriasis	A history of psoriasis in a first- or second-degree relative by patient report
2. Psoriatic nail dystrophy	Typical psoriatic nail dystrophy, including onycholysis, pitting, and hyperkeratosis observed on current physical examination
3. Negative test result for rheumatoid factor	By any method except latex but preferably by ELISA or nephelometry, according to the local laboratory reference range
4. Dactylitis (one of a, b)	Swelling of an entire digit
(a) Current	A history of dactylitis recorded by a rheumatologist
(b) History	
5. Radiologic evidence of juxta-articular new bone formation	Ill-defined ossification near joint margins (excluding osteophyte formation) on plain X-ray films of hand and foot

[a]Current psoriasis scores 2

Complementary Examinations

The pathologic examination of a stable psoriatic lesion classically reveals acanthosis with elongated rete ridges ("clubbing"). The horny layer is thicker than normal skin and focal parakeratosis with hypogranulosis is seen. Elongated and ectatic vessels of the dermis reach the top of the papilla and, together with the suprapapillary epidermal atrophy, explain why the curettage of scale produces bleeding (Auspitz sign). The perivascular inflammatory infiltrate is mild and when neutrophil exocytosis exists, intraepidermal pustules (Kogoj) or microabscesses in the horny layer (Munro) can be seen.

The initial lesion may not show the classic histopathologic features of the disease and, therefore, may not help in the diagnosis. Early papules can show slightly acanthotic epidermis with a mild infiltrate, without neutrophils. Parakeratosis is not a feature, and the presence of mast cell degranulation may be a clue for the diagnosis of eruptive lesions (guttate psoriasis). Examination of the border of expanding papules and plaques

shows suprapapillary edema and vascular tortuosity, and a mild perivascular inflammatory infiltrate is seen. Acanthosis and spongiosis may coexist, and the exocytosis of neutrophils can lead to the formation of the spongiform pustule of Kogoj in the epidermis. The further progression of this collection of neutrophils through the epidermis may lead to the accumulation of cells in the horny layer and the formation of Munro microabscesses. A more exuberant picture of neutrophil exocytosis and accumulation is seen in pustular variants [27].

Differential Diagnosis

Diseases that may develop erythematous and scaling lesions, with or without pustules, are among those that can mimic psoriasis in its wide range of forms. The concurrence of lesion in classic sites (extensor aspects of joints, scalp, navel, genitals), lesions on the nails and a positive familial history of psoriasis is frequently enough to confirm the diagnosis of psoriasis. Guttate psoriasis can be confounded with syphilis, and a serologic examination is mandatory. Pustular drug reactions can develop the same features as seen in generalized pustular psoriasis (von Zumbusch's) and the history of the disease is important in deducing a causal relation between drug intake and the development of lesions. Histologic examination in this case may be of lesser value as both diseases have similar features, with the exception of the occurrence of eosinophils in the examination, which may favor the diagnosis of pustular drug eruption. Palmoplantar keratoderma, hand eczema, and pompholyx are also differential diagnoses of psoriasis of palms and soles. The most common differential diagnoses are as follows [7, 19].

– *Atopic dermatitis:* Scaling in atopic dermatitis is less prominent and the affected sites are usually the opposite of those seen in psoriasis (flexural aspects instead of extensor aspects). Pruritus is variable in psoriasis and almost a rule in atopic dermatitis.
– *Seborrheic dermatitis:* Sometimes indistinguishable from mild psoriasis, especially in the face and scalp, sometimes leading to confirmatory skin biopsy. Scales tend to be smaller and not as flaky as in psoriasis, and severe infiltration is seldom seen in seborrheic dermatitis.
– *Cutaneous T-cell lymphoma (CTCL):* Sometimes a disease leading to erythroderma, CTCL can mimic psoriasis. Localized forms can be distinguished from psoriasis by lack of the coarse desquamation, seen in psoriasis, and by superficial atrophy with skin wrinkling seen in CTCL. In case of erythroderma, biopsy is required, as are laboratory examinations for *Sézary syndrome.*
– *Squamous cell carcinoma:* Can be suspected if there is only one or a limited number of treatment-resistant lesions, limited to sun-exposed areas.
– *Tinea:* Usually a cause of confusion with psoriasis if it occurs in palms and soles or flexural sites. KOH examination is needed to confirm the diagnosis.
– *Pityriasis rubra pilaris (PRP):* Can be a cause of erythroderma, but may mislead the diagnosis even if with fewer lesions. The brownish/copperish hue, the areas of spared skin among lesions, and the fewer inflammatory features of palmoplantar lesions in PRP are often sufficient to distinguish it from psoriasis.

Therapeutic Approach

Psoriasis is a chronic disease and its treatment should involve a long-term commitment between doctor and patient, whereby it is important to treat both the physical and psychological impacts of the illness. The concept of quality of life is as important as the concept of "cure," and the impact of therapies over the patient's life should also be taken into account. As different patients with psoriasis showing the same features may respond differently to the same treatment offered, an individualized approach is generally used.

Psoriasis treatment has greatly evolved since the understanding of the immune nature of the disease. There are several treatment guidelines available, almost all with a concordance of opinion. Patients should be assessed for disease severity and extension, which is made using the PASI, BSA, or DLQI. If any of these scores are 10 or higher (PASI ≥10, BSA ≥10, DLQI ≥10), the patient has moderate to severe psoriasis and topical treatment should not be used as monotherapy. The treatment goal should be at least 75% of improvement over baseline PASI, but 50–75% improvements can be tolerated if the patient is satisfied with current therapy, which is measured buy a DLQI less than 5 (Fig. 19.10) [25].

There is almost general consensus among available guidelines [28] that mild disease is initially treated with topical therapy. Nonresponders may undergo phototherapy and, sometimes, systemic therapy. Moderately to severely affected patients should not use topical treatment as monotherapy, and phototherapy/photochemotherapy is a first option for those who have no contraindication. Systemic antipsoriatic therapy has greatly evolved since the introduction of biologics and small-molecule inhibitors, following the greater understanding of the pathophysiology of the disease. Psoriatic arthritis should be always referred to a rheumatologist, and initial therapy usually comprises disease modifying antirheumatic drugs (DMARDs), such as methotrexate or leflunomide, with or without nonsteroidal anti-inflammatory drugs. Nonresponders

Fig. 19.10 Treatment goals and strategy for changing therapeutics according to clinical response

should promptly use biologics, and anti-TNF drugs are first-line therapeutics [25].

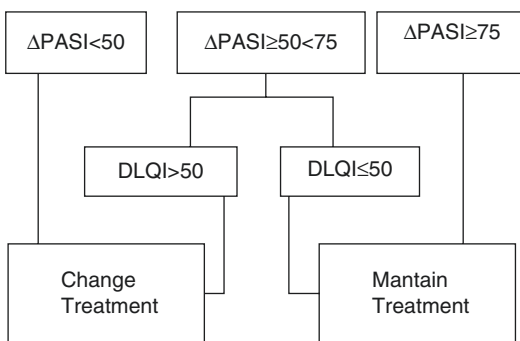
Mild Psoriasis

Mild psoriasis can be treated with topical drugs, which include potent corticosteroids, vitamin D analogs, calcineurin inhibitors, topical retinoids, and tar/liquor carbonis detergens (LCD) formulations.

First-line therapy is the combination of a topical corticosteroid and a vitamin D analog, usually betamethasone propionate and calcipotriol. This can be used until lesions are cleared. Caution should be taken with extended application of the compound for more than 30 consecutive days, but continuous long-term safe treatments of 52 weeks have been published in trials. After clearance is achieved, corticosteroid can be tapered down and, sometimes, only calcipotriol monotherapy can be maintained. In the event that the combination therapy is insufficient to achieve resolution of plaques, betamethasone can be replaced by a more potent corticosteroid, such as clobetasol propionate or halobetasol propionate.

Calcineurin inhibitor cream and ointments are not properly absorbed by thick skin, and are therefore used mainly on the face and genitals, and in flexural psoriasis. At those sites, response is similar to that of topical corticosteroids but without the risk of atrophy. Irritation after application is the major side effect in some patients.

Topical retinoids are a second-line option, but their use is limited by local irritation, which also occurs with anthralin. Therefore they cannot be used in unstable, very inflammatory lesions. Anthralin can stain the skin and, as its use is complicated by the limited time of the exposure to the drug by the patient, must be used by patients who can effectively comply with it. Absorption into the skin for longer periods of time than prescribed can lead to extreme irritation.

Tar and salicylic acid compound are useful adjuvants, but are generally not sufficient to treat psoriasis as monotherapy. Tar, and to a lesser extent LCD, has a pungent odor, which can be unpleasant especially for women [7].


Phototherapy is also an option for patients who are not responsive or can no longer use corticosteroids because of side effects (most commonly atrophy) [25].

Moderate to Severe Psoriasis

Patients with moderate to severe psoriasis should no longer use topicals as monotherapy. After generalized disease is established, phototherapy/photochemotherapy is usually effective. Narrow-band ultraviolet B (UVB) without using oral drugs or UVA associated with the use of oral psoralens (PUVA) are both effective. Two to three sessions a week are needed for clearance and the amount of time per session is determined by testing the minimal erythemal dose. Some contraindications for phototherapy are current use of phototoxic drugs (e.g., hydrochlorothiazide), concomitant acquired or genetic photosensitive diseases or diseases prone to the development of skin cancers (e.g., lupus,), and history of worsening psoriasis with sun exposure and previous history of skin cancers (especially melanoma). Failure to achieve 50–75% improvement in the disease severity score (PASI, BSA, or DLQI) should prompt a treatment change [29].

Methotrexate is a potent inhibitor of the enzyme dihydrofolate reductase and is similar in its structure to folic acid. As it binds with great affinity to the enzyme of which folic acid is substrate, it prevents folic acid from mediating the conversion of dihydrofolate reductase to tetrahydrofolate. As tetrahydrofolate is necessary for the synthesis of purine nucleotides, methotrexate acts by inhibiting cell division (S phase). In psoriasis, the effect of methotrexate is achieved by immunosuppression rather than by inhibiting keratinocyte proliferation, inhibiting DNA synthesis in immunologically competent cells. Metabolism is hepatic but excretion is made through the kidneys. It can be administered orally, subcutaneously, and intravenously. It is available in 2.5-mg tablets or in 2-ml vials with a concentration of 50 mg/2 ml or 25 mg/ml [30]. Usual antipsoriatic doses ranges from 7.5 to 30 mg per week, and can be administered as a single oral or subcutaneous dose or as three divided oral doses over a 24-h period. Oral administration of methotrexate achieves a plateau of absorption after intake of 15 mg. Therefore, if higher doses are needed the subcutaneous route is preferable. Controversy still endures about the need of a lower test dose to access possible myelosuppression. Acute myelosuppression is rare, but a blood count should be taken after 1–2 weeks of treatment to evaluate its possibility. Folic acid supplementation is mandatory (1 mg/day).

Leucovorin is an antagonist of methotrexate and should be administered in cases of suspected toxicity. Long-term liver fibrosis is an adverse event of the chronic use of this drug whose occurrence can be diminished by lowering the methotrexate dose to a minimum of 2.5 mg after clinical response is obtained, by sequential liver tests (every 3 months in stable chronic users), and by accessing liver fibrosis after 4 g of cumulative dosage (fibroscan/liver biopsy) [25, 30].

Acitretin is a systemic retinoid, a vitamin A analog that has antiproliferative effects over the epidermis. It acts directly on gene transcription after binding to nuclear retinoid receptors. Immunomodulatory effects are known but are not of great importance in the psoriatic inflammatory cascade. Acitretin is teratogenic and should not be used in women of childbearing age. It is available in 10-mg and 25-mg tablets and usual doses for psoriasis range from 25 to 50 mg/day, but doses higher than 35 mg are restricted by side effects, generally xerosis and elevation of blood lipids [31].

Cyclosporine is a potent immunosuppressive agent found on a soil fungus (*Tolypocladium inflatum* Gams), and its effect on psoriasis was discovered after treatment of rheumatoid arthritis and psoriatic arthritis patients whose psoriasis lesions cleared after intake of the drug [32]. Although its mechanism is still not completely understood, its action in inhibiting the enzyme calcineurin leads to inactivation of T cells, mainly due to decreased IL-2 secretion. Cyclosporine is used today in a microemulsion form, and capsules are available in 25 and 100 mg and also in a 100-mg/ml solution. It is not cytotoxic or terato-

genic, and does not cause myelosuppression. Usual doses range from 2.5 to 5 mg/kg. There are two approaches when prescribing cyclosporine in psoriasis: one starting with a lower dose of 2.5 or 3 mg/kg and increasing the dose for optimal results if necessary, and the other starting with a higher dose of 4–5 mg/kg and decreasing the dose as soon as optimal results are achieved. Because of potential severe long-term side effects (nephrotoxicity, malignancies), the drug is reserved for severe recalcitrant psoriatic patients who had failed or had contraindications/reactions to previous classic therapies, such as phototherapy/photochemotherapy, methotrexate, or acitretin, and its use should be on a short-interval basis (up to 16–20 weeks). It is very useful to rescue patients from a severe flare or when patients have to be promptly cleared of their lesions (surgery, social events), as cyclosporine exerts its effects within a few days or weeks [33]. Contraindications to cyclosporine are decreased renal function, uncontrolled hypertension, presence/history of malignancies, and hypersensitivity to the drug. A full laboratory workup should be made before initiating the drug, and sequential monitoring of the renal function is mandatory [31].

Anti-TNF-α drugs are molecules that block the cytokine and prevent its action on the psoriatic inflammatory pathway. They are highly efficacious both in psoriasis and psoriatic arthritis [34]. *Etanercept* is a fully human fusion protein that mimics the TNF-α natural receptor, binding to TNF α. It is used as 50-mg subcutaneous injections twice a week for 12 weeks and then lowered to 50 mg per week. As it is not a monoclonal antibody, antidrug antibody formation is rare [34, 35]. *Infliximab* is a chimeric (25% murine, 75% human) immunoglobulin (Ig)G1 monoclonal antibody that binds to both soluble and transmembrane TNF-α. It comes as a powder in 100-mg vials that must be reconstituted in sterile water. Induction dose is 5 mg/kg intravenously on weeks 0, 2, and 6 and then every 8 weeks. As it is an intravenous infusion it is administered in a clinic/hospital setting. Infusion must be slow, taking no less than 2 h to avoid reactions. As it is a chimeric drug, antidrug antibody formation is expected to be more common after infliximab

infusions, but the clinical relevance of development of antibodies is still under debate [34, 36]. *Adalimumab* is a fully human IgG1 monoclonal antibody that binds to TNF-α and prevents it interacting with its natural cell surface receptor. In the presence of complement, it may lyse surface TNF-expressing cells. It is supplied in 40-mg prefilled syringe or pen, and dosage is 80 mg subcutaneously in week 0, 40 mg in week 1, then 40 mg every 2 weeks. Although it is fully human it may cause antidrug antibody formation, albeit low and of limited clinical relevance [34, 37].

Ustekinumab is a fully human monoclonal antibody IL-12/-23 inhibitor that binds to the p40 subunit shared by both cytokines and prevents Th1 and Th17 signaling, thus consequently altering the release and action of several other cytokines and chemokines (TNF-α, IFN-γ, IL-2, -6, -17, and -21). It is available in 45- or 90-mg prefilled syringes and doses are prescribed based on weight: 45 mg weeks 0 and 4 and then every 12 weeks if the patient weighs less than 100 kg, and 90 mg on the same administration scheme if patient is 100 kg or more. The same safety concerns used to establish a screening workup for TNF-α blockers are used for ustekinumab. One case of reversible posterior leukoencephalopathy syndrome (RPLS) was reported [34, 38].

Apremilast is a phosphodiesterase-4 inhibitor that blocks the conversion of cyclic adenosine monophosphate (cAMP) into AMP inside inflammatory cells. High intracellular levels of cAMP have an inhibitory effect on inflammation, downregulating the release of proinflammatory cytokines (TNF-α, IL-17, Il-23) and upregulating the release of anti-inflammatory cytokines (IL-10). It is available in 10- and 30-mg tablets and is administered orally, titrating the dose from 10 mg/day on day 1 to 60 mg/day on day 6 and after, with the aim of reducing gastrointestinal symptoms. Patients with severe renal impairment should use half the dose. Depression was reported in clinical trials, and caution is advised when used in patients with depression or a history of depression. Weight loss may be a side effect, and the use of apremilast together with rifampin, carbamazepine, phenytoin, or any CYP450 enzyme inducer may decrease the efficacy of apremilast [39].

Secukinumab is a fully human monoclonal IgG1 antibody that blocks IL-17A. IL-17 is a pivotal cytokine in psoriasis pathophysiology whose blockage results in downregulation of inflammation. Secukinumab is available in 150-mg prefilled syringes, pen, or lyophilized powder vial. The approved psoriasis dosage is 300 mg at weeks 0, 1, 2, 3, 4, and then every 4 weeks. A lower dose of 150 mg is sometimes acceptable for some patients. Screening and monitoring are the same as made for anti-TNF blockers and, as for all immunosuppressants, live vaccination should not be administered. Flares or even new cases of inflammatory bowel disease may happen after secukinumab treatment, and its use should be made with caution in patients with those conditions. It was recently approved for psoriasis by the FDA [40].

Glossary

Auspitz's sign Pinpoint bleeding following methodic curettage of the scales in a psoriatic lesion.

Clubbing Histopathologic term referring to elongated and widened rete ridges, which look like a club.

Erythroderma Scaling erythematous dermatitis that affects 90% or more of the body surface area. Psoriasis is one of the causes of erythroderma, but other diseases may also be causes.

Sézary syndrome A late stage of cutaneous T-cell lymphoma that is characterized by the epidermotropism of neoplastic CD4$^+$ T lymphocytes, which form microabscesses (Pautrier's microabscesses). Lymphadenopathy and presence of atypical T cells (Sézary cells) in the peripheral blood are signs of late-stage disease.

Tricophytoid lesion Lesion similar to a skin fungal infection (tinea). Its characteristic is a annular lesion with a more prominent border (active border), where the fungal activity resides.

von Zumbusch psoriasis Also called Von Zumbusch generalized pustular psoriasis, this is a severe and generalized form of pustular psoriasis. Pus consists of neutrophils. Drugs, emotional stress, infections, and sudden withdrawal of systemic steroids are some of the eliciting factors.

Seborrheic Dermatitis

Juliano de Avelar Breunig
and Marco Otavio Rocha Couto

Key Points

- Seborrheic dermatitis (SD) is a chronic inflammatory skin disorder and the affected areas are rich in sebaceous glands
- The prevalence of SD varies between 3% and 5%
- SD can cause visible scaling in hair and clothes, oily appearance, and foul odor. All these manifestations may be socially embarrassing, especially because they can be judged as poor hygiene
- Pruritus, scaling, facial erythema, odor, and the absence of a cure are the reasons for a decrease in the quality of life.
- Treatments include eradication of fungi, attenuation of the inflammatory process, and reduction of the sebum production.

Introduction

Seborrheic dermatitis (SD) is an inflammatory skin disorder, with a predilection for skin rich in sebaceous glands, affecting 3–5% of the population. It presents poorly demarcated red patches and greasy scaling on the scalp, face, upper aspect of the trunk, flexures, and groin. SD is an easily recognizable chronic dermatosis [1]. It affects infants and adults, often being associated with increased sebum production by the skin. The affected skin presents as erythematous, edematous, and covered with scales (or even crusts) that are yellowish, erythematous, or brown. SD ranges from mild to severe, including psoriasiform and erythrodermic forms. Pityriasis capitis (PC), or dandruff, is the denomination for mild cases without erythema and with reduced and dry scaling on the scalp.

SD and PC are characterized by epidermal hyperproliferation, increased intercellular and intracellular lipids, corneum envelope interdigitation, and parakeratosis [2]. SD can cause pruritus, and secondary infections occur occasionally.

A variety of treatment modalities is available, including eradication of fungi, reduction or attenuation of the inflammatory process, and decreased production of sebum [3]. Regarding the costs imposed by this cutaneous affection on public health, it is estimated that in the United States the annual direct, indirect, and intangible costs (from SD alone, excluding PC cases)

achieve the total sum of US$1.2 billion. Furthermore, studies using quality of life assessment questionnaires have shown that the impact of SD is considerable [4]. The absence of a cure and the scant knowledge of its pathogenesis, in addition to the symptoms, substantiate these findings.

Epidemiology

SD is often described as common in adolescents and young adults. In patients older than 50 years, SD once again becomes frequent [5, 6]. The clinically significant estimated prevalence is 1–3% in young adults in the United States [7]. In a study conducted from 1971 to 1974 involving a representative sample of people from 1 to 74 years old in the United States population (through the National Health and Nutrition Examination Survey), the prevalence of SD, determined by dermatologists, was 11.6% on the whole. Cases in which the need for medical consultation was considered have been estimated at 2.8% (2.6% for men and 3% for women). In that sample the prevalence of SD needing medical consultation was lower in children under 12 years of age (less than 1%) and higher among people between 35 and 44 years (4.1%) [8]. This work, which was the most representative population study, demonstrated that SD is not rare in middle age, as described in many articles. When PC (dandruff) was considered, the observed prevalence exceeded 50% [9].

While SD was reported as rare among black persons [10, 11], it has also been described as common in black West Africans [12], although these data are contradictory. Prevalence of SD becomes quite high in patients with acquired immunodeficiency syndrome (AIDS), ranging from 30% to 80% [13–15].

Etiopathogenesis

Many theories exist regarding the etiology of SD, which remains controversial. Seborrhea or excessive sebum production is known as a predisposing factor for SD, but it is not detected in all affected patients [16].

Sebum is involved in epidermal structure development and in the maintenance of the epidermal permeability barrier [17], transport of antioxidants to the skin surface [18], protection against microbial colonization, and generation of body odor and pheromones [5]. Sebum has more recently been linked to specific hormonal signaling of the skin, epidermal differentiation, and skin protection against ultraviolet radiation [19, 20].

When secreted, sebum consists of triglycerides and esters, which are broken down by microbes into diglycerides, monoglycerides, and free fatty acids. Free fatty acids play an essential role in the early irritative response that triggers SD. The role of sebum secretion is also seen in the impact of stress and hormones on SD. These are known as factors that affect sebaceous secretion and thus cause SD to worsen [2].

SD in adults tends to appear during puberty, with the increase in cutaneous lipids that occurs during this period. The areas affected by SD are also rich in sebum production; furthermore, factors that increase seborrhea are associated with worsening SD. However, although SD occurs on the oily areas of the skin, we cannot consider seborrhea as the only cause of the disease. Many people have significant skin oiliness without the development of SD, and a study has shown that the rate of sebum production in the skin of individuals affected by SD was the same as in controls without the disease [16]. Another study examining the lipid contents of the forehead skin of 30 patients with SD and of 60 controls found a higher lipid content in SD patients compared with controls ($P = 0.0001$) [21]. Although few studies lead in this direction, and armed with only these data we cannot make a definite conclusion, the second study is methodologically superior and is more consistent with current knowledge about the disease.

Sebaceous gland function is responsive to stimulation by sex hormones and adrenal corticosteroids. Recent data demonstrated that skin treated with α-bungarotoxin, an acetylcholine receptor antagonist, markedly decreased sebum

production and pore sizes, suggesting that local neuronal stimulation may regulate sebaceous function [22]. The amount of sebum excretion has a bimodal distribution: it is high in the neonatal period under the influence of maternal sex hormones and then it rapidly decreases in childhood, correlating with the high prevalence of atopic dermatitis in this age group. Sebum secretion rate increases throughout the teens, and remains steady until its decline in both genders, although sebum excretion remains higher in males. These physiologic changes correlate with the timeline of how children "grow out" of their childhood atopic dermatitis, and the aging adult develops xerotic dermatitis.

A study assessed the link between the sebaceous glands and *Malassezia* [23]. There was an increase in the synthesis of neutral lipids in the presence of extracts of *Malassezia globosa* and *Malassezia restricta*. In this same study, the interleukin (IL)-8 production by human keratinocytes exposed to *Malassezia* extracts increased significantly compared with controls. In particular, two species, *M. globosa* and *M. restricta*, exerted a significant increase in IL-8, and of the two organisms *M. globosa* showed a significant effect.

The oral administration of isotretinoin, commonly used to treat acne, also reduces SD [24]. Since isotretinoin acts mainly by reducing the sebum production rate, it is thought that in this way it controls SD. However, isotretinoin also reduces epidermal proliferation, and this mechanism may also influence the improvement of SD (because in SD there is epidermal proliferation).

Some authors suggest hyperproliferation of the epidermis as another causal factor [25]. It has been proposed that the inflammatory process in SD causes an increase in turnover of keratinocytes and an incorrect maturation of the stratum corneum, resulting in a malfunction of the epidermal barrier [26].

SD was reported in a patient in whom seborrhea and unilateral SD developed on the face after facial nerve paralysis [27], and also in patients with torso paralysis [28]. These reports suggest that the paralysis could also be a triggering factor for SD. The reason why paralysis might have association with SD would be the faulty drainage of the pilosebaceous canal sebum. Such drainage, induced by skin movement, would occur in persons not affected by paralysis.

Another factor that can influence SD is the fungus of the genus *Malassezia* [29]. Although this genus of fungus is a member of the normal skin flora, it has been known to play roles in human diseases, such as PC, SD, pityriasis versicolor, and folliculitis caused by *Malassezia*. It could also cause exacerbation in atopic dermatitis and psoriasis [25, 30]. This fungus is common in areas rich in sebum.

Sebum secretion in human skin is a mixture of triglycerides, fatty acids, wax esters, steroid esters, cholesterol, cholesterol esters, and squalene [31]. When secreted, sebum consists primarily of triglycerides and esters, which are broken down by commensal microbes in diglycerides, monoglycerides, and free fatty acids. Human sebum contains saturated and unsaturated fatty acids, with a preponderance of the unsaturated.

The role of specific fatty acids becomes apparent when we examine the metabolism of *Malassezia. Malassezia* lipases and phosphatases hydrolyze sebaceous lipids, resulting in decreased triglycerides and a corresponding increase in free fatty acid by-products. *Malassezia* uses saturated fatty acid, leaving behind irritating unsaturated fatty acid such as oleic acid. These fatty acids can cause skin inflammation. To demonstrate that fatty acids produced by *Malassezia* can induce scaling in the human scalp, researchers applied a marked fatty acid (oleic acid) to the human scalp. Even when *Malassezia* was removed from the product containing oleic fatty acid produced by it, the product still prompted reaction with scalp scaling in susceptible individuals [31].

However, the same authors have shown that the use of oleic acid produced by *Malassezia* did not induce scaling in individuals not susceptible to PC or SD. Such a finding provides evidence of the role of these fatty acid metabolites in the development of scaling and suggests underlying differences among some individuals predisposed to develop PC or SD. An individual's sensitivity to the irritating free fatty acid penetration and the

resultant inflammatory response ultimately determines one's susceptibility for SD development.

Immunodeficiencies such as AIDS allow excessive proliferation of *Malassezia*, resulting in serious and extensive SD. Furthermore, some of the histologic features of SD have been reproduced by the inoculation of dead *Malassezia* in animal skin [32]. The wide variety of cytokines expressed in inflammation is similar to those seen in other fungal infections [33].

The difference between susceptible and nonsusceptible individuals remains unclear. Multiple possibilities exist, including innate differences in the barrier function of the stratum corneum, skin permeability, and immune response to free fatty acids or proteins and polysaccharides of *Malassezia* [9]. Subsequent studies are needed for us to understand comprehensively the susceptibility to SD.

Lipases may play a role in the life course of the species of *Malassezia* on the skin. For a better understanding of this role, one research group isolated the lipase of *Malassezia globosa* [34]. The protein was sequenced and the gene corresponding to the lipase (LIP1) was cloned and sequenced. This work was a first step toward the molecular description of lipid metabolism in the scalp and a better understanding of the role of microbial metabolism in the etiology of SD and PC. Based on the limited activity of LIP1, the authors concluded that *Malassezia* probably has other lipases, and that more studies are needed to delineate the complete metabolic pathway.

The genome of the most prevalent *Malassezia* in SD and PC has been completely sequenced. The *M. globosa* genome is 9 Mb, the smallest of any known free-living fungi [35, 36]. For proper identification of genes, the prediction of the protein-coding structures has been enhanced by the transcript sequencing of mRNA, allowing the prediction of 4289 protein-coding genes. Despite the small number of genes, the genome encodes the metabolic components for glycolysis, the tricarboxylic acid cycle, and the synthesis of all 20 canonical amino acids and of 5 bases of nucleic acids, probably revealing that most of the species of *Malassezia* are dependent on fatty acids for growth. In contrast to *M. globosa*, the genomes available to all other free-living fungi contain fatty acid synthases.

The necessity by *Malassezia* of assimilating external fatty acids is also reflected in the number of multiple lipases and phospholipases secreted (13 and 9, respectively). Reverse transcription–polymerase chain reaction (PCR) and proteomic experiments confirmed the expression of multiple lipase and phospholipase genes on human scalp.

The enzymes would need, therefore, to be in the extracellular environment to interact with the host's sources. Proteomic experiments were thus performed to identify more than 50 secreted proteins [9]. Some of the most abundant secreted proteins were, as hypothesized, lipases. In addition, many other secreted proteins have been identified, including aspartyl proteases, family members of phospholipase C, glucose-methanolcholine oxidoreductases (known as *Malassezia* allergens) [37], cell wall-modifying enzymes, and unknown proteins. Because these proteins are secreted, they would be more likely to interact with the skin and then mediate the pathogenicity of *Malassezia*, and could be therapeutic targets.

The lipid layer of *Malassezia* might also modulate the production of proinflammatory cytokines by keratinocytes [38].

Besides SD, *Malassezia* has also been associated with PC. This kind of fungus needs lipids for in vitro growth, corroborating its occurrence in humans in areas with increased production of sebum [39].

A 2008 study detected with PCR that the species of *Malassezia* most frequent in SD is *restricta*. However, the author himself concludes that we cannot yet determine if this fungus is pathogenic or not [29]. Another study found a higher prevalence of *Malassezia* (82%) in control patients than in patients with SD (76%) [40]. Bergbrant examined 30 people with SD and 60 controls, finding no significant differences in the average number of organisms (*Malassezia*) for both groups of patients [21]. However, Tajima has found in skin affected by SD a population of *Malassezia* three times higher than in unaffected skin in 31 patients with SD [29]. *M. restricta* and *M. globosa* were predominant among the species, comprising

93.5% and 61.5% respectively. Although Tajima has found a larger population of *Malassezia* in the affected skin compared with the unaffected, the study was conducted comparing them only in affected patients. The other studies, with a control group, found no difference or found greater populations of *Malassezia* in controls.

An important piece of evidence is that antiseborrheic shampoos (also called anti-dandruff) containing active agents against *Malassezia* are effective in SD [1, 41–43]. Improved scaling after treatment is accompanied by a reduction in the levels of *Malassezia* on the scalp [9]. Furthermore, the recolonization of *Malassezia* in SD recurrences corroborates its role [44]. With regard to improvement with systemic antifungal agents, since they have anti-inflammatory effects associated with antifungal effects, it cannot be said that the fungi are the only factors in SD. The data concerning the role of *Malassezia* in SD are still controversial. Piérard claims that diseases in which *Malassezia* is involved are caused by a lack of control of natural innate antimicrobial defense mechanisms [45]. He argues that the simple skin contamination by *Malassezia* spp. commensal does not induce a clinically relevant response of the host. Thus the corneocytes, or only a few of them, could play this role in inflammatory diseases caused by *Malassezia*. Individuals predisposed to PC and SD would be those who do not respond adequately to the presence of *Malassezia.* Thus, the epidermal cells could fail to express the skin's defense mechanisms. In response to the secondary accumulation of fungi, there would be an inflammatory reaction ranging from mild to severe [46]. Consequently, as in most inflammatory skin diseases, scaling of corneocytes would then be altered, with the occurrence of a scaly aspect. The most likely and accepted fact is that SD is an association between fungal infection of the genus *Malassezia*, seborrhea, and individual sensitivity [47].

Also regarding the immunologic hypothesis, theories based on SD immunologic studies propose that the disease's pathogenesis is due to an inadequate immune response of the host to the fungus, the toxins produced by the fungus, or irritants produced by the fungus. Epidemiologic data showing a higher prevalence of SD in immuno-compromised individuals (previously mentioned in the text) suggest that the disease is due to an inadequate immune response to *Malassezia*. However, Perry and Sharpe have refuted such an idea by quantifying antibody production in response to *Malassezia* antigens in 19 patients with SD, as well as the cellular immune response to *Malassezia* antigens in 16 patients with SD [48]. The comparison of these data with those of healthy controls matched for age and sex found no significant differences, suggesting that SD is not the result of an increased or decreased immune response to fungi.

Another study compared the *Malassezia* cultures of 28 human immunodeficiency virus (HIV)-positive individuals (including 7 with SD) with a control group of 20 HIV-negative individuals (including 10 with SD) [49]. Results of the cultures of HIV-positive individuals with SD clinical signs demonstrated a very small or missing content of fungi, while the results of HIV-negative individuals with SD exhibited significantly higher content of *Malassezia*. These findings suggest that SD in HIV-positive persons may suffer a distinct pathogenic mechanism in relation to classic SD in immunocompetent individuals. However, such data come from a study with a very limited number of patients.

Prohic found no differences in the distribution of species of *Malassezia* in SD lesions among immunocompetent and immunocompromised individuals [50]. However, the larger amount of positive cultures in immunocompromised patients would confirm that cellular immunity could facilitate the survival of skin fungi.

In an in situ study of inflammatory cells and mediators in SD patients' skin, an increase was found in nonimmunogenic stimuli such as neurokinin-1, CD16+, and complement [33]. These data suggest that irritative products produced by *Malassezia* can cause a rise in the response activated by the complement. There is also an increased level of inflammatory interleukins and lymphocyte-stimulating interleukins T helper-1 (Th1) and Th2 in both the affected skin and the skin not affected by SD, possibly due to stimulation of the immune host system by *Malassezia*.

Authors have proposed that fungi of the genus *Malassezia* could induce an inflammatory reaction, producing toxic mediators released only under specific growing conditions [48]. The unpredictable course of SD could be explained by this theory. Studies on fungi of the dermatophyte class have identified a liposoluble molecule that features the function to mediate chemotaxis of neutrophils and induce inflammatory reactions in the host [51]. The researchers named this substance chemotaxin lipid-like leukocyte activator (LILA). Cross-sensitization experiments have shown that several species of fungi can produce LILA or structural variants of it, representing a signal to the host's phagocyte system similar to the N-formylated methinyl peptides in bacterial infections. In addition to the possible inflammatory response induced by LILA, the lipase activity of *Malassezia* produces irritating fatty acids and arachidonic acids, which can also contribute to the inflammatory reaction of SD [52].

In the past there were only few reports regarding SD susceptibility and human leukocyte antigen (HLA). All were carried out in the 1970s and reported A30 and/or A31 and B12 (corresponding to HLA-B*44 or HLA-B*45) association. However, a recent study added the alleles A*32 for class I and DQB1*05 and DRB1*01 for class II [53].

Associated Factors

Hormones

The hypothesis of a relationship between SD and hormones would make sense because the condition appears in infants (by the transfer of maternal hormones), disappears spontaneously with the elimination of these hormones (up to 12 months of age), and reappears more prominently at puberty [1]. However, it does not explain why it reappears after the age of 50 years (at which stage the hormones are declining).

Sex

In the study by Gupta et al. [54], the predominant sex in patients with SD was male. These results were attributed to a stronger action of androgens on the pilosebaceous unit in males. The largest study, however, from which to draw conclusions on the influence of sex on SD would be NHANES, previously described, in which cases with a considered need for medical consultation were estimated at 2.8% (2.6% for men and 3% for women).

Body Fat, Body Mass Index (BMI), and Hypertension

A study by the authors of this chapter, involving 2201 patients, has found an association between scalp SD and increased body fat (confirmed by tricipital skin folds and BMI) [55]. The BMI data are only in the doctoral thesis [56], while the article has described the relationship with tricipital skin folds. The mechanisms involved in this association are not known. Obesity is related to insulin resistance, but a study did not find high levels of insulin associated with scalp SD [57]. However, obesity can lead to hyperandrogenism and elevation of testosterone levels, which could account for the increase in seborrhea [58, 59]. Data demonstrating the effect of antiandrogens on seborrhea treatment support the role of hyperandrogenism in SD.

Treatment of women with oral contraceptives containing antiandrogenic properties led to improvement or resolution of seborrhea [60, 61]. Another observation is that the use of anabolic steroids by competitive sports practitioners can cause SD [62]. The mechanism proposed was sebaceous gland hypertrophy, resulting in increased sebum production.

Two studies, each comprising more than 2000 teenagers or young adults, found no association between acne and SD [55, 63].

Besides being associated with an increase in body fat, a recent study of 9255 patients found an

association between SD and hypertension in adults [64], further corroborating inflammatory dermatoses such as SD and metabolic syndrome.

Emotional Stress

As a triggering factor, emotional stress has always been considered by individual clinical observations, but there is little scientific evidence corroborating such data. In a small study of SD patients emotional stress was associated with the triggering or relapse of SD [65]. This study was conducted in two phases. The first phase collected, by a questionnaire, individual data such as psychiatric history, SD characteristics, and identity. Information about SD triggering factors was obtained through an open questionnaire. The patients were then questioned about psychological stress during the week or month preceding the active episode.

A second questionnaire containing the same questions was applied 4 months later. The two questionnaires contained psychopathologic evaluation scales designed to detect symptoms of anxiety and depression (HAD: Hospital Anxiety and Depression scale; Beck; STAI: State-Trait Anxiety Inventory) and determine the perceived stress (PSS: Perceived Stress Scale). SD was linked to stress and anxiety, but not to depression. However, patients with SD on the face were more depressed (Beck scale).

Sun Exposure

In adolescents and adults with chronic SD, there is a worsening during the winter period. However, the effect of solar radiation is still unclear. Although there is some evidence that sun exposure can improve the clinical appearance of SD [66], it has also been reported that some people may develop SD when subjected to phototherapy with psoralen and ultraviolet A radiation (PUVA) [67]. PUVA-induced SD can be prevented by covering the face during irradiation.

More evidence that solar radiation would not have a beneficial effect on SD comes from the fact that there is a high prevalence of SD among mountain guides, who are constantly subjected to sunlight [68].

Medications

Medications, abnormalities in neurotransmitters, physical factors, nutritional disorders, genetic factors, and immunodeficiencies all have possible association with SD [54].

Drugs that might exacerbate or trigger SD include haloperidol, lithium, buspirone, chlorpromazine, auranofin, cimetidine, ethionamide, gold, griseofulvin, interferon-α, methyldopa, phenothiazines, psoralens, stanozolol, and thiothixene [3, 69, 70].

Neurogenic Theory and Parkinson's Disease

A neurogenic theory for the development of SD exists due to its association with parkinsonism and other neurologic disorders, including cerebrovascular accidents, epilepsy, head trauma, facial nerve paralysis, and syringomyelia induced by neuroleptic drugs with extrapyramidal effects [71]. The prevalence of SD in Parkinson's disease patients ranges from 52% to 59% [72]. Parkinson's disease patients, when treated with L-dopa, undergo remission in SD [73]. Although associations with neurologic diseases are well established, they represent a minute proportion of SD cases.

There are three theories regarding the association between SD and Parkinson's disease [74]. The first, one of the most supported theories, states that a depletion of dopamine in Parkinson's disease leads to a decrease in release of endocrine factors, especially the melanocyte-stimulating hormone (MSH), which would increase sebum production and cutaneous manifestations typical of SD. The effects of dopaminergic agents have

been studied in parkinsonian patients, resulting in findings of a reduction in sebum production.

Another hypothesis is that the stiffness and amimia of parkinsonian patients could give rise to an increase in the static pool of secreted sebum and thereby support the growth of *Malassezia* yeasts, with ensuing emergence of SD. Treatment with levodopa would be beneficial for recovering skin mobility and therefore eliminating accumulated sebum in the pilosebaceous canal.

The third hypothesis states that SD would be the cause of Parkinson's disease, and not the opposite. This is the least accepted hypothesis and the one that makes least sense.

AIDS

SD is also one of the most common cutaneous manifestations in patients with HIV, being more serious and prevalent in these patients [13]. SD incidence ranges from 30% to 83% in this group [15]. In these patients a greater body length is affected, especially when CD4 numbers fewer than 400 cells per mm^3 [75]. There may be sudden onset in patients with HIV, a situation that should generate suspicion in the clinician. Remission is usual with antiretroviral therapy [13].

An increased risk of inflammatory dermatoses has been reported in patients positive for both HIV and human T-lymphotropic virus 1, indicating possible importance of this group of infections in the development or worsening of certain dermatologic diseases [76, 77].

There are also sporadic reports and small studies linking other conditions to SD, such as familial amyloidosis and chromosome 21 trisomy [78, 79].

Skin Color

SD is described as rare in persons with black skin [10, 11]. In such cases, HIV infection should be suspected. However, SD was also described as common in black Africans from the West [12]. The data are contradictory, and few studies

evaluate this aspect in a methodologically correct way. Perhaps SD is underdiagnosed because of the fact that in some black patients SD presents itself only as hypochromia in the affected areas of the face. In addition, the SD erythema may be less visible in people with darker skin.

Quality of Life

SD in adults is very prevalent, chronic, and often uncomfortable, causing pruritus, bad aspect, and unpleasant odor, especially in the face and scalp [25]. Improvement in the quality of life of patients is possible if effective treatment of is carried out [80].

Clinical Presentation

SD commonly affects young adults, adolescents, and infants (Table 20.1). In the case of infantile SD, eruption begins in the period between 2 weeks and 6 months of life. It affects up to 70% of infants in the first months of life, but disappears until 12 months [81]. It may start on the scalp or in the diaper area. Later the skin folds, face, and trunk may be affected. The rash com-

Table 20.1 Clinical forms of SD

Infantile	Begins between 2 weeks and 6 months of life
	Affects up to 70% of infants in the first months of life
	Disappears until 12 months
	Usually starts on the scalp or diaper area
	May evolve to skin folds, face, and trunk
	The rash comprises well-defined areas of erythema and scaling
	Usually more intense on the scalp
Adolescents and adults	Mainly the scalp
	Can also affect the forehead, eyebrows, eyelids, nasolabial folds, chin, ears, central chest, and interscapular areas
	More than 50% of the adults are affected by dandruff (PC). Between 3% and 5% of adults are affected by SD that requires a medical consultation

Fig. 20.1 Auricular SD

Fig. 20.2 Glabela, eyebrows and forehead with mild SD

Fig. 20.4 Mild desquamation and erythema in the medial eyebrow

prises well-defined areas of erythema and scaling. It is usually more intense on the scalp. On the skin folds there is often an intense erythema. The scales are rather adherent; they are yellow-brown in color, large and greasy in the scalp, but smaller, whiter, and drier in other areas.

In adolescents and adults, SD affects mainly the scalp but can also affect the forehead, eyebrows, eyelids, nasolabial folds, chin, ears, central chest, and interscapular areas (Figs. 20.1, 20.2, 20.3, 20.4, 20.5, 20.6, 20.7, 20.8, and 20.9). The region most affected by SD is the scalp, with

Fig. 20.5 Nasolabial fold and nose with SD
Fig. 20.6 Postauricular SD- a common affected area

Fig. 20.7 Intraauricular SD

the occurrence of erythema and scaling of vary-ing extent. When there is only peeling, without erythema, PC or dandruff is characterized [1]. Some authors believe that this may be the nonin-flammatory variant of SD [82]. Although there is no visible inflammation, only scaling, the inflam-matory process is present and is demonstrated in the histology. More than 50% of adults are affected by PC or SD, and the socioeconomic impact is very high [9].

SD can cause visible scaling in hair and clothes, oily appearance, and foul odor. All these manifestations may be socially embarrass-ing, especially because they can be judged as poor hygiene [75]. A study of 3000 patients with SD demonstrated, based on the Dermatology Life Quality Index (DLQI), that SD affects the quality of life of its carriers [4]. Pruritus, scaling,

facial erythema, odor, and the absence of a cure were the reasons for this decrease in the quality of life. PC carriers showed significantly better quality of life indices than individuals with SD (5.34 ± 4.67 points compared with 7.73 ± 5.3 points, respectively; $p < 0.001$).

The other areas where SD may occur (also characterized by erythema and scaling) are the nasolabial folds, the glabella, the eyebrows, the retroauricular regions, the external audi-tory canal, the mentum, the anterior chest, and the interscapular region [1]. In an unusual manifestation, it may occur on flexural areas or become widespread over the whole body or part of it [83].

Fig. 20.8 SD in the preauricular area

Fig. 20.9 Scalp SD

Table 20.2 Diagnosis

Clinical	Almost all cases
Dermoscopy	Mainly to differentiate from scalp psoriasis
Histology	Nondiagnostic in SD
	Could be useful to differentiate it from other diseases
	Depends on the clinical stage of the disease
Confocal microscopy	Could be used when there is need for biopsy but the patient does not accept it

(16/20, 80%), hairpin vessels (17/20, 85%), white scales (10/20, 50%), and punctate hemorrhages (12/20, 60%). By contrast, SD was characterized by arborizing vessels (16/20, 80%), atypical red vessels (13/20, 65%), featureless areas (20/20, 100%), and honeycomb pigment (9/20, 45%) [84].

Histology is nondiagnostic in SD, although it may be useful to differentiate it from other diseases. The histopathology of SD depends on the clinical stage of the disease [85]. In the acute and subacute phases, an inflammatory infiltrate composed principally of lymphocytes and histiocytes is found in association with mild to moderate spongiosis and psoriasiform hyperplasia combined with parakeratosis around follicular ostia ("shoulder parakeratosis"). During the chronic phase, in addition to the aforementioned findings, there is marked psoriasiform hyperplasia with dilatation of the capillaries and venules of the superficial plexus, which makes it very similar to psoriasis. In psoriasis vulgaris, the histopathologic findings are similar except for spongiosis.

For the less common cases, when there is need for biopsy but the patient does not accept it, confocal microscopy may be used if available. However, this remains an expensive method with limited availability. Agozzino has used confocal microscopy to differentiate SD from psoriasis on the face. He has found specific and easily recognizable confocal patterning in SD, supporting clinical differentiation with psoriasis [86].

Diagnosis: Dermoscopy, Confocal Microscopy, and Histology

The diagnosis of SD is essentially clinical, although dermoscopy can help in the differentiation of scalp SD and scalp psoriasis (Table 20.2). One study demonstrated that the most significant dermoscopic features of scalp psoriasis included dotted vessels (10/20, 50%), glomerular vessels (13/20, 65%), red loops

Differential Diagnosis

Among possible differential diagnoses are psoriasis, atopic and contact dermatitis, candidiasis, erythrasma, impetigo, rosacea, dermatophytosis, Langerhans cell histiocytosis, Wiskott–Aldrich syndrome, cutaneous lupus erythematosus, dermatomyositis, vitamin B deficiency, zinc deficiency, and drug eruption (Box 20.1). However, the diagnosis is clinical with strong emphasis on history and physical examination of the patient, being simple for the dermatologist [3, 87]. In children, however, SD may be mistaken for tinea capitis [3].

Box 20.1 Differential Diagnosis
Psoriasis
Atopic dermatitis
Contact dermatitis
Candidiasis
Erythrasma
Impetigo
Rosacea
Dermatophytosis
Langerhans cell histiocytosis
Wiskott–Aldrich syndrome
Cutaneous lupus erythematosus
Dermatomyositis
Vitamin B deficiency
Zinc deficiency
Drug eruption
Tinea capitis

Therapeutic Approach

Besides being very prevalent, SD is a chronic disease, and treatments are prolonged or continuous. There are different forms of treatment, including eradication of fungi, reduction or attenuation of the inflammatory process, and decrease of sebum production [3] (Box 20.2).

SD treatment is based mainly on topical antifungals. Among the most extensively studied agents are ketoconazole, bifonazole, and ciclopirox olamine, which are available in creams, gels, foams, and shampoos. Despite its activity against fungi, many of them also have anti-inflammatory activity. For example, certain antifungals (such as ketoconazole, itraconazole, and bifonazole) inhibit 5-lipoxygenase, which then blocks leukotriene B4 synthesis in the skin, causing reduction of inflammation [46]. Since such drugs have this effect, perhaps we cannot attribute the improvement only to the antifungal effect but to a combined effect. However, this weak anti-inflammatory effect alone would not be sufficient.

Propylene glycol (propane-1,2-diol) and other agents found in many topical therapies have potentially beneficial action mechanisms for SD [88]. This may be the explanation for the great improvement found in placebo groups [89].

In 2015 the Cochrane Collaboration conducted a review of studies with topical antifungals in SD [90]. Included were 12 ketoconazole trials ($N = 3253$), 11 ciclopirox trials ($N = 3029$), two lithium trials ($N = 141$), two bifonazole trials ($N = 136$), and one clotrimazole trial ($N = 126$) that compared the effectiveness of these treatments versus placebo or vehicle. Nine ketoconazole trials ($N = 632$) and one miconazole trial ($N = 47$) compared these treatments with steroids. Fourteen studies ($N = 1541$) compared one antifungal with another or compared different doses or schedules of administration of the same agent with one another.

Topical ketoconazole 2% treatment showed a 31% lower risk of failed clearance of rashes compared with placebo (risk ratio (RR) 0.69, 95% confidence interval (CI) 0.59–0.81, eight studies, low-quality evidence) at 4 weeks of follow-up, but the effect on side effects was uncertain because evidence was of very low quality (RR 0.97, 95% CI 0.58–1.64, six studies); heterogeneity between studies was substantial ($I^2 = 74\%$). The median proportion of those who did not have clearance in the placebo groups was 69%.

Ketoconazole treatment resulted in a remission rate similar to that of steroids (RR 1.17, 95% CI 0.95–1.44, six studies, low-quality evidence), but occurrence of side effects was 44% lower in the ketoconazole group than in the steroid group (RR 0.56, 95% CI 0.32–0.96, eight studies, moderate-quality evidence).

Ketoconazole yielded a remission failure rate similar to ciclopirox (RR 1.09, 95% CI 0.95–1.26, three studies, low-quality evidence). Most comparisons between ketoconazole and other antifungals were based on single studies that showed comparability of treatment effects. Ciclopirox 1% led to a lower failed remission rate than placebo at 4 weeks of follow-up (RR 0.79, 95% CI 0.67–0.94, eight studies, moderate-quality evidence) with similar rates of side effects (RR 0.9, 95% CI 0.72–1.11, four studies, moderate-quality evidence). Among other antifungals, clotrimazole and miconazole efficacies were comparable with those of steroids on short-term assessment in single studies. Treatment effects on individual symptoms were less clear and inconsistent, possibly because of difficulties encountered in measuring these symptoms. Evidence was insufficient to conclude that dose or mode of delivery influenced treatment outcome. Only one study reported on treatment compliance. No study assessed quality of life. One study assessed the maximum rash-free period but provided insufficient data for analysis. One small study in patients with HIV compared the effect of lithium versus placebo on SD of the face, but treatment outcomes were similar [91].

Intermittent use of shampoos containing ketoconazole can maintain the disease in remission. In one study, 312 patients with scalp SD (resolved with the use of ketoconazole shampoo 2% twice a week) were subsequently included in a placebo-controlled clinical trial for another 6 months. The relapse rates were 47% for patients using placebo, whereas patients using ketoconazole shampoo once every 2 weeks had relapses in 31% of cases, and only 19% had relapses with the use of ketoconazole shampoo once a week [92].

In the authors' experience, when the antifungal is not effective the most appropriate measure is to combine topical corticosteroids of low or medium potency with topical antifungal initially (instead of using isolated corticosteroid), keeping the antifungal as maintenance. There is a risk of atrophy and hypertrichosis when using topical corticosteroids for a chronic condition [87].

The use of shampoo containing selenium sulfide 2.5% for scalp SD was more effective than placebo but less so than the treatment with 2% ketoconazole shampoo [93]. Topical lithium succinate and gluconate have been more effective alternatives than placebo in SD treatment in areas other than the scalp, but less effective than ketoconazole [87, 91]. Lithium's mechanism of action is poorly understood.

The use of an antibiotic was also effective in SD treatment. Metronidazole gel proved to be as effective as ketoconazole cream in treatment of facial SD. However, this result was found in a small randomized double-blind study [94].

Most over-the-counter antiseborrheic shampoos have zinc pyrithione in its formulation, and are used in concentrations ranging from 1% to 2%. Its pharmacologic action seems to be fungistatic, antimicrobial, keratolytic, and sebum-reducing [46, 95, 96]. Randomized clinical trials have shown that its effectiveness in shampoos was lower than that of ketoconazole [46].

Another recent Cochrane review analyzed the anti-inflammatory treatments for SD of the face and scalp [97]. Thirty-one randomized clinical trials were found that examined topical steroids, seven that examined calcineurin inhibitors, and three that examined lithium salts. Overall, the median rate of achieving total clearance was 53% (13–100%) with anti-inflammatory treatments (topical steroids, calcineurin inhibitors, or lithium salts) across studies, and the median (range) rate of adverse effects was 7% (0–57%). The most commonly reported adverse effects were burning, pruritus, erythema, and dandruff.

In the short term (4 weeks) there were no statistically significant differences between steroid therapy and calcineurin inhibitor therapy in total clearance (relative risk (RR), 1.08; 95% CI, 0.88–1.32). Steroids and calcineurin inhibitors were comparable in all other outcomes as well. Adverse events were less common in the steroid group compared with the calcineurin inhibitors group in the short term (RR, 0.22; 95% CI, 0.05–0.89). Also in the short term, the rates of total clearance were comparable between the topical steroid and azole groups (RR, 1.11; 95% CI, 0.94–1.32), but there was less erythema and scaling associated with steroid use.

In general, mild and strong steroids had comparable therapeutic effects and adverse events, but total clearance took longer in the low-potency group. Treatment with lithium salts resulted in total clearance more often than treatment with azoles (RR, 1.79; 95% CI, 1.10–2.90, 4 weeks) but had similar rates of reported adverse effects.

Only minor differences in treatment effects among anti-inflammatory treatments were found. Strong steroids were more effective than azoles in reducing erythema, scaling, and pruritus, but both treatment modalities were comparable regarding safety profiles. The efficacy of steroids was also comparable to that of calcineurin inhibitors, but with fewer adverse effects. Mild and strong steroid compounds were comparable in achieving total clearance at short-term follow-up. No significant differences between calcineurin inhibitor and azole treatments in effectiveness or adverse effects were found. Lithium salts were more effective than azoles but had a similar frequency of adverse effects. On the basis of this review, there are no clear differences in treatment effects among the assessed treatment options.

Combination treatments with multiple different classes of topical therapies were not included. In general, the level of evidence was low to moderate according to Grading of Recommendations Assessment, Development and Evaluation (GRADE) criteria.

In a 20-week, prospective, multicenter, comparative study conducted at nine centers in Korea, tacrolimus ointment twice a week was used to maintain remission in patients treated with tacrolimus ointment for up to 4 weeks [98]. A total of 27 SD patients (30.0%) experienced adverse events that were assessed by the investigators of this study. Burning sensations, erythema, folliculitis, and pruritus at application sites were common adverse events, some of which overlapped with each other. Among these, six SD patients requested to be withdrawn from the study because of adverse events. Fifty-four patients (65.0%) in the SD group had no disease exacerbation during the 20 weeks of treatment phase. In a previous study [99], a double-blind, vehicle-controlled, multicenter trial using 0.1% tacrolimus ointment in facial SD, all of the ten patients of the placebo group had disease exacerbation in 10 weeks. Eight patients of the placebo group had disease exacerbation at 2 weeks, one patient at 4 weeks, and the other patient at 6 weeks. This study was conducted with a total of 75 patients who had had their SD stabilized with a 2-week course of treatment using 0.1% tacrolimus. After stabilization, randomization was carried out in a double-blind fashion to treatment with 0.1% tacrolimus once a week, 0.1% tacrolimus twice a week, or vehicle twice a week, for 10 weeks (maintenance). Significant improvement in erythema, scaling, and pruritus compared with baseline was maintained during the maintenance phase in both tacrolimus groups, but not in the vehicle group. The mean recurrence rate according to global assessment was significantly higher in the tacrolimus once-weekly group than in the twice-weekly group. This study concluded that twice-weekly treatment with 0.1% tacrolimus ointment had superior effects in keeping facial SD in remission.

This remission maintenance therapy of skin diseases with twice-weekly tacrolimus ointment has already been used in atopic dermatitis and vitiligo with excellent results. Now, in this study, it showed similar outcomes in SD control.

However, in public health we have to take into account that topical tacrolimus is a high-cost medication. Since inexpensive medications such as topical ketoconazole have response rates similar to those of tacrolimus, we should consider primarily using these more cost-effective medications. As for maintaining remission, cheaper medications possibly also work well in most patients, although there are no studies with regard to SD of the face. Therefore we can, primarily, exercise maintenance with cheaper topical medications. There are excellent outcomes in the authors' experience with 2% ketoconazole cream once to seven times per week, according to the need (unpublished data). We usually start after the control of SD, with 2% ketoconazole three nights per week, subsequently increasing or decreasing the frequency according to control and tolerance. If there is no control, we then try the tacrolimus.

As the areas affected by SD are usually thin-skin areas such as the face and skin folds, we must be careful when using topical corticosteroids, even more so for a chronic condition whereby patients, on their own, can maintain the usage for long periods. Another interesting characteristic of tacrolimus for its use in SD is the fact that it has been found to be active against fungal strains, including *Malassezia furfur* and various other *Malassezia* strains that are closely related to the pathophysiology of SD.

A small randomized, placebo-controlled trial assessed oral itraconazole in SD treatment [100]. Sixty-eight patients with moderate to severe SD were randomly assigned to the itraconazole (*n* = 35) or placebo (*n* = 33) groups. Itraconazole 200 mg/daily or placebo was prescribed for 1 week and then for the first 2 days of every month for the following 3 months. Patients were followed for 4 months and the Seborrheic Dermatitis Area Severity Index (SDASI) was measured on nine anatomic sites. Statistically significant improvement was observed in SDASI of both itraconazole and placebo groups (*p* = 0.000), but the itraconazole group showed significantly higher efficacy compared with placebo (*p* = 0.023). Clinical improvements of 93.8%, 87.5%, and 93.1% were observed at the end of 2 weeks, 1 month, and 4 months, respectively, in the itraconazole group, and 82.1%, 64.3%, and 53.6% in the placebo group. Furthermore, the recurrence rate in the itraconazole group was significantly lower than in the placebo group (*p* = 0.003). No blood test abnormality was seen in any patient.

One study compared fluconazole and terbinafine in patients with moderate to severe SD [101]. Sixty-four patients with moderate to severe SD were enrolled in a randomized, parallel-group study. One study group took terbinafine 250 mg daily (*n* = 32) and the other fluconazole 300 mg (*n* = 32) weekly for 4 weeks. Terbinafine showed greater reduction in disease intensity.

Two randomized controlled trials assessed oral terbinafine, 250 mg daily, for 4–6 weeks, demonstrating superiority over the placebo group.

One randomized controlled trial assessed the use of ketoconazole, 200 mg/day, for 4 weeks or an unspecified duration. Significant improvement compared with placebo was seen in scalp scaling, scalp erythema, and SD scores at other sites.

Other open noncomparative trials assessed the systemic use of other antifungal agents, isotretinoin and prednisone, in SD, but the quality of evidence is too low [102].

Abraham et al. reported a case involving the successful treatment of SD with isotretinoin in a 42-year-old man [103]. The patient was previously unresponsive to oral and topical antibiotics/antifungal therapies. Treatment consisted of 20 mg daily of isotretinoin and topical ketoconazole for a period of 1 year. No relapse was noted. Although it is merely a case report, in patients who do not respond to all other possible therapies it may be the only alternative.

The problem of studies conducted with SD patients is that they are short-term. Since SD is a chronic condition, treatment will be long-term, and side effects should be considered in this context. Another concern with the short-term studies is their effectiveness in chronic use. Studies with larger numbers of participants would also be interesting to arrive at a better understanding of their real effectiveness.

Because short-term total clearance was achieved in only half of the patients with currently available agents, there is a need to identify more efficacious treatments or methods for designing innovative regimens that combine existing treatments. In practice, but not in the studies, this large number of patients who do not respond to treatment can be effectively managed with the combination of treatments (authors' experience, unpublished data). A commonly used treatment is the combination of a topical corticosteroid with an antifungal initially, keeping only the antifungal as maintenance. If there is no maintenance with the antifungal, one may use tacrolimus, systemic antifungals, or even oral isotretinoin.

The treatment of infantile SD consists primarily of emollients [104] that help loosen scales (e.g., olive oil, petroleum jelly). Scales can then

be removed by rubbing with a cloth or infant hair brush. One study showed that ketoconazole 1–2% cream is effective and seems to be safe when used twice daily for 2 weeks. There are no shampoos that have been approved by the US Food and Drug Administration for treatment of SD in children younger than 2 years of age. In the authors' experience, when there is significant associated inflammation, there is a need to use topical corticosteroids for a few days, keeping moisturizers and topical antifungals as maintenance when needed.

Box 20.2 Common Treatments for SD
Scalp:
Ketoconazole 2% shampoo daily initially, then twice per week
Selenium sulfide shampoo twice per week
Zinc pyrithione shampoo twice per week
Coal tar shampoo twice per week
Ciclopirox 1% shampoo daily until remission, then twice per week
Betamethasone valerate foam 0.12% twice daily
Clobetasol 0.05% shampoo twice weekly
Fluocinolone 0.01% shampoo daily
Fluocinolone 0.01% solution once or twice daily

Face and body:
Ciclopirox 0.77% gel or cream twice daily for up to 4 weeks
Ketoconazole 2% cream, foam or gel twice daily for 8 weeks, then as needed
Sertaconazole 2% cream twice daily for up to 4 weeks
Pimecrolimus 1% cream twice daily
Tacrolimus 0.1% ointment twice daily
Betamethasone valerate 0.1% cream or lotion once or twice daily
Desonide 0.05% cream, foam, gel, lotion, or ointment once or twice daily
Fluocinolone 0.01% cream, oil, or solution once or twice daily
Hydrocortisone 1% cream or ointment once or twice daily

Glossary

Calcineurin inhibitor Calcineurin (CaN) is a calcium- and calmodulin-dependent serine/threonine protein phosphatase. Calcineurin inhibitors suppress the immune system by preventing interleukin-2 (IL-2) production in T cells.

Chemotaxis A mechanism by which bacteria efficiently and rapidly respond to changes in the chemical composition of their environment, approaching chemically favorable environments and avoiding unfavorable ones.

Human leukocyte antigen (HLA) The major histocompatibility complex (MHC) in humans, controlled by genes located on chromosome 6. It encodes cell surface molecules specialized to present antigenic peptides to the T-cell receptor (TCR) on T cells.

Psoralen The parent compound in a family of natural products known as furocoumarins. Psoralen is a light-sensitive drug that absorbs ultraviolet (long wave, UVA) light and acts like ultraviolet radiation.

Acne Vulgaris

Marina de Almeida Delatti, Renan Lage,
Elisa Moraes, Beatrice Abdalla, Marcel dos Santos,
and Adilson Costa

Key Points

- Acne vulgaris is a chronic inflammatory disease that is multifactorial and immune-mediated and affects the pilosebaceous unit consisting of a sebaceous gland and hair follicle [1, 2].
- Acne vulgaris is probably the most common skin disease, affecting 85–100% of the population at some point in life [2].
- Lesions may progress to scarring and despite not presenting any life threat, has sizable psychosocial effects in the setting of low self-esteem and depression among patients [1–3]
- Treatment should be initiated early and with a prolonged course [4, 5].

Epidemiology

Acne vulgaris is a high-frequency dermatosis affecting more than 40 million people worldwide [1]. It is predominant during adolescence, with an incidence of 79–95%, reaching 100% in both sexes, and is more common in males (70%) than in females (60%). Girls have an earlier onset, with an average age between 11 and 13 years, compared with boys, between 13 and 14 years, with more intense and severe forms [6, 7].

Usually acne vulgaris spontaneously resolves in late adolescence or around 20 years of age. However, currently incidence has increased among adults, mainly females, being 54% in women and 40% in men [6, 8].

It is believed that the degree of acne is directly proportional to the genetic influence, with 88% contribution to the noninflammatory form, and 86–100% for papulopustular and nodule-cystic forms [6, 9]. In patients without skin disease, familial occurrence is 40% [6, 9].

Etiopathogenesis

Acne has a multifactorial etiology that is still not completely understood. It is now believed to be secondary to the interaction of several factors such as follicular hyperkeratinization corroborating the formation of comedones, increased production and quality of sebum, and

colonization of pilosebaceous follicles mainly by *Propionibacterium acnes* and inflammation [3, 4, 10].

Follicular Hyperkeratinization

For a better understanding of the pathogenesis of acne, it is very important to know the pilosebaceous structure [11]. The sebaceous glands are present in all areas of the human body except for the palmoplantar regions [11].

In acne vulgaris, sebaceous follicles are the main affected structure, with primary distribution in the regions of the face, back, and chest [4]. A sebaceous follicle consists of a follicular infundibulum, divided into an acroinfundibulum distally and an infrainfundibulum proximally by the sebaceous gland and sebaceous gland duct that joins the infundibulum [11].

The size and quantity of sebaceous glands are acquired by hereditary means, and their activity increases during adolescence as a result of hormone production [10].

During follicular hyperkeratinization, follicular hyperproliferation of the keratinocytes occurs, with a reduced the scaling rate, increased production of corneocytes, and increased adhesion between them as a result of the increased cohesion of desmosomes [12, 13]. However, the exact mechanism responsible for these changes has not been fully demonstrated [14].

It is believed that hormonal stimuli, proinflammatory cytokines such as interleukin (IL)-1α, follicular deficiency of linoleic acid and integrins [15], and biofilm production by *P. acnes* [16] are responsible for such as changes. Finally, the hyperkeratinization process obstructs the infundibulum with keratin and sebum, in its proximal portion, which leads to the formation of the comedo [10].

Sebaceous Hypersecretion

Sebaceous glands are activated by the action of androgens that originate from the adrenal gland,

ovaries, and testes and are produced by the pilosebaceous unit via dehydroepiandrosterone (DHEA) and androstenedione conversion into testosterone and dihydrotestosterone by the 5α-reductase, 3β-hydroxysteroid dehydrogenase, and 17-hydroxysteroid dehydrogenase enzymes [10, 17].

Sebum hypersecretion can occur as a result of increased sebaceous gland response to hormones through the increase in gonadal and adrenal androgens; or their free portion, as a result of decreased sex hormone binding globulin (SHBG) [4, 10].

Another mechanism responsible for increased sebum production is the stimulation of growth hormones in the liver, which leads to increased production of insulin-like growth factor 1 (IGF-1), responsible for stimulating the production of androgens by the adrenal gland and lipogenesis [18].

In addition to the increased production of sebum there is a change in its composition. It is originally composed of a mixture of lipids such as cholesterol, squalene, fatty acids, steroids, esters, and triglycerides [19]. In the patient with acne there is a decrease in linoleic acid and an increase in squalene, besides the production of palmitic, oleic, sapienic, and lauric acids [19].

Inflammation

There is evidence to show that inflammation is present in all stages of the pathogenesis of acne vulgaris, and the type of inflammatory response corresponds to the clinical state of the patient [20]. The pustule occurs when there is a predominance of neutrophils, whereas in papules, nodules, and cysts there is a prevalence of T-helper lymphocytes, giant cells, and neutrophils [20]. Scars are also an impacted inflammatory response when acne vulgaris is unspecific and early scarring is less evident, but are more intense when specific and with late onset [20].

The changes in sebum composition with decreased linolenic acid causes loss of function of the epidermal barrier and, thus, the release of IL-1α and penetration of proinflammatory fatty

acids and microorganisms in the dermis, besides an increase in lymphocytes and tumor necrosis factor, all of which contribute to the inflammation of acne vulgaris [10].

Colonization of the Pilosebaceous Follicle

There are three major microorganisms found on the skin: *P. acnes*, *Staphylococcus epidermidis*, and *Malassezia* spp. [15]. In acne vulgaris the main bacterium involved is *P. acnes*; to date, there is no evidence of pathogenicity of other microorganisms [10].

P. acnes is a Gram-positive bacillus of facultative anaerobic, diphtheroid type, which is nonspore-forming [16, 21]. It is mainly distributed in areas with higher sebum production, such as the face and upper trunk [3].

The pathogenicity of *P. acnes* is given by the production of proinflammatory mediators, and participation in the formation of comedones and their rupture through lipases [10, 11, 16]. Interaction with the innate immune system still occurs by promotion of an inflammatory response [10, 11, 16].

One of the action mechanisms of *P. acnes* on innate immunity is through toll-like receptors, which are responsible for the recognition of microorganisms by monocytes, macrophages, and polymorphonuclear cells [10, 11]. When activated, they trigger the inflammatory response by producing tumor necrosis factor, interferons, IL-6, -8, -12, and -1β, and chemotactic factors, culminating in the degradation of the bacterial cell array [10].

Antimicrobial peptides (cathelecidins, defensins, and granulysin) are also released secondary to toll-like receptor activation, which functions as epithelium protection, particularly by β-defensin-2, which protects invasion of the pilosebaceous unit by *P. acnes* [10, 11].

Another receptor activated by innate immunity when in contact with *P. acnes* is the nodlike3 receptor that interacts with nuclear factor κB and activates the caspase-1 cascade, releasing proinflammatory cytokines such as IL-1β and IL-18 to intensify the inflammatory process [10].

There is also a humoral immunity response involved in the inflammation of acne vulgaris, namely the production of anti-*P. acnes* antibodies, whose presence is proportional to the severity of the disease [3].

Nowadays it is well known that the main factor responsible for the pathophysiology of acne vulgaris is the presence of *P. acnes* causing activation of the inflammatory response [10].

Other Factors

Diet

The importance of diet in the emergence and worsening of acne is currently much discussed. In the past this association was not considered important. However, the contrast of the presence of acne vulgaris between Western and Eastern societies suggests that diet may be a relevant factor and, consequently, recent studies have shown some associations [2, 22–24].

The increase in the glycemic index in diets causes the increase in basal insulin and IGF-1 values, which contributes to increased production of androgens and leads to overproduction of sebum and follicular hyperkeratinization [24]. The opposite also seems true in patients with hyperinsulinemia, in whom a diet with low glycemic index leads to improvement of lesions [25].

Other foods that seem to be involved in the worsening of acne vulgaris are milk and dairy products because they lead to an increase in IGF-1 besides having precursors of 5α-dihydrotestosterone and growth hormones in their formulas [26].

Regarding essential fatty acids, there is no consensus in the literature; populations with diets rich in fish appear to have less acne compared with the general population, but such data are still under study. It is believed that oral supplementation with essential fatty acids may influence, in a subtle way, the level of fatty acids present in sebum [18, 27, 28].

However, more studies are needed to confirm the true correlation between diet and the presence of acne vulgaris.

Menstrual Period

Two days before the start of the menstrual period, the diameter of the opening of the pilosebaceous follicle decreases, leading to lower flow of sebum to the skin surface and, thus, worsening of acne [2].

Other factors that seem to aggravate the injury are emotional stress, smoking, and use of comedogenic makeup [2, 10], although studies are lacking.

Clinical Presentation and Classification

Acne presents pleomorphic lesions with different clinical conditions from individual to individual, and is divided into noninflammatory and inflammatory lesions [11].

Noninflammatory lesions consist of microcomedones, and closed and open comedones; the microcomedones cannot be viewed and are correlated with severity of the clinical picture. Closed comedones are normochromic to whitened papules about 1 mm in diameter, most commonly viewed by palpation or stretching of the skin [4, 11] (Fig. 21.1). Open comedones are black spots secondary to follicular dilation, being caused by the dark pigment of melanin deposits and lipid oxidation [4, 11].

Inflammatory lesions are made up of papules, pustules, nodules, and cysts [11]. The papules are erythematous lesions of about 5 mm; pustules are similar to papules but with sterile pus at its center [4] (Figs. 21.2 and 21.3). Nodules are erythematous lesions larger than 5 mm that are hardened with dense inflammatory process, which may

Fig. 21.2 Erythematous papules and pustules in the face

Fig. 21.1 Closed comedones in the forehead

Fig. 21.3 Erythematous papules and pustules in the face

indicate greater severity, with deeper cysts consisting of pus and serosanguinous fluid [4, 11] (Fig. 21.4).

Over the years the classification of acne vulgaris has changed and, to date, there is no globally accepted form [4]. The most commonly used classification progresses the forms from levels I to V for noninflammatory and inflammatory acne [4]. The latter is further subdivided into comedonic (noninflammatory), papulopustulous, nodular-cystic, conglobate, and fulminating acne, with gradually worsening severity [4, 6].

Conglobate acne is a severe form with an intense inflammatory process that may lead to drainage of mucopurulent or hematic secretions [4] (Figs. 21.5, 21.6, and 21.7). Fulminating acne occurs predominantly in males, with an abrupt onset and very severe disease, ulcerous-hemorrhagic and necrotic lesions, and is associated with weight loss, fever, prostration, myalgia, and arthralgia, which may impair kidney and liver function as well as bone structure [4, 11].

Diagnosis

> Diagnosis of acne is imminently clinical.

Complementary Examinations

It is rarely necessary for histopathology to confirm the diagnosis. Other additional tests may be required depending on specific acne variants.

Differential Diagnosis

Diagnosis is imminently clinical but owing to polymorphism of the lesions, there may be diagnostic quandaries in some patients. The noninflammatory lesions may resemble milia, keratosis pilaris, flat warts, molluscum contagiosum, and syringomas [2]. The papulopustulous forms must be distinguished from folliculitis, medication-mediated acne, perioral dermatitis, and rosacea [2]. The nodular-cystic form may be confused with facial pyoderma, furunculosis (boils) and abscesses, Sweet's syndrome, tumid lupus, Jessner–Kanoff lymphocytic infiltrate, and insect bites [2].

Treatment

Treatment should start as early as possible to minimize scars and psychological complications of the disease, which are closely related to the clinical form presented by the patient [29].

Aims include to correct the follicular hyperkeratinization, decrease sebaceous hypersecretion, and reduce the population of *P. acnes* and the inflammatory process [4].

Topical Treatment

Retinoids

Retinoids act on follicular hyperkeratinization and possess anti-inflammatory effects, reducing the formation of microcomedones and potentiating the penetration of other drugs. By acting in both follicular keratinization and inflammatory process, they are considered the first-line treatment for all forms of acne [3, 4].

They may have some side effects including local irritation, erythema, dryness, and flaking [11]. Available agents include tretinoin, adapalene, tazarotene, and isotretinoin [11]. In general they are not indicated in pregnant women [11].

Among retinoids, adapalene has lighter comedonic properties than tretinoin and therefore is better tolerated by patients [11]. Generally application at night is recommended, starting with low concentrations that are gradually increased [11]. Sometimes its use is recommended on alternate nights for patients with irritative skin conditions [11].

Bactericidal and Bacteriostatic Agents

These agents were introduced to the therapeutic arsenal of acne vulgaris for the control of the *P. acnes* population, and include erythromycin, clindamycin, benzoyl peroxide, and azelaic acid.

Benzoyl peroxide is an antibacterial agent that reduces the population of bacteria by oxidative mechanisms, reduces the formation of comedones, and has an anti-inflammatory action [4, 5]. Its advantage is that it does not induce bacterial resistance and is inexpensive [30]. Adverse effects are similar to those of retinoids and may also lead to whitened clothes and hair [30].

Erythromycin and clindamycin are bacteriostatic agents with anti-inflammatory action and should be used for a 6- to 8-week period, but have discrete adverse effects [4]. Benzoyl peroxide is recommended to be used concomitantly with these agents or alone, in pulses of 5–7 days, to reduce bacterial resistance [29].

Azelaic acid has bactericidal action and thus reduces the inflammatory acne, besides presenting comedolytic and whitening activity, and is safe during pregnancy and breastfeeding [5].

In inflammatory forms a bactericidal/bacteriostatic agent should be added to therapy to increase the effectiveness of the treatment, and antibiotics must be interrupted when inflammatory lesions begin to convalesce [29]. If not possible, replacement of antibiotics by benzoyl peroxide should be considered [29].

According to current knowledge the best form of treatment for acne vulgaris lies in combination therapy, with a combination of a retinoid and a bactericidal/bacteriostatic agent of choice being used for nearly all clinical forms [29]. Such combined treatment achieves faster and more complete results compared with monotherapy [29].

Salicylic Acid

Salicylic acid is used in the treatment of mild inflammatory and comedonic acne. Adverse effects include scaling and erythema [11].

Systemic Treatment

Antibiotics

Antibiotics are commonly given for cases of moderate to severe acne that does not show significant improvement with topical treatment [29, 31], The action mechanism aims to decrease the population of *P. acnes*, thus reducing the formation of inflammatory substances of bacterial origin and decreasing neutrophil chemotaxis, cytokine production, and macrophage activity [4, 11].

The first line of treatment includes tetracycline 500 mg 12/12 h, doxycycline 50–100 mg 12/12 h, lymecycline 150–300 mg 1×/day, minocycline 50–100 mg 1×/day [5]. Second-line treatment includes erythromycin 500 mg 12/12 h, trimethoprim 300 mg 12/12 h, and trimethoprim-sulfamethoxazole 800/160 mg 12/12 h [5].

Currently there is great concern about bacterial resistance, and it is believed that resistance can include nontargeted bacteria [29]. Bacterial resistance appears to be more common in patients with moderate to severe acne [29]. Therefore, the use of antibiotics must be judicious and limited; if the patient does not show good response to treatment, this should be stopped and if there is good response, a maximum of 8–12 weeks of treatment is recommended [29, 32]. In addition, antibiotics should not be used in monotherapy and combination with topical medicine is necessary, except for the topical antibiotics [29, 32].

In general, antibiotics are well tolerated by patients and the most common side effect is gastrointestinal intolerance [4, 5]. Tetracyclines are contraindicated during pregnancy, lactation, and infancy because it interferes in the axial growth of the fetus and changes the color of enamel [5]. Minocycline can cause photosensitivity reactions, skin and mucous hyperpigmentation, and drug-induced lupus [5]. Doxycycline can cause hypersensitivity reactions and lymecycline can cause Stevens–Johnson syndrome [4].

Hormonal

Hormones are considered second-line therapy for female patients with acne, especially adult women [11]. Oral contraceptives as well as spironolactone are intended to block the production of androgens in the adrenal and ovarian glands and thus reduces sebum production [11]. Spironolactone can be used at a dosage of 100–200 mg a day for a period of 2–24 months [5].

Hormonal therapy details are addressed in "Variants of Acne" with regard to acne in the older woman.

Oral Retinoids

Isotretinoin (13-*cis*-retinoic acid) was introduced to acne treatment in 1976 in Europe and in the 1980s in the United States [5]. It is considered quite effective and is indicated for persistent cases of severe acne, nodular acne, and acne conglobata at risk of permanent scarring and resistant to prior therapies [33].

It features actions in all pathologic mechanisms of acne vulgaris, reducing the volume and secretion of the sebaceous glands; normalizing follicular hyperkeratinization, thereby reducing the production of microcomedones; and reducing *P. acnes* growth. It also has anti-inflammatory activity [4, 5, 11].

The recommended dosage varies from 0.5 to 2 mg/kg per day, with a total cumulative dose of 120–150 mg/kg; duration can vary from 6 to 8 months [4, 11]. For cases of severe inflammatory acne it is recommended to lower the initial dose in order to avoid exacerbation of lesions for the first month [4, 5, 11].

The drug is contraindicated in patients with hypervitaminosis A, uncontrolled dyslipidemia,

hepatic failure, and during pregnancy and lactation [33]. It should be used with caution in cases of renal insufficiency or diabetes [33].

Among the adverse effects are dry skin and mucous membranes, facial erythema, eczema, photosensitivity, hair loss, myalgia, arthralgia, photophobia, worse night vision, nausea, colitis, pancreatitis, abnormal liver function, hyperlipidemia, worsening acne condition ("flare-up"), mood swings, and pseudotumor cerebri syndrome when associated with the use of tetracyclines [5, 33]. It is very important that the clinician explains to the female patient the risk of teratogenicity of the drug, excludes the possibility of pregnancy prior to use, follows up with monthly β-HCG tests, and indicates the need for contraceptive use during treatment and 1 month after its completion [33].

After treatment, recurrence can take place in about 20% of cases, particularly in male patients with early onset, severe acne, and family history [34]. New cycles of isotretinoin may be needed, although some patients respond to conventional therapy [34].

For long-term success of treatment, maintenance therapy is indicated, which is beneficial to patients when maintained for a long period, but there is no consensus in the literature regarding the appropriate time frame [29]. The main therapeutic indication is avoidance of topical retinoids and topical antibiotics because of the risk of bacterial resistance [29].

New Therapeutic Strategies

Lasers are currently receiving some attention for their use in inflammatory acne, when used in conjunction with conventional therapy or for those patients not tolerating such therapy [29]. The aim of this therapy is to reduce the population of *P. acnes* and sebaceous gland function [29]. Despite being a promising therapeutic option, more studies on laser therapy are necessary; at present there is insufficient information to recommend such therapy [29].

Complications

The most common complication in patients with acne is scarring, which can result in both mild and severe forms [29]. It is therefore not possible to predict which patients will progress to scarring [29].

Lesions may be epidermal with erythema and changes in skin pigmentation, or dermal with atrophic, hypertrophic, or keloid scars. Multiple treatment techniques are available nowadays, the combination of which may be required for best results. Some examples are dermabrasion, chemical peels, laser therapy, and surgical techniques [29].

Variants of Acne

Fulminant Acne

A severe form of acne, fulminant acne is a rare condition, more common in male adolescents [35, 36]. It occurs in patients with mild or moderate acne who are resistant to conventional therapy [37, 38]. It is an acute condition of systemic involvement and may include fever, myalgia, polyarthralgia, asthenia, hepatosplenomegaly, weight loss, lytic bone changes, neutrophilic leukocytosis, and altered laboratory inflammatory markers [35, 37]. The lesions are inflammatory, painful, and ulcer-hemorrhagic, being more frequently found on the chest and face [35, 39].

It presents unknown etiology, probably influenced by genetic, infectious, and immunologic factors related to the development of reaction type III and/or IV to *P. acnes* [35, 58]. Isotretinoin is a possible disease precipitant, since it leads to the fragile epithelium of the pilosebaceous duct and allows contact of *P. acnes* with the immune system [40].

It has no response to conventional acne treatment, and the use of oral antibiotics is ineffective in the absence of secondary infection [35]. Hospitalization may be required [40]. The treatment is typically oral prednisolone, 0.5–1 mg/kg/

day for 4–6 weeks, isotretinoin being introduced from the fourth week of corticosteroid therapy [35, 37]. Other options are dapsone, 50 mg/day, or infliximab [40].

Acne in Adult Women

Acne in adult women (AAW) is defined as the presence of acne in women older than 25 years [41]. Its prevalence is steadily increasing, although it is unclear whether this increase is a true one or whether it is due to greater access to information about the disease and treatment, which leads to increased demand for specialized care [42].

Classification and Clinical Presentation

Patients with AAW can be divided into two groups [8]:

- Persistent acne: most common clinical form, beginning in early adolescence and continuing into adulthood [8].
- Late-onset acne: Begins after 25 years of age and involves two subgroups: acne on the chin, with lesions mainly around the perioral region with emergence and worsening during premenstrual period, and sporadic acne, of sudden onset and usually without any apparent cause [8].

The clinical presentation shows a predominance of inflammatory lesions with the presence of papules and pustules, in most cases showing a light to moderate presentation of the disease and refractory to treatment [41, 43] (Figs. 21.8 and 21.9). Lesions are located generally in the lower third of the face and "U" zone of the neck [41].

Fig. 21.8 Erythematous papules on the face

Fig. 21.9 Erythematous papules on the face

Affected women show sensitive skin with postin-flammatory erythema and hypo- or hyperpig-mented scars [43, 44]. The involvement and cosmetic changes on the face have made AAW a disease of great psychological and social impact, strongly compromising patients' quality of life [8, 41].

Pathophysiology

AAW is a multifactorial and incompletely under-stood disease, influenced by several external fac-tors: smoking; obesity; emotional stress; endocrinologic abnormalities such as polycystic ovary syndrome (PCOS) and insulin resistance; drugs (benzodiazepines, lithium, cyclosporine, corticosteroids, progestins and oral contracep-tives, isoniazid, ramipril, and vitamin B com-plex); food with high glycemic load and dietary supplements rich in amino acids; exposure to UV radiation; and use of occlusive cosmetics [41, 43, 45].

To understand the pathophysiology of AAW, one should take into account that the production androgen derived from cholesterol occurs in gonads, adrenal glands, and peripheral tissues, including the skin, which is the area of greater production of androgenic substances [44, 46]. DHEA sulfate (DHEA-S) produced in the adrenal gland is converted to testosterone, which in turn is converted to dihydrotestosterone (DHT) [46]. DHT is a more potent androgen whose production occurs in the sebaceous glands in the presence of the 5α-reductase 1 enzyme [46].

When there is an association with hyperan-drogenism, the most frequent causes are PCOS and adrenal hyperplasia of delayed onset and, in addition to acne, there may be the presence of hirsutism, alopecia, changes in voice, menstrual irregularities, and infertility [42, 47]. Facing sus-picion, there should a serum dosage during the follicular phase of the menstrual cycle of free and total testosterone, DHEA-S, luteinizing hormone (LH), and follicle-stimulating hormone (FSH) in addition to transvaginal ovary ultrasonography [47, 48].

However, the changes seen in patients with AAW resulting from hyperandrogenism occur without the presence of associated endocrine disease, laboratory abnormalities, or menstrual irregularity [42].

The principal factor involved in AAW is increased activity of the sebaceous glands whereby circulating androgens at normal levels act in an exaggerated form in the sebaceous glands by increasing 5α-reductase enzyme activ-ity, associated with hypersensitive hormone receptors in sebocytes and keratinocytes [8].

Peripheral hormonal conversion is also increased, producing the most potent andro-genic hormones such as testosterone and DHT [43, 48].

In addition, peripheral insulin resistance and hyperinsulinemia cause increased IGF-1, which stimulates the production of ovarian androgens and influences the availability of active circulat-ing hormones, therefore reducing the hepatic pro-duction of SHBG and, thus, providing a greater amount of free androgens [49].

Finally, there is an association with a genetic factor attributed to the presence of familial cases in more than 50% of AAW cases [50]. Genetically determined changes occur in molecules involved in innate immunity by inducing reduction of *P. acnes* resistance and chronic inflammation of sebaceous glands [43, 50, 51].

Treatment

AAW follows the general lines of treatment of acne vulgaris [41].

For mild cases, topical agents are used long term, prioritizing simple-to-use agents with good tolerance to obtain adherence of the patient [41, 52].

Topical Treatment

- Topical retinoids: keratolytic action is the best option for maintenance, and adapalene is mostly used and well tolerated [8, 52].
- Benzoyl peroxide: bactericidal, anti-inflammatory, and keratolytic action, often used in combination with other topi-cals [53].
- Azelaic acid: hyperkeratinization normalizes and reduces the proliferation of *P. acnes*, reducing inflammation. Not considered first-line treatment [54].

Systemic Treatment

For more inflammatory, extensive forms and resistance to topical agents, systemic treatment is advised [52].

- Oral antibiotics: preference for cyclin derivatives (tetracyclines, doxycycline, lymecycline), trimethoprim, and macrolides; however, they should not be used for prolonged periods or combined with the use of topical antibiotics, to prevent the induction of bacterial resistance [41, 52].
- Isotretinoin: suitable for severe and resistant forms, can be used in low daily doses to avoid skin irritation in sensitive women [55]. Fails and relapses in 30% of cases [55].

Hormonal Treatment

As an additional option to clinical forms that are unresponsive topical treatment and/or antibiotics, hormonal treatment through the use of oral contraceptives is a viable option, as AAW is an androgen-dependent disease [56]. It is an effective therapy that reduces greasiness of the skin and the number of lesions [57].

- Spironolactone: antiandrogen aldosterone antagonist that has an inhibitory effect on the 5α-reductase 1 enzyme [44, 58]. It can be used individually or in combination with the oral contraceptive form, with optimal clinical response [8, 58].
- Estrogen (ethinylestradiol): directly inhibits sebum production, blocks the hypothalamic-pituitary axis by negative feedback which prevents the production of androgens by the ovaries, and enhances the hepatic synthesis of SHBG, which reduces the free form of active androgens [48, 59].
- Progestins (cyproterone, drospirenone): selective for progestagenic receptors and have antiandrogenic and antimineralocorticoid activity [57]. Ideally used with ethinylestradiol or as an oral contraceptive combined with spironolactone [8].

Side effects of antiandrogens are weight gain, headache, stomach disorders, depression, decreased libido, edema, irritability, melasma, uterine bleeding, and liver abnormalities [60]. Contraindications to its use are the presence of cardiovascular disease, thromboembolic events, pregnancy, genital bleeding, and liver disorders [60].

- Flutamide, an antiandrogen used in the treatment of prostate cancer, and finasteride, an inhibitor of 5α-reductase inhibitors, are not used in the treatment of AAW [57].

For cases with the presence of insulin resistance metformin can be prescribed to sensitize tissues to insulin action, thereby controlling the action of IGF-1 [61].

Pediatric Acne

Neonatal Acne

Acne which may occur at birth or within the first 4 weeks of life is known as neonatal acne [62, 63]. It usually affects boys, and there is a predominance of closed comedones on the forehead, nose, and cheeks, and, less commonly, inflammatory lesions [64] (Fig. 21.10).

Its etiology is linked to increased sebum excretion, because the sebaceous glands are increased in size at birth because of the increased production of DHEA by adrenal glands during this period, in addition to having the extra stimu-

Fig. 21.10 Closed comedones on the cheeks of an infant

lation of these glands by maternal androgens at this stage of life [62–64]. In boys, testicular androgens provide additional stimulus to the sebaceous gland, which explains the higher incidence in males [62, 65]. Another factor contributing to the framework is the colonization of the sebaceous glands by *Malassezia* spp., causing a local inflammatory response [66].

The differential diagnosis of neonatal acne should include virilization disease, congenital infections, maternal use of medications during pregnancy, such as lithium and hydantoin, and use of topical oils and ointments [67].

Most often no treatment is necessary, since it is a mild and limited condition, with spontaneous resolution in 1–3 months [64]. When necessary, topical tretinoin and azelaic acid can be used for mild cases, and a solution of erythromycin and benzoyl peroxide gel for inflammatory forms [63, 66, 68].

Acne in Infants

Acne in infants affects predominantly male children, and may start at 3–6 months of age or later [64]. Its presence increases the risk of developing acne vulgaris, particularly severe forms, in adolescence [6]. It affects the face, most often on the cheeks, presents more pleomorphic and inflammatory lesions than neonatal acne, and also can present papules, pustules, nodules, and cysts [67].

Its causes are due to hyperandrogenism by increased production of androgens in the fetal adrenal glands and testicles, in addition to having the child's skin colonized by *Malassezia* spp. [62].

The differential diagnosis of infantile acne should include diseases that cause virilization, chloracne, and acne induced by the use of creams, lotions, and oils [67].

Most cases resolve spontaneously or with treatment while others remain active until adolescence [62, 67]. The treatment follows the same guidelines of acne vulgaris, using retinoids or topical benzoyl peroxide [66, 68, 69]. When use of oral antibiotics is necessary, erythromycin is the first choice [67]. Tetracyclines are contraindicated until 8 years of age in view of the risk of causing dental changes [66].

Occupational Acne

Elaioconiosis

Elaioconiosis is an acneiform eruption caused by occupational exposure to cutting oils (metal workers) and greases (mechanical) that lead to obstruction of the follicular ostia [70]. Clinically, lesions in the upper limbs are observed, with the presence of comedonic forms with black points in follicular ostia, along with papules and pustules that may be associated with itching and pain [71].

Treatment is slow and the patient should take time off work [71]. The use of a loofah while showering and keratolytics are recommended [71]. Topical or systemic retinoids can be used [71]. The clinical presentation should be prevented with the use of silicone creams, frequent handwashing, appropriate working clothes, and use of personal protective equipment [72].

Chloracne

Chloracne is a severe form of occupational acne caused by environmental contamination or industrial use of chlorinated hydrocarbons included in pesticides and oil products [70, 73]. It begins with redness and swelling on the face, posteriorly presenting noninflammatory comedones, cysts, and scarring on the face and neck [74, 75]. As this disease is caused by intoxication, systemic manifestations can occur, such as fatigue, anorexia, arthritis, neuropathy, and liver disease, among others [75, 76].

After exposure, symptoms begin in 2–4 weeks, but full recovery takes around 2–3 years, as the causative agents are lipophilic and have slow body clearance [74]. Chloracne is resistant to treatments commonly used in acne vulgaris [74]. Exposure to toxic agents should be prevented and if it occurs, the worker should be removed from the site and elimination of the substance should be attempted [74]. The use of Olestra (synthetic substitute of dietary fat) accelerates the fecal elimination of hydrocarbons by up to 30-fold [77].

Acneiform Eruptions

Follicular lesions similar to acne caused by substances in contact with skin or systemic agents

are known as acneiform eruptions [78], which present an inflammatory initial lesion with the emergence of erythematous papules, but can still present pustules and nodules mostly on the face, trunk, proximal limbs, and buttocks [79].

Unlike acne there is no follicular hyperkeratinization, but inflammatory pilosebaceous follicles are noticed [78]. It is of sudden onset and can occur at any age; lesions have a monomorphic aspect and are disseminated, with acute or subacute evolution; Besides the absence of comedones, lesions may be accompanied by systemic signs of toxicity which improves after removal of the cause [45, 79, 80].

Agents responsible for the disease: systemic and topical medications; cosmetics made with fatty vehicles (leading cause in women); halogenated chemicals (chloracne); excessive hygiene with products based on fatty acids or hexachlorophene; friction caused by exfoliating cosmetics, banners, hats, and caps; heat, excessive sun exposure, and use of greasy sunscreens; occupational agents such as oils or greases (elaioconiosis) [81, 82].

The differential diagnosis of acneiform rash should include acne vulgaris, rosacea, and folliculitis [79, 80]. For successful treatment it is necessary to remove the causative agent and use topics such as benzoyl peroxide and retinoids combined or not with antibiotics; the use of systemic medications such as isotretinoin and antibiotics at low doses may be required [45, 82].

Drug-Induced Acne

Acneiform eruption most often occurs as an iatrogenic side effect of systemic or topical medications [78]. Some drugs are excreted by the sebaceous glands with follicular high concentration, and can be cytotoxic and cause an inflammatory reaction [79].

Causative agents are: corticosteroids; B vitamins; hormones (contraceptives, androgens, gestrinone, corticotropin, and thyroid drugs); antiarrhythmics; anticonvulsants (hydantoin); drugs with lithium base; halogens (iodine, bromine, fluorine, and chlorine); phenothiazines and diazepam; quinine; tuberculosis drugs (isoniazid, rifampicin, ethionamide); antibiotics (tetracycline and streptomycin); cyclosporin; azathioprine; biological chemotherapeutics of the type antireceptor monoclonal antibodies of the epidermal growth factor receptor used in the treatment of various cancers (cetuximab, erlotinib, gefitinib); sirolimus (immunosuppressant used in transplants) [78, 80, 81].

Along with erythematous papules of follicular location, punctate vesicles in the center of the papules may be present [81]. Itching is a common symptom [82]. The treatment is the same as for any other acneiform rash and is based on the removal of the causative agent [80]. Antihistamines can be used in cases with accompanying pruritus [81].

Glossary

Comedo A hair follicle infundibulum that is dilated and plugged by keratin and lipids. The lesion is referred to as an open comedo when the pilosebaceous unit is open to the surface of the skin with a visible keratinaceous plug. A closed comedo occurs when the follicular opening is unapparent and accumulates whitish keratin.

Cyst An encapsulated cavity or sac lined with a true epithelium that contains fluid or semisolid material (cells and cell products such as keratin).

Nodule A solid round or ellipsoidal, palpable lesion of diameter larger than 0.5 cm. Depth of involvement and/or substantive palpability, rather than diameter, differentiates a nodule from a large papule or plaque. Nodules are of five main types: epidermal, epidermal-dermal, dermal, dermal-subdermal, and subcutaneous.

Papule A solid, elevated lesion less than 0.5 cm in size in which a significant portion projects above the plane of the surrounding skin.

Pustule A circumscribed, raised cavity in the epidermis or infundibulum containing pus; may contain bacteria or be sterile. Pustules may vary in size and, in certain situations, may coalesce to form lakes of pus.

Rosacea

22

Renan Rangel Bonamigo, Wagner Bertolini, and Sérgio Ivan Torres Dornelles

Key Points Summary
- Rosacea is a frequent chronic dermatosis and may heavily affect the quality of life
- Dermatosis is prevalent on the face and often starts mainly in the intermediate age range
- Rosacea pathogenesis is complex: neurovascular, inflammatory, and dermal deconstruction, with many immunologic mediators
- Clinical subtypes of rosacea are erythematous telangiectatic, papulopustular, phymatous, granulomatous, and ocular.

- Treatment aims at control of symptoms, with a focus on nonexposure to triggering factors, and the use of topical and systemic drugs as well as different laser types

Epidemiology

Despite the large amount of published material, few epidemiologic studies of rosacea have been carried out to date. Most of these studies use different methodologies, populations, and disease definitions. Therefore there is, for example, variation with regard to the prevalence of the disease (between 0.09% and 22%), although the general prevalence is estimated at 10% [1–12]. Most of these studies did not classify rosacea according to its subtypes; the few that did showed a prevalence estimate of around 72–82% for subtype 1 (erythematous telangiectatic rosacea), 18–28% for subtype 2 (papulopustular rosacea), and approximately 1% for subtype 3 (phymatous rosacea), affecting men more than women [6, 10, 13]. Subtype 4, ocular rosacea, can be seen in up to 30% of patients with the other subtypes [14]. An English research study estimated a rosacea incidence of 1.65 per 1,000 persons per year [15].

With regard to distribution by gender, most of the studies indicate equity or a slight female

prevalence [3, 4, 6, 10, 13, 15]. The disease affects mainly Caucasians [16, 17] and adults older than 30 years; it is rare in adolescents and children [5, 15, 18, 19].

Significant predisposition factors for rosacea are ultraviolet (UV) radiation exposure and a large amount of *Demodex folliculorum*, a commensal mite of the pilosebaceous follicle. Other investigated factors include the *Helicobacter pylori* and *Staphylococcus epidermidis* bacteria, although research studies have delivered opposing results [1, 20–23].

A positive family history seems to be a significant risk factor for rosacea [1]. A cohort study with twin brothers was recently published, showing a 50% influence of genetic factors and a 50% influence of environmental factors on rosacea. The study showed a powerful correlation between the scoring levels of the National Rosacea Society (NRS) and age, exposition to UV radiation and fair skin (Fitzpatrick I, II, and III classification); it also showed positive associations between rosacea and body mass index, skin cancer, and cardiovascular disease [24].

Some research studies showed a connection between rosacea and other diseases, such as migraine, depression, and autoimmune diseases [6, 25, 26]. Ingestion of hot beverages or alcoholic drinks, physical exercise, and heat exposure seem to exacerbate rosacea via skin blood vessels [1, 15, 17, 26–28]. An English research study showed a greater risk for rosacea development in nonsmoking persons than in smokers, and a slightly higher risk in former smokers [15].

Most of epidemiologic studies of rosacea conducted to date used adult populations only (working population), predominantly of Caucasian origin; no population-based studies are available using heterogeneous populations.

Etiopathogenesis

Rosacea is a chronic skin disease that affects almost exclusively the central facial region [29, 30]. The exact etiopathogenesis of rosacea remains unknown, although much progress can be acknowledged alongside the appearance of many theories. The main ones are described herein.

Transcriptome Analysis

Epidemiologic data comparing disease and skin phenotype prevalences in different regions suggest that rosacea has a genetic component [1, 31]. A recent analysis of the transcriptome profile of rosacea patients verified the existence of different gene profiles for each disease subtype, although some genes overlap [31–33].

Deregulation of the Innate Immune System

Under normal physiologic conditions the activation of the innate immune system leads to a controlled increase of skin antimicrobial cytokines and peptides. This form of regulation seems to be impaired in rosacea patients [34].

Cathelicidin is the main adenosine monophosphate involved in rosacea; on the skin surface it is subjected to cleavage by the kallikrein-5 serum protease (KLK5) in the LL-37 active peptide (Yamasaki and colleagues 2007). Besides the increased cathelicidin and KLK5 expression, the LL-37 is processed into smaller fragments in rosacea patients [35]. The LL-37 and those fragments function to activate and control immune reactions by increasing the release of cytokines and chemokines by local cells, leukocytes, mastocytes, and keratinocytes [36]; they regulate the expression of the extracellular matrix components and increase endothelial cell proliferation, which may induce a functionally important angiogenesis [37]. Injection of such peptide fragments into the skin of mice led to a "rosacea type" dermatitis, thus lending more support to the theory favoring the pathogenic role of cathelicidins on rosacea [35].

Up to now the least understood part of the pathogenesis is how and which mechanisms lead to the increased cathelicidin and KLK5 in rosacea patients. One of the main responsible elements

would be the high level of the toll-like 2 receptor (TLR2) on the skin, a molecular sensor that triggers immune reactions when activated, such as increased expression level and KLK5 activity level, thus increasing LL-37 and fragment expression [35, 38].

The main TLR2 activators may be *D. folliculorum*-released chitin, a saprophytic mite found in the skin pilous follicle (denser in rosacea patients), and *Bacillus oleronius* Li, a Gram-negative bacterium found in *D. folliculorum* [40, 41].

The metalloproteinases (MMPs) are the other group of molecules that activate KLK5. KLK5 would be released as a pre-proenzime which becomes active after undergoing cleavage by MMP-9. The expression of many MMPs, including MMP-2 and MMP-9, is increased on the skin of rosacea patients [42]. Bonamigo and colleagues found a linear correlation between the presence of *D. folliculorum* and the degree of positivity for MMP-9 expression in rosacea patients' fibroblasts, something not found for MMP-2, and they concluded that MMP-9 may be an explanatory link between the presence of *D. folliculorum* and the clinical expression of some rosacea cases [43].

Muto and colleagues suggested a role of mastocytes in the rosacea inflammatory process induced by cathelicidins [44]. The mastocytes possibly secrete LL-37 and MMP-9 and activate the release of inflammatory cytokines [45].

The LL-37 cathelicidin expression in human keratinocytes is heavily induced by activation of vitamin D. UV light exposure triggers activation of vitamin D in the keratinocytes and the subsequent expression of cathelicidin, which has been mooted to account for the preferred facial topography of rosacea [46]. In a recent research study, Ekiz and colleagues found relatively increased levels of vitamin D in rosacea patients compared with the control group, but larger epidemiologic studies are necessary to verify this finding [47].

Microorganisms

Microorganisms seem to play a significant role, albeit not well understood, in the etiopathogenesis of rosacea. *D. folliculorum*, a mite belonging to the skin microbiota, has been the most widely investigated microorganism [48]. The significance of this parasite is still controversial because they are often found in people without clinical manifestations, and their prevalence may reach 100% in the elderly [49]. However, some research studies identified a prevalence increase in rosacea patients [50]. A meta-analysis showed that mite density and rosacea had a statistically significant association [39].

Nowadays the most relevant hypothesis suggests that the innate immune system favors mite hyperproliferation. The causal relationship of *Demodex* mites with skin lesions as being triggered through many mechanisms is suspected: mites mechanically block follicles, thus leading to their distension or rupture and the triggering of local inflammation [48, 51]; the presence of the chitinous exoskeleton this would act as a foreign body, thus playing a role in granulome formation. Mite-produced residue and/or bacterium-associated residue may activate elements of the innate immune system or stimulate the system through a delayed hypersensitivity reaction mechanism [52]. One of the most acceptable hypotheses is that mite chitin activates TLR2 keratinocytes and then activates KLK5 [34, 53].

Another hypothesis regarding *Demodex* mites in rosacea induction supposes that mites are vectors for other microorganisms that cause and exacerbate skin lesions [54]. Such bacterial endosymbioses could play a significant role in rosacea pathogenesis, which would explain the antibiotic effect on the patients [51]. Lacey and colleagues isolated the *B. oleronius* from *D. folliculorum* and determined the reaction of antigens to rosacea patients' serum but not to those in the control group (healthy subjects). They also identified thermal shock proteins and a lipoprotein in *B. oleronius* antigenic molecules known as TLR2-stimulating agents. According to the hypothesis, mites piling up in the follicles cause follicle distension and damage, thus leading to diffusion of bacterial agents through the follicle walls, resulting in an immunologic reaction [41]. Healthy patients who had their neutrophils exposed to *B. oleronius* showed an increase in the production of

MMP-9, cathelicidin, tumor necrosis factor, and interleukin-8, most of them rosacea inflammatory mediators [55]. Murillo and colleagues, on the other hand, analyzed *Demodex* microbiota through a real-time polymerase chain reaction system and did not identify *B. oleronius*, only a few *Bacillus* spp. [56].

In Australia, Whitfield and colleagues isolated pure colonies of *S. epidermidis* in pustules of 9 out of 15 patients with papulopustular rosacea, whereas they were not isolated in the same patients' adjacent skin with no lesion. Bertolini and colleagues, however, conducted a similar research study in Brazil with 22 patients when such bacteria were not found [20].

Another investigated microorganism in rosacea is the gastric bacterium *H. pylori*, although most of the studies showed contradictory results [57]. A research study by Bonamigo and colleagues concluded that *H. pylori* is a possible risk factor for rosacea in certain groups of individuals, but the previous use of antibiotics to treat rosacea must be regarded as a risk factor for interference in studies on that association, since these drugs are also useful for treating *H. pylori* infection.

Ultraviolet Radiation

The presence of actinic elastosis in rosacea suggests a role of UV radiation in the disease pathogenesis [58]. Despite being postulated as a possible photoinduced dermatosis [59], a recent study that examined exposure time to UV and rosacea prevalence failed in verifying the correlation [5].

UVA light in particular causes MMP overexpression and collagen denaturation, both of which are direct or indirect participants in clinical manifestations of rosacea. UVB light increases the production and secretion of fibroblast growth factor 2 and vascular endothelial growth factor 2 (VEGF2), both playing a role in the skin hypervascularity of rosacea [34].

In addition, significantly high levels of reactive oxygen species (ROS) produced mainly in the skin after UV radiation were noticed in skin samples of rosacea patients [60]. The ROS may account for the initiation of many proinflammatory effects including the expression of cysteine-cysteine 2 (CCL2) and cysteine-X-cysteine 8 (CXCL8) chemokines, thus attracting leukocytes [61], and the activation of the TLR2 receptors, therefore making it easier for the KLK5-cathelicidin inflammatory cascade to spread out [62].

Although acute UV exposure is an indisputable triggering factor for rosacea, it remains unclear as to how much the chronic photodamage plays a part in the disease physiopathology, mainly because photodamage is not a characteristic sign in patients with early rosacea. The dermal architectonic deconstruction possibly plays the main role in chronic UV exposure for rosacea development [45, 63, 64].

Neuroimmune Interactions

The finding of a new class of nonselective cation channels, the transitory receptors of potential channels (TRPs), increased the understanding of how sensorial nerve endings are activated to release vasoactive neuropeptides for pain or inflammation control, with significant implications for rosacea physiopathology. These receptors are clearly expressed in neuronal and non-neuronal tissue including keratinocytes and endothelial cells [65]. Most research studies focus on the vanilloid receptor TRP1 (TRPV1), also known as capsaicin receptor, and on the TRP ankyrin 1 receptor (TRPA1), both involved in pain and inflammation induction [66]. They can be activated by heat, ethanol, spicy food (TRPV1), cold, formalin, and other chemical products (TRPA1), all triggering factors for rosacea. TRPV1 and TRPA1 activation triggers the release of substance P and calcitonin gene-related peptide, important mediators of inflammation and neurogenic pain. Worth noting is the fact that rosacea skin seems to show a significantly lower endurance threshold for temperature and chemical substances by becoming more sensitive than usual [67]. Other less investigated neuropeptides in rosacea are vasoactive intestinal peptide,

somatostatin, neurokinin A, and corticotropin-releasing hormone.

Rosacea sufferers may have a genetic predisposition or some functional gain from a mutating receptor involved in the neurovascular regulation sensitive to the rosacea triggering factors (or TRP overexpression or overstimulation), which results in neuropeptide release (characterized by flushing and edema), followed by erythema (transitory and even persistent) and the recruitment of inflammatory cells to the inflammatory site. The fact that rosacea clinically appears with transitory flushing indicates the involvement or even the main role of the neurovascular system in the early phase of disease [68].

Barrier Abnormal Function

Changes in the physiologic conditions of skin may affect the skin microbiota and its phenotype. It was recently established that the skin of patients with papulopustular rosacea is more acidic and dryer, with a normal fat level, but with a different composition of fatty acids [69]. Ni Raghallaigh and colleagues suggest that the nature of fat, more than its amount, may favor *D. folliculorum* mite development [69].

Epidermal proteases and their inhibitors play central roles in normal skin homeostasis. Matriptase and caspase-14 are essential enzymes for the filaggrin process that has barrier functions in the untouched skin, and the KLK5 and the KLK7 proteases support scaling physiologic processes. In rosacea the increased levels of KLK5 result from TLR2 increase and activation. The increased mediated KLK change of the cathelicidin peptides may lead to an increase of peptides and their fragment levels, which may induce vasodilation and promote leukocyte chemotaxis. Besides, a rise in the amount of serum proteases may result in activation of the TRP supraregulation via and/or activation of the activated protease receptors. In addition, a rise in serum protease activity in rosacea can also be effected by its impaired inhibition. Proteases can control the immune function and induce vasodilation, inflammation, pain, or pruritus [68].

Neurovascular Changes

Activation of the precapillary arterioles in rosacea is followed by vasodilation (flushing, erythema), whereas postcapillary venule activation is followed by protein flight (edema), and leukocyte recruitment via supraregulation of selectins and cell-adhesion molecules. Conversely, after stimulation by VEGF or external stimuli (e.g., UV), the number of blood vessels may increase (angiogenesis) [45, 70].

Activation of α2-adrenergic receptors of the smooth muscle cells of arteries and arterioles (through brimonidine or oxymetazoline, for example) supposedly alleviates rosacea flushing via vasoconstriction and possible anti-inflammatory effects [71, 72].

Expansion of lymphatic vessels, but not lymphangiogenesis, was noticed in all three rosacea subtypes [45]. The early involvement of lymphatic vascular dilation is intriguing even in subtypes with clinically unrecognizable edema, and not only in clinically relevant lymphedema. To date no theory on the physiopathogenesis seems capable of explaining these lymphatic vessel changes in rosacea [68].

Neuromediators

The analysis of the classic neuromediator and receptor genes showed that many neuropeptides, vasoactive amines, or TRPs involved in vasoregulation and pain may also be expressed by skin-dwelling cells and/or by immunologic system cells. PACAP (pituitary adenylate cyclase activating polypeptide), one of the most powerful vasodilators in humans, is increased in all rosacea subtypes up to more than 20-fold, and is capable of being released by activated endothelial cells and degranulated mastocytes [73]. Other supragranulated neuroreceptors are the HTR3A serotonin receptor, the H2R or H3R histamine receptors, and the adrenomedullin receptor. Differently from these, NK1 is not supraregulated, and the expression levels of the TRPV ionic channels show large variation. Serotonin (5-hidroxytriptamine), the important inflammatory and neurosensory mediator, is released by mastocytes, platelets, and other cells,

and its role has been under investigation in many inflammatory skin diseases [45, 74]. The precise role of these mediators and receptors on the physiopathology of all rosacea subtypes, including ocular rosacea, still needs to be clarified.

Clinical Presentation

Rosacea is mainly a facial dermatosis, with other topographies seldom affected (cervical and thoracic regions, scalp, and upper limbs).

Theoretically there must be a permanent facial erythema and history of sudden and repeated episodes of vasodilation (known as flushing) [75]. Injuries belonging to the classic presentation include telangiectasias, inflammatory lesions (papules, nodules with or without pustules), and injuries resulting from dermal hyperplasia and sebaceous hypertrophy (phymas). Ocular changes may also be part of rosacea presentation, therefore providing disease verification.

According to the NRS, the presence of one or more than one primary characteristics, with distribution over the central region of the face, would prompt a rosacea diagnosis. Frequently, the secondary characteristics appear with one or more than one primary characteristics, although they may occur on their own. Box 22.1 summarizes the clinical manifestations according to the NRS.

Four subtypes and one variant of rosacea were described based on the presence of these primary and secondary characteristics. Although it has long been known that the patient may display multiple subtypes simultaneously, the progression from one subtype to another is still controversial [76].

- *Subtype 1 – Erythematous telangiectatic rosacea* (*ETR*): characterized by persistent and facially centered flushing and erythema. The telangiectasias are common but not central to the diagnosis. Edema of the central region of the face and report of burning, pricking, skin roughness, and scaling may occur. History of isolated flushing is common in patients [32] (Fig. 22.1).
- *Subtype 2 – Papulopustular rosacea* (*PPR*): includes persistent erythema with papules, pustules, or both, allotted over the central region of the face, possibly occurring periorificially (perioral, perinasal, periocular). It recalls acne vulgaris except for the absence of comedones. Pricking and burning sensations may occur. This subtype is often connected to subtype 1 [32] (Fig. 22.2).
- *Subtype 3 – Phymatous rosacea* (*PR*): thickened, fibrous skin with nodules, and irregular and increased skin surface. The nasal region is mainly affected, although the mentum, the forehead, the malar, and the auricle regions may be affected (Fig. 22.3). This subtype may occur as a combination of the two previous subtypes [32].

Box 22.1 Clinical criteria and rosacea diagnosis

Primary characteristics:

≥1 with central facial distribution:

  Flushing (transitory erythema)
  Non-transitory erythema
  Papules and pustules
  Telangiectasias

Secondary characteristics:

  Burning or pricking sensations
  Platelet injuries
  Seeming skin dryness
  Edema
  Ocular manifestations
  Peripheral location
  Phymas

Fig. 22.1 Rosacea, subtype 1: erythematous telangiectatic rosacea

Fig. 22.2 Rosacea, subtype 2: papulopustular rosacea

- *Subtype 4 – Ocular rosacea* (*OR*): the diagnosis has to be considered when one or more than one of the following signs or symptoms are detected: interpalpebral conjunctival hyperemia, foreign body sensation, burning and pricking sensations, dryness, pruritus, light sensitivity, blurred vision, conjunctival and eyelid margin telangiectasia. Blepharitis, conjunctivitis, and irregular eyelid margins may also occur. Chronic staphylococcal infection (hordeolum) and chalazion possibly resulting from a dysfunctional Meibomian gland are signs of ophthalmopathies associated with rosacea. Skin symptoms are usually present although they are not crucial requirements for ocular rosacea diagnosis, considering that in about 20% of patients eye signs are displayed earlier than skin signs [32].

Fig. 22.3 Rosacea, subtype 3: phymatous rosacea

- *Variants*: *granulomatous rosacea* (*GR*), characterized by monomorphic, hard, orange, brown, or erythematous papules or nodules, mainly located on the malar regions and periorificial areas, possibly leading to scars. The lesions are less inflammatory than the subtype 2 lesions, often located on a normal skin base. There is no need of other rosacea signs to diagnose this variant. Owing to physiologic differences the following conditions were excluded as rosacea variants: fulminans rosacea (facial pyoderma), and acneiform eruption induced by steroid and perioral dermatitis [32] (Fig. 22.4).

To improve the patient's assessment the clinical presentation of rosacea can be classified as mild, moderate, or severe, although those definitions lack more objectivity.

Complementary Examinations

In the eventuality of clinical characteristics not granting a diagnostic definition, histologically detected dermal changes may be useful [77].

Histologic findings of rosacea include: dilation of blood and lymphatic vessels leading to erythema and edema; perivascular infiltrate resulting from increased T cells, macrophages; and frequently (but not exclusively) actinic elastosis, edema, and crooked and dilated vessels.

Fig. 22.4 Rosacea, granulomatous variant
Fig. 22.5 Rosacea histopathology: dermal inflammatory infiltrate and "microaneurysms" (hematoxylin–eosin, ×400) [77]

Box 22.2 Rosacea diagnosis

1 or more: flush (transitory erythema); nontransitory erythema; papules and pustules; telangiectasias

Subtypes and variant

Secondary characteristics may help

Histopathology may help

The papulopustular form may also show a dense perifollicular infiltrate composed of neutrophils and macrophages [74, 78]. The phymatous form shows sebaceous gland hyperplasia, follicular plugs, telangiectasias, and noticeable dermal thickening and fibrosis, besides large mucin stores [79].

Bonamigo and colleagues [77] noted the main histopathologic characteristics of rosacea: dermal, vascular neoform, and vascular dilations resulting in true "microaneurysms" (Fig. 22.5). Moreover, frequent findings encompass deconstructed dermal framework and elastosis. The presence of the *D. folliculorum* mite (Fig. 22.6), with circumjacent inflammatory process was noted in 12 rosacea patients (35.3% of the sample) and two control patients (6.9%). The difference found between cases and controls regarding the presence of *D. folliculorum* was statistically significant ($p < 0.05$).

Diagnosis

Rosacea diagnosis is basically clinical (Box 22.2)

Differential Diagnoses

Because of its varied clinical forms, rosacea has many differential diagnoses; we list the main diagnoses according to subtype in (Box 22.3). It is worth noting that some diseases may act as a differential diagnosis for more than one subtype and that it is not rare for a patient to show those diseases concomitantly with rosacea.

Box 22.3 Rosacea differential diagnoses

ETR	Seborrheic dermatitis
	Lupus
	Chronic use of steroids
	Contact dermatitis
	Atopic dermatitis
	Dermatomyositis

Fig. 22.6 Rosacea: *Demodex folliculorum* (hematoxylin–eosin, ×250 a zoomed-in detail, ×40) [77]
PPR	Acne
	Periorificial dermatitis
	Bacterial folliculitis
	Demodicidosis
	Iododerma
	Bromoderma
Granulomatous variant PR	Sarcoidosis, periorificial dermatitis
	Leprosy
	Lymphoma
	Leukemia cutis
	Mycosis
OR	Viral conjunctivitis
	Bacterial conjunctivitis
	Seborrheic blepharitis
	Glaucoma

Therapeutic Approach

To date rosacea remains an incurable disease, albeit treatable and controllable. Despite rosacea being a relatively benign disease there is significant morbidity associated with it in terms of the impact on the patient's quality of life and psychological well-being [80]. It is important to conduct a detailed anamnesis and to use some time during the medical appointment to calm down the patient regarding the benign nature of the condition, to explain the disease, to try to identify the triggering factors (e.g., alcohol, heat, cold, physical and psychological stress), and to discuss the treatment aims. Such an approach may improve the

physician–patient relationship and the patient's quality of life [80–82].

The skin condition can be improved and preserved through a wide range of treatments. Treatment aims are:

1. To alleviate signs and symptoms, such as skin irritation or redness, and to decrease papules and pustules
2. To retard or prevent the development of milder and more severe disease presentations
3. To make remissions easier and avoid flares
4. To keep the best skin condition possible
5. To improve the patient's quality of life

The rosacea care triad, which emphasizes patient education on the condition, skin care, and treatment, offers a wide approach to deal with all patient needs and not only the disease's specific signs and symptoms. In ETR, for example, techniques such as relaxation, cognitive-behavioral psychotherapy, biofeedback, or drugs such as antidepressants or β-adrenergic blockers, can be used to deal with the emotional triggers whenever they play a significant role [83].

As regards skin care, the patient must be educated to wash gently, and to use sunscreen with an SPF of 30 at least (decreasing ROS) and moisturizers when necessary [84]. Because the skin of these patients is more sensitive it is sometimes difficult to find the optimum tolerated sunscreen lotion and moisturizer, but symptom improvement and remission prevention are crucial [82].

A revision of the 2015 Cochrane analysis, which included 106 research studies encompassing 13,631 participants, had its conclusions classified into evidence levels of high, moderate, low, and very low quality according to the GRADE (Box 22.4) [85].

Box 22.4 Options to treat rosacea according to the GRADE

	Evidence – GRADE[a]		
	High	Moderate	Low
Topical	Azelaic acid	Metronidazole	Cyclosporine ophthalmic emulsion
	Ivermectin		
	Brimonidine		

	Evidence – GRADE[a]		
	High	Moderate	Low
Systemic	Doxycycline	Tetracycline	Minocycline
	Isotretinoin		Azithromycin
Others			Pulsed dye laser
			Intense pulsed light

[a]*GRADE* Grading of Recommendations Assessment, Development, and Evaluation

Treatment Methods (Box 22.5)

Topical Treatments

High GRADE evidence levels

- *Azelaic acid*: antimicrobial, anti-inflammatory (ROS decrease), and antikeratinous properties [86]; it can reduce KLK5 and cathelicidin expression [87]. Available in gel at a 15% concentration or in cream at a 20% concentration; it can be used twice a day for PPR over 6–8 weeks.
- *Ivermectin*: antiparasitic properties (*D. folliculorum*). Available in 1% cream; it can be used once a day for PPR over 6–8 weeks.
- *Brimonidine*: α2-adrenergic agonist. Available in 0.33% gel, it can be used once a day for RET; it has a 12-h vasoconstrictive effect. Contraindications: heart failure, obliterans thromboangiitis, Raynaud's disease, postural hypotension, Sjögren's disease, scleroderma.

Moderate GRADE evidence levels

- *Metronidazole*: imidazolic antibiotic, with anti-inflammatory properties (ROS decrease). Available in cream or gel at 0.75% or 1%; it can be used once or twice a day for PPR.
- *Other topical treatments*: Clindamycin at 1% and erythromycin at 2%, isolated or combined with 5% benzoyl peroxide, 10% sodium sulfacetamide/5% sulfur emollient foam, 5% permethrin, tretinoin. Cyclosporine ophthalmic emulsion for ocular rosacea.

Systemic Treatment

High GRADE evidence levels

- *Doxycycline*: the main treatment for PPR, it is an antibiotic of the tetracycline class with

anti-inflammatory properties (decreased expression of metalloproteinases, infraregulation of inflammatory cytokines, decreased levels of ROS [88]). Available in 40-mg doses (30 mg of immediate release and 10 mg of slow release, still not available in many countries), and in a 100-mg dose. The 40-mg dose can be used as one tablet per day, preferably 1 h before meals or 2 h after meals. In case the 100-mg dose is the only one available, half of the tablet can be used a day or one tablet every other day. It is recommended that treatment continues for 6–8 weeks followed by a new patient evaluation. After 8 weeks of doxycycline treatment the patient displays excellent reaction of the inflammatory presentation, including partial improvement of the erythema (Fig. 22.7).

- *Isotretinoin*: Can be used for severe or resistant cases of PPR; it decreases TLR2 expression. The recommended dose is 0.3 mg/kg a day over 12 weeks. Available in 10-mg and 20-mg doses. Absolutely contraindicated for pregnant women.

Moderate GRADE evidence levels

- *Tetracycline*: anti-inflammatory properties (decreased metalloproteinase expression, inflammatory cytokine infraregulation, decreased ROS levels). Available in 500-mg tablets; it can be used in a 500–1,000 mg/day dose.

Other systemic treatments

PPR: minocycline, azithromycin, sulfamethoxazole/trimethoprim, erythromycin, metronidazole, lymecycline, ivermectin, dapsone.

ETR: carvedilol. The patient's heart rate and blood pressure must be controlled.

Laser and Light Treatment

These types of treatment basically act on the vascular component by decreasing telangiectasias and basal erythema. The more often used treatments include intense pulse light (IPL), pulsed dye laser, and KTP and Nd:YAG laser. The phymatous component of rosacea can be treated with an ablative laser, such as the CO_2, Er:YAG, Nd:YAG laser.
Fig. 22.7 (**a**) before doxycycline treatment; (**b**) after doxycycline treatment. Therapeutic effect of doxycycline

Surgical Treatment

Particularly used for phyma correction. Electrosurgery is an elective surgery, but trichloroacetic acid may be used.

> **Box 22.5 Rosacea treatment: synthesis of the main drug options, according to clinical subtype**
>
> *Rosacea*
>
> Erythematous telangiectatic: brimonidine topical, oral carvedilol, and LIP
>
> Papular-pustular: oral doxycycline, topical ivermectin, topical azelaic acid, and topical metronidazole
>
> Phymatous: inflammation reduction with isotretinoin or doxycycline after electrosurgery or ablative laser
>
> Ocular: doxycycline, topical cyclosporine
>
> Granulomatous: isotretinoin, doxycycline, dapsone

Glossary

Cathelicidin Antimicrobial peptides found in the mammalian tissue induced by injury or inflammation. They belong to the immune system and work as activators and controllers of immune reactions.

Flushing The most common symptom of rosacea, characterized by a transient facial blush or redness. The skin can be lightly rose as if blushed, or it may seem slightly sunburned. Sufferers may refer to itching or pricking during rosacea flares.

GRADE (Grading of Recommendations Assessment, Development, and Evaluation) System developed by a group of collaborative researchers aiming at the creation of a universal, transparent, and sensitive system to grade the quality of scientific evidence and recommendation power. The GRADE system classifies evidence quality (reliability of the used information) at four levels: high (powerful reliability of the real effect is near the assessed one), moderate (moderate reliability of the assessed effect), low (limited effect reliability), and very low (very limited reliability of the effect assessment). There is a significant uncertainty degree in the findings. Evidence from randomized clinical trials begins with high evidence level; evidence from observational studies begins with low evidence level.

Kallikrein A polypeptide of proteolytic reaction which acts upon protein substrates of varied nature. Kallikrein has a vasodilating direct action, but also an indirect one because of its proteolytic feature.

Metalloproteinases An important group of zinc-dependent proteolytic enzymes (endopeptidases) that account for the degradation of the extracellular matrix and the basal membranes. The metalloproteinases degrade the matrix macromolecules including interstitial collagen, fibronectin, lamina, and proteoglycan, among others. The expression of many metalloproteinases is increased in the skin of rosacea patients.

Photodamage Represented by clinical changes resulting from acute or chronic events determined by biochemical and molecular processes caused by ultraviolet radiation exposure.

Phyma A rosacea phase determined by sebaceous gland hyperplasia, initially showing erythema, edema, and follicular orifice dilation, followed by the development of fibrous tissue. This process can affect the nose (rhinophyma), the mentum/chin (gnatophyma), the forehead (metophyma), the ears (otophyma), and the eyelids (blepharophyma).

Transcriptome The transcriptome corresponds to the genetic code fraction (DNA) transcribed by the RNA polymerase into the RNA molecules, that is, an organ, tissue, or cell lineage's total set of transcripts (RNA messengers, ribosomal RNAs, transporter RNAs, and microRNAs).

Vitiligo

Gerson Dellatorre, Felipe Bochnia Cerci,
Vinícius Medeiros Fava,
and Caio Cesar Silva de Castro

Key Points Summary
- Vitiligo is a highly prevalent chronic systemic disease whose major burden is the impact on patients' self-esteem
- Vitiligo is a neglected disease for which as yet there is no FDA-approved treatment
- Topical corticosteroids are considered a safe first-line treatment option. Head and neck lesions tend to have a better response
- Narrow-band ultraviolet B phototherapy is considered the first line of treatment for generalized vitiligo
- Surgical treatment is an excellent option for patients with stable disease who have failed to respond to previous clinical treatments

Epidemiology

Vitiligo affects individuals worldwide, with prevalence ranging from 0.093% in China to 1.8% in India, according to different endemic settings [1, 2]. No age or gender effect has been reported for vitiligo. The mean age at onset for common vitiligo was estimated as 22.4 years for Caucasians from the United States/Canada and 23.9 years in a mixed population from Brazil [3, 4]. Brazil has no up-to-date epidemiologic data on the incidence and prevalence of vitiligo.

An increased incidence of nonmelanoma cancer and actinic keratoses would be expected in patients with vitiligo because of the lack of melanocytes. However, three recent studies failed to detect a correlation between vitiligo and nonmelanoma skin cancer and melanoma skin cancers in comparison with the general population. In three large studies, the incidence of melanoma and nonmelanoma skin cancers was markedly reduced in vitiligo patients. Teulings et al. [5] did not observe a trend of increasing prevalence of these skin cancers in the subgroup of patients treated with psoralen plus ultraviolet A (PUVA) and narrow-band ultraviolet B (UVB). The study was adjusted for age and time of exposure during life. By contrast, in an independent cohort study Paradisi et al. [6] found a higher risk of both skin cancer groups in patients who underwent phototherapy.

Experimental data have led some authors to hypothesize that the low incidence of skin cancer

in vitiligo might be due to an overexpression of the p53 protein, which has an anticancer effect. Immunohistochemical studies have demonstrated an increased expression of p53 in both affected and normal skin of vitiligo patients compared with the skin of controls with a history of basal cell carcinoma [7, 8]. Furthermore, the reduced expression of GD3, a member of the keratinocyte apoptosis pathway, induces a compensatory mechanism of epidermal thickening to protect the affected skin from ultraviolet radiation damage [9]. Of note, the major alleles of a single nucleotide polymorphism in the *TYR* vicinity have been shown to be associated with vitiligo. The *TYR* gene encodes for a tyrosinase, an enzyme involved in melanin synthesis, and constitutes a major autoantigen in common vitiligo. The minor allele of the same TYR single nucleotide polymorphism associated with vitiligo was shown in association with susceptibility to malignant melanoma. The inversion of the risk allele between vitiligo and malignant carcinoma suggest that TYR mediates different or perhaps even inverse biological mechanisms in these two diseases. Hence, an increased immune surveillance for melanoma is a possible role for TYR in vitiligo [10, 11]. A final explanation to elucidate the reduced incidence of skin cancer in patients with vitiligo is that patients had probably been instructed to use sunscreen lotion in consultation with dermatologists.

Etiopathogenesis

The etiopathogenesis of vitiligo has not been fully elucidated, and several theories have been proposed. Among these, the autoimmune hypothesis is currently the most accepted by experts [12]. In addition to this theory, others have been intensively studied, such as the epidermal adhesion defect and biochemical and neural hypotheses. Some groups have been trying to propose models that integrate the oxidative, neural, genetic, and immune theories [13]. However, the same causal mechanisms might not apply to all cases, and different pathogenetic mechanisms might work together, leading to the same clinical result [14]. Here we discuss the melanocyte and keratinocyte adhesion defect, and autoimmune and biochemical theories.

Autoimmune Theory

The leading pathophysiologic hypothesis to explain melanocyte disappearance in vitiligo is related to a primarily immune-mediated inflammatory reaction targeting melanocytes destroyed by antigen-specific T cells. IT is known that autoreactive cytotoxic T cells are both necessary and sufficient to cause the disease in human skin [15]. These antigenic proteins in vitiligo have been identified, and include gp100, MART1, tyrosinase, and tyrosinase related proteins 1 and 2 [16].

Some studies in animals support the role of the innate immune response, and vitiligo is likely to have a second stage whereby the innate immune system subsequently triggers the adaptive immune system by activating dendritic cells, thereby facilitating targeted autoimmune destruction of melanocytes [14]. In addition to the antigen specificity of adaptive immunity, the innate immune system can rapidly initiate responses without specific antigen recognition, and does so through activation of pattern recognition receptors (i.e., Toll-like receptors), by damage-associated molecular patterns (i.e., reactive oxygen species), inducing melanocyte stress and inflammation initiation [16].

The initial perception that autoimmunity was involved in patients with common vitiligo was based on the frequent co-occurrence of autoimmune diseases in these patients and their relatives, in addition to the favorable response to immunosuppressive therapies such as photochemotherapy with UVA and topical and oral corticosteroids [17–20].

Thyroid diseases are the most common comorbidities in common vitiligo, and a recent systematic review of thyroid diseases in patients with vitiligo identified average prevalence rates of thyroid diseases, autoimmune thyroid diseases, and the presence of thyroid-specific autoantibodies as 15.1%, 14.3%, and 20.8%, respectively. However,

several autoimmune diseases, such as psoriasis, alopecia areata, and type 1 diabetes, have been associated with vitiligo [4].

Some studies have stated that vitiligo is accompanied by abnormal humoral immunity, and high levels of serum circulating autoantibodies have been detected in 5–10% of patients, predominantly of the immunoglobulin G class and particularly antityrosinase 1 and 2 (TRP-1 and TRP-2). However, the role of antimelanocyte antibodies in vitiligo pathogenesis remains uncertain, and it has been suggested that their presence may be secondary to keratinocyte and melanocyte damage, a hypothesis that has been put forward in the past [12]. Melanocytes are capable of presenting antigens in the presence of major histocompatibility complex (MHC) class II, which would allow HLA-DR+ cells present in the perilesional vitiligo area to present antigens in response to trauma or local inflammation, in the latter case leading to autoimmune destruction of melanocytes [21]. Several studies have demonstrated the presence CD8+ lymphocytic infiltrates at the dermo-epidermal junction in perilesional vitiligo skin [21, 22]. It has been observed experimentally that in some patients with common vitiligo there was infiltration of CLA+ T cells in the perilesional skin, raising the possibility that the recruitment of these T cells occurred through dendritic cell activation, which in turn are activated at the epidermal trauma region [23]. Mice with surgically excised melanoma tumors generated cytotoxic T-lymphocyte memory response against melanocytes. These mice that lacked regulatory T cells (TREGs) developed vitiligo, suggesting that TREGs would prevent autoimmunity against melanocytes [24]. There are several reports implicating TREGS to be dysregulated in patients with vitiligo, although there is no clear consensus on specific abnormalities (i.e., decreased numbers, skin homing defects, or functional defects) [16].

Evidence has also been found even in segmental vitiligo, whose pathogenesis was primarily linked to sympathetic nerve dysfunction and mosaicism, that immune-mediated cellular responses including CD8+ T lymphocytes is involved in the early stages of this type of disease [25].

Adhesion Defect Theory

It has been suggested that adhesion defects are involved in the disappearance of melanocytes in vitiligo lesions [26]. The main clinical sign reinforcing this theory is the occurrence of koebnerization or Koebner phenomenon (appearance of vitiligo after an acute or chronic trauma), which may be present in up to 31% of Caucasian patients with common vitiligo [4]. This observation led to the proposal of a new theory that nonsegmental vitiligo is a melanocytorrhagic primary disorder, i.e., an acute loss of melanocytes would probably occur (because most patients have a sudden onset of lesions), with an altered response of melanocytes to friction and possibly other types of stress, which would induce cell detachment and subsequent transepidermal loss. In this context, the authors of this theory speculated that an autoimmune phenomenon might be triggered by antigen release and recognition of affected melanocytes by dendritic cells or memory T cells during transepidermal migration, thereby exacerbating the detachment and loss of more melanocytes [13].

Alterations in the main protein that adheres melanocytes to the epidermis basal layer, DDR1 (Discoidin Domain Receptor 1), have been implicated as one of the aggravating factors in the loss of melanocytes. Initially, genetic association studies found evidence of a connection between nonsegmental vitiligo and DDR1 gene alleles, which was more evident in vitiligo patients with the onset of disease before 25 years of age [27]. Functional studies attempting to explain the involvement of DDR1 and CCN3 protein (which controls the adhesion of DDR1 to epidermis basal layer) observed that perilesional melanocytes did not express CCN3; moreover, the silencing of CCN3 in melanocytes induced a significant inhibition of their adhesion to collagen IV [26, 28]. In this same study, it was demonstrated that the expression of DDR1 in lesional skin was decreased compared with perilesional skin in most patients, and collagen IV expression was diminished in all affected individuals [26]. Along this same research line, two studies confirmed the decreased expression of DDR1 in lesional

epidermis, whereas epidermal expression of DDR1 was secondary only to expression in keratinocytes and not in the basal layer of epidermis, where melanocytes are located. Reichert-Faria et al. hypothesized that the vitiligo is a condition whereby all of the epidermis is affected and not only melanocytes [29]. DDR1 has a role in the impairment of melanocyte adhesion process in vitiligo [30]. Tarlé et al. has recently revealed that alleles of marker rs10431924 of the CDH1 gene are associated with vitiligo, especially in the presence of autoimmune comorbidities [31]. Loss or a dysfunctional E-cadherin could result in morphologic and functional impaired melanocytes and possibly initiate a cascade of immune response and oxidative stress feeding back the process of melanocyte detachment. A recent functional study showed that E-cadherin is absent from or discontinuously distributed across melanocyte membranes of vitiligo patients long before clinical lesions appear. This abnormality is associated with the detachment of the melanocytes from the basal to the suprabasal layers in the epidermis. Using human epidermal reconstructed skin and mouse models with normal or defective E-cadherin expression in melanocytes, the authors demonstrated that E-cadherin is required for melanocyte adhesiveness to the basal layer under oxidative and mechanical stress [32].

Biochemical Theory

The hypothesis that vitiligo could be caused by a metabolic pathway dysfunction, not necessarily related to melanocytes, which would lead to the production of toxic metabolites such as catecholamines, quinones, and reactive oxygen species, has been widely investigated [12, 33]. Several studies report that cellular stress pathways are dysregulated in melanocytes from vitiligo patients, suggesting that melanocyte-intrinsic defects participate in disease pathogenesis [16].

The involvement of oxidative stress damage to melanocytes is supported by evidence suggesting an imbalance between the pro-oxidant/ antioxidant systems in the epidermis of patients with vitiligo. There is an increased sensitivity of melanocytes to oxidative stress [34, 35] and

it has been demonstrated that melanocytes on the lesion borders of vitiligo patients showed increased sensitivity to oxidative stress when in culture [34]. This finding has been attributed to an inherited inability to manage stressors from normal cellular processes (e.g., melanogenesis) or exposure to environmental factors (injury or chemicals: monobenzone and other phenols). In response to stressors, reactive oxygen species are released from melanocytes, initiating a cascade of events with subsequent activation of innate immune cells [14]. Patients with vitiligo have a low level/activity of enzymatic and nonenzymatic antioxidants such as catalase, glutathione peroxidase, and vitamin E, possibly increasing H_2O_2 toxicity [35, 36] and catalase is the principal enzyme implicated in H_2O_2 removal, which is important in the management of oxidative stress. Studies have reported the involvement of the adrenergic and cholinergic systems in vitiligo pathogenesis. It has been demonstrated that high concentration of H_2O_2 inhibits the activity of cholinergic enzymes acetylcholinesterase (AChE) and butyrylcholinesterase (BChE) by oxidation of amino acid residues in the active sites of these enzymes [37, 38]. AChE is an important enzyme in promoting and maintaining oxidative stress, and interestingly, AChE activity is low in vitiligo skin lesions during depigmentation, but returns to normal when the damaged skin starts repigmentation [37].

Vitiligo Genetics

A diverse set of analytical approaches indicates that environmental factors alone are not sufficient to explain human susceptibility to vitiligo. Evidence from observational studies including familial aggregation of cases [39, 40], complex segregation analysis (CSA) [49–51] and twin studies [3] support a genetic component contributing to vitiligo pathogenesis. Using genetic epidemiology approaches such as genome-wide linkage studies (GWLS), genome-wide association studies (GWAS), and candidate-gene based studies, researchers identified genes and genomic loci modulating the outcome of vitiligo. While such techniques have helped to unravel key

aspects of disease pathogenesis (i.e., distinct set of genetic factors controlling vitiligo associated with autoimmune diseases or the involvement of melanocyte adhesion and melanin biosynthesis in vitiligo pathogenesis), they did not explain the totality of the heritability reported by observational studies.

Observational Studies in Vitiligo

The familial clustering of cases and the segregation of disease in a non-Mendelian pattern set vitiligo as a complex multifactorial disease of polygenic inheritance [39, 40]. A study with 194 families, mainly Caucasian from the United States, indicates that 20% of the vitiligo cases had at least one first-degree relative affected by disease [3, 40]. The relative risk for an offspring of a vitiligo case to develop disease was 36-fold higher than that expected for the general population [40]. Sibship and parenthood of vitiligo cases present a 12-fold and 7-fold increase, respectively, for the risk to develop vitiligo in comparison with the general population [40]. An independent study with 2,624 vitiligo probands from the United States and United Kingdom observed 7% of first-degree relatives of index cases being affected by vitiligo and an 18-fold increased risk than the general population [3]. CSAs support the existence of a genetic component cosegregating within families containing vitiligo cases; however, there is no consensus regarding the inheritance model [40–42]. Phenotypic concordance of vitiligo in pairs of monozygotic (MZ) twins and the absence of concordance in pairs of dizygotic (DZ) twins provides additional evidence for a genetic component in vitiligo. A study assessing 46 pairs of twins showed that among 22 pairs of MZ twins the concordance for vitiligo was 23% while in none of the 24 pairs of DZ twins the second sib presented the disease [3].

Genome-wide Linkage Studies to Discover Genes in Vitiligo

GWLS are hypothesis-free approaches that evaluate the nonrandom transmission of genomic regions among affected individuals in a family-based design. A series of GWLS identified multiple loci likely harboring vitiligo susceptibility genes. Hitherto, positional cloning of these linkage regions resulted in only a few candidate genes associated with disease. The first GWLS in vitiligo have shown the chromosome 17p13 linked to the comorbidity of vitiligo and systemic lupus erythematosus (SLE) in a small sample set of 16 families (Figs. 23.1) [43]. An independent study with 102 families confirmed the linkage of the 17q13 region with vitiligo associated with autoimmune diseases [44]. Positional cloning of the 17p13 region identified polymorphisms near the *NLRP1* gene in association with vitiligo as the probable origin of the linkage [45, 46]. The role of NLP1 in vitiligo and in autoimmune diseases is likely due to an upregulation of interleukin (IL)-1β processing via the NLRP1 inflammasome [47]. This mechanism is dependent of a haplotype combination of multiples coding variants associated with risk to vitiligo [47].

The chromosome 22q12 was suggestively linked to vitiligo pathogenesis by two independent GWLS in Caucasians and in Asian populations, respectively (Fig. 23.1) [44, 48]. An expansion of the study in the Asian population to 143 Chinese multiplex families confirmed the linkage with vitiligo on chromosome 22q12 [49]. Fine-mapping of the 22q12 locus identified variants near the *XBP1* gene in association with vitiligo in independent populations [50, 51]. The alleles associated with risk for vitiligo are prone to a higher transcriptional activity of the *XBP1* gene in patients' injured skin [51]. The *XBP1* gene encodes a transcription factor that regulates expression of MHC class II genes and loci frequently associated with autoimmune diseases [52]. Interestingly, the GWLS in the Asian population identified a suggestive linkage for vitiligo on chromosome 6p21–p22, a region where the MHC complex is located [49].

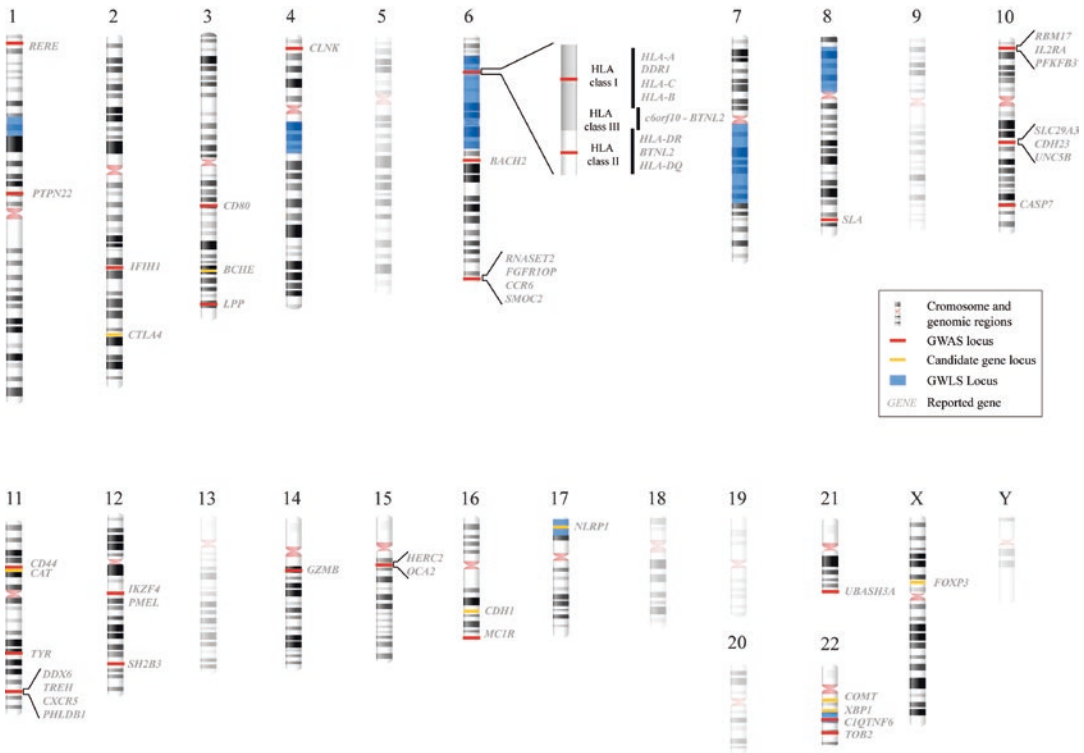
The MHC complex on chromosome 6p21 was observed in linkage with vitiligo in ethnic independent populations from China, Brazil, and Colombia (Fig. 23.1) [53]. Variants near human leukocyte antigen (HLA) class I and


Fig. 23.1 Ideogram presenting genomic regions and genes linked or associated with vitiligo pathogenesis. A summary of genes and genomic regions consistently associated or linked to vitiligo pathogenesis are pointed out according to their genomic location in the 22 autosomes or the sexual chromosomes

HLA class II genes have been consistently implicated in vitiligo pathogenesis [54, 55]. Recent studies denoted a biological function for HLA variants associated with vitiligo [56, 57]. For instance, homozygotes for a vitiligo-risk haplotype located between the *HLA-DRB1* and *HLA-DQA1* genes presented an increased surface expression of HLA-DR and HLA-DQ in monocytes [56]. In peripheral blood mononuclear cells, a vitiligo-risk haplotype near the *HLA-A* gene increases the expression of *HLA-A*02:01* allele by 39% in comparison with the non-risk haplotype [57].

Additional signals of linkage were reported for vitiligo phenotypes; however, no additional candidate genes have emerged from the reported regions. A locus on chromosome 1p31.3–p32.2 was linked to the comorbidity of vitiligo and Hashimoto thyroiditis in one large kindred (Fig. 23.1) [58]. The 1p31.3 region was suggestively linked to vitiligo when 70 independent families were evaluated [59].

An 89.4 cM region on chromosome 7 and a 54.2 cM region on chromosome 8 were linked to vitiligo pathogenesis in 102 families from United Kingdom and United States (Fig. 23.1) [51]. The signal on chromosome 7 derived from vitiligo associated with autoimmune diseases, while in chromosome 8 the linkage was mainly in families without comorbidities [51]. A GWLS in 106 Chinese families reported the chromosome 4q13–q21 linked to vitiligo (Fig. 23.1) [48]. Moreover, a moderate linkage peak for vitiligo was observed on chromosome 1p36. Interestingly, a GWAS approach described variants near the *RERE* gene on chromosome 1p36 associated with risk factors for vitiligo [10].

Genome-wide Association Studies to Discover Genes in Vitiligo

GWAS assess a dense set of genetic variants located across the entire genome for association

with a trait of interest [60]. Population-based GWAS compare the differences in genotype frequencies on cases versus controls using large cohorts. Multiple studies have used the aforementioned approach in the study of the genetic basis of vitiligo pathogenesis.

A population-based GWAS compared 1,514 generalized vitiligo cases and 2,813 health controls [10]. In total, ten independent loci were associated with generalized vitiligo in Caucasians (Fig. 23.2) [10]. The loci reported by the GWAS were independent of comorbidities being significant in the presence or absence of other autoimmune diseases [10]. The exception was the association of variants near the *PTPN22* gene, which were solely observed for vitiligo concomitant with other autoimmune diseases. The *PTPN22* gene is known to be associated with autoimmune related diseases such as rheumatoid arthritis and SLE [61, 62]. In the non-HLA region, variants next to the *TYR* gene were a notable association with vitiligo [10]. *TYR* encodes an enzyme of the melanocyte that is involved in melanin biosynthesis [63]. Mutations impairing *TYR* causes oculocutaneous albinism, a group of diseases characterized by lack of melanin in skin, hair, and eyes [64]. A meta-analysis combining the GWAS in Caucasians with a second GWAS study in a total of 3,187 vitiligo cases and 6,723 controls reported 13 additional new loci associated with vitiligo (Fig. 23.1) [65]. When the Caucasian population from the first GWAS in vitiligo was stratified according to age

at disease onset, only the signal near the *C6orf10-BTNL2* gene was associated with early onset of disease [66].

A population-based GWAS in Chinese subjects containing 1,117 vitiligo cases and 1,429 healthy controls reported a strong association of the HLA region with vitiligo [67]. A second signal of association was observed in a region near the tip of chromosome 6 long arm where multiple candidate genes were located (Fig. 23.1) [67]. An expansion of the study in the Chinese population to 6,857 vitiligo cases and 12,025 controls described an additional three loci associated with disease (Fig. 23.1) [68]. The study also validated three loci associated with vitiligo in the Caucasian population where the *LPP*, *IL2RA*, and *C1QTNF6* genes were located [68].

Mechanistic Candidate Genes in Vitiligo

The candidate gene approach studies gene(s) that are central in key biological processes related to disease pathogenesis. Difference mechanisms were proposed for the etiopathogenesis of vitiligo. Among those supported by biological findings are autoimmunity, defect in melanocyte adhesion, and biochemical metabolic dysfunction [53].

Different hypotheses were proposed for the autoimmunity in vitiligo, such as the production of autoantibodies, loss of self-tolerance magnifying the cytotoxicity of lymphocytes against melanocytes, depletion of regulatory T cells in the skin of affected individuals, and a few other that were further described by Tarle et al. [53]. One hypothesis worth mentioning is the melanocytes' capability to present antigens through MHC after trauma or inflammation [21]. Among the most documented associations with vitiligo are variants with biological impact in the MHC gene such as *HLA-A*, *HLA-DRB1*, *HLA-DQA1*, and HLA class II regulator *XBP1*. It is reasonable to think that some of these variants may contribute to a pathologic inflammatory response directly against melanocytes via a boost in antigen presentation [56, 57].

Fig. 23.2 Segmental vitiligo

It has been proposed that adhesion defects are connected with the disappearance of melanocytes in vitiligo lesions [26]. The defect of melanocyte attachment hypothesis originated from clinical observations of the Koebner phenomenon, an event that affects up to 30% of Caucasian patients with vitiligo [69]. The Koebner phenomenon is characterized by the appearance of vitiligo-like lesions after an acute or chronic trauma. A study of generalized vitiligo cases reported melanocyte detachment after mechanical friction of patient's unaffected skin; the same was not observed in a control group [70]. The *DDR1* gene encodes a transmembrane tyrosine kinase receptor that is the main adhesion protein for melanocyte to the basal membrane via the integrin CCN3 [26]. Lesioned skin of vitiligo patients had lower transcription levels of *DDR1* in comparison with unaffected skin [29]. A family-based association study with 225 families from Brazil reported the association of vitiligo and variants near the *DDR1* gene [27]. The association of *DDR1* and vitiligo was replicated in population-based case-controls in Brazilians and Koreans [27, 71]. The DDR1 forms a complex with the cell-surface E-cadherin that is important for the maintenance of apical junction complexes and epithelial polarity [72]. Variants near *CDH1* gene encoding E-cadherin were associated with vitiligo in Brazilians [31]. The *CDH1* association was particularly stronger in vitiligo associated with autoimmune diseases [31]. Other genes involved in the melanocyte adhesion remain to be studied.

The biochemical metabolic dysfunction hypothesis has been extensively debated [12]. The involvement of oxidative stress leading to a toxic damage to the melanocytes was observed by in vivo experiments showing the accumulation of H_2O_2 in the epidermis of vitiligo patients [73]. The accumulation of H_2O_2 in the epidermis inhibits the activity of cholinergic enzymes BChE [38]. Studies have shown that the epidermal expression of *BCHE* was lower in vitiligo lesions in comparison with healthy skin [37, 38]. Variant near the *BCHE* gene were associated with vitiligo in two independent population samples from Brazil [74]. The vitiligo risk alleles near the *BCHE* gene correlated with a higher enzymatic activity of BChE in plasma [74].

Clinical Presentation

Vitiligo is an acquired chronic systemic disease [53]. It is depicted as a pigmentary disorder of noncontagious etiology. Vitiligo lesions are characterized by achromic or hypochromic macules or patches on the skin, mucous membranes, and hair, resulting from progressive disappearance of melanocytes in affected areas. These lesions appear in different shapes and sizes and may arise in any area of the tegument [53]. Vitiligo is the most common depigmenting disorder, and at least 20% of patients report pruritus and affected areas are more susceptible to burns with sun exposure [75].

Clinical aspects in vitiligo suggest systemic involvement in the disease. Melanocytes in the uveal ocular tract and in the vascular system and modiolus of the cochlea in the auditory apparatus can also suffer damage during the course of disease. Previous studies detected hypopigmented spots on the iris and comorbidities such as uveitis and sensorineural hypoacusis in 16% of patients with vitiligo [76–78]. Despite of the visual aspect of depigmentation, a major burden in vitiligo is the impact on the patient's self-esteem. The consequences can range from severe depression, especially in children, to anxiety, which diminish the quality of life of patients [79, 80].

Classification

The Vitiligo Global Issues Consensus Conference, an international group of experts on vitiligo[81] – held between 2011 and 2012, classified vitiligo in the following clinical forms (Table 23.1)

- Non-segmental vitiligo (NSV): a group that comprises acrofacial, mucosal, generalized or common, universal, and mixed forms, besides some rare forms. The vitiligo lesions usually have a bilaterally distribution and may evolve over time.

(a) Acrofacial: it can affect, face, head, hands, and feet, and preferably involves the perioral

region and the extremities of digits; this form can later progress to the generalized or universal form [14].

(b) Mucosal: affects the oral and genital mucosae. Furthermore, areas of mucosa may also be affected in patients with acrofacial, common, or universal forms; when it involves only one mucosal site it is classified as indeterminate.

(c) Generalized or common (Fig. 23.3): Macules/patches are often symmetric; it can affect any part of the tegument, mainly hands, fingers, face, and trauma-exposed areas. It has a predilection for extensor than flexural surfaces.

(d) Universal: is the form that affects the largest extent of tegument (80–90% of body surface), and is the most common form in adulthood. The generalized or common form usually precedes it.

(e) Mixed: The coexistent involvement of segmental and nonsegmental vitiligo. Most often, the segmental form precedes NSV.

(f) Rare forms: vitiligo punctata, minor (an incomplete defect in pigmentation, with a pale skin color, mainly in dark skinned individuals), and follicular. These types were considered as unclassifiable.

- Segmental vitiligo: This type is characterized by their uni-, bi-, or multiple segments or band-shaped distribution (Fig. 23.4). The unisegmental form is the most common one and consists of one or more white macules on one side of the body, usually respecting the body midline, and there is also involvement of body hair (leukotrichia) besides rapid onset of the condition. Less commonly, it can affect two or more segments and even have bilateral segmental distribution, starting simultaneously or not. Early involvement of the follicular melanocyte reservoir and rapid stabilization occur. Disease onset occurs at an early age [14].

- Unclassifiable forms or undetermined vitiligo

Table 23.1 Vitiligo Global Issues Consensus Conference: classification

Types	Subtypes
Vitiligo/nonsegmentary vitiligo	Acrofacial
	Mucosal (more than one mucosal site)
	Generalized or common
	Universal
	Mixed (associated with segmental vitiligo)
	Rare variants
Segmental	Uni-, bi-, or plurisegmental
Unclassified/undetermined	Focal
	Mucosal (one site in isolation)

Fig. 23.3 Generalized or common vitiligo

Fig. 23.4 Perifollicular pattern of repigmentation is commonly seen after phototherapy

(a) Focal: small, isolated white macules without segmental distribution that have not evolved into segmental or non-segmental vitiligo forms after 1–2 years.

(b) Mucosal: when only one mucosa site is affected.

Association with Other Diseases

Vitiligo may be associated with several autoimmune diseases. Most patients, however, are otherwise healthy. Generalized vitiligo is more likely to be associated with other autoimmune diseases than segmental vitiligo, especially in patients with a family history of vitiligo or other forms of autoimmunity [82, 83]. The associated conditions include autoimmune thyroid disease, pernicious anemia, Addison's disease, lupus erythematosus, rheumatoid arthritis, and adult-onset autoimmune diabetes mellitus [84, 85]. Based on these associations, it is reasonable to screen for selected diseases (thyroid-stimulating hormone, thyroid antibodies, fasting blood glucose level), mainly in children and young women [86, 87]. Investigation of additional antibodies should be performed only if the patient's history, family history, or physical examination suggests other autoimmune diseases [88].

Complementary Examinations

The Wood's lamp, a device that emits UVA waves, is useful for highlighting areas of pigment loss on patients with fair skin [89]. Rarely, a skin biopsy is necessary for the diagnosis: if the diagnosis is uncertain, histopathologic evaluation may be helpful to differentiate vitiligo from other disorders [90]. Punch biopsies from lesional and perilesional skin are recommended. Biopsy findings are typically unremarkable with only sparse cellular infiltrates and few or no melanocytes [91]. Melanocytes on the pigmented edge of vitiliginous skin are larger, often vacuolated, and with long dendritic processes filled with melanin granules. Active lesions may have a lichenoid interface dermatitis [89].

Diagnosis

Box. 23.1 Vitiligo: Diagnosis
Depigmented patches of skin (full-body skin examination should be performed to detect possible hidden lesions)
Wood's lamp (useful and practical, inexpensive)
Histopathology (rarely necessary)

Differential Diagnosis

The differential diagnosis of vitiligo is broad. However, an adequate history and a careful physical examination generally yield a straightforward diagnosis. The differential diagnosis includes postinflammatory hypopigmentation, chemically induced depigmentation, tinea versicolor, pityriasis alba, idiopathic guttate hypomelanosis, nevus depigmentosus (achromic nevus), hypomelanosis of Ito, piebaldism, morphea, and leprosy, among others. Rarely, patients with cutaneous melanoma may present with hypopigmented patches resembling vitiligo [92]. In these patients, vitiligo-like depigmentation is thought to be a marker of an immune response against melanoma cells and may be an indicator of favorable prognosis in advanced disease [93].

Therapeutic Approach

Although vitiligo is still considered by many physicians a cosmetic disorder, its effects can be psychologically devastating, having a significant impact on quality of life. Several treatment modalities are available, although none of them produces predictably good results in all patients. Treatment options include topical corticosteroids, calcineurin inhibitors, vitamin D derivatives, phototherapy, surgical techniques, oral steroids, and systemic immunosuppressants for selected refractory cases. Combinations of treatments have also been tested in the past few years. In addition to repigmentation therapies, the use of sunscreens minimizes tanning, therefore reducing

the contrast between affected and normal skin. Makeups are helpful to camouflage depigmented areas in lighter-skinned patients.

The treatment goals are stabilization of the depigmentation process and repigmentation. Therapy should begin early in the course of the disease for better responses. The choice of therapy depends on the extent, location, and activity of disease as well as the age, skin phototype, and motivation to undergo treatment. At least 2–3 months are usually required to determine whether a specific treatment is effective. Some areas of the body such as the face, neck, mid-extremities, and trunk are more likely to have a better response to therapy. Conversely, distal extremities and lips are the most resistant to treatment. Repigmentation typically occurs in a peripheral and/or perifollicular pattern.

Topical Corticosteroids

Topical corticosteroids are considered a first-line and an adjunctive therapy for vitiligo, owing to its low cost and ease of application. However, its use is limited because of the risk of side effects including epidermal atrophy, telangiectasia, striae, steroid folliculitis, and side effects associated with systemic absorption [94]. Therefore, high-potency topical corticosteroids are more appropriate for small areas, being more effective on the face, elbows, and knees, although some authors prefer to use low-power corticosteroids on the face and flexural areas [95]. A meta-analysis demonstrated higher efficacy and safety of class 3 topical corticosteroids compared with class 4 and intralesional corticosteroids in the treatment of localized vitiligo [96]. To reduce the likelihood of local side effects, its use may be sparse or alternated with other topical therapies. In localized vitiligo, high-power topical corticosteroids should be used for 2 months, and low-power corticosteroids or other immunomodulators should be considered to decrease the risk of adverse events [97]. If no clinical response is seen with topical corticosteroids within 3–4 months, their application should be suspended [98].

The efficacy of topical corticosteroids to treat vitiligo has been supported by many studies. In a retrospective study of 101 children treated with high- or moderate-potency corticosteroids, both groups showed repigmentation in 64% of cases, stabilization in 24%, and worsening in 11%. In the stratified analysis according to corticosteroid potency, no difference was found between the moderate- and high-power drugs ($p = 0.03$), nor in the incidence of local adverse events ($p = 0.3$), However, this study should be interpreted with caution because of its variable product dosages, as well as the small number of cases in the group applying moderate-power corticosteroids [94]. Complete repigmentation rates have been reported to be as high as 49.3% [99]. It is important to mention that higher response rates are seen in children than in adults; and head and neck lesions tend to have the greatest response to treatment [100].

In summary, topical corticosteroids are generally considered a safe first-line treatment option. Head and neck lesions tend to have a better response. Local side effects limit long-term use and merit frequent monitoring. Treatment combination not only reduces the possibility of side effects but also increases response rates [101].

Calcineurin Inhibitors

Calcineurin inhibitors are valuable in treating vitiligo because they have immunomodulatory effects without the typical adverse events of corticosteroids. Calcineurin is an intracellular protein in lymphocytes and dendritic cells. When activated, it acts as a transcription factor for cytokines, such as IL-2 and tumor necrosis factor α (TNF-α). Compared with healthy controls, patients with vitiligo have elevated IL-10, TNF-α, and interferon-γ. Treatment with tacrolimus decreases tissue counts of TNF-α and increases melanocyte and melanoblast proliferation [102].

There are two available topical calcineurin inhibitors: pimecrolimus and tacrolimus. Both may be an effective therapy for vitiligo; however, most of the evidence of their use comes from small case series and uncontrolled trials

[103–105]. Response rates after 3–6 months range from 63% to 89% [103, 105–108] with the head and neck showing the best results. Mean repigmentation rates range from 26% to 72.5% [109, 110]. Lesions on the arms and legs that were previously nonresponsive to topical therapy may improve with occlusion during the night [107, 111]. Calcineurin inhibitors produce results slightly inferior to equivalent repigmentation rates when compared with corticosteroids, although the effect occurs earlier in the course of treatment [99, 112].

In adults with generalized symmetric types of vitiligo, in a small study, topical pimecrolimus for 8 weeks induced 50–100% repigmentation (a similar degree to that seen with topical clobetasol) for lesions on the trunk or extremities. Stinging was a side effect [113]. In children with generalized symmetric vitiligo, topical tacrolimus used over an 8-week period induced nearly 50% repigmentation of vitiligo lesions (a similar degree to that seen with topical clobetasol) for lesions on the face or thorax but not the hands. Stinging was a side effect [99]. Topical calcineurin inhibitors may also be used as adjunctive therapy. The combination of topical tacrolimus with excimer UV radiation appeared to enhance the degree of repigmentation over that for excimer alone, for UV-sensitive sites but not for areas over bony prominences [114, 115].

Regarding safety, both are safe for short-term or intermittent long-term use. Common side effects include erythema, pruritus, burning, and irritation [99, 104–106]. In 2005, the Unites States Food and Drug Administration (FDA) issued an alert about a possible link between topical tacrolimus and pimecrolimus and cases of lymphoma and skin cancer in children and adults, and in 2006 placed a "black box" warning on the prescribing information for these medications [116]. This link is very controversial since it was based on the theoretical risk arising from the systemic use of calcineurin inhibitors in transplant recipients and animal studies. Extensive safety data have been analyzed from more than 20,000 clinical trial participants using tacrolimus ointment. To date, there is no evidence to suggest that there is an increased risk of lymphoma or nonmelanoma skin cancer in adults or children using tacrolimus ointment [117].

In summary, the off-label use of topical calcineurin inhibitors has been shown to be safe and effective in the treatment of vitiligo in both adults and children. Given their lack of local side effects and efficacy comparable with that of topical corticosteroids, they are appropriate for intermittent long-term use. Face and neck lesions respond best, and occlusion may help with recalcitrant lesions on the extremities. Recent data suggest that combination with phototherapy increases responses.

Topical Vitamin D Analogs

Topical vitamin D3 analogs (calcipotriol and tacalcitol) have been reported as a treatment option for vitiligo, either alone or combined with other modalities. Most studies evaluated calcipotriol as adjuvant therapy, but some small studies of calcipotriol monotherapy in children have shown high response rates. Calcipotriol has lower response and repigmentation rates when compared with topical corticosteroids [118]. However, combining both has shown increased repigmentation rates and reduced onset of repigmentation. Areas that respond to treatment tend to have a greater stability of repigmentation compared with either as monotherapy [118, 119]. Furthermore, combination therapy is effective in some previously corticosteroid nonresponsive patients [119].

The use of calcipotriol combined with phototherapy has yet to be elucidated. Some studies suggest that there is no benefit of combining calcipotriol and narrow-band UVB phototherapy, and that it may actually delay repigmentation [120–122]. Other studies, however, report a decreased number of exposures and lower cumulative irradiation dosage required for repigmentation when added to narrow-band UVB and PUVA phototherapies [123, 124].

In summary, topical vitamin D3 analogs are safe and provide the most benefit especially when combined with topical corticosteroids. More studies are necessary to address their real

benefit as monotherapy. Combination therapy with phototherapy is controversial and requires further research.

Systemic Corticosteroid Therapy

Systemic corticosteroid therapy may be used in cases of extensive vitiligo with rapid progression. The use of mini-pulses has been tried in order to minimize adverse events inherent to daily treatment. A meta-analysis demonstrated a lower incidence rate of systemic and cutaneous adverse events with the mini-pulse regimen when compared with daily use of corticosteroids [96].

Some of the adverse events of systemic corticosteroids include insomnia, acne, agitation, menstrual disturbances, weight gain, hypertrichosis, and adrenal insufficiency. In one study of vitiligo patients treated with intravenous steroids, 69% reported systemic side effects [19]. Although systemic corticosteroids have potential in treating specific patients with vitiligo, the lack of data on efficacy and optimal dosing parameters warrant further research.

Systemic Immunosuppressants

Immunosuppression has a clear role in treating vitiligo. However, aside from corticosteroids, there is almost no literature regarding the use of systemic immunosuppressants. This is probably related to the high-risk side-effect profile.

In one randomized controlled study, daily low-dose azathioprine increased the benefits of PUVA phototherapy in vitiligo, without serious side effects [125]. In a recent study that compared oral corticosteroid mini-pulse and low-dose methotrexate in the treatment of unstable vitiligo, both agents were equally effective in controlling the disease activity of vitiligo [126]. The authors suggested that methotrexate can be used in patients with active vitiligo whenever corticosteroids are contraindicated. Another study, however, showed no benefit of methotrexate after 6 months of treatment in six patients who had had vitiligo for several years [127, 128].

Phototherapy and Photochemotherapy

Narrow-Band UVB

This phototherapy modality involves the emission of a wavelength spectrum from 310 to 315 nm, with a peak emission at 311 nm. As no photosensitizer is used, ocular or gastrointestinal side effects are nonexistent [129]. In addition, narrow-band UVB can also be used in children, pregnant or lactating women, and individuals with hepatic or kidney dysfunction [130].

Its mechanism of action has not been completely understood. The induction of T-lymphocyte apoptosis by narrow-band UVB in association with melanocyte mitogenesis, melanogenesis, and migration from outer root sheaths of hair follicles seem to play a role in repigmentation of vitiligo lesions (Fig. 23.2) [129].

Regarding narrow-band UVB therapeutic response, in a large open trial [131] with 110 patients (97 non-segmental and 13 segmental) treated twice weekly for a mean of 7.8 months, 48% of the nonsegmental group showed a good response (>75% repigmentation), 27% a moderate response (25–75% repigmentation), and 25% mild response (<25% repigmentation). When analyzed by site, the patients showed marked response in 76.3% in face lesions, 41.9% in trunk lesions, and 37.6% in limb lesions. None of the patients achieved marked response in the acral areas. In segmental vitiligo, narrow-band UVB phototherapy was less effective. Early treatment onset appears to be correlated with better therapeutic outcomes in segmental vitiligo [132].

As the majority of comparison studies have shown that it is more effective than other phototherapeutic modalities, narrow-band UVB is considered the first-line treatment for generalized vitiligo [129, 133, 134].

The long-term risks of narrow-band UVB in vitiligo patients remain unclear. Although no data are available regarding carcinogenesis in patients with vitiligo, individuals with diseases other than vitiligo receiving narrow-band UVB treatment had an increased risk for basal cell carcinoma in some studies [135, 136].

308-nm Excimer Laser

This equipment emits a monochromatic, coherent, and collimated laser light of 308 nm, inducing photobiological effects similar to those of narrow-band UVB. As a laser, it has the ability to deliver high fluences in a short time. It also has the advantage of being able to treat targeted areas, sparing healthy skin [129]. Repigmentation greater than 75% is usually reported in 12.5–61% of treated lesions according to several studies [137–142]. In an intrapatient comparison of 308-nm narrow-band UVB versus 308-nm Excimer laser on eight patients with symmetric lesions, a slightly higher repigmentation in the Excimer-treated area was observed [143]. Combined treatment with topical tacrolimus has been shown to be useful for accelerating initial repigmentation at the first 6 months of therapy [144]. The disadvantages of this method are the limited size of spots, which can be impractical for treating large areas (>20% of total surface body area), besides the high costs of purchase and maintenance of the equipment [129].

Excimer Lamp

The specific 308-nm radiation wavelength is also available in an incoherent form, commonly called the excimer lamp. Several trials have utilized the lamp for the treatment of vitiligo, reporting excellent repigmentation (>75%) for 25–50% of patients [145–149].

A comparison study of excimer laser versus excimer lamp showed that both devices had similar efficacy [141], although the excimer lamp takes more time to deliver the required dose, making the procedure time consuming for patients with large areas to be treated.

Psoralen plus Ultraviolet A (PUVA)

> **Box 23.2 PUVA**
> PUVA therapy was first used in ancient Egypt and in India, more than 3,000 years ago, when extracts from the plants *Psoralea corylifolia*, in India, and *Ammi majus*, in Egypt, were used as a topical and oral treatments for vitiligo.

Photochemotherapy or PUVA therapy was the mainstay for vitiligo management for a long period, but nowadays is a second-line treatment for adults. It consists in body irradiation with UVA (320–400 nm) after the patient takes or applies a photosensitizer drug. The most used oral photosensitizer is 8-methoxypsoralen (8-MOP), which is taken 2 h before irradiation, at a mean dose of 0.6 mg/kg [129].

Topical PUVA is a good alternative for localized vitiligo in adults and children over 2 years. However, care must be taken with topical preparations of psoralens, as even lower concentrations (usually 0.1% and below) of 8-methoxypsoralen can produce severe phototoxicity. Perilesional hyperpigmentation can be encountered in most cases [129].

Sunlight can also be used as a source of UVA, a therapy called PUVA sol. It is commonly used in countries where the facilities for artificial sources of light are often lacking and where sunlight is in abundance. Although PUVA sol is an inexpensive modality, it lacks adequate controlled parameters, making it unreliable and more prone to phototoxic adverse effects [129, 150].

Commonly encountered short-term side effects include cutaneous phototoxicity, nausea, insomnia, headache, and lightheadedness. Significant long-term effects such as photoaging and increased risk of skin carcinogenesis (melanoma, squamous cell carcinoma, and basal cell carcinoma) are also noteworthy, especially in patients with higher cumulative doses [129].

Contraindications for PUVA are history of skin cancer, premalignant skin lesions, cataracts, altered liver function, pregnancy, lactation, and concomitant immunosuppressive or phototoxic treatment [129]. The lower response rate and greater side effects of PUVA in comparison with narrow-band UVB has led to the first being replaced increasingly by the latter [129, 133, 134].

Surgical Management

Autologous melanocyte transplantation is another treatment option for selected patients with stable disease that has failed to respond to previous clinical treatments [151]. It can produce good

results even for traditionally refractory sites such as distal extremities, elbows, knees, nipples, eyelids, and lips [152].

Although all types of vitiligo are suitable for melanocyte transplantation, segmental vitiligo tends to have a better outcome [153]. Therefore, correct classification of the disease is crucial, as it influences patient prognosis. Disease stability is the most important factor for a successful surgical outcome [154]. Although there is no absolute consensus about stability period criteria, most authors define it as the absence of new lesions and no extension of pre-existing ones over the past year [151, 154, 155]. In doubtful cases, a test can be done implanting 4–5 mini-grafts with a 1- or 1.2-mm punch within the area to be treated and evaluating the repigmentation halo around such grafts after 3–4 months [156]. The absence of Koebner phenomenon in surgical candidates is also important, since surgical manipulation of donor and recipient areas may induce new achromic lesions [151]. Surgical modalities are classified as tissue or cellular techniques according to the type of transplanted graft [151, 155]. Most techniques require de-epithelialization of the recipient site in order to receive the tissue or cellular graft. Generally this is done with dermabrasion, a widely used and cost-effective procedure. Pre- and postprocedure phototherapy is recommended as it is related to better results [157].

Tissue Techniques

Punch Grafting

Punch grafting is a simple, low-cost, and widely used technique for surgical treatment of vitiligo. It consists in harvesting multiple small punches (1–3 mm) from the donor site (e.g., retroauricular area, buttocks, thighs) and transplanting them to the recipient area, which is prepared with a similarly sized or slightly smaller punch [158, 159]. Larger grafts often produce a cosmetically undesirable effect known as cobblestone appearance, which can resolve spontaneously or with treatments such as electrofulguration [160]. Punch grafting is typically limited to the treatment of small areas, but the use of motorized punch equipment can substantially reduce the procedure time, allowing treatment of larger sites [161].

This technique is successful in most patients with vitiligo. In a large study including 880 patients, 90–100% repigmentation was achieved, in 74.55% of them within 2 years of follow-up [158].

Suction Blister Epidermal Graft (SBEG)

This procedure involves induction of suction blisters on the donor area (usually thighs or arms) by applying prolonged vacuum with the aid of a syringe or specific equipment for this purpose (Fig. 23.5a) [151]. It has some advantages over
Fig. 23.5 (**a**) Suction apparatus positioned on the inner thigh. (**b**) Blister formed after 50 min of suction

Fig. 23.6 (**a**, **b**) Preoperative register of segmental vitiligo in the forehead and left cheek. (**c**, **d**) 11 weeks postoperatively, with 85% diffuse repigmentation and good color match

the punch graft method, as the donor area heals with minimal scarring and postinflammatory pigmentation [162]. Furthermore, being a purely epidermal graft there is no cobblestone effect.

According to a recent study, the SBEG technique produces good to excellent results (65–100% repigmentation) in 80% of patients (Fig. 23.6). Although cost-effective, this method is considered a time-consuming technique since it takes approximately 2 h to form a blister using

a 10-ml syringe (Fig. 23.4b). This time can be shortened through infiltration of the dermis with anesthetics or by using a heat lamp over the donor area [163].

Split-Thickness Skin Grafting

Split-thickness skin grafts have the advantage of treating large areas effectively (90–100% repigmentation) with a single procedure. The graft is obtained with the aid of a dermatome, a

procedure that requires skill and experience [164]. Furthermore, the incompatibility of colors in the recipient area and scarring in the donor area are potential side effects of this technique [155].

Cellular Techniques

Noncultured Epidermal Cell Suspension (NCES)

In this technique a thin split-thickness skin graft is taken from the donor area with the help of a shaving blade or a dermatome (Fig. 23.7). After this procedure, the skin sample is incubated at 37 °C in a trypsin–ethylenediamine tetraacetic acid (EDTA) solution, which separates the epidermis from dermis. After some additional steps, a melanocyte–keratinocyte cell suspension is obtained and transferred to the denuded recipient area (Fig. 23.8). This method has the advantage of a donor-to-recipient expansion ratio ranging from five- to tenfold, being able to treat large areas with good results [151, 155]. Good to excellent repigmentation (75–100%) can be achieved in 89% of patients [165]. As disadvantages, this technique requires skill and experience to take the split-skin graft and some specialized laboratory equipment [151].

Noncultured Extracted Hair Follicle Outer Root Sheath Cell Suspension (NCORSHFS)

In this procedure, a cell suspension is obtained from hair follicles harvested using a follicular unit extraction (FUE) technique with the help of a small punch (Fig. 23.9a). Depending on the area to be transplanted, approximately 15–25 pigmented follicles are extracted per subject. Once extracted, the follicular units undergo a laboratory process similar to the NCES procedure to obtain a cell suspension (Fig. 23.9b) [166]. Obtaining cells from hair follicle has some advantages. The hair follicle is an important reservoir of melanocytes and their precursor cells. Furthermore, scarring in the donor area is unnoticeable with the FUE method [167]. In a randomized comparative study of NCES versus NCORSHFS with 30 patients, good to excellent (75–100%) repigmentation extent was achieved in 92% and 78% of lesions, respectively, although this difference was not statistically significant [168].

Cultured Cell Suspension

In vitro cultivation of melanocytes with or without keratinocytes can dramatically increase the transplanted cell number (Fig. 23.10). Therefore, cells from a small piece of normal

The cells were pretreated with geneticin to eliminate fibroblasts and keratinocytes. Throughout 18 days after treatment with geneticin, melanocytes were cultured in a medium supplemented with growth factors (basic fibroblast growth factor and hepatocyte growth factor), allowing the maintenance and proliferation of cells (Image courtesy of Dr. Renata Helena Monteiro Sindeaux and Mariana Kraft Soares, Advanced Core of Molecular Research, Pontifical Catholic University of Parana, Brazil)

skin can be used to treat large depigmented areas, this being one of the major advantages of this technique [169]. Furthermore, this method can provide even greater repigmentation rates relative to the noncultured techniques [169, 170]. The cost factor, the need of cell culture expertise, and requirement of specific laboratory materials are disadvantages [151]. Furthermore, as the growth medium used in cultures contains various types of mitogenic factors, long-term follow-up is recommended because of the theoretical potential of the human melanocytes to transform at a later date after transplantation [170].

Glossary

1. *Single nucleotide polymorphism (SNP)*: A variation in a single nucleotide at defined positions within genomes and are responsible for individual phenotypic characteristics, including a person's propensity toward complex disorders. Each variation is present to some appreciable degree within a population.
2. *Regulatory T Cells* (*TREGs*): A subpopulation of T cells that modulate the immune system and are defined based on expression of CD4, CD25, and the transcription factor FoxP3.

TREGs are crucial mediators of self-tolerance in the periphery, preventing autoimmune diseases and limiting chronic inflammatory diseases.

3. *Koebner phenomenon*: or isomorphic response; refers to the appearance of lesions along a site of injury.

4. *Mosaicism*: A condition whereby cells within the same person have a different genetic makeup, i.e., different cells in the same individual have different numbers or arrangements of chromosomes. It is called "mosaicism" because, in a way, the cells of the body are similar to the tiles of a mosaic. This condition can affect any type of cell, including: blood cells, sperm cells, and skin cells.

Autoimmune Bullous Dermatoses

Hiram de Almeida Larangeira Jr.

Key Points summary
- Bullous dermatoses are acquired conditions arising from pathogenic autoantibodies against structural proteins of cell–cell and cell–matrix adhesions in the skin and mucous membranes
- The clinical presentation of bullous dermatoses shows skin and mucosal fragility with blisters, vesicles, and/or erosions
- Treatment of bullous dermatoses should suppress antibody production with immunosuppression.

Introduction

Autoimmune bullous dermatoses are acquired diseases associated with pathogenic autoantibodies against structural proteins that maintain cell–cell and cell–matrix adhesions in the skin and mucous membranes. The clinical presentation is characterized by fragile skin and/or mucous membranes with blisters, vesicles, and/or erosions.

These dermatoses have been classified as acantholytic (or intraepidermal) bullous dermatoses – the pemphigus group (caused by desmosomal damage) – and nonacantholytic (or subepidermal), caused by hemidesmosomal damage, belonging to the bullous pemphigoid group. In dermatitis herpetiformis, a condition with subepidermal blisters, epidermal detachment is secondary to an inflammatory reaction.

Epidemiology

The bullous diseases particularly affect those in middle age (onset typically at 40–60 years of age) [1, 2]. In Germany an estimated 2,000 new cases of autoimmune blistering skin diseases occur per year. Pemphigus vulgaris is the most common type [3]. Pemphigus foliaceus, triggered by an environmental agent, is endemic in certain regions of central Brazil [4].

Bullous pemphigoid affects elderly individuals, with an annual incidence estimated to range from 12 to 60 new cases per million people [5]. Dermatitis herpetiformis (DH) is a rare bullous dermatosis whose prevalence varies according to the study population [6, 7].

Etiopathogenesis

Skin epithelial cells, keratinocytes, have two major features, namely the synthesis of keratin, which culminates in the formation of the protective barrier (stratum corneum), and adhesion - intercellular and to the dermis, which gives the epithelium its mechanical strength.

Intercellular adhesion is provided by desmosomes. A desmosome consists of proteinaceous plaques attached to the cytosolic face of the plasma membranes of adjacent cells connected by transmembrane linker proteins. They interact, forming a network that binds two cells together.

The most important proteins in intercellular adhesion are desmogleins 1 (DSG1) and 3 (DSG3). DSG1 is expressed throughout the skin and DSG3 in the mucous membranes. When DSG3 is damaged, usually by immunoglobulin G (IgG), adhesion loss occurs in the mucous membrane. This results in loss of adherence of epithelial cells and the formation of intraepithelial blisters, referred to as mucosal pemphigus vulgaris. When the pathogenic IgG damages the DSG1, the skin becomes fragile and blisters form, referred to as pemphigus foliaceus. Some individuals may damage both DSGs, affecting skin and mucous membranes, referred to as mucocutaneous pemphigus vulgaris, the most severe type of pemphigus. Damaged desmosomes result in keratinocyte detachment (acantholysis) (Fig. 24.1a). In these cases the hemidesmosomes are normal and the basal keratinocytes remain adhered to the basal membrane (Fig. 24.1a), revealing a suprabasal cleavage, typical of pemphigus vulgaris.

The epidermis is adhered to the dermis by a structure that is similar that of the desmosomes, known as hemidesmosome, which attaches basal keratinocytes to the extracellular matrix. Transmembranous proteins connect the hemidesmosomal plaque of an epithelial cell to the underlying basement membrane. Similar to pemphigus, pathogenic IgGs damage these proteins, causing
Fig. 24.1 (**a**) Typical histologic features of a bullous dermatosis caused by desmosomal damage with acantholytic keratinocytes (due to adhesion loss) (*thin arrow*). Note that the basal keratinocytes remain attached to the basal membrane (*thick arrow*), since the hemidesmosomes are normal, revealing a suprabasal cleavage. (**b**) Typical histologic features of a bullous dermatosis caused by hemidesmosomal damage, without acantholysis. Note that there are no loose cells in the epidermis (*arrows*) and there is complete detachment of the epidermis, known as dermoepidermal cleavage (Photos courtesy of Prof. Mirian Sotto, University of São Paulo)

complete loss of epidermis (Fig. 24.1b), although without acantholysis, since the desmosomes (formed by other proteins) remain intact. This disease is called bullous pemphigoid.

Dermatitis herpetiformis does not fall into this category because the pathogenic immunoglobulin deposits cause no direct damage to either desmosomal or hemidesmosomal proteins. A deposit of IgA occurs in the upper dermis (papillary dermis). Neutrophils are then attracted to this region, and probably an inflammatory response is triggered, causing blisters and vesicles. Gluten-sensitive enteropathy may be an associated condition; therefore, diet and follow-up by a gastroenterologist are recommended.

Clinical Presentation

Mucosal pemphigus vulgaris is a very frequent clinical presentation [2]. Patients complain of lesions that affect mainly the oral mucosa, with erosions (Fig. 24.2). Sometimes there is detachment of part of the epidermis with elimination of a tissue lamina. It may also affect the conjunctiva, nose, pharynx, esophagus, genitals, and anus [8], causing major impact on the patient's quality of life. After onset in the mucous membranes, some patients develop a disseminated form of the disease, mucocutaneous pemphigus vulgaris, which can also be the initial clinical presentation of the disease. In such cases, disseminated blisters and erosions also occur (Fig. 24.3).

Pemphigus foliaceus is confined to the skin and there is no involvement of mucous membranes. As the intraepidermal cleavage is a little higher than in pemphigus vulgaris, the blisters are flaccid and sometimes absent, and rupture very easily, while only erosions may be seen. The lesions are often scaly and crusty (Fig. 24.4), closely resembling the appearance of seborrheic dermatitis [9].

Fig. 24.2 Erosions on the back of the tongue and in the oropharynx, characterizing mucosal pemphigus vulgaris

Fig. 24.4 (**a**) Disseminated crusted lesions and some erosions in pemphigus foliaceus. (**b**) Detail of the lesions

Fig. 24.5 Disseminated blisters in bullous pemphigoid. There are more inflammatory changes than in pemphigus vulgaris (Fig. 24.3), since the lesions may be preceded by urticarial plaques (Courtesy of the Dermatology Department, Santa Casa de Porto Alegre).

Fig. 24.6 Grouped vesicles in dermatitis herpetiformis (Courtesy of the Dermatology Department, Santa Casa de Porto Alegre).

Diagnosis

Bullous pemphigoid is characterized by tense blisters (Fig. 24.5) on the skin, which may be preceded by pruritic urticaria [5]. Mucosal involvement is rare.

Dermatitis herpetiformis (DH) is clinically characterized by grouped vesicles (Fig. 24.6), such as in herpes simplex. Many patients present discrete lesions without the formation of vesicles, only grouped crusts. In mild cases, the frequently affected locations (elbows, knees, and buttocks) may be useful for a differential diagnosis.

Conventional light microscopy can establish the diagnosis, showing partial loss of the epidermis with acantholysis in patients with pemphigus and total loss of the epidermis without acantholysis in the bullous pemphigoid group (Fig. 24.1).

Direct immunofluorescence complements the diagnosis, showing the deposit of IgG in the epithelium with intercellular pattern, typical of pemphigus (where desmosomes are located) (Fig. 24.7a) and a linear pattern along the basement membrane zone, typical of the bullous
Fig. 24.7 Typical findings of direct immunofluorescence. (**a**) Intercellular pattern (*greenish staining*), demonstrating that the pathogenic antibodies move toward desmosomal transmembranous proteins. (**b**) Linear pattern along the basal membrane zone (*greenish line*), demonstrating that the antibodies move toward the proteins in this zone; in the case of bullous pemphigoid, toward the hemidesmosomal proteins (Photos courtesy of Dr. Cláudia Santi, Hospital das Clínicas, University of São Paulo)

pemphigoid group (Fig. 24.7b). Biopsy is necessary to perform this examination, and the tissue should not be fixed in formalin but placed into transport medium for fresh examination. Indirect immunofluorescence, performed with patient's serum, avoids the biopsy and can detect ciculating autoantibodies at a lower cost.

Commercial enzyme-linked immunoassay (ELISA) tests for DSG1 and DSG3 autoantibodies detected in the sera of patients are now available, but at higher cost. For dermatitis herpetiformis, optical microscopy frequently provides atypical results, as vesicles are clinically rare. Direct immunofluorescence reveals IgA deposits in the upper dermis. Similarly for the diagnosis of pemphigus, ELISA can be used for detection of IgG against the proteins involved (endomysium and tissue transglutaminase antibodies), and can be helpful in the diagnosis.

Therapeutic Approach

The first-line treatment of pemphigus and pemphigoid is high-dose oral corticosteroids. One can start with 1 mg/kg/day of prednisone and decrease the dose, according to clinical response [10].

If patients do not respond to corticosteroids, another immunosuppressant (azathioprine or methotrexate) can be used. Methotrexate can be taken at 15 mg per week [11], as in other autoimmune diseases, e.g., psoriasis and rheumatoid arthritis. The weekly dosing schedule is well tolerated and convenient, but its use should be carefully explained to patients, since accidental doses have been reported when patients took this dose daily instead of weekly. Potential adverse effects from this drug require monitoring of hematologic, renal, and hepatic function; alcohol abstinence and exclusion of viral hepatitis are mandatory.

Some authors recommend initial administration of immunosuppressant with concomitant oral corticosteroid to lessen the cumulative dose of corticosteroid.

Mild cases of bullous pemphigoid can be treated with topical corticosteroids, as it usually affects the elderly and the effects of prolonged use of oral corticosteroid can be avoided. A good response has been reported with oral tetracycline, which may inhibit leukocyte migration and suppress inflammatory changes.

Dermatitis herpetiformis requires a regimen somewhat different from that with immunosuppression, since it generally responds well to dapsone (also

called sulfone) [12], which does not act directly in the production of pathogenic antibodies, but in the inflammatory cascade that follows the deposition of IgA. It is contraindicated for persons suffering from glucose-6-phosphate dehydrogenase deficiency (which should be tested for before treatment) because it increases the risk of hematologic side effects. Hematologic changes (anemia and meta-hemoglobinemia) are not infrequent. Hypersensitivity reactions, similar to those caused by other sulfonamides, can also occur. Previous allergy to this group of drugs contraindicates the treatment.

Unresponsive or corticodependent cases can be treated with biologicals (rituximab) or intravenous immunoglobulin, and should be referred to a specialized center.

Glossary

Acantholysis Loss of epithelial intercellular contact, showing isolated round keratinocytes.

Bullous pemphigoid Blistering dermatoses without acantholysis, caused by hemidesmosomal lesions.

Desmosome Cell structure that adheres epithelial cells to each other, composed of two plaques, one in each cell, connected by transmembranous proteins.

Direct immunofluorescence Laboratory investigation to detect antibodies in tissues.

Hemidesmosome Cell structure that adheres the basal keratinocyte to the basement membrane, composed of one plaque, also connected by transmembranous proteins.

Pemphigus group Blistering dermatoses with acantholysis caused by desmosomal lesions.

Aphthae

Juliana Dumet Fernandes and Marcello Menta S. Nico

Key Points Summary
- Aphthosis is an inflammatory disease characterized by painful recurrent oral ulcerations
- The cause of aphthosis is unknown, and several studies indicate a role for the immune system in the physiopathogenesis of this disease
- Oral lesions appear mainly on nonkeratinized mucosa as painful, regular, round or oval ulcers covered with a gray pseudomembrane and surrounded by an erythematous halo
- The diagnosis of aphthosis is mainly established on clinical grounds
- Drug choice depends on the severity, recurrence rate, and response to previous therapies

Epidemiology

Aphthosis is an inflammatory disease characterized by painful recurrent oral ulcerations. It is considered the most common oral mucosal lesion, with a 3-month recurrence rate as high as 50% [1, 2]. It is more common in female patients, usually begins during childhood or adolescence, and has a tendency to diminish in frequency and severity, resolving spontaneously with age [3–5]. Incidence of aphthous ulcers has been reported ranging from 5% to 66% among different nations [1].

Etiopathogenesis

Although aphthosis is a local reaction, it is always due to a systemic predisposing factor of deregulation in the inflammatory or immune response, often undetected [6]. The cause of aphthosis is unknown, though several studies indicate a role for the immune system in the physiopathogenesis of this disease. Cytotoxicity against oral epithelial cells, decreased CD4-to-CD8 ratio, and increased CD T cells in the peripheral blood and lesions have been demonstrated, but the exact mechanism of the disorder remains to be elucidated [3, 4]

Some conditions, such as stress, hormonal changes, trauma, food hypersensitivity, systemic diseases (inflammatory bowel disease and cyclic neutropenia), hematinic deficiencies (zinc, iron, vitamin B12, and folic acid), and drugs (such as

captopril, gold salts, nicorandil, phenindione, phenobarbital, sirolimus, tacrolimus, and sodium hypochloride) are associated with aphthae [3, 5, 7, 8] (see Box 25.1). Immunocompromised patients are known to have an increased incidence of aphthous ulcers. Human immunodeficiency virus (HIV)–associated recurrent aphthous stomatitis tends to be more severe and to last longer. Aphthosis major, the most severe variant of aphthosis, is reported to be associated with immunosuppression [4].

> **Box 25.1 Main Clinical Associations with Aphthae**
> - Physical and emotional stress
> - Infections
> - Hormonal changes
> - Food hypersensitivity
> - Immune disorder (e.g., HIV)
> - Family history
> - Sodium lauryl sulfate
> - Vitamin and mineral deficiencies: B1, B2, B6, B12, iron, folic acid, and zinc
> - Celiac disease
> - Inflammatory bowel disease
> - Antimetabolites (e.g., methotrexate)
> - Neutropenia (any cause, mainly cyclic neutropenia)

Clinical Presentation

Oral lesions appear mainly on nonkeratinized mucosa as painful, regular, round or oval ulcers covered with a gray pseudomembrane and surrounded by an erythematous halo. The presence of aphthae in keratinized sites of the oral mucosa (i.e., dorsum of the tongue, gingiva, and∕or hard palate) is more frequent in severe clinical cases.

Aphthosis can be classified as minor (lesions <10 mm), major (lesions >10 mm that heal with scarring), and herpetiform (crops of lesions <5 mm), although patients may present more than one pattern simultaneously.

Aphthae minor (Sutton's disease) is the most common form, affecting approximately 85% of aphthous patients. The ulcers are superficial, usually <1 cm in diameter (Fig. 25.1). The

Fig. 25.1 Aphthae minor. Oval ulcers surrounded by an erythematous halo. The ulcers are superficial, usually <1 cm in diameter

Fig. 25.2 Aphthae major lesions are deeper and larger than 10 mm in diameter

number of ulcers varies from one to five [4]. Aphthae minor lesions do not result in scarring and tend to heal within 10–14 days.

Aphthae major lesions are deeper and larger than 10 mm in diameter (Fig. 25.2). It affects approximately 10–15% of all cases, causing significant pain and, sometimes, dysphagia. The ulcers persist for up to 6 weeks and heal with scarring.

Fig. 25.3 Herpetiform aphthae. Multiple ulcers that may be up to 100 lesions in number. These are small in size and measure 2–3 mm in diameter

Herpetiform ulceration is characterized by recurrent crops of multiple ulcers, perhaps up to 100 in number. These are small in size and measure 2–3 mm in diameter (Fig. 25.3). Lesions may coalesce to form large irregular ulcers, which persist for about 10–14 days. Unlike herpetic ulcers, these are not preceded by vesicles and do not contain viral infected cells. This type has a later age of onset than other clinical variants of aphthae [9].

Sites of keratinized mucosa are more resistant to the onset of aphthosis. Similarly, mucosal keratinization attributable to irritative exogenous factors such as nicotine is protective [6]. Several studies reveal a negative association between cigarette smoking and aphthae [9–11].

The appearance of lesions may be acute (single episode), continuous, or subintrant according to the cause or underlying disease. Severe cases can be accompanied by genital ulceration and systemic manifestations such as fever, arthralgia, erythema nodosum, and skin pustules (complex aphthosis). Aphthosis can affect the patient for many years and should not be confused with sporadic aphthous injury, which, in general, is posttraumatic and common in young people [5, 6, 12].

The recurrent episodes of aphthosis may be triggered in susceptible individuals in the course of acute viral infections (Lipschütz ulcer), immunodeficiencies such as AIDS or transplanted patients, inflammatory bowel disease, Behçet's disease, and cyclic neutropenia, among others. It can occur simultaneously with skin disorders resulting from systemic inflammatory changes, such as erythema nodosum and pyoderma gangrenosum.

Whatever the cause and the evolution, the clinical-pathologic substrate for aphthosis is always the same.

Diagnosis

The diagnosis of aphthosis is mainly established on clinical grounds (Box 25.2). Although there is no laboratory diagnostic test, ulceration and superficial tissue necrosis, with presence of neutrophils and lymphocytes infiltrating the epithelium and the lamina propria, with variable spread and endothelial edema, supports the diagnosis. Histochemical and immunohistochemical stains for microorganisms are necessary to exclude infectious processes such as herpes and fungal infections. Salivary gland inflammation and necrosis may also be seen in cases of aphthosis major whereby deep ulceration is present.

> **Box 25.2 Diagnosis of Aphthosis**
> Painful, regular, round or oval ulcers covered with a gray pseudomembrane and surrounded by an erythematous halo on nonkeratinized mucosa.

Complementary Examinations

Blood count if differential diagnoses are suspected: Tzanck smear, histopathology, direct immunofluorescence, syphilis serology. According to presenting signs and symptoms: colonoscopy, ophthalmologic evaluation, HIV serology.

Differential Diagnosis

Herpes simplex virus (HSV) infections may have lesions similar to aphthae; however, HSV lesions are found primarily on attached keratinized mucosa, such as the hard palate or gingiva, and are preceded by vesicles. Other ulcers similar to aphthae are also seen in Behçet's syndrome, Sweet's syndrome, HIV infection, cyclic neutro-

penia, and other immunodeficiencies, and, rarely, in children in association with fever and pharyngitis (periodic fever, aphthous stomatitis, pharyngitis, and cervical adenitis) [13–15].

Differential diagnoses also include varicella zoster virus infections (shingles), Coxsackie virus (herpangina and hand-foot-and-mouth disease), erythema multiforme, Wegener's granulomatosis, pemphigus vulgaris, syphilis, and mainly opportunistic infections such as orificial tuberculosis, histoplasmosis, and acute leukemia.

Therapeutic Approach

The aim of the treatment is to decrease symptoms, reduce ulcer number and size, and increase disease-free periods.

Management of recurrent aphthous ulcer requires good oral hygiene, topical steroids, dapsone, colchicine, and thalidomide. Drug choice depends on the severity, recurrence rate, and response to previous therapies.

The several topical treatments described in the literature are merely symptomatic, so that they have no influence on the course of aphthae episodes because, as already explained, the cause of aphthosis is always systemic (never local) [6].

A topical anesthetic such as 2% viscous lidocaine hydrochloride is used to palliate the pain. Caustic topical treatments that reduce pain by destroying nerve terminations are contraindicated, since they increase the ulcer size, make ulcer healing difficult, and increase the risk of secondary infection.

Mouthwashes of tetracycline and local antihistamines have a mild anesthetic effect. Topical corticosteroids (Orabase adhesive vehicles or mouthwash solution) have an analgesic effect and can be used in mild episodes.

Systemic therapy is the only effective treatment for termination and prevention of new episodes. It is crucial to control the underlying disease (bowel disease, AIDS, etc.) because aphthosis may indicate activity of these processes. In acute episodes, oral corticosteroid therapy is indicated. Medications that inhibit the onset of episodes include colchicine (0.5–2 mg/day) and dapsone (100 mg/day), which can be used alone or in combination [5, 6, 13, 16].

Thalidomide (100–300 mg/day) is the most effective therapy for severe and/or refractory cases [17]. Recently, biological therapies, such as infliximab, have been used in very severe cases [18–20].

Glossary

Aphtha Synonymous to aphthosis. Also used as the description of the individual ulcer of the disease.

Aphthosis A disease characterized by bursts of oral ulcerations, accompanied or not by ulcerations elsewhere (usually genitals) and systemic complaints.

Dapsone Diaminodiphenyl sulfone (DDS), an antibiotic used in the treatment of leprosy and as an anti-inflammatory drug in several noninfectious skin diseases.

Herpetiform ulceration One of several clinical types of aphthae, i.e., one that presents as multiple subintrant small ulcerations.

Oral ulcer Any lesion characterized by loss of the oral epithelium.

Thalidomide An immunomodulatory drug that is the prototype of the thalidomide class of drugs.

Adverse Drug Reactions

26

Paulo Ricardo Criado

Key Points summary

In situations that involve patients with acute adverse drug reaction, certain general principles should be observed:

- If possible identify the physiopathologic mechanism involved in the reaction;
- Identify as rapidly as possible the drug inducing the reaction and always opt for its withdrawal; in some circumstances the choice is difficult as there is no alternative drug and its use is essential for the maintenance of life;
- A careful and intensive observation is recommended for the occurrence of warning signs regarding the appearance of a potentially severe adverse drug reaction, especially in relation to mucous, oral, ocular, and genital involvement and progression of any present cutaneous eruption;
- It is imperative that the drug responsible may be withdrawn on a permanent basis together with chemically related compounds, and this advice is also valid for first-degree relatives who can present the same type of reaction.

Introduction

Adverse reactions to drugs are complications that are of relevance to medicinal therapy [1]. It is estimated that 5–15% of patients treated with some medication develop adverse reactions [1].

The incidence of adverse reactions to drugs among hospitalized patients is roughly 30%, 2–3% of which constitute cutaneous reactions [1, 2]. Such reactions are seldom severe but may lead to high mortality rates [3].

In this chapter, three groups of cutaneous adverse drug reactions (ADRs) are discussed: (i) severe ADRs; (ii) moderate or mild cutaneous ADRs, and (iii) ADRs caused by chemotherapy drugs.

Severe Adverse Drug Reactions

Severe cutaneous adverse reactions to drugs (SCARDs) generally require hospitalization, sometimes in the intensive therapy or burn care unit for observation of vital signs and visceral

function. The aim of this study is to describe these reactions in order to facilitate recognition and treatment. This group of drug reactions includes anaphylaxis, Stevens–Johnson syndrome (SJS), toxic epidermal necrolysis (TEN), and, depending on the systemic involvement, erythroderma. In this chapter we approach the characteristics and treatment of some adverse reactions to drugs, including anaphylaxis, erythroderma, SJS, and TEN.

The prevalence of SCARDs is estimated at 1 in 1,000 hospitalized patients. SJS and TEN are particularly severe [4]. In general, fatal cutaneous drug-induced reactions occur in 0.1% of clinical patients and 0.01% of surgery patients [1].

SCARDs may be defined as usually requiring hospitalization, at times in intensive therapy or burn care units for close observation of vital signs and visceral function. This group of drug reactions includes anaphylaxis, SJS, TEN, drug hypersensitivity, and, depending on the systemic involvement, erythroderma, acute generalized exanthematous pustulosis (AGEP), cutaneous

necrosis induced by anticoagulants, drug-induced vasculitis, and reactions such as serum disease [4].

Quick differentiation between a SCARD and a less severe eruption may be difficult, although essential. Withdrawal of the suspected drug is the surest way of intervening to reduce mortality [4].

Most cutaneous reactions to drugs are usually observed as a morbilliform or maculopapulous exanthema [2, 5, 6]. Unfortunately, erythema morbilliform (Fig. 26.1) most often characterizes the appearance at onset in the severest of cases, including TEN, serum disease, and drug hypersensitivity syndrome [4].

Djien et al. [3], studying 133 patients with reactions to drugs clinically presenting with erythematous cutaneous eruptions (morbilliform and scarlatiniform exanthema, maculopapulous, and small isolated papules), concluded that three types of severe clinical markers exist with respect to this kind of reaction: fever, lymphadenopathy, and extensive cutaneous affection. The authors excluded specific forms from the study, such as
Fig. 26.1 Exanthema morbilliform

Chart 26.1 Symptoms or signs suggesting a progressive severe adverse drug reaction

Clinical findings	Mucocutaneous	Extensive erythema
		Skin pain
		Facial edema or centrofacial involvement
		Cutaneous necrosis
		Palpable purpura
		Bullous lesions or epidermal detachment
		Tongue edema or uvula edema
		Urticaria
		Positive Nikolsky sign
		Erosions on mucous membranes
	General symptoms or signs	High fever (>40 °C)
		Adrenomegaly
		Arthralgia or arthritis
		Tachypnea and or wheezing
		Hypotension
Laboratory abnormalities		Eosinophilia >1,000 mm^3
		Lymphocytosis with atypia
		Abnormalities of liver enzymes or function

SJS, TEN, fixed drug eruption (FDE), AGEP, phototoxicity, and vasculitis. This suggests that in cases of drug-induced reactions with extensive cutaneous affection, with or without lymphadenopathy, a laboratory investigation is required with a complete hemogram and hepatic function test.

In 1994, Roujeau and Stern [4] put forth clinical and laboratory criteria leading to the suspicion that a reaction to drugs could develop into more severe behavior (Chart 26.1).

We next discuss the following reactions: anaphylaxis and anaphylactoid reactions, erythroderma, and the clinical spectrum of SJS and TEN (Lyell's disease).

Anaphylaxis and Anaphylactoid Reactions

Anaphylaxis is a quick systemic reaction usually presenting a risk to life and resulting in immediate hypersensibility mediated by immunoglobulin E (IgE). Anaphylactoid reactions mimic anaphylaxis, although they are not related to immunologic mechanisms [4, 7]. These reactions lead to a powerful activation of mastocytes, with a massive release of mediators [7, 8].

Drugs are not the more important cause of anaphylaxis, as they are responsible for merely 13–20% of cases [8] .Drugs that do cause anaphylactic reactions include β-lactam antibiotics (responsible for 75% of fatal anaphylactic reactions in the United States), cephalosporin, sulfonamides, hemoderivatives, enzymes (trypsin, chymopapain, and streptokinase), insulin (very rare nowadays, owing to use of recombinant human insulin), vaccines (due to preservatives, proteic components, and gelatin; some reports of patients show sensitivity to eggs and allergic reactions to vaccines), allergenic extracts, protamine, and progesterone [7, 8].

Anaphylactoid reactions may occur with acetylsalicylic acid, nonhormonal anti-inflammatory drugs, iodide contrasts, angiotensin-converting enzyme (ACE) inhibitors, and fluorescein [7].

During general anesthesia, anaphylactic and anaphylactoid reactions may occur. These are difficult to differentiate because of the large amount of medications used, such as anesthetics, muscular relaxants, analgesics, nonhormonal anti-inflammatories, and antibiotics [7].

Their clinical emergence tends to occur suddenly, within 30-min to 1-h intervals after contact with the precipitating factor, although delayed reactions are rarer. They show an appearance of pruritus, urticaria (Fig. 26.2), rhi-

Fig. 26.2 Acute urticaria

noconjunctival symptoms, angioedema symptoms (especially laryngitis), hypotension, and lung sounds [7]. The following ailments may be observed: abdominal pain, diarrhea, vomiting, uterine contraction, and cardiac arrhythmia. After a few hours symptoms may reappear during a late phase, although this is by no means automatic [4, 7].

Patients with anaphylaxis must be identified as fast as possible, and treatment must be initiated immediately [8]. This reduces the risk of fatal reactions [8]. The following are signs of anaphylaxis that pose a risk to life: presence of stridor, edema of the glottis, intense dyspnea, lung sounds, hypotension, cardiac arrhythmia, shock, convulsions, and loss of consciousness [7, 8]. In patients using β-blockers, anaphylaxis is often severe and may be resistant to conventional treatment [8].

Various conditions must be considered in the differential diagnosis when suspecting anaphylaxis [8]: cardiac arrhythmias, acute myocardial infarction, food aspiration, convulsive disease, reaction to insulin, pulmonary embolism, syndrome etiology (e.g., the presence of carcinoid tumors or reaction to alcohol and chlorpropamide), hysterical behavior, vasovagal reactions, and fictitious allergic reactions. Vasovagal reactions are most often confused with anaphylaxis [8]. In general they are consequences of procedures such as injections, which present as a clinical condition consisting of facial paleness, nausea, profuse sweating, and syncope, with symptoms improving without treatment 20 to 30 min later [8]. Absence of pruritus in the presence of a slow pulse and normal blood pressure distinguish vasovagal reactions from anaphylaxis [8].

The treatment of anaphylaxis consists of short- and long-term measures [8]. The immediate goal is to maintain the permeability of the airways and blood pressure, in addition to administering oxygen in more severe cases [8]. Epinephrine must be administered as soon as possible, with a standard dose of 0.01 mg/kg of a 1:1,000 solution, up to a maximum of 0.3–0.5 ml, subcutaneously every 10–20 min until the patient is stabilized.

Erythroderma

This is a condition characterized by a state of generalized erythema and scaling (exfoliative dermatitis) of the skin. It has the morphologic appearance of various cutaneous diseases such as psoriasis, atopic dermatitis, T-cell cutaneous lymphoma, and reactions to drugs [9].

The dissemination of a maculopapular condition caused by medication may lead to the emergence of an erythrodermic syndrome. Various types of drug-induced cutaneous reactions (including contact dermatitis, photosensitivity, and maculopapulous reactions) would be responsible for roughly 7.3% of erythroderma cases [10].The secondary drug-induced erythroderma conditions, as opposed to erythrodermas resulting from other etiologies, most often set in quickly and also tend to regress quickly after withdrawal of the medication being used [10].

Pruritus arises 1–4 weeks after starting drug use, in association with diffuse erythema covering roughly 90% of the body surface, followed by lymphadenopathy and scaling. When acute, large amounts of epidermis are exfoliated; when chronic, it produces small elements [9] (Fig. 26.3). Pruritus and a sensation of diffuse burning occur [9].

Exfoliative dermatitis leads to systemic complications such as hydroelectrolytic and thermoregulatory disturbances, high cardiac insufficiency, tachycardia, capillary leak syndrome, and infection [11–13]. The effect of
Fig. 26.3 Exfoliative dermatitis (erythroderma)

exfoliative dermatitis on the organism depends on the intensity and duration of the process [13].

Common laboratory findings in the erythrodermic state include light anemia, leukocytosis with eosinophil, high IgE, an increase of the hemosedimentation process, a drop in serum albumin, and a rise in uric acid [9, 13]. Increased IgE and eosinophil is a nonspecific finding and is found only in secondary drug-induced erythrodermas, although it might also be due to atopic dermatitis [9, 13].

Multiple cutaneous biopsies performed simultaneously on distinct points of the skin might increase the accuracy of the diagnosis of the base disease [9]. In drug reactions vacuolar alterations may be observed on the epidermis, as well as necrotic keratinocytes [9].

The initial treatment of drug reaction in an erythrodermic patient is identical to that for erythrodermas of other causes [9, 13]. Suspending the drug is the quickest way to improve the patient's condition. One ought to consider the nutritional state and hydroelectrolytic replacement, as well as administering local measures such as antiseptic baths, humid compresses on the crusts, application of soft emollients, and low-strength corticosteroids [9].

Classic oral antihistamines may be prescribed to alleviate the pruritus and anxiety. They provide the patient with a warm and humid environment so as to prevent hypothermia and improve cutaneous hydration [9, 13].

Symptoms and signs of cardiac and respiratory insufficiency may require emergency assistance and hospitalization [9]. The most aggressive and debilitating erythrodermic states may require care similar to that offered to SJS or TEN patients.

The differential diagnosis must be performed with other types of secondary erythrodermas to cutaneous diseases, such as psoriasis, contact dermatitis, seborrheic dermatitis, lichen planus, bullous pemphigoid, and pemphigus foliaceus, as well as systemic diseases such as leukemias, T-cell cutaneous lymphoma, and Hodgkin's lymphoma, in addition to erythrodermic states secondary to internal cancer [9, 13].

Clinical Spectrum of Stevens–Johnson Syndrome and Toxic Epidermal Necrolysis (Lyell's Syndrome)

What currently exists is a combination of concepts according to which spectrum of erythema multiforme (EM), including EM minor and EM major (EMM), is separated from another spectrum of reactions, which includes SJS and TEN (Lyell's syndrome), referred to here as the SJS/TEN spectrum [14–17].

However, according to Assier et al. [18], it seems possible to separate EMM patients from true SJS patients based on clinical symptoms and disease origin. These authors define the EMM pattern as consisting of characteristic mucous erosions and cutaneous lesions (typical targets, with or without blisters), symmetrically distributed and commonly acral. SJS would be represented by mucous erosions and disseminated cutaneous purpuric macules that are frequently confluent, with a positive Nikolsky sign and epidermal scaling limited to less than 10% of the body surface [14, 18]. EM would include recurrent, postinfectious cases (especially related to herpes simplex and mycoplasma), or eventually related to exposure to medication, with a low mortality rate and without lethality. On the other hand, SJS would comprise a severe ADR with high mortality rates and a reserved prognosis for many cases [4, 14, 19].

In 1993, Bastuji-Garin et al. [19] put forward a clinical classification of the spectrum that included ME bullosa up to TEN. To better understand this classification [19], we note the characteristics of the dermatologic lesions of which the group consists, defined as follows:

- Epidermal detachment: refers to epidermal loss, which at times occurs in flaps (Fig. 26.4).
- Typical targets: lesions less than 3 cm in diameter, in disc shape, with well-defined borders, and exhibiting at least three distinct zones, namely two concentric halos around a central disc (Fig. 26.5).
- Atypical flat targets: lesions that are not raised, but are round or disc shaped, with two zones and/or borders that are not well defined.

- Atypical raised targets: round or disc-shaped lesions, palpable or raised, but without the two zones and/or well-defined borders.
- Macules/spots: erythematous or purpuric stains, irregularly shaped or confluent, with or without blisters (Fig. 26.6).

Insofar as the area of epidermal necrolysis makes up one of the two main factors of prognosis, a consensus was reached on classifying the spectrum [14, 19]: (i) SJS in cases with mucous erosions and disseminated purpuric macules and scaling of the epidermis below 10%; (ii) SJS/TEN superposition or transition in cases with epidermal scaling between 10%

Fig. 26.4 Epidermal detachment in TEN

Fig. 26.6 Purpuric macules found in TEN and SJS
Fig. 26.5 Typical targets in the erythema multiform spectrum

and 30% of the body surface; and (iii) TEN in cases with disseminated purpuric macules and epidermal scaling above 30%; or (iv) in rare cases with disseminated necrolysis (over 10% scaling) without any of the lesions described above.

Stevens–Johnson Syndrome

SJS is an entity characterized by the presence of lesions similar to those of EM, but with purpuric macula and widely distributed blisters or even lesions in atypical targets dispersed over the dorsal aspect of the hands, palms, soles of the feet, extensor region of the extremities, neck, face, ears, and perineum; the face (Fig. 26.6) and trunk (Fig. 26.7) are prominently involved [4]. Incidence of SJS is estimated at roughly one in three cases per million residents yearly [20–22].

SJS may be preceded by a discrete maculopapulous eruption similar to exanthema morbilliform [19]. Blister formations are possible, though usually not determined by an epidermal detachment of over 10% of the body surface [4, 14, 19]. Mucous involvement occurs in roughly 90% of cases, generally on two distinct mucous surfaces; this may precede or follow cutaneous involvement [4, 14, 19]. Onset begins with enanthema and edema, which give rise to erosions and pseudomembranous formations on the eyes, mouth, genitals, pharynx, and upper airways [19]. Some 10–30% of cases occur with fever and lesions in the gastrointestinal and respiratory tracts [4]. Its prognosis seems to not be affected by the type and dose of the drug responsible, nor by human immunodeficiency virus (HIV) infection [4].

The therapeutic options for SJS are limited and controversial [4, 23, 24]. Corticosteroids are frequently used [25], although some cases have not shown a satisfactory response [24]. In agreement with most authors, the use of systemic corticosteroids on the initial SJS and TEN forms do not currently demonstrate any proven benefits. The advanced forms of this spectrum of relations

Fig. 26.7 Purpuric macules in SJS

have clearly deleterious effects on the patient [26]. The treatment and prognosis of SJS are tackled in combination with that of TEN.

Toxic Epidermal Necrolysis or Lyell's Syndrome

TEN is an entity characterized by extensive scaling of the epidermis in the wake of necrosis (epidermal necrosis) [4, 14, 15]. The term "toxic epidermal necrosis" was introduced by Lyell in 1956 [14]. Fortunately, it consists of a very rare adverse reaction to drugs. In Europe, its incidence is estimated to be at 1.1 [4] cases per million residents yearly [26].

In AIDS patients, however, the risk of this reaction does rise, estimated at one case in every 1,000 patients yearly [14]. In general, there is a slight predominance among women (1.5–2 cases in females for every male case). Indeed, the disease's occurrence in AIDS patients ends up balancing out the incidence rate between the sexes [14].
Fig. 26.8 Toxic epidermal necrolysis (TEN)

Fig. 26.9 TEN resulting from cephalexin

The initial characteristics of TEN are nonspecific influenza-like symptoms, such as fever, sore throat, coughing, and burning eyes. These are considered prodromic manifestations preceding a cutaneous and mucous affection by 1–3 days [4]. An erythematous eruption emerges symmetrically on the face (Fig. 26.8) and the upper part of the trunk, extending to the craniocaudal region and provoking symptoms of burning or painful skin [4, 14].

The individual cutaneous lesions are, for the most part, characterized by erythematous macules with poorly defined contours and a purple center. They progressively spread over the anterior thorax and back [4, 14]. Less commonly, the initial eruption may consist of an extended scarlatiniform exanthema. In roughly 2–5 days or, at times, within a few hours, or more seldom in about a week, complete extension of the cutaneous condition occurs [14]. At first, some cases may present lesions persisting in sun-exposed areas of the skin [14]. The apex of the process consists of characteristic denuding of the necrotic epidermis, standing out as veritable red strips or flaps on the areas affected by the base erythema (Fig. 26.9) [4, 14].

The epidermis is raised by the serum content of flaccid blisters, which are progressively confluent and provoke rupture of the blisters and detachment of the skin. This causes an aspect of severe burns on the patient's skin, with the skin denuded, bleeding, and with an erythematous-purple color, as well as continued elimination of serosity, which contributes to hydroelectrolytic unbalance and accentuated protein loss [4, 14]. The Nikolsky sign is positive over widespread areas of the skin [4, 14].

The areas of the skin subjected to pressure, such as the lower shoulders, back, and buttocks, are the first to release epidermal flaps [4, 14]. Cutaneous extensor affection might determine a state of acute cutaneous failure [15, 27]. The cutaneous surface can virtually be 100% affected, although scalp affection is exceptional [14].

The mucous membranes are affected in 85–95% of patients, commonly preceding skin involvement by a day or two [14]. In the order of frequency, the disease afflicts the oropharynx, eyes, genitalia, and anus [14]. Extensive and painful erosions lead to labial crusts, salivation, feeding obstruction, photophobia, and painful urination and evacuation [14].

Severe eye sequelae, with the formation of synechiae between the eyelids and conjunctiva by pseudomembranous conjunctival erosions, and blindness may occur [4, 14]. Ceratitis and corneal erosions have been reported, as well as a secondary sicca-like syndrome [14].

High fever or hypothermia may occur because of a thermoregulatory imbalance until complete healing, even in the absence of concomitant infections [14]. The abrupt drop in temperature is more indicative of sepsis than of fever itself [14]. Psychomotor agitation and

mental confusion are not uncommon, and usually indicative of hemodynamic complications and sepsis [14]. Many internal organs are affected by the same pathologic process that involves the skin and determines a spectrum of systemic manifestations [4, 14].

Systemic involvement occurs, causing erosion in the esophagus and gastrointestinal tract, which may progress to esophageal constrictions, transaminase increases in 50% of cases (hepatitis in 10%), pseudomembranous colitis, and pancreatitis [23]. In the respiratory tract tracheobronchial erosions and secondary pulmonary interstitial edema, with the correction of hypovolemia, can be found [15]. Anemia can be constantly observed, as well as lymphopenia in up to 90% of patients [15]. Thrombocytopenia is found in 15% of patients; neutropenia occurs in 30% of cases, and when present indicates a worse prognosis [15, 23].

The medications most commonly causing TEN are sulfas, phenobarbital, carbamazepine, dipyrone, piroxicam, phenylbutazone, aminopenicillin, allopurinol, and nevirapine. However, it is necessary to consider that new drugs are continually being reported as triggering TEN [4, 14, 15, 23].

Considerations on the Physiopathology of SJS and TEN

The exact mechanism by which SJS and TEN develop is not well defined.

Some authors have suggested the participation of the altered metabolism of drugs with the predominance of a slow acetylator genotype in SJS and TEN patients, and a deficiency in the mechanisms involved in detoxification of reactive intermediary metabolites [28–30].

In addition to the metabolic mechanisms, there is evidence to suggest that, especially in TEN, the epidermal necrosis is mediated immunologically [4, 14, 30]. It is known today that SJS and TEN are disturbances mediated by T cells, similarly to acute graft-versus-host disease (GVHD), with cytotoxic T cells being responsible for the epidermal necrosis through an apoptosis in keratinocytes [14, 30].

Posadas et al. [31] have shown the association of high tumor necrosis factor α (TNF-α) levels with the severity of the reaction. This cytokine has been related to an induction in the adhesion and activation of T cells and monocytes. It also participates in apoptosis, irrespective of the action of perforins [31]. It has been demonstrated also that apart from TNF-α, the perforins granzyme B (GRB) and Fas ligand (FasL) are found to be high in the initial stages of a drug reaction, particularly in SJS and TEN. This reinforces the hypothesis of the participation of cytotoxic mechanisms [31]. Nowadays, cytotoxic reaction caused by granulosin liberation from T cells is the major mediator involved in cell apoptosis, and the spectrum of SJS/TEN is grouped in Type IVc of immune reactions, as classified by Pichler.

Correia et al. [32] have observed a similar seric cytokine profile between TEN and acute GVHD. These authors showed a significantly high serum level of interleukin (IL)-6 and IL-10 in TEN and acute GVHD patients as opposed to normal blood donors [32]. IL-6 is a multifunctional proinflammatory cytokine produced by various cells, including keratinocytes. It consists of a main circulating endogenous pyrogen [32]. This explains the presence of fever that is unrelated to the infection in the first days of TEN and GVHD [32]. In turn, IL-10 is an endogenous antipyrogen agent. It is produced by keratinocytes with the purpose of blocking inflammatory cytokines such as IL-1, IL-6, and TNF-α, in addition to being a powerful suppressant of macrophage, T-cell, and natural killer cell functions [32].

By contrast, as IL-10 recruits CD8+ lymphocytes from the peripheral blood, its increase in blister fluid explains the high number of these cells in patients' epidermis [32] .The elevation of IL-10 creates a natural mechanism against excessive tissue inflammatory reaction [32].

Chosidow et al. [33] have suggested that the cellular cytotoxic targets are viral antigens with a potential to alter immune responses resulting from exposure to medications.

Considerations on Treating SJS and TEN

Treatment for SJS and TEN patients is similar to that for patients who have suffered extensive burns, with a number of rare exceptions [23]. All patients have to submit to cutaneous biopsy to confirm the diagnosis [23]. The patient must be observed in an intensive therapy unit, in an isolated and heated environment so as to avoid any cutaneous trauma [4, 14, 23]. The treatment must proceed by suspending any drug that is not essential to the patient's life and begin replacement of intravenous fluid, mainly when an oral mucous lesion obstructs liquids from being ingested [4, 14, 23]. Isolation and feeding must be carried out through the nasogastric probe because the patient shows calorie and protein loss [4, 14, 23].

Corticosteroids should only be administered within 48 h of the condition's onset. It has not proved to be beneficial after this period because of its delaying epithelialization and increasing protein catabolism, in addition to increasing the risk of infection [23, 26].

Antibiotic therapy has to be administered to cases whereby a sudden drop in temperature occurs and with a concomitant drop in the general status or increase of cultivated bacteria on the skin with a predominance of a single strain [23, 26]. It must be emphasized that during the first days, the most common infections are by *Staphylococcus aureus* and later by Gram-negatives (*Pseudomonas aeruginosa*) or *Candida albicans* [23].

Noncontrolled reports and studies on the treatment of TEN exist, reporting the use of intravenous immunoglobulin, cyclosporine, cyclophosphamide, plasmapheresis, and anticytokine monoclonal antibodies, among others, in an attempt to curb the process of epidermal necrosis. The value of these studies has been questioned, however, particularly owing to the fact that in most patients who are hospitalized the phenomenon of necrosis virtually comes to a halt [15].

Prins et al. [34] published a multicenter, retrospective study on intravenous immunoglobulin use in treating TEN patients, which obtained excellent results. A 48-patient cohort, average age 43 years (±24) and consisting of 24 women and 24 men, with a 10–95% variation of epidermal detachment of the total body surface area, was treated. Mucous membrane was affected in 91.7% of these patients. The patients received intravenous infusion of gammaglobulins begun on average 7 days after onset of TEN (with a variation of 2–30 days). It was administered over a period of 1–5 days, in doses varying from 0.65 to 5.8 g/kg (mean total dose of 2.7 g/kg). An objective positive response to treatment occurred with a break in the progression of TEN, observed in 43 (90%) of the 48 patients. In all there were six deaths. The authors concluded that early use of intravenous gammaglobulin is safe, with a recommended dose of 1 g/kg daily for 3 days in a row. In contrast to the studies of Prins et al. [34], a French group (Bachot, Revuz, and Roujeau) led a noncomparative prospective study of 34 patients diagnosed with SJS (nine patients), SJS/TEN overlapping (five patients), and TEN (20 patients). They concluded that intravenous gammaglobulin in a 2-g/kg daily dose, administered for 2 days in a row, did not reduce patient mortality [35].

Until such discrepancies in the results have been cleared up, intravenous gammaglobulin use in treating TEN will remain controversial [36]. However, as the volume of data encourages its application and effective alternative therapies remain lacking, it seems difficult to not suggest a high dose of intravenous gammaglobulin, especially as a way of intervening early in quickly progressing TEN cases.

Considerations on the Prognosis

Whereas mortality rate is low for EMM (<1%) and SJS (roughly 5%), it is above 40% for TEN patients with macules [37]. The mortality rate

Chart 26.2 SCORTEN grade for TEN prognosis on hospital admission

Prognostic factors	Parameters	Estimated mortality related to point score
Age	≥40 years old	1 (3.2%)
Heart frequency	≥120 bpm	2 (12.2%)
Cancer presence	Yes (1 point); No (0 points)	3 (35.5%)
Percent of epidermal detachment over total body area	>10%	4 (58.3%)
Serum urea (BUN)	>28 mg/dl or >10 mmol/l	≥5 (90.0%)
Serum bicarbonate	<20 mEq/l	
Serum glucose	>14 mmol/l (or >252 mg/dl	

rises with age range and increased surface area of the epidermal scaling [37].

We reiterate the classification methodology adopted by multicenter studies, prospectively named SCARD (Severe Cutaneous Adverse Reactions). The results of the latter were recently published based on the analysis of 552 patients and 1,720 controls [38]. This classification system (named SCORTEN) is summarized in Chart 26.2.

Despite the large range and amount of drugs that may pose a great risk of contracting SJS and TEN, an annual risk rate of five cases per year among medication users has not been exceeded [39, 40].

Drug Hypersensitivity Syndrome: DRESS (Drug Rash with Eosinophilia and Systemic Symptoms) [41–43]

DRESS syndrome is an acronym derived from the term "Drug Rash with Eosinophilia and Systemic Symptoms" coined by Bocquet et al. Also known as drug-induced hypersensitivity syndrome (DIHS), it was first recognized in 1950 by Chaiken in a patient using an anticonvulsant. There are many synonyms used, most of them referring to the origin of the drugs involved in the drug reaction, such as dapsone syndrome, allopurinol hypersensitivity syndrome or the anticonvulsant hypersensitivity syndrome. Although a

dermatosis is usual in DRESS, the extent of skin involvement is variable and therefore the "R" in DRESS was subsequently changed from "rash" to "reaction."

Clinically, in its complete form, this syndrome includes an extensive mucocutaneous rash, fever, lymphadenopathy, hepatitis, and hematologic abnormalities with eosinophilia and atypical lymphocytes, and may involve other organs with eosinophilic infiltration, producing damage in several systems, especially in kidney, heart, lungs, and pancreas. This multivisceral involvement differentiates DRESS from other common skin reactions to drugs. Another unique feature of this syndrome is its late onset in relation to the period of introduction of the causative drug, i.e., at around 3 weeks to 3 months, and its possible persistence or worsening despite the withdrawal of the offending drug.

Incidence

The incidence of this syndrome is estimated to vary from one case among 1,000–10,000 drug exposures. Adults are more affected than children, and although the precise incidence of drug reaction has not yet been determined, it is much more common than SJS, which has an incidence of 1.2–6 cases per million person-years, and most cases are sporadic, with no gender predilection. Recognition of this syndrome is of paramount importance, since the mortality rate is about 10–20% and a specific therapy may be necessary.

Etiopathogenesis

The exact mechanism of DRESS/DIHS remains to be determined but, in cases related to anticonvulsant drugs, three components are considered: (i) deficiency or abnormality of the epoxide hydroxylase enzyme that detoxifies the metabolites of aromatic amine anticonvulsants (metabolic pathway); (ii) associated sequential reactivation of herpesvirus family; and (iii) ethnic predisposition with certain human leukocyte antigen (HLA) alleles (immune response).

Drugs Involved and Metabolism

This type of reaction is most commonly seen using seven different drug groups: (i) anticonvulsants, such as the aromatic anticonvulsants (phenytoin, carbamazepine, phenobarbital, primidone), mexiletine, lamotrigine, valproate, ethosuximide, and zonisamide; (ii) antidepressants (desipramine, amitriptyline, fluoxetine); (iii) sulfonamides and sulfones (dapsone, sulfasalazine, trimethoprim-sulfamethoxazole, salazosulfopyridine); (iv) anti-inflammatory drugs (piroxicam, naproxen, diclofenac, sundilac, phenylbutazone, ibuprofen); (v) anti-infectives (abacavir, cidofovir, terbinafine, nevirapine, minocycline, linezolid, doxycycline, telaprevir, nitrofurantoin, zalcitabine, spiramycin, metronidazole, piperacillin-tazobactam, ceftriaxone); (vi) angiotensin-converting enzyme inhibitors (captopril, enalapril); and (vii) β-blockers (atenolol, celiprolol). Cases have been reported with allopurinol, gold salts, thalidomide, calcium channel blockers (diltiazem), ranitidine, sorbinil, azathioprine, dobutamine, methimazole, propylthiouracil, and efamizulab.

The cases more consistent with DRESS/DIHS were caused by aromatic anticonvulsants, dapsone, salazosulfopyridine, allopurinol, and minocycline. Other drugs causing less typical cases are reported in the literature, but less frequently. Aromatic anticonvulsants have an estimated occurrence of DRESS/DIHS of one case for every 5,000 people exposed to the drug, and the reaction is especially common among black patients. The aromatic anticonvulsant drugs that have been associated most frequently with DRSS/DIHS are phenytoin, phenobarbital, and carbamazepine. However, newer anticonvulsant medications also containing aromatic structure (felbamate, oxcarbazepine, zonisamide, and lamotrigine) can also be involved, and the cross-reactivity between the various aromatic anticonvulsant drugs is well documented, varying between 40% and 80%. Nonaromatic anticonvulsant drugs (topiramate, levetiracetam, tiagabine, ethosuximide, valproic acid, and gabapentin) appear to be safe.

Cacoub et al. recently reviewed the literature of published cases of DRESS and found 44 drug-related out of 172 case reports published in the literature in PubMed/MEDLINE from January

Chart 26.3 Drugs reported as possible cause of DRESS/DHIS

Drugs related to DRESS
Abacavir
Allopurinol
Amoxicillin plus clavulanic acid
Amitriptyline
Atorvastatin
Aspirin
Captopril
Carbamazepine
Cefadroxil
Celecoxib
Chlorambucil
Clomipramine
Clopidogrel
Codeine phosphate
Cotrimoxazole/cefixime
Cyanamide
Dapsone
Diaphenylsulfone
Efalizumab
Esomeprazole
Hydroxychloroquine
Ibuprofen
Imatinib
Lamotrigine
Mexiletine
Minocycline
Nevirapine
Olanzapine
Oxacarbamazepine
Phenobarbital
Phenylbutazone
Phenytoin
Quinine and thiamine
Salazosulfapyridine
Sodium meglumine ioxitalamate
Sodium valproate/ethosuximide
Spironolactone
Streptomycin
Strontium ranelate
Sulfasalazine
Sulfamethoxazole
Tribenoside
Vancomycin
Zonisamide

1997 to May 2009. In about one-third of cases, the aromatic anticonvulsant drugs were more related to the onset of ADR (Chart 26.3).

Some patients experience a prodrome of flu-like symptoms about 4 weeks before the clinical reaction. There are reports of DRESS/DIHS even in patients using anticonvulsants for about 40 years.

The pathogenic mechanism of idiosyncratic reactions to drugs, such as DRESS/DIHS, has not been fully elucidated. Sullivan and Shear proposed a multifactorial model for the pathogenesis of DRESS/DIHS. Its occurrence would be determined by the combination of exposure to a drug capable of causing adverse reaction given in sufficient dosage and period of use to a susceptible patient.

A certain group of drugs associated with DRESS/DIHS, including the aromatic anticonvulsants, is metabolized to reactive oxygen intermediates that appear to be inefficiently detoxified in patients with acquired or pharmacogenetic variations in the metabolism of these drugs.

Aromatic anticonvulsants such as carbamazepine, phenytoin, and phenobarbital are metabolized by the hepatic cytochrome P450 enzymes and undergo oxidation by aromatic hydroxylation, with subsequent formation of arene oxides. Arene oxides are toxic reactive intermediates that are normally enzymatically converted to nontoxic metabolites by epoxide hydroxylase or glutathione transferase. In addition, spontaneous conversion to nontoxic phenol derivatives can occur. In cases of defective or deficient epoxide hydroxylase, arene oxides can accumulate and cause direct cellular toxicity or immune response (Fig. 26.10).

Drug interactions can be important in this syndrome. Concomitant use of lamotrigine and valproic acid increases the occurrence of the syndrome. It is thought that the mechanism for this drug interaction is the competition between valproic acid and lamotrigine for hepatic metabolism by glucuronidation, which doubles the half-life of lamotrigine and predictably would increase the possibility of adverse effects.

Positive patch tests and testing of blast transformation of lymphocytes indicate the presence of an immune reaction in which T cells participate in specific core function. Clones of drug-specific T cells have been isolated from patients sensitive to carbamazepine and lamotrigine.

Sequential Reactivation of Herpesvirus in DRESS/DIHS

Several clinical similarities that could be observed between DRESS/DIHS and infectious mononucleosis (IM) have led researchers to implicate a possible range of viruses as triggers for this syndrome. In addition, unique features of this syndrome are its late onset in relation to the period of introduction of the causative medication and frequent clinical and laboratory deterioration, as well as episodes of exacerbation despite the withdrawal of the offending drug, so that these characteristics are not necessarily typical of a reaction of specific drug etiology.

Although there are conflicting views on the pathogenesis of DRESS/DIHS in different parts of the world, recent studies have suggested a close relationship between human herpesvirus 6 (HHV-6) and the development of DRESS/DIHS.

Sporadic reports have shown that not only HHV-6, but also other herpesviruses such as HHV-7, Epstein–Barr virus (EBV), and cytomegalovirus (CMV), can be reactivated during the course of the DRESS/DIHS.

Results obtained with analysis by polymerase chain reaction showed that various herpesviruses are sequentially reactivated during the course of DRESS/DIHS in most patients. The cascade of viral reactivation is initiated by EBV or HHV-6 and extends over a period to HHV-7 and eventually to CMV [1]. In some patients, the clinical manifestations of this syndrome persist despite discontinuation of the drug involved, coinciding with the reactivation of herpesvirus, as shown in Fig. 26.11.

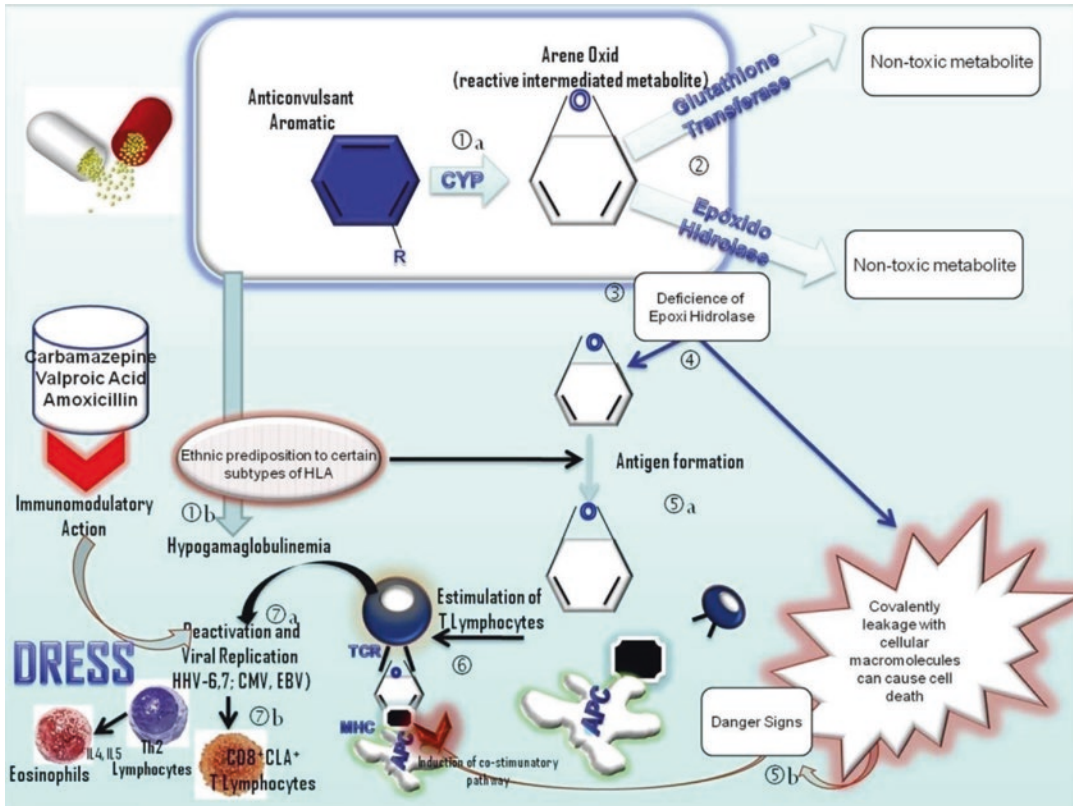
The reactivation of HHV-6 is evidenced by increases in the titers of IgG anti-HHV-6 DNA levels, and HHV-6 is commonly found in the second or third week after the onset of rash, despite the high variability of clinical manifestations among patients with this drug reaction. Since the reactivation of HHV-6 can be detected only in patients with DRESS/DIHS, but not other ADRs, in Japan this diagnostic test has become sensitive and specific for the diagnosis of all patients with DRESS/DIHS [7]. The detection of HHV-6 reactivation seems to be the gold-standard diagnostic test for DRESS/DIHS in Japan, with other Asian countries and Europe helping to confirm the identification of this condition.


Fig. 26.10 Sequence of events of drug-virus-immune system interaction in patients with DRESS/DIHS triggered by aromatic anticonvulsants. Aromatic anticonvulsants are metabolized by the oxidation system of cytochrome P450 in arene oxide radicals (intermediate reactive metabolite). (*1a*) These arene oxides are detoxified by glutathione transferase and epoxide hydrolase in nontoxic metabolites. (*2*) In genetically predisposed individuals or by additional factors, an impaired detoxification and accumulation of these metabolites occur (*3*), which can cause cellular damage generating danger signs that can stimulate resting T cells, inducing costimulatory pathways (*4*). In addition, ethnic predisposition to certain HLA types may contribute to the formation of neoantigens from the combination of these intermediary reactive metabolites with tissue macromolecules and formation of haptens (*5a*), which can be presented via the human histocompatibility complex class I (HLA-DR) or class II (HLA-A, -B or -C), to CD4 or CD8 T cells (*6*). It was demonstrated that carbamazepine, valproic acid, and amoxicillin are able to exert immunomodulatory actions by inhibiting histone decarboxylase on B lymphocytes, producing a hypogammaglobulinemia that precedes the clinical onset of DRESS/DIHS. The clonal expansion of T cells requires sequential reactivation of latent herpesvirus, and at the same time CD8$^+$ CLA$^+$ T cells are produced, which are directed toward skin, CD8$^+$ CCR4$^+$ T cells addressed to the lungs (*7b*), and CD4$^+$ IL-4, IL-5 producer and IL-17 CD4 Th17$^+$ producer that cause tissue and peripheral eosinophilia

However, it is still unknown how detection of the viral genome in peripheral blood reflects the true status of viral reactivation in progress in many different organs and systems. Specifically, it is possible that in different compartments and organs such as spleen and lymph nodes, different herpesviruses can reactivate in sequential order completely independent of what occurs in the blood, which would explain why blood samples negative for the viral genome are obtained during the clinical activity of DRESS/DIHS.

What remains unclear is the role of herpesvirus in early DRESS/DIHS. There are two possibilities:

(i) DRESS/DIHS began as an "allergic" immune reaction to a particular drug, which seems to possess an innate ability to stimulate T cells.
Fig. 26.11 DRESS (Drug Reaction with Eosinophilia and Systemic Symptoms)/DHIS: successive events since drug exposure, symptom onset, and viral replication

In the context of T-cell activation is a massive activation of herpesvirus housed in these cells, since the stimulation of T cells by the drug may reactivate the viral genome into the cell. Thus, the drug in turn can activate a specific cellular and humoral immune response to herpesvirus. This could explain why different herpesviruses are activated and because in another intense immune process, so-called GVHD, a similar reactivation can be observed.

(ii) The viral reactivation can occur but is initially clinically unapparent. However, T cells stimulated by virus present significant cross-reactivity with certain drugs, and exposure to these drugs leads to an expansion of T cells specific to the drug (and viruses), which persists even after drug withdrawal due to persistence of viral antigens. The simultaneous appearance of multiple concurrent viral reactivation could be explained by the ability of

HHV-6 and HHV-7 counterparts to reactivate virus. Thus, if the symptoms of DRESS/DIHS are mediated by both the various gene products and herpesvirus immune responses to viral replication, the frequent deterioration or the several exacerbations that occur despite withdrawal of the offending drug could derive, at least in part, from the sequential activation of this herpesvirus.

The viral reactivation may provide a "danger signal" (danger sign) that stimulates massive clonal expansion of both CD8[+] and CD4[+] non-specific T cells and causes the complete development of the syndrome. Shiohara et al. proposed the possibility that the clinical symptoms during the course of evolutionary DRESS/DIHS do not seem to be only mediated by oligoclonal expansion of drug-specific T cells, but also by antiviral T cells that cross-react with drugs.

Therefore, necessary for the occurrence of DRESS/DIHS are: (i) drugs; (ii) the virus; and (iii) their interrelationship with the immune system. A genetic predisposition has been linked to DRESS/DIHS.

How is HHV-6 acquired? HHV-6 infects almost all humans around 2 years of age. Most infections arise through the exchange of infected saliva during the first year of life, although perinatal transmission can occur. It was demonstrated that the DNA of HHV-6 can be integrated into the host DNA, and once part of the human DNA, congenital transmission can occur [7]. This was also demonstrated in the course of the DRESS/DIHS.

The temporal relationship between onset of drug use and the onset of DRESS/DIHS (3 weeks to 3 months) suggests that viruses have no primary function in the syndrome, favoring primary pathogenesis related to drug allergy.

Immune Aspects Involved in DRESS/DIHS

Patients with DRESS/DIHS have decreased total serum IgG, IgA, IgM, and B-lymphocyte count at onset, while there is an expansion of memory T cells that cross-react with both drug and virus. It is noteworthy that the lymphocyte transformation test is negative in the first week of illness and remains negative in 90% of patients 2 weeks after the onset of symptoms, becoming positive only 5–7 weeks after the initial drug reaction. This could be due to the expansion of regulatory T cells (which suppress the proliferation of memory T cells) in the early stages of the disease and its subsequent reduction by apoptosis.

Several cytokines are increased during DRESS/DIHS. In particular, levels of TNF-α and IL-6, which are typically proinflammatory cytokines, are elevated in this syndrome before the reactivation of HHV-6. Interestingly, IL-6 becomes undetectable during viral replication and increases again after the infection in most patients.

DRESS/DIHS is an entity distinct from other serious ADRs because of the dynamic changes in the immune response observed during the course of the disease. The phenotype of circulating CD4+ T cells is changed to CD8+ phenotype at the time of viral reactivation. Regulatory T cells are initially increased in number in the circulation and skin, but decrease in parallel the function of the different organs or systems.

The reactivation of HHV-6 is considered a condition requiring immunosuppression, demonstrated on several immune abnormalities in the early syndrome: marked decrease of serum immunoglobulins, the number of circulating B cells, and regulatory T-cell dysfunction.

Moreover, the participation of skin inflammation may be involved in the induction of immunosuppressive conditions. Sugita et al. demonstrated a reduction in the number of plasmacytoid dendritic cells (pDC) in peripheral blood of patients, but an increase in the expression of these cells in skin affected by the rash. The pDC human leukocyte subtypes are capable of producing large amounts of interferon-α (IFN-α), which induces the maturation of B cells in order to produce IgG and plays a critical role in antiviral defense. The pDC from circulation may accumulate in the skin and thus reduce the number of pDC in the circulation. Therefore, antiviral responses may be reduced, facilitating viral reactivation in peripheral blood and tissues other than the skin.

Although the terms DRESS and DIHS are often and mistakenly used interchangeably, there is currently a tendency to believe that the DIHS represents the most severe cases of DRESS, with reactivation of HHV-6 detected in a large majority of patients and only in a limited number of patients with DRESS [6].

Associations of HLA Alleles with DRESS/DIHS and Maculopapular Eruption Induced by Aromatic Anticonvulsants or Other Drugs (Pharmacogenomics)

The most popular hypothesis to explain the immunoallergic reactions to drugs is the theory of hapten/pro-hapten: according to this hypothesis, the drug (or metabolite) is processed by antigen-presenting cells (APCs) and expressed in the cell membrane in the context of HLA-A, -B, or -C type I (MHCI) or HLA-D type II (MHCII). The complex HLA drug (hapten) is presented to

native T cells (naive) via their T-cell receptor (TCR), which initiates different types of immune responses, depending on the HLA expressed on the APC and the cytokine environment.

The story of "HLA–drug" correlation truly began in the twenty-first century with abacavir. In 2002, two independent groups observed the abacavir hypersensitivity syndrome and that this was restricted to the allele HLA-B*5701, which conferred an elevated odds ratio (>100). GlaxoSmithKline (London, UK) led the largest international randomized pharmacogenetic clinical trial to date, which demonstrated the correlation between abacavir hypersensitivity reactions and patients with this allele, and proved that the exclusion of abacavir introduction to the patients with this allele resulted in the disappearance of the syndrome, which was first seen in 5% of patients overall who received the drug during the first weeks of antiretroviral treatment. This allele test is now routinely used before the introduction of abacavir in several countries.

The HLA alleles have a high negative predictive value but low positive predictive value in relation to ADRs, indicating that these biogenetic markers are necessary but not sufficient to trigger the allergic immune reactions. According to the theory of HLA–drug (hapten), the complex hapten only triggers an immune-allergic reaction in the presence of a specific HLA allele.

Thus, prospective HLA screening should prevent some patients from having serious idiosyncratic reactions such as DRESS/DIHS, SJS, and TEN if they have a specific risk allele by not receiving the drug related to it. HLA pharmacogenomics is a recent field of study that has been rapidly developed and implemented into clinical practice and has improved drug prescription, which is likely to become more and more important in coming years.

Besides causing SJS and TEN, carbamazepine also induces other types of ADRs, including maculopapular exanthema (MPE) and DRESS/DIHS. The association between HLA-B*1502 and carbamazepine-induced MPE was not detected in populations of ethnic Han Chinese and Hong Kong or Thai populations. Studies involving 18 Han Chinese residents in Taiwan and 56 Caucasians showed no association between cases of DRESS/DIHS caused by carbamazepine and HLA-B*1502. These data indicate that the association between HLA-B*1502 and cutaneous ADRs induced by carbamazepine are specific to SJS/TEN.

Kano et al. showed that in four of their 13 Japanese patients (30.8%) with DRESS/DIHS in whom reactivation of HHV-6 was proved, the syndrome was triggered by aromatic anticonvulsants (carbamazepine in ten, phenobarbital in two, and phenytoin in one) had HLA-B*1301. The frequency of this allele was much higher than in the Japanese population (1.3%). Although this difference was not statistically significant after correction for multiple comparisons, the authors proposed that the presence of certain alleles of HLA-B on the reactivation of the virus contributed, at least in part, to the association of HLA-B allele with DRESS/DIHS.

Kashiwagi et al. demonstrated a significant association between adverse skin reactions to carbamazepine and HLA-A*3101 among 22 Japanese patients, including erythema multiforme, erythroderma, DRESS/DIHS, SSJ, and other drug reactions. Eleven of these patients (50%), including two patients with SJS and others, were carriers of HLA-A*3101 and allele frequency was much higher in these patients (25%) than in the Japanese population (7.1%) ($p = 4 \times 10^{-4}$, odds ratio (OR) = 4.33).

In a case-control study in a Han-Chinese population a strong association between the presence of HLA-B*5801 and SJS/TEN, or DRESS/DIHS triggered by allopurinol among 51 patients (100%) was found, compared with 20 out of 135 (15%) allopurinol-tolerant patients and 19 out of 93 controls (20%) (p (Pc value $4.7 \times 10(-24)$, OR = 580).

Japanese patients with different clinical types of cutaneous ADRs caused by allopurinol, including SJS, TEN, and DRESS/DIHS, had the same HLA-B*5801 allele.

Pirmohamed et al. found an increased frequency of HLA-DR3 and HLA-DQ2 in a group of patients with carbamazepine-induced DRESS/DIHS (respectively $p = 0.01$, OR = 3.3; $p = 0.04$, OR = 2.7). It was demonstrated that activation of CD4+ T cells with IL-2 is essential for the spread

of HHV-6 in vitro. Genotyping of patients revealed that they had positive HLA-DR3 (DRB1*0301) and HLA-DQ2 (DQB1*0201).

Thus, in recent years increased attention has been given to genetic factors as a cause of variation in both the interpersonal effectiveness and adverse effects of medicines. Idiosyncratic reactions are often mediated through immune, usually severe, and unpredictable course. The main region of human DNA with genetic variations that predispose to drug hypersensitivity reactions is the region HLA. This region harbors the gene locus of most diseases and contains many genes associated with immune functions.

Although strong associations have been demonstrated between certain HLA alleles and some types of adverse skin reaction to drugs, there is no definitive evidence or published data concerning the functions involved in these alleles. The activation of T cells restricted to HLA is necessary for the induction of immune reactions and, moreover, there is the possibility that some HLA proteins have high binding affinity combined with other drugs or a metabolite of the drug through covalent and noncovalent mechanisms. On the other hand, a protective effect of HLA has also been suggested. Alfirevic et al. reported a potential protective effect of HLA-B*0702 against severe adverse skin reactions induced by carbamazepine in Caucasian patients.

The implications of pharmacogenomics are varied; one example is the recommendation of the US Food and Drug Administration (FDA), which currently recommends genetic testing for users of more than ten drugs currently marketed in that country.

Histopathology

Histopathology of the skin shows a diffuse, dense superficial and/or perivascular lymphocytic infiltrate. Eosinophils in the dermis or swelling may or may not be present (Fig. 26.12a). On some occasions there is a band-like infiltrate with atypical lymphocytes simulating epidermotropism such as mycosis fungoides.

Fernando et al. described a patient with DRESS/DIHS triggered by carbamazepine whose rash biopsy presented an unusual form of superficial perivascular inflammatory infiltrate, in which tiny granulomas along with a moderate number of lymphocytes were found. The authors speculated that granuloma formation may be due to a sustained exposure to the drug, even after the onset of DRESS/DIHS. The expansion of CD4+ T cells producing IFN and other cytokines results in recruitment of macrophages which, as a result of maintained exposure to the drug and persistence of cytokine release, promote differentiation into epithelioid cells, which then secrete TNF to promote fusion of these cells into multinucleated giant cells.

Thus, biopsies of organs involved in DRESS/DIHS, such as skin and liver, on a significant number of patients may demonstrate the true frequency of granulomatous infiltration in the disease and assist in understanding the pathogenesis of the reaction.

Symptoms and Signs

The syndrome usually develops within 2 months after drug introduction, more often in 3 weeks to 3 months of the introduction of the drug, or earlier if constituting readministration. Fever, often high (38°–40 °C), which is the most common symptom (seen in 90–100% of cases), and rash (87% of cases) are the first signs, especially when related to antiepileptic drugs. The cutaneous eruption consists of a morbilliform rash, which is indistinguishable from the rash of other less severe reactions (Fig. 26.12b, c).

The face, upper trunk, and upper extremities are initially affected, with subsequent progression to the lower extremities occurring in about 90% of cases, which later spreads to the legs and the development of erythrodermic rash.

The maculopapular eruption later becomes infiltrated with edematous follicular accentuation. Swelling of the face, with marked periorbital involvement, is a warning for the diagnosis, occurring in about 25% of patients, and can be so intense that the patient becomes disfigured.

Fig. 26.12 Clinical and histopathologic findings in a patient with DRESS caused by dapsone during leprosy treatment. (**a**) Epidermis showing spongiosis, apoptotic keratinocytes, exocytosis of lymphocytes, and inflammatory infiltrate in the superficial dermis (hematoxylin–eosin, ×200 OM); (**b, c**) Exanthema in DRESS in Caucasian woman
Vesicles may arise, and fine bubbles caused by edema of the dermis can be present. No necrosis of the epidermis such as TEN occurs, except in rare cases of overlapping DRESS/DIHS and TEN. Small sterile perifollicular pustules and nonfollicular pustules may appear, which are different from acute generalized exanthematous pustulosis and do not predominate on the main ridges of the skin. Often atypical targets may arise. Over time the rash becomes purplish, with sharp definition on lower limbs and the resolution of scaling Another form of presentation is a picture of exfoliative dermatitis, which may be associated with mucosal involvement, such as cheilitis, erosions, pharyngitis, and enanthematous enlarged tonsils.

Bilateral edema and infiltration of the salivary glands with xerostomia has been frequently reported.

Lymphadenopathy is common (70–75% of cases), limited to the lymph nodes or generalized, and painful, gradually resolving with the withdrawal of the drug. The lymph nodes may reveal two distinct types of involvement: a benign pattern of lymphoid hyperplasia with maintenance of normal lymph node architecture, and another

standard pseudolymphomatous aspect, with obliteration of normal architecture by a polymorphous infiltrate composed of atypical cells, plasma cells, histiocytes, and eosinophils, with areas of necrosis, edema, and mitotic figures but no Reed–Sternberg cells or capsular invasion. This histopathologic pattern can simulate a malignant lymphoma.

Various hematologic abnormalities are observed, which consist of marked leukocytosis, eosinophilia (30% of cases), and atypical lymphocytes similar to mononucleosis. These findings guide the diagnosis toward DRESS, but can sometimes be difficult to distinguish from viral infections such as infection by EBV or hematologic diseases. Lymphopenia, leukopenia, or leukocytosis usually precedes it, although they often are not detected because they occur several days before establishment of the clinical syndrome. Leukocytosis may be high, up to 50,000 leukocytes/mm^3, and eosinophilia reaches values higher than 20,000/mm^3. The eosinophilia may determine the involvement of internal organs with pulmonary infiltrates. In general, eosinophilia may be observed about 1–2 weeks after the onset of the syndrome, or may even occur after the increase in liver enzymes has normalized.

Hemophagocytic syndrome (HPS) can rarely be observed in the course of DRESS/DIHS. HPS is associated with and triggered by various conditions, including viral infections, particularly EBV, malignant tumors, or autoimmune diseases. When involved with the course of DRESS/DIHS, HPS usually occurs 2 weeks after the onset of drug eruption. There is a decrease in white blood cells and platelets that are detected simultaneously with elevation of lactate dehydrogenase (LDH). Bone marrow aspirate reveals hemophagocytosis in an increased number of macrophages.

Multiorgan involvement may include a wide variety of organs and systems with myocarditis/myositis, pericarditis, interstitial nephritis (11% of cases), necrotizing granulomatous vasculitis in kidney, brain involvement (encephalitis or meningitis), colitis, and thyroiditis. This potentially fatal visceral involvement form may be symptomatic or not, and begins 1–2 weeks after the onset of rash. We observed a patient who

developed acute pancreatitis that evolved into a lethal course.

There are reports of shock and respiratory distress syndrome with hypotension, pyrexia, hepatitis, and renal failure related to a hydantoin reaction.

Arthritis or arthralgia may occur in the context of this syndrome, including myositis.

Liver involvement is the most common visceral manifestation (50–60% of patients) after lymphadenopathy. Hepatomegaly may constitute a finding on physical examination. Hepatitis with isolated elevation of liver transaminases is common (51% of cases), usually anicteric, but liver failure is a leading contributory factor to mortality. Liver biopsy shows central lobular necrosis and dense inflammatory infiltrate of lymphocytes and eosinophils or granulomas. The reaction is accompanied by cholestasis and hepatocyte necrosis. In more severe cases, widespread or focal hepatic necrosis may be present. The presence of an active coinfection with hepatitis viruses B and/or C often determines deterioration in liver function and prolonged liver dysfunction.

There are few cases reported in the literature of DRESS/DIHS with severe acute hepatitis (defined by the presence of alanine aminotransferase (ALT) to more than 10× upper limit of normal and/or acute liver failure, such as coagulopathy and encephalopathy), mostly observed in women between the second and fourth decade of life, especially in relation to the use of sulfasalazine. About 15% result in death or liver transplantation, and the course of the disease is apparently unchanged by the use of immunosuppressants. The rapid recognition of the syndrome and prompt withdrawal of the drug can limit the liver damage, although this may be possibly even worse for several weeks and take months to resolve.

Renal involvement occurs in about 11% of cases, being particularly evident in cases arising from the use of allopurinol, whereby there was an increase in serum creatinine and urea and decreased creatinine clearance. In urine tests, increased content of eosinophils can be observed.

Although pulmonary involvement is rarely reported in DRESS/DIHS, interstitial pneumonia

with eosinophilia is often observed among patients whose syndrome was triggered by minocycline. Possibly the cases with lower intensity of pulmonary manifestations are less reported, leading to a bias in the published literature. Pulmonary complications include acute interstitial pneumonitis, lymphocytic interstitial pneumonia, and adult respiratory distress syndrome (ARDS).

Myocarditis may develop at the beginning of the syndrome or up to 40 days after establishment. Symptoms include heart failure, chest pain, sudden tachycardia, dyspnea, and hypotension in early DRESS/DIHS, but some patients are asymptomatic. The echocardiogram shows a reduction in ejection fraction, chest X-ray demonstrates cardiomegaly, and the electrocardiogram shows nonspecific changes in the ST-T segment. There is an increase in enzymes such as CPK and CK-MB, but no apparent changes in levels of troponin-1.

Neurologic complications include meningitis and encephalitis. Meningoencephalitis occurs about 2–4 weeks after initiation of drug reaction, and may lead to coma, seizures, headaches, disorders of speech, and paresis and paralysis of the cranial nerve.

Gastrointestinal bleeding may be an abrupt complication caused by ulcers derived from CMV. Endoscopic examination reveals arterial bleeding from punched-out gastric ulcerations.

Kennebeck compiled the frequency of clinical manifestations and laboratory data of the anticonvulsant hypersensitivity syndrome: fever (90–100%), cutaneous eruption (87–90%), lymphadenopathy (70%), hepatitis (50–60%), hematologic abnormalities (23–50%), periorbital and orofacial edema (25%), myalgia and arthritis (20%), nephritis (11%), pharyngitis (10%), and pulmonary manifestation (9%).

The visceral involvement in acute DRESS/DIHS until resolution of clinical disease is, therefore, extensive and varied, some of these events being closely related to HHV reactivation: enterocolitis and intestinal bleeding, hemophagocytic syndrome (HPS), hepatitis, limbic encephalitis, myocarditis, nephritis, mumps, pneumonia, pleurisy, and the syndrome of inappropriate antidiuretic hormone (SIADH).

The exclusion of other serious infections, particularly bacteremia, neoplastic diseases (lymphoma, leukemia, hypereosinophilic syndrome, paraneoplastic syndrome), and autoimmune or connective tissue conditions (adult-onset Still's disease, lupus erythematosus, vasculitis) is necessary for an accurate diagnosis of DRESS/DIHS.

Complications are rare and include limbic encephalitis, thyroid disease, renal failure, splenic rupture, eosinophilic colitis, eosinophilic esophagitis, enterocolitis, and fatal CMV.

The mortality rate can reach 20%, especially in cases related to advanced age, renal impairment, jaundice, and hepatitis with reactivation of CMV. By contrast, cases where there is a reactivation of EBV seem to have a less severe course, but are more likely to later (usually after several years) develop autoimmune diseases such as diabetes mellitus type 1 and autoimmune hypothyroidism.

Several authors have reported the occurrence of autoimmune diseases and/or the production of autoantibodies after the resolution of DRESS/DIHS, in a period ranging from several months or years after the resolution of the syndrome, and some are similar to those seen after bone marrow transplant. The related conditions include diabetes mellitus type 1, lupus erythematosus, Hashimoto's thyroiditis, enteropathy, sclerodermiform lesions, GVHD, and bullous pemphigoid.

Diagnostic Criteria

The diagnosis is difficult since there are incomplete or less characteristic clinical features, for example, hepatitis without rash, or merely pulmonary infiltrate with eosinophilia. Bocquet, Bagot, and Roujeau were the first authors who proposed criteria for DRESS diagnosis. According to these authors the diagnosis is established if there are at least three criteria present:

1. Drug rash
2. Hematologic abnormalities
   (a) Eosinophilia >1,500/mm^3
   (b) Presence of atypical lymphocytes

3. Systemic involvement (adenopathy (>2 cm in diameter) or hepatitis (transaminase elevation at least twice the normal values) or interstitial nephritis, pneumonitis, or carditis.

There is still no international consensus on the best criteria for the definition of DRESS/DIHS diagnosis. Bocquet et al. and Southeimer and Houpt have proposed different definitions and nosology for DRESS/DIHS in order to clarify clinical and pathologic characteristics of this syndrome.

The Japanese study group for severe cutaneous adverse reactions to drugs (SCAR-J) has adopted other criteria, as presented on Chart 26.4.

However, the universal adoption of these criteria may be impaired, because one of the criteria is viral replication during the course of infection, and some tests, such as measurement of IgG titer anti-HHV-6, are not yet routinely available in all hospitals or laboratories.

In our view, the criteria adopted by the European group RegiSCAR, published by Kardaun et al. in 2007, is the best to meet the needs in the diagnosis of DRESS/DIHS. Here the use of a system score for the diagnosis of DRESS/DIHS was suggested, based on the presence of symptoms and clinical and laboratory signs, as displayed in Table 26.1.

Complementary Tests During Follow-Up of Patients with DRESS/DIHS

Given the suspicion of the syndrome relevant examinations should be performed, keeping in mind that this syndrome has evolutionary behavior. The initial tests are oriented to verify the data and research into hematological visceral involvement, as proposed by Descamps et al. At admission: complete blood count, ALT, aspartate aminotransferase (AST), total bilirubin, γ-glutamyl transferase, alkaline phosphatase, sodium, potassium, creatinine and creatinine clearance, 24-h urine protein and urinary eosinophil count, CPK, LDH, ferritin, triglycerides, calcium and parathyroid hormone, blood glucose, prothrombin time and activated partial

Chart 26.4 Diagnostic criteria for DRESS/DIHS proposed by Japanese group

1. Maculopapular rash developing >3 weeks after starting therapy with a limited number of drugs
2. Persistent clinical findings after drug withdrawal
3. Fever (>38 °C)
4. Hepatic abnormalities (glutamic pyruvic transaminase >100 U/l)[a]
5. Leukocyte abnormalities (at least one present)
(a) Leukocytosis (>11,000/mm^3)
(b) Atypical lymphocytosis (>5%)
(c) Eosinophilia (>1,500/mm^3)
6. HHV-6 reactivation[b]

The diagnosis is confirmed by the presence of the seven criteria (typical DIHS) or of the first five criteria (atypical DIHS)

[a]This can be replaced by other organ involvement such as renal involvement

[b]Reactivation is detected from the second to third week after symptom onset, through IgG anti-HHV-6 titer elevation

thromboplastin time, lipase, protein electrophoresis, C-reactive protein, quantitative PCR for HHV-6, -7, EBV, and CMV, blood culture, and antinuclear factor.

Follow-up (two times per week): complete blood count, ALT, AST, creatinine, LDH, and other laboratory tests according to changes found on admission tests. Evolutive follow-up: quantitative PCR for HHV-6, -7, EBV, and CMV, complete blood count, ALT, AST, alkaline phosphatase, creatinine, LDH, ferritin, and triglycerides.

Treatment

The early recognition of ADRs and withdrawal of the offending drug is the most important and essential steps toward clinical improvement. Empiric treatment with antibiotics or anti-inflammatory drugs should not be administered during the acute disease, since they may confuse or worsen the clinical picture of patients because of an unexplained cross-reactivity between drugs.

Prognosis is generally worse in the elderly while the recovery is usually faster and usually complete in children.

For many years, the treatment of DRESS has been based on the use of systemic corticoste-

Table 26.1 Scoring system for classifying DIHS/DRESS cases as definite, probable, possible, or no case (Adopted by RegiSCAR (Register of Severe Cutaneous Adverse Reactions) [44])

Score	−1	0	1	2	Max	Min
Fever ≥38.5 °C	No/U	Yes			−1	0
Enlarged lymph nodes		No/U	Yes		0	1
Eosinophilia:		No/ U			0	2
Eosinophils			0.7–1.499 × 210^9 l^{-1}	≥1.5 × 10^9 l^{-1}		
Eosinophils, IF leukocytes <4.0 × 10^9 l^{-1}			10–19.9%	≥20%		
Atypical lymphocytes		No/U	Yes		0	1
Skin involvement					−2	2
Skin rash extent (% body surface area)		No/U	>50%			
Skin rash suggesting DRESS	No	U	Yes			
Biopsy suggesting DRESS	No	No/U				
Organ involvement*:					0	2
Liver		No/U	Yes			
Kidney		No/U	Yes			
Muscle/heart		No/U	Yes			
Pancreas		No/U	Yes			
Other organ		No/U	Yes			
Resolution ≥15 days	No/U	Yes			−1	0
Evaluation of other potential causes:						
Antinuclear antibody (FAN)						
Blood culture						
Serology HAV/HBV/HCV						
Chlamydia/mycoplasma						
*If none positive and ≥3 of above negative			Yes		0	1
Total score					−4	9

U unknown/unclassifiable, *HAV* hepatitis A virus, *HBV* hepatitis B virus, *HCV* hepatitis C virus

After exclusion of other explanations: *1* one organ, *2* two or more organs. Final score <2, no case; final score 2–3, possible case; final score 4–5, probable case; final score >5, definite case

*Organ involvement

roids (dose equal to or greater than 1–1.5 mg/kg/day of prednisone or equivalent) with marked improvement of symptoms and laboratory parameters only several days after the start of treatment. Systemic corticosteroids should have their dose reduced, after clinical and laboratory control of the disease, slowly over 6–8 weeks to prevent recurrence of the symptoms of disease. Abrupt deterioration of various symptoms is observed when the withdrawal is accidental or by rapid reduction of the dose of corticosteroids. Shiohara et al. recommend that all patients should be hospitalized even when the initial presentation is mild.

If symptoms worsen despite the use of oral corticosteroids, other options used in case series are the use of pulsed methylprednisolone (30 mg/kg intravenously for 3 days), intravenous immunoglobulin (IVIG), and plasmapheresis, or a combination of these therapies. It should be remembered that the immunosuppressive therapies may increase the risk of infectious complications and sepsis. Mild cases can recover simply by drug withdrawal and supportive treatment after a few weeks, even without the use of corticosteroids. However, even in mild cases, the monitoring of liver function tests should be conducted and appropriate tests ordered to rule out the involvement of other organs such as lungs, thyroid, and heart.

Special attention should be given to possible reactivation of CMV, especially in patients with severe DRESS/DIHS. Physicians should also pay attention to a proper balance between the needs of corticosteroids for relief of symptoms and

clinical signs and their possible negative influence on viral load.

High doses of IVIG have two immunologic effects: (i) it compensates for the decrease in concentration of immunoglobulins in patient's blood and the defects in immune protection against HHV-6; and (ii) high doses of IVIG have an anti-inflammatory effect that can regulate immune responses, as seen in the treatment of autoimmune diseases.

The French Society of Dermatology published the results of a consensus of experts on the therapeutic management of DRESS/DIHS regarding drug reactions:

- Absence of signs of gravity: corticosteroids (potent or very potent), emollients, H1-antihistamines
- Presence of signs of severity (transaminases >5 times normal renal organic, pneumonia, hemophagocytosis, cardiac, etc.): corticosteroids equivalent to 1 mg/kg per day of prednisone, multidisciplinary evaluation
- Life-threatening signs (hemophagocytosis with bone marrow failure, encephalitis, severe hepatitis, renal failure, respiratory failure): steroids generally associated with IVIG at a dose of 2 g/kg over 5 days. The IVIG should not be proposed without associated steroids. These treatments to be conducted through multidisciplinary evaluation
- Presence of signs of gravity with confirmation of a major viral reactivation: Combining steroids and antiviral (ganciclovir) and/or IVIG

Kano et al. reported the occurrence of herpes zoster in 3 of 28 patients with DRESS/DIHS within 6 months after the onset of DRESS/DIHS; all three patients had been given systemic corticosteroids and the ADR was triggered by anticonvulsants. The authors suggested that the administration of systemic corticosteroid for the treatment of DRESS/DIHS may have contributed to the increased risk of herpes zoster. Indeed, herpes zoster was not detected in patients with DIHS/DRESS who were treated with only supportive care. Presumably, the altered underlying immunologic pathomechanism of DIHS/DRESS caused by the systemic corticosteroid might have played an important role in the onset of herpes zoster. It has been shown that DIHS/DRESS is a manifestation of newly observed immune reconstitution syndrome (IRS), and herpes zoster is observed as the most common manifestation of IRS after highly active antiretroviral therapy for AIDS. Relevant clues related to DRESS syndrome include:

- DRESS/DIHS is an ADR caused by an apparent group of drugs, and one-third of cases are related to anticonvulsants, in addition to sulfonamides and allopurinol, which can cause 10–20% mortality.
- The syndrome is characterized by a latency period ranging between 3 weeks and 3 months after the introduction of the offending drug, and its course is marked by apparent sequential reactivation of HHV and subsequent development of autoimmune diseases, providing an opportunity to establish a connection between viral infections and the emergence of autoimmune diseases.
- In early DRESS/DIHS hypogammaglobulinemia and reduced peripheral B cells are found, and CD4+ CD25+ FoxP3+ (regulatory T cells) levels are high at the beginning of the syndrome, regardless of whether or not patients are treated with corticosteroids. This clonal expansion of regulatory T cells appears to prevent activation of antiviral T cells in an appropriate manner and sequential reactivation of virus is presented in the syndrome. These regulatory T cells have the phenotype CCR4+ and CLA+, which address the skin. In the last stage of the syndrome's activity, phenotype of cytotoxic T cells becomes prominent and CD4+ lymphocytes are intensely diminished. These cells are depleted over time, suffering apoptosis and becoming reduced after the resolution of the syndrome, which could be a predisposing factor for the development of autoimmunity.

Acute Generalized Exanthematous Pustulosis [45]

AGEP is a clinical entity that appears in the intertriginous areas or on the face as a diffuse erythema (scarlatiniform) with acute presentation. Patients

Fig. 26.13 AGEP. Several pinhead sterile pustules over erythematous skin
Fig. 26.14 AGEP. Detail of confluent pinhead pustules

report pruritus or local burning sensation. After this appearance, the erythema is replaced by hundreds of nonfollicular sterile small pustules (<5 mm in diameter) (Figs. 26.13 and 26.14). These pustules may sometimes converge and

mimic Nikolsky's sign, leading to misdiagnosis as TEN. Intense edema of the face may occur, with purpuric lesions mainly on the legs and the onset of lesions similar to EM of the legs.

There may be mucous involvement in about 20% of the patients, although it is usually mild and self-limited, occurring in just one location. The cutaneous symptoms are almost always accompanied by fever of >38 °C. Frequently there is leukocytosis in the blood count, and eosinophilia may also occur in one-third of the patients.

Usually this eruption regresses within 4–10 days after withdrawal of the drug and in typical cases leaves a lamellar or punctiform desquamation. Disease prognosis worsens when there is hyperthermia or infection of the lesions, and when it affects elderly individuals, who should be hospitalized.

The drugs described as a cause of AGEP are most frequently β-lactams (penicillin, cephalosporins), macrolides (azithromycin, erythromycin), cyclines (doxycycline), sulfonamides (trimethoprim, sulfasalazine), chloramphenicol, isoniazid, streptomycin, vancomycin, quinolones (ciprofloxacin, norfloxacin), itraconazole, terbinafine, allopurinol, carbamazepine, phenytoin, diltiazem, nifedipine, chromium picolinate, diclofenac, enalapril, disulfiram, furosemide, hydroxychloroquine, paracetamol, mercury, thalidomide, protease inhibitors, and bamifylline.

Sidoroff and et al. proposed some characteristics that might aid in the differentiation between pustular psoriasis and AGEP. In the latter, a history of psoriasis is rare, the lesions are most frequent in the cutaneous folds, the duration of the fever and the pustules is short, and there is usually a history of recent exposure to the drug; arthritis is rare.

Histopathology may show subcorneal and/or intraepidermal spongiform pustules, edema of the papillary dermis, vasculitis, exocytosis of eosinophils, and focal necrosis of keratinocytes (Fig. 26.15). On the other hand, in pustular psoriasis a history of psoriasis is common, the involvement is generalized, the duration of the fever and the pustules is longer, history of drug exposure is less frequent, arthritis occurs in about 30% of the patients, and histopathologic
Fig. 26.15 AGEP histopathology. Subcorneal pustule without psoriasiform epidermal hyperplasia

examination shows subcorneal and/or intraepidermal pustules, papillomatosis, and acanthosis of the epidermis.

Skin tests for late-phase reactions may be useful tools for identifying the etiologic agent of AGEP when the systemic readministration is potentially dangerous. Approximately 50% of the cases of AGEP present positive contact tests for the suspect drug, usually reproducing the lesion in both a clinical and histologic form.

Recently, Britschgi and colleagues demonstrated high expression of IL-8 in these patients. It is known that IL-8 is a chemokine with potent activity in the recruitment of neutrophils, which is produced by the keratinocytes and mononuclear cells of the cutaneous inflammatory infiltration. These authors concluded that AGEP might be the expression of a reaction whereby a cell bound to the drug triggers a drug-specific CD4$^+$ and CD8$^+$ immune response, which results in high expression of IL-8 (Type VId in the Pichler classification).

Drug-Induced Serum Sickness [45]

In 1905, Von Piquet and Shick described serum sickness in children treated with horse serum containing diphtheria antitoxin. More recently serum sickness has been observed in patients treated with horse antithymocyte globulin or vaccines of rabbit antihuman diploid cells. This constitutes a type III hypersensitivity reaction, mediated by immunocomplexes deposited on the walls of the vessels, activation of the complement, and recruitment of granulocytes.

It presents particular cutaneous manifestations: typically there is erythema in the lateral portion of the fingers and toes that precedes a more disseminated eruption (occurring in 90% of cases), which frequently is morbilliform (two-thirds of the patients) and sometimes urticariform. The presence of urticaria, leukocytoclastic vasculitis, and multiform erythema is rarely observed. In half of the cases there is visceral involvement [1]. The following clinical findings are common: fever, cutaneous eruption, constitutional symptoms, arthritis, and arthralgia.

The disease begins about 8–14 days after the initial exposure to the foreign protein. The drugs related with this type of manifestation are the heterologous sera and vaccines. Serum sickness-like reactions can also be caused by penicillin, cephalosporin, minocycline, propranolol, streptokinase, and nonhormonal anti-inflammatories. There are no data on the prevalence of this disease in Brazil, although reports of cases of this disease are not infrequent in the medical literature.

Fractions C3 and C4 of the complement are strongly decreased in serum sickness while they are usually normal in serum sickness-like reactions.

Treatment of the disease constitutes withdrawal of the drug allied to the use of systemic corticosteroids, in addition to antihistamines for symptomatic relief of pruritus when present. Careful observation of the clinical course of the patient's systemic involvement is imperative.

Drug-Induced Vasculitis [45, 46]

Several medications can induce a cutaneous vasculitis-type response, the histopathologic definition of which is the presence of inflammation and necrosis in the wall of the cutaneous blood vessels. Clinically it presents as tangible purpura or maculopapular purpuric eruption. This disease can also occur in the form of hemorrhagic blisters, urticaria, ulceration, nodules, Raynaud's disease, and digital necrosis. The same vasculitis

process can involve internal organs, such as the kidneys, liver, gastrointestinal tract, or the central nervous system, and any area of the tegument, including the mucous membranes and the palmar and plantar regions.

The disease develops about 7–21 days after initiating the drug; however there can be a longer time interval, and any medication instituted within the 2 months prior to the presentation should be considered suspect. Given the absence of confirmatory tests for this entity, one should value anamnesis and the correlation with drug exposure, which in general occurs 1–3 weeks before onset of the cutaneous picture. However, the exposure can have occurred in periods as disparate as 2 days to 9 years. Withdrawal of the drug leads to a rapid resolution of the picture, and systemic corticosteroids can benefit some patients. The process is usually solved without sequels.

The clinical, epidemic, and pathologic characteristics of drug-induced vasculitis have been little reported in the medical literature, since there is no consensus in the definition of this disease, with various revisions using different criteria for inclusion of cases. Vasculitis attributed to exposure to medicines is rare, but seemingly account for about 10–20% of dermal vasculitis cases. It is difficult to quantify the frequency with which drug-induced vasculitis is strictly cutaneous.

Clinical experience suggests that most of the cases are confined to the skin and have a self-limited course, although it can be associated with varied degrees of systemic symptoms including arthralgia, indisposition, and fever. Visceral involvement is well described and pathologically heterogeneous. Glomerulonephritis and interstitial renal disease, varied degrees of hepatocellular damage, and formation of granulomas in the liver have been described, besides involvement of the heart, lungs, and central nervous system. Furthermore, there are rare cases of drug-induced vasculitis with renal and hepatic involvement in the absence of cutaneous disease.

The drugs most frequently referred to in the literature, in the form of case reports or series studies, as causative of vasculitis are propylthiouracil, hydralazine, granulocyte colony-stimulating factor (G-CSF), cefaclor, minocycline, allopurinol, D-penicillamine, phenytoin, isotretinoin, and methotrexate.

As many of the cases of drug-induced vasculitis are not reported in the literature, other drugs are also possible important causative agents of this reaction type. Other drugs have been reported less often as causal agents of vasculitis: several antibiotics, etretinate, didanosine, zidovudine, acebutolol, atenolol, sotalol, propranolol, chlorothiazide, furosemide, diltiazem, nifedipine, methyldopa, captopril, enalapril, lisinopril, losartan, procainamide, quinidine, antithyroid medications, painkillers and antipyretics, levamisole, tamoxifen, arabinoside C, interferon, interleukin-2, sulfasalazine, etanercept, gold, carbamazepine, antidepressants, zafirlukast, chromalin, cimetidine, ranitidine, L-tryptophan, radiocontrast, streptokinase, heparin, coumarin, chlorpromazine, metformin, pimagedine, and diphenhydramine.

Drugs that induce vasculitis associated with antineutrophil cytoplasmic antibodies (ANCA) include hydralazine, propylthiouracil, minocycline, and anti-TNFα biological agents.

About 20% of the patients who use propylthiouracil develop ANCA, a fact that is related to a higher risk of glomerulonephritis. A particularly relevant form among the drug-induced vasculites is propylthiouracil hypersensitivity vasculitis. There are cases with other antithyroid compounds, such as methimazole, thiamazole/methylthiouracil, and carbimazole, which, similarly to propylthiouracil, contain a thioamide group and cause allergic cross-reactions. Although uncommon, nowadays a larger number of case reports of this entity are observed, suggesting that cases were previously not reported or were included among other nosologic entities, since propylthiouracil is a drug classically dedicated to the treatment of hyperthyroidism.

The clinical symptoms and signs begin after initiating propylthiouracil. Although the duration of drug use is extremely variable, from 1 week to 13 years, it appears under a classic tetrad of symptoms that include fever, sore throat, arthralgia and cutaneous eruption; there can also be myalgia, fatigue, weight loss, conjunctivitis, rhinitis, and hemoptysis.

The disease course is that of a systemic vasculitis. There can be a lupus-like syndrome, Wegener-like granulomatosis, or nodular-like polyarthritis with multiple involvement of organs, such as kidneys, joints, lungs, and others associated with cutaneous lesions. The cutaneous lesions usually consist of plaques or acral purpuric nodules arranged in a livedoid pattern, with a preference for the extremities (Fig. 26.16), face, breasts, and characteristically the lobes and helices of the ears, mimicking the leprosy type reaction of Lucio's phenomenon. Hemorrhagic blisters appear on these lesions that progress to central necrosis of the skin, which can be so extensive that it simulates the clinical presentation of purpura fulminans observed in septic infectious states with disseminated intravascular coagulation.

Laboratory tests reveal anemia, leukopenia, and platelet depletion in the blood count; increased erythrocyte sedimentation rate, urea, creatinine, transaminases, and bilirubin; hypoalbuminemia; alterations in the coagulation time, prothrombin time, and partial activated thromboplastin time; and immunological abnormalities such as positive ANCA, rheumatoid factor, and hypergammaglobulinemia can be found. Positivity can also be present in anti-SSA, anti-double-stranded DNA, anticardiolipin, anti-smooth muscle antibodies, antimitochondrial, parietal, and antiadrenergic antibodies, besides hypocomplementemia, cryoglobulinemia, and elevation of C-reactive protein.

Histopathologic study demonstrates a leukocytoclastic vasculitis of the superficial and profound vessels of the dermis. The finding of immunocomplexes deposited in the vascular wall is uncommon, such that some authors have named them pauci-immune ANCA-positive vasculitis. Most of the patients recover completely following withdrawal of propylthiouracil, although some develop impairment of the kidneys or other internal organs, or skin, requiring high doses of prednisone for several months.

The dermatologic findings in patients with drug-induced vasculitis associated with ANCA include plaques and purpuric acral nodules, which appear more commonly on the extremities, face, breasts, and ears. In addition, the patients report the same signs and symptoms as found in other small-vessel vasculites associated with ANCA (Wegener's granulomatosis, Churg–Strauss syndrome), including glomerulonephritis, pulmonary hemorrhage, and digital gangrene.

Besides withdrawal of the offending drug, it is generally necessary to use corticosteroids in high doses or in pulse therapy, plasmapheresis, and immunosuppressants for several months. The mortality rate is approximately 10%.

Fig. 26.16 Retiform purpura in drug-induced ANCA-positive vasculitis caused by propylthiouracil

Anticoagulant-Induced Skin Necrosis [45]

This is a rare and severe adverse effect from treatment with warfarin (anti-vitamin K agents), occurring with cutaneous necrosis secondary to occlusive thrombosis in the vessels of the skin and subcutaneous cellular tissue. It usually presents 3–5 days after use of the drug, as painful

Fig. 26.17 Anticoagulant-induced skin necrosis caused by warfarin. Note thrombosis of femoral vessels in histopathologic examination

erythematous plaques that course to necrosis (Fig. 26.17), with hemorrhagic blisters or necrotic scars in the areas rich in subcutaneous tissue, such as buttocks, breasts, and hip. The risk of this disease increases in patients who are female, obese, and users of high doses of the medication [1]. The necrotic tissue requires debridement and grafts. This type of reaction has also been described with the use of heparin.

Moderate or Mild Cutaneous Adverse Drug Reactions (CADRs) or Uncomplicated CADRs

This kind of ADR is represented by several conditions related to drug exposure, which do not represent life-threatening conditions to the patients except discomfort. There is no severe temporary or permanent remaining lesions or long-term internal organ sequelae and, in most of cases, no mortality or severe impact on patients' health. In contrast to severe ADRs, in the clinical setting of uncomplicated CADRs admission to the intensive care or burn unit is usually not necessary for the majority of patients.

For this reason, the physician must be able to identify the signs and symptoms that indicate severe CADR [47]. In particular, dermatologists must pay attention to identifying these reactions, since the skin is among the most common organs or systems of clinical manifestation of ADRs and concurs with at least 15% of ADRs [47].

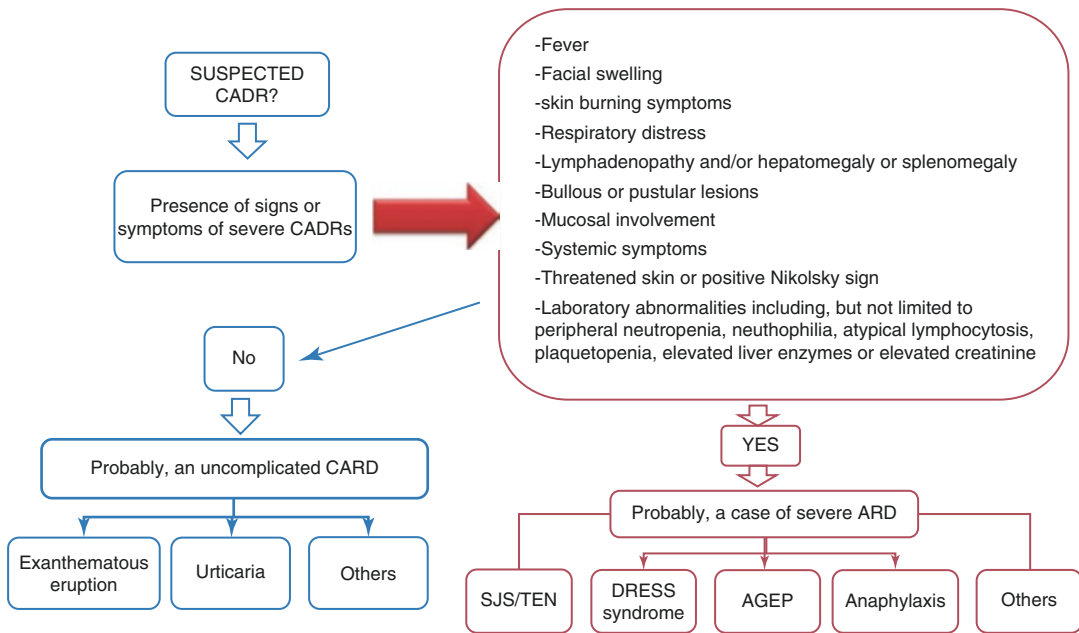
The most common forms of CADRs are urticarial and exanthematous eruptions, which together constitute 90–95% of all CARDs [47]. These two types carry few to no long-term consequences [47]. The severe ADRs (SADRs), described earlier in this chapter, probably represent around 2% of all ADRs [47]. SADRs often are associated with high levels of morbidity and mortality, and therefore a prompt recognition of the reaction, withdrawal of all possible offending agents, and appropriate triage, hospital admittance, workup, and specific treatment are critical [47].


Fig. 26.18 Algorithm for evaluation of patients with ADR based on signs and symptoms indicating a severe or an uncomplicated ADR

Regarding studies of severe versus uncomplicated ADRs, Swanson and Colven [47] proposed a staged patient evaluation as shown in Fig. 26.17. Signs and symptoms severe ADR are listed in Fig. 26.18, and in this clinical scenario the physician should have a low threshold to admit the patient to hospital, perform a complete workup including evaluation of other medical specialties, withdraw suspected medications, and initiate adequate therapy when indicated [47].

Another relevant aspect in recognizing the type of ADR is the time from medication introduction to the onset of a cutaneous reaction, since this is related to the subtype of ADR, as proposed in Fig. 26.19 [47]. Often patients have been exposed to several medications in the same period, and creating a "drug list" that details the dates of all medications taken is helpful in narrowing down the most probable culprits [47].

Physicians should pay attention to prodromal symptoms (skin pain, fever, malaise, throat pain or discomfort, arthralgia, etc.) that can to precede the cutaneous eruption, and associated internal symptoms (abdominal pain, ocular discomfort, dysuria, respiratory distress, etc.), and proceed to complete physical examination including full skin examination of groin, genitalia, eyes, oropharynx, thorax auscultation, abdomen, and lymph node palpation [47].

The physician needs remember that several risk factors for the development of more severe cutaneous ADRs have been identified, including female gender, older age, viral infections (herpesvirus family or HIV), genetic susceptibility (specific single-nucleotide polymorphisms in the HLA region), iatrogenic immunosuppression, underlying immune-mediated diseases, and cancer [48].

Exanthematous Drug Eruptions [48, 49]

Exanthematous or maculopapular drug eruptions, sometimes inappropriately designated "drug rashes" or "drug eruptions" by some generalists, are the most common ADRs in the skin. The eruption usually occurs between 4 and 14 days after the initiation of a new medication or chemical substance, although it can develop sooner,

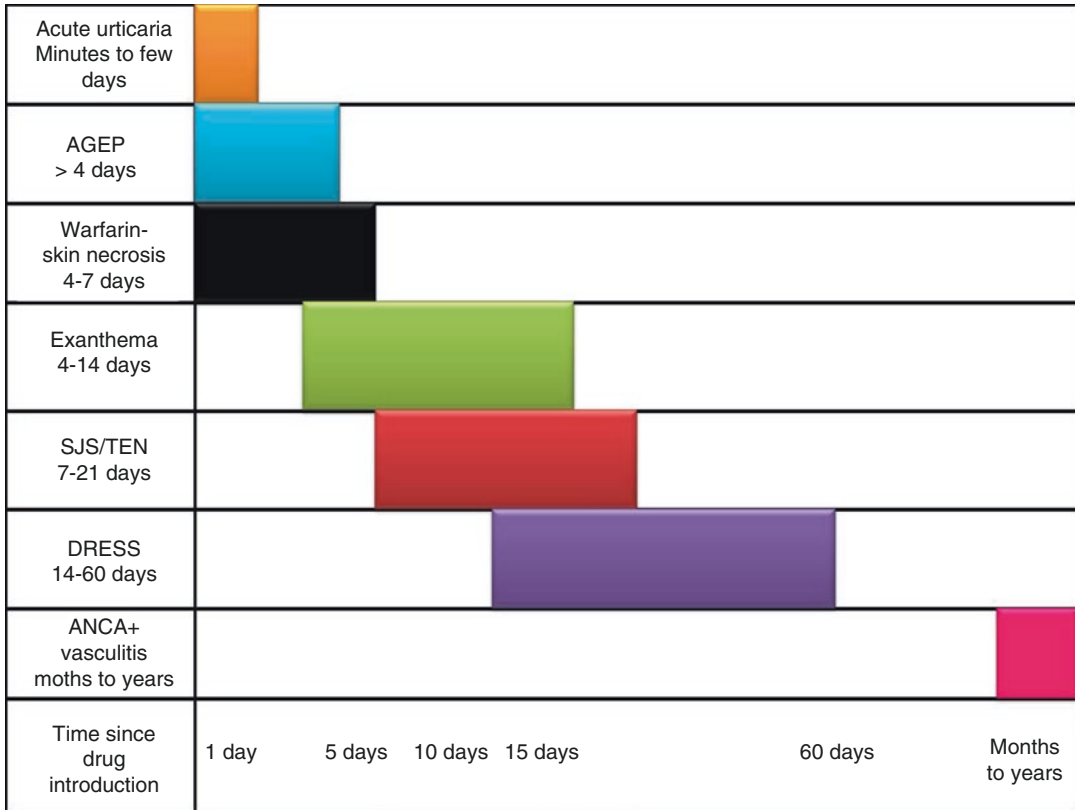
Acute urticaria Minutes to few days						
AGEP > 4 days						
Warfarin-skin necrosis 4-7 days						
Exanthema 4-14 days						
SJS/TEN 7-21 days						
DRESS 14-60 days						
ANCA+ vasculitis moths to years						
Time since drug introduction	1 day	5 days	10 days	15 days	60 days	Months to years


Fig. 26.19 Approximate timing of drug eruptions after the onset of drug introduction

especially in case of a new exposition to the same or parent drug. Uncomplicated exanthematous drug reactions usually resolve in a few days when the causative drug is stopped.

Exanthematous eruptions generally are composed of erythematous macules and/or papules and more rarely by vesicles or pustules, usually with a pattern of symmetric distribution on skin. The eruption often begins on the trunk followed by centrifugal dissemination to the proximal limbs. Skin lesions progressively become confluent and may cover large areas of the body (Fig. 26.20). Pruritus and/or low-grade fever are often associated with the exanthema. In some patients the exanthema may progress to erythroderma or more severe reactions such as SJS/TEN or DRESS syndrome after some days or weeks.

Under histopathology examination this type of ADR demonstrates interface dermatitis with vacuolar changes in keratinocytes at the basal

Fig. 26.20 Morbilliform drug-induced exanthema

layer of the epidermis, and upper dermal mononuclear cells infiltrate with some eosinophils. The pathogenesis involves the overexpression of several cytokines of Th2 pattern, such as IL-5 and IL-13, causing epidermal damage by

molecules of perforin, granzyme B, and peripheral blood eosinophilia (a type IVb delayed cell-mediated immune mechanism, as proposed by Werner Pichler).

Uncomplicated exanthematous drug eruptions can occur with almost any medication, but the following drugs have higher risks (more than 3% of patients): allopurinol, aminopenicillins, cephalosporins, antiepileptic drugs, and antibacterial sulfonamides. Viral infections may increase the incidence of morbilliform drug eruptions, as seen in the setting of mononucleosis infection under treatment with ampicillin, or in severe exanthema with internal damage as in DRESS syndrome related to the HHV family (EBV, cytomegalovirus, HHV-6 and -7).

Morbilliform reaction is the most common presentation of exanthematous drug eruption. Morbilliform is defined as a rash resembling measles and is clinically depicted by erythematous macules and/or papules, often coalescing into larger plaques. Many studies have shown that cutaneous biopsy alone cannot distinguish with certainly that a reaction is due to a drug. There are some clues that suggest the diagnosis: (i) Epidermis (mild spongiosis is the most consistent feature, with occasional hyperplasia of the epidermis. Few lymphocytes are commonly present in the epidermis. In 97% of biopsies, vacuolization was found in the dermoepidermal junction); (ii) Dermis (perivascular infiltrate is virtually always present, composed of lymphocytes and in 60% of cases scattered eosinophils); (iii) papillary dermal edema; (iv) dilated lymph and blood vessels.

The primary differential diagnosis for morbilliform eruptions includes viral exanthemas (e.g., EBV, HHV-6, and CMV), bacterial toxin resection (streptococcal or staphylococcal), Kawasaki syndrome, and others such as secondary syphilis, scarlet fever, acute HIV, or acute GVHD.

The treatment is supportive. The first measure is the withdrawal the causative agent. Topical corticosteroids and systemic antihistamines can be administered in the first step. If necessary, this can be combined with a short cycle of systemic corticosteroids (oral prednisone, 0.5 mg/kg/day, with progressively tapering dosages over several days). Antihistamines are indicated as adjuvant therapy in cases of itching.

Acute Urticaria and Angioedema [48–50]

Drug-induced urticaria is the second most common form of cutaneous drug reaction after exanthematous reactions.

Urticarial eruption can be broken down into simple acute urticarial eruptions, those involving angioedema or anaphylaxis, and serum sickness-like reactions as previously described in this chapter. Simple urticarial reactions caused by drugs consist of erythematous and edematous lesions, which have central clearing with a red border. The lesions can be located anywhere on the body and wax and wane over hours to days. Pruritus is an associated symptom. This type of drug reaction takes place minutes to days after exposure to the offending drug.

Common drugs responsible for urticarial reactions include antibiotics, such as penicillins, cephalosporins, sulfonamides, and tetracyclines, generally due to IgE-mediated hypersensitivity reaction. Another common class of drugs related to urticarial eruptions is nonsteroidal anti-inflammatory drugs (NSAIDs). NSAIDs cause most frequently non-IgE-mediated urticaria and angioedema because of their pharmacologic activity of cyclooxygenase-1 enzyme inhibition, particularly of prostaglandin E2, and results in the generation of leukotriene C4 and activation of inflammatory cells.

Urticaria and angioedema are associated in about 50% of cases. Regarding ACE inhibitors, angioedema is described in 0.5% of patients treated with this class of drugs, and often without urticarial lesions. Rarely, angiotensin II receptor blockers result in the same complication.

Oral or injectable antihistamines and systemic corticosteroids are sometimes needed for severe acute urticaria and intramuscular epinephrine for angioedema. In cases of isolated angioedema caused by ACE inhibitors, epinephrine will not control the symptoms and it is necessary to use the selective bradykinin B2 receptor antagonist icatibant in this clinical setting.

Fixed Drug Eruptions [49, 51]

This entity is defined as recurrent lesions that, upon repeated uptake of the causative drug, always appear at the same skin or mucosal sites. FDEs present as well as circumscribed, single or multiple, often pruritic or burning erythematous, dusky patches (Fig. 26.21), ranging from several millimeters to over 10 cm in diameter. Vesicles or even blisters can develop. As the lesions resolve, they leave residual hyperpigmentation. The hallmark of FDEs is geographic memory. If a reaction recurs, it tends to recur in the same location as previously (although a new location can also be involved).

Lips, hands, genitalia (especially male genitalia), and occasionally oral mucosa are favored sites of FDE occurrence, although the lesions can be found anywhere on the skin and mucous membranes. After intake of the offending drug, FDE appears within minutes up to several hours (about 30 min to 8 h). The cutaneous lesions can be accompanied by general symptoms such as fever, nausea, dysuria, abdominal cramps, and diarrhea, though rarely. On occasion the disease presents in an atypical form with blunt-margined, non-pigmented, giant (>20 cm in diameter), urticarial, purpuric, targetoid, linear, reticular, and butterfly-like lesions.

The histopathologic hallmark is brisk interface dermatitis with varying amounts of epidermal necrosis as well as melanophages and eosinophils in the upper dermis. FDEs reveal a reaction pattern with lichenoid or erythema multiforme-like changes. Atypical histopathologic reaction patterns such as leukocytoclastic vasculitis, neutrophilic reaction, and a predominantly dermal reaction without pigment incontinence in what is termed nonpigmented FDE have been reported.

The pathogenesis of FDE is based on the new subclassification of delayed type IV immune reactions (Werner Pichler), a type IVc reaction. In this kind of immune response cytotoxic T cells play a predominant function, whereby autoaggressive $\alpha\beta^+CD8^+$ memory T cells persist intraepidermally in previous FDE sites and play a central role in new flare-ups during drug recall. Under drug exposition, keratinocytes are stimulated to participate in immune response through TNF-α and a rapid expression of ICAM-1 molecule, and then stimulate CD8$^+$ T cells to produce IFN-γ and

Fig. 26.21 Multiple lesions of fixed drug eruption in a patient taking a nonsteroidal anti-inflammatory drug

express FAS-FAS ligand in the epidermal basal layer to induce apoptosis of keratinocytes. On the other hand, transient intraepidermal migration of CD4[+] T cells is capable of releasing a downregulation profile of IL-10, inducing suppression of the flare-up reaction in FDE.

Many drugs have been found to cause FDE, with common offenders including sulfonamides, NSAIDs (e.g., ibuprofen), allopurinol, barbiturates, hydroxyzine, laxatives, tetracycline, phenolphthalein, and feprazone. Usually there is only one causative drug (monosensitivity), although sometimes several drugs can induce FDEs in the same patient (multisensitivity). The most common multisensitivity is the cross-reaction between chemically related drugs such as tetracyclines. Less frequently, multisensitivity can occur because of polysensitivity, whereby two or more chemically unrelated drugs either induce the identical FDE lesion or each drug determine flare-ups in separate lesions.

Treatment is mainly symptomatic with discontinuation of offending agent, topical corticosteroids, and antihistamines.

Acneiform Eruptions [49, 52]

This kind of ADR produces lesions resembling acne vulgaris, but unlike acne vulgaris, drug-induced acneiform eruptions typically are not associated with the presence of comedones (blackheads and whiteheads). Acneiform drug eruptions appear as erythematous papules or erythematous pustules on the face and trunk (Fig. 26.22) and proximal extremities, but sometimes can be present on the forearms and legs, an unusual site in acne vulgaris. The most relevant hallmark is the monomorphous pattern of this eruption and the resolution without scarring. Drug-induced acneiform eruptions represent only 1% of drug eruptions.

Several medications are related to flare-ups of drug-induced acneiform eruptions, the most strongly associated being lithium, androgens, oral contraceptives, corticosteroids, vitamin B complex, and nowadays epidermal growth

Fig. 26.22 Acneiform eruption resulting from the combination of intramuscular injectable vitamin B complex and betamethasone for orthopedic pain

receptor (EGFR) inhibitors for chemotherapy. Iodine, bromide, isoniazid, actinomycin D, and phenytoin have also been associated. In the last decade, the use of supplementary complexes by bodybuilders, such as milk and whey protein-based products, have been reported as being involved in acneiform eruptions. This is an effect caused by elevations of postprandial insulin and basal insulin-like growth factor I plasma levels.

Treatment involves discontinuing the use of the offending drug, except in the case of EGFR inhibitors, when discontinuation may not be possible. Benzoyl peroxide, topical retinoids, and topical or oral antibiotics, such as doxycycline, can be used to treat the reaction, similar to the treatment of acne vulgaris.

Lichenoid Eruptions [49, 53]

Drug-induced lichenoid eruptions are uncommon ADRs that appear similar or even identical to lichen planus, with shiny violaceous polygonal papules and plaques (Fig. 26.23). Drug-induced lichenoid eruptions can present virtually anywhere on the body surface, but certain clues in the distribution can help suggest drug eruption over lichen planus. Drug-induced lichenoid eruptions tend to be absent from the flexor surface of the wrists, genitals, and mucous membranes, whereas these locations are often involved in common lichen planus. Lichen planus drug eruptions also often favor sun-exposed areas of the body.

Several drugs have been reported to be related to drug-induced lichenoid eruptions: gold salts, antimalarials, methyldopa, NSAIDs, penicillamines, lithium, sulfonylureas, phenylenediamine derivatives, thiazide diuretics, β-blockers, omeprazole, and pantoprazole. The time from initiation of the drug to onset of lichenoid drug eruption varies greatly

Fig. 26.23 Lichenoid drug eruption

depending on the causative medication. Reactions caused by naproxen, for example, tend to occur approximately 10 days after administration. By contrast, certain drugs such as lithium, methyldopa, and acebutolol can develop lichenoid eruptions several years later. HIV infection can contribute to lichenoid drug eruptions on photoexposed areas of the body.

Treatment typically is symptomatic, with topical corticosteroids a mainstay. Once discontinuation of the medication has been accomplished, the eruption resolves spontaneously after a period of a few weeks or months.

Photosensitivity Reactions [54–56]

Acute photosensitivity ranges from common polymorphous light eruptions to phototoxicity, or rare photoallergies. Photosensitivity refers to reactions that occur when a photosensitizing agent (chromophore substance) in or on the skin reacts with ultraviolet (UV) radiation, often in doses smaller than those associated with sunburn. Up to 8% of cutaneous drug reactions are photosensitivity eruptions. Typically, a photosensitivity reaction occurs within hours to days of exposure to sunlight and may last for up to 1 week or more.

More frequent reactions are named "phototoxic reactions," in which skin signs resemble moderate to severe sunburn, with erythema, blistering, weeping, and desquamation. Photoallergic reactions resemble eczematous lesions, often in subacute or chronic presentation. Phototoxic and photoallergic reactions occur in sun-exposed areas of the skin; however, widespread eruptions can occur, which may suggest a systemic photosensitizing agent (photoallergy).

These reactions are dose related and are most commonly seen in patients who have been exposed to high doses of both the drug and UV radiation. One's susceptibility to this type of syndrome is variable and likely based on drug absorption and metabolism, as well as the amount of melanin in the skin.

Piroxicam, fluoroquinolone antibiotics, tricyclic antidepressants, and NSAIDs are classes
Fig. 26.24 Photosensitivity due to voriconazole causing severe cheilitis

of drugs that have been reported to be frequent photosensitizers, with fluoroquinolones being the most potent. Other antibiotics, such as TMP-SMX and tetracyclines, have also been implicated. Recently voriconazole, a third generation of azole antifungal agents, has been reported as a photosensitivity agent, especially in phototoxic reactions (Fig. 26.24), in 8% of outpatients treated, besides increasing the potential of nonmelanoma skin cancer (particularly squamous cell carcinomas) arising from potential photocarcinogenesis related to voriconazole.

Phototoxic reactions are the most common dermatologic adverse effect of amiodarone therapy, affecting 25–75% of patients on long-term treatment. Photoallergy is considerably less likely to occur, but the risk also increases with prolongation of the therapy. Skin changes usually occur after at least 4 months of therapy and with the minimal cumulative dose, which is 40 g.

Management of photosensitivity reactions includes limiting exposure to sunlight, using potent sunscreen, and wearing protective clothing. Oral and topical corticosteroids agents may be employed in the treatment.

Drug-Induced Coma Blisters [57, 58]

Coma blisters are uncommon skin eruptions seen in patients with impaired consciousness. The original case was described in a patient who was heavily sedated because of barbiturate intoxication. Subsequently anticonvulsants have been reported, including certain benzodiazepines such as clobazam (Fig. 26.25), and valproic acid and amitriptyline overdose. There were a few reports of coma blisters and peripheral neuropathy caused by amitriptyline overdose. These blisters are most often seen in pressure areas, particularly over bony prominences in contact with hospital beds.

The hallmark histologic feature that defines coma blisters is eccrine gland necrosis in the skin. Differential diagnosis with bullous pemphigoid is obtained with a negative direct immunofluorescence biopsy of the skin. Until recently, coma blisters were thought to be a self-limiting process that did not require withdrawal of the offending agent. However, in some patients the eruption resolves only upon withdrawal of the drugs.

Fig. 26.25 Coma blisters in forearm of a patient with stroke under medication with barbiturates
Drug-Induced Erythema Nodosum [59]

Erythema nodosum is a skin reaction manifested by tender or painful erythematous subcutaneous nodules, located usually on the extensor aspects of the lower extremities. Histologically it is a septal panniculitis without vasculitis. Several conditions can be induce and act as an antigenic stimuli, including drugs, benign and malignant systemic diseases, leprosy, and bacterial (e.g., tuberculosis) and fungal infections. Frequently the cause is unknown.

Drugs that may cause erythema nodosum are antimicrobial agents (amoxicillin, penicillin, sulfonamides), bromide, iodine, gold salts, analgesics and antipyretics (including paracetamol), carbimazole, isotretinoin, azathioprine, vemurafenib, GM-CSF, oral contraceptives (estrogens/progesterones), and estrogens. Erythema nodosum disappears within a couple of weeks after withdrawal of the causative drug.

Drug-Induced or Exacerbating Psoriasis [57, 60]

Drug-induced psoriasis is well documented. Such eruptions may occur in patients with pre-existing

Fig. 26.26 Psoriasis exacerbation after using anti-TNF-α agents

psoriasis (exacerbation phenomenon) or those without a personal or family history. Lesions typically improve with drug withdrawal, although persistent disease is possible. More frequent drugs involved are β-blockers, lithium, antimalarials, NSAIDs, anti-TNFα agents (Fig. 26.26), and bupropion.

Exacerbation of psoriasis caused by the following medications has also been observed: adrenergic antagonists, IFN, gemfibrozil, iodine, digoxin, and clonidine.

Symmetric Drug-Related Intertriginous and Flexural Exanthema [61]

In individuals previously sensitized to an allergen through contact, systemic exposure results in the development of a condition classically termed systemic contact dermatitis. One of the most common manifestations of this condition is so-called baboon syndrome (BS).

A subsequent study by Hausermann et al. [62] examined a series of 100 cases of BS and found that about half of the patients exhibited no evidence of prior skin sensitization. For that group the authors proposed the term "symmetric drug-related intertriginous and flexural exanthema" (SDRIFE) to describe a peculiar form of drug rash with symptoms similar to those of true BS.

BS is historically often equated with a mercury-induced exanthem in patients with previous contact sensitization. SDRIFE specifically refers to the typical clinical pattern of this drug eruption, and the following diagnostic criteria are proposed [62]: (1) exposure to a systemically administered drug either at the first or repeated dose (excluding contact allergens); (2) sharply demarcated erythema of the gluteal/perianal area and/or V-shaped erythema of the inguinal/perigenital area; (3) involvement of at least one other intertriginous/flexural localization (Fig. 26.27); (4) symmetry of affected areas; and (5) absence of systemic symptoms and signs.

Several drugs are reported to induce SDRIFE [63]: (i) β-lactam antibiotics (amoxicillin, ampicillin, amoxicillin/clavulanic acid, pivampicillin, penicillin V, ceftriaxone, cefuroxime, cephalexin) and non-β-lactam antibiotics (including clindamycin, roxithromycin); (ii) corticosteroids: deflazacort; (iii) radiocontrast barium; (iv) other drugs: sulfate iomeprol, iopromide, monoclonal antibodies (cetuximab, glembatumumab), vedotin (CR011, vcMMAE), psychopharmaceuticals (risperidone loflazepate ethyl), allopurinol, cimetidine hydroxyurea, heparin (intravenous), IVIG, mitomycin C, naproxen, oxycodone, pseudoephedrine, salsalate, terbinafine, and valacyclovir.

Nicolau Syndrome or Embolia Cutis Medicamentosa (ECM) [64, 65]

In 1924, Freudenthal described full-thickness dermal necrosis associated with intramuscular injection of oily bismuth suspension, which was

Fig. 26.27 Symmetric drug-related intertriginous and flexural exanthema (axillae and groin)

used to treat syphilis at that time. He described the histologic appearance of these suspended particles deep within the cutaneous arteries, distant from the injection site. This condition was also described by Nicolau the following year, and the syndrome more often bears his name despite Freudenthal's precedence in the literature.

Nicolau syndrome is an iatrogenic syndrome caused by intramuscular injection leading to variable degrees of tissue necrosis, with variable severity, including the skin and deeper tissues. Intense pain in the immediate postinjection period and purplish discoloration of the overlying skin, with or without a reticulate pattern (livedo racemosa-like pattern), is highly characteristic of this syndrome. Intramuscular, subcutaneous, intravenous, and intra-articular injections have been reported to produce this syndrome. The skin necrosis resolves with severe and disfiguring scarring. It is therefore important that dermatologists and cutaneous surgeons are aware of this agonizing and deforming iatrogenic complication of injections.

Discoloration of the skin may result in necrosis and ulceration, which might involve the subcutaneous tissue and the muscular layer. Paralysis of the lower extremities has been reported and attributed to embolization of the medication, mainly resulting from the force of injection from the gluteal vessels into the internal iliac arteries, and ischemia of sciatic nerve. Application of cold devices or compress tends to aggravate the tissue injury and necrosis.

Several drugs are related to ECM: (i) intramuscular injections (vitamin K, NSAIDs, hydroxyzine, vaccination, bismuth, benzathine penicillin, penicillin G); (ii) intravenous injections (polidocanol 1%); (iii) subacromial injection (triamcinolone acetate); (iv) subcutaneous injection: pegylated IFN-α, glatiramer acetate; and (v) intra-articular: glucocorticoid.

Aspirating just before injecting has been suggested as a method of preventing Nicolau syndrome, as it is thought to help prevent embolism caused by intra-arterial deposition of medication. However, it is doubtful as to whether Nicolau syndrome can be prevented by this method, as the spasm of the vessel or vasocompressive effect in Nicolau syndrome is usually difficult to recognize.

The essential difference between those cases of ECM and the pathophysiology seen with vascular obstruction by dermal fillers (hyaluronic acid, polymethylmethacrylate microspheres) is that the former often involves inflammatory pathways being activated by the injected material, whereas the latter typically involves a more purely mechanical vascular obstruction (although some dermal fillers may promote blood clotting, hyaluronic acid-based dermal fillers by design are minimally reactive in tissues). The phenomena are similar in that the inciting event is accidental intravascular injection, followed by some degree of intravascular transport, finally resulting in distal vascular obstruction, ischemia, and so forth, such that the ultimate clinical presentation is the same.

Diagnosis is mainly clinical; cutaneous biopsy reveals necrotic changes caused by ischemia. Ultrasonography study of the skin and magnetic resonance imaging help in delineating the extent of damage. Prompt treatment has been reported to avert necrosis of the skin. In the immediate post-event period, treatment is based on various approaches to improve blood supply such as pentoxyphylline, hyperbaric oxygen, intravenous alprostadil, and thrombolysis with heparin. Intralesional corticosteroid has also been used to reduce inflammation. Surgical debridement of the necrotic scar is of utmost importance as it reduces infection and enhances wound healing.

Drug-Induced Linear IgA Bullous Dermatosis (LABD) [49, 66]

LABD often presents a singularity in its presentation. It has been reported that almost two-thirds of LABD cases may be drug induced, although this is rare in children, in whom LABD behaves as an idiopathic autoimmune blistering disease.

The clinical picture consists of an acute development of vesicles and bullous lesions often on sites of noninflamed skin. Typically, new lesions develop around previous lesions forming rosette-like plaques, widely distributed on the face, trunk, and extremities, especially around the perioral and genital areas. Mucosal involvement in drug-induced LABD is less common than in

the autoimmune form. The most commonly used medication associated with this kind of ADR is vancomycin; however, other drugs include amiodarone, atorvastatin, captopril, ceftriaxone, diclofenac, furosemide, lithium, metronidazole, penicillin, phenytoin, piroxicam, rifampin, and trimethoprim-sulfamethoxazole.

Treatment of drug-induced LABD includes discontinuation of the causative agent and treatment with topical or systemic steroids, dapsone, and/or nonsteroidal systemic immunosuppressive agents.

Drug-Induced Bullous Pemphigoid [49]

This entity is very similar to the autoimmune form. Multiple tense bullous lesions appear on the skin and pruritus is a common symptom. Often the medications associated with drug-induced bullous pemphigoid include furosemide, ACE inhibitors (especially captopril and enalapril), penicillin, ampicillin, chloroquine, psoralen-UVA treatment, and sulfasalazine.

Treatment is aimed at discontinuation of the offending drug as well as topical or systemic corticosteroids and steroid-sparing immunosuppressive drugs as indicated.

Drug-Induced Pemphigus [49]

Similar other drug-induced reactions related to counterpart autoimmune conditions, drug-induced pemphigus most closely resembles pemphigus foliaceus, with flaccid vesicles or bullae that rupture, creating crusted or desquamated erosions, with mucous membranes often spared.

The histologic hallmark of this drug-induced eruption is the acantholysis of epidermal cells, but this phenomenon is not a pathognomonic sign of this type of ADR. Both autoimmune (idiopathic) and drug-induced pemphigus have a positive Nikolsky sign, as observed in the SJS/TEN spectrum, although SJS/TEN does not demonstrate acantholysis in the skin biopsy.

Drugs containing thiol molecules (penicillamine, thiopurine, pyritinol, gold sodium thiomalate, captopril) are responsible for 80% of the cases, and other drugs implicated include levodopa, penicillin, phenobarbital, piroxicam, propranolol, and rifampicin. Drug-induced pemphigus can occur any time within the first year of initiation of one of the offending drugs. Treatment generally consists of withdrawal of the drug and use of systemic corticosteroids.

Adverse Mucocutaneous Reactions to Chemotherapeutic Drugs [44, 67–70]

The skin, mucous membranes, annexes (sebaceous and sudoriferous glands), and the phaneros (hair and nails) are tissues with rapid cellular proliferation and are thus susceptible to adverse reactions (toxic or hypersensitive) resulting from systemic chemotherapeutic treatment.

Antineoplastic agents are defined as substances that inhibit or prevent the proliferation of neoplasms. Because of their high metabolic rate, the skin, mucous membranes, and annexes are the most important target organs of the toxicity associated with chemotherapy. Reactions can present with disseminated exanthematous eruptions, nonspecifically, or as distinct cutaneous lesions. Some drugs can trigger localized reactions caused by extravasation to tissues adjacent to the areas of application.

Exanthematous reactions, such as nonspecific erythema multiforme, are more common, and many of them are attributed to hypersensitivity mechanisms. Certain local toxicity, such as alopecia, mucositis, nail alterations, or hand-foot syndrome, is more specific and less common, frequently associated with particular drugs or groups of drugs.

The identification of the reaction pattern associated with the trigger drug and of the possible dose-limiting toxicity is of extreme importance to the physician, as is the differential diagnosis with infectious processes and specific manifestations of the neoplasm.

Alterations of the Phaneros and Cutaneous Annexes [44, 67–70]

Alopecia [44, 67–70]

Alopecia is the most common adverse skin manifestation of chemotherapeutic treatment. There are two types of drug-induced alopecia: the anagen effluvium and the telogen effluvium. In the anagen effluvium hair loss occurs because of the sudden interruption of the mitotic activity of the hair matrix, 1–2 weeks after the start of chemotherapy, leading to lack of hair production or its thinning (Pohl–Pinkus constrictions). The weakening of the hair shaft in this context predisposes the hair to breakage and shedding during the act of combing. They involve the hair, eyebrows, beard, axillary hair, and pubic hair. It is dose-dependent and reversible. New hairs often grow back with a different color and texture. In the telogen effluvium, hairs move prematurely to a resting phase with subsequent loss of normal hair.

The antineoplastic agents that most frequently cause the anagen effluvium lead to diffuse hair loss, of sudden onset, from 7 to 10 days after the start of chemotherapy. Hair loss becomes more pronounced about 1–2 months after the start of treatment. Even though hair loss is intense, about 10% of the pilous follicles are usually in a resting phase at the time of the administration of the drug, and this determines incomplete hair loss. With repeated treatment cycles, alopecia totalis may occur. This type of effluvium is generally reversible when treatment is suspended, and occasionally permanent with the use of cyclophosphamide and busulfan. Hair grows around 1 cm per month, possibly showing new texture and color. The chemotherapeutic drugs more often associated with alopecia when used in isolation are: (i) complete alopecia (cyclophosphamide at high dose, doxorubicin, docetaxel, dactinomycin, irinotecan, topotecan, bleomycin, paclitaxel); (ii) incomplete alopecia (etoposide, ifosfamide, mitomycin C, 5-fluorouracil, melphalan, mitoxantrone, gemcitabine, vinca alkaloids).

Most reactions can be reversed by dose reduction or by increasing the interval between doses. Some toxic effects can be successfully treated or prevented. Medication administered before the chemotherapeutic treatment can prevent hypersensitivity reactions. The use of oral antiseptic solutions is useful in the control of mucositis.

Some dermatologic reactions to new antineoplastic agents, such as EGFR inhibitors, have been associated with anticancer efficacy.

Other adverse effects may be mistaken for reactions to chemotherapeutic drugs and include infections resulting from immunosuppression, paraneoplastic syndromes, GVHD, nutritional deficiencies, development of skin malignancies, and metastatic primitive tumor.

There are several classifications of reactions to antineoplastic drugs. The lack of a systematized multidisciplinary approach does not provide all the microscopic data and physiopathogenic mechanisms that delineate the lesions. Therefore, the classification adopted didactically groups with the eruptions based on the target cells and mechanism of action of the drugs.

Preventive measures to limit hair loss have had limited success. Hypothermia of the hair scalp or tourniquets applied in this region may reduce the perfusion of the drug in the pilous follicles and delay the start of or minimize hair loss. This procedure is contraindicated for patients with hematologic neoplasms such as leukemias, lymphomas, and other potentially metastatic tumors of the hair scalp. Topical minoxidil is not effective in the prevention of drug-induced alopecia, but may shorten its duration.

Trichomegaly and Hair Curling [44, 67–70]

Hair alterations with acceleration of growth and shaft changes are observed with the use EGFR inhibitors (Fig. 26.28).

Ungual, Subungual, and Periungual Alterations [44, 67–70]

Nail alterations can present with a reduction of the nail growth speed, fragility, lines of discoloration (Mees' lines), transversal depressions (Beau's lines), hyperpigmentation, onycholysis with subungual aseptic abscesses, photo-onycholysis, paronychia, and pyogenic granulomas of the periungual folds. Nearly all antineoplastic agents

Fig. 26.28 Blepharitis and trichomegaly caused by cetuximab (image under dermoscopy, ×10)

Fig. 26.29 Ingrown nail and pyogenic granuloma in a patient using erlotinib

can lead to reduction of growth speed, nail fragility, Mees' lines, and Beau's lines.

Hyperpigmentation can occur after the use of cyclophosphamide, hydroxyurea, fluoropyrimidines such as 5-fluorouracil, and especially anthracyclines such as doxorubicin and daunorubicin. Painful onychomycosis and subungual abscesses are due to the use of taxanes (docetaxel/paclitaxel) and anthracyclines (doxorubicin).

Ingrown nails, paronychia, and pyogenic granuloma are associated with the use of tyrosine kinase inhibitors of EGFR (Fig. 26.29), such as erlotinib and gefitinib. The fenestration or avulsion of the lamina should be considered when abscesses that involve more than 50% of the nail bed are present. In these more severe cases, the temporary suspension of treatment, longer

intervals between cycles, and dose reduction should be considered.

Neutrophilic Eccrine Hidradenitis [44, 67–70]

This rare, nonspecific disease often occurs when chemotherapeutic drugs are used in combination, making it difficult to know which drugs are responsible for causing the disease.

Cytarabine is the most commonly cited drug; however, others are also implicated, such as bleomycin, chlorambucil, cyclophosphamide, cytarabine, doxorubicin, lomustine, mitoxantrone, busulfan, carmustine, cisplatin, cyclophosphamide, etoposide, 5-fluorouracil, methotrexate, and thiotepa. Some authors consider neutrophilic eccrine hidradenitis (NEH) as a paraneoplastic phenomenon, since it has been found in an early case of acute myeloid leukemia not yet treated. It has been associated with HIV infection, *Nocardia*, *Serratia*, *Enterobacter*, *Staphylococcus*, and with patients receiving GM-CSF. The mechanism is unknown, but may be due to the excretion of the chemotherapeutic drug by the eccrine glands and its direct toxic effect on the eccrine epithelium.

The clinical condition may be preceded by fever and unspecific clinical signs. Skin eruptions are distributed in the head, neck, trunk, and extremities, with lesions that vary from erythema, papules, nodules, and pustules to papular plaques. Lesions may be purpuric or hyperchromic, single or multiple. They appear between 2 days and 3 weeks from the start of treatment, regressing spontaneously without scarring or sequelae 1–4 weeks after the suspension of the drug.

The differential diagnosis is vast and includes sepsis, septic embolism in a post-chemotherapeutic neutropenic patient, vasculitis, leukemia cutis, hypersensitivity reaction, urticaria, polymorphous erythema, and neutrophilic dermatoses such as Sweet's syndrome, bullous pyoderma gangrenosum, and atypical pyoderma gangrenosum.

Owing to the unspecific clinical presentation of the disease and the great number of differential diagnoses, some authors suggest that NEH be included in the diagnostic hypotheses of any

eruption that may occur in patients undergoing chemotherapy, and its final diagnosis is established by histopathology. Therefore, histopathology is essential for conclusive diagnosis. It is constituted by a dense neutrophilic infiltrate, inside and around the eccrine glands, with necrosis of the eccrine epithelium cells. Involvement of the apocrine glands has been reported. Occasionally, squamous syringometaplasia, hemorrhage and edema of the dermis, spongiosis and/or vacuolization of the basal layer of the epidermis, necrosis of keratinocytes, and mucin deposits inside and around the eccrine glands may occur.

In patients with severe neutropenia, the neutrophilic infiltrate may be absent; however, necrosis of the eccrine epithelium is typical. NEH is a self-limiting adverse reaction. Frequently the process resolves within a month, without treatment. In other chemotherapy cycles, 60% of the patients may relapse. The efficacy of the prophylactic or therapeutic use of systemic corticosteroids, dapsone, or nonhormonal anti-inflammatories is still questionable.

Eccrine Squamous Syringometaplasia
[44, 67–70]

Eccrine squamous syringometaplasia is an unusual adverse reaction to chemotherapeutic drugs. It can also be found in association with chronic ulcerations, skin tumors, exposure to toxic agents, and several inflammatory processes. Therefore, it is not a histopathologic reaction exclusive to the use of chemotherapeutic drugs. The mechanism of neutrophilic eccrine hidradenitis is unknown, but it can be the result of the excretion of the drug by the eccrine glands and its direct toxic effect on the eccrine epithelium. It is postulated that eccrine squamous syringometaplasia represents the final noninflammatory spectrum of adverse reactions to chemotherapeutic drugs in the eccrine glands.

Similarly to NEH, eccrine squamous syringometaplasia also has an unspecific clinical presentation, constituted by erythematous maculae, papules, and papular plaques or vesicles, localized or disseminated. Lesions develop between 2 and 39 days after the start of chemotherapy and improve spontaneously after 4 weeks.

The diagnosis is histopathologic, characterized by the presence of squamous metaplasia of the eccrine glands in the papillary dermis. Minimal and focal necrosis of the eccrine gland epithelium, fibroblastic proliferation, and edema of the periductal stroma may occur. Contrary to NEH, the neutrophilic infiltrate is minimal or absent. Squamous eccrine syringometaplasia has been described as an accidental histologic finding in other conditions not associated with chemotherapy.

Eccrine squamous syringometaplasia does not appear to be associated with a specific chemotherapy agent or malignancy. Numerous drugs have been related such as cytarabine, mitoxantrone, daunorubicin, cisplatin, 5-fluorouracil, doxorubicin, cyclophosphamide, etoposide, methotrexate, busulfan, melphalan, and carmustine.

Eccrine squamous syringometaplasia has been observed in association with palmoplantar erythrodysesthesia syndrome, in radiation-induced memory reactions, and in patients who underwent bone marrow transplantation and received high doses of chemotherapeutic drugs. The condition often spontaneously resolves.

Acral Erythema or Palmoplantar Erythrodysesthesia Syndrome [44, 67–70]

First described in 1974, this syndrome is also known as Burgdorf's syndrome, palmoplantar erythema, hand-foot syndrome, and toxic erythema of the palms and soles. It occurs more frequently in patients treated with cytarabine and, fluoropyrimidines, especially capecitabine, which is the oral 5-fluorouracil prodrug.

After alopecia and mucositis, it is the most common adverse reaction to chemotherapy. Other agents less frequently associated with palmoplantar erythrodysesthesia syndrome are cisplatin, cyclophosphamide, cytarabine, doxorubicin, daunorubicin, doxifluridine, etoposide, floxuridine, hydroxyurea, mercaptopurine, methotrexate, mitotane, paclitaxel, docetaxel, and vinorelbine.

It is estimated that this adverse reaction occurs in 6–64% of the patients treated with different chemotherapeutic regimens.

Most patients show a prodrome of dysesthesia, with a tingling (pins and needles) sensation on the palms and soles. Within a few days the reaction evolves to a feeling of pain and burning with a well-demarcated edema and erythema. The erythema is symmetric and sometimes more pronounced on the soft parts of the distal phalanges. Hands are often more affected than feet (Fig. 26.30a). Some patients show light scaling with or without erythema. A bullous variant has been described (Fig. 26.30b), representing a more severe form of the reaction, specifically associated with cytarabine and methotrexate. Lesions are aggravated if the treatment is not suspended, and the associated pain and edema may limit the movement of fingers. When the drug is suspended, the reaction progressively improves within 2 weeks.

In some patients, when treatment is maintained despite the development of erythrodysesthesia syndrome, palmoplantar keratodermia may occur. The reaction occurs more frequently in patients who undergo oral or continuous infusional therapy with fluoropyrimidines (2–18%), as compared with those submitted to bolus therapy (0.4–3%).

It is thought that in the pathogenesis of the process the local accumulation of the drug leads to degeneration with necrosis of the sweat glands, because its microscopic aspects are similar to those of eccrine squamous syringometaplasia and neutrophilic eccrine hidradenitis.

In the differential diagnosis the following should be considered: polymorphous erythema, erythromelalgia, eccrine squamous syringometaplasia, and neutrophilic eccrine hidradenitis. The most relevant differential diagnosis is acute GVHD. The fundamental difference is that acute GVHD occurs in patients who have received a bone marrow transplant, in addition to extracutaneous involvement with gastrointestinal alterations (abdominal pain and diarrhea, elevation of hepatic enzymes). In cases of acute GVHD without extracutaneous manifestations, differentiation may be difficult.

Nevertheless, acute GVHD presents with diffuse erythema and can form papules, whereas palmoplantar erythrodysesthesia syndrome shows a well-demarcated erythema and edema. There are no relevant histopathologic differences between them, except for necrosis of the satellite cell in all layers of the epidermis (apoptotic keratinocytes adjacent to lymphocytes) in acute GVHD and sometimes presence of squamous syringometaplasia in palmoplantar erythrodysesthesia syndrome. The differentiation between these two disorders is essential because the use of cyclosporine is necessary to treat acute GVHD, but worsens the patient's pain if used in the treatment of palmoplantar erythrodysesthesia.

Apart from dose reduction, longer intervals between the cycles of chemotherapy and, as a last resort, the suspension of the drug, there is no specific treatment for palmoplantar erythrodysesthesia syndrome that has proved to be effective in a large series of cases. Some treatments have been suggested for small series of patients or case reports. General measures should be taken, such as reduction or suspension of the drug, longer intervals between chemotherapy cycles, dressings, elevation of the extremity, cold compresses, analgesic medication, and emollients.

As a specific treatment, pyridoxine can be used if 5-fluorouracil, liposomal doxorubicin, doxorubicin, docetaxel, and etoposide have been administered; hand cooling (docetaxel); oral corticosteroids (doxorubicin, 5-fluorouracil); strong topical corticosteroids (liposomal doxorubicin, cisplatin, and 5-fluorouracil); and topical dimethyl sulfoxide (DMSO) at 99% (liposomal doxorubicin). Symptoms can be relieved with lesion care to prevent infection and elevation of the limb to reduce the edema.

Cooling of hands and feet during treatment reduces the blood flow in these areas and may decrease the severity of the reaction. Strong topical corticosteroids have been used with mixed results when associated with emollients. Systemic corticosteroids are useful in some situations. Pyridoxine (vitamin B6) in doses of 200–300 mg/day can be useful to treat and prevent this reaction, except when cytarabine or vincristine is used. Topical DMSO at 99% four times a day for 14 days has cured some cases of palmoplantar erythrodysesthesia syndrome induced by pegylated liposomal doxorubicin.

Toxic Erythema Caused by Chemotherapeutic Drugs [44, 67–70]

Some authors prefer to associate toxic erythema caused by chemotherapy with clinical lesions that present with painful erythema, with or without edema, often affecting the hands and feet, intertriginous areas such as the axillary and inguinal regions, and less frequently the elbows, knees, and auricular pavilion. These eruptions may have a bullous component, are self-limited, and generally evolve with resolution and scaling associated with postinflammatory hyperpigmentation.

Many denominations used refer to histopathologic findings or those given by various authors on different occasions. Disorders such as eccrine squamous syringometaplasia, NEH, acral erythema, and palmoplantar erythrodysesthesia syndrome would be, according to these authors, grouped under toxic erythema caused by chemotherapeutic drugs.

The objective to group many disorders under the same denomination seeks to emphasize the superposition of clinical characteristics and promote an easy dialogue between medical specialties and with the patient.

The clinical characteristics of the toxic erythema associated with chemotherapy are: (1) maculae or erythematous and/or edematous plaques on the hands and feet, intertriginous areas, and less frequently on the elbows, knees,

and auricular pavilions, often appearing 2–3 days after the administration of the drug; (2) associated symptoms of pain (that may be debilitating), burning, paresthesia, pruritus, and/or hypersensitivity; (3) pale color, petechiae, and/or sterile blisters, followed by erosion in areas of intense erythema; (4) scaling and spontaneous resolution without specific treatment; and (5) chance of relapse if an equal or higher dose is administered.

Isolated papules may be found in the periphery of plaques. Papules and plaques may also be found in the head, cervical region, trunk, and extremities. Onset of lesions after 2–10 months can be observed.

The histologic characteristics observed are atypia (larger cells and nuclei and nuclear pleomorphism), apoptosis of keratinocytes, mitotic figures and bizarre mitotic configurations (astral mitosis), loss of polarity of the epidermal cells and apoptosis of keratinocytes, vacuolar degeneration of the basal layer of the epidermis, dermal edema, and eccrine squamous syringometaplasia. Moreover, necrosis of the upper epidermis, similar to the alterations observed in pellagra, may also occur. The inflammatory infiltrates are usually minimal despite their abundant clinical profile. From these observations, it has been suggested that erythema is secondary and results from damage to keratinocytes, leading to the release of cytokines and vasodilation.

Acneiform Eruption [44, 67–70]

Acneiform eruption is the adverse effect more often associated with the use of EGFR inhibitors. Onset occurs 1 week after the start of treatment with the EGFR inhibitor as a self-limiting eruption, dose-related, that affects the face, central region of the thorax, upper dorsum and, more rarely, limbs.

It presents with follicular erythematous papules, pustules with or without comedones, and scaling of the interfollicular skin (Fig. 26.31). Often an association with the following conditions is observed: acral asteatosis, paronychia with pyogenic granuloma, oral and nasal aphthous ulcerations, and hair alterations.

Palms and soles are often free of lesions. Excessive follicular hyperkeratosis leading to the

Fig. 26.31 Cetuximab-induced acneiform eruption on trunk

obstruction of the ostium with formation of a follicular corneal plug, rupture of the glandular wall, and consequent inflammatory process are suggested as pathogenic mechanisms.

In the histopathologic examination a prominent corneal plug, with dilated infundibulum, with or without neutrophilic folliculitis, is observed. There is a positive correlation between the severity of the eruption and the tumoral response and survival. We emphasize the need for attention to the eruption to improve adherence to the chemotherapeutic treatment. The use of topical anti-acne agents and oral tetracyclines improve the condition. Topical emollients are indicated to treat xerosis.

Mucous Membrane Alterations [44, 67–70]

Stomatitis [44, 67–70]

Oral mucositis is the main dose-limiting reaction of most chemotherapeutic drugs. About 40% of the patients being treated show some type of oral complication. These complications are often associated with drugs that affect the synthesis of DNA. The main causative agents are antimetabolic drugs and antitumoral antibiotics.

The drugs more frequently associated with stomatitis are bleomycin, dactinomycin, methotrexate, topotecan, and 5-fluorouracil. Unusually, the stomatitis caused by 5-fluorouracil is related to its continuous infusional administration or to the use of its oral prodrug, capecitabine, and is less frequently observed when 5-fluorouracil is administrated in bolus. The main mechanism is the direct toxicity of the drug, but it can result secondarily from the indirect effects of the drug on the bone marrow. In patients with head and neck tumors, cisplatin used during radiotherapy acts as a strong radiosensitizer. In these cases there is more tumoral control but also greater severity of stomatitis caused by a boost in the direct effect of radiotherapy.

Since oral epithelium cells have a high mitotic index (renewal every 7–14 days), they become susceptible to the toxic effects of chemotherapeutic drugs. Moreover, there is atrophy of the oral mucosa, causing odynophagia, burning, xerostomia, and mucous membrane ulcerations. Ulcerations may be initially focal and then become diffuse and confluent, with occasional vesicles and blisters. These alterations are more common in the nonkeratinized mucosa and appear 4–7 days after use of the drug. Resolution of lesions may occur after treatment is suspended, often within 3–4 weeks.

Spontaneous or induced hemorrhage, especially gingival, may occur when the platelet count is below 10,000/mm^3. Patients at a higher risk of developing stomatitis are those with hematologic neoplasms, those who are under 20 years old (high mitotic activity of the epithelium), and patients with pre-existing oral disease and poor mouth hygiene.

Preventive measures include proper maintenance of oral hygiene by washing the mouth with water, saline solution, sodium bicarbonate, or hydrogen peroxide. The use of cold water to prevent mucositis induced by 5-fluorouracil and melphalan in high doses appears to be helpful. Other alternative clinical procedures, still not fully proven, consist in the use of chlorhexidine gluconate, β-carotene, and benzydamine chlorhydrate or sucralfate.

Treatment essentially consists of support with oral care, using agents such as magnesium or aluminum hydroxide and vitamin E. In addition, pain-relief drugs such as paracetamol and opioids (codeine and morphine) may be necessary when the use of topical anesthetics such as benzocaine and lidocaine are not effective. Additional complications occur because of secondary bacterial, viral, or fungal infections that may become systemic.

Palifermin, when used prophylactically, reduces the occurrence and duration of severe stomatitis in patients with hematologic tumors and submitted to bone marrow transplantation. Palifermin is a human recombinant factor of keratinocyte growth and protects various epithelial tissues. It acts not only on stomatitis but also on mucositis in general. A possible tumoral stimulating factor still limits its use in patients with epithelial tumors.

Scrotum Ulcer After Intraperitoneal Hyperthermic Chemotherapy with Mitomycin C [71–73]

Peritoneal carcinomatosis frequently signals the terminal stage in some cancers of gastrointestinal and gynecologic origins. Cytoreductive surgery and intraperitoneal hyperthermic chemotherapy was introduced in the early 1990s and has become the mainstay of treatment in particular clinical settings for patients with peritoneal carcinomatoses, especially in pseudomyxoma peritonei, significantly improving overall survival rates.

There are four case reports of this recently described entity using a new procedure to treat peritoneal carcinomatosis after intraperitoneal hyperthermic chemotherapy with mitomycin C. One of them was described [71] in a male patient after 9 days of the procedure. The patient developed pain and scrotal necrosis on the anterior aspect of the scrotum (Fig. 26.32).

Two possible causes of the scrotal ulcers were proposed. (i) A patent processus vaginalis, allowing mitomycin C to become sequestered in the scrotum, inducing an inflammatory reaction, resulting in scrotal wall inflammation and subsequent ulceration (Fig. 26.33). This was proposed since previous studies have shown that intradermal

Fig. 26.32 Scrotal necrosis on anterior aspect of scrotum caused by intraperitoneal hyperthermic chemotherapy with mitomycin C
Fig. 26.33 Probable mechanism of mitomycin C deposition in a patent processus vaginalis into the scrotum

administration of mitomycin C inhibits wound healing and induces skin necrosis. (ii) Local spillage of mitomycin C onto the scrotal skin, with resulting inflammation and ulceration.

Previous studies with patients on continuous ambulatory peritoneal dialysis (CAPD) have shown that 10% of CAPD patients developed

genital swelling [3]. A possible cause of the scrotal swelling is a patent processus vaginalis causing a communicating hydrocele, which can be found in 15–37% of adult men and may not be clinically evident until CAPD has begun.

Patients may develop this complication months after the surgery; hence, any complaint of scrotal pain or discomfort in these patients should warrant immediate investigation and attention, even if the complaints present much later.

Our group suggests that an image investigation, such as computed tomographic peritoneography, should be considered for male patients prior to intraperitoneal chemotherapy, since this complication is potentially serious for the patient.

Vascular Conditions Associated with Chemotherapy [74]

Vasomotor Changes [74]

Various vascular alterations have been described, probably as a result of a direct effect on arterial smooth muscle fibers or by acting on the autonomic nervous system.

Manifestations may include blood vessel spasms with livedo, Raynaud's phenomenon, and distal necroses, which may be triggered by bleomycin and cisplatin. Vasodilatation with erythema and flushing may result from the use of bleomycin, cisplatin, asparaginase, dacarbazine, taxanes, 5-fluorouracil, doxorubicin, cyclophosphamide, gefitinib, and carmustine.

Flushing [74]

Flushing consists of a temporary erythema of the face, neck, upper chest, ears, or upper abdomen. The mechanism responsible for flushing is a transitory vasodilation mediated by the autonomic nervous system or by the direct effect of circulating substances that act on the musculature of the vessel walls.

The nerves of the autonomic nervous system also control the sweat glands so that flushing mediated by these nerves is known as "wet flushing," whereas when the substance acts directly on the vascular wall muscles it is known as "dry flushing." Derivatives of biological agents

such as L-asparaginase and bleomycin are notorious for causing flushing, which occurs soon after infusion. Irinotecan, a topoisomerase I inhibitor, causes dysautonomia, the symptoms of which include diarrhea, bradycardia, and flushing.

Hormonal agents such as antiestrogens (tamoxifen, anastrozole), LHRH analogs (leuprolide), and antiandrogens (flutamide and diethylstilbestrol) may result in flushing. Other agents that also deserve mention include 5-fluorouracil, carboplatin, cisplatin, cyclophosphamide, dacarbazine, doxorubicin, etoposide, and methotrexate.

Interactions with Radiation [74]

Interaction with UV Light [74]

Eruptions resulting from photosensitivity are caused by various agents, principally following exposure to UV radiation. Phototoxicity caused by dacarbazine, fluoropyrimidines (systemic 5-fluorouracil, topical 5-fluorouracil, tegafur, and capecitabine) and vinblastine has been well documented.

Phototoxicity caused by dactinomycin, doxorubicin, hydroxyurea, procarbazine, brequinar sodium, mitomycin, 6-thioguanine, and flutamide, as well as by the porphyrin compounds that are used in photodynamic therapy, is uncommon.

Reactivation of sunburn is a well-documented adverse effect following the use of methotrexate. It occurs when the drug is administered 1–3 days after exposure to UV radiation, when the erythema from the previous exposure has been in the process of disappearing. Leucovorin does not prevent this reaction.

Phototoxic reactions resemble intense sunburn in areas of the skin that are exposed to light, with erythema, edema, pain, or pruritus. Blisters may be present and desquamation may occur in severe cases. Residual hyperpigmentation may persist for months.

Hydroxyurea has been described as being associated with development of dermatomyositis-like eruption due to photosensitivity (Fig. 26.34) [74, 75].

Hydroxyurea is an anticancer agent that inhibits DNA synthesis through its action on the enzyme ribonucleotide reductase [75]. It is used in chronic myeloproliferative diseases such as polycythemia vera, chronic myeloid leukemia, and essential thrombocytosis, although it has also been prescribed to patients with refractory psoriasis [75]. Patients on long-term therapy with hydroxyurea can develop various side effects, including a wide variety of mucocutaneous manifestations, which appear in 10–35% of patients [75]. The most common skin changes are facial erythema, hyperpigmentation, xerosis, alopecia, skin atrophy, melanonychia, and ulcers on the

Fig. 26.34 Dermatomyositis-like eruption caused by hydroxyurea

Fig. 26.35 An aggressive squamous cell carcinoma on the ear of a patient under treatment with hydroxyurea

lower limbs [75]. Other less frequent adverse effects are dermatomyositis-like rash and non-melanoma skin cancer (Fig. 26.35) [75].

Dermatomyositis-like rash resembles true dermatomyositis both clinically and histologically [75]. It presents as desquamating erythematous papules or plaques on the dorsum of the hands, typically associated with facial erythema and pronounced xerosis of the skin. Patients rarely report other accompanying symptoms and there are usually no significant alterations of laboratory tests [75]. Histologically, a lichenoid inflammatory infiltrate is found at the dermoepidermal interface, with vacuolization of the basal layer, dyskeratosis, and, rarely, mucin deposition (Fig. 26.36) [75].

Diagnosis is made according to the distribution of the lesions and by the temporal relationship between chemotherapy and light exposure. Treatment includes discontinuation of the agent and protection from the sun for at least 2 weeks. Physical sunscreens are recommended. Cold compresses, systemic antihistamines, and topical or oral corticosteroids are used as associated symptomatic treatment.

Radiation Recall [74]

This is a phenomenon whereby the chemotherapeutic agent induces an inflammatory reaction in an area previously exposed to radiation. These reactions are predominantly cutaneous; however, they may affect internal organs such as the lungs, heart, bladder mucosa, esophagus, oral or bowel mucosa, and supraglottic larynx.

It occurs more often with the use of doxorubicin, dactinomycin, and gemcitabine and is less common with bleomycin, etoposide, hydroxyurea, methotrexate, trimetrexate, vinblastine, 5-fluorouracil, lomustine, daunorubicin, melphalan, cyclophosphamide, cytarabine, docetaxel, edatrexate, idarubicin, paclitaxel, tamoxifen, and vinblastine.

The mechanism of radiation recall is unknown but it is probably related to DNA repair. Relapsing dermatitis or radiation recall may occur between 8 and 15 days following radiotherapy and generally appears hours to days after administration of the chemotherapeutic agent.

Clinically, the patient may or may not experience a painful erythema with or without vesiculation, edema, desquamation, and pruritus. The borders of the lesion are well defined and correspond to the exact site at which the radiation was applied. In severe cases, necrosis and ulceration may occur.

The severity appears to directly reflect the brevity between radiation and chemotherapy as well as the doses of both radiation and chemotherapy. The reaction improves spontaneously within hours or weeks following cessation of chemotherapy, treatment being symptomatic.

The use of systemic corticosteroids associated with the discontinuation of chemotherapy generally results in a marked improvement and may permit reintroduction of the treatment.

Exacerbation of Radiation [74]

This occurs when a chemotherapeutic agent increases the toxicity of radiotherapy. This phenomenon may occur in virtually all the organs of the body including the skin, mucosa, esophagus,
Fig. 26.36 Interface dermatitis on elbow of a patient under treatment with hydroxyurea

lungs, heart, digestive tract, kidneys, liver, brain, bladder, and eyes.

The agents most associated with exacerbation of radiation are bleomycin, gemcitabine, dactinomycin, doxorubicin, 5-fluorouracil, hydroxyurea, 6-mercaptopurine, oxaliplatin, and methotrexate.

Clinically, the reaction resembles residual dermatitis secondary to acute dermatitis from radiation, with erythema, edema, vesiculation, blisters, or erosions. The reaction generally appears at the site of radiation; however, the area affected may be more extensive. Severe mucositis may occur.

The reaction is associated with the dose, the type of drug used, and the sequence of time between radiation and the use of chemotherapy. Toxicity may be additive or supra-additive (synergic). In supra-additive toxicity, the reaction is greater than that of the sum of each one of the types of treatment alone.

Treatment is symptomatic: applying cold compresses, taking precautions at the site to prevent infection and avoiding trauma, heat, and UV light. Sequelae such as fibrosis, skin atrophy, and telangiectasia-related disorders may occur.

Hypersensitivity Reactions Caused by Chemotherapy Agents [74]

In theory, all chemotherapeutic agents may trigger hypersensitivity eruptions. With certain drugs derived from biological agents such as L-asparaginase, mitomycin C, and bleomycin in addition to paclitaxel, the incidence of hypersensitivity reactions is high. In the case of paclitaxel, this is due to the fact that it is dissolved in Cremophor EL castor oil.

According to the classification system defined by Gell and Coombs, the majority of hypersensitivity reactions are type I, i.e., IgE-mediated. They present as urticaria, pruritus, angioedema, and anaphylaxis. They generally occur within the first hour after use of the drug, but onset may be delayed until up to 24 h after using the medication.

Type III reactions occur because of formation of circulating immunocomplexes, and cause eruptions such as polymorphous erythema and vasculitis. Nonetheless, L-asparaginase and procarbazine cause urticarial reactions via type III reactions.

Allergic contact dermatitis, a type IV reaction, may occur, principally as a consequence of the topical use of nitrogen mustard (mechlorethamine).

Other severe reactions may occur, such as SJS and TEN, as well as exanthematous eruptions, all currently classified as type IV reactions according to the extended Gell and Coombs classification, i.e., SJS and TEN, respectively (type IVc, mediated by Fas, granzymes, and perforin) and exanthematous eruptions (type IVb, mediated by T cells with IL-5 production, with chemotaxis of eosinophils).

Local Reactions to Chemotherapy Agents [74]

Local Toxicity [74]

Antineoplastic drugs may be classified according to their potential aggressiveness toward blood vessels and adjacent tissues. They may be non-irritating, irritating, or vesicant, causing effects that range from mere local discomfort to tissue necrosis.

Nonirritating drugs (thioguanine, asparaginase, bleomycin, cyclophosphamide, chlorambucil, methotrexate, hydroxyurea) provoke an edema that is indicative of a site of extravasation; however, they do not cause necrosis or tissue irritation.

Irritating drugs (5-fluorouracil, carmustine, docetaxel, and etoposide) cause tissue damage that does not progress to necrosis. They trigger erythema, pain, inflammation at the puncture site and along the venous pathway, burning, and local edema, without blistering. The vesicant drugs (dactinomycin, doxorubicin, melphalan, vincristine, vinblastine, and dacarbazine) cause severe skin irritation with pain, erythema, edema, blistering, and necrosis with functional and aesthetic damage.

Drug Extravasation [74]

This is defined as the leakage of a chemotherapeutic drug from the vessel bed to the surrounding tissues, either as a result of vascular rupture or by direct infiltration.

The frequency of this event in adults is estimated at 0.1–6% and it is more common among children. Severe sequelae are rare. The severity of tissue damage is related to the type of chemotherapeutic agent used and the quantity and concentration of the drug administered.

Cytotoxic agents are classified as irritants or vesicants as a function of their potential for local toxicity. An irritant is defined as an agent that causes an inflammatory reaction, paresthesia, pain, or phlebitis at the puncture site or along the venous pathway.

Clinical signs include sclerosis and hyperchromia along the passage, as well as burning, increased temperature at the site, discomfort, erythema, and pain at the area of extravasation. Necrosis does not occur with this condition. The symptoms are generally short-lived and leave no sequelae. The drugs most associated with this complication are 5-fluorouracil, carboplatin, cisplatin, bleomycin, mitomycin, dactinomycin, idarubicin, daunorubicin, dacarbazine, ifosfamide, cyclophosphamide, mechlorethamine, carmustine, mitoxantrone, paclitaxel, docetaxel, streptozotocin, vinblastine, vinorelbine, and etoposide.

The vesicant agents (melphalan, bleomycin, mechlorethamine, carmustine, mitomycin, mitoxantrone, cisplatin, paclitaxel, dacarbazine, dactinomycin, daunorubicin, streptozotocin, doxorubicin, epirubicin, vinblastine, vincristine, etoposide, vindesine, and vinorelbine) have the potential to cause more severe and long-lasting tissue damage, including necrosis of the affected area.

The initial manifestations are often subclinical and may appear immediately following extravasation or after several days or weeks. The initial signs include local burning or paresthesia at the site of infusion, mild erythema, pruritus, and edema. A change in the infusion rate or the absence of venous return in the aspirate may

indicate the occurrence of extravasation. After 2–3 days, erythema increases and there is pain, a brownish discoloration, induration, dry desquamation, or the appearance of blisters. If the amount extravasated was small, the signs and symptoms may disappear in the following weeks. If a significant amount was extravasated, the following symptoms may appear in the coming weeks: necrosis, formation of eschar and painful, necrotic ulceration with raised, erythematous borders and a yellowish base. There is generally no granulation tissue with these ulcerations. They may resolve slowly or persist, increasing gradually in area. Involvement of the tendons, nerves, and vessels may occur if appropriate treatment is not given, leading to severe sequelae such as nerve compression syndrome, a reduction in joint mobility, contractures, neural deficits, and reflex sympathetic dystrophy. Cellulitis and the formation of abscesses are rare events.

The interval between detecting the condition and adopting the appropriate measures should be short as possible. The nursing team should be trained in this respect.

Preventive measures should be adopted such as avoiding puncturing emaciated limbs, lower limbs, limbs with multiple punctures, limbs with phlebitis or those that have been subjected to radiation, the ipsilateral limb to a mastectomy, in vena cava syndrome, and in veins that protect joints, nerves, and tendons. It is important to evaluate the venous conditions of the patient and, if necessary, to use an indwelling catheter.

The use of common needles for venous access should be avoided. Adequate fixation should be performed and blood reflux should be tested, with an infusion of 0.9% saline solution or 5% glucose-saline solution used for every 2 ml of the chemotherapeutic agent. After administration of all the drugs, 20 ml of saline or glucose-saline solution should be infused to reduce any possibly toxic residues.

Vesicant drugs should always be given first. In prolonged sessions of chemotherapy (those lasting over an hour) with vesicant drugs, central venous access should be used. Always listen to the patient's complaints. If extravasation occurs, stop the infusion immediately.

Remove the puncture device and elevate the affected limb. In the case of extravasation of drugs such as etoposide, paclitaxel, vinblastine, vincristine, and vinorelbine, apply local heat (leading to vasodilation and dilution of the drug) for 30 min and ice (venous constriction and greater degradation of the toxic metabolites in addition to alleviating pain and inflammation) every 30 min, six times a day in the first 48 h. For the other drugs, apply ice every 30 min, six times a day. When indicated, the specific antidote for the drug in question should be used.

The use of intralesional corticosteroid and sodium bicarbonate should be avoided. Ulcers that fail to heal may require debridement and grafting. In case of persistent edema and erythema and pain without ulceration that persists despite conservative therapy or in the presence of extensive areas of necrotic tissue or skin ulceration, surgery may be indicated.

Periorbital Edema [74]

Edema of the eyelids has been described with the use of gemcitabine.

Cutaneous Eruption of Lymphocyte Recovery [74]

Cutaneous eruption of lymphocyte recovery (ELR) is observed in leukemia patients who receive bone marrow ablation. In general, it appears between the 6th and 21st days after chemotherapy. This point corresponds to the beginning of the recovery of peripheral lymphocytes following the nadir of leukocyte count induced by chemotherapy.

Although the exact mechanism has yet to be clarified, it is believed that the eruption is caused by the return of immunocompetent lymphocytes to peripheral circulation with cutaneous cytotoxicity. T lymphocytes and Langerhans cells are found on histopathologic evaluation of these reaction sites.

Clinically, the condition consists of pruriginous, erythematous macules, papules, or papulous plaques that become confluent. Erythrodermia may occur. In addition, this

condition is associated with an elevation in body temperature that occurs together with the appearance of the eruption.

The temperature falls in the following 2–3 days and the skin eruption tends to diminish after several days, progressing with desquamation and mild residual hyperchromia. The drugs most associated with these reactions are cytarabine, daunorubicin, amsacrine, etoposide, cyclophosphamide, and vincristine.

Differential diagnosis should be made with sepsis, viral exanthems, GVDH, leukemia or lymphoma cutis, and drug hypersensitivity or toxicity. Histopathology is nonspecific. The most characteristic findings are superficial perivascular mononuclear cell infiltrate, mild epidermal alterations such as spongiosis, vacuolar alteration of the basal cell layer, and loss of keratinocyte maturation secondary to chemotherapy.

Dyskeratotic keratinocytes are rare and eosinophils are absent. On occasions when the patient was treated with GM-CSF associated with IL-3, atypical lymphocytes with large pleomorphic and hyperchromatic nuclei were found at histopathology.

Differentiation may be difficult between ELR and GVHD.

Skin Toxicity Associated with Epidermal Growth Factor Receptor Tyrosine Kinase Inhibitors [74]

Anti-EGFRs currently consist of panitumumab, cetuximab, erlotinib, and gefitinib. Skin toxicity with anti-EGFRs is actually more of a pharmacologic effect than a hypersensitivity reaction, since this is a clinical marker of the efficacy of the inhibiting effect of these drugs on the tumor, with the severity of the eruption corresponding to tumor response.

The skin effects observed with the anti-EGFR are alterations in capillary growth and in the texture of the hair, paronychia with or without secondary infection, or the formation of pyogenic granuloma, generalized asteatosis, skin desquamation, and blepharitis.

The most characteristic and intense manifestation is a papulopustular, follicular, comedone, or non-comedo (acneiform eruption) that occurs on the head, neck, and the central portion of the chest and back, which later disseminates.

There may be pruritus, which differentiates this reaction from the acneiform eruptions caused by corticosteroids, antiepileptic drugs, and vitamins B6 and B12. Acneiform eruptions occur in more than 50% of patients with use of cetuximab, and this percentage may reach as high as 75–100%. The manifestations generally occur in the first weeks (2 days to 6 weeks) after the beginning of treatment (cetuximab and panitumumab).

The eruption is dose dependent; however, the duration of the condition does not correlate with the duration of treatment. The acneiform eruptions induced by monoclonal antibodies are more severe and extensive than those resulting from the use of tyrosine kinase inhibitors. Blepharitis caused by anti-EGFRs may range from mild to intense.

Histopathology of the papulopustular lesions shows no increase in sebaceous gland activity, comedones, or follicular rupture that would explain the inflammation, differentiating it from acne vulgaris. The follicles are rather wide and at times obstructed by an excess of keratinocytes. In the dermis, neutrophilic infiltrate may be found, particularly involving the follicular infundibulum. Intraepidermal acantholysis may be present in association with the eccrine gland ducts. In the lesions of patients using gefitinib, there is an expressive thinning of the stratum corneum layer with loss of the normal basket-weave pattern.

Paronychia occurs in around 10–15% of patients who are using cetuximab and gefitinib, appearing at 6–8 weeks of treatment or sometimes after 6 months. It affects various fingers and the first toes. Treatment consists of potent topical corticosteroids. In case of onychocryptosis, anti-EGFR may be temporarily interrupted and canthotomy performed. Asteatosis occurs in around 35% of patients, particularly with the use of gefitinib. There is a predilection for the areas previously or simultaneously affected by acneiform eruption.

Fig. 26.37 Intense xerosis caused by erlotinib

Some patients have xerosis of the vaginal mucosa, with dysuria. Xerosis may progress to chronic asteatotic eczema (Fig. 26.37), with a greater susceptibility to *Staphylococcus aureus* infection or HHV-1.

Emollients and topical corticosteroids should be used for the eczema. Fissures can be treated with a solution of 50% propylene glycol under plastic occlusion or a hydrocolloid dressing.

Glossary

Adverse drug reactions (ADRs)   Include all unintended pharmacologic effects of a drug except therapeutic failures, intentional overdosage, abuse of the drug, or errors in administration. They can be classified as predictable (type A – 80% of the ADRs) or unpredictable (type B).

Anaphylaxis   An immediate systemic reaction that occurs when a previously sensitized individual is re-exposed to an allergen. It is caused by rapid IgE-mediated immune release of vasoactive mediators from tissue mast cells and blood basophils with a potential late component. This is a systemic severe ADR affecting skin, mucous membranes, gastrointestinal tract, respiratory tract, and cardiovascular system.

Drug allergy   An immunologically mediated response to a pharmaceutical and/or formulation (excipient) agent in a previous sensitized patient.

Drug idiosyncrasy   An abnormal and unexpected effect that is unrelated to the intended pharmacologic action of a drug and has an unknown mechanism. It is not mediated by a humoral or cellular immune response but is reproducible on readministration. It may be due to underlying abnormalities of metabolism, excretion, or bioavailability.

Drug intolerance   An undesirable pharmacologic effect that may occur at low or conventional doses of the drug without underlying abnormalities of metabolism, excretion, or bioavailability of the drug. Humoral or cellular immune mechanisms are not thought to be involved, and a definitive mechanism for such exaggerated responses has not been established (e.g., acetylsalicylic acid-induced tinnitus at low doses).

Pseudoallergic (anaphylactoid) reactions   Immediate systemic reactions that mimic anaphylaxis but are caused by non–IgE-mediated release of mediators from mast cells and basophils. Often caused by radiocontrast agents.

Severe ADRs   Include all adverse effects which are unpredictable life-threatening ADRs and need prompt recognition to reduce integumentary and internal organ damage and, thus, morbidity and mortality.

Uncomplicated ADRs   Include mild or moderate adverse drug effects on healthy patients, not involving life-threatening situations.

Part V

Dermatologic Diseases in Public Health: Environment and Skin Diseases

Cold and Heat

27

Clarissa Barlem Hohmann
and Renan Rangel Bonamigo

Key Points Summary
- Skin is responsible for maintaining the body temperature and thermal balance
- Cold injuries are frequently associated with some degree of circulatory impairment
- Burns are the most prevalent heat injury; they are potentially serious and should be avoided
- In cold and heat diseases it is always recommended to evaluate the presence of an underlying disease

Cold Injuries

Frostbite

Epidemiology

Frostbite is damage caused by the freezing of tissue upon exposure to extreme cold [1]. Several known risk factors are associated with this injury (Box 27.1), especially psychiatric problems, alcohol consumption, and drug use [2–4]. Alcohol and sedative drugs decrease the awareness of cold and impair the judgment necessary to warm up. Alcohol also inhibits shivering and causes cutaneous vasodilatation, predisposing to frostbite at warmer temperatures [2]. Typically, frostbite occurs when tissues are exposed to temperatures below the freezing point (typically −0.55 °C) for a period of time [5]. Frostbite most frequently affects the hands and feet (90% of reported injuries), but can also affect the face (nose, chin, ears, cheeks, and lips), buttocks/perineum, and penis [2, 3, 6].

Box 27.1 Risk factors for frostbite
General: prolonged exposure to cold, inadequate clothing, homelessness, smoking, dehydration, old age, high altitude.
  Systemic disease: diabetes, neuropathy, paraplegia, Raynaud's disease.

Mental illness or dementia.

Drugs: sedatives, β-blockers, and neuroleptics.

Intoxication: alcohol and illicit drugs.

Etiopathogenesis

In response to cold exposure, the body tries to preserve its temperature (vasoconstriction) and attempts to generate more heat energy (shivering) [2]. Cold injuries result from the limited capacity of the human body to cope with cold [6]. The effects result from direct and indirect freezing damage. Direct tissue injury occurs through the formation of intracellular and extracellular ice crystals. In the extracellular space, the ice crystals increase the oncotic pressure, dehydrating cells through outward diffusion of water and resulting in intracellular electrolyte disturbance [4]. The effects of damage to capillaries, microvascular occlusion, and progressive ischemia include generation of oxygen free radicals, production of prostaglandins and thromboxane A_2, release of proteolytic enzymes, and generalized inflammation [7, 8]. When the tissues rewarm, lysis of ice-containing cells and production of a prothrombotic microenvironment occur. Frostbite also causes less blood flow through localized vasoconstriction, an increase in viscosity, and microvascular damage through cooling of the vascular contents, which precipitates local transcapillary plasma loss and edema formation [4].

Clinical Presentation

Clinical manifestations of frostbite vary widely depending on the time since injury and the depth of injury [9]. The standard classification is divided into four degrees of injury. Clinically it is more useful to categorize frostbite as superficial (first and second degrees) or deep (third and fourth degrees) [6] (Box 27.2).

Box 27.2 Classification of cold injury
Superficial:
 1st degree.
 Partial skin freezing
 Erythema, edema, and hyperemia
 No blister or necrosis
 Occasional skin desquamation
 2nd degree.
 Full-thickness skin freezing
 Erythema, substantial edema
 Vesicles with clear fluid
 Blisters, desquamation, and black eschar formed
 Deep:
 3rd degree.
 Full-thickness skin and subcutaneous freezing
 Violaceous/hemorrhagic blisters
 Skin necrosis
 Blue-gray discoloration
 4th degree.
 Full-thickness skin, subcutaneous tissue, muscle, tendon, and bone freezing
 Little edema
 Initially mottled, deep red or cyanotic
 Eventually dry, black, and mummified

Most patients describe an initial feeling of cold, numbness, and sensory loss. The extremity will feel cold to the touch and patients often describe clumsiness and anesthesia, like "a block of wood" [3, 6]. It is often difficult to initially estimate the severity of frostbite injury, and there may be a wide discrepancy between the degree of damage to the skin and degree of damage to the deeper tissues [1]. The signs of good prognosis are normal skin color, blisters with clear fluid, and early formation of edema. Signs of poor prognosis are firm skin, lack of edema, nonblanching cyanosis, and small, proximal, dark hemorrhagic vesicles [6]. Physical examination helps to differentiate superficial from deep injury. Deep injuries are more frequently associated with blisters (clear or hemorrhagic). The most severe fourth-degree cold injury can present with a blue to gray skin color, with a hardened feeling to the skin on palpation [9].

Diagnosis

Diagnosis of frostbite is made clinically after a history of cold exposure. The patient describes a cold numbness with accompanying sensory loss.

The extremity will feel cold to the touch and may appear mottled blue, violacious, yellowish-white, or waxy [6].

Complementary Examinations

Technetium-99 bone scanning can be used to evaluate perfusion of bone and soft tissues. It has been shown to be useful at 2–3 weeks post injury to help clarify the extent of tissue loss [1, 2]. Angiography and magnetic resonance imaging may also help frostbite evaluation [5]. Plain radiographs are not helpful for early diagnosis, unless there is suspicion of concomitant fractures [1].

Differential Diagnosis

Chilblains is a benign condition related to a more chronic cold exposure characterized by pruritic, red-purple papules, macules, plaques, or nodules on the skin and often associated with edema or blistering, related to chronic vasculitis of the dermis. Trench foot is a nonfreezing injury caused by chronic exposure to wet conditions and temperatures just above freezing and is associated with arterial vasospasm and vasodilatation, with the affected tissue becoming cold and anesthetic, and then hyperemic after 24–48 h of exposure [8].

Therapeutic Approach

Firstly it is very important to treat life-threatening conditions before treating frostbite, especially if the patient is hypothermic. Next, frostbite should be treated with rapid rewarming by immersion in water at 37–39 °C, usually for 15–30 min. It is very important not to allow thawed tissue to refreeze, as it can lose its viability. If environmental conditions are such that thawed tissue could refreeze, it is safer to keep the affected part frozen until a thawed state can be maintained, especially if transport to medical care will take less than 2 h. Thawed areas should be air-dried rather than dried with a towel in order to avoid further skin damage [3, 10].

Most patients are dehydrated, and resuscitation with warm fluids is an important part of early management. Intravenous fluids should be warmed to 42 °C to prevent iatrogenic hypothermia [3, 8]. After rewarming, the treatment goals are to prevent further injury while awaiting the demarcation of irreversible tissue destruction. The injured extremities should be elevated to decrease edema. Tetanus prophylaxis should be given according to the usual protocol. Prophylactic antibiotics are seldom necessary and reserved only for identified infections [2, 3, 8]. Clear fluid-filled blisters should not be routinely debrided because they provide a biological dressing and protect underlying epithelialization; however, if the blister is tense and at high risk for rupture, it can be aspirated [8]. Hemorrhagic blisters should not be aspirated or debrided. Topical aloe vera (a thromboxane inhibitor), nonsteroidal anti-inflammatory agents (e.g., ibuprofen), or aspirin are usually applied to decrease production of prostaglandins and thromboxanes that can lead to vasoconstriction, dermal ischemia, and further tissue damage [10].

Patients with deep injuries at risk for amputation should be considered for thrombolytic treatment with tissue plasminogen activator (tPA) plus heparin within 24 h of thawing [3, 10, 11]. Contraindications for tPA use include concurrent trauma, neurologic impairment, recent surgery, or hemorrhage [1].

Iloprost is a prostacyclin analog with vasodilatory properties that may also affect platelet aggregation and, therefore, decrease microvascular occlusion. The intravenous form of the medication is not approved by the US Food and Drug Administration. Iloprost can be used when there is a history of trauma or when the exposure has occurred over the last 24 h, unlike tPA [5, 10].

Complete demarcation of tissue necrosis may take longer if performed after damage has occurred. As a general rule, amputation and surgical debridement are delayed for 2–3 months, unless infection with sepsis occurs [8, 10]. Angiography, technetium-99 bone scan, or magnetic resonance imaging may be used to evaluate the injury and guide additional therapy [3, 8, 10].

Acrocyanosis

Epidemiology

The incidence of acrocyanosis is not definitely known and probably is misdiagnosed. It is more prevalent in children and young adults (usually

younger than 30 years). There are risk factors associated with acrocyanosis including exposure to cold, outdoor occupations, and low body mass index [12]. Primary (idiopathic or essential) acrocyanosis is more common in women. Secondary acrocyanosis may be associated with other conditions such as the use of certain medications and malignancies [14] (Box 27.3).

> **Box 27.3 Causes associated with acrocyanosis**
> Hypoxemia
>   Acrocyanosis of infancy
>   Cold agglutinin disease
>   Cryoglobulinemia
>   Anticardiolipin antibodies
>   Medications
>   Toxins
>   Malignancies
>   Infections
>   Malnutrition
>   Spinal cord injuries
>   Inherited metabolic disorders
>   Palmoplantar keratoderma syndromes

Etiopathogenesis

The exact etiology of acrocyanosis is unknown. The pathophysiology involves a decreased basal flow through the acral cutaneous microcirculation. Peripheral arterial vasoconstriction, resulting from increased tone of the arterioles associated with secondary vasodilatation in capillary and postcapillary venules with consequent cyanosis, has been described [12, 13]. Changes in blood viscosity, decreased oxyhemoglobin, and increased platelet adhesiveness have been associated with this disease [13].

Clinical Presentation

Acrocyanosis is an uncommon condition characterized by persistent and symmetric erythrocyanotic discoloration of the hands, feet, and face, which is not preceded by paleness (Fig. 27.1) [15]. The nose, ears, lips, and nipples are also often affected. The disease is temperature dependent and generally worsens with cold exposure [14].

Fig. 27.1 Acrocyanosis (courtesy of Dermatology Service of UFCSPA)

Diagnosis

The diagnosis of acrocyanosis is made clinically through history and physical examination. It is important to be differentiated from other acrosyndromes and vaso-occlusive diseases.

Complementary Examinations

There is no specific examination for the diagnosis. Laboratory investigation and imaging studies are needed to investigate the etiology of secondary acrocyanosis if it is suspected.

Differential Diagnosis

Erythrocyanosis is characterized by a dusky cyanotic discoloration that occurs over areas with thick layer of subcutaneous fat (lower legs and thighs). Chilblains occur after cold exposure as burning, erythematous, or purplish swellings, especially on fingers and toes, nose, and ears. Other symptoms such as itching, burning, and pain are often present, in contrast to acrocyanosis. Raynaud's phenomenon is characterized by paroxysmal episodes of triphasic color change (white, red, and bluish discoloration) of fingers and toes caused by exposure to cold or emotional stress. In vaso-occlusive disease the pulse is usually low or absent, different from acrocyanosis. The acrocyanotic limb becomes pale when elevated, different from venous occlusion [12].

Therapeutic Approach

There is no standard or curative treatment for acrocyanosis. General supportive actions to keep

the skin warm are important to control the disease (gloves, slippers, avoidance of exposure to cold, no smoking). In severe cases, drugs such as α-adrenergic blocking agents (prazosin) and calcium channel blockers (nifedipine, diltiazem) can be used with variable results. Other options that can be beneficial include topically applied nicotinic acid derivatives and minoxidil. Sympathectomy is rarely indicated [12–14].

Chilblains

Epidemiology

The prevalence of chilblains (or perniosis) is not exactly known and is believed to be misdiagnosed. It is relatively common in European countries with damp, nonfreezing cold climates, in the northern regions of the United States, and in the southern regions of South America [16]. Women, children, and persons with low body mass index are most often affected [17].

Etiopathogenesis

The pathogenesis of idiopathic perniosis remains poorly understood. Some evidence suggests a disruption in the regulation of dermal blood flow, resulting in a challenge to thermal homeostasis [16]. In the majority of cases chilblains are idiopathic, but can be associated with some diseases [16, 18] (Box 27.4).

Fig. 27.2 Chilblains (perniosis) (courtesy of Dr. Francine Seibt)

hands, feet, and less frequently the face (nose, cheeks, earlobes) and legs (heels, shins, thighs, hips) (Fig. 27.2). Lesions are frequently associated with pain, pruritus, or burning. It can progress to blisters, erosions, ulcers, and permanent skin discoloration. Chilblains are induced by a cold, damp environment (humidity enhances air conductivity) in the late winter and early spring months [17, 19]. The lesions usually resolve slowly in 1–3 weeks, depending on the degree of trauma.

Box 27.4 Diseases associated with chilblains
Chronic myelomonocytic leukemia
  Systemic lupus erythematosus
  Behçet's disease
  Cryoglobulinemia
  Cryofibrinogenemia
  Cold agglutinin disease
  Raynaud's phenomenon
  Peripheral arterial occlusive disease
  Anorexia nervosa
  Obesity

Clinical Presentation

Chilblains is characterized by red-to-purple papular lesions involving the acral skin, especially

Diagnosis

Chilblains are diagnosed by clinical features associated with a history of prolonged exposure to moderate cold and damp conditions. A careful physical examination reveals the classic lesions described above.

Complementary Examinations

In suspect cases of associated signs of systemic disease, chronicity, or recurrence, laboratory tests

should be performed. These include a complete blood cell count, antinuclear antibody titer, serum chemical profile, serum protein electrophoresis, anti-double-stranded DNA, anti-Sm, anti-RNP, anti-SSA/Ro, anti-SSB/La, C3, C4, cryoglobulin, cryofibrinogen, and cold agglutinin analysis to rule out cryopathy or connective tissue disease [16, 19]. There are no characteristic histopathologic features that confirm the diagnosis, but biopsy of the affected area may exclude the presence of other disorders, although rarely needed.

Differential Diagnosis

The differential diagnosis of chilblains is broad, depending on the appearance and locations of lesions and the clinical history. Atheromatous embolization, thrombotic embolization, and peripheral artery disease can be associated with blue toes. Erythema nodosum, cold panniculitis, erythema induratum (Bazin's disease), and nodular vasculitis can be associated with erythematous, nodular, and ulcerative lesions. Leukocytoclastic vasculitis can be associated with palpable purpuric lesion. Raynaud's disease and acrocyanosis are vasospastic disorders that may coexist with perniosis. Lupus pernio or chilblain lupus is a disorder seen in patients with systemic lupus erythematosus (SLE). The endothelial damage imposed by the inflammatory reaction seen in SLE causes ischemic tissue changes and skin lesions similar to those seen in idiopathic perniosis [16].

Therapeutic Approach

First of all, it is important to explain to the patient the association of the disease with cold and damp conditions and encourage the use of adequate clothing (gloves, socks, hats, scarves, and proper shoes) to keep warm and seek shelter during cold-weather conditions. The patient needs to avoid any form of nicotine consumption because of its capacity of amplify the vasospastic responses to cold [16]. Nifedipine, a calcium channel blocker, has been shown to reduce the duration, severity, and recurrence of pernio lesions and symptoms. It is usually used at 20–60 mg daily [16, 20]. Side effects of nifedipine include flushing, headaches, dizziness, and occasional hypotension [19]. The treatment is usually continued while the weather is cold, even when the lesions are resolved, as a secondary prophylaxis, especially in patients with frequent recurrences. Commonly used topical corticosteroids are sometimes helpful. Other unproven treatments include topical vasodilators (such as nitroglycerin creams), heparin ointment, calcium preparations, intramuscular vitamin preparations, and sympathectomy [16].

Cold Urticaria

Epidemiology

The prevalence of cold urticaria is not well defined, and it is most commonly noted in young adults [21]. Women are affected twice as often as men [22]. The most common form is the idiopathic form in 96% of cases [23].

Etiopathogenesis

Most forms of cold urticaria are primarily acquired (idiopathic). Some cases can be secondarily acquired, and these are associated with underlying conditions such as malignancies, cryoglobulinemia, and infectious and autoimmune diseases. A familial form of cold urticaria, a rare autosomal dominant condition with onset at an early age, has also been described [21, 22, 24].

Clinical Presentation

Cold urticaria is a form of physical urticaria that occurs after cold exposure. It is characterized by the development of weal-and-flare type skin reactions and/or angioedema caused by release of histamine, leukotrienes, and other proinflammatory mast-cell mediators. Symptoms typically occur minutes after the skin is exposed to cold, air, liquids, or objects, and are usually limited to cold-exposed areas [22]. The greatest risk with cold urticaria is the development of a systemic reaction resulting in hemodynamic collapse during generalized cold exposure (e.g., swimming) [25].

Diagnosis

Diagnosis is clinical and is confirmed with cold stimulation tests, the ice cube test being the most

commonly used. An ice cube is placed in a plastic bag and applied to skin (usually forearm) usually for 5–20 min. A positive reaction is noted by the formation of a wheal during rewarming of the skin [21, 26]. Recently, a more accurate test has been described using a Peltier effect-based electronic device (Temp Test®; Emosystems, Berlin, Germany), which allows exposure of the skin to thermal elements with defined temperatures in a more controlled evaluation [22, 27].

Complementary Examinations

Laboratory tests are indicated to exclude major underlying diseases and identify possible associated causes. Investigation may include complete blood count, erythrocyte sedimentation rate, antinuclear antibodies titer, serology for syphilis, borreliosis, human immunodeficiency virus (HIV), Epstein–Barr virus, search for cryoglobulins, cold agglutinins, and cryofibrinogens [21, 28].

Differential Diagnosis

Cold erythema is a reaction to cold exposure with local pain and erythema but not urticaria. Ice cube testing is negative, merely producing pain and erythema. In cold panniculitis the lesions appear 1–3 days after cold exposure and subside spontaneously within 2 weeks. Application of an ice cube to the skin will result in an erythematous plaque 12–18 h later [24].

Therapeutic Approach

Avoidance of exposure to cold (including ice cream, cold beverages, and cold water) is the first step in the treatment and prevention. In patients with secondary cold urticaria, the underlying disease must be treated to resolve the skin symptoms. Antihistamines are considered first-line treatment for urticaria. Traditionally, first-generation antihistamines (e.g., chlorpheniramine, diphenhydramine, hydroxyzine) were used. Second-generation (e.g., cetirizine, loratadine, ebastine) and third-generation (e.g., desloratadine, fexofenadine, levocetirizine) antihistamines are effective and well-tolerated treatments with less sedation than first-generation antihistamines, and nowadays can be used as the first-line treatment for cold urticaria [29]. If the standard doses are not effective, increasing the dosage up to four-fold is recommend to better control the symptoms and treat the disease.

Cryoglobulinemia

Epidemiology

Cryoglobulinemia is a small-vessel vasculitis associated with the presence of circulating cryoglobulins. Cryoglobulins consist of immunoglobulins that precipitate at temperatures under 4 °C, and dissolve when heated at 37 °C [30]. Cryoglobulinemia affects mainly the skin, joints, peripheral nervous system, and kidneys. The prevalence and incidence of cryoglobulinemia are unknown, especially because of the heterogeneity in the etiology, clinical presentation, and geographic distribution. It appears to be more common in patients aged 45–65 years, and more frequent in women [31].

Etiopathogenesis

Cryoglobulinemia is classified into three types according to the immunochemical analysis. Type I cryoglobulinemia is characterized by single monoclonal immunoglobulins linked to a B-cell lymphoproliferative disorder. Type II cryoglobulinemia is characterized by polyclonal immunoglobulin G (IgG) with monoclonal IgM with rheumatoid factor activity. Type III cryoglobulinemia is characterized by polyclonal IgG and polyclonal IgM with rheumatoid factor activity. Types II and III are also referred to as mixed cryoglobulinemia [32]. This disease can occur secondarily to underlying autoimmune (e.g., Sjögren's syndrome, systemic lupus erythematosus, rheumatoid arthritis), infectious (e.g., hepatitis C virus (HCV), hepatitis B virus, HIV), and malignant process (e.g., multiple myeloma, Waldenström's macroglobulinemia, B-cell lymphoma, monoclonal gammopathy of unknown significance), but rarely there is no known cause (i.e., essential cryoglobulinemia) [30, 33]. HCV is the most common cause and is especially associated with type II mixed cryoglobulinemia [34, 35].

Clinical Presentation

The main clinical manifestations are due to hyperviscosity, vascular occlusion, and deposition of immune complexes. Most frequently affected sites are skin, nerves, kidney, and joints. Clinical features are variable, ranging from mild clinical symptoms (e.g., purpura and arthralgia) to fulminant life-threatening complications (e.g., glomerulonephritis, widespread vasculitis) [31]. Dermatologic features include palpable purpura, ulcers, Raynaud's phenomenon, and acrocyanosis (Fig. 27.3). Neurologic features include peripheral neuropathy, and most frequently distal symmetric sensorimotor polyneuropathy. The central nervous system is rarely involved. Renal features include hematuria, proteinuria, glomerulonephritis, and renal insufficiency. Renal involvement is associated with worse prognosis. Musculoskeletal features include symmetric arthralgia, with polyarticular involvement of metacarpophalangeal joints, shoulders, knees, and ankles the most common presentation. Other features are fatigue, malaise, abdominal pain, headaches, confusion, small airway disease and interstitial lung disease, blurry vision, and oronasal bleeding [31, 33, 36].

Diagnosis

Diagnosis is based on the detection of serum cryoglobulins in association with purpura, arthralgia, and weakness, and sometimes with renal or neurologic involvement. Cryoglobulins are evaluated by the detection of protein precipitates in the

Fig. 27.3 Cryoglobulinemia

patient's serum maintained at 4 °C for at least 7 days, which dissolve when heated at 37 °C [31].

Complementary Examinations

The presence of cryoglobulins is essential for diagnosing cryoglobulinemia [33]. Other laboratory abnormalities frequently seen are low C4 serum complement fraction, increased erythrocyte sedimentation rate, increased C-reactive protein level, presence of rheumatoid factor activity, and mild normochromic normocytic anemia [31, 33]. It is mandatory to evaluate for underlying diseases such as lymphoproliferative, autoimmune, and infectious disorders, especially HCV infection.

Differential Diagnosis

The differential diagnosis is made especially with other vasculopathies (thromboangiitis obliterans, Henoch-Schönlein purpura, leukocytoclastic vasculitis), hematologic diseases (protein C or S deficiency, disseminated intravascular coagulation, thrombotic thrombocytopenic purpura), autoimmune diseases (lupus erythematosus, scleroderma, dermatomyositis, rheumatoid arthritis, antiphospholipid antibody syndrome), and drug-related reactions with Raynaud's phenomenon, livedo reticularis, and purpura [36].

Therapeutic Approach

Treatment of cryoglobulinemia should be based on the severity of clinical manifestations, etiopathogenic mechanisms involved, and the associated underlying disorders. In HCV-associated mixed cryoglobulinemia, antiviral therapy with pegylated interferon (IFN) plus ribavirin is indicated [31, 34]. Rituximab, an anti-CD20 monoclonal antibody, has been indicated for the treatment of HCV-positive mixed cryoglobulinemia with severe organ involvement and/or without an early viral response [34]. Type I cryoglobulinemia is life-threatening because of the severity of cutaneous and visceral involvement and the underlying malignant hemopathy. The treatment is based on polychemotherapy, but specific treatment including plasma exchange, rituximab, corticosteroids, bortezomib, and

lenalidomide may also be indicated depending on the severity of clinical manifestations and the underlying hematologic disorder. In patients with mild to moderate noninfectious mixed cryoglobulinemia, therapeutic management includes resting, avoidance of cold temperatures, nonsteroidal anti-inflammatory drugs, and colchicine. In cases of severe disease the treatment is based on corticosteroids, immunosuppressants, plasmapheresis, and rituximab [30, 31].

Cold Panniculitis

Epidemiology

Cold panniculitis is more frequent during infancy and childhood following exposure to severe cold. There is no gender difference in incidence in children, and it usually occurs on the cheeks and chin. In adults it usually appears in women associated with horseback riding, and usually occurs on the thighs [37].

Etiopathogenesis

Although the exact mechanism is unknown, the pathogenesis of cold panniculitis is postulated to be similar to that of subcutaneous fat necrosis of the newborn, with high concentration of saturated fatty acids in the subcutaneous fat of neonates alongside increased susceptibility to crystallization and necrosis under cold temperatures [38]. Subcutaneous fat in newborns is rich in saturated oils such as palmitic and stearic acids, which have a higher solidification point. The subcutaneous fat tends to become more unsaturated with aging, and the solidification temperature diminishes [37, 39]. In adults it is usually associated with female gender, obesity, smoking, and exposure to cold weather for long time.

Clinical Presentation

There are two main types of cold panniculitis. Haxthausen's disease or "popsicle panniculitis" affects infants exposed to severe cold and occurs 48–72 h after exposure, and presents as erythematous, firm, tender nodules on the cheeks and chin in infants and small children [39–41].

The term popsicle panniculitis is used when children develop cheek lesions after sucking on an ice cube or popsicle. Cold panniculitis in children has also been reported after ice therapy in supraventricular tachycardia. Equestrian cold panniculitis is characterized by erythematous, violaceous, tender plaques on the upper lateral aspects of the thighs in young women practitioners of horseback riding [39, 40]. Wearing tight clothing for long periods in cold weather, heavy smoking, and age under 35 years predispose to equestrian cold panniculitis [42].

Diagnosis

The diagnosis of cold panniculitis is made by obtaining a history of exposure of the skin to cold. The vast majority of cases do not need further investigation. If necessary, biopsy may be indicated.

Complementary Examinations

Cold panniculitis usually does not require complementary examinations unless the diagnosis is not clear. Biopsy specimens show a lobular panniculitis with a mixed inflammatory cell infiltrate, most prominent at the dermal-subcutaneous junction [38]. There are no specific laboratory tests for the diagnosis, and further evaluation is not necessary in clinically typical cases.

Differential Diagnosis

In some cases, a clear distinction between cold panniculitis and subcutaneous fat necrosis of the newborn is difficult, and a cutaneous biopsy may be considered. Other causes of subcutaneous fat necrosis, such as hypercalcemia, α_1-antitrypsin deficiency, post-steroid, trauma, frostbite, and facial cellulitis, must be considered. Sclerema neonatorum is another disease in response to cold, but tends to occur in sick neonates, beginning in the lower extremities and often fatal [43].

Therapeutic Approach

Cold panniculitis resolves spontaneously and usually does not require treatment. Patients usually recover within several weeks after cold exposure and require only symptomatic relief and slow rewarming [40, 44].

Heat Injuries

Burns

Epidemiology

Burn accidents rank fourth among all injuries, ranked behind vehicle accidents, falls, and violence [45]. Children are the most affected by burn injuries. Scalding (hot objects or liquids) accounts for 80% of burns in young children, and flame-related injuries are more common in patients older than 6 years. Another group at high risk of burn injury are the elderly [46]. Preventive measures may lower the incidence in burns, especially in children, and it is recommended to alert parents and the population in general. The annual all-injury mortality and age-adjusted death rates caused by burns are 55 and 48 per 100,000 persons, respectively. These numbers are around three- to five-fold higher in developing countries [47].

Etiopathogenesis

Burn injuries occur frequently after exposure to hot objects or liquids, flames caused by lighters, lighter fluid, firecrackers, alcohol, and gasoline. These injuries can cause skin lesions with different degrees of damage and extension. There is a local and systemic response to the damage depending on the degree of burn injury. Damage depends on the temperature of the thermal energy source and the duration of contact [48]. The local response is coagulation of tissue with progressive thrombosis of surrounding vessels after the injury. If the burn exceeds 20% of the patient's body surface, there is a systemic response. In this case, there is release of mediators with a secondary loss of capillary integrity and consequent fluid loss. The systemic response leads to a hypermetabolic state, increasing the physiologic cardiac output over the first 48 post-burn hours. The burn wounds than are colonized by bacteria, and different degrees of secondary injury develop depending on the depth and gravity of the burn [36, 48].

Clinical Presentation

Burns can be classified by depth [46, 48] (Box 27.5).

Box 27.5 Burn degrees
1. *Superficial (first-degree) burns* (Fig. 27.4)
   - Only the epidermis
   - Pink, dry, and painful
   - No risk for scarring
   - Heal in 5–10 days
2. *Superficial partial-thickness (superficial second-degree) burns* (Fig. 27.5)
   - All the epidermis and part of the underlying dermis
   - Clear blisters
   - Wet, erythematous, and edematous
   - Generally do not cause scarring
   - Heal within 2 weeks

Fig. 27.4 First-degree burn

Fig. 27.5 Second-degree burn

3. *Deep partial-thickness (deep second-degree) burns*
   - All the epidermis and deeper layers of the dermis (i.e., reticular dermis)
   - White
   - Scarring
   - Heal in 3 weeks or more
4. *Full-thickness (third-degree) burns*
   - Involve full thickness of the dermis
   - Leathery, dry, insensate, and waxy
   - Often require skin grafts
   - Scarring and contractures
5. *Fourth-degree burns*
   - Destroy all skin layers
   - Extend through the subcutaneous soft tissue to tendon or bone
   - Risk of limb loss

Diagnosis

The diagnosis of burn injury is made by obtaining a history of exposure to a heat source and by skin examination. It is essential to determine the depth and the extension of burn injury, because this will determine the initial steps of burn assessment and management. Burn size is determined by estimating the percentage of the patient's body surface area that is covered by partial-thickness and full-thickness burns. First-degree burns are not included in the estimation of burn size [46]. The "rule of nines" diagram is the most used to determine this percentage (Fig. 27.6).
Fig. 27.6 "Rule of nines" diagram

Complementary Examinations

Burns usually do not require complementary examinations for the diagnosis. The most important evaluation concerns extent of the burn to determine the type of treatment the patient will need and the seriousness of the injury.

Differential Diagnosis

The differential diagnosis is directed to analyze clinical parameters and extent of burns to classify the degree of burn, the gravity, and the specific management necessary.

Therapeutic Approach

Most minor burns can be successfully managed in the outpatient setting. A tetanus shot is indicated for all patients with more than a first-degree burn. Cool running water after minor thermal burns is often used to reduce the depth of injury and increase re-epithelialization, but human studies are still limited in proving its effectiveness [46]. Management of blisters is controversial, but recommendations are usually to keep small (less than 6 mm) blisters intact [46]. Large blisters, blisters that prevent proper movement, and blisters that are likely to rupture can be drained. It is recommended to maintain the "ceiling" of the blister as a natural dressing. Some specialists recommend that the burn wound should be debrided before applying topical treatment. Many different kinds of topical treatments are used nowadays for partial-thickness burns. Topical antibiotics are frequently used to keep the wound moist, control pain, and slow bacterial growth. Silver sulfadiazine is one of the most worldwide topical treatments used because of its bactericidal activity that reduces inflammation and promotes healing [48]. However, there is limited evidence supporting improved mortality, wound infection, healing, or re-epithelialization rates in humans by silver sulfadiazine. Newer occlusive dressings can be used instead of silver sulfadiazine on the grounds that they result in faster healing, decreased pain, fewer dressing changes, and improved patient satisfaction. Some studies show that silver sulfadiazine has been consistently associated with poorer healing outcomes than biosynthetic (skin substitute) dressings,

silver-containing dressings, and silicon-coated dressings. Burns treated with hydrogel dressings appear to heal more quickly than those treated with usual care [49, 50]. Rare but serious side effects associated with silver sulfadiazine have been reported, such as agranulocytosis, leukopenia, Stevens–Johnson syndrome, anaphylaxis, toxic epidermal necrolysis, hemolytic anemia, hyperbilirubinemia, methemoglobinemia, and bacterial resistance [49]. Silver sulfadiazine is also relatively contraindicated in pregnant and lactating women, newborns, and patients with sulfa allergy [46]. Other topical treatments used are lotions, honey, and aloe vera. The lipid component of these products helps repair damaged skin and reduces drying. Honey has lately acquired a growing interest from the international scientific community and has demonstrated anti-infectious, anti-inflammatory, antiexudative, antioxidant, wound-healing, wound-debriding, and nutritional properties [51]. Topical corticosteroids are not recommended for the treatment of superficial thermal burns or sunburns as there is no evidence that they reduce the inflammatory reaction [46]. There is no scientific evidence that prophylactic systemic antibiotics improve mortality, so they are not recommended as a hospital management routine [46, 52]. According to the American Burn Association, referral to a burn center is indicated in patients with burns that involve the face, hands, feet, genitalia, perineum, or major joints; circumferential burns, because of the risk of compartment syndrome; partial-thickness burns on more than 10% of the total body surface area; and third-degree (full-thickness) burns in any age group [46]. Severe burn injuries create a hypermetabolic response that makes recovery difficult. Some treatments with anabolic agents, β-adrenergic receptor antagonists, and anti-hyperglycemic agents have successfully helped post-burn morbidities, especially catabolism, catecholamine-mediated response, and insulin resistance [45]. The most useful and studied drugs in these cases are propranolol, insulin, metformin, testosterone, and oxandrolone, recombinant human growth hormone, and insulin-like growth factor 1 (IGF-1) [45, 47, 53]. Treatment of severe burn injuries

also includes the biological skin substitutes that provide easier re-epithelialization recovery, especially because of the presence of a basement membrane. Cadaveric skin allograft, porcine skin xenograft, and amnion are the most widely used biological skin substitutes available in the burn centers, and are a helpful and inexpensive way to treat burns [54].

Erythema Ab Igne

Epidemiology

Erythema ab igne is seen more commonly in women and in patients who are overweight [55]. This skin disease is associated with chronic exposure to moderate heat, usually in people who sit in front of open fires, but also with the local use of hot water bottles, heating blankets, frequent hot bathing, heating pads, and, more recently, laptop computers [56].

Etiopathogenesis

The pathogenesis of this disease is poorly understood, but the radiation induces changes in dermal elastic fibers that are similar to those seen in actinic keratosis [57]. Heat exposure seen in erythema ab igne is presumed to induce damage to superficial blood vessels, leading to dilation and deposition of hemosiderin with the characteristic reticulate distribution [58].

Clinical Presentation

Erythema ab igne is characterized by reticular, erythematous, and hyperpigmented patches resulting from chronic exposure to external heat sources (Fig. 27.7) [55]. It is usually asymptomatic, but burning and itching can occur. Skin lesions are usually located on the shins and inner thighs when the patient sits close to fireplaces or heaters. It can be also located on the lumbar region and abdomen in patients who use heat sources [59]. There have been many case reports of laptop-induced lesions in recent years. In these cases the lesions are typically located on the thighs, especially on the left anterior thigh because of the location of the battery, optical drive, or heating elements of the laptop [57, 58].

Fig. 27.7 Erythema ab igne (Courtesy of Dr. Francine Seibt)

Diagnosis

The diagnosis of erythema ab igne is clinical, by obtaining a history of skin exposure to a heat source and presenting with the typical skin damage. If necessary, biopsy may be indicated.

Complementary Examinations

Biopsy usually shows variable features that are nonspecific. It can show increased epidermal atrophy, basal vacuolar changes, pigment incontinence, squamous cell atypia, dilation of post-capillary venules, and increased elastic tissue in the dermis [55]. Sometimes it could histologically resemble actinic keratosis, and chronic changes can lead to squamous cell carcinoma or, rarely, Merkel cell carcinoma [56].

Differential Diagnosis

The differential diagnosis of erythema ab igne includes poikiloderma, livedo reticularis, erythema dyschromicum perstans, vasculitis, and sun damage (actinic keratosis) [55, 60]. Graft-versus-host disease should also be considered as a differential diagnosis [59].

Therapeutic Approach

The first step in treatment is to discontinue use of the heat source. Early-stage lesions usually fade over months. Chronic lesions are more associated with hyperpigmentation that can persist for years. Treatment with topical 5-fluorouracil cream has shown good results when used for epithelial

atypia associated with erythema ab igne, which reflects histopathologic association with actinic damage [57]. Other treatments reported are topical tretinoin, corticosteroids, hydroquinone, and laser therapy [55, 59].

Glossary

Cellulitis A bacterial skin infection characterized by a swollen, red area of skin that feels hot and tender.

Chilblains Also known as pernio or perniosis, these are skin lesions resulting from abnormal response to cold temperature and characterized by erythematous or purplish lesions localized on fingers, toes, ears, and nose.

Cryoglobulins Immunoglobulins that precipitate in vitro at temperatures below 4 °C, and dissolve after rewarming at 37 °C.

Frostbite Defined by freezing, cold thermal injury, which occurs when tissues are exposed to temperatures below their freezing point for a sustained period of time.

Panniculitis An inflammation of the subcutaneous adipose tissue. Cold panniculitis is a form of traumatic panniculitis caused directly by cold exposure.

Raynaud phenomenon An intermittent ischemia of the fingers or toes characterized by severe pallor and often accompanied by paresthesia and pain, induced by cold and relieved by heat.

Ultraviolet Radiation and Idiopathic Photodermatosis

28

Sérgio Ivan Torres Dornelles, Renan Rangel Bonamigo, Lúcio de Almeida Dornelles, and Marcel de Almeida Dornelles

Key Points

- The solar spectrum band of interest for human beings contains UV-C (200–280 nm), UV-B (280–320 nm), and UV-A (320–400 nm) radiation
- Severe skin effects resulting from ultraviolet radiation can be divided into four categories: acquired idiopathic, photodermatoses from faulty DNA repair, photosensitization by exogenous or endogenous drugs or chemicals, and photoexacerbated dermatoses not directly resulting from UV radiation
- Solar polymorph eruption is regarded as the most prevalent idiopathic dermatosis, possibly reaching 20% of medical care for sun-related diseases in southern Scandinavia and 10% in the United States
- Actinic prurigo is more prevalent in females, with onset during childhood, frequently disappearing in adolescence; however, it may have lifelong persistence. Calcineurin inhibitors, such as tacrolimus and pimecrolimus, are used both for healing treatment and prophylaxis in specific cases
- In hydroa vacciniforme, a prevalence of 0.34 cases per 100,000 inhabitants is estimated, with similar onset when sexes are compared
- Chronic actinic dermatitis can develop in an absolutely normal skin, or in a body region previously displaying eczema, photoallergy, photosensitivity to drugs, or even solar polymorphic eruption
- The radiation spectrum which triggers solar urticaria shows variation depending on the geographic location and ethnicity, although its band ranges from UV-B to visible light

Ultraviolet Radiation

Electromagnetic radiation (defined in Box 28.1) comprises waves or energy packages called photons and is part of a large variation of wavelengths from the high-energy X-ray (0.1–10 nm) to the low-energy radio wave (>10^6 nm) [1, 2].

The important radiation spectrum bands for human beings are untraviolet (UV)-C (200–280 nm), UV-B (280–320 nm), and UV-A (320–400 nm) (Fig. 28.1). When this energy enters the skin it is either dispersed or absorbed by some molecules (chromophores), possibly resulting in local biological reaction [1, 3]. It is important to note that the literature shows variations in the values of the spectrum bands of the ultraviolet radiation, both at the wavelength that divides UVC from UVB and from UVB with UVA. We use information from authors who reported the greatest wavelength difference between UVC and UVA.

Box 28.1 Ultraviolet radiation definition
UV radiation can be defined as the portion of the electromagnetic spectrum between the X-ray and the visible light band, that is, between 10 and 400 nm. It is worth noting the existence of vacuum UV radiation (10–200 nm), a band not present on the Earth's surface.

Being informed about the skin interaction with this radiation is crucial to understanding more than 100 known dermatologic diseases that have some dependence on solar exposure for their onset. This chapter focuses on a narrow band of the electromagnetic spectrum comprising UV radiation (200–400 nm) and visible light (400–760 nm). It is known that radiation with wavelengths less than 280 nm is absorbed by the stratospheric ozone layer and thus does not reach the Earth's surface. Long-wave UV, or UV-A (320–400 nm), on the other hand, is called black light, as it determines the emission of fluorescent brightness to some substances. About 95% of this UV radiation spectrum reaches the Earth's surface. UV-A is further divided into UV-A I (340–400 nm) and UV-A II (320–340 nm); the latter band has proved more harmful than the longer waves within this spectrum [1, 4].

Visible light (400–760 nm) is defined as the electromagnetic band with colors noticed by the retina. The short wavelengths are called the infrared (IR) band, which lies between 760 nm and 1 mm, and is subdivided into three bands: IV-A (760–1440 nm), IV-B (1440–3000), and IV-C (3000 nm – 1 mm). IV-A can penetrate the dermis, thus determining biological effects, whereas IV-B and IV-C are detected on the skin by a feeling of warmth [1, 4].

The UV-band electromagnetic radiation has many effects on the skin because of its action on the chromophores found in many skin layers. The direct action on the DNA leads to genetic mutations that may determine some skin cancers. Another mechanism for skin cancer development that also depends on UV rays is immune system impairment resulting from UV-B-induced action [5].

To deepen our understanding of the biological effects of UV radiation on the skin, we need to
Fig. 28.1 Electromagnetic radiation bands

recall that its action is not limited to the effects on the keratinocyte DNA; it also changes some superficial molecules and induces the synthesis of immunomodulatory factors, including the interleukins (IL-1, IL-6, IL-8), tumor necrosis factor α (TNF-α), and prostaglandin E2 (PGE₂), among others. In addition, UV-B-irradiated keratinocytes bring about two potent immunosuppressant cytokines (IL-10 and TNF-α). IL-10 has as its main mechanism the inhibition of the ability of Langherans cells' to present antigens [5].

The skin exposed to UV radiation reacts with the epidermis directly after proliferation, mainly on the corneal layer but also on the dermal layer. Thus, hyperplasia occurs 24–48 h after this physical aggression. A light-skinned person exposed for 2 weeks, with suberythematogenic daily doses, shows a 20–40% increase in corneal layer thickness [5, 6].

Some research shows that this mechanism is the most important for protection of fair skin when it is exposed to UV rays [5]. Skin tanning is another defense used by the skin. UV-A exposure triggers a rapid pigmentary reaction with a transient change of the melanin already present in the skin through photo-oxidation, as well as melanosome redistribution, a process known as immediate pigment darkening. This process is followed by persistent pigment darkening, with stability for up to 2 h after UV-A exposure [5, 7].

Late pigmentation, known as melanogenesis, is a reaction to UV-B radiation, resulting from the increased amount and activity of melanocytes. This effect reaches its peak after a 10- to 30-day interval, depending on skin type and amount of radiation exposure. The activity of tyrosinase, a transmembrane glycoprotein in the melanocyte, determines the rhythm of the melanogenesis process [7].

Practically, melanogenesis aims at providing a reaction to the aggression on DNA, thus decreasing future damage resulting from UV radiation to this chromophore. A second mechanism used to help prevent skin cancer development is the individual ability related to DNA restoration mechanisms [5]. This protective arsenal includes the antioxidative mechanisms, various enzymatic and non-enzymatic processes that work to decrease oxidative damage. Superoxide dismutase, catalase, and thioredoxin reductase are examples of this protection system's enzymes. Besides these there are the natural antioxidants, such as vitamins A, C, E, and glutathione, responsible for the direct prevention of the development of O₂ radicals [5].

Although it still seems early to categorically state the role of vitamin D in cancer development, experimental studies have shown that vitamin D metabolites increase malignant cell apoptosis, inhibit angiogenesis and cell proliferation, and increase cell differentiation of the original tissues. Thus, they enhance the attenuation of skin cancer and improve the prognosis [8–12].

The severe skin effects resulting from UV radiation can be divided into four categories: acquired idiopathic (immunologically mediated photodermatoses, according to some authors), photodermatoses due to faulty DNA repair, photosensitization by drugs or endogenous and exogenous chemicals, and photoexacerbated dermatoses not directly caused by UV radiation [13, 14]. In this chapter the photodermatoses are described, which, although accepted by some authors as immunologically mediated, other authors still uphold the expression of idiopathic photodermatoses.

Idiopathic Photodermatosis

Polymorphic Light Eruption

Epidemiology

Polymorphic light eruption (PLE) is classified in the idiopathic photodermatoses, together with actinic prurigo, hydroa vacciniforme, solar urticaria, and actinic chronic dermatitis. Box 28.2 summarizes the main features of PLE. It is considered the most prevalent idiopathic dermatosis, responsible for up to 20% of medical appointments in southern Scandinavia, while in South Australia the prevalence is lower (5%) [13, 14]. It shows an incidence inversely proportional to geographic latitude [15]. Females are mostly affected, reaching 60% of the reported cases in some research studies [16]. Nearly 70% of cases occur before 30 years of age, and 11% after age 50 years [17].

Box 28.2 PLE: Essential features
- Polymorphic light eruption is the most prevalent disease in this group of diseases.
- It starts minutes after, or hours after sun exposure.
- The pathogenesis is suggestive of a hypersensitivity reaction to induced antigens, or antigens activated by ultraviolet radiation.
- The traditional cutaneous changes are described as papules and papular, erythematous, pruriginous lesions, or light-exposed skin plaques. They do not leave scars.

Etiopathogenesis

In general, the lesions start after sun exposure during early summer and in temperate climates. Experimentally, lesions can result from patients submitted to sources of UV-A, UV-B, and high-intensity visible light. The pathogenesis suggests that it is a hypersensitivity reaction to induced neoantigens, or activated by UV radiation [15]. After a 5-h submission to solar irradiation a prevalence of CD4$^+$ T lymphocytes are noted [14, 18]. However, 72 h later CD8 lymphocytes are largest in number, with Langerhans cells and dermal macrophages also showing increased amounts. These findings are very suggestive of a late hypersensitivity reaction.

Clinical Presentation

The dermatologic presentation develops a few minutes or hours after solar exposure (rarely, days). Other situations, such as sun reflections on the snow, or even artificial tanning beds, can also determine the presentation onset. Sometimes the possibility of onset decreases or is interrupted in sunny summers [13, 14].

Cutaneous changes have been described as papules (and papular), erythematous, pruriginous, vesicular lesions, or skin plaques exposed to light (Fig. 28.2). Scars do not develop. Other clinical presentations include hemorrhagic, erythema multiforme-like form, with an insect-bite

Fig. 28.2 Polymorphic light eruption

pattern, or strophulus-like form. In general, lesions are symmetrically organized (bilaterality) but irregular. When additional exposure to UV radiation is avoided, eruptions recede in hours or up to 2 weeks, leaving the skin completely normal. The sites mostly involved are the face, neck, upper anterior and posterior thorax, extensor portions of the upper limbs, and hands [14].

A phenomenon called induration, characterized by a decrease in clinical presentation features, even with ongoing solar exposure, may be observed in some cases, possibly determined by development of immunological tolerance thus showing a diminished clinical presentation.

Systemic symptoms, such as general malaise, cephalea, fever, and nausea, rarely emerge. The presentation has an episodic evolution over very long periods, possibly up to as long as 30 years [16].

Diagnosis

The diagnosis is made through analysis of the morphological characteristics of lesions, helped by the presence of more common symptoms, cutaneous location with prevalence in sun-exposed areas, and detailed history through reported relationship with sun exposure. Diagnosis is also helped by laboratory tests that enable preclusion of differential diagnoses, as well as compatibility with anatomopathologic findings.

Complementary Examinations

To rule out clinically similar diagnoses some tests can be important: for example, antinuclear factor (ANF); anti-Ro (SSA); anti-La (SSB); urinary, blood and stool porphyria levels; UV-A, UV-B, and visible light phototesting [14].

Histopathologic examination may help by revealing epidermal moderate acanthosis and spongiosis, and surface dermal edema. A histologic pattern may also be noticed with some dense dermal surface infiltrate and subepidermal edema, mainly in clinical lesions such as plaques. A compact perivascular lymphocytic dermal surface and deep infiltrate may be found. Direct immunofluorescence is common [16].

Studies revealed that in biopsy materials increased CD1$^+$ cell population was seen throughout the dermis of PLE patients. Current data suggest that this increase of the CD1$^+$ cell population represents the migrating of epidermal Langerhans cells to the regional lymphatic ganglia to display their antigen and trigger an IV-type immunologic response [16].

Differential Diagnosis

When considering the clinical characteristics, one must pay attention to history and physical examination details. Special attention must be paid to morphology, location, seasonal variation, evolutionary time, and lesion resolution following UV radiation.

Among the differential diagnoses, lupus erythematosus, reactions resulting from photosensitivity to drugs, photoaggravated dermatoses (atopical dermatitis and contact dermatitis), Jessner lymphocytic infiltrate, eczema, solar urticaria, erythropoietic protoporphyria, and sunburn can be included [16].

Therapeutics

Photoprotection is the most basic therapeutic measure. Good results may also be achieved with narrow-band UV-B phototherapy (UV-B NB) or psoralen photochemotherapy (PUVA) over 15 sessions at some time preceding the summer. This measure generally provides a favorable outcome lasting many months. For UV-B NB therapeutics (emission spectrum with a peak between 311 and 313 nm) an initial dose of 50–70% of the minimum erythematous dose (MED) is recommended, with increases of 10–15% at each treatment, applied two to three times a week. With PUVA, 0.5–0.6 mg/kg topical 8-methoxypsoralen is used, ingested 1 h before UV-A exposure. The UV-A irradiated dose varies from 0.5 to 3 J/cm^2, adjusted to the involved phototype. A systemic corticosteroid can be used in the first week, with an oral dose of 0.5–1 mg/kg body weight corresponding to that of prednisone. Achieving so-called skin induration may be tried through possible immunologic tolerance, with an indication of sun exposure of 15 min per day. Results with antimalarial drugs have not always been favorable, although some studies have shown a presentation improvement with hydroxychloroquine 400 mg/day. Ophthalmologic control every 6 months must be conducted as a function of the drug-related side effects [13, 14, 16]. Carotenoids at a dosage of 25 mg (10 mg of β-carotene + 15 mg of canthaxanthin) prescribed three times a day over the first month have shown good results. Carotenoid doses can be increased up to 150 mg/day (60 mg of β-carotene + 90 mg of canthaxanthin) in the second month [16].

Some studies have shown good results when using a substance called polypodium leucotomos, aimed at preventing PLE outbreaks, at doses varying from 720 mg/day (for individuals weighing less than 55 kg), 960 mg/day (individuals of 55–70 kg), and 1200 mg/day (for those >70 kg). This substance is extracted from a plant and has anti-inflammatory properties resulting from its strong antioxidant action, mainly due to the presence of polyphenols in its formula [15, 19].

Nicotinamide at a 1-g dose, three times a day (a total of 3 g/day), is also a good therapeutic option. Azathioprine (1.5–2.5 mg/kg/day) and cyclosporine (3.5–5 mg/kg/day) may be useful in cases of difficult management [13, 16].

Actinic Prurigo

Epidemiology

Hutchinson prurigo, or hydroa aestivale, is a disease related to exposure to UV rays, described for the first time in 1879 by Hutchinson; this condition was renamed by Londoño in 1968 with the term actinic prurigo (AP) [13].

AP impairs all races and starts during childhood, with resolution many times occurring during adolescence, although it may be a lifelong condition. AP is common in native North Americans, mainly mixed race individuals of American Native or European origin, and individuals living in places of high altitude. It is also described in Europe and East Asia [13, 14].

A family history of PLE or AP may occur in up to 20% of cases. History of atopia is less common, occurring in 10% of persons with AP [14, 20].

Etiopathogenesis

UV radiation is the main determinant in AP lesions. In the spring and summer this disease displays a higher prevalence. The immunologic nature of AP may be found in a research study by Estrada et al. showing an excellent response to thalidomide as a function of the inhibited synthesis of TNF-α, and the CD3 modulation that produces interferon-γ [21].The presence of dense lymphocytic infiltrates and lymphoid follicles in biopsy samples of lesions also provides evidence to support the immunologic hypothesis [22].

AP may represent a clinically more persistent form of PLE, since the association between AP and PLE has been noticed in studies of specific families [23]. A noticeable association with HLA-DR4 (DRB1*0401) and the DRB1*0407 subtype has been seen either in United Kingdom patients and mixed-race patients, with the genetic factor possibly changing PLE into AP [20, 24].In fact, the presence of this subtype is powerfully suggestive of the diagnosis.

Clinical Presentation

AP is more prevalent in females and it has its onset in childhood, frequently disappearing in adolescence. However, it may maintain lifelong persistence.

The clinical presentation is characterized by papular and nodular lesions, sometimes with hemorrhagic crusts resulting from excoriations, mostly located on the face (including the nose) and limb extremities. The excoriations result from the characteristic pruritus symptom. Eventually, eczematous or lichenified presentations may be observed (Figs. 28.3 and 28.4). Distribution can be disseminated or dense, in areas with no sun protection, gradually evolving to reach the covered areas. Cheilitis and conjunctivitis may be noticed. Some superficial small linear hypopigmented scars may be seen on the face. Box 28.4 summarizes relevant AP features [14, 22].

> **Box 28.4 AP: Essential features**
> - More prevalent among females
> - More prevalent in spring and summer
> - Involving areas with no protection against the sun
> - Papular and nodular lesions, as well as excoriations and lichenifications
> - Cheilitis and conjunctivitis may occur

Diagnosis

The diagnosis is made through analysis of the morphologic characteristics of the lesions and presence of classic symptom of pruritus, its cutaneous location with a prevalence in areas of sun exposure, detailed history through reports of solar exposure, and laboratory tests as a support to rule out differential diagnoses, as well as compatibility with the anatomopathologic findings.

Complementary Examinations

Among the possibly requested tests, we may include antinuclear factor (ANFFAN), anti-Ro (SSA), anti-La (SSB), all useful to rule out lupus erythematosus. Laboratory typing or identification of the human leukocyte antigen (HLA), DRB1*0401 (DR4) type, or DRB1*0407, this second one mainly, can reinforce AP diagnosis [13, 14].

The anatomopathologic test displays the presence of moderate acanthosis, exocytosis,

Figs. 28.3 and 28.4 Actinic prurigo. (Courtesy of Dermatology Service of UFCSPA)

and spongiosis in the epidermis. On the dermis, the lymphohistiocytic infiltrate is moderate mainly in perivascular areas. Rarely the pathologist may find it difficult to make the differential diagnosis of lymphoma. In clinically persistent lesions nonspecific findings may occur, such as acanthosis, lichenification, and dense mononuclear infiltrate [14].

A phototest can confirm light sensitivity in 50% of cases, although it does not distinguish it from other photodermatoses [14].

Differential Diagnosis

Clinical differential diagnoses to be focused on include polymorphic solar eruption, lupus erythematosus, atopic eczema, seborrheic eczema, photoexacerbated atopic eczema, insect bites, nodular prurigo, and, very rarely, scabies [15].

Therapeutics

If a diagnosis was previously confirmed, prevention of development of the disease may be tried during a period before seasons when the disease develops more often through the prophylactic use of calcineurin inhibitors, such as tacrolimus and pimecrolimus.

Restricted sun exposure and use of a wide-spectrum and highly potent sunscreen may be advised, although their effect is limited.

Oral thalidomide at 50–100 mg at night, used intermittently, is almost always effective, even in resistant presentations [25]. However, possible side effects include somnolence, cephalea, constipation, and weight gain. Watchful control related to neuropathy development is an impor-

tant measure to be implemented. Owing to the high embryotoxicity with its well-defined effects, thalidomide is not approved in Brazil for this disease.

Oral corticosteroid in doses equivalent to prednisone at 0.5–1 mg/kg/day is very useful. Narrow-band UV-B phototherapy, or UV-A, chiefly after a corticosteroid is used for outbreak control, can be useful. In exceptional cases, azathioprine (a 1.5–2.5 mg/kg/day) and cyclosporine (3.5–5 mg/kg/day) are necessary.

Hydroa Vacciniforme

Epidemiology

Hydroa vacciniforme (HV) is a childhood disease first described in 1862. The Greek word *hydroa* means "watery eggs" as representation of a vesicular eruption. The word "vacciniforme," on the other hand, conveys the idea of "variola" pox-like scars that are left after blisters have healed [26, 27].

Estimates mention a prevalence of 0.34 cases for each 100,000 population, with the disease developing equally in both sexes. However, males show a higher impairment rate for HV when severe cases are considered, whereas milder cases are more prevalent among females. Familial cases are not common. In men the disease onset is late and the condition lasts longer. Distribution is bimodal, with peaks between 1–7 years and 12–16 years [27].

This chronic photodermatosis is rare, leads to scarring, and is characterized by groups of papu-

lar vesicles and vesicles, most often seen on the face and hand dorsum. It usually starts during childhood an lasts until puberty, when it shows a spontaneous relapsing trend. However, lifelong cases have been documented.

Some authors classify this disease as a scar presentation of PLE. Box 28.5 summarizes general concepts of HV.

Etiopathogenesis

The pathogenesis of this disorder is not yet well defined, although sunlight mainly in the UV-A band has shown great significance as a determinant factor when possible HV presentation with exposure to this radiation band is considered. The latent infection by the Epstein–Barr virus (EBV) has been referred to as an important factor in this association, since a high amount of DNA copies of EBV in the peripheral blood have been found as well as small codes of ribonucleic acid in cutaneous lesions. Cases of a large quantity of EBV copies are associated with patients with the worst prognosis [27, 28].

Clinical Presentation

The classic eruption starts in summer, with feelings of burning and twinges, and development of erythema possibly followed by local edema. Development of papules and vesicles then takes place, some of them displaying umbilication a few hours after sun exposure (Fig. 28.5). In a few

Fig. 28.5 Hydroa vacciniforme. (Courtesy of Dermatology Service of UFCSPA)

weeks pustules, crusts, and hypopigmented scars may develop. A larger number of lesions are seen on the cheeks, but also on other facial locations. The dorsum of hands and extensor aspects of the upper limbs may also show symmetric lesions. Oral ulcerations and eye changes are seldom although the can occur. Ophthalmologic complications, such as moderate photophobia, corneal ulcer, keratoconjunctivitis, uveitis, scleritis, and other manifestations can occur. Other sites are rarely affected [14, 27].

Complementary Examinations

It is important to rule out cutaneous porphyria from the diagnosis by requesting concentration of porphyria in blood, urine, and stool. Lupus erythematosus must also be considered and checked for with free α-amino acids (FAN) titration.

In the anatomopathologic test, spongiosis with development of intraepithelial vesicle spongiosis and keratinocyte necrosis will be found, associated with perivascular infiltrate of lymphocytes and neutrophils [14].

Differential Diagnosis

The differential diagnoses to be considered include herpes simplex, erythropoietic porphyria, polymorphic light eruption, subacute cutaneous lupus, and xeroderma pigmentosum [13].

Therapeutics

Therapeutic measures include restricted sun exposure and use of wide-spectrum and high-protection factor sunscreen. Sometimes antimalarials can be useful, although their routine administration is not well established. β-Carotene does not seem useful. Narrow-band UV-B phototherapy, or mainly UV-A, may be useful. Their application, nevertheless, must be careful and judicious to avoid exacerbation. Despite a low expectation regarding results, topical and/or systemic corticoids can be used, besides calcineurin inhibitors. Immunosuppressant drugs may be tried but are usually ineffective [13, 14, 27].

Chronic Actinic Dermatitis

Epidemiology

This condition is characterized as a rare chronic eczematous disease that usually affects middle-aged men, although it may also affect people older than 60 years. Some individuals present an atopic manifestation. The anatomopathologic test findings may sometimes be similar to those for pseudolymphomatous infiltrations. Persistent light reaction, actinic reticuloid, photosensitivity dermatitis, and photosensitive eczema are seen as clinical variants of chronic actinic dermatitis (CAD).

It is a disease diagnosed in many parts of the world, mainly in temperate areas. Box 28.6 shows its main features [13].

Etiopathogenesis

The pathogenesis of CAD is not yet well defined, but immunohistochemical and histologic studies have suggested a late hypersensitivity reaction even in the severe forms of pseudolymphomatous infiltration (so-called actinic reticuloid), whereby the same clinical and histologic characteristics are found in long-term contact dermatitis. Solar exposure as determinant of a reaction against photoinduced endogen antigens is suspected [14, 29, 30].

The necessary dose to trigger the clinical presentation is smaller than the necessary dose to determine a plain erythema. The presentation may be determined by exposure to UV-B and UV-A radiation, and even visible light. These are situations possibly indicating the existence of different photoallergens [14].

Therefore, there is a strong suspicion that CAD is a reaction similar to the one that occurs in allergic contact dermatitis, although against an altered DNA molecule by UV radiation or against another as yet identified molecule. There is also the possibility of increased immunologic reactivity due to a concomitant contact dermatitis resulting from an airborne material in individuals with prolonged exposure to allergens as well as and also UV radiation [14].

Clinical Presentation

CAD may develop in any normal skin or in a place where a presentation of eczema, photoallergy, drug photosensitivity, or even polymorphic light eruption was previously noticed. Concomitantly, a contact allergic process may be found, resulting from plants, airborne substances, perfumes, or even sunscreens. The condition worsens in summer and its onset is rapid after sun exposure. It is manifested through papules or erythematous plaques, dispersed or generalized; bright, infiltrated, pseudolymphomatous changes can be seen in severely affected individuals. The condition may display an acute, subacute, or chronic phase when showing plain lichenification. Pruritus is a characteristic. In sun-exposed areas there is a clear impairment compared with the non-exposed skin, with the areas protected by clothes clearly apparent. Lack of involvement of non-exposed areas can be noticed in skin grooves (wrinkles), upper eyelids, skin under ear lobes, and behind the ears. In severe cases, changes on the hand palms and foot soles can be identified. Eyebrows, eyelashes, and hair may fall out as a result of scratching (Fig. 28.6). There are rare cases of erythroderma in severe cases. Involution is estimated in 10% of the cases after 5 years, 20% after 10 years, and 50% after 15 years [13].

Complementary Examinations

As in most sun-associated diseases, it is important to rule out the hypothesis of subacute lupus and other forms of this disease. Thus, FAN titra-

Fig. 28.6 Chronic actinic dermatitis. (Courtesy of Dermatology Service of UFCSPA)

tion must be requested and, depending on the test result, anti-DNA, anti-Ro (SSA), and anti-La (SSB) must also be requested. With regard to lymphoma suspicion, care must be taken to interpret the presence of CD8+ Sézary cells because they can be present in CAD, even when a malignant disease is not present. Ruling out the presence of HIV virus as a predisposing virus is also important.

In the anatomopathologic examination, acanthosis and spongiosis with lymphocytic infiltration are found, usually limited to the upper dermis, with moderate cases displaying presentations of chronic eczema. More severe cases may histologically be similar to a cutaneous lymphoma of T cells, possibly resembling Pautrier's

epidermal microabscesses with a noticeable mononuclear infiltrate even with giant cells, but with no large quantities of mitoses [31].

The phototest may be crucial in confirming the diagnosis. Exposure to UV-B, UV-A, or visible light always shows reactions with erythema, eczema, or pseudolymphomatous aspects. The test must be applied to areas not routinely exposed to the sun when the diseased individual is not undergoing topical or systemic corticosteroid therapy [14].

Differential Diagnosis

The most frequent differential diagnoses include seborrheic eczema and atopical photoexacerbated eczema, photosensitivity reactions to drugs, T-cell lymphoma, and eczematous AP [13, 14].

Therapeutics

Treatment of CAD is difficult and displays limited reactions. Strict control of sun protection and exposure to contact sensitizers are key. High-potency corticosteroids, such as clobetasol propionate, provide noticeable symptomatic relief without local side effects, even when used for long periods. Systemic corticosteroids are also very useful in worsening outbreak phases. Calcineurin inhibitors, either tacrolimus and pimecrolimus, are also useful if well tolerated [13, 14].

For the less responsive cases to oral immunosuppressant therapy, azathioprine at 1.5–2.5 mg/kg/day usually leads to remission. In the winter the dose can be decreased or even suspended. Cyclosporine, 3.5–5 mg/kg/day, may also be useful. This choice generally provides a more effective outcome although with possible increased side effects. Mycophenolate mofetil is less useful in these cases, but if used is administered at a dose of 1–2 g/day. Phototherapy with low doses of UV-A, multiple

- Potent topical corticosteroids, tacrolimus, pimecrolimus, and oral immunosuppressants can control the disease

times per week, may be useful in some cases, whereby concomitant control with topical and systemic corticosteroids is necessary to avoid exacerbation.

Solar Urticaria

Epidemiology

Some authors refer to solar urticaria (SU) as first being described in 1905 in a 47-year-old woman, whereas others propose that this name was suggested by Duke in 1923 when he reported a 43-year-old woman with a presentation of pruritus, erythema, and edema while being exposed to sunlight in a swimming pool [32]. In the literature there is a small prevalence of females in the fourth and fifth decades of life. SU possibly occurs worldwide at a rate of 3.1 in every 100,000 persons, comprising 1% of all forms of urticaria [14, 32].

Most diagnosed individuals can be permanently affected (68%) by radiation transmitted through glass (83%) and thin clothing (76%), as shown by Beattie et al. [33]

Etiopathogenesis

Like other forms of urticaria, the mastocytes have a significant function. Degranulation determinant factors are not well defined, although an immunoglobulin E (IgE)-mediated reaction against endogenous cutaneous or photoinduced circulating antigens is a possible mechanism, i.e., a type 1 hypersensitivity reaction. Two types of SU have been proposed, both resulting from the same action mechanism (IgE-mediated type 1 hypersensitivity). In type 1, the allergen would be generated only in SU patients, whereas in type 2 the allergen would be generated in both SU patients and normal individuals. Research studies have shown that the photoallergen molecular weights are different in each type, as are the electromagnetic radiation spectra [14].

There are reports of some medications inducing US development, such as some oral contraceptives, tetracyclines, and other drugs.

The spectrum of radioactive action that triggers SU is varied depending on the geographic location and ethnicity, but there is a band from UV-B to visible light. Nevertheless, Scottish research studies with a sample of 87 patients showed that 41% reacted to UV-A radiation and 30.9% to visible light only [27, 33].

In France, a research study reported that in 61 volunteers who had the disease, more than half of the cases resulted from UV-A exposure [34]. On the other hand, some studies complemented that statement by showing that more than half of the cases (63%) are triggered by two bands of electromagnetic radiation [33].

Clinical Presentation

The first outbreak usually happens after intense sun exposure or treatment with artificial tanning equipment. A classic presentation develops 5 or 10 min later, or, rarely, 20–30 min after exposure, with development of pruritus and erythema, followed by confluent urticarial plaques, with resolution in up to 1–2 h. Much less frequently, only pruritus may be noticed, starting many hours after sun exposure. When facing an extensive presentation, the patients may present cephalea, nausea, bronchospasm, and even syncope [33].

Lesions develop in all exposed areas with macular erythema, often followed by development of edema in the lesions, thus characterizing urticarial lesions. A demarcation can be seen between the exposed areas and those protected against radiation. Sometimes the face and the hand dorsum are spared because of tolerance to UV radiation (Figs. 28.7 and 28.8).

Very severe cases of SU can lead very rarely to fatal vascular collapse.

Fig. 28.7 Solar urticaria

Fig. 28.8 Elementary lesions of solar urticaria

Complementary Examinations

As previously described, in most sun-associated diseases it is important to rule out the hypothesis of clinical manifestation of lupus erythematosus. Therefore, tests such as FAN, anti-DNA, anti-Ro (SSA), and anti-La (SSB) must be requested. Blood, urine, and stool levels of porphyrins can rule out cutaneous porphyria [14].

Findings in the anatomopathologic examination include edema, dermal vasodilation, and neutrophilic and eosinophilic perivascular infiltration that develop a few minutes after UV exposure. Endothelial edema also shows early development. A large amount of eosinophilic granules are seen on the dermis 2–24 h after exposure, suggestive of eosinophilic degranulation [31].

Differential Diagnosis

Polymorphic light eruption, subacute lupus erythematosus (rarely coexisting with SU), seborrheic and atopical photoexacerbated eczema, erythropoietic protoporphyria (possibly secondarily causing SU), hepatic porphyria, and photosensitivity to drugs are significant differential clinical diagnoses [14].

Therapeutics

Strict rules for sun exposure associated with sunscreen use, as well as protective clothes, are useful measures to decrease UV-A exposure, although not enough for SU-inducing visible light. Dark clothes are more effective for protection than light-colored clothes.

The use of H1-antagonist antihistamines in higher doses than traditionally prescribed, ingested 1 h before exposure, is very useful in 30% of cases and partially effective in another 30% of cases.

In a case report cimetidine, an H2 receptor antagonist, led to a promising outcome [35].

Doxepin, an antagonist of H1 and H2 receptors, showed controlling effects with regard to this condition [36].

Phototherapy may be useful in patients who have developed sun-ray tolerance, although there is a need to maintain the therapeutics for long time; therefore, risks related to long-term use must be assessed. In addition, extra care must be taken to avoid anaphylaxis during treatment. The clinic where treatment occurs must be properly equipped so that risks for severe complication in this type of care can be minimized.

Oral cyclosporine at an oral dose of 4.5 mg/kg/day showed good results. Intravenous immunoglobulin can also be of use, with infusion doses of 1.4–2.5 g/kg from 2 to 5 days. The number of courses varies from one to three, with 2- to 9-month breaks. Remissions are sometimes reached 1 year later [27]. There are good reported outcomes with omalizumab, a recombined monoclonal anti-IgE antibody, at a dose of 150 mg every 2 weeks. This drug can be used for patients with high levels of IgE who have not obtained favorable results with other drugs [27]. Phototherapy, photochemotherapy, and intravenous immunoglobulin have been described as therapeutic alternatives that bring about good outcomes [27].

Box 28.7 SU: Essential features
- Small prevalence in females
- Larger prevalence in the fourth and fifth decades of life
- 3.1 in every 100,000 inhabitants
- Pruritus and erythema, followed by confluent urticarial plaques, with a resolution up to 1–2 h after solar exposure interruption
- In severe cases cephalea, nausea, and bronchospasm may develop
- Sun exposure restriction associated with use of sunscreen
- Doxepin, H1 antagonist antihistamines, phototherapy, cyclosporine**,** omalizumab

It is noteworthy that SU is a chronic disease requiring lengthy treatments with antihistamines or combinations. There are reported cases of spontaneous remission. Box 28.7 summarizes the essential features of this disease.

Glossary

Calcineurin inhibitors Suppress the immune system by preventing interleukin-2 production in T cells.

Catalase A common enzyme found in nearly all living organisms exposed to oxygen. It catalyzes the decomposition of hydrogen peroxide to water and oxygen.

Chromophores Molecules that absorb light. Visible light that hits the chromophore can thus be absorbed by exciting an electron from its ground state into an excited state.

Endothelin 1 A potent vasoconstrictor peptide originally isolated from endothelial cells.

Fluorescence The emission of light by a substance that has absorbed light or other electromagnetic radiation.

Human leukocyte antigen (HLA) A gene complex encoding the major histocompatibility complex (MHC) proteins in humans. These cell-surface proteins are responsible for the regulation of the immune system in humans.

Neoantigens Structures often associated with tumor antigens and found in oncogenic cells. Neoantigens can be formed when a protein undergoes further modification within a biochemical pathway such as glycosylation, phosphorylation, or proteolysis.

Phototest Specialized tests that confirm the presence of an abnormal sunburn reaction. This may occur when a photosensitivity is due to medications or chronic photosensitivity dermatitis.

Polyphenol A phytochemical antioxidant. It protects cells and body chemicals against damage caused by free radicals, reactive atoms that contribute to tissue damage in the body.

Psoralen The parent compound in a family of natural products known as furocoumarins, a class of phototoxic plant-derived compounds.

Superoxide dismutase An important enzyme with antioxidant action in almost all living cells exposed to oxygen.

Thioredoxin reductase A family of selenium-containing pyridine nucleotide-disulfide oxidoreductases. Thioredoxin reductase reduces oxidized thioredoxin in the presence of NADPH (nicotinamide adenine dinucleotide phosphate).

Wavelength The distance between identical points in the adjacent cycles of a waveform signal propagated in space or along a wire.

Dermatoses by Plants

29

Maria Antonieta Scherrer and
Vanessa Barreto Rocha

Key Points Summary

- Although many affected individuals do not consult dermatologists, dermatosis by plants is a frequent and important source of contact among workers
- The main reactions are irritant contact dermatitis, phytophotodermatitis, contact urticaria, and allergic contact dermatitis
- The botanical identification of the contact plants is fundamental to performing specific investigations
- The main sensitizers are lactones, phenols, terpenes, aromatic alcohols and aldehydes, and usnic acid
- The most appropriate gloves and barrier creams for protection vary depending on the plant responsible

Epidemiology

The frequency of skin reactions caused by plants is unknown since many affected individuals never consult their general practitioner and some reactions may be trivial and self-limiting or wrongly diagnosed. An exception is poison ivy/oak dermatitis in the United States, which is probably responsible for more cases of allergic contact dermatitis than all other provocations combined. Allergic contact dermatitis to poison oak and ivy is a major cause of occupational disability among workers, especially in the western United States [1, 2].

Gardeners, horticulturalists, agriculturalists, farmers, florists, foresters, and botanists all have frequent contact with plants. A large number of other occupations may also involve exposure to plants or plant products, such as sawyers, carpenters, wood machinists, antique restorers, builders, aromatherapists, herbalists, homeopaths, pharmacists, dentists, perfumers, beauticians, cosmetologists, food handlers, chefs, bar workers, military on exercises, and housewives. Some other activities may involve plant exposure, such as sports, especially golfing, fishing, cycling, rambling, hiking, mountain climbing, and camping. Romantics rolling in the hay and children at play are also at risk (phytophotodermatitis is common in children) [2].

Table 29.1 Cutaneous reactions to plants and plant products [2, 4]

Type		Etiopathogenesis	Onset	Duration	Characteristics
Irritant		Nonimmunologic	Minutes to hours	Hours to days	Polymorphous, restricted to areas of skin contact, itchy
Contact urticaria	Nonimmunologic	Toxin-mediated	Seconds to minutes	Minutes to hours	Urticaria, erythema, edema, pruritus
	Immunologic	IgE-mediated release vasoactive mediators such as histamine	Minutes to 1 h	Hours to 1 day	Urticaria, may be associated with atopy and worsen with subsequent exposure
Phytophotodermatitis		Nonimmunologic. Phototoxic	>8–48 h	Days to years	Caused by to psoralens, streaky, vesiculobullous, hyperpigmentation
Allergic contact dermatitis		Delayed-type hypersensitivity (type IV)	24–48 h	4–10 days	Polymorphous, itchy at areas of contact but may spread. Worsens with subsequent exposure

Etiopathogenesis

The major types of reactions resulting from plant contact are irritant contact dermatitis, phytophotodermatitis, contact urticaria, and allergic contact dermatitis (Tables 29.1 and 29.2).

Irritant contact dermatitis is not an immunologic reaction; it is caused by mechanical irritation such as macro- or microtraumas or chemical irritation from plants. Damage to the epidermal skin barrier occurs from contact irritants and subsequent activation of unspecific innate immune response, leading to inflammatory reactions [2, 3].

Phytophotodermatitis is mainly a phototoxic reaction that develops after contact with sensitizers on areas of bare skin that have been exposed to the sun [2].

Contact urticaria is an immediate response with immunologic and nonimmunologic mechanisms. When caused by nonprotein chemicals, it is most often due to nonimmunologic mechanisms. The immunologic type involves specific immunoglobulin E (IgE) synthesis, mainly to proteins, and can be severe with generalized or systemic symptoms, as observed in latex allergy [2, 3].

Allergic contact dermatitis is a type IV reaction or a cell-mediated hypersensitivity to antigens; prior contact with the allergen is necessary before the elicitation phase. Chemical allergens penetrate the skin and activate skin immune cells and skin structural cells. In particular the dendritic cells (DCs), such as Langerhans cells and different subsets of dermal DCs, become activated. These DCs then upregulate costimulatory molecules, migrate to the skin-draining lymph nodes, and present contact allergens in the context of major histocompatibility complex molecules in naive T cells, owing to a contact allergen–dependent polarization process. DCs secrete a combination of cytokines that polarize the T-cell response to Tc1/Th1 and Tc17/Th17 effector/memory cells. The inflammatory milieu is needed to overcome constitutive immune regulation. It removes the brakes on the immune system and enables a contact allergen–specific T-cell response. The priming of naive T cells seems to be paralleled by the induction and expansion of contact allergen–specific regulatory T cells (Tregs) that fail to prevent allergic contact dermatitis in the case of sufficiently strong allergens, but may prevent allergic contact dermatitis caused by weak contact allergens. In the elicitation phase, these Tregs help to downregulate the immune response. In their absence, the immune response is stronger and prolonged. The elicitation phase is initiated by repeated contact with the sensitizing contact allergen. The innate inflammatory response triggers the release of cytokines and T-cell-attracting chemokines. Endothelial cells are activated, and the contact allergen–specific T cells infiltrate the inflamed skin to exert their effector function [4].

Clinical Presentation

Irritant contact dermatitis starts minutes to hours after the contact and lasts hours to days. It has a polymorphous appearance, including dry skin, fissuring, pruritus, erythema, edema, vesicles, or necrosis. The lesions are usually restricted to areas of skin contact; however,

Table 29.2 Examples of dermatitic plants and plant products [2]

Types of plants	Irritant	Urticaria	Phytophotodermatitis	Allergic contact dermatitis
Garden plants	Borage, spurge, bulbs especially hyacinth	*Loasa, Iris, Tulipa*	*Dictamnus albus, Ammi majus, Ruta*	*Alstroemeria*, chrysanthemum, dahlia, feverfew, geranium, marigolds, bulbs especially *Narcissus*
Garden shrub/tree/climber	Thorns (rose), *Berberis, Pyracantha*	*Grevillea*		Gingko, grevillea, ivy, jasmine, Leyland cypress
Weeds	Ranunculus, *Euphorbia peplus*	Nettles (*Urtica*)	Cow parsley, cow parsnip, wild carrot	Dandelion, poison ivy/oak, yarrow
House plants	Cacti, croton	*Monstera deliciosa*		Chrysanthemum, orchid, *Primula obconica*, croton, ferns, *Philodendrum scandens*, *Euphorbia pulcherrima* Scheffler
Herbs	Borage, chives, comfrey		Parsley, rue	Anise, chamomiles, dill, lavender, mint
Countryside	Thorns (rose), tumbleweed, *Pulsatilla*	Nettles (*Urtica*), *Dendrocnide*	*Anthriscus, Heracleum, Angelica*	Ivy, lichens, liverworts, poison ivy/oak, ragweeds, *Helenium*
Ointment/cosmetics	Tea tree oil, apricot kernel, plant lipids (folliculitis), fragrances	Fragrances in toothpastes, henna, castor oil, cloves, sesame oil	Psoralens in essential oils and sun care products	Aromatherapy oils, ointments containing *Aloe, Arnica, Calendula*, fragrances, balsams of Peru
Occupational florists	*Codiaeum, Dieffenbachya*			*Alstroemeria*, chrysanthemum, ferns, orchids, *Primula obconica*
Food handlers	Garlic, onion, chives, peppers, lettuce, cereals, tomato plants	Lettuce, nuts, spices coffee, cereals	Celery, carrot, parsnip parsley, figs, citrus fruit	Asparagus shoot, carrot, cashew, chicory, citrus fruit, lettuce, mango, onion, peppers

glochids may cause an extensive pruritic eruption simulating scabies.

In phytophotodermatitis the reaction is typically erythematous, streaky, and vesicobullous, occurring within 8–48 h after contact with the plant. It appears precisely at sites of contact in sun-exposed areas and is associated with or followed by brown hyperpigmentation at the same site, which can persist for several weeks or months.

Nonimmunologic contact urticaria is a toxin-mediated reaction that provokes a reaction seconds to minutes after the contact. Erythema, edema, and pruritus last minutes to hours. On the other hand, immunologic contact urticaria starts within minutes to 1 h from the contact and lasts hours to 1 day, and may be associated with atopic patients. Vasoactive mediators are released, causing erythema, edema, and pruritus, which often worsen with subsequent exposure. In severe cases anaphylaxis may occur.

Allergic contact dermatitis often develops progressively within 1–3 days after exposure and lasts for 4–10 days. It is usually pruritic and streaky, with polymorphous appearance which may include erythema, vesicles, and edema. It starts at areas of contact but may spread outward. Recurrent episodes are typical, each lasting several days and usually followed by scaling. Each episode may be worse than the last. Minimal hyperpigmentation may occur. Airborne contact dermatitis typically affects the face, neck, forearms, and hands, simulating photosensitivity [2, 5] (Tables 29.1 and 29.2).

Irritant Contact Dermatitis

This is an inflammatory response to a physical and/or chemical injury and is not immunologically mediated. It depends on the barrier function of the individual's skin in addition to the potency and duration of the irritant stimulus. Therefore, mild irritants can cause a chronic cumulative dermatitis after repeated exposures. On the other hand, strong acids or alkalis from the sap of some plants may produce an acute toxic reaction with hemorrhagic bullae and necrosis [2, 3, 5].

Plants can irritate the skin by mechanical or chemical means. Although irritant contact dermatitis is very common, most patients do not seek a dermatologist because of the frequency of mild reactions. Its diagnosis is clinical and the patch testing is not recommended. Irritant plants often cause confusing patch test results and may even lead to chemical burns (Fig. 29.1 and Table 29.3).

Macrotraumas can be provoked by spines, prickles or thorns, and fall of branches or fruits. Leaves may act as knives. Such mechanical damage may lead to the development of infections.

In addition, microtraumas from trichomes or glochids (bristles or barbs) are also seen. These structures can penetrate the outer layer of the skin and cause papular irritant eruption, which sometimes mimic scabies, prurigo, or eruption similar to that caused by fiber glass. Some plants have stiff hairs that induce a stinging reaction, while others bear hooks or spines on their stems or fruits. Among these plants are species of *Cereus*, *Cephalocereus*, *Opuntia* as cactos-mandaracu (*Cereus jamacaru*), xiquexique (*Pilocereus gounelei*), and palms (*Opuntia vulvaris*) commonly found in northeastern Brazil. The implantation of cactus spines or hooks is an occupational hazard among pear pickers, and can cause a pruritic popular eruption called sabra dermatitis. Spine and glochids may also induce foreign body granulomata. Additionally they can introduce infective organisms such as *Clostridium tetani*, *Staphylococcus aureus*, *Sporothrix schenckii*, *Berberis*, numerous species of *Mycobacterium*, and actinomycosis [2, 3, 5–7].

Several plants contain chemical irritants and many possess irritant hairs or spines as well as chemicals. Chemical irritation is caused by either crystalline calcium oxalate, which has also a physical irritant effect, and a wide range of chemicals dissolved or suspended in latex or housed in specific organelles, including alkaloids, glycosides, proteolytic enzymes, saponins, phenolic compounds, and anthraquinones. Some members of the daisy family may produce an irritant reaction when crushed on the skin. Cactus-like plants contain a copious milky latex that is very caustic. Among them are the species of the Euphorbiaceae

Indian fig *(Opuntia fícus-indica)*

Agave

Borage

Euphorbiaceae

Dieffenbachia picta, the dumb cane
Fig. 29.1 Examples of irritant plants

Table 29.3 Irritant contact dermatitis [2]

Injury	Examples
Mechanical/physical	
Major traumas	Falling branches, fruits
Thorns	Roses (Rosaceae), bougainvillaea
Sharp-edged leaves and leaf hooks	Agave, *Yucca*
Spines and glochids	Cacti, *Opuntia*
Stem/leaf hairs	Borage, compositae (*Bidens*)
Irritant fibers	Rose hips, tulip bulbs
Chemical	
Stinging hairs	Urticaceae, Euphorbiaceae, Loasaceae, Hydrophyllaceae
Irritant sap/latex	Spurge (Euphorbiaceae), Ranuculaceae
Calcium oxalate crystals	Bulbs (Amarilidiaceae), Araceae, Bromeliaceae

family such *Euphorbia milli* (coroa-de-cristo), *Euphorbia pulcherrima* (bico-de-papagaio), *Euphorbia cyparissias* (erva-da-verruga), and *Euphorbia brasiliensis* (erva-de-leite), among others. Ingenol mebutate, the active agent (a macrocyclic diterpene ester) in the sap of the plant *Euphorbia peplus*, is used as a traditional remedy for several different skin lesions, including actinic keratosis and skin cancers. It provokes a severe skin reaction with erythema and blisters before the complete clearance of the actinic keratosis [8].

In the Araceae family, *Philodendrum* (costela-de-adão), *Monstera* (cara-de-cavalo), and *Dieffenbachia picta* (comigo-ninguém-pode) contain calcium oxalate. The last one is known as the dumb cane because it provokes edema, with blisters on the tongue and oral mucosa, leading to difficulty speaking. Plants of the mustard and radish family contain the glucoside sinigrin, which is harmless in the dry state but is converted to an irritant in the presence of water. Certain vegetables such as tropical gourds and cucumbers contain a juice that can irritate the skin. Pineapples contain bromelin, a proteolytic enzyme that is also an irritant [1–3, 5–7].

Acute irritant dermatitis can arise after some minutes or hours and include erythema, edema, papules, and vesicles, which are limited to the sites of contact. Chronic irritant contact dermatitis from plants, following repeated exposure to

the irritant, is commonly associated with xerosis, hyperkeratosis, and fissures. Patients may have more striking manifestations such as superficial necrosis, hemorrhagic blisters, and ulceration. The clinical picture may be further complicated by the presence of systemic findings, such as when the plant or plant product is consumed or inhaled [2, 3, 5].

Phytophotodermatitis

Phytophotodermatitis is a reaction caused by sun exposure after contact with plants. The reactions are phototoxic, owing to photosensitizing substances found in certain plants. An exception is the photoallergic contact dermatitis related to *Parthenium*. However, individuals exposed to volatile allergens such as Compositae oleoresin may become abnormally sensitive to light (persistent light reactivity).

Furocoumarins (psoralens) appear to be primarily responsible for phytophototoxic reactions in humans. Coumarin derivatives such as isopimpinellin also possess photosensitizing properties. They are seen in large amounts in citrus peel. Another category of photosensitizers are the furoquinolines [2, 3].

The most common plant families causing these reactions are Umbelliferae, Rutaceae, and Moraceae. Among them are parsnip, carrot, celery, lemon, lime, fennel, and parsley (Figs. 29.2 and 29.9). An interesting finding is that under attack by fungus, celery produces psoralen as a defensive mechanism [1, 2].

The eruption is related to areas of contact with the plant or plant product, followed by exposure to sunlight or an artificial UV-A light source. The distribution may be bizarre. Lesions develop 8–24 h after contact with these plants. They are linear dusky red lesions, often bullous and associated with brown pigmentation. During the summer in Brazil it is common to see young women who develop extensive and very severe bullous dermatitis after the use of home-made sun-tan fig lotions followed by sun exposure. Phototoxic contact dermatitis may present as berloque dermatitis, induced by perfumes or perfumed cos-

metics containing a high amount of psoralens, especially bergamot. In general it affects the neck or trunk. The hyperpigmentation that follows this eruption may last months or years, although it is now rare as such fragrances containing psoralens are no longer on the market. It can sometimes be observed with artisan or traditional fragrances [1–3, 9, 10].

A phototoxic reaction can follow the systemic ingestion of certain plants containing psoralen such as those from families Chenopodiaceae and Plantaginaceae. After eating, patients have to stay under the sun for at least 1 h. Massive edema and livid purple plaques, cyanosis and necrosis, vascular damage, hyperglycemia, and diabetes mellitus may develop [9]. In Brazil, the plant *Bidens pilosa*, known as "picão," is used in folk medicine for the treatment of jaundice and liver diseases. Consumed in topical preparations for baths as well as in teas for ingestion, it can develop phototoxic reactions due to phenyl heptatriene [6]. In Japan, phototoxicity was reported in patients who ingested a preparation containing an alga (*Chlorella* species) as a natural health food [2]. Furthermore, there are a few reports of phototoxic reaction to tobacco (*Nicotiana tabacum*) from cigarette smoke and snuff [11] (Fig. 29.2).

Contact Urticaria

The lesions are typical wheals that are short-lived (less than 24 h), associated with itch and tingling, limited at the site of contact and resolving without trace. Some plants may induce them by their pharmacologic mechanisms and others may provoke a type I hypersensitivity. The latter is caused by a plant-specific component, mainly proteins, and can be severe.

Nonimmunologic Contact Urticaria
Some species have sharp hairs on the surface of the leaves and stem. After contact they deliver a cocktail of irritant chemicals as a defense mechanism, provoking urticaria. Therefore, after puncture an irritant liquid containing several proinflammatory mediators, including histamine,

reaction due to snuff   *rustica L*

Fig. 29.2 Phytophototoxic reactions and photoirritants

acetylcholine, and 5-hydroxytryptamine is released into the skin. This reaction occurs at the site of contact and is immediate. The four main families with urticating hairs are Urticaceae, Loasaceae, Euphorbiaceae, and Hydrophyllaceae. Cansanção (*Cnidosculos urens*, *Fleurya aestuans*, *Loasa rupestris*), "favela" (*Cnidosculos phyllacantus*), "urtiga-cipó" or "urtiga-mamão" (*Dalechampia scandens*), "marmeleiros," "mucunã-brava," or "cabeluda" (*Mucuna urens*) are found in Brazil. Other plants with pharmacologic elicitors of urticaria are *Myroxylon pereirae* (balsam of Peru) and cinnamic acid derivatives therein contained, *Thapsia garganica* releasing thapsigargin, and species of capsicum with capsaicin [2, 3, 6].

Immunologic Contact Urticaria

Immunologic contact urticaria is an immediate type I contact reaction occurring in a previously sensitized individual. There is a specific IgE synthesis, mainly to proteins from a plant or plant product, which can cause a severe reaction with generalized or systemic symptoms. The reactions can occur with trivial symptoms such as itch, erythema, or wheals, or severe due to, for example, henna (*Lawsonia inermis*) in hair dye or celery.

Even fatal anaphylaxis to rubber latex has been described. It is commoner in atopics and individuals who have increased exposure to the allergen. The cutaneous reaction is at first at the site of contact, but the eruption can generalize. Cross-reactions can occur between botanically unrelated species.

Protein contact dermatitis is a reaction resulting from plant or plant products presenting as urticarial wheals or as an acute vesicular eczema at the site of contact, which is observed 30 min after exposure. It is mostly seen in persons with atopy who handle food, meat, or vegetables and have a previously chronic dermatitis (irritant or allergic) mainly on the hands and forearms. It has been frequently associated with food such as onion, lettuce, potato, carrot, or asparagus [2, 3].

The diagnosis is made by history and tests, among them which prick testing is indicated, using parts of a vegetable or commercial extracts with two readings: immediate and after 15–20 min. A scratch test may also be performed, but the former is safer and preferable. Serologic tests such as a radioallergosorbent test (RAST) to specific proteins can be used as an adjunct to skin testing or as an alternative when the prick test is contraindicated. The serum sample is assayed for

the presence of specific antibodies against the suspected substances. More recently the UNICAP system has also been used [2, 3].

Oral allergy syndrome (OAS) or pollen-food allergy syndrome is a hypersensitivity reaction to plant-based foods manifesting mainly on the lips, tongue, and mouth. The reaction occurs after prior sensitization to plant inhalant allergens. It is triggered by a cross-reaction between allergens in pollen and allergens in fresh fruits and vegetables. However, some plant allergens are resistant to heating, and patients may develop OAS after eating cooked food. Because digestive enzymes in the gastrointestinal tract break down the food allergens, the symptoms are typically limited to the oropharynx. It occurs in patients with a history of atopy. Systemic reactions rarely occur (Fig. 29.3).

OAS is a type 1 immediate hypersensitivity reaction, mediated by IgE induced by sensitization to pollen, which leads to subsequent development of cross-reactivity to food allergens.

The symptoms appear minutes after the exposure to the offending fruits or vegetables and last from minutes to hours. Reactions can develop from small doses of triggering allergen or in response to intimate or casual contact with someone who had consumed or handled the trigger. The symptoms are typically limited to the oropharynx and are usually mild and transient. Pruritus on the lips and palate region is common, although there may also be oral and perioral angioedema. Seldom extraoral symptoms include facial rash, nasal and otic pruritus, occasionally mucosal vesicles or blistering along the oral cavity, conjunctivitis, congestion, or coryza. On physical examination tongue swelling, uvular edema, erythema, swelling of the lips, perioral urticarial eruption, and facial edema (including the periorbital area) are apparent. Five percent of the patients have a generalized allergic reaction with systemic symptoms or even anaphylaxis. Risk factors for these reactions are a history of systemic reactions to food, a positive skin-prick test to commercial antigen, and prior reaction to peaches or tree nuts.

Many plants have developed proteins to protect against pathogen invasion. These are called pathogenesis-related or pathogen-response proteins (PR) and have been classified into 17 fami-
Fig. 29.3 Examples of inhalant allergens that cross-react with some fresh vegetable/fruit allergens provoking oral allergy syndrome

lies implicated in IgE cross-reactivity resulting in OAS. The PR-10 proteins are the most important family associated with pollen-allergy food. The major birch allergen Bet v1 is a member of this family, associated with hypersensitivity to various fruits and vegetables such as apple, cherry, apricot, pear, peach, hazelnut, celery, carrot, parsley, and potato [12].

Patients with atopic dermatitis who are sensitized to birch pollen may experience a worsening of their eczema after consumption of birch pollen-related foods.

The diagnosis is based on a history of oropharyngeal symptoms associated with ingestion of specific raw fruits or vegetables in patients with pollen allergies. Skin-prick testing with the suspected fresh food or with commercial extracts may be performed, the former being more reliable. Radioallergosorbent testing is more sensitive than skin-prick testing with commercial extracts but is less sensitive than skin-prick testing with fresh extracts. CAST-ELISA (cellular antigen stimulation test in combination with enzyme-linked immunosorbent assay) measures sulfidoleukotriene released by sensitized leukocytes after specific allergen stimulation. Although its utility in discriminating between sensitization and true allergy is questionable, it is useful to analyze cross-reactivity in patients with multiple sensitizations to plant foods and pollens.

The main treatment is the avoidance of known food triggers [12].

Allergic Contact Dermatitis
